## SUBJECT: Status Report on Davis-Besse Analyses

The attached Figs. 1-6 provide a summary of the Davis-Besse analyses performed to date under the new Task 9 of JCN Y6533. In Fig. 1, the cladding properties used in the current study are presented: (a) true stress versus true strain and (b) thermal expansion coefficient versus temperature. The remaining figures address a specific sub-task described in the workscope for Task 9.

Sub-task 9.1D requires an estimate for crack driving forces as a function of flaw size and applied membrane stress in cladding.

Figure 2 depicts the first step carried out in preparation for the *J*-integral analyses, i.e., calculation of an updated estimate of the exposed cladding "footprint" based on the recent "dental mold" cast from the D-B cavity. That footprint area was estimated to be 28.23 in<sup>2</sup>. Comparisons of the latest "footprint" statistics with previous ORNL interpretations are given in the table of Fig. 2(b). The newly calculated "footprint" area was used to define a burst disk having the same cross-sectional area.

Table 1 presents ductile tearing data for three-wire series-arc stainless steel weld overlay cladding published in NUREG/CR-5511 [1]. The ductile-tearing data presented in Table 1 are plotted as a function of temperature in Fig. 3.

Figure 4 presents the three finite-element models developed for this phase of the analysis. For a constant flaw length, surface breaking flaws were centrally located in each burst disk. The three relative flaw depths investigated were 0.5, 0.25, and 0.05. The constant total flaw length was 2.0 inches (50.8 mm).

Each of the three models were loaded with an increasing lateral pressure until the solution approached a numerical breakdown. The resulting *J*-integral loading paths for the three models are shown in Fig. 5. Figure 5 also presents a value of  $J_{Ic}$  for a temperature of 318.3 °C (605 °F) estimated by extrapolating from the data in Fig. 3a using a 4<sup>th</sup> order polynomial curve-fit.

Figure 6 compares the critical pressures (determined from the results shown in Fig. 5) for two potential failure modes of the burst-disk models. The ductile-tearing critical pressure is calculated from the point at which the load path for each flaw crosses the  $J_{Ic}$  line in Fig. 5. The plastic-collapse critical pressure was estimated from the load at which each model began to approach a numerical instability in the analysis. From the curves in Fig. 6, the controlling failure mode for the two larger flaws in the current study was ductile tearing. The shallow flaw (a/t = 0.05) was close to the  $J_{Ic}$  line when it began to fail by plastic collapse. An estimate of the applied tearing modulus was calculated using the data from the three flaws at a pressure of 6.4 MPa (0.928 ksi). As indicated by the comparison in Fig. 3b, this estimate of the applied tearing modulus indicates a stable ductile tearing for the largest flaw, thus implying stable tearing for the smaller flaws as well.
