Bolling AFB, DC 20032-7050

SUBJECT: RESPONSE TO REQUEST FOR 10 CFR 20.2002 EXEMPTION
FOR KIRTLAND AFB

Dear Lt. Col. Nicholson,

The U.S. Nuclear Regulatory Commission (NRC) is in receipt of a letter from the Department of the Air Force, 377th Aerospace Medicine Squadron (AFMC) addressed to Mr. Larry Camper, Division of Waste Management and Environmental Protection. The letter is a request for NRC 20.2002 Exemption for remediated soils at Kirtland AFB, including RW-06, RW-068, and Mesa del Sol sites. I have enclosed the subject request since all correspondence to and from the NRC regarding licensed radioactive materials under NRC License 42-23539-01AF, should come through the USAF Radioisotope Committee (RIC).

If the USAF RIC determines that an NRC 10 CFR 20.2002 exemption request is necessary, then please provide the exemption request and supporting documentation to the NRC Region IV office, attention Ms. Rachel Browder, Project Manager of the USAF Master Materials License (MML).

In accordance with 10 CFR 2.390 of the NRC's "Rules of Practice," a copy of this letter and its enclosure will be available electronically for public inspection in the NRC Public Document Room or from the NRC's document system (ADAMS). ADAMS is accessible from the NRC Web site at: <http://www.nrc.gov/reading-rm/adams.html>.

If there are any questions, please do not hesitate to contact me at (817) 276-6552.

Sincerely,

A handwritten signature in black ink, reading "Rachel S. Browder", is positioned above the typed name.

Kirtland AFB NM 87117-5270

SUBJECT: NRC 20.2002 Exemption

1. The U.S. Air Force (USAF), Kirtland Air Force Base (AFB), New Mexico, seeks approval by the U.S. Nuclear Regulatory Commission (NRC) to dispose of specified soil contaminated with low concentrations of byproduct and source material at the US Ecology Idaho (USEI) RCRA Subtitle C disposal facility located in Grand View, Idaho. We request that NRC authorize alternate disposal pursuant to the provisions of 10 CFR 20.2002 and issue 10 CFR 30.11 and 10 CFR 40.14 specific exemptions at the time the 20.2002 authorization is granted.
2. The waste has been characterized and a Safety Assessment has been performed demonstrating that alternate disposal at the USEI facility will be protective of human health. These materials consist of approximately 2,000 to 3,000 tons of contaminated soils either already removed or to be removed from former waste disposal and remediation sites at Kirtland AFB including the RW-06, RW-068, and Mesa del Sol sites. The Waste Characterization and Safety Assessment, including supporting documentation, is provided in the attachment to this letter.
3. Kirtland AFB respectfully requests an expedited review and issuance of the requested alternate disposal authorization and related NRC exemptions. Please contact me at (505) 846-3624 with any questions.

Waste Characterization and Safety Assessment

ATTACHMENT

Waste Characterization and Safety Assessment

Evaluation Supporting Request for 10 CFR 20.2002 Alternate Disposal Authorization and 10 CFR 30.11 and 40.14 Exemptions

1. INTRODUCTION

Cabrera Services, Inc. (CABRERA) and US Ecology Idaho, Inc. (USEI) has developed this safety assessment for waste generated as the result of soil contaminated with radionuclides used in military research and operations at the Kirtland Air Force Base (AFB) in Albuquerque, New Mexico. The material is intended for disposal at USEI's Grand View, Idaho RCRA Subtitle C hazardous waste disposal facility as exempt quantities of source and byproduct material in accordance with 10 CFR 20.2002 and specific 10 CFR Part 30.11 and 10 CFR 40.14 exemptions.

USEI has performed a conservative radiological dose assessment of the proposed action and determined that the potential dose to workers during transportation and disposal of the material and to members of the general public after site closure will be no more than a few millirem per year total effective dose equivalent (TEDE). This dose is a small fraction of the NRC decommissioning limits for exposure to members of the public of 25 millirem/yr TEDE. This safety assessment demonstrates that the intended disposal action is adequately protective and that an alternate disposal authorization and specific 10 CFR 30.11 and 10 CFR 40.14 exemptions related to this authorization are warranted.

A description of the material to be disposed is included in Section 3. The description includes physical and chemical properties of the material important to risk evaluation and the proposed conditions of waste disposal.

2. DISPOSAL SITE CHARACTERISTICS

A description of the USEI facility located near Grand View, Idaho is attached (Appendix A).

3. DESCRIPTION OF THE WASTE

The waste (Appendix B) consists of approximately 3,000 tons of soil contaminated with material equal to or less than the radionuclide concentrations listed in Table 3-1. The waste will be disposed in a permitted RCRA Subtitle C disposal unit at USEI's Grand View facility.

Table 3-1. All concentrations are in pCi/g

Ac-227	Co-57	Co-60	Cs-137	Pb-210	Ra-226	Sr-90	Th-228	Th-230	Th-232	U-234	U235	U-238
0.5	0.0052	0.0026	0.42	1.03	1.026	0.0244	0.5	0.5	0.5	1.5	0.51	1.42

4. RADIOLOGICAL ASSESSMENTS:

In the following scenarios the dose equivalent for the Maximally Exposed Individual (MEI) is demonstrated not to exceed a few (e.g., five (5)) millirem/yr. This standard of a “few millirem/yr” to a member of the public is defined in NRC Regulatory Issue Summary 2004-08. The transportation workers and workers at the USEI site are treated as members of the public since the site is not licensed by the NRC. Evaluations of both potential external and internal dose hazards to the transportation worker are discussed below.

4.1. Transport Dose to Public

Given the very low average concentrations of the Kirtland AFB radionuclides the potential external dose to members of the general public, individually and as a whole is anticipated to be very low. The materials may be transported by rail or by truck to USEI. For normal highway transport conditions the material will be enclosed and pose no potential for internal dose to a member or members of the public. External dose, as has been demonstrated in the worker dose assessment below, will be less than one millirem for the worker that would be expected to receive the highest dose from the project and can, therefore, be reasonably expected to be much less for any member of the general public. The potential for dose to a member of the general public during rail transport can reasonably be expected to be lower than that for highway transport. If the material is to be transported by rail, it will be enclosed so as to preclude any potential for intake.

4.2. USEI Worker Dose Assessment

Receipt by Rail

Gondolas will be received at USEI’s rail transfer facility (RTF). Prior to being off-loaded, each gondola will be surveyed. The survey normally takes an operator 20 minutes to complete. The operator will stand approximately one meter from the gondola car when conducting the survey. The dose rate at one meter for the maximum concentration of Kirtland AFB radionuclides to be received will be $6.51\text{E-}6$ mSv/hr ($6.51\text{E-}4$ mrem/hr) (Appendix C). The surveying work is shared between 2 RTF operators. The estimate of the total dose for the project to each gondola surveyor is estimated to be $3.25\text{E-}5$ mSv ($3.25\text{E-}3$ mrem).

An excavator operator will then remove the material from the gondola and load it into dump trucks for transport to the disposal site. It normally takes the excavator operator up to 45 minutes to unload a gondola. The operator occupies a position approximately 2 meters from the material and will be in a radiation field of $3.44\text{E-}6$ mSv/hr ($3.44\text{E-}4$ mrem/hr) (Appendix D). There are two excavator operators

per shift; therefore the total dose for the project to an excavator operator is calculated to be $3.87\text{E-}5$ mSv ($3.87\text{E-}3$ mrem).

After each truck and its trailer are loaded, both are surveyed prior to driving to the disposal site. The survey usually requires 5 minutes to perform. Again, the surveyor will stand an average of one meter from the exterior of the truck. The dose rate at that distance from the truck is calculated to be $3.75\text{E-}5$ mSv/hr ($3.75\text{E-}3$ mrem/hr) (Appendix E). Two individuals will usually perform the truck surveys. The dose for the project to a truck surveyor will be $2.81\text{E-}4$ mSv ($2.81\text{E-}2$ mrem). The trip to the disposal site takes 45 minutes. The calculated dose rate in the driver's position is $5.63\text{E-}5$ mSv/hr ($5.63\text{E-}3$ mrem/hr). 15 trucks make the circuit to the site from the RTF. The expected dose to an individual driver for the total project is $2.52\text{E-}4$ mSv ($2.52\text{E-}2$ mrem) (Appendix F).

To estimate the potential maximum inhalation dose to a USEI employee, the DAC fractions for each radionuclide were calculated using a dust loading of 5 mg/m^3 . This dust loading is an average for the rail transfer facility, the disposal cells and the stabilization building. The DAC fractions were summed and multiplied by the maximum number of hours of exposure to a USEI employee (the excavator operator) and then by 2.5 mrem per DAC-hour. The excavator operator remains in the airborne area the longest of all employees. Potential inhalation dose is expected to be $1.12\text{E-}3$ mSv ($1.12\text{E-}1$ mrem) for the entire project assuming the operator did not wear a respirator. In practice, all workers participate in a respiratory protection program and are required to wear respirators while working with any materials. With an applied respiratory protection factor of 10, all potential doses from inhaled radioactive material are reduced by a factor of ten.

Some dose will also be accrued by disposal cell workers who will spread and compact the material once it has been deposited in the cell. For this exposure scenario, a dose rate from the deposited material was calculated to be $1.44\text{E-}5$ mSv/hr ($1.44\text{E-}3$ mrem/hr) (Appendix G). This is based on the amount of material contained in one gondola. Two operators run the heavy equipment in the cell. Assuming 15 minutes to spread and compact each gondola's contents, the total dose to each of those workers for the project was calculated to be $5.4\text{E-}5$ mSv ($5.4\text{E-}3$ mrem).

All personnel working in the disposal cell are required to wear respirators. Assuming all other factors equal, the shorter exposure time of cell workers would result in a lower dose from airborne radionuclides than for the excavator operator.

Receipt by truck

The distance from Albuquerque to the USEI disposal facility is approximately 1,000 miles. Assuming an average speed of 50 miles per hour, the trip can be expected to take 20 hours. The dose rate calculated for the driver is $3.75\text{E-}5$ mSv/hr ($3.75\text{E-}3$ mrem/hr). Reasonably assuming 10 trucks are used to haul the

material and each truck carries 25 tons of material, twelve rounds will be made by each driver. The total dose for the project to each driver under those assumptions would be $9.0\text{E-}3$ mSv ($9.0\text{E-}1$ mrem). Upon receipt by USEI, the material will be surveyed, screened and then taken directly to the disposal cell. The surveyors of the trucks can be expected to receive doses identical to those received by the truck surveyors at the rail transfer facility. Heavy equipment operators will spread the material and compact it. This process takes approximately 15 minutes, as described above. The dose projected for the operators of the heavy equipment is $5.4\text{E-}5$ mSv ($5.4\text{E-}3$ mrem) for the total project.

4.3. Post Closure Dose to the General Public

USEI's permit requires that the operator demonstrate that no person will receive a dose exceeding 15 millirem for 1,000 years after closure of the facility. RESRAD was used to make that demonstration. A number of default parameters in the model have been replaced with site-specific parameters. As shown in the RESRAD report (Appendix H), the maximum dose projected by the model for the disposal of the Kirtland AFB radionuclides is approximately 0.1 mrem/year in year 1,000.

Appendix A

Disposal Site Characteristics

GENERAL DESCRIPTION (IDAPA 58.01.05.012 & 40 CFR 270.14(B) (1))

US Ecology Idaho (USEI) owns and operates an approximately 160-acre RCRA Subtitle C Treatment, Storage and Disposal Facility (TSDF). This facility is located at the end of Lemley Road approximately 10½ miles west of the town of Grand View, Owyhee County, Idaho.

The site had previously operated as a waste storage and landfill disposal facility by a different owner from 1973 to 1981. Current activities at this facility include storage, treatment, and disposal at an on-site landfill(s) of industrial, toxic and hazardous wastes and certain low activity radioactive materials. USEI serves multiple industries including chemical, manufacturing, steel, petroleum and pharmaceutical industries as well as the federal government. Wastes are generated on-site from various site activities. These activities include leachate generation from landfills, liquids collected from various containment areas/systems and other waste streams generated during the operation of various on-site waste management units including the Stabilization Facility, Stabilization Building, Containment Building, various container management units, landfill(s), surface impoundments, and other existing hazardous waste management units and support facilities.

The active disposal portion of the facility is comprised of two (2) active landfill disposal cells, designated as Cells 14 and 15 and four (4) surface impoundment disposal units, designated as the Evaporation Pond and Collection Pond #'s 1, 2 and 3. Additionally, there are two landfill disposal units, Trenches 10 and 11, which completed a five year evaporative cap performance demonstration which began during the year 2000 and are now closed. Former Trench 5 has also been closed using a standard RCRA facility cap.

Historically, the site was primarily used for management of non-hazardous and hazardous wastes and PCB under a separate TSCA permit. Throughout the 1970's, the facility was operated by Wes-Con, Inc. as an industrial waste landfill and received wastes for disposal in the abandoned on-site Titan missile silos and then active chemical waste landfill. In 1980 Wes-Con, Inc. (Now operated by USEI) obtained interim status under RCRA for management of hazardous wastes, including treatment, storage and disposal of approved hazardous wastes. USEI received a "Hazardous Waste Treatment, Storage and Disposal Facility Permit" from U.S. EPA and IDEQ on December 15, 1988.

