APPENDIX A

REVIEW OF NRC COMMENTS ON THE INDIAN POINT PROBABILISTIC SAFETY STUDY

The issues addressed in this review of the Indian Point Probabilistic Safety Study (IPPSS) [4] are those identified in NUREG/CR-2934 [11] and listed in NSAC-151 [12]. The references are to documents listed in Section 8 of the main IPE report.

Issue 1: Anticipated transient without scram (ATWS)--loss of main feedwater (MFW)

NRC Comment: The NRC reviewers assigned a 33% probability that loss of main feed was total. This fraction is important for ATWS events since, if some main feedwater is available, the reactor coolant system (RCS) peak pressure would not be expected to reach 3200 psi.

Applicability to IP3 IPE: In the IPE, this scenario was modeled with other T2 events--transients with loss of the main feedwater system prior to or at the unit trip.

Issue 2: ATWS--Reactor protection system (RPS)

NRC Comment: The NRC reviewers accepted the 2×10^{-5}/demand failure probability for the RPS because it compared favorably with the 3×10^{-5}/demand failure probability derived in NUREG-0460. However, they criticized the omission of certain failure modes.

Applicability to IP3 IPE: The RPS failure probability used in the IPE was 1.62×10^{-5}. Manual scrams were addressed explicitly.

Issue 3: Common-cause failures

NRC Comment: The NRC reviewers commented that use of one Beta factor throughout the IPPSS was inappropriate.

Applicability to IP3 IPE: In the IPE, different Beta factors were assigned to specific component types.

Issue 4: Common-cause failures--diesel generators

NRC Comment: The NRC reviewers referenced and applied a study that derived "generic" probabilities of common-cause failure of two and three diesel generators requiring cooling water of 7×10^{-4} and 2×10^{-4}, respectively. A slight reduction in station blackout frequency resulted.

Applicability to IP3 IPE: In the IPE, the common-cause failures of two and three diesel generators were modeled as separate events; Beta factors of 0.038 and 0.018 being applied to the respective events [9]. Coupled with a diesel generator failure rate of 2.63×10^{-3}/demand, the predicted common-cause failure rate for two diesel generators is 10^{-4}/demand and the predicted common-cause failure rate for three diesel generators is 4.74×10^{-5}/demand.

Issue 5: Common-cause failure--operator recovery actions

NRC Comment: The NRC reviewers noted that some common-cause Beta factors were conservative because they did not consider operator recovery actions.

Applicability to IP3 IPE: The same conservatism was applied in this study--no operator recovery actions were considered that are specific to common-cause failures (other than the recovery of pre-accident human errors).

Issue 6: Common-cause failures--service water systems

NRC Comment: The common-cause failure analysis was not applied consistently to all systems.

Applicability to IP3 IPE: The common-cause failure analysis was applied consistently to all systems. In particular, common-cause pump failures were considered in all multi-train systems.

Issue 7: Containment failure

NRC Comment: The IPPSS did not model core melts caused by containment failure due to overpressurization. While such failures have been shown to be important in other probabilistic risk assessments (PRAs), the effect of this potential sequence was found to be negligible because of the low probability of having core cooling but not containment heat removal.

Applicability to IP3 IPE: Core melts caused by containment overpressurization and failure were modeled in the IPE.

Issue 8: Failure data

NRC Comment: The NRC reviewers objected to the use of the 5th and 95th percentiles from WASH-1400 as the 20th and 80th percentiles of known frequency distributions of generic data. They noted that the rationale for discretization of data was not well explained and that the way in which discrete values were chosen may affect results.

Applicability to IP3 IPE: Generic data were used as presented; the stated frequency distributions were not manipulated.

Issue 9: Failure data assumptions

NRC Comment: The NRC reviewers objected to the lack of documentation regarding in changes to assumptions, especially those that impacted the results.

Applicability to IP3 IPE: The changes to the assumptions that so concerned the NRC reviewers were not made in this study--generic data distributions were accepted as cited.

Issue 10: Failure data methodology

NRC Comment: The NRC reviewers noted that the effect of prior distributions is generally unimportant when plant-specific data exist. When such data are not available or used, estimates are quite sensitive to the assumed prior distributions.

Applicability to IP3 IPE: A Bayesian update process was used to aggregate plant and generic data.

Issue 11: Failure data--valves

NRC Comment: The NRC reviewers calculated the unavailability of valves because of stem failures to be 4.8×10^{-5}/demand.

Applicability to IP3 IPE: Stem failures were not addressed as a specific failure mode in this study. They were, however, considered with other valve hardware failures.

Issue 12: Bleed-and-feed

NRC Comment: The NRC reviewers found instances in which the original study took credit for operator actions that were not outlined in the plant emergency operating procedures (EOPs). The reviewers questioned this approach.

Applicability to IP3 IPE: In the IP3 IPE, credit was taken only for operator actions addressed in emergency operating procedures, off-normal operating procedures, and operating procedures. The bleed-and-feed procedures characterized in 1982 by the NRC reviewers as being "limited" have been fully developed (e.g., functional restoration procedure FR-H.1, "Loss of Secondary Heat Sink").

Issue 13: Bleed-and-feed

NRC Comment: The IPPSS assumed that the main feedwater (MFW) system would not be available for removing post shutdown decay heat after all internal and external events. The NRC reviewers noted that this was an unnecessary conservatism since the MFW system would be available, or could be restored, in most reactor trips not caused by a loss of offsite power, and that this conservatism especially impacted the "bleed-and-feed" accident sequences.

Applicability to IP3 IPE: Credit was taken in the models for the potential restoration of the MFW system. However, the probability assigned to this action was very low because current procedures for loss of secondary cooling call for the MFW system to be tripped and the condensate system to be restored.

Issue 14: Flood--circulating water

NRC Comment: In the IPPSS, flood scenarios involving the failure of circulating water systems were assumed to be self-limiting because the condensate pump motors and 6.9-kV switchgear would be flooded, resulting in reactor trip and loss of offsite power, respectively. The NRC reviewers noted that this logic presumes that failure events could be counted upon to limit the event, and recommended that the basis for it should be further qualified.

Applicability to IP3 IPE: Internal flooding scenarios initiated by the rupture of the condensate system in both the turbine and auxiliary feedwater buildings was examined in some detail in the internal flooding analysis. It was concluded that the rupture of the circulating water system within the turbine building will result in a rapid reactor trip (a T2 event), the flooding of circulating water pumps in the pump bay and submergence damage to the 6.9-kV switchgear. It is therefore entirely appropriate to regard the rupture of the condensate system to be self-limiting in that continued discharge is unlikely. Though the cessation of condensate flow into the turbine building will not serve to mitigate the event. In contrast, the rupture of the condensate system in the auxiliary feedwater building was not assumed to be self-limiting.

Issue 15: Flood--control building

NRC Comment: Flooding in the control building due to a service water break was considered. The importance of the 480-V switchgear located at the 15-ft elevation was recognized. The reviewers questioned whether floor drains in the control building would be available and sufficient to mitigate this flooding scenario. While the reviewers concluded that the frequency of power loss due to other causes would exceed that caused by service water line breaks, they requested that further analysis be performed to demonstrate that this additional frequency is small.

Applicability to IP3 IPE: Flooding scenarios initiated by breaks in the service water, fire protection system, and instrument air closed cooling water lines in the control building were examined in great detail in the internal flood analysis prepared for this study. This internal flood analysis is described in Appendix C.

Issue 16: Flood--internal

NRC Comment: The NRC reviewers recommended that the methodology adopted for the internal flooding analysis allow a thorough, systematic analysis of critical events and event sequences that might lead to a transient.

Applicability to IP3 IPE: The methodology adopted for the internal flooding analysis entailed the identification of flood sources and susceptibilities, the development of flood scenarios, the determination of whether the scenario could lead or contribute to core damage, quantification of scenarios in a screening risk assessment to eliminate unimportant scenarios,

and the creation and quantification of event trees for the remaining flooding scenarios that could lead to core damage. This methodology satisfies the criteria set forth by the NRC reviewers.

Issue 17: Human reliability

NRC Comment: The NRC reviewers reduced the probability of recovery actions when an important instruction was placed as a note in a procedure.

Applicability to IP3 IPE: In the HRA performed for this study, steps addressed in notes or cautions were given less credit than steps clearly described in the procedures. Steps addressed in notes or cautions transformed the action from a step-by-step procedure to a dynamic task.

Issue 18: Human reliability

NRC Comment: The NRC reviewers noted that the IPPSS did not calculate a probability for all operator actions which could affect the course of an accident sequence, but rather assumed the operator performed a task with negligible failure probability.

Applicability to IP3 IPE: This comment does not apply to this study--realistic human error probabilities were assigned for all operator actions that could affect the course of an accident sequence.

Issue 19: Human reliability--dependence

NRC Comment: The NRC reviewers accepted the moderate level of dependence assigned to situations in which all control room staff are engaged in the same activity. The NRC reviewers objected, however, to the same (moderate) level of dependence being assigned when some of the control room staff were involved in different activities.

Applicability to IP3 IPE: This study used a different methodology for HRA than was used in the IPPSS. In this study, a high to complete dependency was assigned to post-accident operator actions.

Issue 20: Human reliability--dependence

NRC Comment: The NRC reviewers objected to an assumption applying to the restoration of two or more valves that moderate dependence would be assessed for the restoration of two valves and complete dependence for all other valves where written procedures are used. They believed that if an operator failed to restore one of two or more valves, the operator would always fail to restore the other(s).

Applicability to IP3 IPE: The assumption of complete dependency recommended by the NRC reviewers was used in certain instances. In the IPE, dependencies between pre-accident

human actions were defined as follows: zero dependence was assessed for pre-accident human actions related to series systems/components as with such systems or components, dependency is a moot point. For parallel systems/components, the following dependencies were assumed:

a. Zero dependence was assumed for maintenance errors because maintenance activities will be separated in time.

b. Zero dependence was assumed between maintenance and test errors.

c. Complete dependence was assumed for actions taken in the same step of a given procedure that do not involve individual check-offs.

d. High dependence was assumed for actions taken in the same step of a given procedure that involve individual check-offs.

e. High dependence was assumed for actions taken in different steps of a given procedure that are performed within 2 minutes of each other.

f. Low dependence was assumed for actions taken in different steps of a given procedure that are not performed within 2 minutes of each other.

g. Zero dependence was assumed for actions taken in different procedures or by different crews.

Issue 21: Human reliability--documentation

NRC Comment: The NRC reviewers concluded that the human reliability analysis should be documented in a systematic and reproducible manner so as to allow independent evaluation.

Applicability to IP3 IPE: The human reliability analysis for pre-accident human error is described in Section 3.3 of the report and the results presented. The human reliability analysis for post-accident human error is summarized in Section 3.3 of the report and delineated in Appendix H. In the appendix, the rationale for the selection of all human error probabilities is described.

Issue 22: Human reliability--expert opinion

NRC Comment: The NRC reviewers concluded that little confidence could be placed in data derived from expert opinion because no evidence was provided to show that recognized methods were employed to solicit expert opinion.

Applicability to IP3 IPE: Expert opinion was not used to determine HEPs in this study.

Issue 23: Human reliability--methodology

NRC Comment: The NRC reviewers objected to the use of multiple independent operator actions in the same sequence of events without modifying their human error probabilities (HEPs) to account for the added stress, reduced time, and lack of familiarity with sequence involving multiple faults.

Applicability to IP3 IPE: HEPs assigned to post-accident operator actions accounted for stress, including the failure of previous actions, time available and familiarity with the task (Section 3.3.3).

Issue 24: Human reliability--methodology

NRC Comment: The NRC reviewers objected to obtaining time estimates for various tasks by interviewing personnel when it would have been possible to take actual measurements.

Applicability to IP3 IPE: This study relied on time measurements made in simulator exercises and simulated out-of-control room activities.

Issue 25: Human reliability--staff response

NRC Comment: The NRC reviewers accepted the assumption that, for certain major events, two control board operators, a watch supervisor and a shift technical advisor would be in the control room within half an hour of event initiation.

Applicability to IP3 IPE: The same assumption as to control room staffing was made in this study. It is anticipated, however, that these staff would be present in the control room within 15 minutes.

Issue 26: Human reliability--uncertainty

NRC Comment: The NRC reviewers noted that the use of the upper bound as the 90th percentile of a lognormal distribution would result in more conservative human reliability analysis (HRA) models.

Applicability to IP3 IPE: The HRA performed in this study used the ASEP-HRAP methodology and data. No undue conservatism was therefore introduced into the human reliability analysis.

Issue 27: Initiating event

NRC Comment: The NRC reviewers accepted the handling of initiating events that were not addressed explicitly in the IPPSS but included in the data used to calculate the frequency of reactor trip.

Applicability to IP3 IPE: The scope of initiating events considered in this study is described

in Section 3.1.1.1.

Issue 28: Initiating event

NRC Comment: The NRC reviewers noted that one of the most important tasks in a PRA was to search for failures which could simultaneously cause a reactor trip and fail safety systems.

Applicability to IP3 IPE: Such failures were explicitly addressed in this study and described in Section 3.1.4.

Issue 29: Initiating event--loss of component cooling water (CCW)

NRC Comment: The NRC reviewers noted that a loss of CCW induced by a pipe break was not analyzed in the IPPSS despite the fact that the system responses for such an event are quite different to those following a loss of CCW resulting from other causes.

Applicability to IP3 IPE: A loss of CCW induced by a pipe break was explicitly modeled in this study (Section 3.1.4.4).

Issue 30: Initiating event--loss of instrument and control power

NRC Comment: The NRC reviewers concluded that the analysis of this event was bounded by loss of ac or dc buses.

Applicability to IP3 IPE: In this study, the loss of ac and dc buses, and, in particular, the loss of 118-Vac instrument buses was examined as potential special initiators (Section 3.1.4.4). It was concluded, however, that the loss of a 118-Vac instrument bus is not a special initiator.

Issue 31: Initiating event--loss of ventilation

NRC Comment: The NRC reviewers accepted a report that predicted no safety-related equipment failures within the first 24 hours of a loss of primary auxiliary building ventilation. This loss of ventilation was not addressed in the IPPSS.

Applicability to IP3 IPE: Loss of PAB ventilation will not cause a reactor trip. Accordingly, it was not treated as an initiating event (Section 3.1.4.4).

Issue 32: Initiating event--reactor vessel rupture

NRC Comment: The NRC reviewers questioned the assertion in the IPPSS that the RV rupture event could be ignored because its frequency is small compared to other events that lead to the same plant damage state. Their concern was that the IPPSS did not analyze a

vessel rupture initiated by pressurized thermal shock.

Applicability to IP3 IPE: Accident sequences initiated by reactor vessel rupture were explicitly addressed in this study (Section 3.1.4.6). In addition, the possibility of reactor vessel rupture being initiated by pressurized thermal shock was addressed in the evaluation of main steam line breaks (Section 3.1.4.2).

Issue 33: Initiator frequency--pipe break in CCW.

NRC Comment: The NRC reviewers derived the component cooling water pipe break frequency of 1.5×10^{-4}/year using the piping analysis presented in the IPPSS. The IPPSS did not evaluate this event as an initiating event.

Applicability to IP3 IPE: The pipe break induced loss of CCW was explicitly modeled in this study (Issue 28 and Section 3.1.4.4). The pipe break frequency assumed was derived from data presented by Eide et al [43].

Issue 34: Initiator frequency--small LOCA

NRC Comment: The NRC reviewers stated that the reactor coolant pump (RCP) seal failure initiating event should be treated as a small LOCA. However, the IPPSS did not include this failure in determining small LOCA frequencies though this omission was compensated for by a failure to consider the recovery of stuck-open pressurizer power-operated relief valves (PORVs) by closure of PORV block valves.

Applicability to IP3 IPE: In this study RCP seal failures were addressed as small LOCA events. Spontaneous seal failures were considered as initiating events but were lumped into S2 terms.

Issue 35: Interfacing LOCA

NRC Comment: The NRC reviewers revised the causes of the dominant V-sequence LOCA, the concurrent failure of two motor-operated valves (MOVs) in the RHR suction line.

Applicability to IP3 IPE: Interfacing system LOCAs are addressed in detail in Sections 3.1.4.5 and 3.1.5.

Issue 36: Methodology

NRC Comment: The NRC reviewers, in summary, noted that the following were not treated in the IPPSS:

(a) Pressurized thermal shock.

(b) Steam generator tube rupture coincident with a stuck-open secondary safety valve.

(c) Safety system failure caused by core meltdown phenomena.

(d) A pipe break in the component cooling water system.

(e) Reactor coolant pump seal failures (as a cause of small LOCAs).

(f) Steam generator overfill scenarios.

(g) Cold shutdown events.

(h) Design and construction errors and the effects of aging.

Applicability to IP3 IPE: The items were addressed as follows in this study:

(a) Pressurized thermal shock--in Sections 3.1.4.2 and 3.1.4.6. See Issue 31.

(b) Steam generator tube rupture coincident with a stuck-open secondary safety valve. This possibility was considered in the evaluation of steam generator tube rupture initiating events (Section 3.1.4.3).

(c) Safety system failure caused by core meltdown phenomena--such failures were addressed in the "back end" analysis (Section 4).

(d) A pipe break in the component cooling water system--in Section 3.1.4.4. See Issue 28.

(e) Reactor coolant pump seal failures (as a cause of small LOCAs)--see Issue 33.

(f) Steam generator overfill scenarios--addressed in station blackout and steam generator tube rupture sequences (Sections 3.1.3.3 and 3.1.4.3, respectively).

(g) Cold shutdown events--these events were specifically excluded from this study as dictated by the NRC [1].

(h) Design and construction errors and the effects of aging--to the best of the analysts ability, the plant was modeled as is, reflecting all errors of which Authority staff are aware. In addition, design-related inadequacies were specifically sought in the analysis of subtle system interactions (Section 3.2.3.4). The effects of aging were not addressed specifically but are intended to be reflected in the reactor vessel rupture event (Section 3.1.4.6).

Issue 37: Methodology--documentation

NRC Comment: The NRC reviewers emphasized the need for reliability and reproducibility of the documentation, references and calculations.

Applicability to IP3 IPE: The event trees, failure and unavailability data, and fault tree assumptions are presented in the IPE report. The fault trees and all computer files have been retained.

Issue 38: Methodology--LOCAs

NRC Comment: The NRC reviewers noted that the assumption that fan coolers would be available to mitigate the core melt accident after a LOCA was potentially non-conservative.

Applicability to IP3 IPE: The operation (and unavailability) of the containment fan coolers was explicitly addressed in the LOCA event trees (Section 3.1.3.1).

Issue 39: Missiles

NRC Comment: The NRC reviewers recommended that missiles be considered in system models as a failure mode of components in the vicinity of components capable of producing missiles.

Applicability to IP3 IPE: Potential spatial interactions between components were searched for in plant walkdowns and, where appropriate, included in the models.

Issue 40: Operator action--dc bus failure

NRC Comment: The NRC reviewers noted that the IPPSS did not provide adequate details for the operator action "noticing a failed dc power fuse." The IPPSS assumed that fuse failure would be noticed during the operator check of the status panels each shift.

Applicability to IP3 IPE: Fuse failures were modeled in a manner that accounts for the detection of the failure. The failure of fuses associated with 480-V bus protective devices are annunciated in the control room. These failures will therefore be noted immediately. The failure of all other fuses should be noted at the shift-change checks in the control room.

Issue 41: Operator action--high-head recirculation

NRC Comment: The NRC reviewers felt that the human error probability assumed in the IPPSS for the switchover to high-head recirculation was too high and suggested a 10^{-6} value instead.

Applicability to IP3 IPE: Human error probabilities of 4.8×10^{-4} and 8.6×10^{-4} were assumed for this event during small LOCAs and intermediate LOCAs, respectively. The

justification for these conservative numbers is presented in Appendix H.

Issue 42: Operator action--turbine-driven auxiliary feedwater (AFW) pump

NRC Comment: The NRC reviewers noted that after a total loss of ac power, the operator would have to take local control of the turbine-driven AFW pump because instrument air would not be available. This needs be done within 1 hour. The NRC reviewers assigned a failure to recover probability of 0.1 to this event, a value typically used for situations in which no procedures exist but where the postulated operator action seems likely.

Applicability to IP3 IPE: The instrument air supply to AFW system valves is backed up with an independent nitrogen supply (Section 3.2.2.2). Accordingly, a loss of ac power would not itself lead to a loss of control over the pump. However, it was assumed that once dc power is lost, control of the steam-turbine-driven AFW pump would also be lost.

Issue 43: Operator action--RWST (refueling water storage tank)

NRC Comment: The NRC reviewers did not accept the assumption that the operator will act to refill the RWST if depleted instead of going to the recirculation spray mode by drawing water from the sump.

Applicability to IP3 IPE: In this study, it was assumed that the operators would switch to recirculation modes of operation on depletion of the RWST. Refilling the RWST using the primary water make-up system was considered only if recirculation core cooling is unavailable. Refilling the RWST is addressed in Sections 3.1.4.3 and 3.2.2.14 and in Appendix H.

Issue 44: Plant damage state (PDS)

NRC Comment: The NRC reviewers defined the following PDSs in place of the 22 PDSs used in the IPPSS:

(a) Early core melt with containment cooling

(b) Early core melt without containment cooling

(c) Late core melt with containment cooling

(d) Late core melt without containment cooling

(e) Containment bypass before core melt

(f) Direct containment failure due to a seismic event

(g) Steam generator tube rupture with a stuck-open secondary safety valve.

Applicability to IP3 IPE: The plant damage states defined in the IPE are described in Sections 3.1.5 and 4.3.

Issue 45: Plant response model

NRC Comment: In the IPPSS, two potential problem areas in plant design pertaining to internal events were identified for IP3 and commitments were made to rectify them. The proposed modifications were to:

(a) Rearrange the diesel generator fuel oil transfer pump power supplies such that the primary transfer pump for each diesel is powered from one of that diesel's electrical buses.

(b) Implement plant modifications for ATWS mitigation.

Applicability to IP3 IPE:

(a) The supply of fuel oil to the diesel generators was rearranged to preclude the possibility of the failure of one diesel generator preventing the transfer of fuel oil to a second diesel generator.

(b) ATWS mitigation system actuation circuitry (AMSAC) has been installed and is modeled in this study (Section 3.2.2.2).

Issue 46: Plant response model

NRC Comment: The NRC reviewers noted that the IPPSS did not adequately model RCP seal LOCAs following a sustained loss of component cooling water or service water, systems that respond to a seal LOCA, and station blackout initiated by a loss of service water and followed by a loss of offsite power.

Applicability to IP3 IPE: The initiating events in question were modeled thoroughly in this study (Sections 3.1.3 and 3.1.4).

Issue 47: Plant response model--pressurizer safety valve

NRC Comment: The NRC reviewers noted that the IPPSS did not model demands on the pressurizer safety valves in response to a transient. However, they noted that no important accident sequences were missed because of this.

Applicability to IP3 IPE: In this study, pressurizer safety and power-operated relief valves were addressed in both the event tree and system models (Sections 3.1.3, 3.1.4, and 3.2.2.12).

Issue 48: Operator action--seal LOCA

NRC Comment: The NRC reviewers assigned a failure to recover probability of 0.9 to the recovery action in which the operators connect a spool piece and establish city water cooling to the charging pumps in 20 min. The basis for this probability was that procedures did not address this action and that connection of a spool piece within 20 min. is unlikely.

Applicability to IP3 IPE: At IP3, city water is permanently connected to the charging pumps--the connection of spool pieces is not required. Procedure ONOP-CC-1 addresses the establishment of city water cooling to the charging pumps.

Issue 49: Steam generator tube rupture (SGTR)

NRC Comment: The NRC reviewers found several problems with the treatment of SGTRs. The most significant finding was that the IPPSS event tree did not include the effect of stuck-open secondary safety valves.

Applicability to IP3 IPE: The possibility of stuck-open PORVs was addressed in SGTR models (Section 3.1.4.3). See Issue 36.

Issue 50: Station blackout recovery

NRC Comment: The NRC reviewers noted that diesel generator recovery values used in the IPPSS appeared optimistic when compared to past experience.

Applicability to IP3 IPE: Diesel generator recovery was not examined in this study. Power recovery addressed the recovery of offsite power and the "Appendix R" diesel as alternative sources of power.

Issue 51: Station blackout--seal LOCA

NRC Comment: The NRC reviewers noted that the IPPSS omitted sequences in which a service water system failure was followed by a loss of offsite power. Should ac power not be restored within an hour, an RCP seal LOCA could occur followed by core melt.

Applicability to IP3 IPE: The sequences of concern were addressed in this study (Sections 3.1.4.4 and 3.1.3.3).

Issue 52: Success criteria--diesel-generator cooling

NRC Comment: The NRC reviewers felt that the failure criterion used for diesel generator cooling by service water in the IPPSS was too conservative. They noted that all three diesel generators can be cooled by one essential service water header pump.

Applicability to IP3 IPE: In this study, success of the essential service water system header was defined as adequate flow from at least two of three pumps. This definition was based on the assumption that single pump operation with containment fan cooler temperature control valves TCV-1103/1104/1105 open may result in pump runout and failure--while one essential service water pump was assumed capable of providing adequate heat removal, pump runout concerns mandate two pumps operating in each service water header unless manual action is taken to isolate various loads (Section 3.2.2.6).

Issue 53: System model--containment sprays

NRC Comment: The NRC reviewers noted that after core meltdown, the spray recirculation system may fail because of the failure of motor-operated valves to open (as a result of hydrogen burns or radiation exposure) or because of the failure of two recirculation pumps and two RHR pumps (as a result of core-melt debris in their sump water supply). The NRC reviewers further noted that the IPPSS took no credit for operation of the spray recirculation system after core meltdown.

Applicability to IP3 IPE: In this study, the operation of the spray recirculation system after core meltdown was considered. The probability of the system failing is sequence dependent. Phenomema such as core debris in the sump were considered in the containment event tree.

Issue 54: Station blackout--containment sprays

NRC Comment: The NRC reviewers felt that the containment spray injection system (CSS) was given more credit in the IPPSS than was due because the IPPSS assumed that if the CSS were available in the injection phase, it would also be available in the recirculation phase. The NRC reviewers pointed out that for this to be true, the RWST must be refilled by the operators for use during recirculation, an action not mentioned in the emergency operating procedures.

Applicability to IP3 IPE: In this study, a clear distinction was made between containment spray injection and containment spray recirculation. Success of containment spray injection implies an adequate RWST inventory and the use of at least one containment spray pump to provide early containment decay heat removal. Containment spray operation can continue after RWST depletion if a portion of the long-term recirculation core cooling flow is diverted to the containment spray headers. Recovery of containment spray injection after RWST depletion was not modeled. The containment spray system is addressed in Sections 3.1.3.1, 3.1.3.2, 3.1.4.2, 3.1.4.3, 3.1.4.4, 3.1.4.6, and 3.2.2.3 of this report.

Issue 55: System model--containment sprays

NRC Comment: The NRC reviewers noted that in the IPPSS, no credit was taken for the containment spray recirculation system.

Applicability to IP3 IPE: Containment spray recirculation was modeled in this study. The

impact of the failure of equipment shared by low-pressure recirculation systems and containment spray recirculation systems was addressed in the system and event tree models.

Issue 56: System model--electric power

NRC Comment: The NRC reviewers noted that lightning could cause multiple inverter failures and fail the entire electric power system if circuit breakers fail to open and interrupt the power surge.

Applicability to IP3 IPE: In this study, faults in the offsite power lines and circuit breaker failures were modeled explicitly.

Issue 57: System model--service water

NRC Comment: The NRC reviewers noted that the IPPSS did not consider maintenance unavailability of the essential service water header even though this header could be out for eight hours for maintenance.

Applicability to IP3 IPE: Maintenance of the essential and non-essential service water systems was modeled in this study.

Issue 58: Unavailability--containment sprays

NRC Comment: The NRC reviewers recalculated the unavailability of the containment spray system to account for common-cause pump failures. The recalculated value was 5.3×10^{-4}; the value reported in the IPPSS was 3×10^{-5}.

Applicability to IP3 IPE: The common-cause failure of pumps was included in the containment spray system models (Section 3.2.2.3). The unavailability calculated for this system was 4.9×10^{-4}. The common-cause failure of pump discharge valves was also modeled.

Issue 59: Unavailability--high-head safety injection system

NRC Comment: The NRC reviewers recalculated the unavailability of the high-pressure injection system to account for common-cause pump failures.

Applicability to IP3 IPE: The common-cause failure of valves and pumps was included in the high-head safety injection system models (Section 3.2.2.4).

APPENDIX B

THERMAL-HYDRAULICS ANALYSES

Table of Contents

B1 Introduction B-1

B2 LOCA Containment Decay Heat Removal B-2

B2.1 Containment Decay Heat Removal B-2

B2.1.1 Containment Spray System (CSS) B-2

B2.1.2 Containment Fan Coolers (Emergency Mode Operation) B-2

B2.1.3 Long-term Containment Heat Removal through the RHR Heat Exchangers B-4

B2.2 LOCA Core Cooling B-4

B2.2.1 Large LOCA Core Cooling B-7

B2.2.2 Intermediate LOCA Core Cooling B-7

B2.2.3 Small LOCA Core Cooling B-7

B3 Transient Initiators B-12

B3.1 Timing of Events After Loss of AFW System Cooling B-12

B3.2 System Response Following Bleed and Feed Operation B-12

B4 Steam Generator Tube Rupture B-18

B4.1 Isolation of the Ruptured Steam generator B-18

B4.2 Early RCS Cooldown and Depressurization B-19

B4.3 Late RCS Cooldown and Depressurization B-19

Section B1

INTRODUCTION

This Appendix describes the analyses performed to support LOCA, transient initiator, steam generator tube rupture and station blackout initiator event tree development. These analyses define event tree success criteria and the assumptions necessary to characterize the accident sequences. The analyses do not, however, focus on the timing of events in as far as this affects the quantification of post-accident human error.

The thermal-hydraulic behavior of IP3 was analyzed using version 192 14APR87 of the Meltdown Accident Response Characteristics Code (MARCH) [1] and version 3.0B, Rev. 16 of the MAAP PWR code [2].

Section B2

LOCA CONTAINMENT DECAY HEAT REMOVAL

B2.1 CONTAINMENT DECAY HEAT REMOVAL

Early and late containment heat removal requirements were calculated assuming the occurrence of a large LOCA. This event was selected in preference to other LOCA events because it rapidly releases a large amount of energy into the containment atmosphere and so poses a greater threat to containment integrity than does any other LOCA. Consequently, the requirements for containment heat removal in a large LOCA exceed those of smaller LOCAs.

The containment spray, fan cooler, and RHR (long-term cooling) systems were addressed in evaluating containment heat removal.

B2.1.1 CONTAINMENT SPRAY SYSTEM (CSS)

Although early CSS operation is not required to prevent core damage or containment failure should a large LOCA event occur, it is included in the event tree because it will significantly affect the timing of containment failure. Early CSS operation will reduce the net transfer of heat into the containment atmosphere and sumps, curtail the increase in containment pressure, and lead to a subsequent gradual decrease in containment pressure.

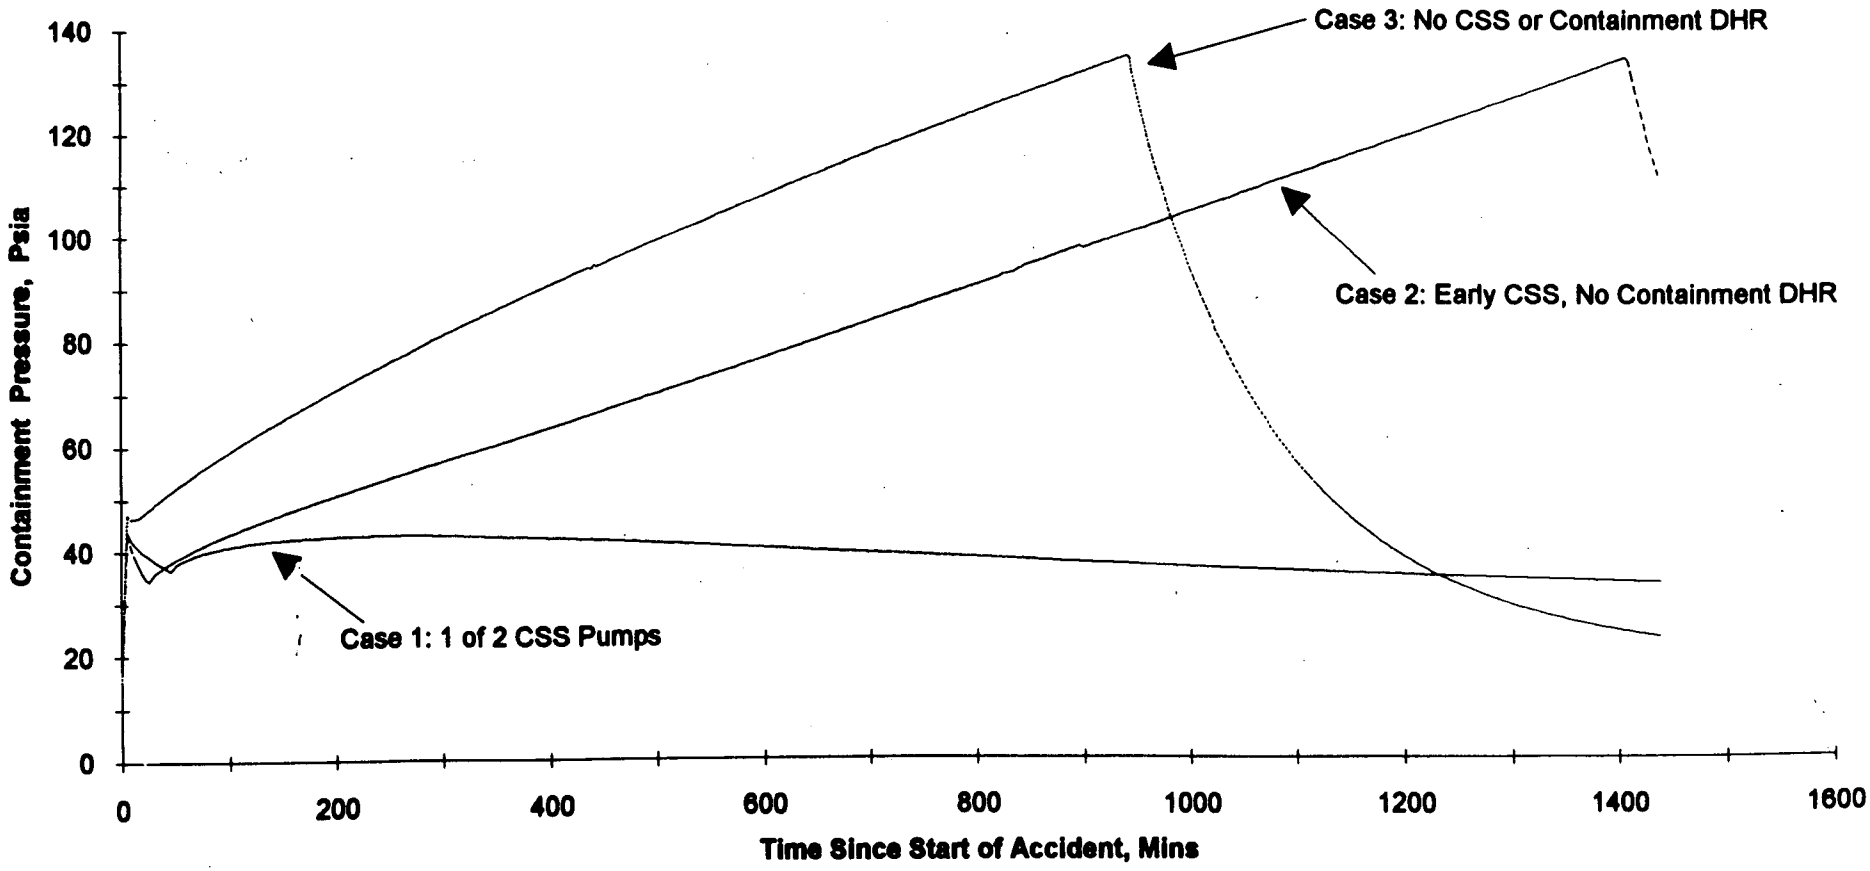
Calculations performed using the MARCH code determined that, if one containment spray pump operates early with a spray flow rate of 2600 gpm, the initial containment atmosphere pressure never rises above its 62-psia design set point (Case 1, Figure B2.1.1).