The Grand View, Idaho waste management facility has been in operation since 1973. Prior to the purchase of the facility by USEI, portions of the Titan missile silo complex were used for waste disposal in addition to the on-site trenches. Because of the timing of the USEI purchase of the site and the promulgation of current environmental regulations, the only information available regarding past disposal practices is the records that were maintained at the facility by previous owners and information that USEI has been able to obtain from past owners and long-term employees at the site.

In recent years, the facility has accepted large volumes of low activity radioactive material from the federal government's Formerly Utilized Site Remedial Action Program (FUSRAP), other federal agencies, and private entities including NRC and Agreement State licensees. These materials include naturally occurring and accelerator produced radioactive material in low concentrations, as well as source and byproduct material generally or specifically exempted from regulation under the Atomic Energy Act for disposal purposes.

GENERAL HYDROGEOLOGIC INFORMATION

Regional Setting

Introduction

The following is a summary of the Physiographic Setting and Regional Hydrogeology of USEI Site B presented in the 1986 Site Characterization Report (CH2M HILL, February 1986). This information has been assembled pursuant to IDAPA 58.01.05.012 (40 CFR 270.14(c)(2)).

Physiography

USEI Site B is situated in the western portion of a 20,000-square-mile physiographic unit known as the Snake River Plain. The plain extends from the vicinity of Ashton, Idaho, to north of Ontario, Oregon. The Snake River Plain is approximately 350 miles in length and varies in width from 25 to 75 miles. USEI Site B lies within the lowland area of the Owyhee subunit of the Snake River Plain at an elevation of between 2,525 ft. and 2,635 ft.

The Snake River, which flows to the northwest, lies approximately three (3) miles east of the site and is the most prominent water resource of the area. The site is approximately 250 ft. higher than the Snake River flood plain, which locally extends outward up to one mile along either side of the river. Castle Creek, a perennial stream that flows northward to the Snake River, lies approximately one mile west of Site B. Cloudburst Wash, a small ephemeral (intermittent) stream, lies about two (2) miles to the east of Site B and also empties into the Snake River. The facility straddles the Castle Creek and Cloudburst Wash drainage basins. However, since the facility contains all runoff from active areas, it does not contribute runoff to either drainage. The area is characterized by badlands-type topography and exhibits varied relief. Major topographic features of the area include several prominent buttes, remnant basaltic cinder cones, and canyons cut by the Snake River. Vegetation in the area is typical of a semiarid environment. The lowland area within which the site is located is inhabited by low brush and grasses, including sagebrush, rabbit brush, wheat grass, and cheat grass. Land use in the area consists of undeveloped rangeland and some limited irrigated agriculture. Irrigation water in the area is derived from the Snake River, Castle Creek, and from the deep, regionally extensive, geothermal groundwater system. The area is sparsely populated with isolated farms and ranches being the dominant habitation.

Climate

The semiarid western portion of the Snake River Plain has one of the highest annual average temperatures in the state. For a 64-year period (1933 to 1996) at the Grand View U.S. Weather Bureau Station, located ten (10) miles east of the site, the average temperature was 52.2 degrees Fahrenheit (EarthInfo, Inc., 1997). The range in temperature during the winter months of December through February was -1 degree Fahrenheit to 58 degrees Fahrenheit. From March to November, the temperatures ranged from 12 degrees Fahrenheit to 101 degrees Fahrenheit.

The site is influenced by prevailing westerly maritime winds via the Columbia River and Snake River valleys; consequently, most precipitation falls during the winter. Over the same 64-year period at the Grand View U.S. Weather Bureau Station, the average annual total precipitation was 7.1 inches. The precipitation in this area is evenly distributed from November through June, with only a minor amount falling during the summer, usually associated with isolated thunderstorms. The mean annual pan evaporation for the Grand View area is approximately 53 inches (U.S. Weather Bureau, 1959).

Regional Well Inventory

A records search of the well log files at the Idaho Department of Water Resources (IDWR) in March 2003 turned up 26 logs for wells installed within a 3-mile radius of Section 19. There were no new wells drilled in this search area between the 1998 and current submittals of this permit application document. Note that the test well LP-40 discussed previously was not included in this summary.

Figure E-6 shows the approximate location of the wells based on the location information included on the log. Included in Figure E-6 is a table showing the well depth, date drilled, and stated use. Four (4) of the well logs were for USEI monitoring wells and there were two duplicate logs filed for the same well (well No. 13). The plugged and abandoned water well exploratory well drilled west of Site B by USEI to a depth of 800 ft. is shown as well No. 18 and the plugged and abandoned deep artesian well drilled by the U.S. Air Force in 1958 is shown as well No. 14. Appendix E.1 provides copies of the well logs as filed with IDWR.

There are five existing wells in the immediate vicinity of Site B that are of interest because they may be hydraulically downgradient of the facility. Four of these wells, Nos. 12, 13, 21, and 22, are domestic wells that probably cannot be impacted by shallow groundwater at Site B because they are deep artesian wells (greater than 600 ft. deep) and either flow at the surface or have very shallow static water levels (less than 12 ft. bgs). The fifth well, No. 23, was drilled for stock watering and draws water from sands and gravels with a reported yield of over 50 gallons per minute. The location provided on the Well Drillers Report places this well about 1.5 miles west of the Snake River (one mile east of Site B) in an area where saturated gravel deposits are not expected. However, in a telephone interview with the owner of the well, the actual location of the well is approximately ½ mile west of the Snake River and 50 ft. northwest of the Grand View Irrigation Canal. This places the well approximately 2.0 miles east of Site B in the NW ¼ NE ¼ of Section 21 as shown in Figure E-6, not NW ¼ NE ¼ of Section 20 as stated on the Well Driller's Report. Based on well No. 23's proximity to the Snake River and the irrigation canal, and the lithology provided in the Well Drillers Report, this well apparently draws water from saturated gravels that are recharged by the Snake River and possibly the canal. Thus, well No. 24 will not likely be impacted by shallow groundwater at Site B.

Regional Geology

Several investigators have been active in the delineation of the geology of the area at the regional scale. Malde and Powers (1962), Littleton and Crosthwaite (1957), Anderson (1965), and Ralston and Chapman (1969) have all contributed to establishing the geology of southwestern Idaho, including the general area of Site B. The information from these researchers is summarized and synthesized in this section to provide an overview of the geologic setting. The intent of this section is not to provide a definitive and detailed examination of the geology of the area, but only to place the site in the regional geologic framework as a basis for the detailed site geology and hydrogeology.

Stratigraphy

The regional stratigraphy of the area is dominated by the Idaho Group of Miocene to Pleistocene Age. This depositional sequence consists of up to 5,000 ft. of sedimentary and interspersed basaltic lava deposits that accumulated in the Snake River Plain over a basement of thick, older silicic volcanic rocks, primarily rhyolites.

The sedimentary deposits of the Idaho Group were laid down under three distinct episodes of lava damming (and subsequent dam breaking) of the ancestral Snake River. These episodes resulted in the formation of large lakes across the region. Fine-grained (silt and clay) lacustrine (lake bed) deposits are frequently intertongued with coarser-grained (silt and sand) of fluvial (river) and flood plain deposits throughout the area. These discontinuous and interbedded sand, silt, and clay beds form complex stratigraphic relationships on a regional scale. As a general rule,

the deposits are unconsolidated except for some minor sandstone and freshwater limestone and localized, discontinuous, basaltic lava beds. Generally, however, the lacustrine deposits predominate and form the most contiguous sedimentary beds across the Snake River Plain and the Site B area. The lacustrine and fluvial sediments of the Glens Ferry Formation of the Idaho Group are the primary strata of concern at Site B.

The several-hundred-foot-thick Snake River Basalt forms a cap rock over the Idaho Group sediments throughout much of the area and is the youngest formation in the regional sequence. Locally, the Snake River has eroded through the Snake River Basalt and into the underlying Idaho Group sediments. The Idaho Group sediments north of the Snake River, north of Site B, are capped by the resistant Snake River Basalt that forms steep cliffs adjacent to the river. The Idaho Group sediments south of the river (and within the vicinity of Site B) generally lack the protective basalt cap and have been eroded, forming the badlands topography characteristic of the area.

Structure

The Snake River Plain appears to be a downdrop fault-block basin, or graben, bounded by normal faults to the northeast and the southwest. Subsidence in the center of the basin was greatest and, consequently, the Idaho Group sediments are thickest near the center. The regional dips (angle from horizontal that the strata slopes) of the Idaho Group sediments range from near horizontal near the center of the basin to a maximum of about ten (10) degrees toward the margins of the basin. In the vicinity of Site B, regional dips of 2 to 4 degrees have been reported, with strike directions (perpendicular to direction of dip) approximately north 70 degrees west.

As a result of the structural attitude (dip) of the Idaho Group strata, older units tend to be exposed at a considerable distance south of the Snake River, with younger units exposed progressively nearer the river. Faults are apparent throughout the region because of differential settlement of sedimentary beds and movements along the principal regional faults that border the Snake River Plain. Minor faults locally cut older units of the Idaho Group; the younger units, however, are generally unaffected since they were deposited after the faulting occurred. The faults typically parallel the plain; faulting transverse to the plain is not common.

Local Geology

This section focuses on the characteristics of the Idaho Group sediments present in the vicinity of Site B.

Local Stratigraphy

In ascending order (deepest and oldest first), the localized formations are the Poison Creek (600+ feet thick); the Banbury Basalt (200+ feet thick); the Chalk Hills (200+ feet thick); the Glens Ferry (1,500+ feet thick); and the Bruneau (0 to 100+ feet thick). A detailed stratigraphic column prepared from the driller's log for the artesian well drilled in 1958 at Site B illustrates the stratigraphic sequence at Site B.

The Chalk Hills and Poison Creek Formations represent two individual lacustrine periods affecting the central and western portions, respectively, of the Snake River Plain. In some reports, particularly in many of the older geologic reports concerning the area and on numerous deep-drilling logs, the Poison Creek Formation is shown as occurring stratigraphically above the Banbury Basalt. This is due to lithologic similarities between the Chalk Hills and Poison Creek Formations and the volcanism responsible for the deposition of Banbury Basalt into the lacustrine environments present.

The Glens Ferry and Bruneau Formations are of prime interest to the site; the Glens Ferry is the unit where groundwater is first encountered and the Bruneau forms the uppermost geologic

unit beneath Site B. Together, these two units form a composite thickness of about 1,600 ft. The deeper Banbury Basalt and Poison Creek Formations are of secondary importance to site-scale hydrogeology only because of their depth. However, these formations provide a regional source of deep-flowing artesian groundwater, generally obtained from depths in excess of 2,000 ft. to 3,000 ft. beneath Site B. The artesian aquifer discussion is provided below. Because of the importance of the Bruneau and Glenns Ferry Formations to the Site B characterization, these units are discussed in detail below.

Glenns Ferry Formation

The Glenns Ferry Formation is of interest since the uppermost zone of saturation beneath Site B exists within the upper portions of this formation. Although the Glenns Ferry Formation is approximately 1,500 ft. thick in the site area, the following discussion focuses on roughly the upper 800 ft. The Glenns Ferry Formation was deposited in the area under three ancestral depositional environments: lacustrine, fluvial, and flood plain. The three stratigraphic facies, each representing a different energy of deposition that is reflected in the typical grain size of the sediments, differ from one another in lithologic composition and areal persistence and tend to grade vertically from one facies to the next. The overall sedimentary pattern in the upper few hundred feet of the Glenns Ferry Formation is of upward coarsening, reflecting the climate and drainage pattern changes that ultimately led to the complete disappearance of the Glenns Ferry lake.

For discussion purposes, the Glenns Ferry Formation has been divided into two units. The lower unit of the Glenns Ferry Formation consists of a lower lacustrine facies that upwardly becomes increasingly interbedded with fine-grained fluvial sands. The upper unit of the Glenns Ferry Formation consists of predominantly fluvial sands grading vertically into flood plain facies. The lacustrine facies is the most extensive and areally persistent sedimentary body in the Glenns Ferry Formation. Because of the structural dip of the beds in the Snake River Plain, all three facies are exposed at the land surface within the general area.

The extensive lacustrine facies consists of a thick-bedded, silty clay to clayey silt that grades with depth into a massive clay. Within the lacustrine facies are discrete intervals of thin lenses of very fine, tuffaceous sand interbedded with thicker, clayey, silt beds. These intervals represent periods of unstable lake margins. As water levels fluctuated, lake margin and fluvial sands were deposited farther into the lake. When the lake levels rose again, the sand lenses were covered with additional fine-grained lacustrine sediments. Where these sand zones are saturated, they represent the water-bearing portions of the lacustrine facies of the Glenns Ferry Formation. The water-bearing zones being monitored at Site B consist of two groups of these thin sand beds sand beds interbedded in the lacustrine sediments. At some exposures, the thick-bedded silt unit is overlain by several feet of very fine sand, alternately interbedded with additional silt. In many exposures, the fine sands are cross-bedded and show the presence of ripple marks. The fine sands generally denote the regional top of the lacustrine facies.

A less extensive fluvial facies overlies the lacustrine deposits, and generally consists of a fine- to medium-grained sand reaching a thickness of about 60 ft. Frequently, a 1" thick, tuffaceous, fine-grained sandstone is found at the top of the fluvial sand. Some cross-bedding is evident in the fluvial facies and, on a local scale, the sand unit intertongues laterally with the lacustrine facies.

The flood plain facies, where present, overlies the fluvial facies and denotes the top of the Glenns Ferry Formation; it consists of an interbedded sequence of clay, silt, and sand beds. Individual beds vary in thickness from about two (2) to four ft. (4) in the general area and laterally persist for several hundred feet. The flood plain sediments are areally discontinuous, however, and range from being absent to about 200 ft. thick. Plant fragments and other detritus are evident in the flood plain facies. Texturally, the flood plain deposits appear banded (that is, possessing thin, laminae-like alternating beds) compared to the more homogeneous underlying fluvial and overlying Bruneau Formation sediments.

Bruneau Formation

The Bruneau Formation consists of a variety of lithologic types ranging from unconsolidated lake deposits that contain basalt flows and tuff beds to high energy river gravels. In the vicinity of Site B, the formation is approximately 100 ft. thick, but the thickness varies greatly and the formation is absent in some locations. The Bruneau Formation is generally more coarse-grained than the underlying Glens Ferry Formation and has been divided regionally into a basal gravel unit (approximately 40 ft. thick), an overlying lower unit (approximately 70 ft. thick), followed by an upper unit (approximately 20 ft. thick). A 10- to 15-foot tuff layer separates the upper and lower units.

The basal gravel unit is composed of rounded pebbles, cobbles, and coarse-grained, cross-bedded sand lenses. The origin of the unit is interpreted as a river and beach deposits of ancestral Lake Bruneau. The lower unit, which overlies the basal gravel, consists of a thin, basaltic, cinder bed, an intervening mottled clay, and a fine-grained tuffaceous sand. The upper unit of the Bruneau is lithologically similar to the lower unit, but regionally occurs above the 10- to 15-foot-thick tuff layer. Locally, the thicknesses and lithologic characteristics of the Bruneau units can vary considerably. Only the basal gravel unit of the Bruneau Formation is present at USEI Site B.

Minor recent and Pleistocene surficial deposits are also intermittently present in the local area and consist of Snake River terrace gravels, colluvium, and stream alluvium. The stream alluvium exists along the margins of permanent drainages, and the colluvium consists of random slope debris. These minor deposits are difficult to distinguish from the unconsolidated coarse-grained Bruneau Formation deposits on a local scale. For purposes of classification in this report, all surficial deposits in the vicinity of Site B are considered to be part of the Bruneau Formation, even though they may be of more recent geologic origin.

Regional Hydrogeology

The groundwater resources of the area have been examined at the regional scale by several investigators. Mundorff, Crosthwaite, and Kilburn (1964) prepared a report on the occurrence of groundwater within the entire Snake River Plain. Ralston and Chapman (1969) investigated the groundwater resources of northern Owyhee County, and Young and Lewis (1982) examined the hydrology of deep thermal groundwater in southwestern Idaho. Several other groundwater availability and geothermal resource studies have been performed in the region, most notably by Brott, Blackwell, and Mitchell (1978) and Young, Lewis, and Bracken (1979). On the basis of these principal research studies, an overview of the groundwater resources of the region is presented in the following sections.

Principal Groundwater Systems

The regional studies indicate that three groundwater systems are present in the area of Site B. These systems are as follows:

1. A deep groundwater system found primarily within the silicic volcanics, Banbury Basalt and the Poison Creek Formation. Groundwater is found at depths ranging from 600 to more than 3,000 ft. in this system. Water in this system is under considerable artesian pressure and geothermally heated. Many wells tapping the aquifer are capable of flowing at the land surface. Several flowing geothermal wells in the Castle Creek drainage are used for irrigation and contribute to the general water resources available in that area. In the 3,000-foot-deep water supply well drilled by the U.S. Air Force (USAF) at Site B, the first significant water was encountered at 2,980 ft. The USAF test well flowed at over 300 gpm at a temperature of 170 degrees Fahrenheit. The USAF geothermal well was plugged and abandoned in 1986 by USEI (CH2M HILL, June 1986). The geothermal aquifer system, herein referred to as the deep artesian aquifer, is the most important groundwater resource in the area. Recharge to

the deep artesian system in the area is believed to originate in the Owyhee Mountains, where precipitation exceeds 50" annually.

2. A local veneer of saturated alluvium exists along Castle Creek. The alluvium and the creek are reported to be hydraulically connected. Some shallow domestic wells have been installed in the alluvium, generally to depths not exceeding 50 ft. Most of this alluvial system development occurs approximately eight (8) miles southwest and upstream of Site B (Ralston and Chapman, 1969). As Castle Creek flows northeastward from this area to the Snake River, it passes to within one (1) mile of Site B. It can reasonably be assumed that a veneer of saturated alluvium exists along Castle Creek in this downstream area as well. Recharge to this system is primarily by surface water runoff derived locally from precipitation and from the Owyhee Mountains.
3. Groundwater is found within the fine-grained sand beds and interbedded silts of the upper parts of the Glenns Ferry Formation at depths on the order of 140 to 350 ft. below ground level. Well yields and water quality in this system vary greatly. The Glenns Ferry Formation provides water to scattered low-yielding stock watering and domestic wells in the general vicinity of the site. In the area of the town of Oreana, seven (7) miles southwest of Site B, numerous wells provide groundwater for small irrigation and domestic uses from the Glenns Ferry Formation (Ralston and Chapman, 1969). In this area, local leakage from the Catherine Creek alluvial system probably contributes significantly to the recharge and well yields from the Glenns Ferry Formation. Recharge to the shallow Glenns Ferry aquifer comes from direct precipitation on exposed permeable beds, infiltration where the formation is exposed to surface water sources, and by vertical leakage from underlying artesian zones on a broad regional scale. The potential for recharge to the Glenns Ferry Formation from Site B is minimal because all site runoff is directed to lined collection ponds.

The water-bearing intervals being monitored at USEI Site B are in the upper portion of the shallow Glenns Ferry Formation. At Site B, however, the formation is not very permeable and most wells yield less than 0.5 gallon per minute. The shallow Glenns Ferry aquifer as it exists at Site B is not a true aquifer in the context of water resources because of low yield. The detailed characterization of the water-bearing properties and geochemical properties of the shallow Glenns Ferry system beneath Site B is provided in Section E.3.c.

Regional Flow Characteristics

Deep Artesian System

Groundwater in the deep artesian system generally moves from the mountains toward the Snake River, which are the regional hydrologic base level and therefore the likely discharge point for at least a portion of the groundwater in the deep artesian system. The observed northeast direction of flow in this system is consistent with the generalized orientation of the landscape, the trend of regional surface water drainages, and the regional trend of the Owyhee Mountains relative to the position of the Snake River. Strong upward gradients exist between the deep artesian system and shallower systems over most of the area. Where intervening confining strata are thin, more permeable, or breached by faults or wells, the deep artesian system also has a vertical flow pattern and contributes water to shallower systems. This is particularly noted to be occurring in the Castle Creek drainage area southwest of Site B where uncased or uncontrolled artesian wells are contributing to the base flow of Castle Creek and therefore also to the localized alluvial groundwater system in communication with the creek.

Shallow Glenns Ferry Groundwater

Because of the remoteness and sparsely populated nature of the area, coupled with the limited and sporadic groundwater resource potential of the Glenns Ferry Formation, there is insufficient information available to make definitive regional interpretation of flow directions and rates for the Shallow Glenns Ferry system. In general, the shallow groundwater system flows toward, and

probably discharges into, the Snake River. However, smaller scale flow directions are expected to be highly variable because of localized points of recharge from surface waters and vertical leakage from the deeper system, and from localized discharge points such as wells and natural drainages. Locally, southeasterly, northeasterly, and easterly flow directions have been identified in the shallow Glenns Ferry groundwater system at Site B. All of these flow directions are generally toward the Snake River where it either discharges directly or enters the local alluvial groundwater system along the Snake River.

Relationship of the Deep Artesian System to Site B

A deep artesian well was drilled on Site B by the USAF in 1958 as a water supply well (Shannon and Wilson, 1959). The artesian well was plugged and abandoned by USEI in 1986 (CH2M HILL, June 1986). The well abandonment was completed methodically and thoroughly using oil-field cementing techniques and cementing service contractors. There have been no data suggesting any vertical leakage from the deep artesian well, either before or after plugging. Although the well was abandoned, because of the location of the artesian well in the center of Site B and because much of the understanding of the deeper geologic formations beneath Site B came from the artesian well records, it is appropriate to preserve the documentation of the well in this application. Pertinent information regarding the deep artesian well is summarized below. In addition, important information on the nature of the deep regional flow system can be gained by a review of the characteristics of this well.

The geologic section beneath Site B is dominated by blue clays and shales. The aquifers of interest at Site B occupy a very small portion of the uppermost geologic formation.

The shut-in pressure of 70 psi at the wellhead reported in 1958 was confirmed in 1986 prior to well abandonment. This value represents a head approximately 160 ft. above the land surface at Site B and approximately 335 ft. above the heads observed in the shallow Glenns Ferry Formation at Site B. These data confirm that a strong upward hydraulic gradient exists between the deep artesian system and the shallow Glenns Ferry system immediately beneath Site B. The driller log of the artesian well did not report any major aquifer zones between the shallow Glenns Ferry system and the deep artesian zone, spanning an interval of several thousand feet. This was confirmed at the 800-foot-deep exploratory borehole that was drilled by USEI as an exploratory water well west of the site in 1984. Drilling logs from this well indicate that strata below 300 ft. are predominantly blue clay and shale, which is consistent with the driller's log recorded for the artesian well. This hydrogeologic setting and head relationship indicates it is not possible for waste constituents from the site to migrate downward to the deep artesian aquifer. Therefore, the shallow water-bearing zones within the Glenns Ferry Formation are the primary "aquifers" of interest in this Document, and the remainder of this section is devoted to describing, in detail, the characteristics of these two groundwater systems.

Site Hydrogeologic Characteristics

Introduction

In this section, the results of the site-specific hydrogeologic investigations conducted at Site B are presented in detail. The goal of the hydrogeologic investigations to date has been to characterize the geologic and hydrogeologic properties of the uppermost aquifer and any aquifer hydraulically connected to it. At Site B this involved a detailed investigation of the upper 400 ft. of unconsolidated sediments beneath the site. This information has been assembled pursuant to IDAPA 58.01.05.012 (40 CFR 270.14(c)(2)).

The uppermost water-bearing zone beneath Site B actually consists of two discrete, low-yielding, finely bedded sand zones that are separated by a 20- to 30-foot-thick confining clay bed. Under the nomenclature used in this report, these two zones are called the Upper and Lower Aquifers, respectively. Both zones occur in the Glenns Ferry Formation.

An unsaturated zone, ranging from 140 ft. to 200 ft. in thickness, overlies the uppermost aquifer and consists of silts and clays of the Glenns Ferry Formation overlain by coarser-grained sands, silty sands, dense clay beds, and sandy gravels of the Bruneau Formation.

The following sections develop in detail the generalized concepts presented above. A description of the site-specific subsurface geology is provided, followed by a detailed examination of the hydraulic and hydrochemical aspects of the uppermost aquifer system. The system is complex as a result of subtle stratigraphic differences within the Glenns Ferry Formation and the effect of dipping strata. To orient the reader, an overview of the uppermost aquifer concept is presented in Section E.3.c.(3), following the site-specific geology discussion below.

Site Geology

Formation Identification

Quaternary and Tertiary sediments of the Bruneau and Glenns Ferry Formations directly underlie the site. The veneer of surficial gravels present over much of the site is interpreted as basal conglomerate of the Pleistocene-Age Bruneau Formation (Benfer, 1984). Fine-grained sediments of the Pliocene- to Pleistocene-Age Glenns Ferry Formation underlie the Bruneau Formation gravels. The Glenns Ferry then persists throughout the remaining depth of the investigation.

Stratigraphy

Throughout the remainder of this section, references will be made to the observed thicknesses of various geologic strata penetrated. Qualitative descriptive terms have been numerically classified according to Krumbein and Sloss (1963).

Geologic and geophysical logs have been used to construct several geologic cross sections depicting the stratigraphy at USEI Site B. Previous reports and submittals on file with DEQ contain these large cross section plates which are not reproduced in this application.

With two minor exceptions, the basal gravels of the Bruneau overlie the entire site. The exceptions are where the basal gravels are thinly covered by recent soil or ash layers, or where they have been removed by site construction activities. Typically, the gravels are present only to about 50 ft. bgs but were found to extend to approximately 100 ft. in the southeast and northeast corners of the site.