Other MARCH calculations show that with a complete loss of containment decay heat removal and no early CSS operation, the ultimate containment failure pressure of 132 psia is reached at 11 hours (Case 2, Figure B2.1.1). However, early CSS operation delays the rise to the ultimate containment failure pressure until 16 hours (Case 3, Figure B2.1.1).

B2.1.2 CONTAINMENT FAN COOLERS (EMERGENCY MODE OPERATION)

One containment fan cooler can remove 76.3 x 10^6 BTU/hr (0.74 percent of full power) in its emergency mode of operation. At this rate of heat removal, 3 fan coolers can prevent overpressure failure by providing sufficient early and late (long-term) cooling of the

Figure B2.1.1 Large LOCA Containment Pressure Profile -- Impact of CSS Operation



containment atmosphere and thus, by condensation, cooling of recirculation water flowing to the recirculation or containment sumps. The containment pressure profile predicted by a MARCH code analysis of this scenario is presented in Figure B2.1.2.

B2.1.3 LONG-TERM CONTAINMENT HEAT REMOVAL THROUGH THE RHR HEAT EXCHANGERS

Long-term containment heat removal can then be accomplished using the containment spray system with one RHR heat exchanger in service. Each RHR heat exchanger can remove 56.4 x 10^6 BTU/hr in its accident mode of operation assuming a primary temperature at 213°F and a component cooling water temperature at 126°F. As noted in Section B2.1.1, early operation of the containment spray system is not required to prevent containment failure. However, late operation of the containment recirculation spray system is required--in a large cold-leg LOCA, the recirculation or RHR pumps are unable to force coolant through the hot-leg and steam generator tubes to the break location and consequently, cooling water will bypass the core and flow out of the break. Thus the steam produced by core decay heat (the core is covered by water because of the gravity head in the vessel downcomer) flows directly to the containment atmosphere, and the RHR heat exchangers will not remove core heat unless the containment spray system is functioning (Figure B2.1.3, Cases 1 and 2)..

The criteria for heat removal in intermediate and small LOCAs differ because core injection flow will fill up the vessel and hot legs and thus transfer core decay heat to the circulating water. Consequently, if a containment fan cooler unit is operating, containment spray recirculation operation does not affect the timing of containment failure or the effectiveness of the RHR heat exchangers for heat removal. Therefore, for intermediate and small LOCAs, long-term containment heat removal is achieved by placing a RHR heat exchanger in service. The containment pressure profile for an intermediate LOCA (6-in. break) with a RHR heat exchanger in service is presented as Case 3 in Figure B2.1.3. No containment failure will occur.

B2.2 LOCA CORE COOLING

Following a LOCA event, core decay heat removal is achieved by adequate core water inventory control using one or more coolant injection systems. Core decay heat is then removed by break flow or, in the early stages of a small LOCA, by secondary heat removal. Because the pressure and flow requirements depend upon the size of the break, different LOCAs have different core cooling requirements.

Figure B2.1.2 Large LOCA Containment Pressure Profile -- Impact of Fan Coolers

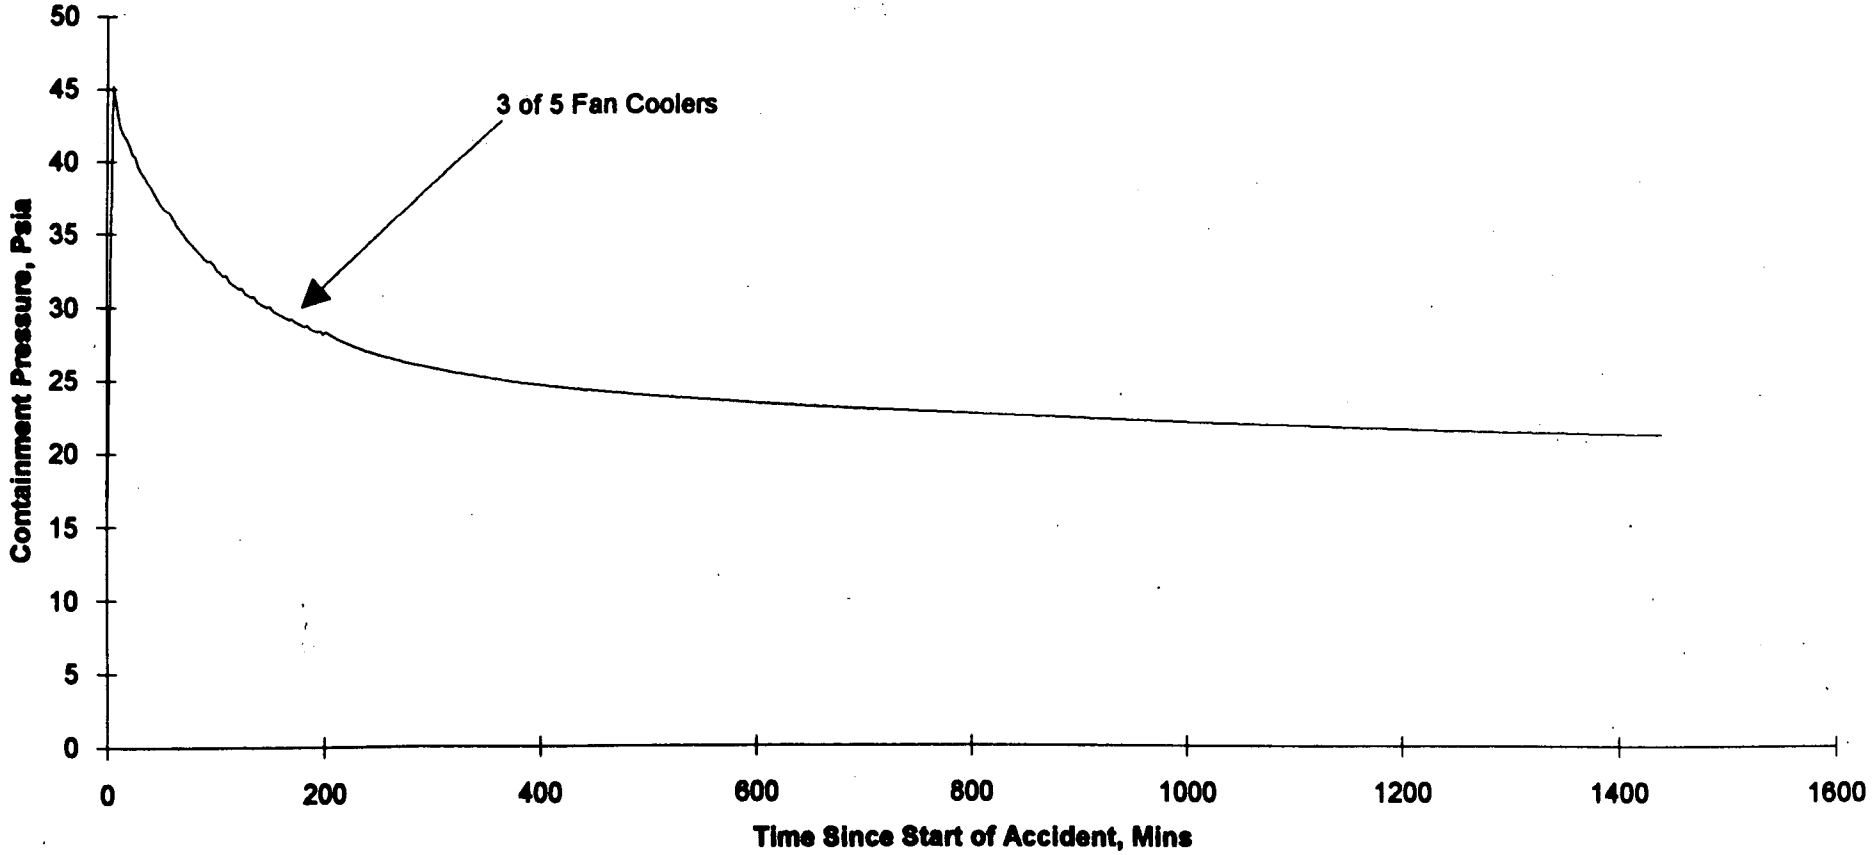


Figure B2.1.3 Large LOCA Containment Pressure Profile -- Impact of Heat Removal

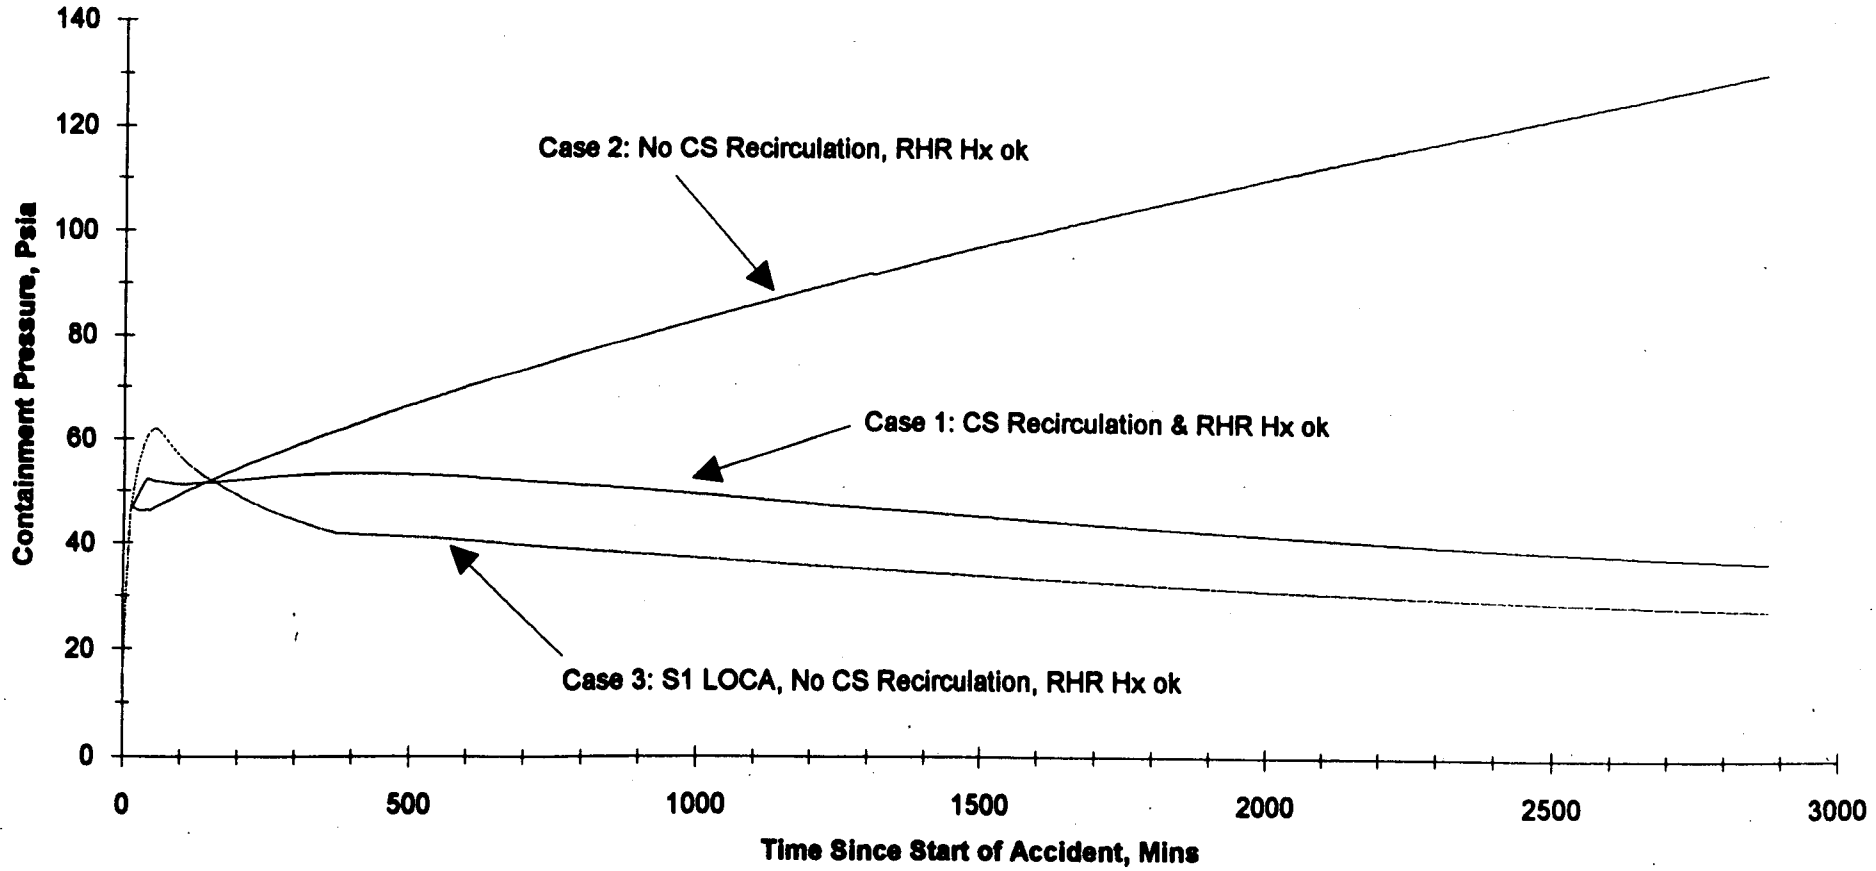

B2.2.1 LARGE LOCA CORE COOLING

The success criteria presented in Table 3.1.3.1 for a large LOCA (diameter >6 in.) are based on MARCH code analyses. These analyses show that in a large LOCA, initial core cooling can be provided by a low-head safety injection (RHR) pump injecting through one 10-in. RCS cold leg. Alternatively, initial core cooling can be provided by two of four accumulators discharging through their associated RCS 10-in. cold legs and by two high-head safety injection pumps injecting through two 2-in. RCS cold legs. Reactor vessel downcomer water level profiles for these alternatives are presented in Figure B2.2.1.

Long-term core cooling for LOCAs is provided by cold-leg recirculation flow from a recirculation or RHR pump, the coolant being injected into at least one RCS 10-in. cold leg.

B2.2.2 INTERMEDIATE LOCA CORE COOLING

Intermediate LOCAs result from RCS breaks with diameters of 2 to 6 in. MARCH code analyses for break sizes 3 to 6 in. show that sufficient RCS depressurization occurs to allow the accumulators to discharge and low-head core cooling to be provided by RHR pumps. As with large LOCAs, at least one RHR pump must inject coolant into one RCS 10-in. cold leg.

For break sizes of 2 to 3 in., adequate core cooling is provided by one high-head safety injection pump discharging into two RCS 2-in. cold legs and two accumulators discharging into their associated RCS cold legs. Secondary heat removal or RCS depressurization are normally not required. However, failure of high-head core cooling will lead to core damage, unless RCS depressurization (through secondary-side depressurization of the steam generators to 95 psig or the opening of a PORV) occurs and a low-head safety injection pump provides low-head injection.

B2.2.3 SMALL LOCA CORE COOLING

Small LOCAs are RCS breaks with diameters of 1/2 to 2 in. MARCH code analysis shows that flow through such breaks does not remove sufficient heat and therefore both secondary heat removal and high-head safety injection flow are required to achieve stable conditions. Figure B2.2.2 shows vessel downcomer elevation for two cases in which high-head injection is provided: in the first, AFW secondary heat removal fails; in the second, AFW secondary heat removal succeeds. From these results, it was concluded that at least one high-head safety injection and one AFW pump must operate to provide core cooling.

Figure B2.2.1 Large LOCA Vessel Downcomer Profile
-- Impact of High-head Safety Injection

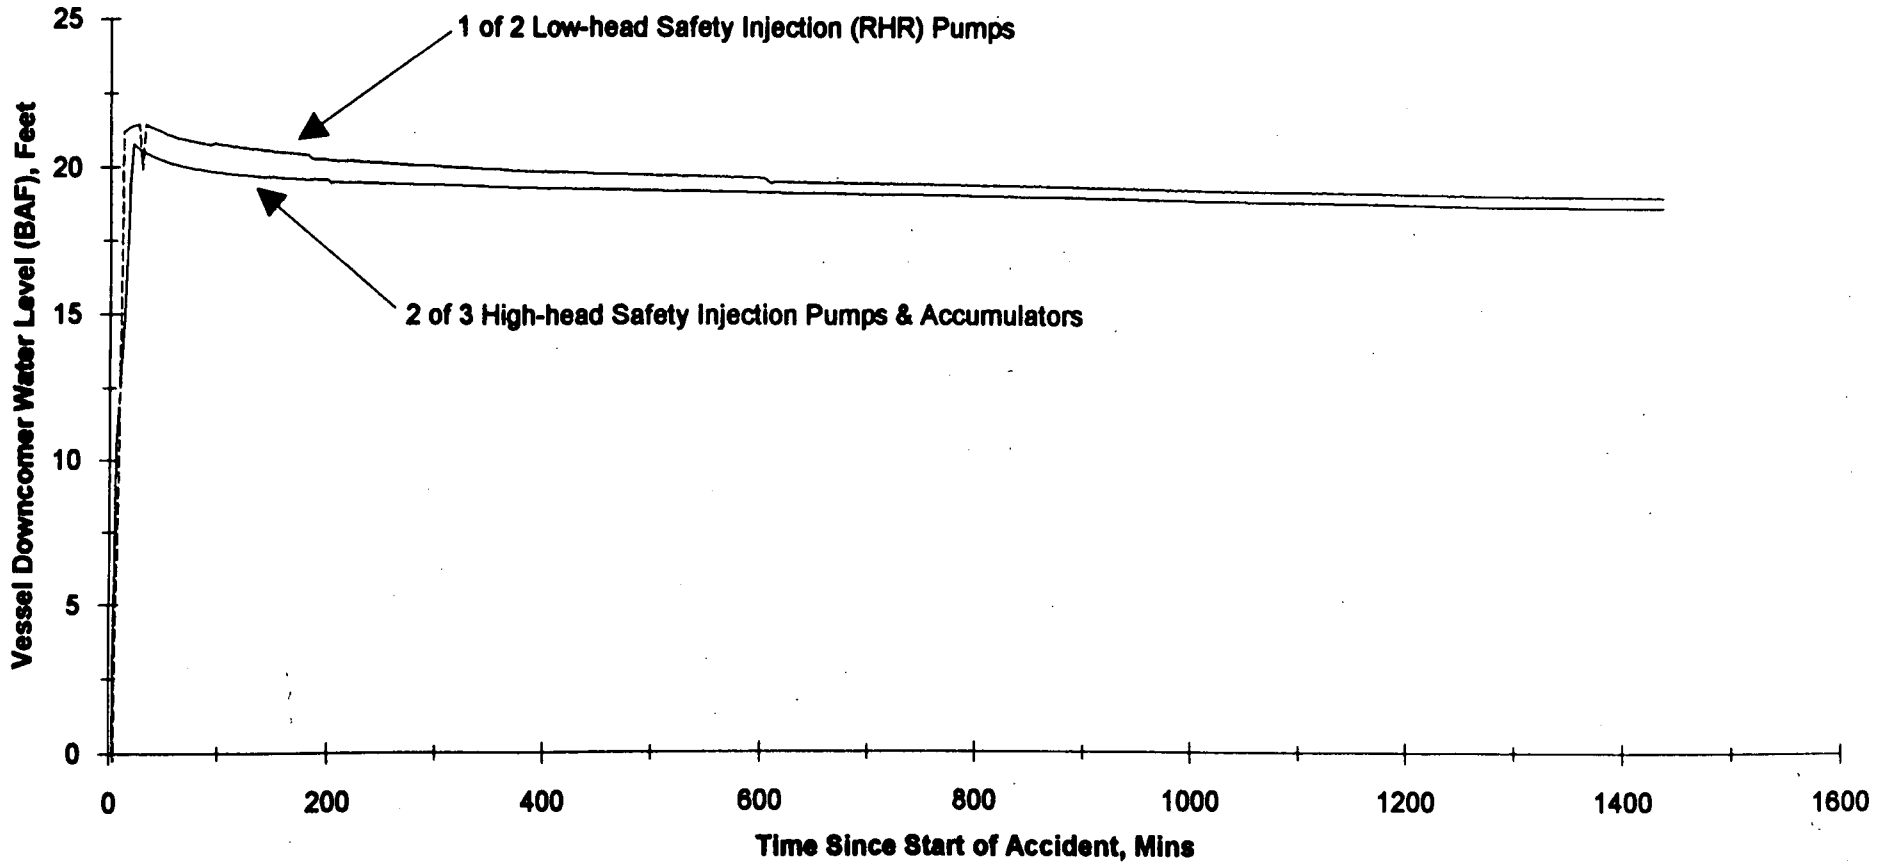

Figure B2.2.2 Small LOCA Vessel Downcomer Profile
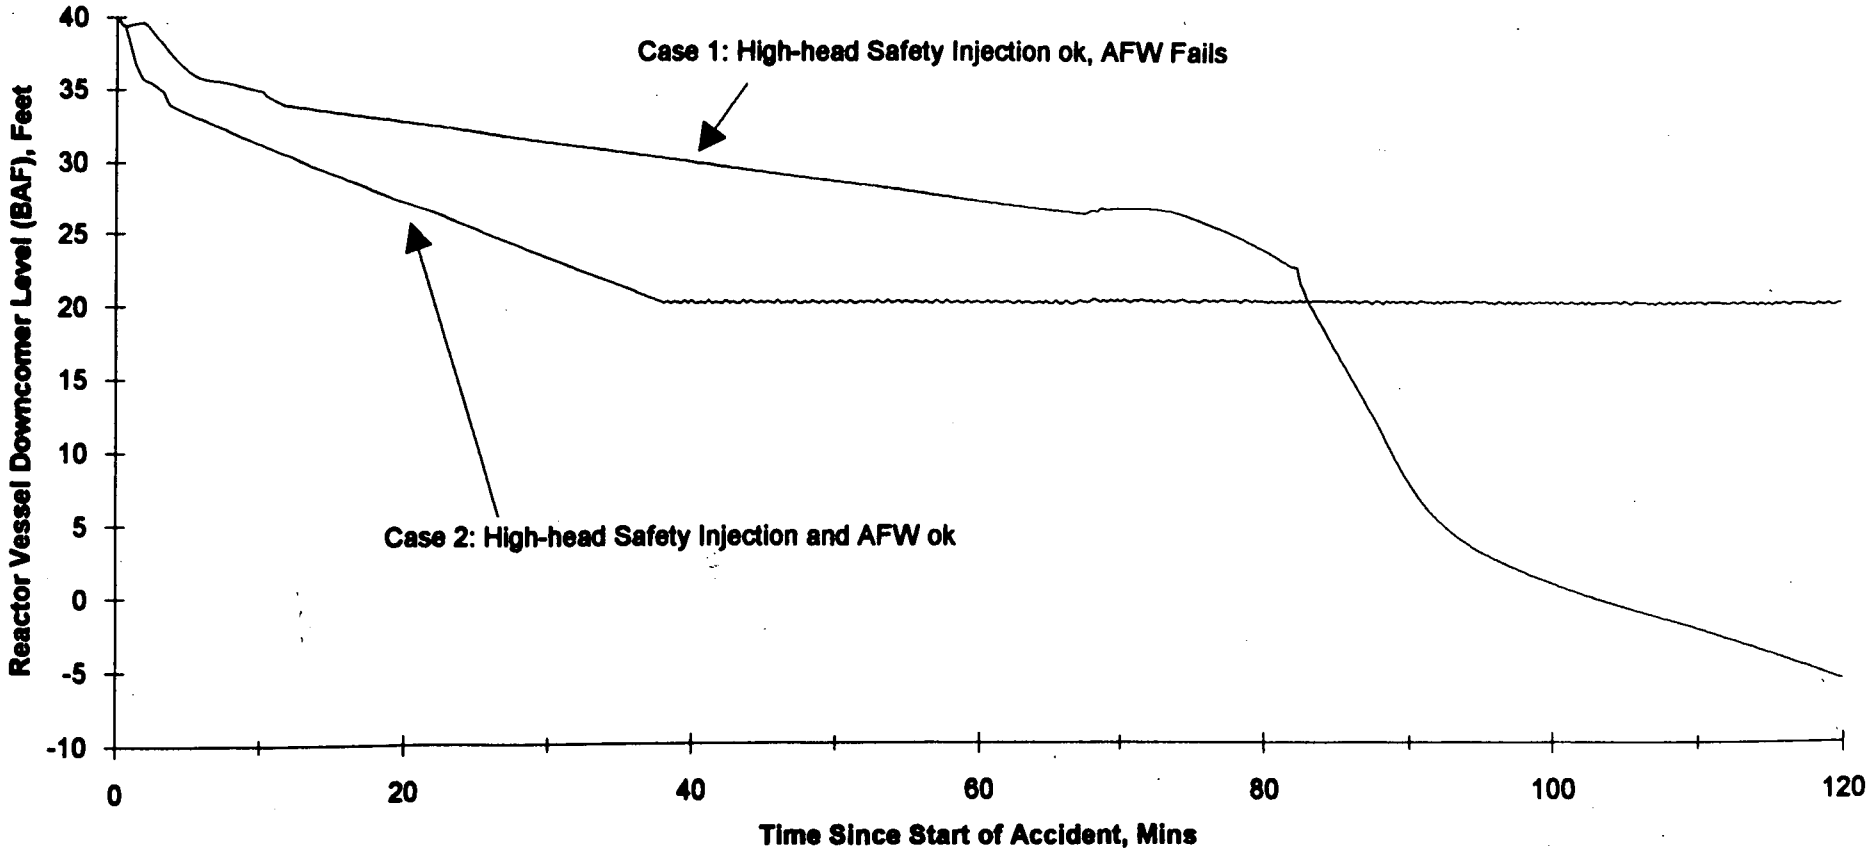
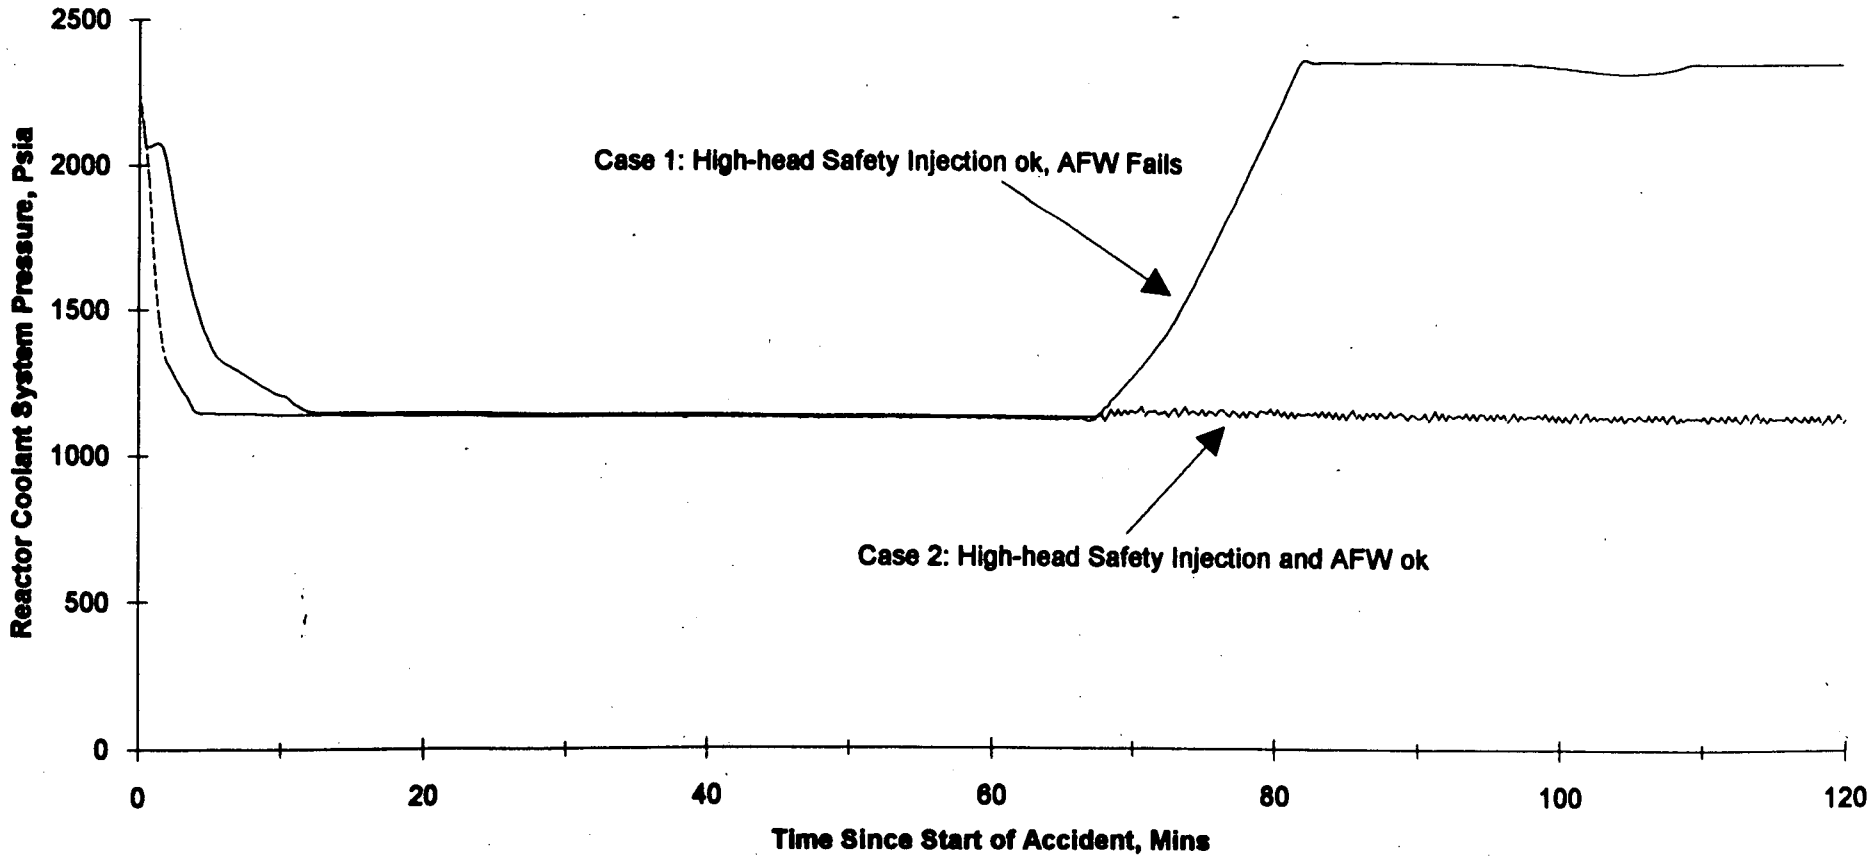
-- Impact of High-head Safety Injection



If secondary heat removal fails, MARCH predicts that at least one PORV must be opened within 50 minutes to remove energy from the core and depressurize the RCS. Failure to open a PORV leads to RCS pressure cycles around the PORV setpoint (Figure B2.2.3). Because this pressure is above the shut-off head of the high-head safety injection pumps, injection flow from the high head safety injection pumps will be lost, and vessel boil-off and core damage result. Thus core cooling at this time requires the operation of at least one high-head safety injection pump and, should secondary heat removal fail, the opening of both PORVs.

If the high-head safety injection pumps are unavailable, the RCS must be depressurized to allow for low-head safety injection. In these circumstances, successful core cooling requires RCS depressurization and the operation of one low-head safety injection pump within 120 minutes. RCS depressurization is accomplished by depressurizing the steam generators (opening all steam dump valves) or by opening both PORVs and running all reactor coolant pumps.

Figure B2.2.3 Small LOCA RCS Pressure Profile
-- Impact of High-head Safety Injection



Section B3

TRANSIENT INITIATORS

B3.1 TIMING OF EVENTS AFTER LOSS OF AFW SYSTEM COOLING

A generic analysis has shown that, in the event of a loss-of-feedwater transient, bleed-and-feed cooling must begin within 25 minutes from the start of the transient [3]. However, given that IP3 PORV capacity is less than that assumed in the generic case (118 lb/hr/MWt versus 139 lb/hr/MWt), a second analysis was performed using the MAAP PWR computer code. This analysis verified that, in a loss-of-feedwater transient, bleed-and-feed cooling must be initiated within 25 minutes of the reactor scram, provided the reactor coolant pumps are tripped five minutes after reactor scram.

Should bleed-and-feed cooling not be aligned, steam generator dryout is predicted to occur 76 minutes after reactor scram (Figure B3.1.1). Once the steam generator is dry, RCS pressure increases rapidly to the PORV setpoint (Figure B3.1.2) and primary inventory begins to leak to the pressurizer relief tank (Figure B3.1.3). Approximately 85 minutes after reactor scram, the primary relief tank rupture disk fails discharging sufficient coolant into the containment to generate a high containment pressure signal. This signal starts the containment fan coolers in their emergency mode of operation. MAAP PWR predicts that the core is uncovered (vessel water level at top of active fuel) 106 minutes after reactor scram. Subsequently, core damage occurs 167 minutes after reactor scram, at which time the fuel cladding temperature exceeds 2200°F.

According to the generic analysis [3], feedwater flow must be restored before the core is uncovered to preclude core damage. Therefore, according to the MAAP PWR results described above, the recovery of feedwater flow within 106 minutes of the reactor scram will mitigate the transient. Later recovery of feedwater flow will not prevent core damage.

B3.2 SYSTEM RESPONSE FOLLOWING BLEED-AND-FEED OPERATION

In developing the transient event trees, the final stable operating condition following bleed and feed must be determined. If the 350°F, 450-psig entry conditions for RHR shutdown cooling are reached before depletion of RWST water inventory, the RHR system can be used for long-term decay heat removal. Otherwise, recirculation core cooling is required.

Figure B3.1.1 Steam Generator Water Level Profile
-- Impact of Loss of AFW Operation

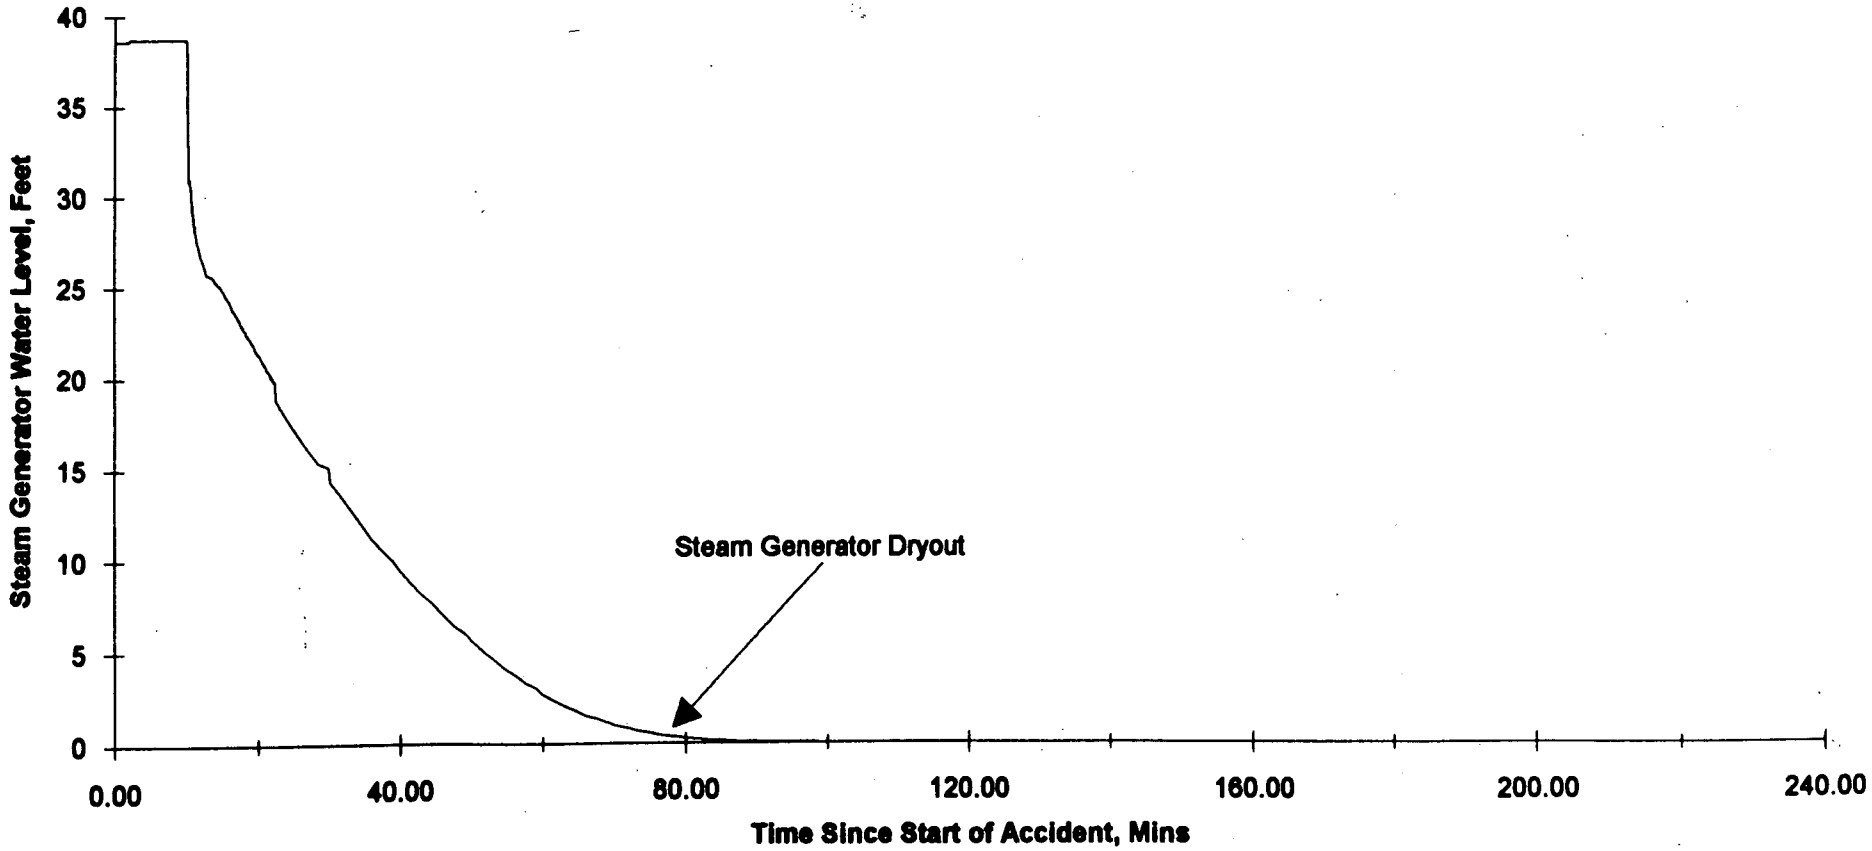


Figure B3.1.2 Reactor Coolant System Pressure Profile
-- Impact of Loss of AFW Operation

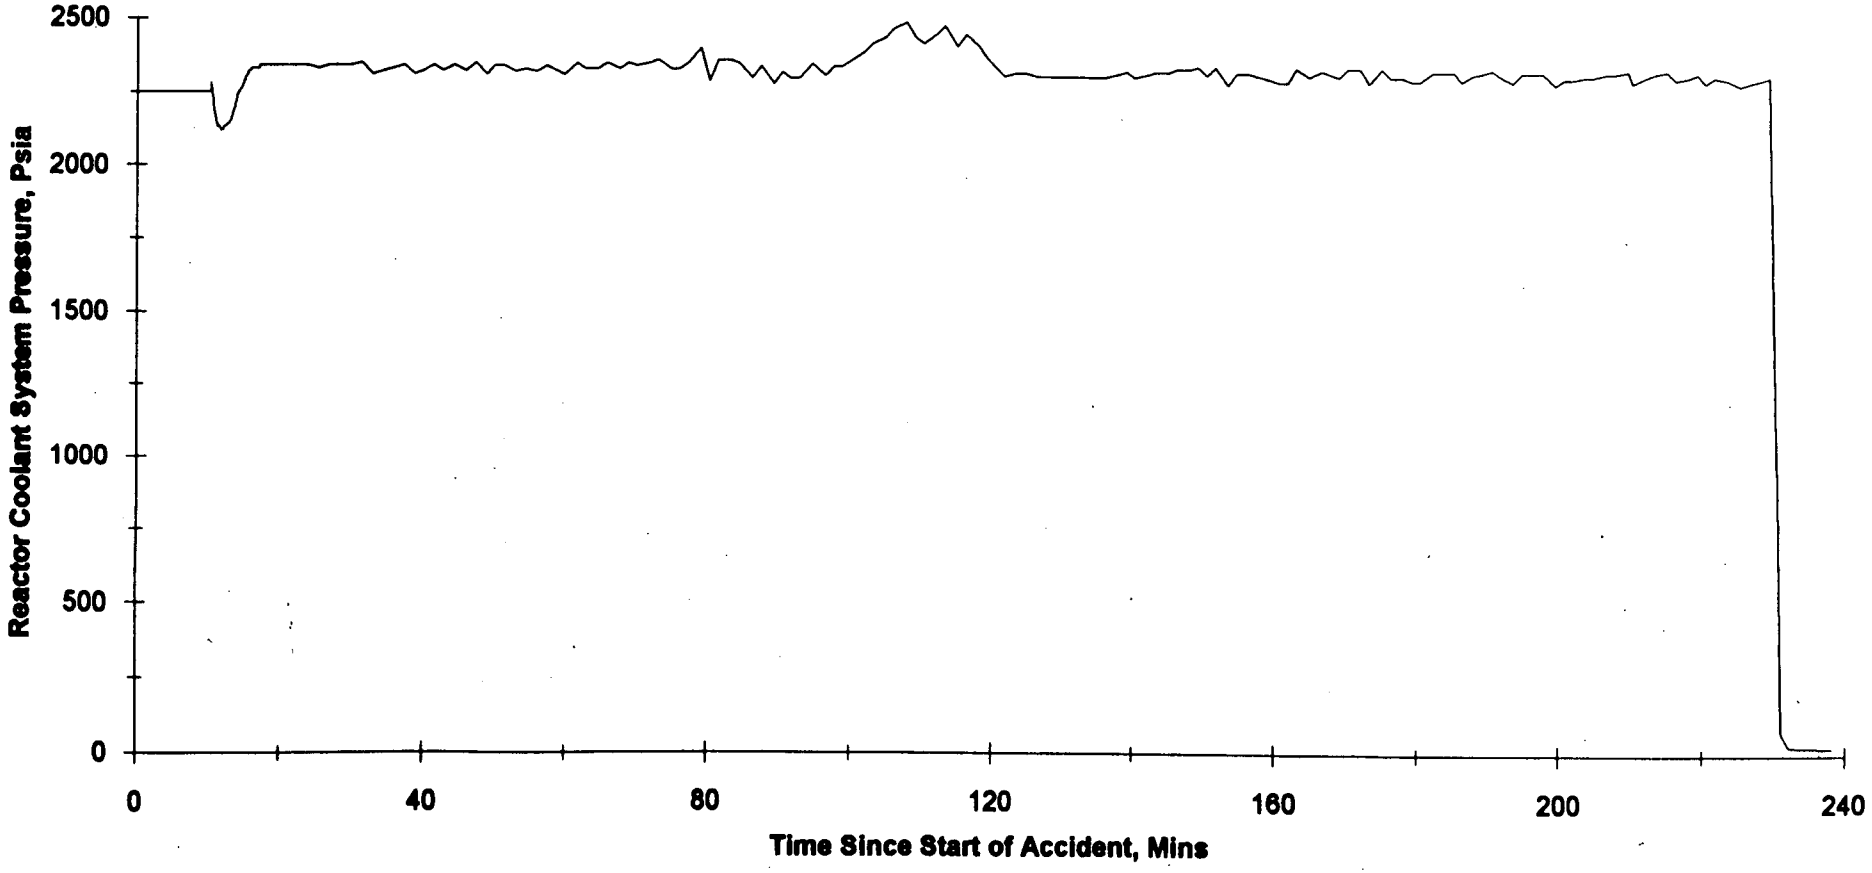

Figure B3.1.3 Reactor Coolant System Water Level Profile
-- Impact of Loss of AFW Operation

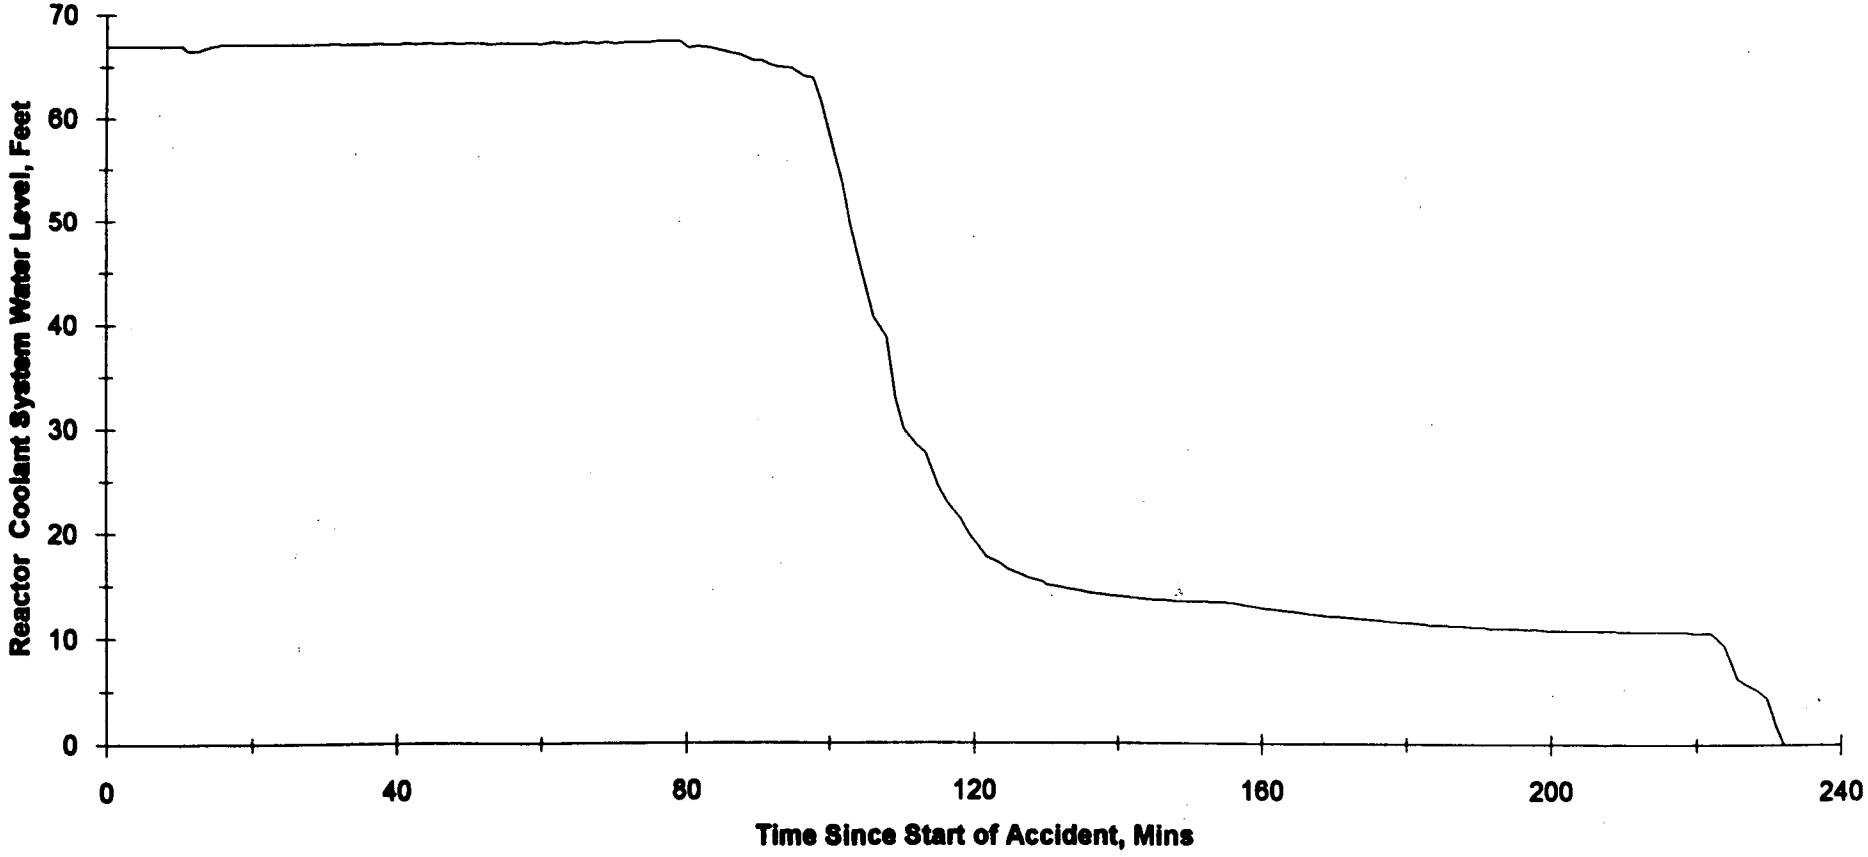

Figure B3.2.1 presents RCS temperature and pressure profiles following bleed-and-feed operation, calculated using MAAP PWR. In this scenario, two PORVs opened and three high-head safety injection pumps are running 5 minutes into the transient. High containment pressure (>3.0 psig) is reached at 99 minutes and results in the containment fan coolers starting in their emergency mode of operation. Recirculation core cooling is implemented 179 minutes after reactor scram upon RWST depletion. Since the RWST inventory depletes before the RHR entry point is reached, recirculation cooling is modeled in the transient event trees instead of RHR shutdown cooling. However, shutdown cooling can be established later when conditions allowing its operation are satisfied.

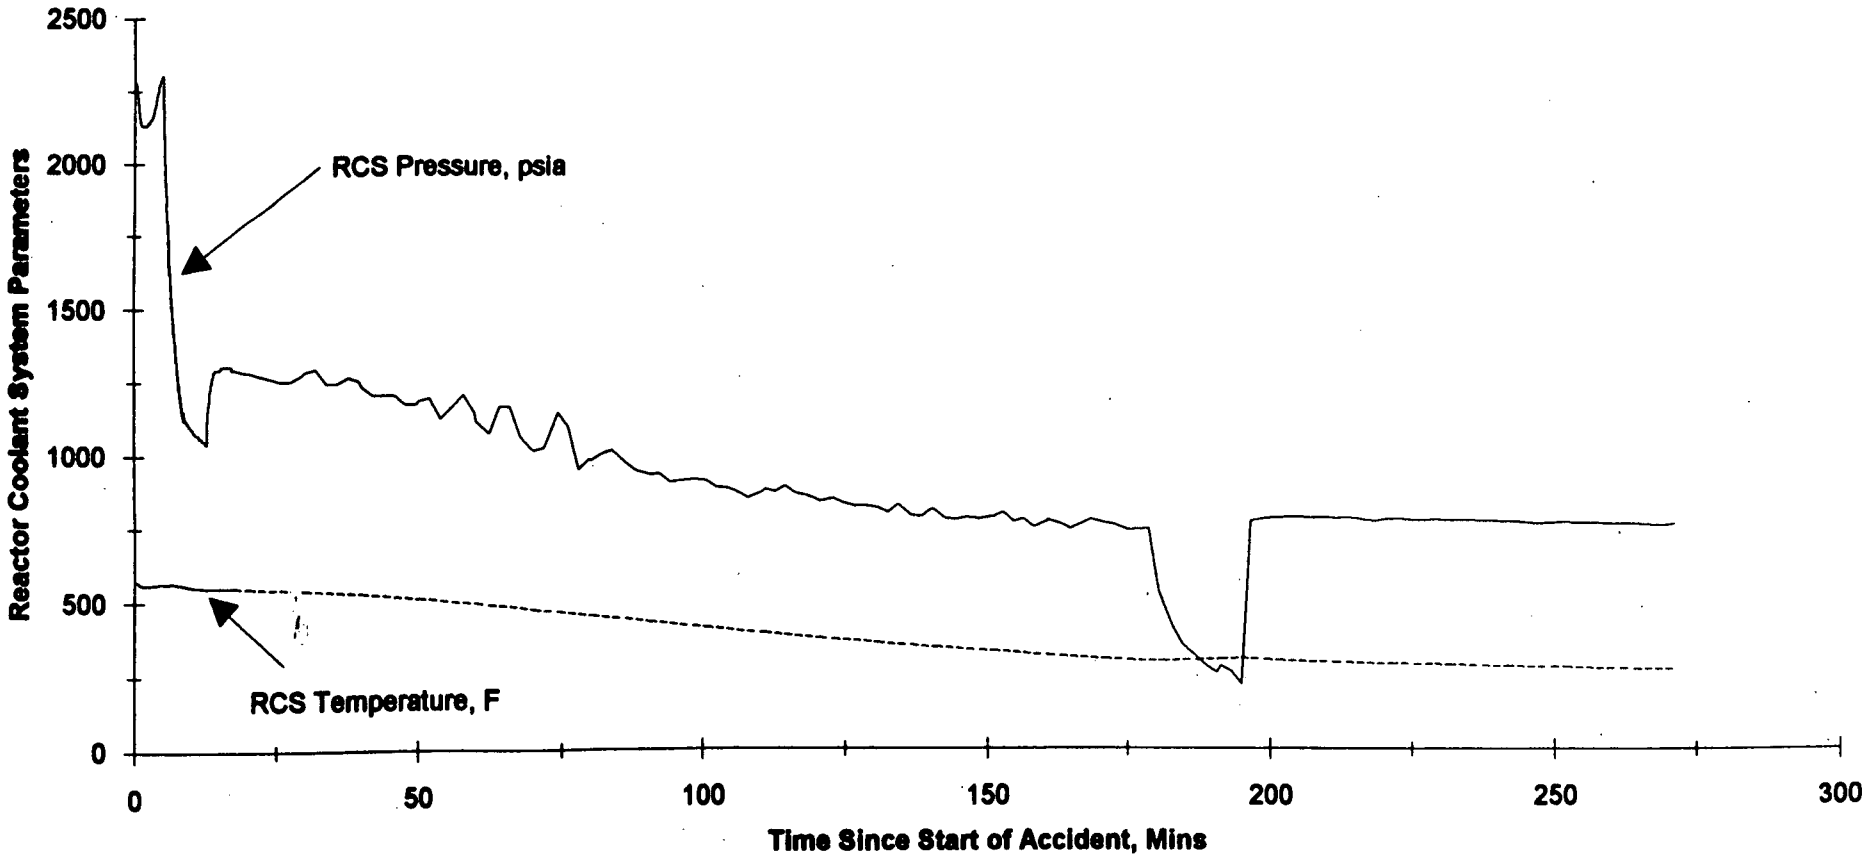
Figure B3.2.1 RCS Temperature and Pressure Profile
-- Impact of Bleed and Feed Core Cooling



Section B4

STEAM GENERATOR TUBE RUPTURE

The operator actions critical to the mitigation of steam generator tube ruptures are:

- Isolation of the ruptured steam generator
- Early RCS cooldown and depressurization
- Late RCS cooldown and depressurization
- Alignment of RHR shutdown cooling
- Refilling the RWST.

These actions will now be examined.

B4.1 ISOLATION OF THE RUPTURED STEAM GENERATOR

Because steam generator tube rupture provides several potential paths for the release of reactor coolant outside containment, RCS flow into the secondary side must be stopped should tube rupture occur. To accomplish this, the ruptured steam generator must be isolated and RCS pressure reduced below the pressure of the ruptured steam generator. Failure to perform these actions in a timely fashion increases the likelihood of a LOCA event in which the containment is bypassed.

The main concern in early RCS cooldown and depressurization failure is the possibility of overfilling the ruptured steam generator. The flow of water through the SRVs from an overfilled steam generator can result in the SRVs failing open. Furthermore, the main steam line can rupture if it is pressurized to steam generator relief pressure with water because the line is not designed to be filled with water.

The time at which the ruptured steam generator overfills depends on the leak rate through the ruptured tubes and AFW flow to the ruptured steam generator. The initial tube leak rate was assumed to be 400 gpm through a break 0.0033 ft^2 in area; the steam generator vapor space was estimated to be 15,880 gal. Overfilling would then occur 41 minutes after the SGTR event, given AFW isolation 20 minutes after the SGTR event, or after 31 minutes, if the AFW system is not isolated and a 200-gpm AFW flow to the failed steam generator is assumed.

B4.2 EARLY RCS COOLDOWN AND DEPRESSURIZATION

Should high-head safety injection be unavailable, the operator must initiate RCS cooldown using the intact steam generators to allow the accumulators to inject coolant and so ensure adequate core cooling until low-head safety injection is possible. The latest time at which cooldown can be initiated is 5 hours after the incident starts because core damage occurs at 7.5 hours, at least 1 hour is required for RCS cooldown to 650 psig (490°F), the pressure at which accumulators will inject coolant, and at least one more hour is required to bring the RCS below the shutoff head of the RHR pumps. The timing for core damage was taken from a MAAP PWR run in which a 400 gpm RCS break and no emergency core cooling injection were assumed.

B4.3 LATE RCS COOLDOWN AND DEPRESSURIZATION

This action is interrelated with the early RCS cooldown and depressurization action. Failure to perform early RCS cooldown and depressurization leads to overfilling of the ruptured steam generator and a subsequent inability to isolate the ruptured steam generator. A LOCA bypassing containment results. Core damage is prevented only if cooldown and depressurization to cold shutdown conditions (an average RCS temperature < 200°F) is achieved using the RHR system before the RWST depletes its inventory. Under these conditions the time to initiate late RCS cooldown and depressurization depends on the times to reach RHR entry conditions (350°F, 450 psig) and achieve cold shutdown. MAAP PWR code runs showed that for an initial ruptured tube leak rate of 400 gpm, RWST depletion occurs at 8 hours. If it is assumed that the operator takes 2 hours to bring the RCS to RHR entry condition using high-head safety injection (cooldown rate, 100 deg. F/hr) and an additional 3 hours to bring the reactor to cold shutdown (cooldown rate, 50 deg. F/hr), the operator should initiate cooldown within 3 hours for the RCS to be in cold shutdown before a low-low RWST water level is reached.

B4.4 ALIGNMENT OF RHR SHUTDOWN COOLING

Should a containment bypass LOCA be caused by an inability to achieve timely RCS depressurization, or should a ruptured steam generator SRV fail to reclose, cold shutdown is the only effective stable condition. Hot shutdown is not stable because RCS inventory continues to boil off to the atmosphere through the bypass path and consequently, RWST inventory injected into the RCS will be discharged into the atmosphere rather than the containment sumps. Subsequently, with the containment sumps bypassed, long-term recirculation core cooling is unavailable. To preclude core damage, the RCS is cooled down and RHR shutdown cooling is aligned to achieve cold shutdown and prevent any further RCS leakage to the atmosphere. Therefore, as noted in Section B4.3, the operator should initiate RHR shutdown cooling within 3 hours of RCS cooldown for the RCS to be in cold shutdown before a low-low RWST water level is reached after 8 hours.

B4.5 REFILLING RWST

Failure to reduce RCS pressure to a pressure below that of the ruptured steam generator secondary side leads to continued loss of RCS water (RWST inventory) from containment and thus to a lack of make-up for long term recirculation cooling. Under these conditions, replenishment of the RWST is the only effective way to prevent core damage. MAAP PWR calculations predict that core damage occurs 16 hours after RWST depletion, the core being uncovered 6.95 hours after RWST depletion. Therefore, to prevent core damage, the operator should begin to refill the RWST within 6 hours of receiving a low-low RWST water level signal.

Section B5

STATION BLACKOUT

B5.1 TIMING OF CORE DAMAGE FOLLOWING STATION BLACKOUT

During a station blackout, core damage can be prevented in certain sequences if ac power is restored in time. Therefore, to establish the time available for the recovery of ac power, it is important to determine the time to core damage. Three factors that affect this time are: the occurrence of a stuck-open PORV, RCP leakage, and the availability of the steam-turbine-driven AFW pump.

Figure B5.1.1 presents the time to core damage as a function of total RCP seal leak rate and steam-turbine-driven AFW pump operating time. Figure B5.1.2 presents the time to core damage following loss of the AFW steam-turbine-driven pump. Figure B5.1.3 presents the time to core damage as a function of total RCP leakage assuming continuous operation of the steam-turbine-driven AFW pump. Figure B5.1.4 presents the core melt progression as a function of time, assuming one stuck-open PORV, and AFW operation.

The actual time for ac power recovery can be calculated assuming that power must be restored about 30 minutes before core damage occurs to allow sufficient time for the operator to perform the necessary system recovery actions. The lower curve in Figure B5.1.2 represents this timing.

B5.2 REACTOR COOLANT PUMP SEAL LOCA

The station blackout RCP seal LOCA model is based on a Westinghouse analysis detailed in WCAP-10541 [4]. This analysis determined the probability of the core being uncovered and subsequent core damage as a function of time, given non-recovery of ac power and RCP seal failure (Figure B5.2.1). For unqualified RCP seal material, such as is used at IP3, the probability of the core being uncovered after 8 hours is 0.109, with RCS cooldown, and 0.55, without RCS cooldown. At 10 hours the core is assumed to be uncovered. The steam-turbine-driven AFW pump was assumed to be available after RCP seal failure until the core is uncovered.

INTRODUCTION

This appendix summarizes an assessment of the potential for core damage resulting from internal flooding at the Indian Point Unit 3 Nuclear Power Plant (IP3). The internal flood analysis was performed in response to Generic Letter 88-20 (November 23, 1988) issued by the U.S. Nuclear Regulatory Commission (NRC), which required that an Individual Plant Examination (IPE) be performed on all operating nuclear power plants. The Generic Letter stated that "licensees are requested to proceed with examinations...for internally initiated events (including internal flooding)."

The scope and major assumptions of this internal flood analysis are presented in Section C2. The methodology used is presented in Section C3. The presentation of the results and conclusions follows in Sections C4 and C5, respectively.

Section C2

SCOPE OF ANALYSIS

To focus the analysis on those internal floods that contribute to a severe accident, the following assumptions and guidelines were employed:

- Only the buildings and areas associated with power production were considered: the primary auxiliary, control, diesel generator, auxiliary feedwater, turbine, service water and fuel buildings and the main steam/feed enclosure and pipe bridge. These buildings and areas comprise the power block and the service water building.

- The plant was assumed to be initially running at full power.

- An internal flood can be the initiating event itself or can occur subsequent to some other initiator.

- Pipe breaks, tank and heat exchanger failures, valve and pump failures, and maintenance-induced floods are potential flood sources. Valve and pump failures include ruptures of glands, seals, and gaskets.

- The effects on equipment of steam (including condensation) and of submergence, spraying, and splashing were addressed.

- A series of conservative screening rules was used to eliminate internal flooding events with a low probability of occurrence or a limited potential for core damage. In particular, accident scenarios that result in a contribution to core damage frequency of less than 10^{-8}/yr were not developed.

- Flooding resulting from a loss of primary or secondary coolant [e.g., loss of coolant accidents (LOCAs) and interfacing LOCAs] was not addressed because its potential for core damage is already covered elsewhere in the IPE.

- Missile or whiplash damage resulting from the rupture of high energy lines was not considered.

- The collapse of walls was not considered because rooms in which substantial accumulations of water are possible have concrete walls that are most unlikely to fail.

- Leakage through construction joints was not considered because this leakage will be very small in comparison to flow through or under doors or through drains and piping penetrations.

Subject to these assumptions and guidelines, all potential flooding scenarios were investigated. However, floods of greatest concern are analagous to special initiating events in that they will both require or cause a reactor trip and negate safety functions.

Section C3

METHODOLOGY OVERVIEW

The methodology used to perform the internal flood analysis entailed:

- Identifying potential plant floods and affected areas
- Defining flooding scenarios and eliminating those found to be unimportant
- Quantifying important flooding scenarios and their contribution to core damage frequency.

Figure C3.1.1.1 displays an overview of the internal flooding methodology. Each task is described in the following subsections.

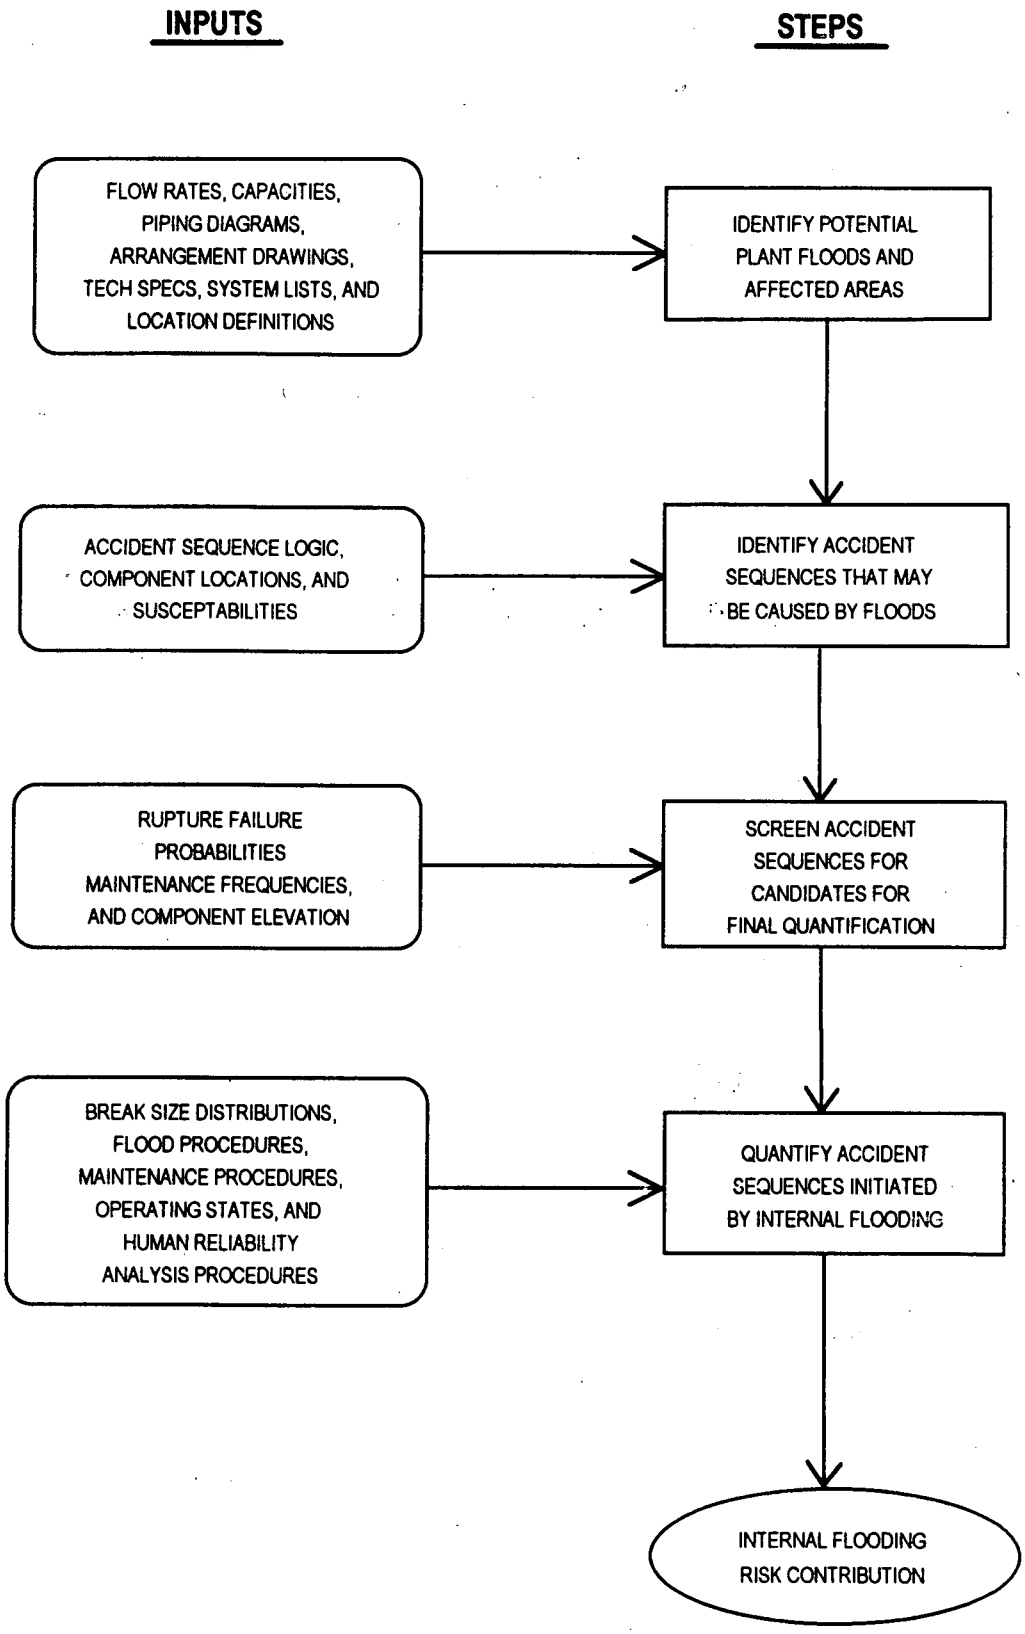
C3.1 IDENTIFICATION OF POTENTIAL PLANT FLOODS AND AFFECTED AREAS

To determine the effects of internal floods on plant operation, the potential sources of floods, the portions of the plant that can be affected (the flood zones), and the routes taken by flood water (the flood propagation pathways) were identified. This information was required to determine how internal flooding could result in core damage.

C3.1.1 PLANT FLOOD ZONES

The flood zones are individual plant areas that could reasonably contain or delay propagation of water. Potential flood zones were identified by dividing the major buildings and areas into "room areas" according to their elevations and whether they are enclosed. Structural considerations, such as walls and doors, and spatial considerations, such as distances from stairways, were used to identify the zones. While flood zones have some degree of independence, particularly with regard to spraying and environmental effects, they may also have interconnections (doors, drains, etc.) that lead to flood propagation. In this analysis, individual rooms were not considered to be individual flood zones if floodwaters cannot propagate from other rooms on the same level or, conversely, if there is no impediment to their propagation.

Figure C 3.1.1.1 Internal Flooding Methodology Overview



C3.1.2 FLOOD SOURCES

Potential flood sources were identified from drawings, walkdowns, and lists of systems and equipment in each flood zone.

The sizes of flood sources were determined assuming guillotine breaks of lines or the catastrophic rupture of valves, tanks, and heat exchangers. This approach is consistent with the NRC Standard Review Plan, Sections 3.6.1 and 3.6.2, for high-energy lines and components. For the medium-energy lines of concern in this analysis, however, the approach is more conservative in that the NRC Standard Review Plan assumes through-wall leakage.

No distinction was made between the various causes of floods because the rupture frequency data used included all floods. However, maintenance-induced floods and water hammer-induced valve or pipe rupture resulting from the failure of open butterfly valves such that the valve disk rotates freely and slams shut are failures of particular concern. Conversely, the mitigating effects of inspection and replacement programs were not addressed as there are no data to quantify these effects.