The Glenns Ferry is present beneath the Bruneau gravels and represents sedimentary deposition in a large lake system with peripheral and capping fluvial and flood plain facies (Smith et al., 1982). As such, the Glenns Ferry consists of lake-margin deposits containing fluvial deposits (stream and beach shoreline sands and near-shore silts). Underlying the fluvial deposits are the lacustrine facies (lake deposits) of the Glenns Ferry. The entire sequence exhibits upward coarsening (finer grained with depth). As such, this represents a period of lake regression (a lowering of the water level in the ancient lake [Selley, 1972]). Lithologic and facies contacts are gradual and are controlled by the predominance of grain size and bedding.

The upper (fluvial) sequence of the Glenns Ferry Formation contains very thick-bedded (greater than ten (10) ft.) fine sands and silts containing a few clay seams. Typically, the sands are well sorted, moderately indurated, and thickly bedded. Calcite cementing predominates. The clay seams distributed within the sand are generally thin-bedded (several inches to one (1) ft. thick) and are plastic (soft and moldable). Near the base of the sequence, thin-bedded carbonates (limestone) occur. These sedimentary sequences are representative of lake margin environments (Selley, 1972). This section persists to approximately 130 ft. in depth at the center of the site, where the finer grain size and thinner bedding exists. Where the predominance of finer grain size and thinner bedding exists, this facies change is interpreted as the bottom contact of the fluvial facies overlying lacustrine sediments of the Glenns Ferry Formation.

The lacustrine facies consists of thick-bedded clays and silts containing very thin beds of silt, sand (generally less than one ft. (1) thick), and sand-silt lamina. The sequence expresses cyclic sedimentation for the depth investigated. The formation transcends through thick-bedded sequences of clay and silts containing discrete, thinly bedded sands (one ft. (1) thick or less) and reflects deposition representative of a lacustrine environment as the lake waters rose and fell. The sands and silts (linear and lense-like in form) represent near-shore and shoreline deposits. Portions of this sequence are deltaic in nature and contain abundant plant debris. Sheet-like clay and finer silts are representative of offshore and deeper lacustrine deposition.

The first sequence of shoreline and near-shore deposits underlying the fluvial facies occurs at an approximate depth of 160 ft. at the center of the site. In the northwest portion of the site, the sequence contains numerous thin-bedded silty sands and lamina that are separated by thin- to thick-bedded silts and clays. These sand beds appear to pinch and thin toward the south and east, forming thickly bedded clay and silt in those directions. Although a continuous zone exists, individual sand beds appear discontinuous across the site. This may indicate that the source of the sands was from the northwest, where increased bedding and coarser grain sizes would be expected. This may also be a result of a lateral facies change, such as a transition to a flood plain or deltaic sequence, occurring within the northern portion of the site, or may represent younger deposition upon paleo-erosional surfaces. It is this zone of thin, discontinuous, and laterally variable sands and silts that represents the Upper Aquifer. Within the upper portion of the sequence, the unit changes color from brown to gray, which may represent a change from oxidizing to reducing conditions at the time of deposition?

These near-shore deposits transcend downward into offshore (deep lake) deposits consisting of thickly bedded clay containing silt. This clay unit is approximately 20 ft. thick at the center of the site, extending to a depth of approximately 230 ft. This zone thickens from approximately 20 ft. thick in the northwest portion of the site to more than 30 ft. thick in the southeast portion of the site. This unit is the confining bed separating the Upper and Lower Aquifers.

This offshore deposit transcends into another shoreline and near-shore sequence, generally comprising thick-bedded silt and thin-bedded clay that contains thin-bedded sands and sand lamina. This zone (the Lower Aquifer) is continuous across the site, although individual sand beds gradually thin and pinch out. This unit extends to a depth of approximately 250 ft., where again, deposition transcends into deeper offshore deposits of thick-bedded clay and fine silt, which provide the basal confinement of the Lower Aquifer. It appears from the limited information and from the deep borings that this facies again transcends into another sequence of near-shore sands and silts at approximately 290 ft. in depth. These sands are very thin-bedded and have not been investigated.

The drilling logs of the deep artesian well onsite and the 800-foot-deep exploratory water well (WWI) west of the site indicate that the strata below 300 ft. are predominantly blue clay and shale to at least 1,770 ft.

Structure

Units of the Glenns Ferry Formation at the site strike north 69 degrees west, and dip approximately 3.5 degrees to the northeast. Gradual differences have been noted within the formation and reflect changes in depositional environment reflective of lacustrine sedimentation and Snake River Plain downwarping. The upper near-shore sequence (i.e., the Upper Aquifer measured at its base) strikes north 70 degrees west and dips 1.8 degrees northeast. The next near-shore sequence (i.e., the Lower Aquifer measured at its center) strikes north 70 degrees west and dips 2.4 degrees northeast, as measured from Coreholes D-32, D-22, and D-21.

No evidence of faulting exists within the depths of the investigation at the site as determined by surface mapping of existing trenches and analysis of geologic cores. Units can be traced across

the site using geophysical logs and direct core logs, all of which conform to measured strike and dips. No indications of faulting (such as displacement, associated fracturing, or alteration) have been witnessed throughout the entire geologic section investigated.

Site Hydrostratigraphy

This section will describe in detail the hydrologic and hydrochemical properties of two interbedded sand zones that have been defined as uppermost aquifer(s) beneath the site pursuant to IDAPA 58.01.05.012 (40 CFR 270.14(c)(2)).

Overview

Two low-yielding, water-bearing zones denoted as the Upper and Lower Aquifers have been identified within the shallow Glenns Ferry Formation beneath Site B. Although neither zone would be classified as an aquifer for water resources development because of the definition of the uppermost aquifer in the regulatory context; they represent the uppermost aquifer(s) of concern for groundwater monitoring purposes. The Upper Aquifer at Site B consists of finely bedded, fine, silty sand in 80 ft. to 90 ft. of silt and clay. The top of the Upper Aquifer sequence is a gradational contact with the overlying fluvial facies of the Glenns Ferry Formation. The top of the Upper Aquifer section is 120 to 160 ft. below ground level. A massive clay, 20ft to 30 ft. thick, hydraulically separates the Upper Aquifer from another group of fine, silty, and clayey sands referred to as the Lower Aquifer. The top of the Lower Aquifer is 220 ft. to 275 ft. below ground level and the aquifer section is 30 ft. to 40 ft. thick. Because of structural dip, both aquifers slope to the northeast at approximately 2 to 4 degrees.

As a result of the northeasterly structural dip, the Upper Aquifer sands gradually emerge out of the water from north to south across the site. The entire Upper Aquifer becomes unsaturated along a general east-west trend that crosses the south-central portion of the site. South of this emergence, the sands comprising the Upper Aquifer are present but they are above the potentiometric surface and are not saturated. Conversely, the saturated thickness of the Upper Aquifer increases from south to north as more sands become saturated.

The potentiometric surface of the Upper Aquifer varies from 140 ft. to about 200 ft. below ground level. Groundwater in the Upper Aquifer flows into the site all along the northern border, but most enters from the northwest corner. Flow in the Upper Aquifer is to the east and southeast. The permeabilities of the Upper Aquifer are low, and sustained well yields are generally less than 1.0 gpm.

The Lower Aquifer consists of two (2) ft. to nine (9) ft. of thinly bedded, very fine sand and silty sand seams in a 30- to 40-foot-thick section of silts and clays. Most sand beds are found within a 15-foot-thick interval. The Lower Aquifer is saturated beneath the entire site. The permeabilities of the Lower Aquifer are low, and well yields are generally less than 0.5 gpm. Water in the Lower Aquifer is under moderate artesian pressure. Along the northern edge of the site, water levels rise 60 ft. to 80 ft. above the top of the aquifer. Groundwater in the Lower Aquifer flows to the northeast.

Upper Aquifer

The Upper Aquifer sequence consists of thinly bedded sands and sand lamina separated by thin- to thick-bedded silts and clays. The individual sand seams range from less than 1.5 ft. thick to partings less than 1/16 of an inch thick. Most are between 0.5ft. and 0.1 ft. thick and consist of very fine-grained, silty sand. Lateral continuity of individual sands is difficult to demonstrate, but the aquifer sequence is present across the entire site. The total cumulative thickness of the sand beds changes laterally east and west because of depositional variations.

In the northwest portion of the site, the cumulative thickness of saturated sand beds in the Upper Aquifer ranges from about eight ft. (8) ft. to 36 ft., occurring over approximately 70 ft. of fine- to

thick-bedded silts and clays. The individual sand beds thin and pinch-out toward the east and south. Therefore, the Upper Aquifer contains less sands and therefore does not yield as much water to the east and south. The cumulative thickness of bedded sands underlying the water table in the eastern portion of the site is approximately two (2) ft. to 12 ft., occurring over approximately 20 ft. to 50 ft. of fine- to thick-bedded silts and clays.

The bottom of the aquifer sequence is represented by a relatively rapid gradational change from bedded silts and silty clay to the massive silty clay and clay of the underlying confining bed. The bottom of the Upper Aquifer section ranges from 185 ft. to 250 ft. below ground level.

The top of the Upper Aquifer is also a gradational contact. As discussed earlier, the Upper Aquifer is developed in the lacustrine facies of the Glenns Ferry Formation. The contact between the lacustrine and overlying fluvial sediments is a gradational facies change represented by a thinning of beds and dominance of silts and clays from fluvial to lacustrine. The top of the lacustrine facies (top of the Upper Aquifer sequence) ranges from 120 ft. below ground level in the northwest corner to about 160 ft. below ground level in the northeast corner; across the central portion and eastern sides it is 120 ft. to 140 ft. below ground level. Thickness of the sequence ranges from 80 ft. to 90 ft.

The top of the saturated water-bearing portion of the Upper Aquifer is a function of the intersection of the dipping stratigraphic sequence and the potentiometric surface. Because of the dip, the section rises above the potentiometric surface and becomes unsaturated across the southern portion of the site. From south to north, the dip causes progressively more sand seams to intercept the potentiometric surface and become saturated. Consequently, the saturated thickness of the aquifer increases to the north and the top of saturation is found progressively higher in the geologic section comprising the Upper Aquifer.

Each individual saturated sand seam is probably under confined conditions as a result of the adjacent silt and clay beds. Given the scale of the bedding, it is impossible to isolate individual sand seams to verify this assumption. Taken as a whole, however, there appears to be little evidence of vertical gradient within the Upper Aquifer section, and, therefore, the aquifer is considered to be unconfined.

Intermediate Clay Bed

The inner confining clay between the Upper and Lower Aquifers ranges from 20 ft. to 30 ft. thick across the site. As discussed in the previous section, the top of the inner confining clay is gradational with the silts of the bottom of the Upper Aquifer. A similar transitional contact exists between the bottom of the confining clay and the top of the Lower Aquifer. In both cases, the gradational contact occurs within about five ft. (5). This clay consists of blue-gray, massive to thickly bedded clay. In Corehole D-23, in the northwest corner, there are seven (7) to ten (10) silty sand lamina (less than 1/8" thick) within the 20 ft. thick clay, while along the east side, no sand lamina are found in the entire 20 ft. thick section.

This clay unit is persistent and consistent across the site and hydraulically separates the Upper and Lower Aquifers. This hydraulic separation is evidenced by differences in water level, flow directions, and water chemistry between the Upper and Lower Aquifers. These indicators of hydraulic separation are discussed in more detail in subsequent sections.

Lower Aquifer

The Lower Aquifer is a sand sequence within silts and clays of the Glenns Ferry Formation. Although the persistence and thickness of individual thinly bedded sands varies laterally, the aquifer is present and saturated everywhere beneath the site.

The bedded sands occur within a 30 ft. to 40 ft. thick sequence of thick-bedded silts and clays. The majority of sands occur within a 10 ft. to 15 ft. interval. Cores and geophysical logs of borings indicate that the bedded sands pinch and thin toward the west and south, forming very thin-bedded sands and sand lamina less than ¼" thick. Some sands are discontinuous and pinch out. The total cumulative thickness of bedded sands in the western portion of the site is less than four (4) ft.

Along the east side of the site, the individual beds range from sand lamina (less than ¼ inch thick) to one ft. (1) thick bedded sands, the latter consisting of fine- to very fine-grained silty sand. Most of the water is probably being carried in the upper portion of the sequence, where greater sand thickness and persistence exist. The total cumulative thickness of bedded sands in the Lower Aquifer along the eastern side is less than nine ft. (9). The top of the Lower Aquifer section is 205 ft to 275 ft. below ground level, and the bottom is 305 ft. to 250 ft. below ground level. The Lower Aquifer section generally ranges from 30 ft. to 40 ft. thick.

Basal Confining Clay

Underlying the Lower Aquifer is a massive to thickly bedded clay at least 25 ft. thick. This clay was penetrated in only a few borings, and it has not been tested extensively. Visual descriptions indicate it to be massive (does not contain sand lamina) and "fat," having high plasticity. Properties of this clay are expected to be similar to the inner confining clay.