C3.1.3 PROPAGATION PATHWAYS

The pathways along which floods can propagate from one flood zone to another were identified as a precursor to identifying all the systems and equipment that could be affected by flooding. These pathways include stairways, floor penetrations, drains, doorways (i.e., open doors and leakage around closed doors), and air conditioning ducts. The plant general arrangement drawings and plant walkdowns were used to identify these pathways; the resultant pathways were depicted using schematic drawings.

C3.1.4 EQUIPMENT AND SYSTEMS SUSCEPTIBLE TO FLOODING

Equipment that is safety-related (or impacts accident sequences) and is susceptible to possible submergence, spray/splashing, or exposure to steam was identified. The procedure followed was to use the guidelines presented in Table 3.1.4.1 and then to employ the IPE systems analysis to identify components that are important to system functionality and the prevention of core damage. The results were presented in tables listing flood sources and components important to system operation.

In this review, spray and splashing effects on equipment in all areas were identified by determining the separation of unshielded equipment and flood propagation pathways from elevation to elevation or flood sources. While the possibility of submergence was considered in all cases, submergence is usually not a problem above the lowest elevations

Table C3.1.4.1 Component Flooding Effects

Component Type	Effect of Flood		
	Submergence	Spray	Steam
Valves:			
Motor	Fail as is	Fail as is	Fail as is[1]
Air	Fail	OK	OK
Hydraulic	Fail	OK	OK
Solenoid	Fail	Fail	Fail[1]
Manual	OK	OK	OK
Check	OK	OK	OK
Pumps (motor or turbine)	Fail	Fail	Fail[1]
Compressors	Fail	Fail	Fail[1]
Fans	Fail	Fail	Fail[1]
Diesels	Fail	Fail	Fail[2]
Electrical (excluding cables)	Fail	Fail	Fail
Cables	OK	OK	OK
Junction boxes	Fail[3]	OK	OK
Cable splices	Fail	OK	OK
Instrumentation	Fail	Fail	Fail[1]
Strainers/filters	OK	OK	OK
Heat exchangers	OK	OK	OK
Tanks/accumulators	OK[4]	OK	OK
Piping	OK	OK	OK
Duct work	OK	OK	OK
Room air unit coolers (excluding fan)	Fail	OK	OK
Vaporizers/heaters	Fail	Fail	Fail
Steam air ejectors/oil separators	OK	OK	OK

1 Although failure is predicted, equipment qualification testing/analysis may provide a basis for reclassifying the effect as OK.

2 Although this scenario is unlikely, failure was assumed for screening purposes if exposure to steam is possible.

3 Failure was assumed for screening purposes.

4 Tanks and accumulators were assumed to be full.

because stairs, piping penetrations, and air conditioning ducts will drain water away quickly if curbs are lower than critical flood heights and doors are open. In identifying equipment susceptible to floods, particular attention was paid to electrical equipment and especially to MCCs and switchgear.

C3.2 IDENTIFICATION OF FLOODING SCENARIOS

Flooding scenarios that could initiate or contribute to core damage accident sequences were identified. Each core damage accident sequence comprises an initiator and system failures (or possibly system successes) that result in a particular core damage state. The different flood sources and flood propagation pathways were examined to identify the systems that might fail as a result of flooding--in developing accident sequences, particular attention was paid to the possibility of flooding that both causes a reactor trip and fails systems required to help ensure a safe shutdown.

If the flood alone was sufficient to lead to core damage, it was subjected to detailed analysis. Otherwise, it was examined further to determine whether the flood, coupled with one random system failure, could lead to core damage. If more than one random failure has to occur in conjunction with a flood before core damage results, it was not examined further because such combinations of events are unlikely: typically the predicted frequency of flooding in a given flood zone is 10^{-4}/yr or less, and the probability of independent random failures of systems or trains of systems is 10^{-2} for each failure.

In defining the various flood scenarios, additional assumptions based on previous flood analyses [1,2,3] were made to limit the scope of the analysis:

- A flood source flows at full flow until it is isolated or its water supply is exhausted. Flood growth in a zone is halted by termination of the flood source or by outflow from the flood zone matching the flow of flood water into the zone. Isolation requires the operator to detect the flood and take appropriate action to isolate or depressurize the flood source, or otherwise reduce the flow from the system. The time required for isolation therefore depends on indications of flooding, such as fire-pump start indications or observations made by operators in their normal course of duties, and on the ease with which isolation can be accomplished.

- The effects of spraying and splashing from a flood were assumed to be restricted to within 30 ft of the source. Where barriers (walls, equipment, other pipes) are present, the distance will be less. While the actual distance traversed by a jet will depend upon the height and direction of release, the rate at which water escapes, and the aperture size, the dependence on pipe diameter is weak [4,5]. Calculations show that a 30-ft distance is reasonable for the pipe breaks expected here.

- Where the flow of steam is unrestricted, steam effects from a flood are limited to the room area or flood zone in which the steam release occurs. However, subsequent condensation or flood propagation effects were considered.

- Credit was always taken for installed floor drains of 24-in. diameter or greater. Without checks or maintenance of the drains, however, the functioning of smaller drains (typically of 4-in. diameter) cannot be assumed. Therefore, the consequences of flooding were normally calculated for scenarios in which the drains function and scenarios in which they are blocked.

To determine whether a flood (with or without additional random failures) would result in core damage, the impact of the flood on system components in each flood zone was evaluated. The height reached by flood water in the flood zones was calculated by integrating differential equations describing the influx of floodwater, drainage from the flooded area, and the resulting change in water volume and height. The flow rates from ruptured pipes and valves were calculated accounting for frictional resistance in the piping [5] and, where appropriate, pump run out. The rate at which water drains under doors was calculated assuming negligible frictional resistance to flow under the door. Flow through drains was calculated as described in Brater and King [6] assuming that, at low water depths, flow into a drain resembles flow over a broad-crested weir.

If the levels achieved before isolation or other mitigating actions could be taken would not affect equipment of importance in the area of interest, the equipment was considered unaffected by submergence. Spray, splashing, and steam damage could fail the equipment, however.

Finally, the frequency with which the flood might occur was considered. If the anticipated frequency of flooding from a specific source is so low that its contribution to the core damage frequency is negligible (i.e., $<10^{-8}$/year), the scenario was eliminated from further consideration. The rupture frequencies used to determine flood frequencies are presented in Table 3.2.1.1. These data were derived from two sources [7,8]. Eide et al. [7] presented rupture data for piping, valves, pumps, flanges, tanks and heat exchangers, distinguishing between primary coolant system piping and eqipment and other piping and equipment. Jamali [8] presented separate data for sections of piping in service with:

- Reactor coolant system (RCS)

- Safety injection and recirculations systems (SIR)

- Other safety-related systems (OSR)

- Main and auxiliary emergency feedwater and condensate systems (FWC)

- Main, auxiliary and extraction steam and turbine systems (ST).

Table 3.2.1.1

Rupture Frequencies

When the fluid involved is not the primary coolant:

Pipe rupture	
--general	1.2×10^{-10}/hour.ft [7]
--feedwater, condensate, steam and safety-related (<2-in. diameter)	6.3×10^{-10}/hour.section [8]
--feedwater, condensate, and steam (2 to 6-in. diameter)	10^{-9}/hour.section [8]
--safety-related (2 to 6-in. diameter)	6.4×10^{-11}/hour.section [8]
--feedwater, condensate, and steam (>6-in. diameter)	8.1×10^{-10}/hour.section [8]
--safety-related (>6-in. diameter)	1.1×10^{-10}/hour.section [8]
Valve rupture	4×10^{-10}/hour [7]
Pump rupture	1.2×10^{-9}/hour [7]
Flange rupture	10^{-10}/hour [7]
Tank/heat exchanger shell rupture	4×10^{-10}/hour [7]
Heat exchanger tube rupture	4×10^{-9}/hour [7]

When the fluid involved is the primary coolant:

Pipe rupture	3×10^{-11}/hour.ft [7]
Valve rupture	10^{-10}/hour [7]
Pump rupture	3×10^{-10}/hour [7]
Flange rupture	10^{-10}/hour [7]
Tank/heat exchanger shell rupture	10^{-10}/hour [7]
Heat exchanger tube rupture	10^{-9}/hour [7]

Data for other systems (e.g., fire protections sytems) was judged to be incomplete. Analysis of Jamali's data shows significant differences between piping rupture rates for safety injection and recirculation systems and other safety-related systems piping and the rupture rates for FWC/ST piping in pipes of 2-in. diameter of more. Accordingly, the following rupture data were used in this study:

- Piping rupture rates for safety injection and recirculation systems and other safety-related systems derived from the data of Jamali [8].
- Piping rupture rates for feedwater/condensate and steam systems derived from the data of Jamali [8].
- For other piping and all equipment (e.g., fire protection system piping and valves), the rates presented by Eide et al., [7].

Both Eide et al. and Jamali defined ruptures as breaks that result in the release of water at a rate exceeding 50 gpm. While Eide et al. expressed pipe rupture rates in terms of a rate/unit length, Jamali expressed rupture rates as a rate/pipe section, a pipe section being defined as a segment of piping between major discontinuities such as valves, pumps, reducers, etc. However, there would appear to be no basis for asserting that either approach is better.

In determining the consequences of internal flooding, recovery actions were also considered. If their effect is to reduce the frequency of occurrence of the scenarios to insignificant levels, the scenarios were eliminated without performing a detailed quantification.

C3.3 QUANTIFICATION OF POTENTIALLY IMPORTANT FLOOD SCENARIOS

Flooding scenarios that remain after screening were rigorously quantified by making a detailed assessment of the frequency of breaks of the size required to cause flood damage; the probability of isolating the break; the random failure of any unaffected systems that, when coupled with the flood, might cause core damage; and the probability of recovering systems in time to avoid core damage.

This quantification entailed the modification and requantification of event trees and fault trees constructed for the IP3 internal events PRA to obtain flood-induced accident sequence frequencies. Those flooding scenarios in which the bounding contribution to core damage frequency is less than 10^{-8}/yr were not considered further.

Finally, the flood-induced accident sequence frequencies from each flood scenario that meets the core damage frequency criterion were summed to obtain the overall contribution of flooding to the IP3 core damage frequency and plant damage state frequencies. The contribution to core damage frequency, CDF, was calculated by quantifying the following equation:

$$CDF = \sum_i FD_i (\sum_j P_{ij})$$

where P_{ij} is the probability of the core damage state j given flooding scenario i with its frequency FD_i.

Section C4

ANALYSIS OF INTERNAL FLOODING

C4.1 POTENTIAL PLANT FLOODS AND AFFECTED AREAS

Potential flood sources, flood zones, and flood propagation pathways were identified. This information is required to determine how internal flooding could result in core damage.

C4.1.1 FLOOD ZONES

The plant contains five major buildings vulnerable to internal flooding that could subsequently cause or contribute to core damage. These buildings and areas are:

- Primary auxiliary building (PAB)
- Control building (CTL)
- Diesel generator building (DGB)
- Auxiliary feedwater pump building and main steam/feed piping enclosure (AFW)
- Turbine building (TBL).

The fuel storage building and the intake structure (service water building) are not susceptible to, or sources of, internal flooding. The fuel storage building is a separate structure that contains the spent fuel pit and the new fuel storage facility. While the spent fuel pump pit heat exchangers, which are cooled by the component cooling water system, and spent fuel pumps are located on the lowest (55-ft) elevation, no equipment required for safe shutdown is located in the fuel building. Although the fuel building connects to the containment and the PAB fan house, the only potential flood pathway is via door 319, located at the 95-ft elevation. Since there are no large flood sources on or above this elevation in the fuel building and ample drainage is provided within the fuel building via stairway 1, significant flood propagation to the PAB from the fuel building is most unlikely. Therefore the fuel storage building was not considered further in this internal flooding analysis.

The intake structure is located by the river and is separate from other plant buildings. The building contains the six main circulating water pumps and six service water pumps together with associated travelling screens. While most major circulating water and service water piping is below grade, the pump motors themselves are located above grade. Should a pipe break, therefore, water should simply run back to the river and not pose a flooding hazard. One exception to this situation is the rupture of service water piping in the service water valve

pit. While this piping is below grade, flooding of the service water strainer motors located in the valve pit is possible. However, the continued operation of these motors is not required to provide service water for accident mitigation. There is also some small-bore screen wash water piping that is located above grade in the intake structure. While rupture in this piping may spray/splash the circulating water or service water pumps, no damage is expected to result because the pump motor enclosures are designed for outdoor service. Consequently, the only possible impact on plant operation from pipe rupture in the intake structure results from the initiating event itself. Because the loss of service water initiating event is already modeled elsewhere in the IPE and the loss of circulating water is enveloped by the loss of main feedwater initiator that is also modeled elsewhere, no further consideration of intake structure flooding was required.

The layout of the buildings and areas vulnerable to internal flooding is shown in Figure C4.1.1.1. Each of these buildings was examined to determine whether it should be divided into separate flood zones. Drawings depicting the boundaries of these flood zones and doors, stairwells, and other connections between flood zones at various elevations are presented as Figures C4.1.1.2-15.

It will be noted that the diesel generator and diesel generator valve rooms comprise a single zone as does the turbine building. Drains in the diesel generator and diesel generator valve rooms are so large that flood propagation between the rooms is of no consequence and thus the treatment of the rooms as separate zones adds nothing to the analysis. In the turbine building, the floor drains and open structure ensure that floods at higher elevations rapidly propagate to the 15-ft elevation.

It will also be noted that rooms that share a common hallway or access were also lumped together to form a single flood zone provided water does accumulate in the common hallway or access to the rooms. Thus, in the PAB, the 73-ft, 55-ft and 15-ft elevations comprise single flood zones, the pipe tunnel on the 41-ft elevation is placed in the same flood zone as the other rooms, and the pipe tunnel and pipe penetration areas on the 32- and 35-ft elevations are placed in the same flood zone as rooms on the 34-ft elevation.

C4.1.2 FLOOD PROPAGATION PATHWAYS

This section describes the pathways by which floods can propagate through the buildings of concern. While flood propagation pathways between buildings can be distinguished from pathways within buildings, this distinction is not particularly useful in developing flood scenarios unless floods propagating from one building to another follow a single pathway. As, at IP3, multiple flood propagation pathways exist between many of the buildings, the approach taken was to examine each building in turn, addressing all flood propagation pathways relevant to that building, regardless of their source or destination. The flood propagation pathways are discussed below.

C4.1.2.1 Flood Propagation Through the Primary Auxiliary Building

Flood water may propagate from one elevation to another within the primary auxiliary building (PAB) and between the PAB and the control building. The flood propagation pathways are shown schematically in Figure C4.1.2.1.

The main pathways from elevation to elevation within the PAB are:

- Stairway 3 (from the 73-ft elevation to the 55-ft elevation)
- Stairways 2 and 4 from the 55-ft elevation to the 41-ft elevation
- Stairway 1 from the 55-ft elevation to the 34-ft elevation and from there to the 15-ft elevation
- A stairway from the 67-ft elevation to the 41-ft elevation.

In addition, water will flow from flood zone PAB73 to flood zone PAB55 and from flood zone PAB55 to flood zone PAB41 through open gratings around the CCW heat exchangers. However, at the 73-ft elevation, a 4-in. curb around the grating will preclude floods from all but the CCW lines and fire protection system from propagating down to the 55-ft elevation. Piping penetrations allow flood propagation from flood zone PAB34 to flood zone PAB15; from flood zone PAB41 to flood zone PAB34; and from flood zone PAB34 to flood zone PAB15. No significant propagation will occur from the stairways to flood zones at higher elevations.

Water released at higher elevations within the PAB will flow to the 15-ft elevation impeded by no more than 4-in. curbs between rooms on each level and the hallways and stairways. Water may accumulate at the 15-ft elevation if 4-in. floor drains near the yard door at the

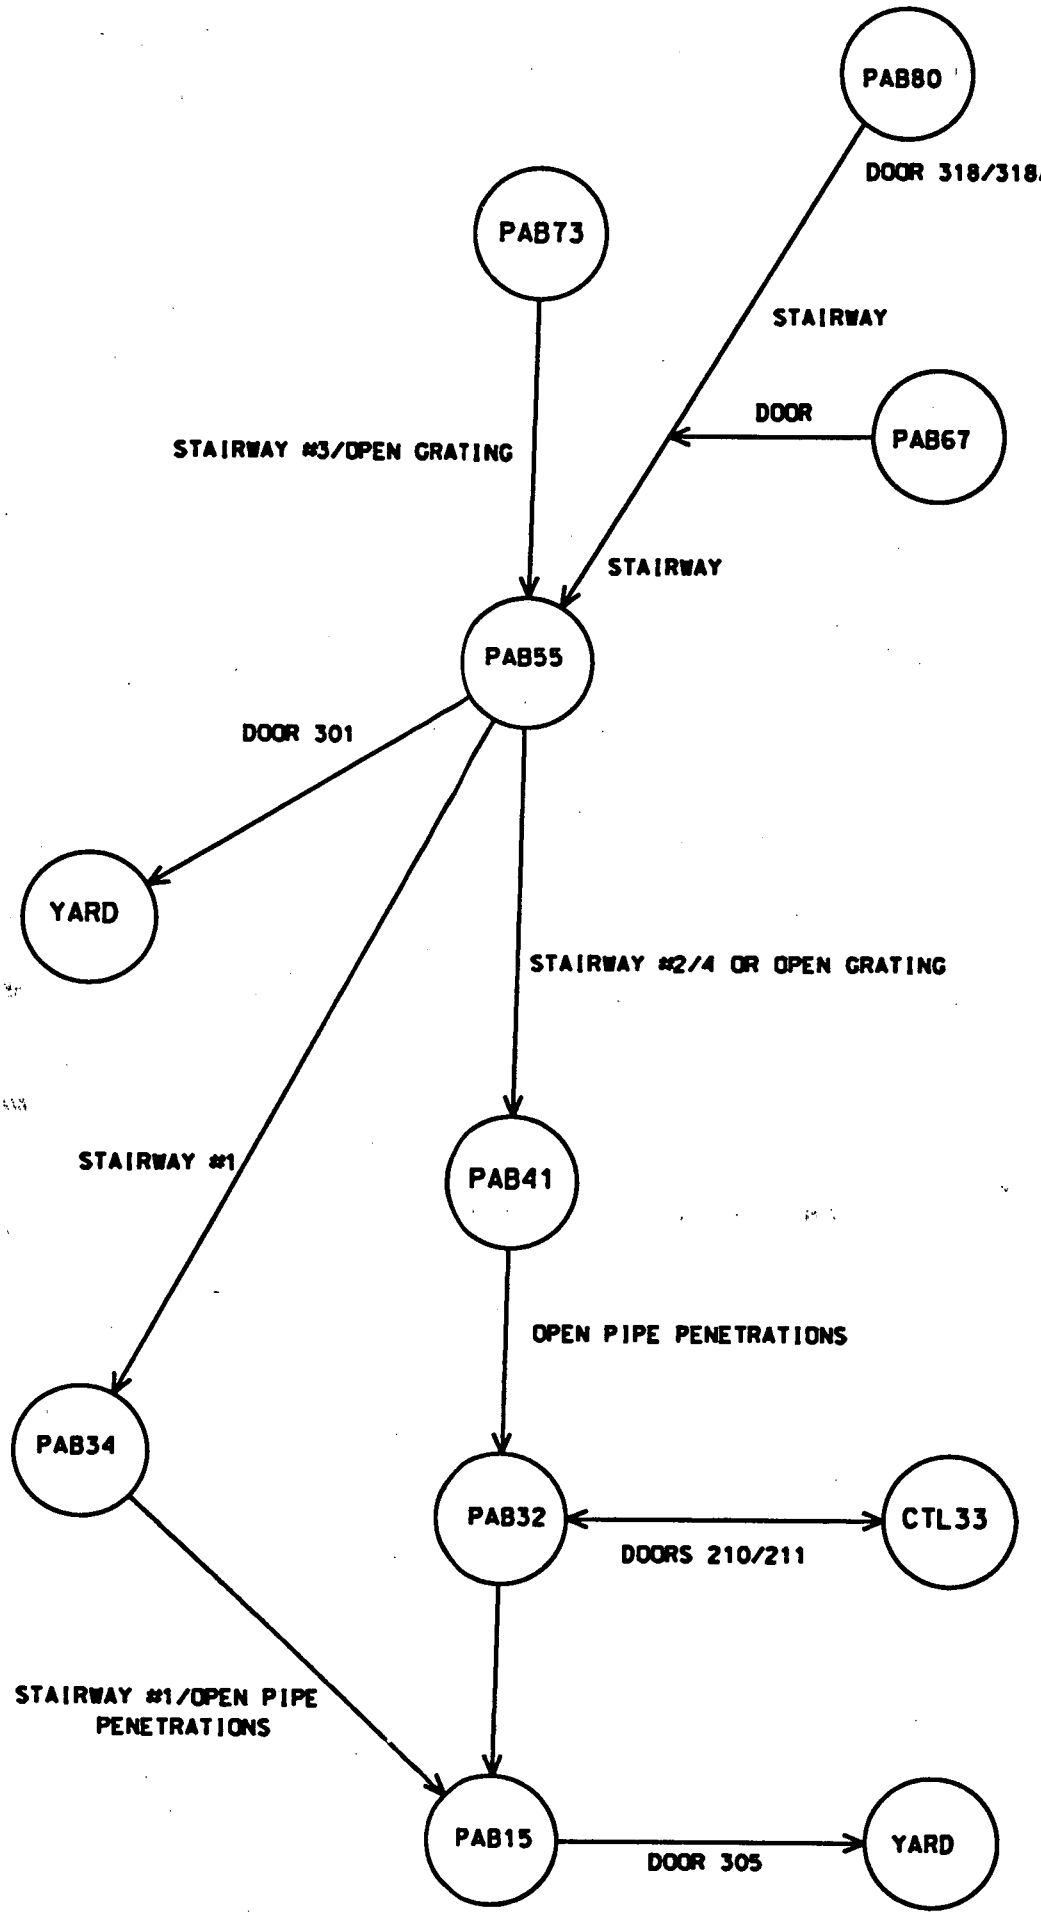

Figure C4.1.2.1 Flood Propagation Pathways in Primary Auxiliary Building

15-ft elevation are inadequate or blocked. Although water will eventually discharge to the outdoors through roll-up door 305 in the east wall of the PAB next to the valve corridor, the base of this door is 43.5 in. above the floor level and thus above the 39-in. critical flood height for the RHR pumps. Furthermore, outflow is restricted to a 0.5-in. gap at the bottom of the door because the original flap in the roll-up door has been welded closed.

The backflow of water through floor drain systems into flood zone PAB15 is a means of flood propagation that was analyzed previously in response to NRC Information Notice No. 83-44 and Supplement 1 to the notice (dated August 1990). However, as this route of flood propagation essentially duplicates other routes, it was examined no further.

Flood propagation between primary auxiliary building flood zone PAB32 and control building flood zone CTL33 could occur through fire doors 210 and 211. However, significant flood propagation between flood zones PAB32 and CTL33 is unlikely because water will not accumulate in either flood zone and propagation would have to occur under closed flood doors.

C4.1.2.2 Flood Propagation Through the Control Building

Flood water may propagate from one flood zone to another within the control building and between the control building and the PAB or the diesel generator building. These flood propagation pathways are shown schematically in Figure C4.1.2.2.

Excepting the 15-ft elevation, each elevation within the control building is designated as a single flood zone. The main pathway from higher elevations to the 15-ft elevation is the east stairway. Water can propagate from flood zones CTL53 and CTL33 to the stairwell at the 15-ft elevation (flood zone CTL15-3) through fire doors 206 and 204, respectively. This flow of water would be unimpeded--there are no curbs between the rooms at higher elevations and the stairway. No significant propagation will occur from the stairways to other flood zones at higher elevations and all piping and other penetrations between the zones are sealed.

Should water be released in flood zone CTL33, most is expected to drain to the yard through a 4-ft x 4-ft HVAC duct in the cable tunnel floor or through seven 4-in. floor drains. A 4-in. floor drain is located close to the IACCW head tank. This drain acts as a potential flood propagation path from flood zone CTL33 to flood zone CTL15-1 should the hub drain in CTL15-1 be blocked.

At the 15-ft elevation, flood water may propagate between the emergency switchgear room (flood zone CTL15-1) and the stairwell (flood zone CTL15-3) by overflowing a 6-in. high curb under interconnecting double fire door 202. Because door 202 opens into the emergency switchgear room from the stairwell, it may fail open should water accumulate in the stairwell,

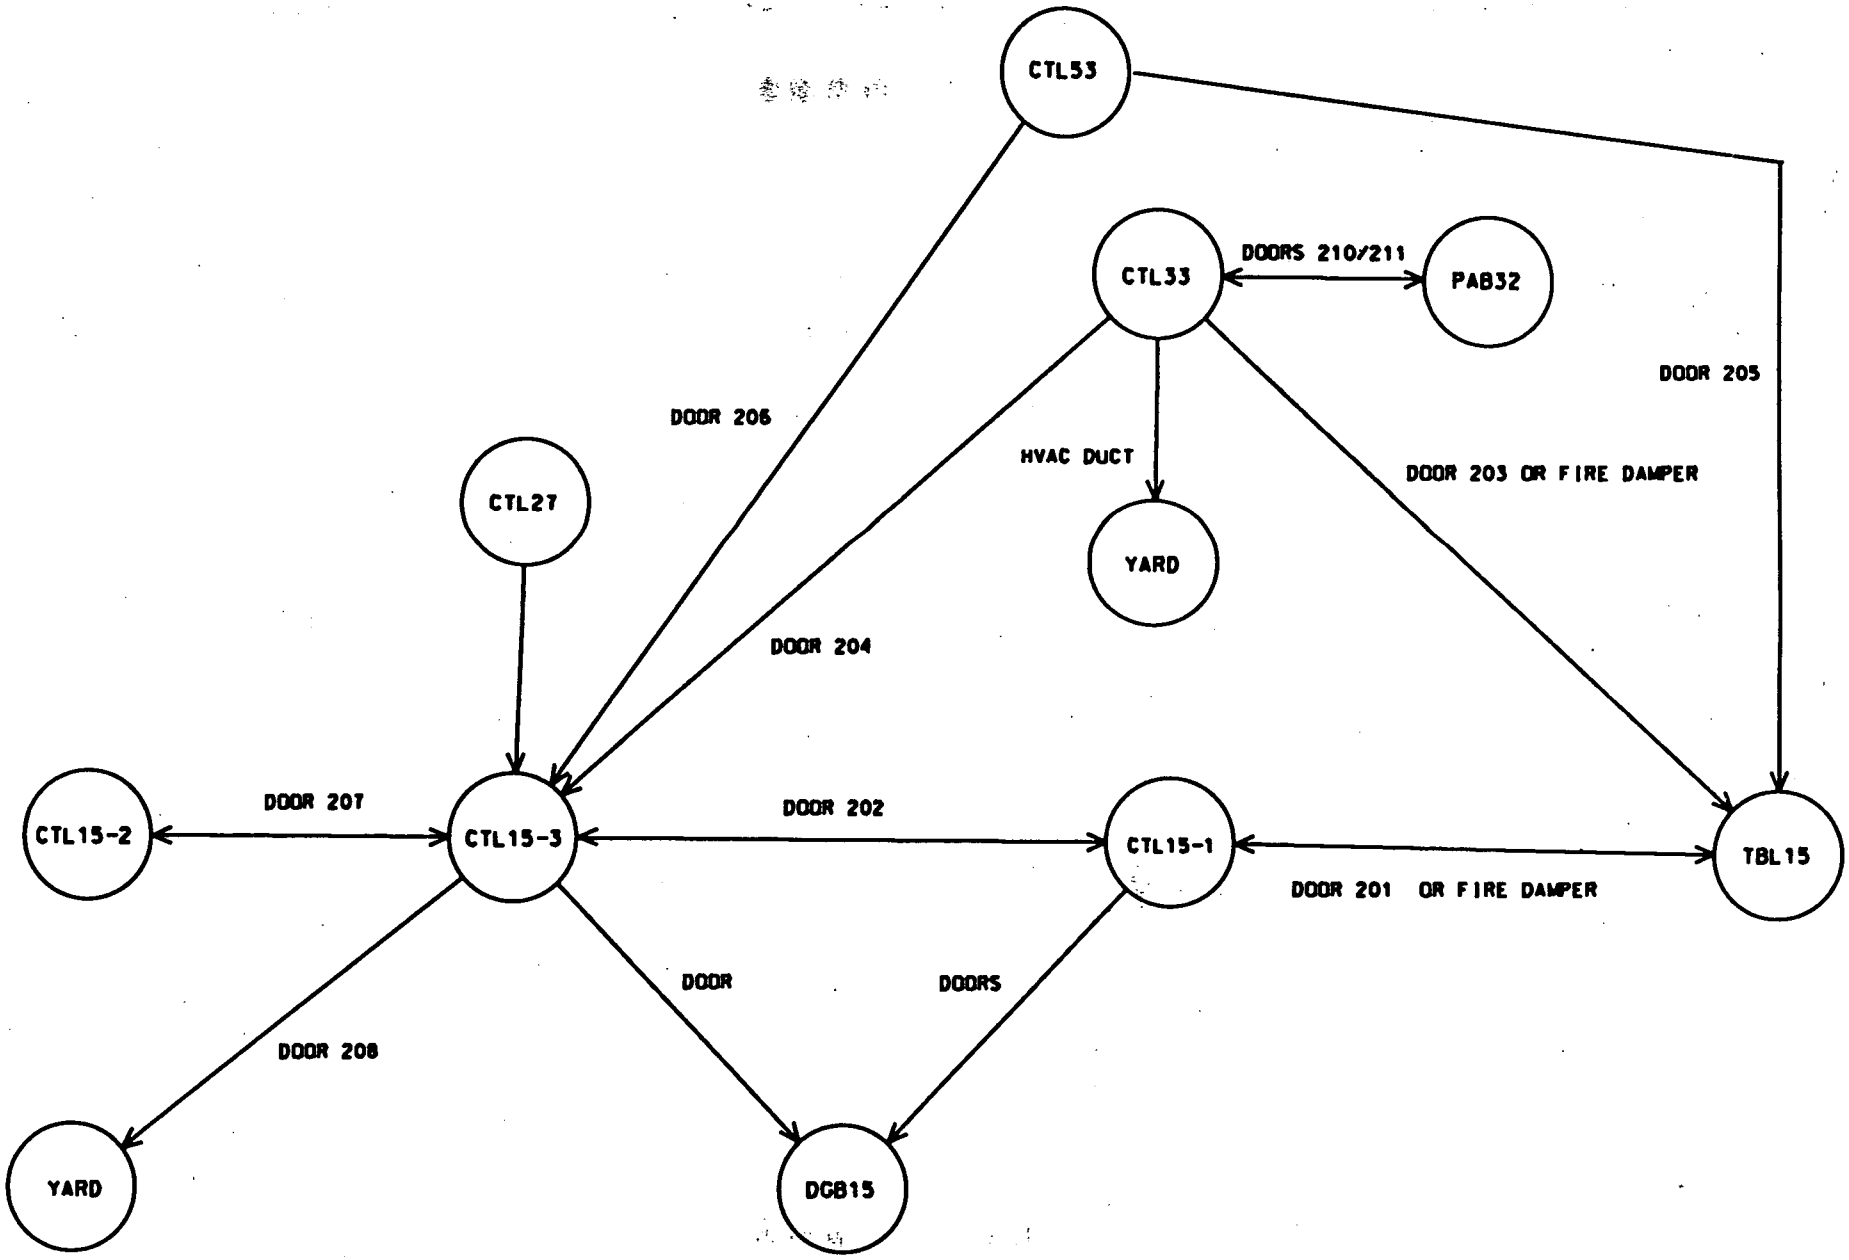

Figure C4.1.2.2 Flood Propagation Pathways in Control Building

causing submergence, spray and splashing within the switchgear room. Flood water may also propagate between the stairwell (CTL15-3) and the AC equipment room (flood zone CTL15-2) by overflowing a 6-in. high curb under door 207. Finally, water may propagate between flood zones CTL15-1 and CTL15-2 through shared drains: the four 4-in. hub drains and one 4-in. floor drain in CTL15-2 and the three 4-in. floor drains and eleven 4-in. hub drains in CTL15-1 discharge through a common line to a common sump. The air intake opening through the exterior wall will not drain CTL15-2. The opening of fire door 208 to the yard will only drain flood zone CTL15-3 when water there is more than 3-ft deep.

At the 15-ft elevation, water will flow from the stairwell (flood zone CTL15-3) into the diesel generator building valve room, flood zone DGB15, through a 0.25-in. gap under the close-fitting interconnecting door. Because the sump pumps and large drainage system in DGB15 can accommodate flows of 20,000 gpm, drainage from CTL15-3 will be limited by the flow rate under the door. Because the door into the diesel generator valve room opens out into the stairwell, it is unlikely to fail open should water accumulate in flood zone CTL15-3. Water will also flow from the switchgear room, flood zone CTL15-1, into flood zone DGB15 through a short hallway and 0.25-in. gaps under double interconnecting doors.

Flood propagation between primary auxiliary building flood zone PAB34 and control building flood zone CTL33 could occur through fire doors 210 and 211. However, as noted in Section C4.1.2.1, propagation through these doors is unlikely to be significant.

Floods can also propagate between the turbine building and the control building at the 53-ft, 33-ft, and 15-ft elevations. At the 53-ft elevation, double fire door 205 opens out from the control room (flood zone CTL53) to the turbine building. Water that accumulates within the control room can be drained off by opening this door. Positive pressures within the control room are, however, expected to prevent the entry of steam through the normally closed fire door into the control room should a high-pressure steam line rupture in the turbine building.

At the 33-ft elevation, fire door 203 opens out from flood zone CTL33 into the turbine building. In addition, a 3-ft x 3-ft HVAC wall duct and a fire damper 52 in. above the floor of flood zone CTL33 will allow steam to enter flood zone CTL33 from the turbine building but provide no drainage of flood water from CTL33-1.

At the 15-ft elevation, double fire door 201 and a normally open 4-ft x 6-ft fire louver above the door connect the switchgear room (flood zone CTL15-1) and the turbine building (flood zone TBL15). A 4-ft high dike protects the fire door on the turbine building side. To overflow this barrier, a discharge of more than 10^6 gal. is required and the only flood source capable of achieving such flooding within 30 minutes, the circulating water system, will itself terminate when the 6.9-kV switchgear in the turbine building is damaged at a flood height of 3 in. Furthermore, two 15-ft wide roll-up doors would probably buckle under a 4-ft head of water, releasing the water from the turbine building into the yard. However, while water is unlikely to overflow the dike, the rupture of 10-in. turbine building fire protection system piping adjacent to and directly above the dike could result in water being sprayed through the louver into the emergency switchgear room.

C4.1.2.3 Flood Propagation Through the Diesel Generator and Valve Rooms (Flood Zone DGB15)

Flood zone DGB15 comprises three diesel generator rooms and a valve room. Fire doors separate the rooms. Each room has a 24-in. drain that discharges to an enclosure at the 10-ft elevation and into the river. Each drain has a capacity of 20,000 gpm. In addition, each room contains a large trench drained through 8-in. lines to the valve room sump. Three sump pumps, one of 50-gpm capacity and two of 500-gpm capacity empty the sump. It can therefore be concluded that little water can accumulate in the diesel generator or valve rooms or flow between the rooms other than through the sumps.

Natural pathways for flood propagation to the diesel generator building valve room (flood zone DGB15) exist from the stairwell of the control building east stairway (flood zone CTL15-3) and from the emergency switchgear room (flood zone CTL15-1). Because drains within DGB15 can accommodate flows of over 20,000 gpm, they offer a means of mitigating the effects of flooding in the 15-ft elevation in the control building if the door is opened. Propagation into the diesel generator valve room will, however, normally be restricted to flow through a narrow gap under the door.

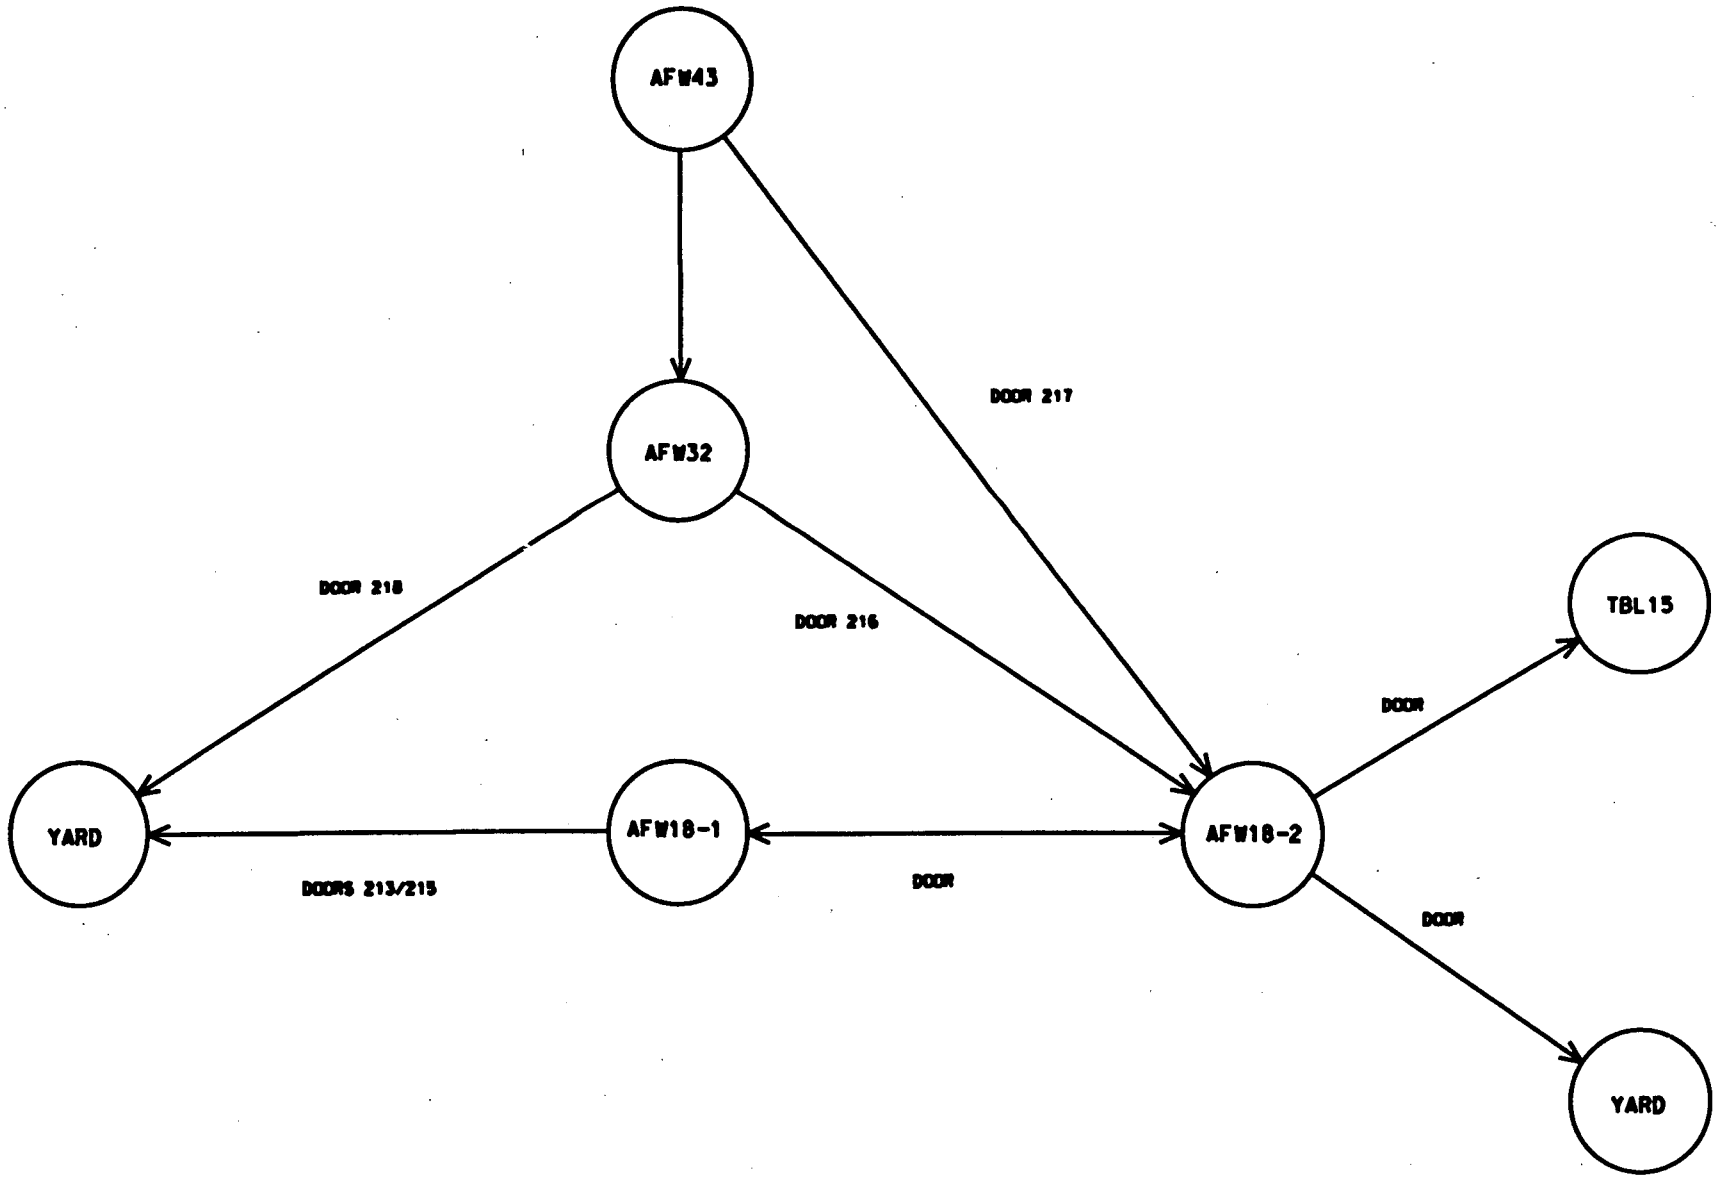
C4.1.2.4 Flood Propagation Through the Auxiliary Boiler Feedwater Pump Building

Flood water may propagate from flood zone AFW43 (the main steam/feedwater piping enclosure and bridge) to flood zone AFW32 through open piping penetrations, and to flood zone AFW18-2, through the open wire fence door 217. From flood zone AFW32, flood water may drain to the yard through 6-ft wide door 218, and to flood zone AFW18-2 through fire door 216. Propagation to flood zone AFW18-1 is unlikely as the accumulation of water in flood zone AFW32 will be insufficient to cause the silicone foam fire sealant in floor penetrations to fail. Water can drain from flood zone AFW18-1 to the yard through doors 213 and 215 and from flood zone AFW18-2 to the yard through a door. Finally, door 215 provides a pathway for flood propagation between flood zones AFW18-1 and AFW18-2.

The flood propagation pathways through the auxiliary boiler feedwater pump building are shown schematically in Figure C4.1.2.3.

Figure C4.1.2.3

Flood Propagation Pathways through Auxiliary Boiler Feedwater Building



C4.1.2.5 Flood Propagation Through the Turbine Building (Flood Zone TBL15)

Flood zone TBL15 comprises the entire turbine building. As noted in Section C4.1.1, the building was treated as a single flood zone because the floor drains and open structure ensure that floods at higher levels rapidly propagate to the 15-ft elevation. Steam releases will also pervade the entire building. Water accumulations at the 15-ft elevation in the turbine building will drain to the condensate pump pits or to the yard through two 15-ft wide roll-up doors.

Floods can propagate between the turbine building and the control building at the 53-ft, 33-ft, and 15-ft elevations. At the 53-ft elevation, double fire door 205 opens out from the control room (flood zone CTL53) to the turbine building. By opening this door, water that accumulates within the control room can be drained off.

At the 33-ft elevation, fire door 203 opens out from flood zone CTL33 onto the turbine building. In addition, a 3-ft x 3-ft HVAC wall duct and a fire damper, 52 in. above the floor of flood zone CTL33, connect CTL33 to the turbine building but will not drain flood water from CTL33-1.

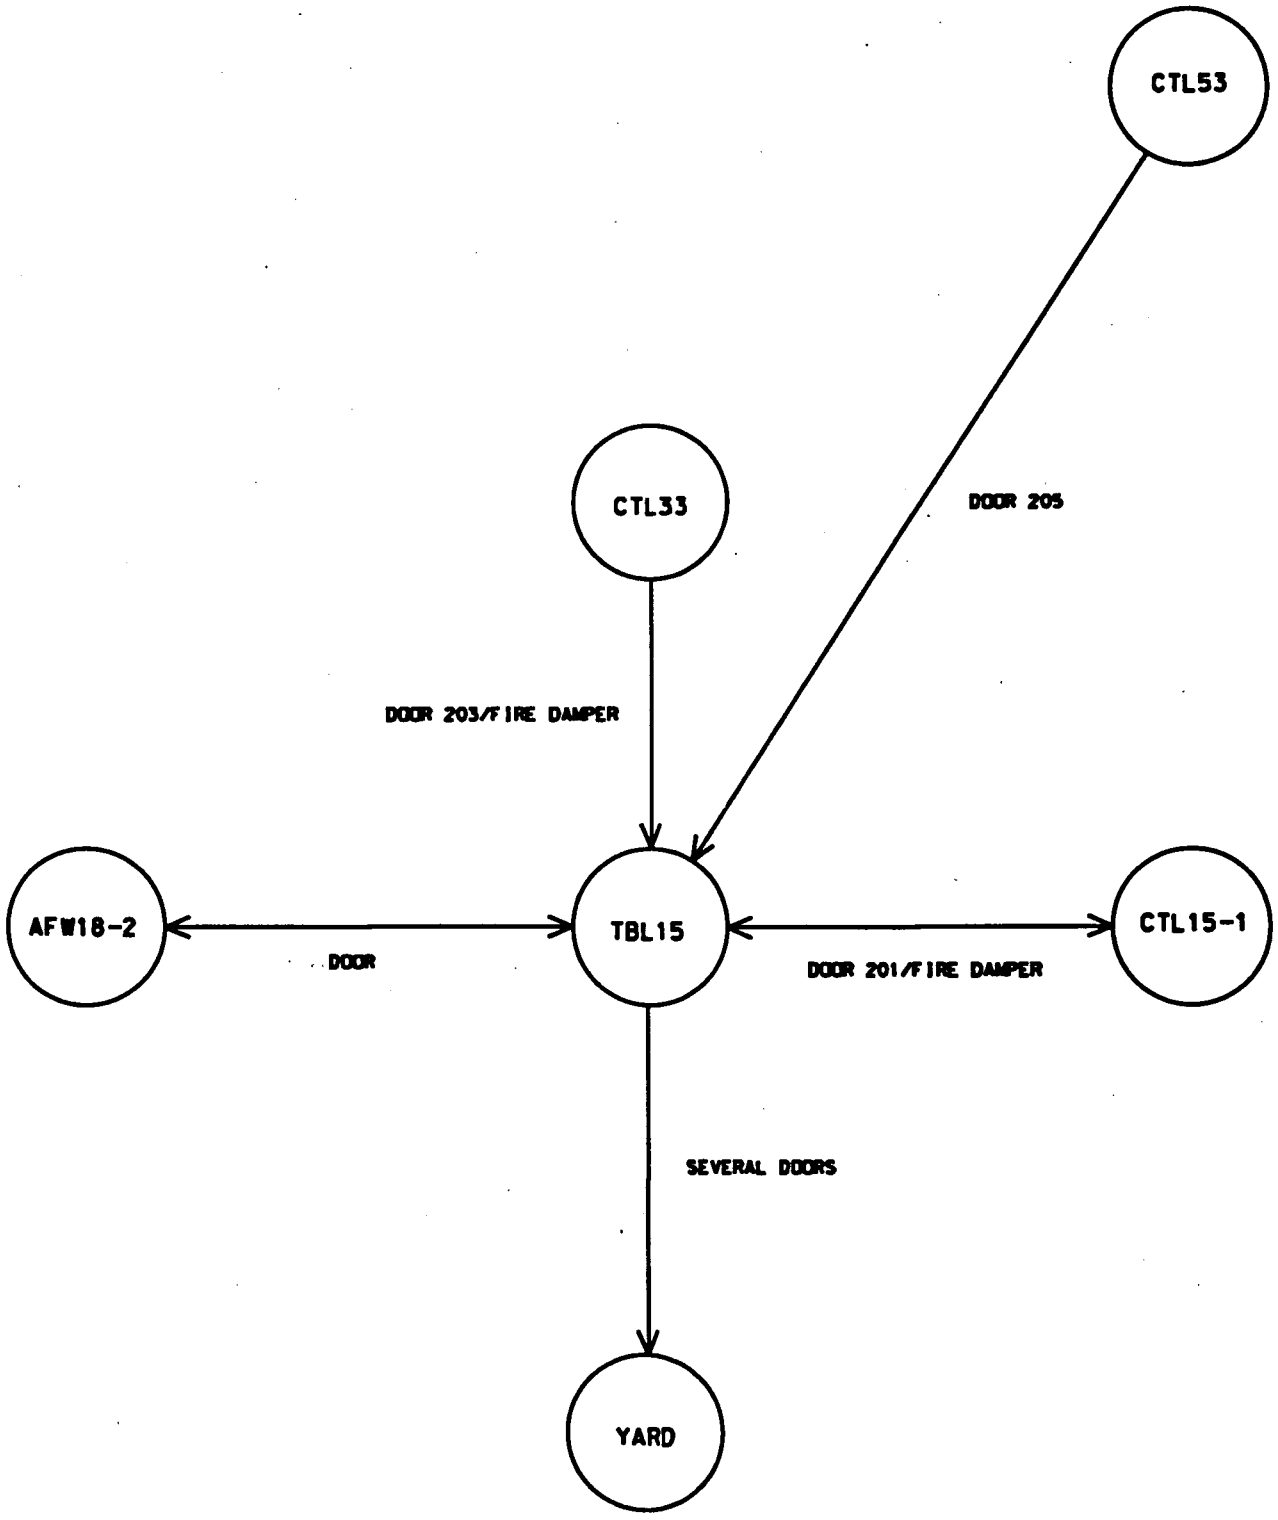
At the 15-ft elevation, double fire door 201 and a normally open 4-ft x 6-ft fire louver above the door connect the switchgear room (flood zone CTL15-1) and the turbine building (flood zone TBL15). A 4-ft high dike protects the fire door on the turbine building side. However, while water is unlikely to overflow the dike, the rupture of 10-in. turbine building fire protection system piping adjacent to and directly above the dike could result in water being sprayed into the emergency switchgear room through the louver.

Floods can also propagate between the auxiliary boiler feedwater pump building, flood zone AFW18-2, and the turbine building through a door.

These flood propagation pathways are shown schematically in Figure C4.1.2.4.

Figure C4.1.2.4

Flood Propagation Pathways through Turbine Building



C4.1.3 FLOOD SOURCES AND VULNERABILITIES

The "contents" of each flood zone--the potential flood sources and the systems and equipment affected by floods--were identified by walkdowns and the examination of drawings. The rationale for identifying flood sources and determining the susceptibility of equipment to internal floods will now be presented for each building.

C4.1.3.1 Primary Auxiliary Building

Potential flood sources exist at all levels of the primary auxiliary building. These sources include piping, valves, and tanks associated with the essential and non-essential service water (SW), component cooling water (CCW), refueling water storage tank (RWST), chemical and volume control system (CVCS), auxiliary steam, fire protection, city water, and waste disposal systems, and steam generator blow down and condensate return lines. Flooding occasioned by the rupture of the waste disposal line was eliminated from further consideration because of its small (1-in.) diameter, and because flow through the line would be intermittent and at low pressure. Similarly, the adverse effects of a rupture of the auxiliary steam line were ignored because a restriction orifice and pressure controls outside the PAB will limit the entry of steam into PAB flood zones should the auxiliary steam line rupture.

The systems in the PAB that are potentially vulnerable to flooding and important in preventing core damage include:

- High-head safety injection systems
- Residual heat removal (RHR) system
- Chemical volume control system (charging pumps)
- Component cooling water system
- Support systems (e.g., MCC-36A).

Table C4.1.3.1 lists the flood sources and equipment susceptible to flooding in the PAB.

The rationale for determining the susceptibility of equipment in the PAB to internal floods will now be presented. Spraying and splashing are the flooding effects of principal concern in flood zones above the 15-ft elevation--these zones have stairways and other pathways to drain away water.

Flood Zone PAB80. No equipment on the 80-ft elevation is susceptible to flooding and there are no flood sources on that level.

Flood Zone PAB73. On the 73-ft elevation, the only equipment susceptible to spray/splashing are the boric acid flow control valves that are used only for emergency boration in ATWS events. As the probability of the simultaneous occurrence of a flood and an ATWS event is negligible, concern over the effects of flooding on the 73-ft level can be dismissed.

Flood Zone PAB67. On the 67-ft elevation both the CVCS containment isolation valves (CH-205, CH-222, CH-226, CH-250A/B/C/D, CH-441, CH-442, CH-443, CH-444) and the auxiliary component cooling water pumps are susceptible to spray/splashing from ruptured essential service water lines.

Flood Zone PAB55. On the 55-ft elevation, SC-141A/B/C, the hydraulic flow controllers for charging pumps 31, 32, and 33, are susceptible to spray damage. However, because they are used only in emergency boration and can be overridden from the control room, and because the probability of the simultaneous occurrence of a flood and an ATWS event is negligible, the effects of flooding on these controllers are of little concern.

The MCCs located on the 55-ft elevation of the primary auxiliary building distribute ac power to safety-system pumps and MOVs. These MCCs are within range of water spraying from a break in the fire protection piping in the stairway leading from the 55-ft elevation to the 34-ft elevation. However, only MCC-36A and the motor starter components located within it will be affected by spray as it will shield the other MCCs. The MCCs are not vulnerable to submergence because their critical flood height is 10 in. and flood waters deeper than 4 in. will drain to lower levels from PAB55 through the open stairways. Because spray-induced damage to MCC-36A is unlikely to be recoverable in a short period of time, a manual plant shutdown is dictated by the technical specifications. While main and auxiliary feedwater will be available for this operation, components supplied by MCC-36A will be unavailable. These components include auxiliary component cooling pumps 31 and 33, boric acid transfer pump 31, hydrogen recombiner 32, and MOV AC-730. In addition, the motor starter compartments for MOVs AC-744 and SI-1810 will be affected by the splashing of MCC-36A.

Boric acid transfer pumps 31 and 32 are susceptible to spray damage but not to submergence effects--their critical flood height is 12 in. but flood heights will not exceed 4 in.

Charging pumps 31, 32, and 33 are also susceptible to spray damage but not to submergence effects--their critical flood height is 20 in. Spray damage will result from the rupture of city

water, component cooling water, and RWST lines, but, because the pumps are in different rooms, only one pump would be damaged in any one incident.

Motor-operated valve CH-333 (at the boric acid filter outlet) charging pump suction level control valve CH-LCV-112B, and flow control valve CH-HCV-142 (in the charging line) are susceptible to spray damage. However, as these valves are used only in emergency boration and the probability of the simultaneous occurrence of a flood and an ATWS event is negligible, concern over the effects of flooding on them can be dismissed.

Flood Zone PAB41. CCW pumps 31 and 32 in flood zone PAB41 are located in an open area 14 ft from the nearest point at which water cascading through the roof grating would strike the floor. Given this separation, CCW pumps 31 and 32 are unlikely to be susceptible to spray damage if floods propagate from the 73-ft, 67-ft or 55-ft elevations through open grating around the CCW heat exchanger. CCW pumps 31 and 32 are, however, susceptible to SWS or CCW piping ruptures in flood zone PAB41. CCW pump 33 is protected from spray damage, other than from spray from the CCW lines feeding it, by an 8-ft high Appendix R wall.

Containment spray pumps 31 and 32 in flood zone PAB41 and their pump outlet motor-operated discharge valves SI-866A/B are susceptible to spray from ruptured primary water, city water, and RWST lines.

Flood Zone PAB34. HHSI system valves SI-842, SI-843, SI-850A/C, SI-851A/B, SI-885A/B, SI-887A/B, SI-888A/B, SI-1851A/B and SI-1852A/B are located in the SI pump room in flood zone PAB34. These valves are susceptible to spray effects resulting from the rupture of SI, RWST and CCW systems. The SI pumps in flood zone PAB34 are distant from flood propagation pathways and are protected in the SI pump room. The SI pumps are not susceptible to submergence caused by flood propagation from other sources because their critical flood height is 31 in. while flood accumulation in flood zone PAB34 is limited to 4 in.

LHSI system valves AC-743, AC-744, SI-882, SI-883, SI-885A/B, SI-1810, AC-1870 and HHSI motor-operated valves SI-1835A/B are located in the pipe penetration area in flood zone PAB34. These valves are susceptible to spray and submergence effects resulting from the rupture of SI or RWST lines in the area.

Flood Zone PAB15. The RHR pumps located on the 15-ft elevation are susceptible to submergence resulting from flood propagation from higher elevations of the PAB or from the rupture of RHR, RWST, CCW, fire protection or city water lines on the 15-ft elevation of the PAB should the floor drains in the flood zone be blocked or be inadequate.

The RHR pumps are also susceptible to spray damage resulting from the rupture of pipes on the 15-ft elevation. It is unlikely, however, that more than one pump would be affected by a single source of spray.

C4.1.3.2 Control Building

Table C4.1.3.2 lists the flood sources and equipment susceptible to flooding in the control building.

The flood sources of principal concern are the 10-in. fire protection headers in the deluge station (flood zone CTL15-1) and cable tunnel (flood zone CTL33); the 4-in. fire protection headers in the east stairway (flood zone CTL15-3); and the 3-in. service water piping in the switchgear room (flood zone CTL15-1) and AC equipment room (flood zone CTL15-2). In addition, instrument air closed cooling water (IACCW), city water lines and tanks and auxiliary steam piping are present in the control building. The fire protection system sprinkler lines were eliminated from consideration as flood sources because the sprinkler system has dry pipes with normally closed sprinklers. Sanitary lines were also eliminated from consideration as a flood source because of their low pressure and intermittent flow.

The systems in the control building that are potentially vulnerable to flooding and important in preventing core damage include:

- The controllers, switches, relays and dc distribution panels in the control room (flood zone CTL53)
- The batteries and associated equipment in the battery rooms (flood zone CTL33)
- The switches, relays, circuit breakers and buses in the switchgear room (flood zone CTL15-1)
- The instrument air compressors (flood zone CTL15-1).

In identifying equipment susceptible to the effects of flooding, spray and splashing effects were considered for equipment in all areas. The determination of the susceptibility of equipment in the control building to internal floods is as follows.

Flood Zone CTL53. Controllers, switches, relays, and dc distribution panels, etc., are located in the control room, flood zone CTL53. However, city water lines on the 53-ft elevation are located in the adjacent locker room and thus will not pose a spraying hazard. While the rupture of the auxiliary steam lines in the same area could cause high temperatures and humidity within the control room, the closure of doors and isolation of the steam line break eliminate this as a source of concern. Because the critical flood height is 4 in., submergence is a potential problem in the control room. In reality, however, damage there is most unlikely--operators in the control room would discover the flood almost immediately and isolate it or drain the water from the control room by opening of doors to the control building east stairway or the turbine building.

Flood Zone CTL33. 480-Vac MCC-39, 118-Vac inverters 31 to 34, battery chargers 31, 32 and 34, dc panels 31, 32 and 34, batteries 31, 32 and 34, and associated instrumentation are located on the 33-ft elevation of the control building. However, these components are either remote, or shielded by walls, from potential flood sources that might create sprays. Furthermore, their 4-in. critical flood height and the presence of the 4-ft x 4-ft HVAC duct at the entrance to the cable spreading rooms preclude the possibility of submergence. The instrumentation in flood zone CTL33 may, however, be susceptible to high temperatures and humidity resulting from steam line breaks within the turbine building. The 2-in. component cooling water line in flood zone CTL33 is sleeved and thus is not a potential source of water spray. Furthermore, the line is located at least 25 ft from equipment susceptible to spraying. The IACCW piping is located in the south west corner of the cable spreading room next to the battery room. The location, however, is such that the battery room wall would shield equipment from any spraying resulting from a breach of IACCW piping.

Flood Zone CTL27. The control building fan room, flood zone CTL27, contains no flood sources and is not subject to flood propagation from other flood zones. Accordingly, this room is not relevant to the internal flooding analysis.

Flood Zone CTL15-1. In flood zone CTL15-1, the 480-V switchgear and dc panels, the instrument air compressors, and the instrumentation associated with them are susceptible to submergence and to spray effects from service water system, fire protection system, and IACCW system rupture.

Flood Zone CTL15-2. The control room air conditioning units and air handling units located in flood zone CTL15-2 are susceptible to flooding and spray damage and to the high temperatures and humidities resulting from a steam line break.

Flood Zone CTL15-3. Flood zone CTL15-3 contains no equipment that is susceptible to flooding effects. It does, however, contain fire protection and service water system lines that are potential flood sources.

C4.1.3.3 Diesel Generator and Valve Rooms

Table C4.1.3.3 lists the flood sources and equipment susceptible to flooding in the diesel generator and valve rooms, flood zone DGB15.

The flood sources of concern in flood zone DGB15 are 10-in. fire protection headers and 3-in. service water piping.

As noted in Section C4.1.2.3, submergence effects pose no problem in the diesel generator rooms. Furthermore, spray and splashing effects are restricted to individual rooms--no one flood source can cause spray or splashing damage to more than one diesel generator or its controls and other associated components.

C4.1.3.4 Auxiliary Boiler Feedwater Pump Building

Table C4.1.3.4 lists the flood sources and equipment susceptible to flooding in the auxiliary boiler feedwater pump (ABFP) building.

The flood sources of principal concern in the ABFP building are: the 18-in. boiler feedwater lines in flood zone AFW32; the line from the condensate storage tank and the city water line in the auxiliary boiler feed pump room (flood zone AFW18-1); and the steam line to the AFW steam turbine-driven pump, the 28-in. main steam line, 18-in. feedwater/condensate, and 8-in. fire protection system water lines in the main steam/feedwater piping enclosure (flood zone AFW43).

Equipment in the ABFP building that is potentially vulnerable to flooding and important in preventing core damage includes the two motor-driven and one steam turbine-driven AFW pumps and their associated equipment in flood zone AFW18-1 and a variety of valves and instrumentation. These susceptibilities will now be examined in more detail.

Flood Zone AFW43. Main steam isolation valves MS-1-31/32/33/34, solenoid valves SOV-1230 to 1244, power-operated relief valves PCV-1134/1135/1136/1137, and AFW steam supply isolation valve PCV-1310A are located on the main steam/feedwater line piping enclosure on the 43-ft, 65-ft and 77-ft elevations. These valves will not, however, be submerged and are not susceptible to spray effects or steam as they are qualified for severe environments.

Flood Zone AFW32. The only equipment in flood zone AFW32 that is susceptible to the effects of flooding is PCV-1310B, the second auto-isolation valve that functions in the event of a steam line break in the AFW pump room (flood zone AFW18-1). This valve is susceptible to submergence, should water accumulate in flood zone AFW32, but not to spray or steam effects.

Flood Zone AFW18-1. In flood zone AFW18-1, AFW valves, pumps, instrumentation, and an electrical panel are susceptible to exposure to steam and to submergence and spray effects from the rupture of the fire protection header, city water piping, and condensate and boiler feedwater piping. Of this equipment, the pumps will be affected by submergence first--their critical flood height is 10 in., as opposed to 37 in. for most valves. It is unlikely that a single flood source could cause spray damage to more than two pumps. The feedwater flow and main steam pressure transmitters in flood zone AFW18-1 are susceptible to submergence but not to steam or sprays--the transmitters are qualified for a severe environment.

C4.1.3.5 Turbine Building

Table C4.1.3.5 lists the flood sources and equipment susceptible to flooding in the turbine building.

Most turbine building equipment is located on three floors:

- 53-ft elevation - the turbine generator and reheater/moisture separators
- 36.75-ft elevation - feedwater heaters, steam jet air ejector
- 15-ft elevation - condensate pumps (in pits), heater drain tanks and pumps, main boiler feedwater pumps, and the turbine oil reservoir and storage tank. The 6.9-kV switchgear and non-safety-related MCCs are also located here. The 96-in. circulating water piping is located in the condenser inlet and outlet wells on the 12-ft elevation.

The flood sources of principal concern in the turbine building are the 28-in. main steam line, 96-in. circulating water line, 28-in. feedwater/condensate line, 10-in. fire protection system line, 8-in. auxiliary steam line, 4-in. component cooling water line, 4-in. service water line, 2-in. city water line, and 4-in. primary water line, and the feedwater heaters.

The equipment in the turbine building that is potentially vulnerable to flooding and important in preventing core damage includes:

- 6.9-kV switchgear
- Main boiler feedwater pumps
- Condensate pumps
- 480-V switchgear (buses 312 and 313) for Appendix R, alternative safe shutdown.

The rationale used to determine the susceptibility of equipment to internal floods follows.

Table C4.1.3.5

Systems and Equipment in Turbine Building

Flood Zone	System	Equipment Located in Flood Zone			Critical Flood Height	Vulnerable to Splashing
		Piping	Valve	Other		
TBL15	6.9-kV			Switchgear	3"	
TBL15	MFW/ cond.	Main boiler feedwater pumps: 24" suction 20"- 386 discharge Condensate pumps 30" suction 16" discharge 28" steam		MFW pumps 31/32 Condensate pumps		
TBL15	Alternative safe shutdown			MCC-312 MCC-313		
TBL15	SW	4"				
TBL15	TBCCW	4" 6"				
TBL15	Circulating water	96" - 1/2 84" - 3/4/5/6/7/8				
TBL15	Auxiliary steam	8" -				
TBL15	Fire Prot.	10"- FP-TBL15-10	FP-74 FP-76 FP-155			
TBL15	City Water	2" 1"				
TBL15	Primary water	4"				

Switches and transmitters are assumed to fail should they be submerged, sprayed, splashed, or exposed to high temperatures and humidity as a result of a steam line break. Thus all this equipment is assumed to be vulnerable to spraying or splashing as a result of the failure of the service water, main steam, turbine building component cooling water, circulating water, auxiliary steam, fire protection header, city water piping, and boiler feedwater/condensate piping.

The 6.9-kV switchgear provides offsite power to balance-of-plant and emergency loads. Buses 312 and 313 located on the 15-ft elevation distribute ac power to component cooling water pump 32, service water pump 38 and charging pumps 31 or 32 as part of the Appendix R, alternative safe shut down.

Other equipment in flood zone TBL15 that is susceptible to the effects of flooding includes the main boiler feedwater and condensate pumps. The latter are located in pits at the 11.6-ft elevation.

C4.2 FLOODING SCENARIOS

The development and evaluation of flooding scenarios entailed the examination of flood sources and the system failures or degradation that will ensue should equipment be damaged as a result of flooding. The resulting accident sequences were then defined and the probabilities that they will lead to core damage calculated.

C4.2.1 PRIMARY AUXILIARY BUILDING

Flooding scenarios for the primary auxiliary building generally entail a breach in a water system (e.g., SW, CCW, fire protection, city water, and RWST) that disables equipment, causes flooding, and requires a manual plant trip.

C4.2.1.1 Rupture of the CCW System

The rupture of CCW system piping or tanks will require a manual reactor scram; this is characterized as a TCCW event. TCCW events initiated by the rupture of the CCW system are specifically addressed in Section 3.1.4.4 of the IPE. CCW system ruptures with no other consequences of flooding are therefore addressed in the special initiator event trees. Flooding damage, beyond that caused to the CCW system, that might result from the rupture of the CCW system inside the PAB includes spray damage to one of the three charging pumps in flood zone PAB55. While CCW rupture may also cause spray damage to HHSI motor-operated valves in flood zone PAB34, this does not exacerbate the accident as HHSI pump failure will result from a loss of CCW cooling water. Furthermore, the propagation of CCW-

induced floods to the 15-ft elevation will not result in damage to the RHR pumps because the total capacity of the CCW system is less than the 120,000 gal. required to reach the 39-in. critical flood height at the 15-ft elevation.

Therefore, the rupture of the CCW system within the PAB can be characterized as a TCCW event caused by piping rupture, coupled with the failure of one of three charging pumps should CCW system rupture occur in flood zone PAB55. Should the AFW system then fail, core damage will occur. However, this scenario was modeled explicitly in the TCCW event tree and, therefore, was not addressed further in the internal flooding analysis.

A rupture of the 1-in. CCW line providing pump seal and jacket cooling to RHR pump 32 will result only in the loss of that pump. A rupture of the 1-in. CCW line to RHR pump 31 will result in the loss of that pump if the operator fails to align the city water back-up. As there are no other consequences, this event was pursued no further--the predicted frequency of 1-in. CCW line rupture, 3.6×10^{-5}/yr, is small compared to the 2.14×10^{-4}/yr frequency of other causes of RHR pump failure.

C4.2.1.2 Rupture of Non-Essential Service Water System in Flood Zones PAB55 and PAB73

The rupture of the non-essential service water system piping in flood zones PAB55 and PAB73 will require a manual reactor scram. However, as noted in Section 3.1.4.4 of the IPE, accident sequences initiated by loss of non-essential service water transients are similar to those resulting from a loss of component cooling water (TCCW) initiator.

Floods originating in the 55-ft or 73-ft elevations will propagate to the 15-ft elevation of the PAB. The maximum flow rate from the ruptured non-essential service water line is about 22,500 gpm assuming that 3 pumps are running. This flow rate will cause submergence damage to the RHR pumps within 9 minutes of rupture, even allowing for hold-up on intermediate elevations. While the service water low pressure alarms in the control room can be expected to alert the operators to shut down the pumps on the non-essential header, it is not certain that this action would be taken before the RHR pumps are damaged. Therefore, it can be concluded that the consequences of non-essential service water header rupture in flood zones PAB73 and PAB55 are a TSWS*NON-ESSENTIAL initiating event coupled with a loss of the RHR pumps. Given a predicted 3.3×10^{-5}/year frequency for the rupture of the non-essential service water system in PAB55 or PAB73, and the fact that core damage will occur should the AFW system fail, this scenario was examined further.

Smaller ruptures will have a lesser impact. Consider a rupture equivalent to that of a 3-in. line. The flow rate from this rupture will be $\approx$2000 gpm and will be unlikely to trip the low pressure alarms in the non-essential service water header. However, at this flow rate, 74 min. will elapse before the critical flood height for the RHR pumps in flood zone PAB15 is reached and it is very unlikely that such flooding would not be discovered in that time.

C4.2.1.3 Rupture of Essential Service Water System in Flood Zone PAB34

The rupture of the essential service water system piping in the pipe tunnel in flood zone PAB34 will result in a loss of flow to the containment fan cooler units and propagation of flood water to the pipe penetration area and down to flood zone PAB15. The former will require a manual trip. The 22,500 gpm flow rate from the rupture of 10- or 18-in. service water lines in flood zone PAB34 will also result in service water low pressure alarms and submergence of the RHR pumps. This flooding scenario thus leads to a TSWS*ESSENTIAL event accompanied by loss of the RHR system. The predicted frequency of the rupture of the essential service water system is 1.8×10^{-5}/yr. Given this frequency and the fact that at least two other systems must fail for core damage to occur, this scenario was examined no further.