Hydraulic Properties

Introduction

Pursuant to IDAPA 58.01.05.012 (40 CFR 270.14(c)(2)), the hydrogeologic regime at USEI Site B was characterized as part of the initial permit application process (CH2M HILL, February 1986). Subsequent to the issuance of the permit, considerable additional information has been developed on the hydraulic properties of the Upper and Lower Aquifers at Site B. This portion presents a complete reexamination of the hydrologic properties of Site B, using both previously presented information and new information. The objectives of the hydrologic characterization program were to 1) examine the factors that influence the rate and direction of groundwater movement; 2) evaluate overall groundwater availability; 3) evaluate the degree of hydraulic separation of the Upper and Lower Aquifers; and 4) estimate the degree of containment afforded by the clays and other sediments found above, below, and between the aquifers.

Information from the available data were used individually and conjunctively to determine the hydraulic characteristics that define the groundwater flow properties at USEI Site B. The aquifers at Site B consist of finely bedded, fine sand and silt beds in a predominantly silty clay matrix. Because most groundwater flow, and therefore most of the potential contaminant migration, would occur in the sand beds, the ultimate aquifer property being sought from the aquifer test data was the hydraulic conductivity (K) of the sand beds, as opposed to a composite hydraulic conductivity of the entire saturated thickness. Most of the test data available, however, provided either an estimate of the composite K or the transmissivity (T) of the entire saturated thickness of the aquifer.

To estimate the K of the sand beds, the T and/or K values from the aquifer tests were adjusted to reflect only the cumulative thickness of sand beds identified in the wells as estimated from review of the geologic and geophysical logs for each well. Once a K was determined, an estimated groundwater velocity was calculated. Aquifer transmissivities were also used to compare the relative water flux across the site through and between aquifers.

To evaluate the degree of containment afforded by the clays and other sediments found above, below, and between the aquifers, laboratory testing was performed on soils collected from the Upper and Lower Aquifers and the inner and lower confining units. Grain-size analyses and

permeability testing were performed on 79 samples of materials from three (3) borings, D-21, D-22, and D-23, at the USEI site. These data were previously reported in CH2M HILL (February 1986) as part of USEI's 1985 Part B permit application.

Results

Usable data are not available on all wells but the large amount of data that was available provides valuable information on both aquifers beneath all portions of the site. Soil hydraulics testing data are presented in CH2M HILL (February 1986).

In Section E.3.b., a transmissivity value was estimated for each pumping and recovery test, slug test, and specific capacity test (Table E-9). Based on the individual tests, an average T value for each well was calculated as shown in Table E-9. The average T value is the average of all aquifer tests performed over the lifespan of the well. Additionally, if an individual test was analyzed by more than one analytical technique and more than one analytical technique provided a valid solution, then all valid solutions are included in the calculation of the average T value.

K values were calculated from the average transmissivity data through the relationship $K = T/b$ where b = the saturated aquifer thickness. Representative thickness values were obtained for 22 of 28 test wells in the Upper Aquifer and 14 of 15 test wells in the Lower Aquifer where successful transmissivity values were obtained. Representative thickness values were determined via an interpretation of subsurface conditions at each respective test site. Information from all geologic and geophysical logs was used to estimate the actual thickness of sand beds present within each test interval. This was done to adjust the aquifer test results under the premise that most of the aquifer response during the tests occurs from the sandier aquifer zones, and not the adjacent confining zones, a portion of which is generally included in the test interval. This resulted in a conservative reduction in the thickness values and an associated conservative increase in hydraulic conductivities.

As a supplement to the in situ determination of hydraulic conductivity provided by the aquifer tests, hydraulic conductivity values were also calculated from grain-size distribution information by the Hazen Method. Thirteen (13) of the 79 samples had grain-size analysis performed on the most permeable beds in the Upper and Lower Aquifers. Table E-11 summarizes the calculated hydraulic conductivity estimates for these 13 soil samples based on the Hazen Method. The Hazen Method is one of several predictive equations that relate hydraulic conductivity values to the grain-size distribution of representative aquifer materials. The techniques are approximation methods, but generally provide useful estimates of hydraulic conductivity (Freeze and Cherry, 1979). Todd (1980) cautions that the empirical formulas may not give reliable results because of the difficulty of including all possible variables in porous media. Therefore, field and laboratory methods are preferable as a general rule.

The Hazen Method estimates K through the following relationship (Equation E.3-2):

$$K = A (d_{10})^2$$

where:

K is the hydraulic conductivity, A is a conversion factor (equal to 1.0 when K is reported in cm/sec and grain size in millimeters [mm]), and d_{10} is the grain-size diameter at which ten (10) percent by weight of the particles are finer.

Upper Aquifer

For the Upper Aquifer, transmissivity values were obtained from 28 test wells. Average T values ranged from a low of 0.1 ft²/day for U-26 to a high of 51.1 ft²/day for D-18 (abandoned). The mean transmissivity for the Upper Aquifer is 7.0 ft²/day, based on an average of the average T values. Figure E-12 denotes the average transmissivity values obtained for each Upper Aquifer

test site. Figure E-12 also shows the distribution of T values in the Upper Aquifer. In Figure E-12, T values are grouped into ranges of α 0.1 ft²/day, 0.1 to 2.0 ft²/day, 2.0 to 5.0 ft²/day, and $>$ 5.0 ft²/day. The highest T values of the Upper Aquifer occur beneath the north/northwest portions of the facility and generally decrease toward the south and east.

To understand the significance of these transmissivity values, they can be compared to minimum values required for a domestic water supply. The U.S. Bureau of Reclamation (USBR) has investigated and published the transmissivity values necessary for water supply development purposes (USBR, 1977). Transmissivity values below one (1) ft²/day are considered infeasible for domestic well purposes, while transmissivity values between one (1) ft²/day and 10 ft²/day are considered poor. Fair well potential can be achieved with transmissivity values between 10 and 100 ft²/day. Thus, the transmissivity values obtained for the test sites are generally in the infeasible to poor well potential range, with only five (5) average T values of the Upper Aquifer test locations falling in the fair range. As shown in Figure E-12, the five higher-yielding wells are located in the north/northwest portion of the Upper Aquifer.

The calculated hydraulic conductivity values derived from the average T for the Upper Aquifer materials range from a minimum of 4.0×10^{-2} ft/day (1.4×10^{-5} cm/sec) at U-26 to a maximum of 4.2 ft/day (1.5×10^{-3} cm/sec) at UP-7. These values are representative of very fine sands and mixtures of sand, silt, and clay, which are reported to have conductivity values ranging from 10^{-3} cm/sec to 10^{-6} cm/sec (Todd, 1980). Consistent results were observed between the geologic classification of subsurface materials and their calculated conductivity values. From Table E-11 it can be seen that the range of empirically derived hydraulic conductivity values (Hazen Method) in the Upper Aquifer is significantly lower than the range determined with the pump tests. For the Upper Aquifer, empirically derived hydraulic conductivity values ranged from 2.6×10^{-2} ft/day (9.0×10^{-6} cm/sec) to 0.5 ft/day (1.69×10^{-4} cm/sec). The hydraulic conductivity values obtained from the grain-size analyses may include finer-grained materials from the confining zones that are adjacent to the sandier aquifer zones. This could account for the somewhat lower values observed. It is important to note that the hydraulic conductivity values obtained from the grain-size analyses were not used in the computation of groundwater velocities. Rather, they have been included for exemplary purposes and as an additional check on pumping test-derived hydraulic conductivities.

Lower Aquifer

For the Lower Aquifer, transmissivity values were obtained from 15 test wells. Average T values ranged from a low of 0.4 ft²/day for MW-6 (abandoned) to a high of 3.3 ft²/day for MW-5 (abandoned). The mean transmissivity for the Lower Aquifer is 1.0 ft²/day, based on an average of the average T values. T values in the Lower Aquifer are low and do not appear to follow a discernible distribution pattern. Based on the USBR criteria discussed above, the transmissivity values obtained from the Lower Aquifer test sites are in the infeasible to poor well potential range for a domestic water supply.

The calculated hydraulic conductivity of the Lower Upper Aquifer materials range from a minimum of 6.9×10^{-2} ft/day (2.4×10^{-5} cm/sec) at L-38 to a maximum of 8.3×10^{-1} ft/day (2.9×10^{-4} cm/sec) at MW-5 (abandoned). Similar to the Upper Aquifer, these values are representative of very fine sands and mixtures of sand, silt, and clay, which are reported to have conductivity values ranging from 10^{-3} cm/sec to 10^{-6} cm/sec.

The range of empirically derived hydraulic conductivity values (Hazen Method) in the Lower Aquifer is lower than the range determined with the pump tests. For the Lower Aquifer, empirically derived hydraulic conductivity values ranged from 2.8×10^{-3} ft/day (1.0×10^{-6} cm/sec) to 0.6 ft/day (1.96×10^{-4} cm/sec). As noted above, the hydraulic conductivity values obtained from the grain-size analyses may include materials from the confining zones that are adjacent to the sandier aquifer zones. This could account for the somewhat lower values observed. It is important to note that the hydraulic conductivity values obtained from the grain-size analyses

were not used in the computation of groundwater velocities. Rather, they have been included for exemplary purposes and as an additional check on pumping test-derived hydraulic conductivities.

Intermediate (Inner) and Basal Confining Layers

Soil samples collected from D-21, D-22, and D-23 that represent the inner and basal confining zones are identified in Table E-10. The vertical coefficient of permeability was determined for ten (10) of the confining material samples. The range in vertical permeabilities for the two confining zones was 1.1×10^{-4} to 1.4×10^{-1} ft/day (4×10^{-8} to 5.0×10^{-5} cm/sec). The single sample (boring D-22, sample S-31) with the 5.0×10^{-5} cm/sec value is probably due to bedding fractures within the clay as noted on the well log (CH2M HILL, February 1986) or may represent a silty or sandy seam in the confining bed. Without including this sample, the vertical conductivity of the confining beds ranges from 5.7×10^{-3} ft/day (2×10^{-6} cm/sec) to 1.1×10^{-4} ft/day (4×10^{-8} cm/sec) and the mean value is 2.8×10^{-4} ft/day (1×10^{-7} cm/sec).

As shown in Table E-10, the moisture content for the soil samples collected from the inner and lower confining zones ranged from 23.0 % to 31.0 % and averaged 28.1 %, and the degree saturation ranged from 89.4 % to 98.7 % and averaged 93.7 %. These data indicate that moisture was present in the confining zones at near-saturated field conditions. According to the field drilling logs, the moisture content within the inner and upper confining zones ranged from dry to moist, supporting the presence of some moisture in the soils in the confining zones. However, the moisture content in soils below 100 ft. may have been affected by water used in rotary drilling.

Groundwater Flow Properties

Water Level and Hydraulic Gradient

Depth to Water Level Measurement Corrections

The results of gyroscopic surveys at piezometers U-26, UP-28, and UP-29 and monitoring well L-28 indicate that UP-28, UP-29, and L-28 significantly deviate from vertical, and U-26 does not significantly deviate from vertical. As a result, the depth to water measurements at UP-28, UP-29, and L-28 have been corrected based on regression analysis.

Based on the corrected depth to water measurements, the water level elevation anomaly indicated on potentiometric surface maps of the Upper Aquifer in the vicinity of UP-28 does not appear to be directly associated with the inclination of the piezometer off of vertical. However, the water level elevation anomaly indicated on potentiometric surface maps of the Lower Aquifer in the vicinity of UP-28 does not appear to be directly associated with the inclination of the piezometer off of vertical.

Potentiometric Data

Groundwater levels at USEI Site B are measured semiannually in the monitoring wells and piezometers included in the permitted Detection and Compliance Monitoring Systems. The period of record for each well varies according to when the individual well was installed. Some of the wells in the groundwater monitoring system were installed as test wells for site characterization prior to USEI receiving the permit. Consequently, they have periods of record extending back to 1984. Most of the active monitoring wells were installed after the Part B permit was issued and, therefore, the effective period of record begins in 1989.

The pre-1989 data sets tend to have more scatter than the post-1989 wells for several reasons: 1) insufficient water level re-equilibration time between frequent sampling and testing activities; 2) variable wellhead configurations and therefore various measure points between wells and over time for the same well; and 3) non-standardized equipment. As the new and existing wells were brought into the permitted Detection Monitoring System, wellheads and measuring points were

standardized, dedicated water level probes were used and written field procedures and data recording formats were adopted. These measures significantly reduced the data scatter in these records.

Water level data and hydrographs for the pre-1989 period are presented in CH2M HILL (February 1986). Appendix E.6 includes the tabulated data and hydrographs for all 50 wells in the current groundwater monitoring system for the period from April 1989 through April 2001. As discussed in the next section, water levels have been rising at Site B. In 1999 a Rising Groundwater Study was completed (CH2M HILL, 1999b). In 2001, as required by DEQ, the rising groundwater was re-evaluated (CH2M Hill 2001). The 2001 re-evaluation report provides updated hydrographs through April 2001. The next scheduled re-evaluation of the rising groundwater at Site B will be completed in Fall 2003. The rising groundwater study is further discussed in the next section.