C4.2.1.4 Rupture of Essential Service Water System in Flood Zone PAB67

The essential service water piping in the pipe tunnel of flood zone PAB67 carries water away from the fan cooler units. The rupture of this piping will thus have no direct impact on plant operation. It will, however, cause spray damage to auxiliary component cooling water (ACCW) pumps 31 to 34 and propagation of flood water down to flood zone PAB15 where it will submerge the RHR pumps. The loss of all four ACCW pumps will require that the plant be shut down. The flow rate from the rupture of a 10- or 18-in. service water line will also result in service water low pressure alarms. This flooding scenario thus leads to a T3 event accompanied by the loss of the RHR system. The predicted frequency of the rupture of the essential service water system in flood zone PAB67 is 1.9×10^{-5}/yr. Given this probability and the fact that both the AFW and MFW systems and long-term core cooling would have to fail for core damage to occur, this scenario was examined no further.

C4.2.1.5 Rupture of RWST Piping Inside Flood Zones PAB15, PAB34 and PAB41

The rupture of RWST piping will require a plant shut down and will render the RHR and HHSI systems unavailable because of the loss of their water source. Conservatively, therefore, RWST piping rupture is assumed to result in a manual trip with main feedwater available (a T3 event) but with RHR and SI systems unavailable. The accident progression resulting from RWST piping rupture in PAB15 will not lead to core damage, however, unless the AFW system fails and the operator fails to restore the MFW or condensate system. Given this and the 4.7×10^{-5}/year predicted frequency of RWST line rupture in flood zones PAB15, PAB34 and PAB41, the predicted frequency of core damage initiated by RWST line rupture in these flood zones is below the 10^{-8}/year screening criterion and thus the scenario was considered no further.

It should be noted that RWST rupture in flood zones PAB15, PAB34 and PAB41 may result in flood damage to the RHR pumps, HHSI and LHSI motor-operated valves, and SI pumps.

However, this damage will not exacerbate the accident as the RHR and HHSI systems were assumed to be unavailable because of the loss of their water supply.

Alternatively, RWST piping rupture could occur in the course of another accident progression. However, as noted in Section 3.1 of the IPE, RWST rupture during LOCAs was eliminated from consideration because the predicted frequency of simultaneous RWST failure and occurrence of a LOCA initiator falls below the 10^{-8}/year screening value. The probability of RWST piping rupture during the course of a transient-initiated accident progression can be calculated. Assuming one transient/year requiring use of the water in the RWST or the systems affected by RWST piping rupture and a 24-hr exposure before stable reactor conditions are achieved, the 4.7×10^{-5}/yr predicted frequency of a breach in RWST system piping results in a 1.3×10^{-7}/yr frequency for this scenario. Furthermore, core damage would still require the failure of the AFW system and a failure to restore the MFW or condensate system. The frequency of scenarios in which core damage is facilitated by RWST piping rupture in the course of another transient-initiated accident progression is therefore below the 10^{-8}/year screening criterion and thus this scenario was considered no further.

C4.2.1.6 Rupture of Primary Water System

The primary water system is present in flood zones PAB73, PAB55, PAB41 and PAB15. The rupture of the primary water system with its 2- and 3-in. lines within the PAB should have no direct impact on normal plant operation. Neither will it cause spray damage to other equipment. However, the propagation of flood water from the ruptured system may cause submergence damage to the RHR pumps and RHR system unavailability. Given the lack of other consequences, this scenario was not examined further.

C4.2.1.7 Rupture of Fire Protection System Piping in Stairway #1 in Flood Zone PAB55

The fire protection system is normally maintained at a pressure of 100-110 psig by two jockey pumps. When the pressure within the system drops, as a result of system demand or rupture, motor- and diesel-driven pumps start automatically and an alarm is given in the control room.

The rupture of fire protection system piping in stairway #1 at the 55-ft elevation could result in spray damage to MCC-36A. Because spray-induced damage to MCC-36A is unlikely to be recoverable in a short time, a manual shutdown is dictated by the technical specifications. While main feedwater will be available, components supplied by MCC-36A will be unavailable. These components include auxiliary component cooling pumps 31 and 33, boric acid transfer pump 31, hydrogen recombiner 32, motive power for MOVs used in high- and low-head safety injection and recirculation, and partial loss of ventilation to the diesel generator rooms. However, this flood is unlikely to damage the RHR pumps in flood zone PAB15--the flood flow rate of 1801 gpm will take 97.5 min. to rise to the critical flood

height, if the drains in the PAB 15-ft elevation function, and 82.5 min., should the drains fail. Given that all automatic fire protection systems alarm in the control room when actuated and that on receipt of the alarm, operators will be despatched to isolate the water by closing manual valves, it is unlikely that flooding will persist.

Assuming the rupture of a 10-ft length of 4-in. pipe or of a 0.5-in. hose connection could cause spray damage to MCC-36A, this event has an estimated initiating frequency of 10^{-5}/yr. Although such a rupture may cause a plant trip and other damage to several systems, core damage requires that the AFW system also fail and that the operator fails to restore the MFW or condensate system. As these systems are independent of the spray-damaged systems (e.g., they include no loads supplied by MCC-36A), the frequency of core damage resulting from this sequence is below the 10^{-8}/year criterion. Accordingly, this scenario was examined no further. Furthermore, it should be noted that this event is bounded by the TAC5A special initiator.

C4.2.1.8 Rupture of Fire Protection System Piping in Flood Zones PAB67, PAB34 or PAB15

The rupture of fire protection system piping in flood zone PAB67 could result in the flood water propagating to flood zone PAB41 through the open grating around the CCW heat exchangers. Spray damage to CCW pumps 31 and 32 is, however, unlikely. Furthermore, as noted in Section C4.2.1.7, subsequent flood damage to the RHR pumps is unlikely given an 1800 gpm flow rate after the guillotine rupture of 4-in. fire protection system piping and the fact that all automatic fire protection systems alarm in the control room when actuated. Thus flooding initiated by the rupture of fire protection system piping in PAB67 will not cause a plant shutdown or have additional consequences. Accordingly, this flooding scenario can be eliminated as a matter of further concern.

Similarly, the rupture of fire protection system piping in flood zones PAB34 and PAB15 would cause no direct damage to safety-related systems. While flood water would propagate to flood zone PAB15, it would be unlikely to submerge the RHR pumps. This flood scenario would therefore result in no additional likelihood of core damage and thus can be eliminated as an item of concern.

C4.2.1.9 Rupture of Fire Protection System Piping in Flood Zone PAB41

Fire protection system piping rupture in flood zone PAB41 may cause spray damage to one CCW pump. More than one pump is unlikely to be affected, however, because of the physical separation of the pumps. Furthermore, as noted above, while flood propagation to flood zone PAB15 will occur, damage to the RHR pumps is unlikely. Given that shutdown is not required and that this rupture has no further consequences, this scenario was considered no further.

C4.2.1.10 Rupture of City Water Piping

The only direct consequence of a loss of the city water system is a loss of a back-up cooling system--a plant trip is not required. While the rupture of primary or city water lines in flood zone PAB55 could also result in spray damage to a single charging pump and charging pump suction level control valve LCV-112B, the propagation of the flood water to flood zone PAB41 through the open grating around the CCW heat exchangers is unlikely to damage CCW pumps 31 and 32. Furthermore, given the maximum flood flow rate of 170 gpm through a ruptured 2-in. city water line, submergence damage to the RHR pumps in flood zone is also most unlikely--even if the drains in PAB15 fail to function, the critical flood height will not be reached within 8 hours. Accordingly, because this flooding scenario requires no plant shutdown, it was eliminated from further examination.

The rupture of city water piping in flood zone PAB41 is also of little consequence as it will cause spray damage to only one CCW pump at most because of the physical separation of the CCW pumps.

The rupture of city water piping in flood zones PAB73, PAB34 and PAB15 will result in water accumulating at the 15-ft elevation. However, damage to the RHR pumps is unlikely as it will take over 8 hours for the critical flood height for these pumps to be reached. Again, therefore, this flood scenario was eliminated as a cause for further concern.

C4.2.1.11 Rupture of CVCS System

The only consequence of a rupture of the CVCS system in flood zone PAB73 is a loss of the boric acid supply, an event that is of importance only should an ATWS occur. While rupture of the CVCS system is assumed to require a manual trip, the flooding scenario devolves into a T3 event in which the predicted frequency of initiation (i.e., the frequency of CVCS rupture in PAB73) is 2.2×10^{-5}/yr. This frequency is significantly less than the 3.6/yr frequency of T3 initiating events resulting from other causes. Therefore this flood scenario was eliminated from further consideration.

The direct consequence of a rupture of the CVCS system in flood zones PAB67 and PAB55 is a loss of flow to the RCP seals. Subsequently, while water may propagate to flood zone PAB41 through the open grating around the CCW heat exchangers, damage to the CCW pumps is unlikely. In these circumstances, the flooding scenario devolves into a TCCW event accompanied by RCP seal degradation and possibly an RCP seal LOCA. The predicted frequency of initiation (the frequency of CVCS rupture in PAB67 and PAB55) is 10^{-4}/yr. Given this frequency and the possible consequences, this scenario was eliminated from further consideration.

C4.2.1.12 Rupture of Containment Spray System

The rupture of the containment spray system in flood zone PAB41 downstream of the normally closed pump outlet motor-operated discharge valves will require a plant shutdown. Flooding effects will be minimal, however. As core damage will require the subsequent failure of both the MFW and AFW systems, this scenario was eliminated as a cause for further concern.

The rupture of the containment spray system in flood zone PAB41 upstream of the normally closed pump outlet motor-operated discharge valves will also require a plant shutdown. In addition, it will result in the same consequences as an RWST piping rupture inside flood zone PAB41--the loss of RHR and HHSI systems. However, as core damage will require the subsequent failure of both the MFW and AFW systems, this scenario was also eliminated from further examination.

C4.2.1.13 Rupture of SI System in Pipe Penetration Area in Flood Zone PAB34

The rupture of an SI valve or line in the pipe penetration area in flood zone PAB34 will result in the submergence of the RHR pumps in PAB15, thus requiring a plant shutdown. In addition, SI valves in PAB34 may also suffer spray damage--the two normally closed motor-operated valves SI-1835A/B at the exit to the BIT would not open should the HHSI system be required. This scenario thus devolves into a T3 event in which the RHR pumps have failed and the HHSI system is degraded. However, as core damage will require the subsequent failure of the AFW system and a failure to restore the MFW or condensate system, this scenario was eliminated from further examination.

C4.2.1.14 Rupture of SI System in SI Pump Room in Flood Zone PAB34

The rupture of an HHSI valve, line, or pump in the SI pump room in flood zone PAB34 will result in damage to the HHSI system and in the submergence of the RHR pumps in PAB15. A plant shutdown will be required. This scenario thus devolves into a T3 event in which the RHR pumps have failed and the HHSI system is unavailable. However, as core damage will require the subsequent failure of the AFW system and a failure to restore the MFW or condensate system, this scenario was eliminated from further examination.

C4.2.2 CONTROL BUILDING

C4.2.2.1 Rupture of City Water System in Flood Zone CTL53

The 2-in. city water line and tank are potential flood sources in flood zone CTL53. The accumulation of water in the stairwell, flood zone CTL15-3, can be calculated: assuming a

guillotine line rupture, a 60-psig city water pressure at the 14-ft elevation, and that the operators having failed to isolate the rupture, allow the water to drain down the control building east stairway, the flood flow rate into CTL15-3 is 170.5 gpm. Allowing for drainage through a 0.25-in. gap at the base of the door to the diesel generator valve room (flood zone DGB15), the water will overflow the 6-in. curbs and into the emergency switchgear and AC equipment rooms time within 6 minutes. However, even after 30 minutes the flood levels reached in flood zones CTL15-1 and CTL15-2 will be just 0.5 and 3.6 in., respectively. These water levels will not damage any equipment within the emergency switchgear or air conditioning equipment rooms.

Given that the operators will be immediately aware of the rupture and can simply open a door into the diesel generator valve room or the turbine building to drain the water away, it was concluded that rupture of the a 2-in. city water line or 80-gal. city water tank in flood zone CTL53 poses a negligible risk to the plant.

C4.2.2.2 Rupture of Instrument Air Closed Cooling Water System in Flood Zones CTL33 or CTL15-1

The rupture of the IACCW system, either within the emergency switchgear room or in the cable spreading room, will result in a loss of cooling to the plant instrument air system and eventually to a plant trip: the loss of instrument air is essentially a T2 event. Other flood-induced damage can also result from submergence and spraying effects. Although the capacity of the IACCW system is only 200 gal., the volume in the IACCW head tank will be made up automatically by flow from a 0.75-in. city water line. Thus the rupture of the IACCW line in flood zones CTL33 and CTL15-1 will result in the continued release of water at a rate determined by make-up to the head tank. Should the drains in CTL15-1 function, the critical flood height for switchgear in CTL15-1 will not be reached. However, should the drains fail, the 3-in. critical flood height in CTL15-1 will be reached in 25 min. and all four emergency buses will be lost. The loss of all emergency buses will require that the Appendix R alternative safe shutdown equipment function. The predicted frequency of this event is 2.4×10^{-4}/yr. Because of this frequency and the associated consequences, this scenario was examined in more detail.

Spray damage to two sets of 480-V switchgear (2A and 3A) and battery charger 33 is also possible as a result of the rupture of IACCW piping serving one instrument air compressor in CTL15-1. This piping is 20-ft from the switchgear. However, as switchgear 5A and 6A would still be available, spray damage will not exacerbate the event.

C4.2.2.3 Rupture of Service Water System in Flood Zone CTL15-1

The 3-in. and 2.5-in. service water lines that traverse the emergency switchgear room are potential flood hazards. While the 480-V switchgear, dc power panel 33, dc battery charger

33, and instrument air com[pressors] are too distant from service water piping to suffer spray damage as a result of ser[vice wa]ter line rupture, submergence of this equipment will assure its failure. Assuming a 86-p[si] service water system pressure, the maximum flow rate from the ruptured 3-in. line was c[alcula]ted to be 1359 gpm. At this flow rate, the critical flood height of 3-in. for damage to t[he emer]gency switchgear would be reached in 3.5 min., even if the drains function. The r[upture] of the 3-in line itself would not affect the service water system supply header pressure [However, isolation of a rupture upstream of the IACCW inlet valves (SWN-27-1/2 or SWN[-27-1/]2) would require tripping of the pumps on the associated header or closure of the appr[opriate] 24-in. service header valve--there are no isolation valves in the 3-in. service water li[ne ou]tside CTL15-1. Local isolation of a break downstream of the IACCW inlet valves [would] probably not be attempted unless the four emergency buses were deenergized.

Subsequent to dar[ge to] the switchgear, instrument air compressors 31 and 32, dc power panel 33, and bat[tery cha]rger 33 will be submerged. However, no further consequences will arise from this da[mage].

Thus, it can be co[ncluded] that the most likely outcome of the rupture of a 3-in. service water line in the emerg[ency] switchgear line is the loss of all four emergency buses; a less likely result is a loss of [service] water event. The loss of all emergency buses will require that the Appendix R alte[rnative] safe shutdown equipment function.

The predicted fr[equency] of a rupture of the 3-in. line carrying service water to the IACCW heat exchangers [is] 7.7×10^{-6}/yr. Because of this frequency and the associated consequences, the scenario was [examined] in more detail.

C4.2.2.4 Rupture of Fire Protection System in the Deluge Station (Flood Zone CTL15-1)

The deluge station is a small room adjacent to the emergency switchgear room. It houses a 10-in. fire protection system supply line that feeds four deluge valves associated with the auxiliary, main, and station transformers. While there is no door or flood barrier between the deluge station and the switchgear room, the intervening wall and physical separation preclude spray damage to the switchgear should the fire protection system piping rupture. In this event, a maximum flow rate of 7,500 gpm is expected. This flow rate is the run out rate for the fire protection system pumps. With such a release, the 3-in. critical height for emergency switchgear will be reached in 0.6 min. even if the drains function. Although operators will be alerted by the "fire pump running" alarm and can isolate the break by tripping the pumps locally in the fire pump house or by closing header isolation valve 75 in the turbine building, it is unlikely that isolation will be achieved before damage is incurred. The result of this flood will therefore be the loss of all four emergency buses and the requirement that the Appendix R alternative safe shutdown equipment function.

The frequency of a rupture of the 10-in. fire protection system supply line and valves was calculated as 3.4×10^{-5}/yr assuming 30-ft of 10-in. line, 20 flanges, and 4 deluge valves--the system is dry above the valves. Because of this frequency and the associated consequences, the scenario was subjected to a more detailed analysis.

C4.2.2.5 Rupture of City Water System in Flood Zone CTL15-2

The rupture of the 2-in. city water line in the air conditioning equipment room will cause the loss of control room air conditioning because of the loss of service water to the air conditioning units. While this damage would not require plant shutdown, the rupture of the city water system will pose a flood hazard to equipment other than the AC equipment in flood zone CTL15-2.

Assuming a 60-psig city water system pressure at the 14-ft elevation, the maximum flow rate from the ruptured line was calculated to be 256 gpm. The frequency of 2-in. city water line rupture in flood zone CTL15-2 is 2.1×10^{-5}/yr.

Three flood scenarios were developed for the rupture of the 2-in. city water line in flood zone CTL15-2. The first scenario assumed that the drains function as designed. In this case, a peak water level of 6.1 in. is reached in flood zone CTL15-2, resulting in water overflowing into the stairwell, flood zone CTL15-3, rising to a height of 0.3 in. after 27 min. No flow to the switchgear room will occur in this time. Therefore with no damage to safety-related equipment, this scenario was eliminated from further consideration.

The second scenario assumed that the drains in flood zone CTL15-2 are completely blocked. After 46 min., a water level of 3 in. is reached in flood zone CTL15-1--water will overflow from flood zone CTL15-2 to flood zone CTL15-3 and from flood zone CTL15-2 to flood zone CTL15-1. Should door 202 between the stairwell and the switchgear room fail open when water starts to overflow the 6-in. curb under the door, a 3-in. critical flood height in flood zone CTL15-1 would be reached in 44 min. When the level of water in flood zone CTL15-1 rises to the 3-in. critical flood height, all four emergency buses will be lost, an event that requires the functioning of the Appendix R alternative safe shutdown equipment. Because of its predicted frequency and consequences, this scenario was examined in more detail.

The third scenario assumed that while the drains shared by flood zones CTL15-1 and CTL15-2 are open, allowing water to flow from one flood zone to the other, drainage to or from the sump does not occur. After 30 min., the 3 in. critical flood height is reached in flood zone CTL15-1 as water enters this flood zone through both the drains and under the door. Once the water level in flood zone CTL15-1 reaches the critical flood height, all four emergency buses will be lost. Again, because of the frequency of city water line rupture and its consequences, this scenario was subjected to further analysis.

C4.2.2.6 Rupture of Service Water System in Flood Zone CTL15-2

The consequences of a rupture of the 3-in. service water line will be similar to those of the rupture of city water piping in flood zone CTL15-2.

A flow rate of 1359 gpm was calculated assuming a 86-psig service water system pressure in the 10-in. service water header and a guillotine break of the service water line upstream of the 1.25-in. restriction orifices. This flow rate will cause flood zones CTL15-2, CTL15-3, and CTL15-1 to flood in turn. Even if the drains function as designed, water will reach the critical flood height of 3 in. in flood zone CTL15-1 in 16 min. At that time the levels of water in flood zones CTL15-2 and CTL15-3 are 59 in. and 11.6 in., respectively. Should door 202 between the stairwell and the switchgear room fail open when water starts to overflow the 6-in. curb under the door, the critical flood height in the switchgear room would be reached in 14 min.

All four emergency buses will be lost when the height of water reaches 3 in. and Appendix R alternative safe shutdown equipment will then be required to function. The probability of this scenario can be calculated assuming no detection or mitigation of the flooding before the critical height of water is reached in flood zone CTL15-1. The frequency is 4.2×10^{-6}/yr.

Because of these probabilities and the consequences associated with the rupture of the service water line in CTL15-2, the scenarios were subjected to a more detailed analysis in which mitigating actions were considered together with the probability that Appendix R alternative safe shutdown equipment function. Mitigating actions include the opening of doors between flood zone CTL15-1 or CTL15-3 and the diesel generator valve room and the isolation of the rupture by closing valves in the diesel generator valve room.

Should the service water line rupture downstream of the 1.25-in. restriction orifices, the flow on line rupture will be reduced to 288 gpm. Water released at this rate will cause damage to the emergency switchgear in flood zone CTL15-1 in 60 min. if the drains do not function and mitigating action is not taken. The probability of this scenario can be calculated assuming no detection or mitigation of the flooding before the critical height of water is reached in flood zone CTL15-1 and that the drains are completely blocked. The frequency is 3.8×10^{-7}/yr, assuming a 0.1 probability that the drains are blocked. Given this frequency and the fact that core damage will require the unavailability or subsequent failure of the AFW steam turbine, this last scenario was examined no further.

C4.2.2.7 Rupture of Auxiliary Steam System in Flood Zone CTL15-2

The rupture of a 2-in. auxiliary steam line in the AC equipment room will result in a hot and wet environment in that room and the failure of control room air conditioning. However, no direct damage to safety-related equipment will occur and large volumes of steam will not escape the room. Furthermore, the predicted steam flow rate will create less than 26 gpm of

condensate, a flow rate that will lead to no accumulation in the switchgear room. Accordingly, it was concluded that the rupture of the steam line in the AC equipment room poses no significant hazard to the plant.

C4.2.2.8 Rupture of Fire Protection System in Flood Zone CTL15-3

Assuming guillotine rupture, the maximum flow rate from a ruptured 4-in. line was calculated to be 2492 gpm. Even if the drains function as designed, the rupture of the 4-in. line in the stairway will result in water overflowing the 6-in. curb into the emergency switchgear room and reaching the critical height for the switchgear in 6 min. A frequency of 8.3×10^{-5}/yr can be calculated for this scenario assuming 100 ft of fire protection system piping in the stairway, and no detection or mitigation of the flooding before the critical height of water is reached in flood zone CTL15-1. Because of this frequency, the consequences associated with the rupture of the line, and the short time interval between line rupture and loss of the emergency switchgear, the scenario was examined in more detail.

The maximum flow rate from a ruptured 1.5-in. valve was calculated to be 350 gpm. If the drains function as designed, the rupture of a valve in the stairway will result in water overflowing the 6-in. curb into the emergency switchgear room. However, water will not reach the critical flood height in that room until an hour as elapsed. As the flood will probably be detected within that time, this scenario was examined no further. Should the drains fail to function, the critical height of water in the switchgear room will be reached in 32 min. Once again, however, it was anticipated that the flood will be detected and isolated before 30 min. has elapsed. Accordingly, this scenario too was examined no further.

C4.2.2.9 Rupture of Fire Protection System in Flood Zone CTL33

Most of the water released as a result of the rupture of the fire protection system piping in CTL33 will drain through the HVAC duct to the yard. Without a dike around the IACCW area 4-in. drain in CTL33, however, water will also propagate directly from CTL33 to the hub drain in CTL15-1. In addition, water will propagate from CTL33 to CTL15-3 down the stairs. However, even if the drains to CTL15-1 fail to function, the critical flood height of water in the switchgear room will not be reached Therefore, this scenario was examined no further.

C4.2.2.10 Rupture of Service Water System in Flood Zone CTL15-3

The rupture of the 3-in. essential service water line in the east stairway room will cause a loss of control room air conditioning. While this loss does not require plant shutdown, other consequences are more severe.

Assuming a 86-psig service water system pressure in the 3-in. service water header, the flow rate from a guillotine break of the line was calculated to be 1359 gpm. This flow rate will rapidly cause flood zones CTL15-3, CTL15-2 and CTL15-1 to flood in turn. Even if the drains function as designed, water will reach the critical flood height of 3 in. in flood zone CTL15-1 in 12 min. Should door 202 between the stairwell and emergency switchgear room fail open, the critical height of water in the emergency switchgear room will be reached in 5.6 min. The frequency of this scenario was calculated as 3.9×10^{-7}/yr assuming no detection or mitigation of the flooding before the critical height of water is reached in flood zone CTL15-1. Given this frequency and the fact that core damage will require the unavailability or subsequent failure of the AFW steam turbine, this scenario was examined no further.

C4.2.3 DIESEL GENERATOR ROOMS

Flooding scenarios for the diesel generator rooms, flood zone DGB15, are initiated by failures in the service water or fire protection system and flow of floodwater from the control building east stairwell.

C4.2.3.1 Rupture of Service Water System in Flood Zone DGB15

The rupture of the 10-in. service water line in a diesel generator room will result in a loss of service water to that diesel generator, possible starvation of the service water lines to other diesel generators, and possible spray damage to the diesel generator in the room served by the ruptured service water line. Should the break be upstream of the inlet isolation valve (SWN-62-2/4/6), isolation of the rupture requires closure of the 24-in. service water header valves or the tripping of the service water pumps. Rupture of the service water line downstream of the inlet isolation valve requires only that the valve be closed, removing the emergency diesel generator from service. Thus the worst-case result of a rupture of the service water line is a manual trip following the loss of the service water system. This event was addressed as a special initiator with a frequency of 2.05×10^{-3}/yr. In contrast, the predicted frequency of a line rupture within a diesel generator room is 7.8×10^{-6}/yr. No further analysis was therefore deemed necessary.

C4.2.3.2 Rupture of Fire Protection System in Flood Zone DGB15

The rupture of the 4-in. fire protection system header in a diesel generator room may result in spray damage to a single diesel generator. Assuming a failure rate of 2.96×10^{-5}/year for the fire protection system header in a single diesel generator room and that the diesel generator is subsequently unavailable for a period of one month, the failure of the fire protection system header in the diesel generator room contributes 0.00025 percent to the unavailability of a single diesel generator. This value can be compared to the 0.013 percent unavailability of a

single diesel generator resulting from other causes. No further analysis was therefore deemed necessary.

C4.2.3.3 Propagation of Floodwater from the Control Building, Flood Zone CTL15-3

Floods that originate in or propagate to the control building east stairway, flood zone CTL15-3, will flow into the diesel generator valve room through a gap under the connecting door. Given the narrowness of this gap, flow from the control building to the diesel generator valve room will be slow. Furthermore, regardless of whether the door to the valve room is open, the flows involved can be readily accommodated by the drains within the valve room. Flood sources in the control building therefore pose no hazard to equipment in flood zone DGB15.

C4.2.4 AUXILIARY BOILER FEEDWATER PUMP BUILDING

Flooding scenarios for the ABFP building comprise failures in main steam, AFW steam, boiler feedwater, condensate, fire protection, and city water lines.

C4.2.4.1 Rupture of the Fire Protection System in Flood Zone AFW43

Because valves in flood zone AFW43 are qualified for severe environmental conditions, they are not susceptible to spray damage resulting from the rupture of 8-in. fire protection system piping in that zone. Instead water will propagate through open wire fence door 217 to flood zone AFW18-2 or flow through open penetrations to flood zone AFW32.

Consider first the flow to flood zone AFW18-2. Water will accumulate in AFW18-2, as outflow is initially restricted to flow under the doors to the yard and flood zones TBL15 and AFW18-1. At a flood level of 28-in., however, water will reach open louvers and its level will not rise further and thus remain below the critical flood height of the feedwater flow control valves in AFW18-2. Critical flood heights will also not be reached in AFW18-1 even if the drains in that flood zone fail. Accordingly, this scenario poses no risk of core damage and was not examined further.

Should the louvers in AFW18-2 be closed, however, submergence of the feedwater flow control valves is possible. Assuming the guillotine rupture of an 8-in. fire protection system at the 55-ft elevation, a flood flow rate of 2116 gpm was calculated. Assuming that all this water flows to flood zone AFW18-2 and that the door to the yard from AFW18-2 does not fail, the main feedwater flow control valves will be submerged within 26 min. Critical flood heights will not be reached in AFW18-1, however. Given that the operators will respond to the actuation of the fire protection system and the fact that, if not interrupted, this event is essentially a T2 event with a frequency of 3.2×10^{-5}/yr, the scenario in which the fire

protection system ruptures in flood zone AFW43 ruptures and flood water propagates directly to flood zone AFW18-2 is an insignificant contributor to core damage frequency.

Should water from the rupture of fire protection system piping in AFW43 propagate through the open pipe penetrations to AFW32, it will accumulate in AFW32 as outflow is restricted to gaps under doors. This accumulation is not, however, sufficient to cause submergence and closure of AFW steam supply isolation valve PCV-1310B. Provided the seals and pipe penetrations between flood zones AFW32 and AFW18-1 remain intact, no further flood damage will result--no significant accumulations in flood zone AFW18-2 and AFW18-1 will result from propagation under doors. Calculations show that sealant should withstand the 18-in. head of water anticipated in AFW32. Furthermore, the seals have been reinforced with elastomer. Accordingly, this scenario was deemed inconsequential.

C4.2.4.2 Rupture of Main Feedwater Piping in Flood Zone AFW43

The direct consequence of the rupture of the 18-in. main feedwater line in AFW43 is a T2 event with automatic isolation of the flood source being initiated by a steam:feed mismatch. Before isolation is complete, up to 3876 gal. of water may be released. This volume, however, is insufficient to accumulate or cause further damage in AFW32 or AFW18-2. The event can therefore be regarded as a T2 event with a 4.9×10^{-6}/year frequency. Given this frequency, this scenario was considered no further.

C4.2.4.3 Rupture of Main Steam System Piping in Flood Zone AFW43

The direct consequence of the rupture of the 28-in. main steam lines in AFW43 is a T5 event with automatic isolation of the flood source being initiated by a steam:feed mismatch. However, because the valves in this flood zone are qualified for operation in a severe environment, there will be no other consequences. Given that the predicted frequency of MSS line rupture in flood zone AFW43 is $2. \times 10^{-5}$/yr and that this frequency is included in the 2×10^{-3}/yr frequency of T5 events, this scenario is inconsequential.

C4.2.4.4 Rupture of the Auxiliary Feedwater Steam Line in Flood Zones AFW43 or AFW32

The rupture of the 4-in. AFW steam line will render the steam-driven AFW pump unavailable. It will not, however, initiate a plant shutdown. Furthermore, the probability of the AFW steam turbine unavailability because of steam line rupture is estimated to be 1.6×10^{-5} percent (assuming a rupture rate of 2×10^{-5}/year and a 72 hour allowed outage before the plant must be shut down). In contrast, the calculated probability of AFW steam turbine unavailability is 0.029. The flood hazards resulting from a rupture of the auxiliary

feedwater steam line in flood zones AFW43 or AFW32 can therefore be characterized as being insignificant.

C4.2.4.5 Rupture of the Main Feedwater Line in Flood Zones AFW32 or AFW18-2

The rupture of the 18-in. main feedwater line in flood zone AFW32 will result in a steam:feed mismatch and closure of a valve in the feedwater line. While 3876 gal of water may be discharged before isolation is complete, only 4 in. of water will accumulate in AFW32 and 0.3 in. in AFW18-2. Such water levels will have no effect on equipment in these flood zones. The rupture of the main feedwater line will therefore result in a T2 event. Given the frequency of a rupture of the main feedwater line in AFW32 of 9×10^{-5}/year, this flooding scenario was examined no further.

The rupture of the 18-in. main feedwater piping in flood zone AFW18-2 can also treated as a T2 initiator with a predicted frequency of 3.2×10^{-5}/year. No additional flooding damage will result as the water level in AFW18-2 will not exceed 4.6 in. Given the 0.85/year predicted frequency of other T2 initiating events, this event can be regarded as being insignificant.

C4.2.4.6 Rupture of the Auxiliary Feedwater Steam Line in AFW18-1

The rupture of the auxiliary feedwater steam line in flood zone AFW18-1 will result in a temperature rise and the subsequent closure of the steam supply isolation valves. This will render the steam-turbine driven AFW pump unavailable. However, the other AFW pumps will not be affected by the steam release as they, and the steam generator level, pressure, and flow instrumentation, are qualified for operation in severe environments. Plant technical specifications allow 72 hours of operation if an AFW pump is unavailable. The failure of the AFW steam line poses no immediate threat to plant operations and was thus examined no further.

C4.2.4.7 Rupture of Condensate Water Line in Flood Zone AFW18-1

The rupture of the 6- and 8-in. lines from the condensate storage tank in flood zone AFW18-1 will result in the complete loss of all AFW pumps because of submergence or, possibly, spray damage. This event will therefore lead to the loss of the AFW system. Submergence damage to steam generator level, main steam pressure, and feedwater flow instrumentation is unlikely as these instruments are watertight and environmentally qualified. However, the rupture of the condensate may also result in a loss of condenser vacuum and thus in a possible loss of the main feedwater system and a plant trip. Should the plant not trip, plant technical specifications require that the plant be maintained in a stable configuration on loss of the AFW system. In these circumstances, therefore, a T2 or T3 event will result only if the operator elects to trip the reactor. Given a 3.4×10^{-4}/year estimated frequency of rupture of

the condensate line in flood zone AFW18-1 and the fact that core damage may occur should the reactor trip or be tripped and one more system fail, this event was examined in more detail.

C4.2.4.8 Rupture of City Water Line in Flood Zone AFW18-1

The consequences of the rupture of 6- or 8-in. city water lines in flood zone AFW18-1 are essentially identical to those of the rupture of the condensate lines but without the possible loss of the MFW system (i.e., a T3 event). Accordingly, this scenario was not developed further in light of its low frequency (5.4×10^{-5}/year) and the fact two additional systems would have to fail for core damage to occur.

C4.2.4.9 Rupture of Fire Protection System in Flood Zone AFW18-1

The rupture of the 3-in. fire protection system piping in flood zone AFW18-1 will result in the complete loss of all AFW pumps as a result of submergence within 10 min. Damage may occur sooner as a result of spray damage. Rupture of the 3-in. fire protection system piping will therefore lead to the loss of the AFW system. Submergence damage to steam generator level, pressure, and flow instrumentation will not occur, however. Plant technical specifications require that the plant be maintained in a stable configuration on loss of the AFW system. Therefore, in the absence of other failures while the AFW system is under repair, there is no need to pursue this scenario further. Should, however, the operator implement a manual shutdown because of the loss of the AFW system, the result will be a manual trip with main feedwater/condensate available (i.e., a T3 event). However, for core damage to occur, two other systems would have to fail also. Given an 5.1×10^{-5}/year estimated frequency of rupture of the fire protection system line in flood zone AFW18-1 and an estimated frequency of two additional systems failing of 10^{-4}/year, the frequency of fire protection system water line rupture leading to core damage is below the 10^{-8}/year cut-off. This event was therefore considered no further.

C4.2.5 TURBINE BUILDING

Flooding scenarios for the turbine building comprise failures in the service water, main steam, turbine building component cooling water, circulating water, fire protection, feedwater/condensate, auxiliary steam, city water, and primary water systems.

C4.2.5.1 Rupture of the Fire Protection System in the Turbine Building (Flood Zone TBL15)

The rupture of the 10-in. fire protection system water lines in the turbine building will result in the release of water at 7,500 gpm, the run out rate for the fire protection system pumps. While the control room staff will be immediately alerted to the problem, it was conservatively assumed that 10 min. will elapse before the rupture is isolated. The 75,000 gal. released in the interim will drain to the outlet pipe tunnel, condensate pump bay, and inlet bay as well as through multiple doors to the yard. In the absence of spray damage, this event can be regarded as a T2 event with a frequency of 1.3×10^{-4}/year. Given the predicted frequency of 0.85/year for other T2 events, this event can be regarded as being inconsequential if there are no other consequences.

However, the rupture of the 60-ft length of fire protection piping within 30 ft of the 6.9 switchgear may also damage switchgear initiating a loss of offsite power (T1) event in which there is no possibility of short term recovery of power. The frequency of such a rupture is 4.4×10^{-5}/year. As this frequency is very much smaller than the frequency of other causes of station blackout accompanied by non-recovery of power, it was eliminated as a source of concern.