From April 1989 through the October 1996 sampling event, all water levels were measured with the same water-level probe. Prior to the October 1997 water-level measurements, however, the original probe failed and could not be repaired. Consequently, a new water meter was used for the October 1997 water-level data set. Calibrating the new probe or establishing a measurement offset by collecting comparison water levels from several wells using both probes could not be completed before the old probe failed.

In comparing the October 1996 to October 1997 water levels, many wells exhibited a significant decline in recorded water-level elevations between the two events. Because a correlation could not be established between the two probes, the observed declines in water levels between the successive October water levels are not considered reliable.

Water levels are tabulated after each sampling event and included in the sampling reports contained in the operating record. These reports document the water level data collected between April 2001 and October 2002. The October 2002 water levels are included on Table E-13 and the period of water level record from October 1989 to October 2002 is used in this section to describe the water level trends, potentiometric surfaces, hydraulic gradients, groundwater velocities, and the groundwater flux and water balance for the Upper and Lower Aquifers at Site B.

Water Level Trends

Water levels in the monitoring wells and piezometers at Site B have been generally rising over the period of record. The rate of rise for each well is variable and not consistent between wells or over the period of record for any individual well.

In 1999 a rising groundwater study was completed (CH2M HILL, 1999b). This study examined flow paths, water chemistry and age dating in an effort to determine the source of the rising groundwater. The rising groundwater study determined that the water in the Lower Aquifer water and eastern portions of the Upper Aquifer were of similar ages but that the water in the Upper Aquifer in the extreme northwest corner of the site was much younger. This suggests that the water coming into the site in the Upper Aquifer was being recharged by Castle Creek about one (1) mile to the west. This incoming water is displacing the older water in the Upper Aquifer. The rising hydraulic head in the Upper Aquifer is also affecting the pressure head in the Lower Aquifer, especially where the two aquifers overlap. Because of the potential impacts of rising water levels on groundwater flow rates and directions, monitoring well screen placement and concerns over possible impacts to water quality as the rising groundwater encounters vapors or the missile silos, DEQ requires the rising groundwater trends to be re-evaluated every two years. The first re-evaluation was completed in August 2001 and the next one scheduled for Fall 2003.

The 2001 re-evaluation report used regression analysis to predict future water level elevations based on the assumption that the rising water level trends continue at current rates. In summary,

these projections indicate the Upper Aquifer water levels will contact the bottom of the missile silos in 36 to 53 years (year 2039 to 2056), again, assuming past trends continue unchanged into the future. In many wells the hydrographs show an initial steeper trend followed by a distinct flattening trend beginning in about 1993 so these predictions must be used with caution. The re-evaluation report also concluded that rising water would not seriously impact well construction or placement as the groundwater flow directions have not changed.

The maximum change has been an increase of 10.71 ft. in piezometer UP-4 and the minimum rise is 3.35 ft. in piezometer UP-7. In general, water levels in the Upper Aquifer on the east side of the site have risen faster than those on the west side. This has resulted in a gradual decrease in the west-to-east gradients across the site, although groundwater flow paths have not significantly changed. A contour map showing the change in water levels in the Upper Aquifer between October 1989 and October 2002 is provided in Figure E-14.

Water levels in the Lower Aquifer wells have also risen over this same period. The average rise in the Lower Aquifer is 4.7 ft. and the range is from 0.42 ft. in well L-35 to 8.26 ft. in well LP-15. In general the wells with the highest water level change, are overlain by the Upper Aquifer. Since the Lower Aquifer is confined, the water levels in these wells are believed to be responding primarily to the increase in loading from the water level rise in the Upper Aquifer.

Well L-38 in the extreme southwest part of the study area experienced a sudden water level increase of approximately ten ft. (10) in 1993 that is believed to be caused by surface loading of earth materials stockpiled in the vicinity during the excavation of Cell 14. Since 1993, the water level has been gradually declining back to the trend line that existed prior to the "spike." Similar, but smaller, spikes occurred in wells L-35 and LP-14 during this same time. These wells are also near the soil stockpile area. Well L-36, in contrast, experienced a drop of approximately three ft. (3) in the water level during this same time, apparently in response to the decrease in loading as the nearby Cell 14 trench was excavated. Since 1993, the water level in L-36 has been gradually rising back to the trend line that existed before the sudden drop in water levels. Water level changes in the Lower Aquifer have not significantly affected the groundwater flow paths.

Potentiometric Surface

Lower Aquifer.

There has been little change in the direction of groundwater flow over the period between October 1989 and October 2002. Groundwater in the Lower Aquifer moves into the site from the southwest and flows northeasterly across the southern end of the site. The equipotential lines on the figures are equally spaced and trend uniformly northwest-southeast. The consistency of the equipotential lines is also another indication that geologic matrix and hydraulic properties of the Lower Aquifer of the site are uniform across the southern and southwestern portions of the site. This uniform flow field characteristic is consistent with the geologic descriptions and hydraulic property characterization data presented earlier in this section.

The potentiometric surface in the Lower Aquifer changes character radically northeast of Cell 14. Because the piezometers in this area are linearly aligned along the northeastern side of the site (LP-12, LP-13 and LP-15), it is difficult to determine true flow patterns. However, the data suggest that groundwater flow in the Lower Aquifer changes to an easterly direction and that the gradients flatten out in this area.

Geologic coring, hydraulic property testing, and geophysical logging of the Lower Aquifer sediments in this area do not indicate any changes in the geologic framework or hydrogeologic properties that would account for these flow direction changes. The apparent distortion of the consistent northeasterly flow pattern exhibited by the Lower Aquifer to the southwest appears to be coincidental with the southern limit of saturation in the overlying Upper Aquifer. These data indicate the potentiometric head in the Lower Aquifer is influenced by the overlying Upper Aquifer. This influence is believed to be primarily related to hydraulic pressure, as opposed to leakage.

The hydraulic communication between the Upper and Lower Aquifer is discussed in more detail below.

Based on the October 2002 potentiometric map, horizontal gradients in the southern part of the Lower Aquifer (that portion not overlain by the Upper Aquifer) range from 0.0110 to 0.0440 ft/ft and average 0.0261. It is not possible to establish a gradient for the Lower Aquifer north of the Cell 14 monitoring wells (where it is overlain by the Upper Aquifer) because of insufficient data points.

Upper Aquifer

Water table maps for the Upper Aquifer for the October 1989 and October 2002 periods are provided in Figures E-16 and E-19. Although, as discussed previously, water levels in the Upper Aquifer wells have risen 3.3 ft. to 10.7 ft. over the 1989 to 2002 time period, the overall pattern of groundwater flow has not changed. Water in the Upper Aquifer flows across the site from northwest to southeast. Water also flows into the site all along the northern boundary. This water flows diagonally across the northeastern corner and exits the site along the eastern boundary.

The additional water level data provided by wells UP-28 and UP-29, installed in 1993 along the west central side of the site, suggests a radical and unexplained gradient change in this area as shown on the October 2002 potentiometric map. The data from these wells indicate that along the west central side of the site, water in the Upper Aquifer is flowing from southwest to northeast, which is almost perpendicular to the predominant flow direction in the Upper Aquifer. However, the groundwater flowing from the area of UP-28 and UP-29 eventually converges upon and joins the rest of the system. Detailed site characterization efforts in this area, including a discussion of the high water levels in wells UP-28 and UP-29, are reported in CH2M HILL (June 1993).

Well UP-28 was drilled into the Lower Aquifer to verify the stratigraphy prior to well construction. Although the Lower part of the borehole was plugged with bentonite grout prior to installing the well, upward leakage of Lower Aquifer water cannot be ruled out. It is unlikely, however, that the high water level at UP-28 represents a mounding effect since the Upper Aquifer sediments should be able to accommodate any minimal leakage past the bentonite seal that could be occurring. There are insignificant chemistry differences between the Lower part of the Upper Aquifer and the Lower Aquifer; therefore, there is not a distinctive chemistry profile that can be used to determine if the high water levels represent leakage up the borehole (see Section E.3.c.(6)). Well UP-29 was not drilled into the Lower Aquifer, yet water levels in this well are also higher than expected. This suggests a natural cause for the elevated heads that cannot be explained by the existing data. At this point, the water levels in well UP-28, and to a lesser extent in UP-29, represent the only deviation in the overall northwest-southeast flow direction in the Upper Aquifer.

The irregular spacing and curved equipotential lines for the Upper Aquifer are an indication of the variable Aquifer hydraulic properties of the Upper Aquifer as described previously in Section E.3.c.(4). There are two hydrologic gradient regimes in the Upper Aquifer, illustrated by the distinct spacing of the equipotential lines in Figure E-19. The western 1/2 of the aquifer displays gradients in the range of 0.0049 to 0.0089 ft/ft. The eastern 1/2 has much steeper gradients that range from 0.0140 to 0.0235 ft/ft. The demarcation between the two gradient regimes appears to extend from slightly west of U-26 on the southern extent of the aquifer to between U-5 and UP-7 on the northern site boundary. The area of low gradients in the north and northwest parts of the site coincides with the areas of high hydraulic conductivity and transmissivity. Aquifer properties and well yields are Lower along the eastern side and southern extent of the aquifer. The pattern of hydraulic gradients illustrated in Figure E-19 mirrors and supports the distribution of aquifer properties.

Groundwater Flux and Velocities

Lower Aquifer

The cluster of sand and silty sand seams comprising the Lower Aquifer occurs over an interval 20 ft. to 40 ft. thick. Recalling that aquifer transmissivity, T , is defined as the hydraulic conductivity times saturated thickness, groundwater flux, or the volume of groundwater moving with time through the Lower Aquifer beneath the southern portion of the site, can be estimated by $Q = T \times I \times \text{width}$, where T = the average aquifer transmissivity, I = the average horizontal gradient, and width is the width of the aquifer parallel to the equipotential lines. The average T for the Lower Aquifer determined in wells around Cell 14 is 1.0 ft/d (Table E-9). The average gradient for the southern portion of the site using the October 2002 water level data is 0.0261 ft/ft as discussed previously. The cross-sectional width of the aquifer beneath Cell 14 is approximately 2,000 ft.. Based on these variables, there is about 57 cubic feet (ft³) per day or 20,958 ft³/year of water moving through the entire width and thickness of the Lower Aquifer. To put this flow rate in perspective, a typical household uses 400 gallons per day or 19,600 ft³/year. Because the cross-sectional area, hydraulic conductivity, and hydraulic gradient in the Lower Aquifer do not change significantly across the site, flux into the site from the west side and flux leaving the site on the east side are approximately equal.

Most groundwater movement and, therefore, contaminant transport, will occur through the sand seams making up the aquifer. Groundwater velocities for the sand seams can be estimated by $\text{Velocity} = (K \times I) / n_e$ where K is the hydraulic conductivity, I is the gradient, and n_e is the effective porosity. Effective porosity is defined as that portion of the total porosity through which flow occurs. Effective porosity is almost impossible to determine because of the difficulty in obtaining undisturbed samples. The average porosity of the fine sands in the Upper and Lower Aquifers at Site B was 0.43. Also, as discussed in the 1986 Section E, researchers have concluded that for groundwater flow through granular media, the total porosity can be used in the velocity calculation with little effect. Therefore, velocity calculations for Site B made since 1986 have used the porosity value of 0.43. The K and porosity of the sand beds, as discussed in the Aquifer Properties section, were used in the velocity calculations. Calculated seepage velocities for the Lower Aquifer range from 2.6 ft. to 11.2 ft. per year and average 5.2 ft. per year. Calculated velocities vary with the K and I at each well.

Upper Aquifer

Flux calculations for the Upper Aquifer are more complicated than for the Lower Aquifer because the Upper Aquifer is unconfined, the gradients across the site are highly variable, and the saturated thickness varies from about 70 ft. along the north facility boundary to zero feet across the northern edge of Cell 14 where the last of the aquifer sediments emerge. Consequently, a wedge-shaped, cross-sectional area was used to compute the flux, and separate fluxes were calculated for the west and east sides.

From this exercise, the estimated flux into the site from the west is about 43,122 cubic feet (ft³) per year and the flux leaving the east side of the site is 5,193 cubic feet (ft³) per year. The difference between the two values is a net inflow of 37,929 cubic feet (ft³) per year that must be accounted for. These issues are presented in the Water Balance section (Section E.3.c.(5)(d)), which follows the Upper Aquifer groundwater velocity discussion.

The same approach and assumptions presented earlier for the Lower Aquifer were also used to estimate velocities in the Upper Aquifer sand beds. Calculated seepage velocities for the Upper Aquifer range from 0.2 ft. per year at well U-2 to 81.6 ft. per year at well UP-7. The average for all Upper Aquifer wells is 8.3 ft. per year.

Calculated velocities vary with the K and I at each well. Table E-9 provides the calculated velocity at each Upper Aquifer well for which a K and I value have been determined. Although the composite hydraulic conductivities on the east side of the site are lower than those for the northwest corner, the gradients are higher. Therefore, there are no large and consistent east-west differences in the calculated groundwater velocities in the Upper Aquifer across the site. However the three wells with the highest velocities (UP-7, UP-5 and U-6) are all located in the northeast corner of the site.