Should the rupture of fire protection system piping occur in the section of line above the dike protecting door 201 to the control building, water may enter the switchgear room, flood zone CTL15-1, through the louver above and the gap under the switchgear room door. Given the 50-ft distance between the louver and the 480-V switchgear in flood zone CTL15-1, spray damage to the switchgear is unlikely. However, submergence damage is possible--assuming a 500 gpm flow through the open louvers and additional flow under the door between flood zones TBL15 and CTL15-1, the switchgear will be damaged in 6 min. if the drains in CTL15-1 fail to function. Furthermore, this damage may well be compounded by simultaneous spray damage to the 6.9-kV switchgear and MCC-312A eliminating the supply of offsite power and power from the Appendix R diesel.

Given the consequences of this event and its 1.8×10^{-6}/yr frequency, this scenario was selected for further examination.

C4.2.5.2 Rupture of the Turbine Building Closed Cooling Water System

The TBCCW system comprises a closed loop of 500 gal. capacity. It includes 4-in. piping and a head tank. While make-up to the head tank is provided by a 1-in city water line, make-up is not automatic and thus rupture of the TBCCW system will result in the rapid release of up to 500 gal. but no subsequent continued outflow. This event poses no risk of submergence damage to the equipment in the turbine building. Furthermore, TBCCW system rupture will not cause spray damage to switchgear. Accordingly, this event was considered no further.

C4.2.5.3 Rupture of the Main Feedwater System in Flood Zone TBL15

The rupture of the main feedwater system in the turbine building will result in the release of 3876 gal. of water before the steam:feedwater mismatch results in the isolation of the rupture. This volume of water will cause no flood damage to other equipment in the turbine hall. The result of the rupture of the MFW system is essentially a T2 event with a frequency far less than 0.85 events/year predicted for all causes. Accordingly, this event was examined no further.

C4.2.5.4 Rupture of the Condensate System in Flood Zone TBL15

The rupture of the condensate system in the turbine building will result in a rapid plant trip--a T2 event. As the predicted frequency of rupture is much less than the frequency of other T2 events, this event was considered no further.

C4.2.5.5 Rupture of the Service Water System in Flood Zone TBL15

The rupture of the 4-in. service water piping in the turbine building will result in a TSWS event. It can also cause spray damage to the 6.9-kV switchgear. This possibility, however, was explicitly considered in the development of TWSW event trees and, accordingly, is examined no further here.

C4.2.5.6 Rupture of the City Water System in Flood Zone TBL15

The rupture of the 1-in. city water system in the turbine building will result in a release of 47 gpm. Therefore, this event will result in neither submergence nor spray damage to the 6.9-kV switchgear. Accordingly, the event was eliminated as a source of concern.

C4.2.5.7 Rupture of the Main Steam System in Flood Zone TBL15

The rupture of the main steam system in the turbine building will result in the release of large quantities of steam before the steam:feedwater mismatch results in the isolation of the rupture. This steam may cause a failure of the 6.9-kV switchgear within the turbine building, causing a loss of offsite power. Steam released into the turbine building may also propagate to flood zone CTL33-1, damaging the dc power system. The frequency of this event is 9×10^{-5}/yr. However, as this scenario was modeled as a T5 initiator, it was examined no further here.

C4.2.5.8 Rupture of the Auxiliary Steam System in Flood Zone TBL15

The rupture of the auxiliary steam system in the turbine building will result in the release of significant quantities of steam that may cause a failure of the 6.9-kV switchgear within the turbine building, causing a loss of offsite power. As noted above, steam released into the turbine building may also propagate to flood zone CTL33-1, damaging the dc power system. The frequency of this event is 2.2×10^{-4}/yr. However, because this scenario was modeled in the loss-of-offsite power event and fault trees, it was examined no further in this internal flooding analysis.

C4.3 QUANTITATIVE ANALYSIS

A number of flooding scenarios remain after screening (Table 4.3.1.1). The rigorous quantification of these will now be described.

C4.3.1 DETAILED ASSESSMENT OF BREAK FREQUENCY

In the screening analysis, two conservative assumptions were made:

- All pipe and valve ruptures were assumed to be guillotine ruptures
- Line rupture frequency data included all ruptures that resulted in release rates exceeding 50 gpm [7, 8].

The conservatism in these assumptions results from the facts that the flooding scenarios of concern require flow rates considerably in excess of 50 gpm and that most ruptures result in flow rates lower than those predicted assuming guillotine rupture [3,7,9]. Two approaches can be taken to address the conservatism of the screening analysis: use a lower release rate in conjunction with the line and component rupture data from Eide et al. [7] and Jamali [8]; or use a frequency/rate of release distribution curve.

Table 4.3.1.1

Significant Flooding Scenarios that May Lead to Core Damage

C4.2.1.2	Rupture of non-essential service water system in flood zone PAB55
C4.2.2.2	Rupture of instrument air component cooling water system in flood zones CTL33 or CTL15-1
C4.2.2.3	Rupture of service water system in flood zone CTL15-1
C4.2.2.4	Rupture of fire protection system in the deluge station (flood zone CTL15-1)
C4.2.2.5	Rupture of city water system in flood zone CTL15-2
C4.2.2.6	Rupture of service water system in flood zone CTL15-2
C4.2.2.8	Rupture of fire protection system in flood zone CTL15-3
C4.2.4.7	Rupture of condensate water line in flood zone AFW18-1
C4.2.5.1	Rupture of fire protection system in flood zone TBL15

Justification for selecting a smaller release rate for the low energy piping of concern in internal flooding is provided by NRC Standard Review Plan 3.6.1 and Branch Technical Position ASB 3-1 and its appendices. This plan recomends that discharge be assumed to occur through a through-the-wall crack of much smaller area than that assumed in guillotine rupture. However, limiting maximum release rates to values below the flow rates achieved following guillotine rupture prejudges the mechanism of failure and precludes even the possibility of core damage accident sequences being initiated by internal flooding in scenarios in which guillotine rupture but not through-the-wall cracks initiate the accident sequence. Such an approach is less than conservative because catastrophic failures are more likely to result from operator error or design and construction errors (such as water hammer, the improper handling of dynamic loads, or undetected fabrication errors) than from fatigue or conventional flaw initiation and growth [10]. This approach also ignores the possibility of lesser cracks growing to guillotine ruptures if subjected to dynamic loads. For these reasons it was judged more rigorous to proceed using the empirical leak rate/frequency distribution developed by Prugh [9].

Prugh defined a probability density function for release rate in terms of the release rate resulting from guillotine rupture:

$$f = f_G\left(\frac{w}{2w_G - w}\right)^{-n} \quad (1)$$

where:

f_G = probability density for guillotine rupture,

w is the flow rate,

w_G is the flow rate for guillotine rupture, and

n is an exponent (0.5 for lines, 1.0 for flanges, and 0.9 for valves).

Combining this distribution with the rupture data from Eide et al. [7] or Jamali [8], expressing flow rates in gpm, the probability of rupture can be expressed as:

$$\int_{50}^{w_G} f_G\left(\frac{w}{2w_G - w}\right)^{-n} dw \quad (2)$$

Therefore, the probability of rupture resulting in a flow rate greater than w_*, the minimum flow rate of concern, is:

$$p(w_*) = \frac{\int_{w_*}^{w_G} \left(\frac{w}{2w_G - w}\right)^{-n} dw}{\int_{50}^{w_G} \left(\frac{w}{2w_G - w}\right)^{-n} dw} \quad (3)$$

By determining the minimum flow rate of concern for each of the remaining accident scenarios, the frequencies of the initiating events can be more closely defined.

For releases that trigger an alarm and an immediate operator response, the minimum flow rate of concern is the minimum flow rate that will initiate the accident sequence before the flow can be terminated or mitigated. Such releases include ruptures of fire protection system lines and ruptures of the service water headers. However, for floods that will be detected by plant staff only as they make their rounds (assuming it is detected before accident sequence initiation), the situation is more complicated. Consider the case in which plant staff enter zones with an interval T between inspections. The minimum flow rate of concern will vary according to the time at which the release occurs (i.e., according to the time remaining before plant staff arrive on their rounds). Furthermore, there will be a period immediately prior to the arrival of plant staff in the flood zone during which even flow resulting from guillotine rupture will be insufficient to cause damage before flooding is terminated or mitigated. This situation can be described mathematically as follows:

Probability of accident sequence initiation, given rupture

$$= \frac{1}{T} \int_0^{T_*} p(w_*(T-t)) \, . \, dt \quad (4)$$

where

T_* = latest time in interval T at which flooding (assuming a guillotine rupture) can cause accident initiation

$w_*(T-t)$= the minimum flow rate required over a period T-t to initiate the accident sequence

$p(w_*)$ = probability that the flow rate exceeds the flow rate, w_* [defined in equation (3)].

The resulting revised initiating event frequencies calculated using equations (3) and (4) are presented in Table 4.3.1.2. It should be noted that the use of the -0.5 exponent in equations (3) and (4) will lead to a higher relative frequency of large release rates than was assumed in the Surry IPE.

Table 4.3.1.2
Recalculation of Internal Flooding Event Frequencies

Scenario	Event description	Do drains function ?	Flow rate with guillotine rupture (gpm)	Time to mitigate /inspection interval (sec.)	Rupture frequency (/year)	Probability of accident sequence initiation given rupture	Drain status probability	Initiator frequency (/year)

C4.3.2 EVENT TREES

The nine potentially significant flooding scenarios identified from the screening analysis were grouped into four sets:

- Rupture of the non-essential service water header on the 55-ft elevation of the primary auxiliary building (C4.2.1.2). This event devolves into a loss-of-component-cooling water event coupled with the failure of the RHR pumps (and thus the ability to sustain long-term core cooling).

- The failure of 480-Vac switchgear in the control building switchgear room resulting in both a reactor trip and a non-recoverable loss of safety-related switchgear. Damage to the 480-Vac switchgear can be caused by:

  - Rupture of the IACCW system in the switchgear room coupled with a failure of the drains (C4.2.2.2)

  - Rupture of the service water system in the switchgear room (C4.2.2.3), the 15-ft elevation HVAC room (C4.2.2.6)

  - Rupture of the fire protection system in the deluge room adjacent to the switchgear room (C4.2.2.4), or the control building east stairwell (C4.2.2.8)

  - Rupture of the city water line in the control building 15-ft elevation HVAC room coupled with a failure of the drains (C4.2.2.5).

  In these scenarios, damage can be prevented by operation of the turbine-driven AFW pump and alignment of alternative safe shutdown equipment to MCC-312A.

- Rupture of fire protection system piping above the entrance to the fire protection system in the turbine building above the entrance to the switchgear room (C4.2.5.1). This rupture might result in water being sprayed into the switchgear room (where it might caused submergence damage) and in spray damage to the 6.9-kV switchgear and MCC-312A, the Appendix R diesel generator switchgear.

- Rupture of the condensate line in the auxiliary feedwater pump room (C4.2.4.7). This event might cause loss of both the auxiliary and main feedwater systems.

Event trees were constructed for the four sets of flood scenarios.

C4.3.2.1 Event Tree for Rupture Non-Essential Service Water System in Flood Zone PAB55

The event tree for rupture of the non-essential service water header coupled with RHR pump failure is shown in Figure 4.3.2.1. The top events shown in the event tree are defined as follows:

Transient Initiator (TP55). Rupture of the non-essential service water header in flood zone PAB55. Subsequently, the RHR pumps suffer flood damage and the operator initiates a manual scram.

RPS Scram (C). Success implies all, or all but one, control rods are inserted into the reactor core. Failure leads to an anticipated transient without scram (ATWS) event.

Offsite ac Power Available (B1). Success implies offsite ac power is available. Failure leads to a demand for onsite ac power.

Pressurizer PORV Recloses After Opening During Transient (P). Success implies reclosure of open PORVs when RCS pressure drops below the closure setpoint. The failure of one or two PORVs to reclose is designated as a "P" event.

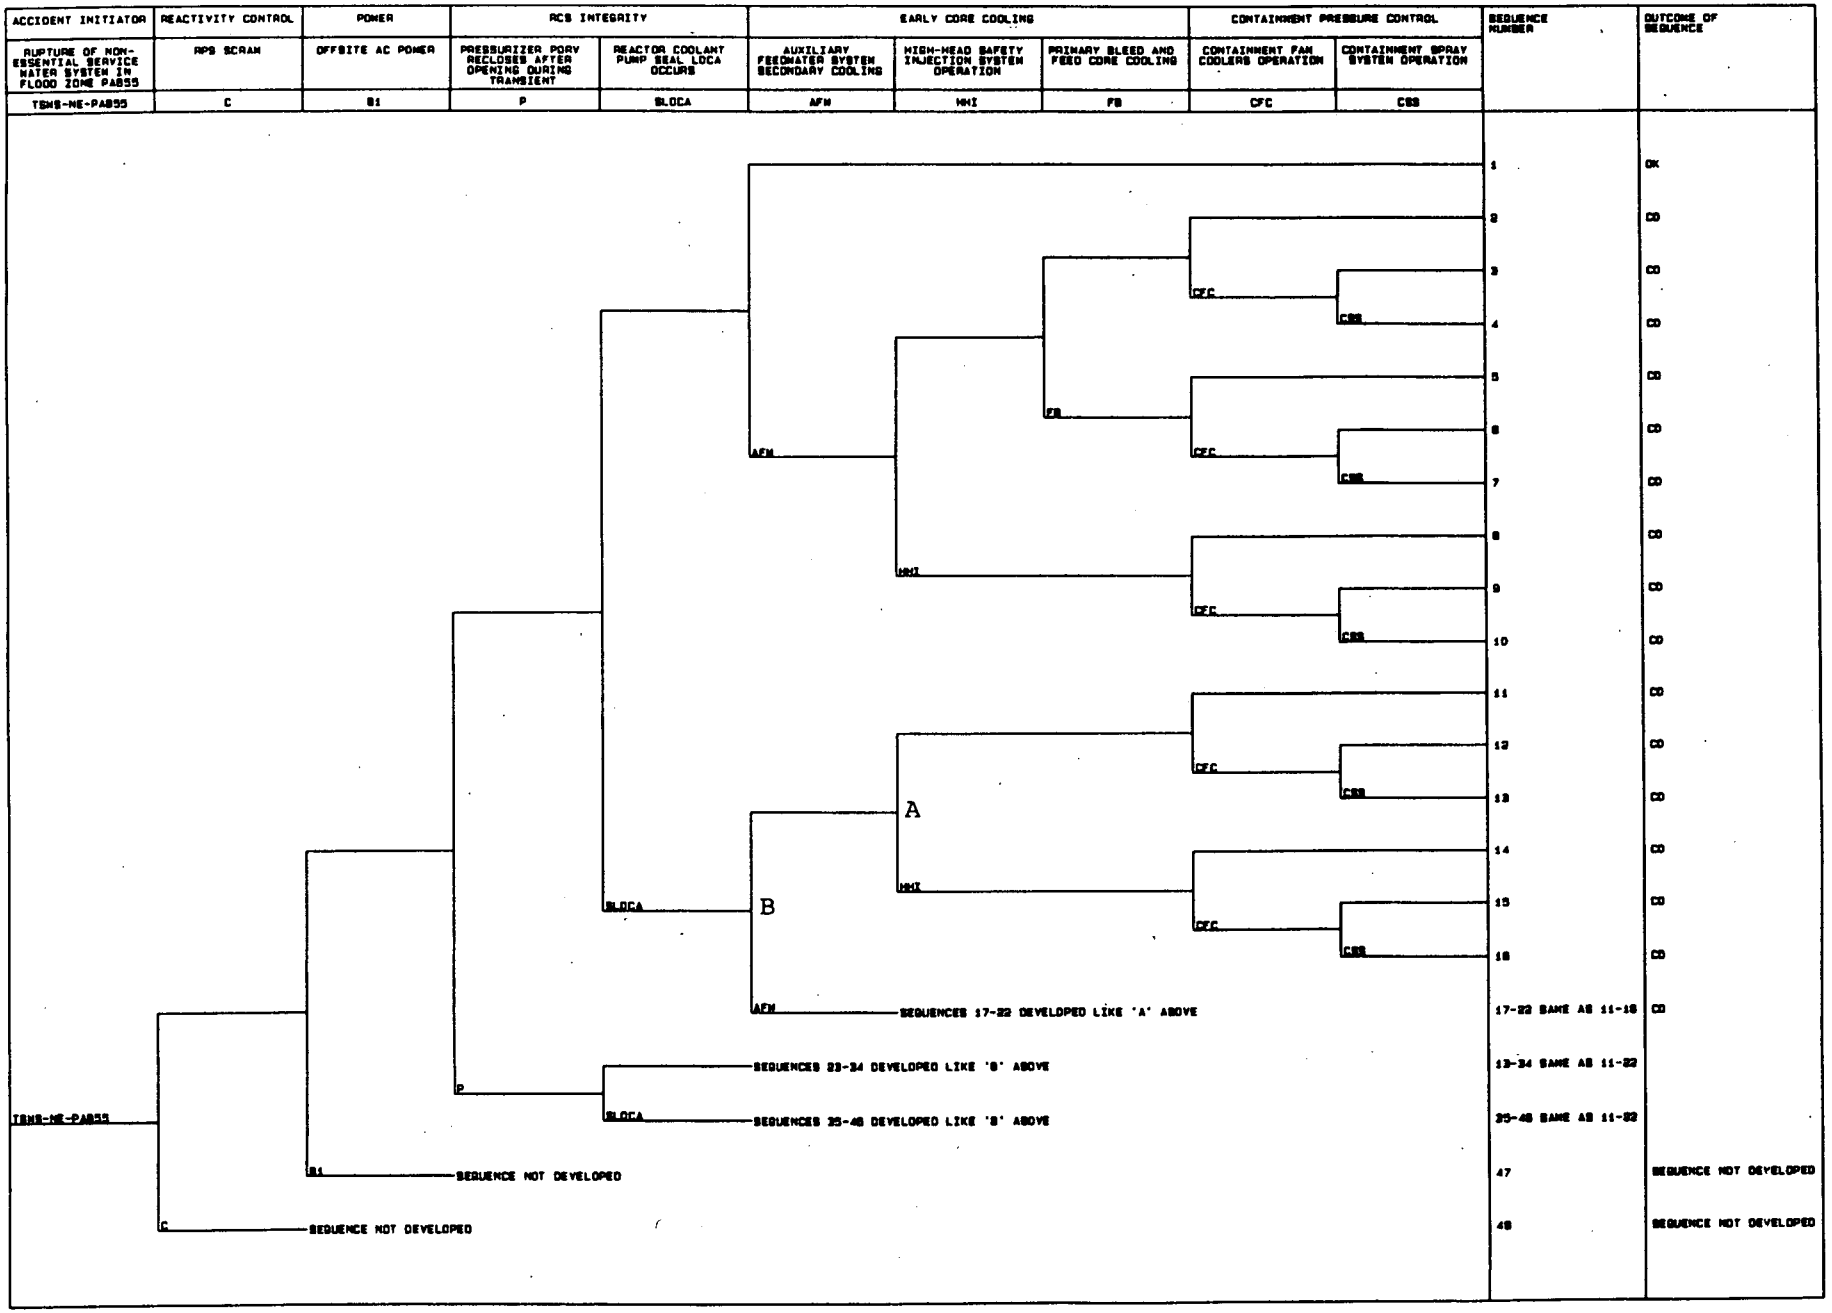
Reactor Coolant Pump Seal LOCA Occurs (SLOCA). Success implies back-up city water flow is aligned within 60 minutes to restore charging pump cooling and maintain charging pump operation for RCP seal injection. Failure leads to RCP seal LOCAs.

Auxiliary Feedwater System Secondary Cooling (AFW). Success of AFW in removing core heat implies that a motor- or steam-driven pump provides feedwater to at least one steam generator.

Primary Cooling Bleed-and-Feed (FB). This event is considered in sequences in which AFW secondary cooling fails. Success implies the manual opening of the PORVs to reduce RCS pressure (bleed) and the injection of water via HHSI pumps for core cooling (feed).

High-Head Safety Injection (HHI). This event is considered for sequences that entail bleed-and-feed operation, a stuck-open PORV, or a RCP seal LOCA. Success implies that at least one pump injects water into at least one 2-in. RCS cold leg. Failure requires that alternative core cooling be established.

Containment Fan Coolers (CFC). Success of the fan coolers in containment decay heat removal implies the operation of at least three fan coolers in their emergency mode and of two essential service water pumps. Failure requires alternative methods for containment decay heat removal. Furthermore, loss of service water precludes long-term decay heat removal by the containment fan coolers.



KEY:

OK - CORE COOLANT IS PROVIDED, CONTAINMENT HEAT REMOVAL IS PROVIDED

CD - CORE DAMAGE

Figure 4.3.2.1 PAB55 Non-Essential Service Water System Rupture Event Tree

Containment Spray System (CSS). Success implies an adequate RWST inventory and the use of at least one containment spray pump to provide early containment decay heat removal. Containment spray operation can continue after RWST depletion if a portion of the long-term recirculation core cooling flow is diverted to the containment spray headers. However, loss of component cooling water and the RHR pumps both preclude long-term decay heat removal by the RHR exchangers and thus the use of containment recirculation spray for containment pressure control.

Transient Sequences. In defining a sequence, a slash (/) preceding an event designator indicates the event is a success. Asterisks (*) separate the event designators.

Sequence TP55-1: TP55*/C*/B1*/P*/SLOCA*/AFW. A rupture of the non-essential service water header in flood zone PAB55 causes a loss of component cooling water transient (TP55). Plant procedures require a manual reactor trip. The reactor scrams (/C). Offsite ac power to the 6.9-kV buses is available (/B1). The pressurizer PORVs reclose, if opened (/P). To prevent RCP seal degradation following the loss of component cooling to the RCP seals and charging pumps, the operator aligns the city water back-up cooling supply to the charging pumps, restoring charging pump seal injection flow to the RCP seals (/SLOCA). The main feedwater system is tripped. The AFW system is initiated and removes core decay heat through the steam generators (/AFW). Continued AFW operation allows eventual hot shutdown. A safe core and containment result.

Sequence TP55-2: TP55*/C*/B1*/P*/SLOCA*AFW*/HHI*/FB*/CFC. Same as sequence TP55-1 except that the AFW system fails to remove core decay heat through the steam generators (AFW). Because RCS pressure remains above the high-head safety injection system pump shut-off head, the operator opens all PORVs, effectively inducing an RCS LOCA. As RCS water inventory decreases, RCS pressure falls enough to allow high-head safety injection system core cooling (/HHI) and RCS bleed-and-feed operation (/FB). Subsequently, with containment pressure increasing because of PORV opening, the fan coolers start in their emergency mode of operation to provide containment overpressure control (/CFC). Because the loss of component cooling water causes the recirculation system pumps to be unavailable for long-term core cooling and both RHR pumps are unavailable, long-term core cooling cannot be maintained. Core damage results.

Sequence TP55-3: TP55*/C*/B1*/P*/SLOCA*AFW*/HHI*/FB*CFC*/CSS. Same as sequence TP55-2 except that the fan coolers fail to start on high containment pressure (CFC). The containment spray system (/CSS) then initiates when containment pressure reaches 22.5 psig. However, upon RWST depletion, no effective means of containment heat removal exists. This sequence results in core damage.

Sequence TP55-4: TP55*/C*/B1*/P*/SLOCA*AFW*/HHI*/FB*CFC*CSS. Same as sequence TP55-3 except that early containment spray operation fails. Core damage results.

Sequence TP55-5: TP55*/C*/B1*/P*/SLOCA*AFW*FB*/CFC. Same as sequence TP55-2 except that the PORVs fail to open when the operator attempts to establish bleed-and-feed operation (FB). This prevents operation of the high-head safety injection system. With low-head safety injection precluded, this sequence results in core damage.

Sequence TP55-6: TP55*/C*/B1*/P*/SLOCA*AFW*FB*CFC*/CSS. Same as sequence TP55-5 except that the fan coolers fail to start (CFC) on high containment pressure. Containment pressure control is then provided by the containment spray system (/CSS). This sequence results in core damage.

Sequence TP55-7: TP55*/C*/B1*/P*/SLOCA*AFW*FB*CFC*CSS. Same as sequence TP55-5 except that both the fan coolers and containment spray system fail to provide early containment pressure control (CFC*CSS). This sequence results in core damage.

Sequences TP55-8 to TP55-10. Same as sequences TP55-5 to TP55-7 except that bleed-and-feed operation is precluded because high-head safety injection fails (HHI). Unable to depressurize the RCS for low-head injection, RCS boil-off occurs at the PORV setpoint. These sequences result in core damage.

Sequences TP55-11 to TP55-16. Same as sequences TP55-2 to TP55-7 except that auxiliary feedwater is available for secondary heat removal (/AFW) but alignment of back-up city water cooling supply to the charging pumps fails. With loss of component cooling water and no charging pump flow to the RCP seals, seal degradation and RCP seal LOCAs occur (SLOCA). Core damage results in all cases.

Sequences TP55-17 to TP55-22. Same as sequences TP55-11 to TP55-16 except that auxiliary feedwater is unavailable for secondary heat removal (AFW). Core damage results in all cases.

Sequences TP55-23 to TP55-34. Same as sequences TP55-11 to TP55-22 except that a single PORV fails to reclose, causing a breach in RCS integrity. No seal LOCA occurs but core damage results.

Sequences TP55-35 to TP55-46. Same as sequences TP55-23 to TP55-34, except that a RCP seal LOCA occurs in addition to the stuck-open PORV. Core damage results.

Sequence TP55-47: TP55*/C*B1. A loss of component cooling water transient (TP55) occurs. A manual reactor trip is required and the reactor scrams (/C). Subsequently, offsite ac power to the 6.9-kV buses is unavailable (B1). At this point the sequence frequency is $<10^{-8}$/year, and additional failures leading to core damage would result in still lower probabilities. Therefore, the sequence was not developed further.

Sequence TP55-48: TP55*C. A loss of component cooling water transient (TP55) occurs, requiring a manual reactor trip. The control rods are not inserted into the core (C). At this

point, the sequence frequency is ~10^{-8}/year, and any additional failures leading to core damage would result in a lower frequency. Therefore, the sequence was not developed further.

C4.3.2.2 Event Tree for Loss of 480-Vac Switchgear in Flood Zone CTL15-1

The event tree for loss of the 480-Vac switchgear is shown in Figure 4.3.2.2. The top events shown in the event tree are defined as follows:

Transient Initiator (TC15). Flooding causes non-recoverable damage to the 480-Vac switchgear in the control building switchgear room.

Pressurizer PORV Recloses After Opening During Transient (PORV). Success implies reclosure of open PORVs when RCS pressure drops below the closure setpoint. The failure of one or two PORVs to reclose is designated as a "PORV" event.

Power is Supplied from MCC-312 (MCC-312A). MCC-312A provides power to CCW pump 32, service water pump 38, and charging pumps 31 or 32. MCC-312A in turn receives power from the 6.9-kV power supply (bus 1).

RCP Seal LOCA (RCP-LOCA). During this incident, insufficient seal cooling exposes the RCP seals to RCS pressure and temperature. Given RCP seal materials, the seals may fail and an RCP seal LOCA will result. Success for this event implies that no RCP seal LOCA occurs; failure implies an RCP seal LOCA occurs and the core is uncovered.

Auxiliary Feedwater System Turbine-Driven Secondary Cooling (AFWT). Core heat removal during this incident implies the use of the steam-turbine-driven AFW pump to provide feedwater to at least one steam generator.

The transient sequences follow. In defining a sequence, a slash (/) preceding an event designator indicates the event is a success. Asterisks (*) separate the event designators.

Sequence TC15-2: TC15*/PORV*/MCC-312A*/RCP-LOCA*/AFWT. Control building switchgear suffers flood damage. The reactor is shut down. Should the pressurizer PORVs open, they reclose (/PORV). Power is supplied from 6.9-kV buses by MCC-312A to alternative safe shutdown equipment (/MCC-312A). RCP seal failures do not occur (/RCP-LOCA). Without main feedwater, operation of the auxiliary feedwater system is required. Although the loss of switchgear renders all motor-driven AFW pumps inoperable, the steam-turbine-driven AFW pump starts and removes core decay heat through the steam generators (/AFWT). No core damage results.

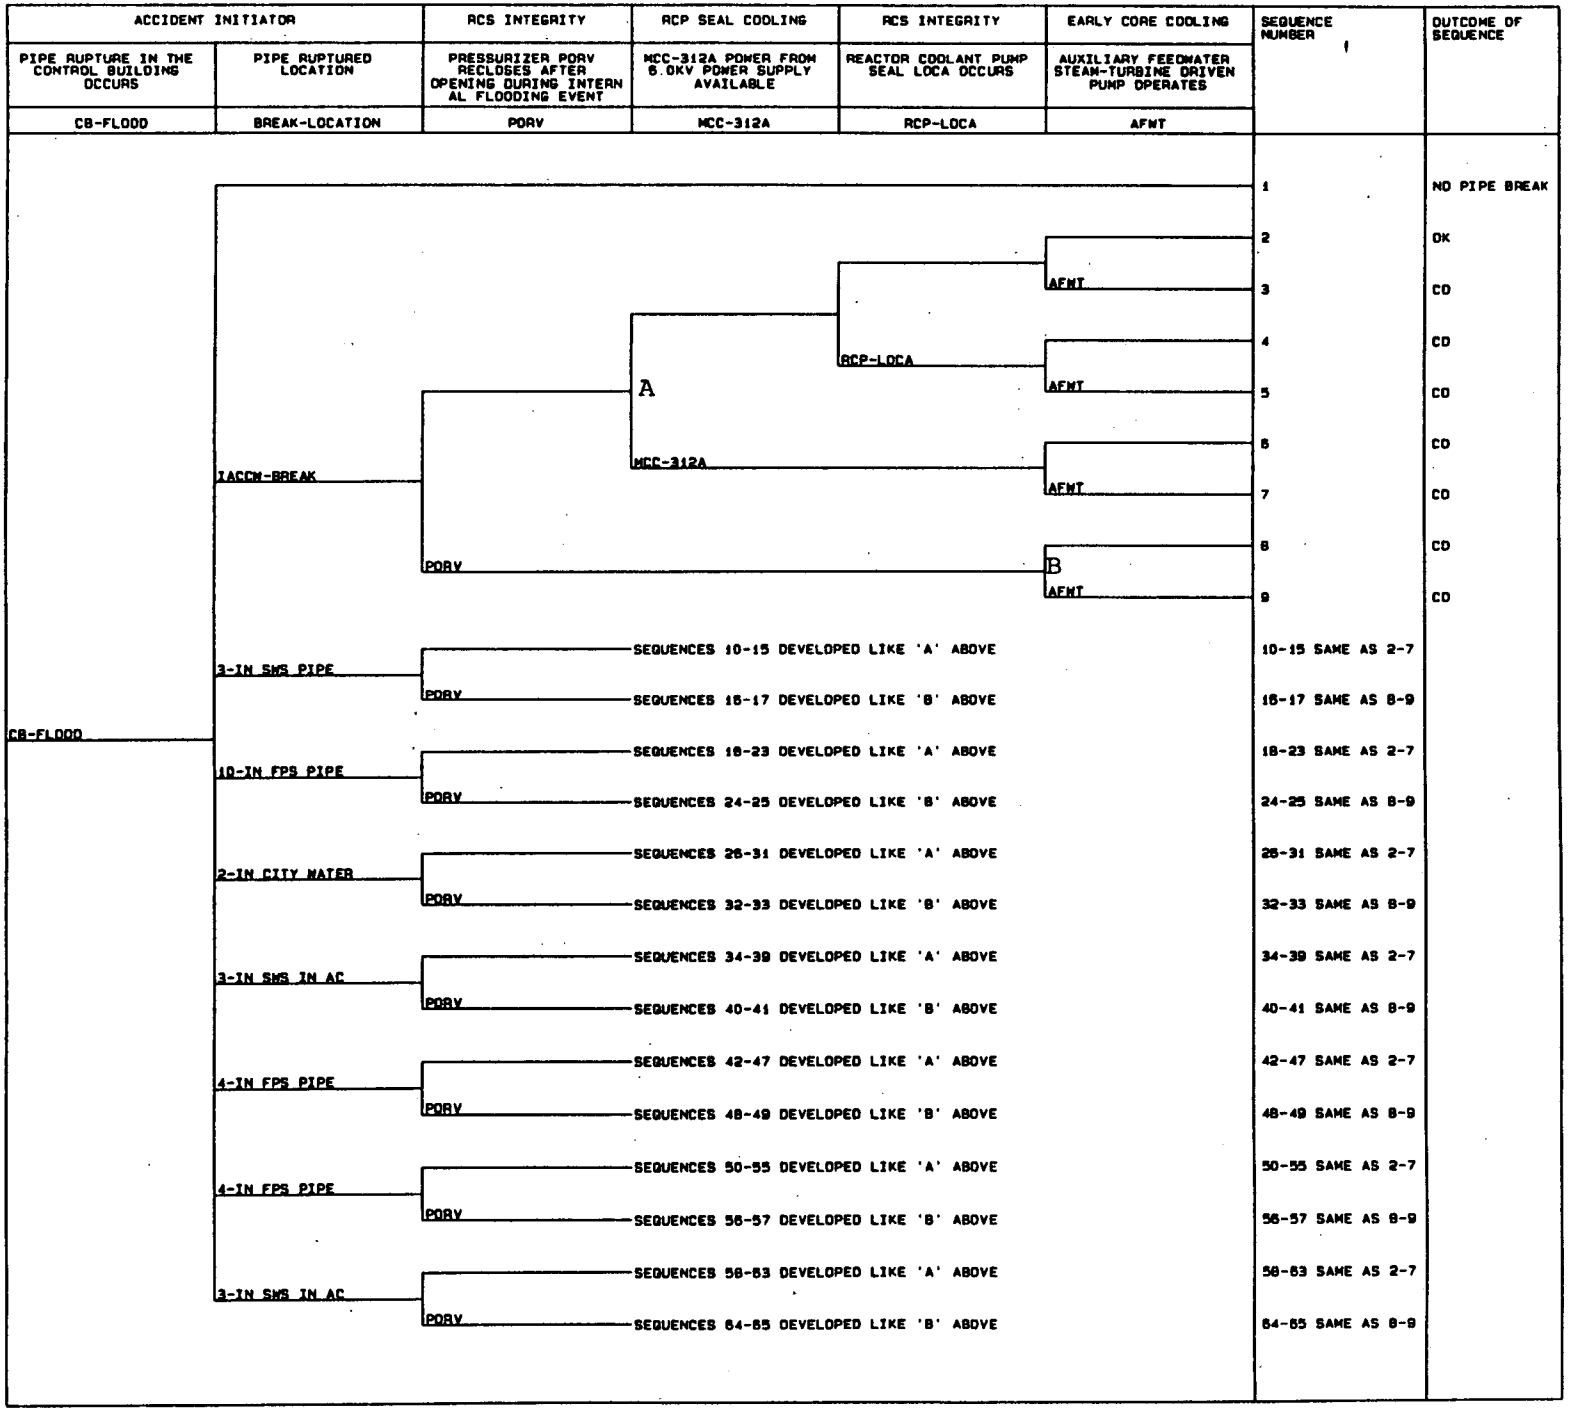


Figure 4.3.2.2 Control Building Switchgear Room Flooding Event Tree

Sequence TC15-3: TC15*/PORV*/MCC-312A*/RCP-LOCA*AFWT. Same as sequence TC15-2 except that the turbine-driven AFW pump fails. Unable to remove core decay heat, core damage results.

Sequences TC15-4 and TC15-5. Same as sequences TC15-2 and TC15-3 except that an RCP seal LOCA occurs. Core damage results.

Sequence TC15-6: TC15*/PORV*MCC-312A*/AFWT. Control building switchgear suffers flood damage. The reactor is shut down. If opened, the PORVs reclose (/PORV). Power is not supplied to MCC-312A (MCC-312A). RCP seal failures occur and the core is uncovered. Core damage results.

Sequence TC15-7: TC15*/PORV*MCC-312A*AFWT. Same as sequence TC15-6, except that the steam-turbine driven AFW pump fails. Core damage results.

Sequence TC15-8: TC15*PORV*/AFWT. Control building switchgear suffers flood damage. The reactor is shut down. A pressurizer PORV opens but fails to reclose (PORV). Core damage results.