Vertical Gradients and Flux

Separating the two aquifers is the inner confining bed, a strata of clay and silty clay 20 ft. to 40 ft. thick. The hydraulic head relationship between the Upper and Lower Aquifers across the inner confining bed varies across the site. Near the southern limit of saturation in the Upper Aquifer north of Cell 14, the hydraulic head in the Lower Aquifer is higher than the water table in the overlying Upper Aquifer. Across a narrow band in the middle of the site there is no significant head difference between the two aquifers, and across the northern 1/2 of the site water levels in the Upper Aquifer are higher than the head in the Lower Aquifer.

Using the October 2002 water level data, there are five Upper Aquifer-Lower Aquifer well pairs available to quantify the gradient across the inner confining bed. The upward gradient, as measured in two well pairs (U-26/L-33 and UP-26/LP-27) averages 0.0378 ft/ft with .77 ft. to 1.5. ft. of actual water level difference. There are much greater water level differences between the Upper and Lower Aquifers across the northeast side of the site. Downward gradients in the three well pairs in this area (U-7/LP-13, UP-4/LP-12, and U-12/LP-15) average 0.1231, with actual water level differences ranging from 1.63 ft. at U-12/LP-15 to 6.77 ft. at U-7/LP-13.

Laboratory tests conducted on geologic cores of the inner confining bed and from similar formations within and beneath the Lower Aquifer provided estimates of vertical hydraulic conductivities of 1×10^{-7} to 1×10^{-8} cm/sec. (CH2M HILL, February 1986). Vertical flow occurs across strata, as opposed to along strata for horizontal flow. Therefore, it is appropriate to assume that in a bedded sedimentary sequence, vertical movement will be controlled by the material having the lowest hydraulic conductivity. To evaluate leakage between the Upper and Lower Aquifers, a vertical conductivity of 10^{-8} cm/sec was used.

Applying Darcy's law and using an average vertical hydraulic conductivity of 10^{-8} cm/sec, the gradients discussed previously, and an upward gradient zone 500 ft. wide by the width of the site (2,000 ft.) results in a flux of 391 cubic feet (ft^3) of water per year moving from the Lower to the Upper Aquifer in the southern part of the site. Doing the same calculation for the area with downward gradients across the northern part of the site indicates a downward flux of 3,822 cubic feet (ft^3) per year moving from the Upper Aquifer to the Lower Aquifer.

Comparing the calculated vertical flux into the Lower Aquifer beneath the northern part of the site to the horizontal flux in the Lower Aquifer south of the area overlain by the Upper Aquifer indicates that about 1/4 as much water is moving vertically into the Lower Aquifer as is coming in horizontally from the southwest. As discussed previously, the horizontal gradients in the Lower Aquifer beneath the northern part of the site appear to flatten and change directions to roughly parallel that in the Upper Aquifer. This gradient change is probably due to a combination of the flux of water coming vertically into the Lower Aquifer and the effect of the hydraulic head imposed by the overlying Upper Aquifer.

There are distinct water chemistry differences between the Upper Aquifer and the Lower Aquifer wells in the northern parts of the site. If leakage from the Upper Aquifer is a significant source of water for the Lower Aquifer as the Darcy flux indicates, then the Lower Aquifer water chemistry beneath the northern part of the site should also reflect the influx of Upper Aquifer water.

In summary, although there are strong downward gradients and therefore by Darcy's law a calculable net flux of water from the Upper Aquifer into the Lower Aquifer, water chemistry data suggest that the actual flow is much less than the calculations indicate.

Water Balance Calculation

To synthesize the elements affecting the movement of water through the Upper Aquifer at USEI Site B, a water balance was prepared. One of the most significant benefits of conducting a water balance analysis is to check the validity of the estimated physical and hydrogeologic characteristics of the aquifer and the overall conceptual model of the system. If it is impossible to achieve an approximate level of water balance by applying the site characterization data, then either the characteristics are not correct or the conceptual model is not correct. As will be presented in the following section, the water balance for the Upper Aquifer at Site B indicates that the site characterization data are both correct and reasonable and that the overall conceptual model is correct.

The elements of a water balance for the Upper Aquifer are: lateral inflow, lateral outflow, vertical inflow from the Lower Aquifer, vertical outflow to the Lower Aquifer, infiltration of precipitation, groundwater pumpage, and change in storage. To examine the water balance at Site B, the 13-year period from October 1989 to October 2002 was used. Each of the elements of the water balance discussed independently in the preceding sections is briefly presented below.

Lateral Inflow and Outflow in the Upper Aquifer

As mentioned previously, in the Upper Aquifer there is approximately 43,122 cubic feet (ft³) per year coming into the site from the northwest and 5,193 cubic feet (ft³) per year leaving along the eastern side. This results in a net influx of 37,929 cubic feet (ft³) per year or a total net gain of approximately 498,265 cubic feet (ft³) over the 1989 to 2002 period.

Vertical Inflow from the Lower Aquifer

The vertical flux calculations provided above account for an influx of 391 cubic feet (ft³) per year from the Lower Aquifer to the Upper Aquifer over the southern portion of the Upper Aquifer. From 1989 to 2002, this added approximately 5,089 cubic feet (ft³) of water to the Upper Aquifer.

Vertical Outflow to the Lower Aquifer

Over the northern portion of the Upper Aquifer, the calculated flux from the Upper Aquifer to the Lower Aquifer was about 3,822 cubic feet (ft³) per year, or 49,683 cubic feet (ft³) over the 1989-2002 period.

Precipitation Infiltration

There is no direct evidence of the infiltration of precipitation at Site B. In fact, the only hard evidence, very dry moisture contents in the vadose zone determined during the vadose zone characterization, suggests no infiltration is occurring. However, infiltration of precipitation occurs under very arid conditions given the right set of circumstances. Therefore, an infiltration component was included. The percentage of annual precipitation that actually infiltrates and reaches the groundwater is highly speculative and in arid ranges may range from essentially zero to about two percent (2 %) of annual precipitation. An infiltration rate of 0.05 inches per year (0.7 % of annual precipitation) was applied to the total square footage of the Upper Aquifer (about 4,000,000) and equates to about 16,667 cubic feet (ft³) per year, or 216,967 cubic feet (ft³) from 1989 to 2002. This calculated amount is intuitively much too large for Site B, especially given the dry vadose sediments present. At Site B where compacted clayey surface soils are prevalent and surface water runoff is channeled into lined ponds, infiltration rates are expected to be very low. The rising groundwater study conducted in 1999 (CH2M HILL, 1999b) found no evidence of recent precipitation water in the Upper Aquifer through either water chemistry or

tritium age dating and it probable that the effective recharge from precipitation is essentially zero at this site. However, for the purposes of the water balance, a low infiltration rate was used. The conclusions of the water balance evaluation are not affected by the inclusion, or exclusion, of precipitation.

Vadose Zone Drilling and Sampling

Two boreholes, D-33 and D-34, were drilled as part of the vadose zone drilling and sampling program.

Laboratory analyses were performed on 40 vadose zone soil samples from D-33 and D-34. The laboratory data were also grouped by geologic formation to determine the average properties of the different soil types encountered in the two boreholes. A total of seven soil types are identified: the Bruneau Formation soils, Glenns Ferry fluvial facies sand/silty sand soils, Glenns Ferry fluvial facies clayey silt soils, Glenns Ferry sandy silt soils, Glenns Ferry lacustrine sand/silty sand soils, Glenns Ferry lacustrine clayey silt soils, and Glenns Ferry blue-gray clayey silt soils.

Two geologic cross sections of the vadose zone at Site B were prepared from available soil boring logs. Cross section K-K' runs north to south along the eastern edge of the site. Cross section L-L' cuts diagonally across the site from the northeast to the southwest corner. Both cross sections show the interpreted locations of geologic formations and facies beneath the site. It should be noted that these cross sections have a large vertical exaggeration and the actual dip of the various geologic units if drawn to scale would appear almost horizontal.

The following is a summary of the results of the vadose zone drilling and sampling program.

1. Auger drilling and continuous sampling provide effective methods for obtaining detailed stratigraphic information on the vadose zone at Site B to depths of approximately 150 ft.
2. Laboratory data indicate the presence of four distinct soil types: 1) sands and gravels of the Bruneau Formation; 2) sands/silty sands of the fluvial and lacustrine facies of the Glenns Ferry Formation; 3) sandy silts of the fluvial and lacustrine facies of the Glenns Ferry; and 4) clayey silts of the fluvial and lacustrine facies of the Glenns Ferry Formation.
3. Saturated hydraulic conductivities of Bruneau Formation soils show the largest variation and range from 10^{-5} to 10^{-2} cm/sec. Saturated hydraulic conductivities of the Glenns Ferry fluvial and lacustrine sand/silty sand soils are on the order of 10^{-3} cm/sec. Saturated hydraulic conductivities of the Glenns Ferry clayey silt soils are on the order of 10^{-6} cm/sec. Saturated hydraulic conductivities of Glenns Ferry soils at the site differ by three to four orders of magnitude between the sand/silty sand and the clayey silt soils.
4. Cross sections prepared with existing soil boring logs and correlations with grain-size distribution data from Shannon and Wilson indicate that the geologic facies described in D-33 and D-34 are horizontally continuous beneath the site. The ranges of hydraulic conductivity found for soil types in D-33 and D-34 describe the range of hydraulic conductivity for similar soil types at the site.
5. Vadose zone strata dip to the north-northeast between 1.5 and 3.4 degrees. The north-northeast dip direction is consistent with the dip of deeper formations in the area that are known to dip toward the Snake River.
6. The most prominent stratigraphic marker in the vadose zone at Site B is the blue-gray clayey silt layer shown in the cross sections in Figures E-22 and E-23. The change from a light brown to blue-gray color is interpreted as a transition from oxidizing to reducing conditions within the soils. The blue-gray color contact does not parallel the present day potentiometric surface in the uppermost aquifer. Instead, the blue gray contact is located between 11 ft. and 75 ft. above the potentiometric surface and appears to parallel the strata in the vadose zone. This indicates the contact may be due to a change in the

depositional environment as, or soon after, the sediments were deposited or is related to a paleo-potentiometric surface in the area.

7. Based on soil boring logs from D-33 and D-34, clayey silt layers comprise 8.6 to 11.0 % (6.5 ft. to 9.4 ft.) of the Glenns Ferry fluvial facies section. Clayey silt layers comprise 67.5 to 75.6 % (28.7 ft. to 36.9 ft.) of the Glenns Ferry lacustrine facies section. The total accumulated thickness of clayey silt layers in D-33 was 43.4 ft. over 155 ft. of borehole. The total thickness of clayey silt layers in D-34 was 38.2 ft. over 153.5 ft.

In situ moisture contents for Site B soils at depths less than 30 ft. are very low and are probably close to the residual value. At these moisture contents, the unsaturated hydraulic conductivity of these soils is also very low, indicating there is a low potential for infiltration and moisture recharge via precipitation at the site.

Computer Modeling

Computer modeling (CH2M HILL, December 1987) was conducted to simulate a release from the bottom of a disposal unit and the movement of a hypothetical leachate plume through the unsaturated zone at Site B. The emphasis was on examining the amount of vertical and lateral movement of leachate through the unsaturated zone. The modeling effort also provided insight into the question of potential leachate plume widths and therefore appropriate monitoring well spacing.

The model SUTRA (Saturated and Unsaturated Transport), developed by the U.S. Geological Survey (Voss, 1984), was used to simulate quasi-3D vertical plume migration in the unsaturated zone. Hydraulic properties of the unsaturated strata underlying Site B used in these simulations were determined in the laboratory on samples collected by continuous coring during the vadose zone drilling and sampling investigation, as described above. The model included 43 separate layers consisting of nine (9) different lithologies based on the cores and vadose zone hydraulic properties analysis.

Simulations were conducted to analyze the effect of both "falling head" (catastrophic release) and "continuous leak for two (2) years" (slow leak based on infiltrating precipitation). The effect on plume spreading of variable leachate source depths and dimensions was also examined. The following represent the relevant conclusions that can be drawn from the simulation results:

1. The results from both simulated scenarios indicate that the unsaturated subsurface beneath Site B acts to completely halt the downward migration of large volumes of source fluid before it can reach the water table. This occurs primarily because the unsaturated zone is thick, relatively dry, and comprised of many low-permeability stratigraphic units that tend to retard and spread out the infiltrating liquids.
2. Simulated dissolved-solute contaminant releases from trenches at Site B, as large as 300,000 gallons and released over a period of two (2) years at a depth of 40 ft., did not reach the water table. A steady-state distribution of concentration for this particular scenario was reached in 15,000 years. At that point in elapsed time, the maximum depth of infiltration was about 130 ft., roughly 50 ft. above the water table.
3. The scale of the leak discussed in item 2 above is the largest leak considered likely to occur through the particular source-area diameter selected (10 ft.). However, should this scale of leak underestimate the size of potential contaminant sources, the results imply that for contamination to reach the water table, and to do so in less than 100 years, it would have to originate from a substantially larger source than the volume of the largest scenario simulated in this investigation.
4. Monitoring well spacing cannot be based solely on the simulation results because the hypothetical plume did not reach the depth of the Upper Aquifer at Site B. Therefore, other criteria must be used to establish appropriate monitoring well spacing and locations. These include location of waste disposal units and aquifer flow rates and flow directions.

Appendix B

Waste Description

**NRC 20.2002 EXEMPTION APPLICATION
KIRTLAND AIR FORCE BASE, NM
WASTE DESCRIPTION**

Kirtland Air Force Base (AFB) is requesting an exemption to transfer and dispose low activity quantities of byproduct and naturally-occurring radioactive materials at the US Ecology Idaho Facility. Waste materials included in this exemption request consist of approximately 2000 to 3000 tons of contaminated soils either already remediated or to be remediated from the RW-06, RW-068, and Mesa del Sol sites at Kirtland AFB. Other sites with similar waste characteristics may be remediated and included in the exemption as appropriate. A brief description of the activities and wastes at the identified Kirtland AFB sites appears below.

Site RW-06

RW-06 occupies approximately 4.5 acres within the riding stables complex in the southeast portion of Kirtland AFB. From 1960 to 1971 the area was part of a 40-acre facility operated by the Radiobiology Laboratory, Biophysics Branch, Air Force Weapons Laboratory (AFWL). The area now designated as RW-06 was used as a radioactive burial site for the disposal of animal carcasses, low-level radioactive material, and other laboratory wastes. Several short-lived (i.e., half-life less than 1 year) radionuclides were disposed in the RW-06 trenches; however, these radionuclides have decayed to insignificant levels. The primary contaminant identified during the testing was cesium-137, with a maximum detected concentration of 13,500 pCi/g. The sampling plan for the RW-06 provided an estimated Strontium (Sr-90) concentration of 9.4 pCi/g; however, Sr-90 was not detected during the 2006 sampling event.

RW-06 consists of nine former burial trenches. Most of the radioactivity is in the form of induced activity and short half-life elements, but it is likely that several millicuries of radioactive elements with longer half-lives may be present. It is estimated that the following numbers of animals were disposed of at the site: sheep, 1000 to 1500; burros, 60 to 75; goats, 40 to 50; chickens, 100 to 120; rats, 500-1000; cows, 5 to 10; and dogs, 50 to 60. Four of the disposal trenches were described as being 50 feet (ft) long by 2 ft wide by 9 ft deep. The dimensions of the other five trenches were less well documented though two of the trenches were described as being 100 ft long by 6 ft wide by 20 ft deep. These trenches were closed by 1965. Some of these trenches were covered with asphalt caps. Wastes placed into the trenches, including animal carcasses, were buried in containers including metal drums and plastic bags and by direct burial without containers. Small amounts of hazardous and toxic chemicals, including acids, mercury, cyanides, and silver were also believed to have been disposed in the trenches.

During the summer of 2006, the Kirtland AFB Radiation Safety Officer identified elevated levels (192 pCi/g) of Cesium-137 (Cs-137) in a location adjacent to RW-06. In October 2006, a Resource Conservation and Recovery Act (RCRA) Facility Investigation (RFI) was conducted at the RW-06 by CH2M Hill and Cabrera Services. Based on the RFI field activities, the wastes documented to have been disposed at the RW-06 site were placed in nine trenches located across the site as expected. The sizes of the disposal

trenches were verified with some trenches being less than 10 ft deep while others extended to greater than 18 ft deep, consistent with historical information. Evidence of buried animal remains and laboratory waste were noted throughout the exploratory excavation. Radioactive materials identified during the RFI were found, confirming the historical record. Some waste materials were buried at shallower depths than expected with some wastes encountered at 1 to 2 ft below ground surface (bgs) in one of the trenches. No evidence of Mercury (Hg) or other RCRA listed or characteristic wastes were found during the field investigation.

Site RW-068

The RW-068 Site occupies a total of 21 acres of land located on Optical Range Road in the southeast corner of Kirtland AFB. RW-068 was used during World War II to smelt aircraft and aircraft pieces that had been destroyed during destructive testing in a nearby area. Radium-226 (Ra-226) was present in the form of luminescent paint applied to dials, gauges, and switches in aircraft components burned at the site. The RW-068 Site was previously remediated and approved for No Further Action (NFA) in 2003. Cabrera Services completed an assessment and spot removal of metal debris and contaminated soil at RW-068 in September 2007. Wastes removed included general debris, luminescent dials, and soils contaminated with up to 245 pCi/g of Ra-226. The general debris and dials were separated out of the waste stream for recycling of non-contaminated metals and disposal of the dials at a facility permitted for that purpose. Only the contaminated soil is intended for disposal at the US Ecology facility.

Mesa Del Sol Broken Arrow Site

The Mesa del Sol site includes diffuse Uranium (U) contamination associated with the high explosives detonation of a weapon containing nuclear materials accidentally dropped from a plane in 1957. A radiological survey of the area was made at the time of the accident and no contamination was found beyond the lip of the crater at which point the level was 0.5 milliroentgens. From 1957 to 2005, several surveys of the area were conducted, however none provided data sufficient to assess residual concentrations of material relative to health based criteria. The site was investigated by Tetra Tech and Cabrera Services in 2006 and 2007. Maximum U concentrations detected at the site include 1630 pCi/g for U-238, 47 pCi/g for U-235, and 612 pCi/g for U-234. Currently, approximately one 55-gallon drum containing contaminated soil is being held in storage at Kirtland AFB. Additional soil may be remediated from the site in the future.

013	Cover depth (m)	3.600E-01	0.000E-00	---		COVER0
013	Density of cover material (g/cm ³)	1.760E+00	1.500E-00	---		DENSCV
013	Cover depth erosion rate (m/yr)	1.000E-04	1.000E-03	---		WCV
013	Density of contaminated zone (g/cm ³)	1.500E+00	1.500E+00	---		DENSCZ
013	Contaminated zone erosion rate (m/yr)	1.000E-03	1.000E-03	---		WCZ
013	Contaminated zone total porosity	4.000E-01	4.000E-01	---		TPCZ
013	Contaminated zone field capacity	2.000E-01	2.000E-01	---		FCCZ
013	Contaminated zone hydraulic conductivity (m/yr)	5.000E-01	1.000E+01	---		HCCZ
013	Contaminated zone b parameter	5.000E+00	5.300E+00	---		ECZ

Site-Specific Parameter Summary (continued)

Menu	Parameter	User Input	Default	Used by RESRAD (If different from user input)	Parameter Name
R013	Average annual wind speed (m/sec)	2.000E+00	2.000E+00	---	WIND
R013	Humidity in air (g/m**3)	not used	8.000E+00	---	HUMID
R013	Evapotranspiration coefficient	7.500E-01	5.000E-01	---	EVAPTR
R013	Precipitation (m/yr)	1.840E-01	1.000E+00	---	PRECIP
R013	Irrigation (m/yr)	2.000E-01	2.000E-01	---	RI
R013	Irrigation mode	overhead	overhead	---	IDITCH
R013	Runoff coefficient	2.000E-01	2.000E-01	---	RUNOFF
R013	Watershed area for nearby stream or pond (m**2)	1.000E+06	1.000E+06	---	WAREA
R013	Accuracy for water/soil computations	1.000E-03	1.000E-03	---	EPS
R014	Density of saturated zone (g/cm**3)	1.500E+00	1.500E+00	---	DENSAQ
R014	Saturated zone total porosity	4.000E-01	4.000E-01	---	TPSZ
R014	Saturated zone effective porosity	2.000E-01	2.000E-01	---	EPSZ
R014	Saturated zone field capacity	2.500E-01	2.000E-01	---	FCSZ
R014	Saturated zone hydraulic conductivity (m/yr)	2.500E+01	1.000E+02	---	HCSZ
R014	Saturated zone hydraulic gradient	1.100E-02	2.000E-02	---	HGWT
R014	Saturated zone b parameter	5.000E+00	5.300E+00	---	BSZ
R014	Water table drop rate (m/yr)	1.000E-03	1.000E-03	---	VWT
R014	Well pump intake depth (m below water table)	1.000E+01	1.000E+01	---	DWIBWT
R014	Model: Nondispersion (ND) or Mass-Balance (MB)	ND	ND	---	MODEL
R014	Well pumping rate (m**3/yr)	2.500E+02	2.500E+02	---	UW
R015	Number of unsaturated zone strata	5	1	---	NS
R015	Unsat. zone 1, thickness (m)	1.000E+00	4.000E+00	---	H(1)
R015	Unsat. zone 1, soil density (g/cm**3)	1.630E+00	1.500E+00	---	DENSUZ(1)
R015	Unsat. zone 1, total porosity	5.200E-01	4.000E-01	---	TPUZ(1)
R015	Unsat. zone 1, effective porosity	1.000E-01	2.000E-01	---	EPUZ(1)
R015	Unsat. zone 1, field capacity	4.500E-01	2.000E-01	---	FCUZ(1)
R015	Unsat. zone 1, soil-specific b parameter	1.100E+01	5.300E+00	---	BUZ(1)
R015	Unsat. zone 1, hydraulic conductivity (m/yr)	1.500E-02	1.000E+01	---	HCUZ(1)
R015	Unsat. zone 2, thickness (m)	4.600E+00	0.000E+00	---	H(2)
R015	Unsat. zone 2, soil density (g/cm**3)	1.690E+00	1.500E+00	---	DENSUZ(2)
R015	Unsat. zone 2, total porosity	5.100E-01	4.000E-01	---	TPUZ(2)
R015	Unsat. zone 2, effective porosity	3.300E-01	2.000E-01	---	EPUZ(2)
R015	Unsat. zone 2, field capacity	7.000E-02	2.000E-01	---	FCUZ(2)
R015	Unsat. zone 2, soil-specific b parameter	2.000E+00	5.300E+00	---	BUZ(2)
R015	Unsat. zone 2, hydraulic conductivity (m/yr)	2.200E+03	1.000E+01	---	HCUZ(2)
R015	Unsat. zone 3, thickness (m)	2.130E+01	0.000E+00	---	H(3)
R015	Unsat. zone 3, soil density (g/cm**3)	1.300E+00	1.500E+00	---	DENSUZ(3)
R015	Unsat. zone 3, total porosity	5.200E-01	4.000E-01	---	TPUZ(3)
R015	Unsat. zone 3, effective porosity	4.000E-01	2.000E-01	---	EPUZ(3)
R015	Unsat. zone 3, field capacity	4.900E-01	2.000E-01	---	FCUZ(3)
R015	Unsat. zone 3, soil-specific b parameter	3.000E+00	5.300E+00	---	BUZ(3)
R015	Unsat. zone 3, hydraulic conductivity (m/yr)	9.000E+02	1.000E+01	---	HCUZ(3)

Site-specific Parameter Summary (continued)

Zone	Parameter	User Input	Default	Used by FESPAD (Is different from user input)	Parameter Name
015	Unsat. zone 4, thickness (m)	1.66(E-01)	0.000E+00	---	H(4)

Site-Specific Parameter Summary (13.11.2001)

ID#	Parameter	User		Used by RESRAD (if different from user input)	Parameter Name
		Input	Default		
01	Volumetric water content of the cover material	2.850E-01	5.000E-01	---	FRICOV
02	Volumetric water content of the foundation	3.000E-01	5.000E-01	---	FRICFL
03	Diffusion coefficient for vapor gas (m/sec):				
03.1	in cover material	7.233E-07	2.000E-06	---	DIFFCV
03.2	in foundation material	3.000E-07	3.000E-06	---	DIFFFL
03.3	in contaminated zone soil	3.000E-07	2.000E-06	---	DIFFCZ
04	Room vertical dimension of mixing (m)	2.000E-01	2.000E-01	---	RMIX
05	Average building air exchange rate (1/hr)	1.500E-02	5.000E-01	---	REMX
06.1	Height of the building (room) (m)	2.500E-01	2.500E-01	---	RMH
07	Building interior area factor	1.000E-01	1.000E-01	---	FBI
08	Building depth below ground surface (m)	1.000E-01	-1.000E-01	---	BMFL
09.1	Emanating power of Rn-222 gas	2.500E-01	2.500E-01	---	EMANA(1)
09.2	Emanating power of Rn-220 gas	1.500E-01	1.500E-01	---	EMANA(2)
101	Number of graphical time points	512	---	---	NPTS
102	Maximum number of integration points for dose	17	---	---	LYMAX
103	Maximum number of integration points for risk	1	---	---	RYMAX

Summary of Pathway Selections

Pathway	User Selection
1 -- external gamma	active
2 -- inhalation (w/c radon)	active
3 -- plant ingestion	active
4 -- meat ingestion	active
5 -- milk ingestion	active
6 -- aquatic foods	suppressed
7 -- drinking water	active
8 -- soil ingestion	active
9 -- radon	active
Find peak pathway doses	active

THF(i) is the thread fraction of the parent nuclide.

\$ is used to indicate summation; the Greek sigma is not included in this font.