Sequence TC15-9: TC15*PORV*AFWT. Same as sequence TC15-8, except that the steam-turbine driven AFW pump fails. Core damage results.

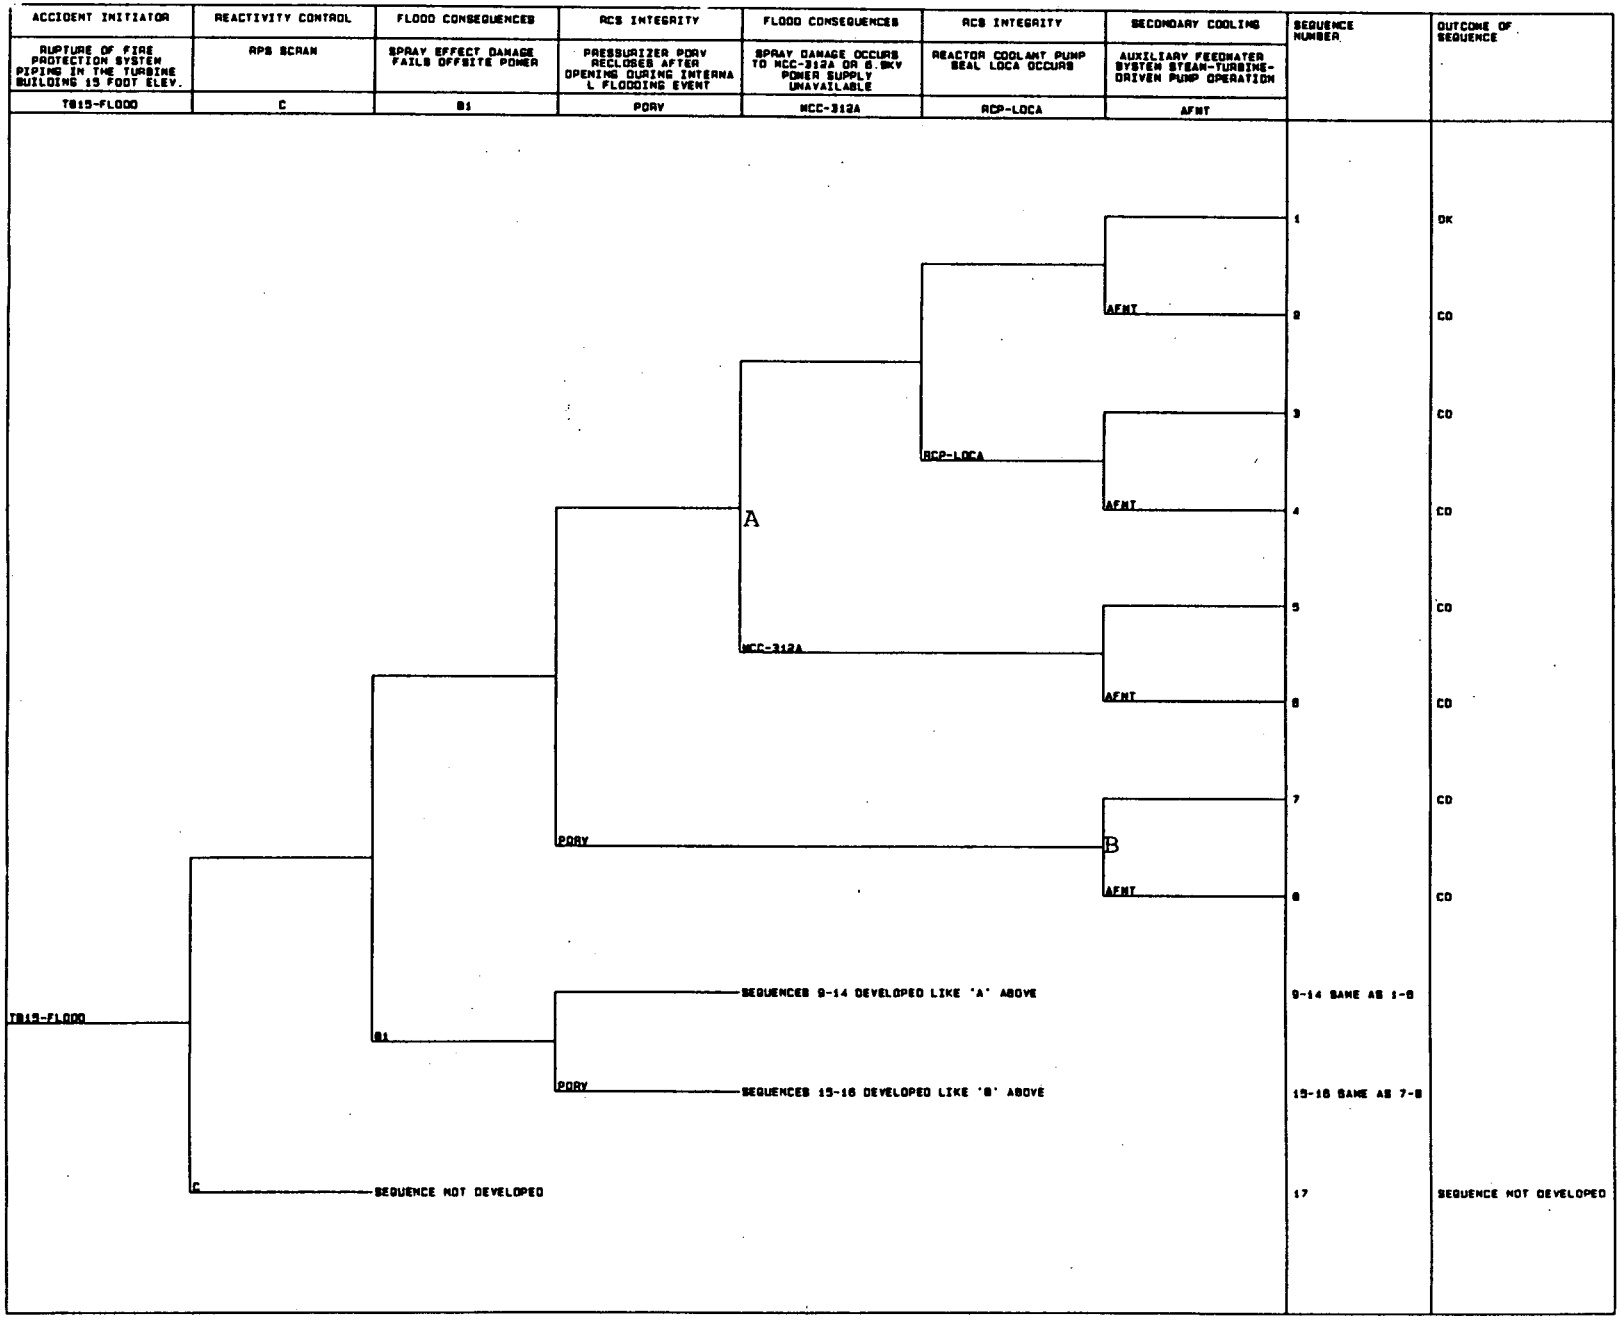
C4.3.2.3 Event Tree for Rupture of the Turbine Building Fire Protection System and Subsequent Loss of 480-Vac Switchgear in Flood Zone CTL15-1

The event tree for rupture of the turbine building fire protection system and loss of the 480-Vac switchgear is shown in Figure 4.3.2.3. The top events shown in the event tree are defined as follows:

Transient Initiator (TT15). Flooding initiated by the rupture of fire protection system piping in the turbine building outside the control building switchgear room causes non-recoverable damage to the 480-Vac switchgear.

RPS Scram (C). Success implies all, or all but one, control rods are inserted into the reactor core. Failure leads to an anticipated transient without scram (ATWS) event.

Offsite ac Power Available (B1). Success implies offsite ac power is available. Failure may be caused by spray damage resulting from the initiating event. Failure required the starting and alignment of the Appendix R diesel generator.



KEY:

OK - CORE COOLANT IS PROVIDED, CONTAINMENT HEAT REMOVAL IS PROVIDED

CD - CORE DAMAGE

Figure 4.3.2.3 Turbine Building Fire Protection System Rupture Event Tree

Pressurizer PORV Recloses After Opening During Transient (PORV). Success implies reclosure of open PORVs when RCS pressure drops below the closure setpoint. The failure of one or two PORVs to reclose is designated as a "PORV" event.

Power from MCC-312A Unavailable (MCC-312A). Spray damage or random failures render MCC-312 unable to provide power to CCW pump 32, service water pump 38, and charging pumps 31 or 32.

RCP Seal LOCA (RCP-LOCA). During this incident, insufficient seal cooling exposes the RCP seals to RCS pressure and temperature. Given RCP seal materials, the seals may fail and an RCP seal LOCA will result. Success for this event implies that no RCP seal LOCA occurs; failure implies an RCP seal LOCA occurs and the core is uncovered.

Auxiliary Feedwater System Turbine-Driven Secondary Cooling (AFWT). Core heat removal during this incident implies the use of the steam-turbine-driven AFW pump to provide feedwater to at least one steam generator.

The transient sequences follow. In defining a sequence, a slash (/) preceding an event designator indicates the event is a success. Asterisks (*) separate the event designators.

Sequence TT15-1: TT15*/C*/B1*/PORV*/MCC-312A*/RCP-LOCA*/AFWT. Control building switchgear suffers flood damage as a result of the rupture of fire protection system piping in the turbine building. The reactor scrams (/C). The 6.9-kV switchgear suffer no spray damage and offsite power continues to be available (/B1). If opened, the pressurizer PORVs reclose (/PORV). The 6.9-kV buses supply power to MCC-312A (/MCC-312A). RCP seal failures do not occur (/RCP-LOCA). The steam-turbine-driven AFW pump starts and removes core decay heat through the steam generators (/AFWT). No core damage results.

Sequence TT15-2: TT15*/C*/B1*/PORV*/MCC-312A*/RCP-LOCA*AFWT. Same as sequence TT15-1 except that the turbine-driven AFW pump fails. Unable to remove core decay heat, core damage results.

Sequences TT15-3 and TT15-4. Same as sequences TT15-1 and TT15-2 except that an RCP seal LOCA occurs. Core damage results.

Sequence TT15-5: TT15*/C*/B1*/PORV*MCC-312A*/AFWT. Control building switchgear suffers flood damage as a result of the rupture of fire protection system piping in the turbine building. The reactor scrams (/C). The 6.9-kV switchgear suffers no spray damage (/B1). If opened, the pressurizer PORVs reclose (/PORV). Power from MCC-312A is unavailable (MCC-312A) and as a result an RCP seal LOCA occurs. The steam-turbine-driven AFW pump starts and removes core decay heat through the steam generators (/AFWT). Core damage results.

Sequence TT15-6: **TT15*/C*B1*/PORV*MCC-312A*AFWT**. Same as sequence TT15-5 except that the turbine-driven AFW pump fails. Core damage results.

Sequence TT15-7: **TT15*/C*/B1*PORV*/AFWT**. Control building switchgear suffers flood damage as a result of the rupture of fire protection system piping in the turbine building. The reactor scrams (/C). The 6.9-kV switchgear does not suffer spray damage (/B1). Pressurizer PORVs open but fail to reclose (PORV). The steam-turbine-driven AFW pump starts and removes core decay heat through the steam generators (/AFWT). Core damage results.

Sequence TT15-8: **TT15*/C*/B1*PORV*AFWT**. Same as sequence TT15-5 except that the turbine-driven AFW pump fails. Core damage results.

Sequence TT15-9 to TT15-16. Same as sequences TT15-1 to TT15-8 except that spray damage renders the 6.9-kV switchgear unavailable.

Sequence TT15-17: TT15*C. Control building switchgear suffers flood damage as a result of the rupture of fire protection system piping in the turbine building. The control rods are not inserted into the core (C). At this point, the sequence frequency is $\sim 10^{-8}$/year, and any additional failures leading to core damage would result in a lower frequency. Therefore, the sequence was not developed further.

C4.3.2.4 Event Tree for Rupture of the Condensate Line in the Auxiliary Feedwater Pump Room, Flood Zone AFW18-1

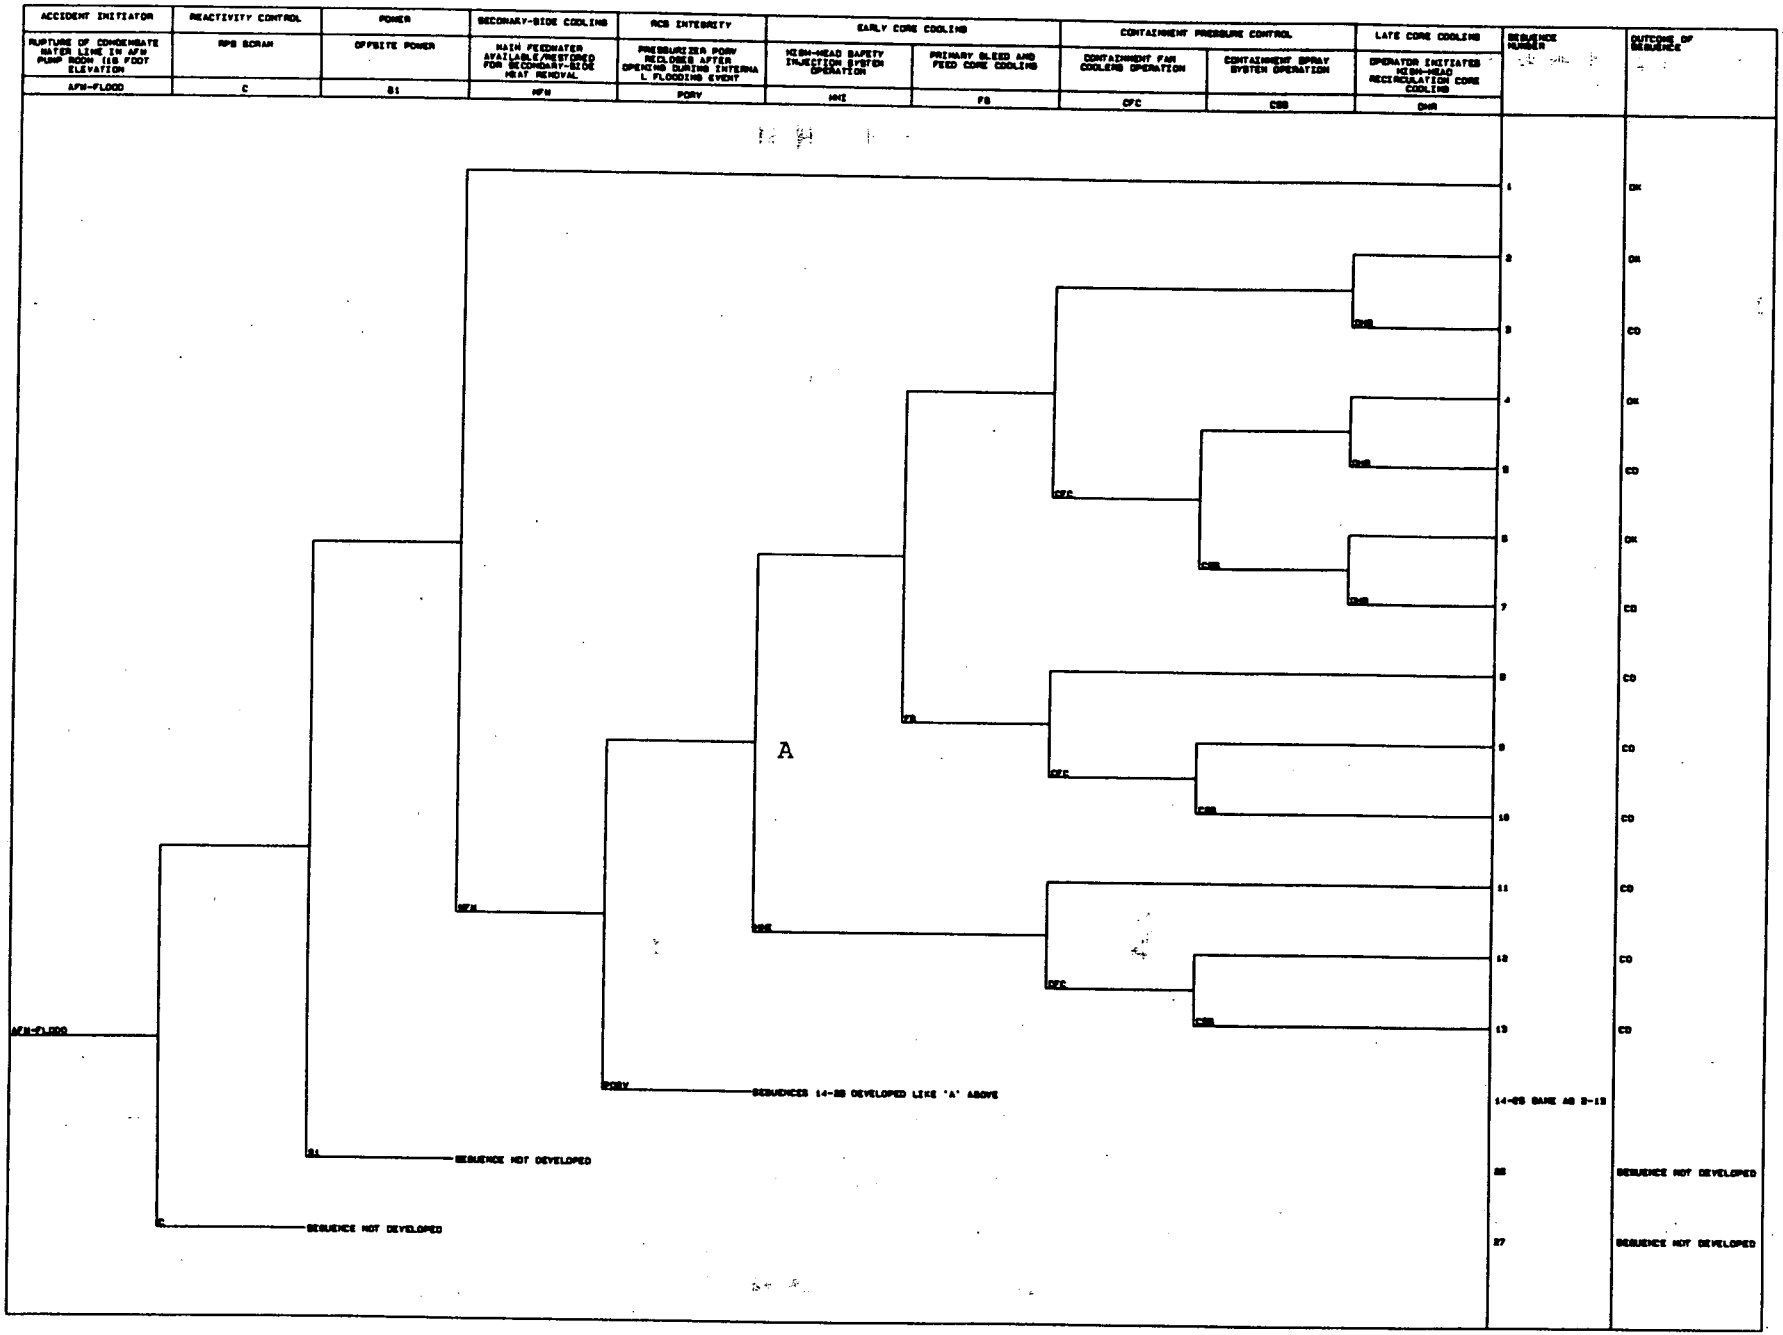
The event tree for rupture of the condensate line in flood zone AFW18-1 is shown in Figure 4.3.2.4. The top events shown in the event tree are defined as follows:

Transient Initiator (TA18). Flooding initiated by the rupture of condensate line in the auxiliary feedwater pump room, AFW18-1. This event causes loss of the AFW system and potential loss of the MFW system.

RPS Scram (C). Success implies all, or all but one, control rods are inserted into the reactor core. Failure leads to an anticipated transient without scram (ATWS) event.

Offsite ac Power Available (B1). Success implies offsite ac power is available. Failure leads to a demand for onsite ac power.

Main Feedwater System (MFW). Success implies that one main feedwater pump provides feedwater to at least one steam generator. Failure requires bleed-and-feed core cooling.



KEY:

OK - CORE COOLANT IS PROVIDED, CONTAINMENT HEAT REMOVAL IS PROVIDED

CD - CORE DAMAGE

Figure 4.3.2.4 Auxiliary Feedwater Pump Room Pipe Rupture Event Tree

Pressurizer PORV Recloses After Opening During Transient (PORV). Success implies reclosure of open PORVs when RCS pressure drops below the closure setpoint. The failure of one or two PORVs to reclose is designated as a "PORV" event.

Primary Cooling Bleed-and-Feed (FB). Success implies the manual opening of the PORVs to reduce RCS pressure (bleed) and the injection of water via HHSI pumps for core cooling (feed).

High-Head Safety Injection (HHI). This event is considered for sequences that entail bleed-and-feed operation, a stuck-open PORV, or a RCP seal LOCA. Success implies that at least one pump injects water into at least one 2-in. RCS cold leg. Failure requires that alternative core cooling be established.

Containment Fan Coolers (CFC). Success of the fan coolers in containment decay heat removal implies the operation of at least three fan coolers in their emergency mode and of two essential service water pumps. Failure requires alternative methods for containment decay heat removal.

Containment Spray System (CSS). Success implies an adequate RWST inventory and the use of at least one containment spray pump to provide early containment decay heat removal. Containment spray operation can continue after RWST depletion if a portion of the long-term recirculation core cooling flow is diverted to the containment spray headers.

High-Head Recirculation Core Cooling (OHR). Success implies that high-head recirculation core cooling is established to remove decay heat. Failure leads to the absence of long-term decay heat removal and core damage.

The transient sequences follow. In defining a sequence, a slash (/) preceding an event designator indicates the event is a success. Asterisks (*) separate the event designators.

Sequence TA18-1: TA18*/C*/B1*/MFW. The condensate return line in AFW18-1 ruptures, causing loss of the AFW system. The operators elect to trip the reactor. The reactor scrams (/C). Offsite ac power to the 6.9-kV buses is available (/B1). Secondary core cooling is maintained using the main feedwater system (/MFW). Hot shutdown and a safe core and containment result.

Sequence TA18-2: TA18*/C*/B1*MFW*/PORV*/HHI*/FB*/CFC*/OHR. Same as sequence TA18-1 except that flood damage or other problems preclude the use of the MFW system to provide secondary cooling. Instead core cooling is established using high-head safety injection system core cooling (/HHI) and RCS bleed-and-feed operation (/FB). If opened, the pressurizer PORVs reclose (/PORV). Subsequently, with containment pressure increasing because of PORV opening, the fan coolers start in their emergency mode of operation to provide containment overpressure control (/CFC). The operators initiate high-head recirculation core cooling (/OHR). A safe core and containment result.

Sequence TA18-3: TA18*/C*/B1*MFW*/PORV*/HHI*/FB*/CFC*OHR. Same as sequence TA18-2 except that the operators fail to initiate high-head recirculation core cooling (OHR). Core damage results.

Sequence TA18-4: TA18*/C*/B1*MFW*/PORV*/HHI*/FB*CFC*/CSS*/OHR. Same as sequence TA18-2 except that the fan coolers fail to start on high containment pressure (CFC). The containment spray system (/CSS) then initiates when containment pressure reaches 22.5 psig. A safe core and containment result.

Sequence TA18-5: TA18*/C*/B1*MFW*/PORV*/HHI*/FB*CFC*/CSS*OHR. Same as sequence TA18-4 except that the operators fail to initiate high-head recirculation core cooling (OHR). Core damage results.

Sequence TA18-6: TA18*/C*/B1*MFW*/PORV*/HHI*/FB*CFC*CSS*/OHR. Same as sequence TA18-4 except that early containment spray operation fails (CSS). A safe core and containment result.

Sequence TA18-7: TA18*/C*/B1*MFW*/PORV*/HHI*/FB*CFC*CSS*OHR. Same as sequence TA18-6 except that the operators fail to initiate high-head recirculation core cooling (OHR). Core damage results.

Sequences TA18-8 to TA18-10: Same as sequences TA18-2 to TA18-7 except that the operator fails to establish bleed-and-feed operation (FB). This prevents operation of the high-head safety injection system and thus recirculation core cooling, regardless as to whether the containment spray and containment fan coolers function. Core damage results.

Sequences TA18-11 to TA18-13. Same as sequences TA18-8 to TA18-10 except that bleed-and-feed operation and recirculation core cooling is precluded because high-head safety injection fails (HHI). Core damage results.

Sequences TA18-14 to TA18-25. Same as sequences TA18-2 to TA18-13 except that the pressurizer PORVs fail to reclose after opening (PORV).

Sequence TA18-26: TA18*/C*B1. The condensate line ruptures in AFW18-1. The reactor scrams (/C). Subsequently, offsite ac power to the 6.9-kV buses is unavailable (B1). At this point the sequence frequency is $<10^{-8}$/year, and additional failures leading to core damage would result in still lower frequencies. Therefore, the sequence was not developed further.

Sequence TA18-27: TA18*C. The condensate line ruptures in flood zone AFW18-1. The operators elect to scram the reactor. The control rods are not inserted into the core (C). At this point, the sequence frequency is $\sim 10^{-8}$/year, and any additional failures leading to core damage would result in a lower frequency. Therefore, the sequence was not developed further.

C4.3.3 QUANTIFICATION

The event trees described in Section C4.3.2 were quantified using the data prepared for the other event trees (Section 3) and sequence probabilities calculated. These probabilities were then combined with the initiating event frequences (Table C4.3.1.2) to determine the contribution of internal flooding to the core damage frequency. The calculations are presented in Table 4.3.3.1. The total contribution of internal flooding to the mean core damage frequency is 6.51 x 10^{-6}/yr. Three internal flooding scenarios are responsible for 84 percent of this contribution and have estimated frequencies greater than 10^{-6}/yr:

- The rupture of the instrument air closed cooling water system in the control building switchgear room (case C4.2.2.2)--1.42 x 10^{-6}/yr
- The rupture of the fire protection system in the control building switchgear room (case C4.2.2.4)--1.76 x 10^{-6}/yr
- The rupture of the fire protection system in the control building east stairwell (case C4.2.2.8)--2.00 x 10^{-6}/yr

Table 4.3.3.1

Internal Flooding Event Tree Quantification

Section	Event description	Initiator frequency (/year)	Contribution to CDF (/year)
C4.2.1.2	PAB55--rupture NESW header	1.43×10^{-6}	3.02×10^{-8}
C4.2.2.2	CTL15-1--IACCW system rupture	2.11×10^{-5}	1.42×10^{-6}
C4.2.2.3	CTL15-1--SWS rupture	5.36×10^{-6}	3.60×10^{-7}
C4.2.2.4	CTL15-1--fire protection system rupture	2.62×10^{-5}	1.76×10^{-6}
C4.2.2.5	CTL15-2--city water line rupture	9.30×10^{-7}	6.15×10^{-8}
C4.2.2.6	CTL15-2--SWS rupture	2.91×10^{-6}	2.12×10^{-7}
C4.2.2.8	CTL15-3--fire protection system rupture	2.29×10^{-5}	2.00×10^{-6}
C4.2.4.7	AFW18-1--condensate system rupture	5.57×10^{-5}	2.50×10^{-7}
C4.2.5.1	TBL15--rupture fire protection system	3.51×10^{-7}	6.48×10^{-8}

Section C5

CONCLUSIONS AND RECOMMENDATIONS

Internal flooding can initiate or exacerbate a core damage accident. A large number of flooding scenarios were evaluated and subjected to deterministic and probabilistic analyses. From these analyses, it was concluded that three flooding scenarios have estimated frequencies exceeding 10^{-6}/yr:

- The rupture of the instrument air closed cooling water system in the control building switchgear room (case C4.2.2.2)
- The rupture of the fire protection system in the control building switchgear room (case C4.2.2.4)
- The rupture of the fire protection system in the control building east stairwell (case C4.2.2.8).

The scenarios can be mitigated by relatively simple measures should cost-benefit analyses and detailed engineering analyses show mitigation to be desirable:

- Replace the automatic make-up to the instrument air closed cooling water system tank with manually controlled make-up or make-up that is restricted to the normally anticipated leak rate. While automatic make-up was presumably installed to compensate for possible leaks, it is clearly counter-productive if large continued leaks lead to the accumulation of water within the control building switchgear room. The elimination of automatic make-up with a high flow rate eliminates case C4.2.2.2, rupture of the IACCW system, as a source of concern.
- Prevent a rupture of the fire protection system in the deluge room from flooding the control building switchgear room. This could be accomplished by closing the open door between the deluge room and switchgear room and establish a means to ensure that water escaping into the deluge room is discharged to the turbine building or outside. This action would eliminate case C4.2.2.4 as a source of concern. Alternatively, the contribution to core damage of accident sequences initiated by rupture of the fire protection system in the deluge room could be reduced significantly by routine non-destructive examination of the valves, welds and pipes in that room and by implementing maintenance isolation procedures for fire protection equipment in that room that require independent verification, with written check-off procedures, of valve closure.
- Replace the present door between the control building switchgear room and the control building east stairwell with a water-tight door. Because the curb below this door is

higher than the critical flood height of the 480-Vac switchgear, drainage through gaps beneath the door will not mitigate flooding initiated within the switchgear room. They will, however, allow floods originating in the control building east stairwell or AC equipment room to propagate into the switchgear room and damage the switchgear. The replacement of the existing door with a water-tight door will therefore eliminate case C4.2.2.8, rupture of the fire protection system in the control building east stairwell, as a source of concern. Alternatively, drainage of flood zone CTL15-3, the control building east stairwell, into the diesel generator valve room could be enhanced to prevent water from flowing into the control building switchgear room from the stairwell.

The susceptability of the plant to internal flooding could also be reduced if a number of other steps are taken:

- Ensure that the floor drains within the control building function properly.
- Enhance drainage of flood zone CTL15-1, the control building switchgear room by installing a trench, with water trap, to allow flow into the diesel generator valve room. A trench may well mitigate the effects of service water and fire protection system rupture in the switchgear room.
- Install shields to prevent the IACCW line from spraying switchgear in flood zone CTL15-1.
- Implement procedures to direct the operators to use SOP-EL-12 to align the alternative safe shutdown equipment to MCC-312A should power from all 480-Vac safeguard buses be lost while offsite power is available. Power to MCC-312A can be supplied via the 6.9-kV switchgear.
- Implement maintenance isolation procedures to require independent verification of water line isolation immediately prior to the start of maintenance should this maintenance require the opening of water lines in the control building.

Section E1

COMPILING COMPONENT FAILURE RECORDS

1. The component boundaries are those defined in Section E5 of this appendix.

2. Only components and failure modes that are modeled in the system fault trees were included in the plant-specific failure data collection.

3. The primary source of failure information used in this study was the maintenance work request (MWR) packages. Additional plant information sources were used as necessary, but only as secondary sources. If the sources give inconsistent information, information derived from the MWR packages was used unless it was clearly wrong.

4. MWR packages on which the equipment ID is illegible or not specified were disregarded unless other plant sources provided the necessary information.

5. MWRs sometimes provide very little information on the problem and corrective action taken. This lack of information makes it difficult to distinguish component failures separate from other maintenance activities. Unless component failure is clearly indicated, it was assumed that the package addresses corrective maintenance.

6. An MWR which does not result in actual maintenance activity was set aside. An example of such an MWR is a request for equipment trouble shooting which failed to duplicate the reported equipment problem and therefore did not lead to maintenance.

7. A canceled work request was not analyzed.

8. Component failure severity classifications used in this study are similar to those used in the INPO NPRDS. In the NPRDS, three levels of failure severity are defined: immediate/catastrophic, degraded and incipient. The only failures of concern in this study, however, were immediate/catastrophic failures and some degraded failures which have critical effects on system from the plant risk perspective.

9. The failure start time was defined to be the time at which MWR was issued unless a specific failure time is specified in the MWR or other plant document source. The failure end time was defined to be the time at which control room shift supervisor signs off the clearance of MWR. If the failure start or end times are unavailable, they were assumed to be 12:00 (noon).

10. Some MWRs describe component failures which do not fit into failure criteria used in this study. Such failures include: failures of components outside the scope of this study; failures with component failure modes outside the scope of the study; and failures not

critical to the failed component but critical to other components modeled (e.g., reverse leakage through check valves). Failure records of the last type were scrutinized to determine if they should be retained. However, special care was exercised when including these failures in failure rate and demand probability calculations, since their inclusion changes the component population. If exposure data corresponding to these failures was unavailable, the failures were omitted from the failure rate and demand probability calculations.

11. MWRs are often issued for components which manifest the effect of other component failures. In this study, such failures were counted against the component that actually failed, and not against the component for which the MWR was issued.

12. Some components consist of many sub-components (e.g., turbine-driven pumps and emergency diesel generators). Failures of such components were tracked at the sub-component level to facilitate documentation but were later aggregated for failure rate and demand probability calculations.

13. Often, maintenance on one component leads to subsequent maintenance on the same component or other components. In general, subsequent maintenance on the same component was treated as part of the initial maintenance unless there was a clear reason for doing otherwise. Subsequent maintenance on other components was normally treated separately though it was evaluated as a potential common-cause event.

14 If an MWR package addressed multiple component failures, failure records were created for each component. The failures were then reviewed further to ascertain if they are common-cause failures.

15. Component/piece part replacements or component repairs initiated by plant design changes/modifications were categorized as scheduled maintenance (SM).

16. If functional degradation of a component is monitored by such means as vibration monitoring and lube oil analysis, and its degraded condition is corrected before failure (either by adjustment or replacement of parts), the corresponding maintenance event was categorized as an incipient failure.

17. Component/system misconfiguration (e.g., reversed wiring on a transmitter), induced, discovered and corrected during testing, was not considered a failure.

18. Failures of piping, pipe support, and steam traps were not analyzed except when the failure could initiate an accident sequence that leads to core damage (e.g., piping failures that cause internal flooding). The basis for this omission is that their probability of occurrence and contribution to core damage accident sequences is minimal.

19. Minor external leakage from a pump assembly, such as leak through flange, was considered to be an incipient failure.

20. If the operating status of component at the time of failure could not be determined from the MWR, the assumed failure modes for failure of standby and alternating pumps will be failure to start (FS) unless it is clear that the pump failure is failure to run (FR). For normally running pumps, the reverse was assumed.

21. In general, valve leakage was considered to be an incipient failure unless it seriously degraded system operation or performance or had to be fixed immediately. Valve leakage problems are usually assigned a "fail to remain closed" (CO) failure mode, although a "fail to close (OO) failure mode is assigned if the valve has to close during an accident.

22. Failures associated with integrated leak rate tests (ILRT) on valves were disregarded. ILRT acceptance criteria are much more stringent than the failure criteria used in this study and seldom represent the functional failures of interest here.

23. Valve repacking performed before a valve test was categorized as preventive maintenance (PM) unless the valve leaked severely before repacking.

24. A minor internal valve leakage through a valve seat was considered to be an incipient failure. This assumption does not apply to a major internal leakage and external leakage. Critical internal leakage through a valve (e.g., internal leakage from AFW system to a steam generator) was considered to be degraded/catastrophic failure and the failure was counted against the valve.

25. Internal (reverse) leakage in a check valve was assigned a "fails to remain closed" (CO) failure mode. However, if the reverse leakage failure mode for a check valve was specifically modeled in a fault tree, then the preferred failure mode was reverse leakage.

26. MWR packages which deal with motor-operated valve actuation (MOVATS) testing were reviewed. MOVATS testing indicates whether there are problems with a valve. If a problem was detected through MOVATS testing, it generated other plant documentation such as an SOR and other MWR which was then reviewed for further information.

27. Pilot valve failures were counted against the master valve unless the pilot valve was specifically modeled in the system fault trees.

28. Only instrumentation directly associated with major components (such as pumps, valves, compressors, etc.) was analyzed in this study. This is consistent with the component population scope used in the system fault tree development.

29. A transmitter failure (e.g., transmitter wire burn out) was ignored if the failed transmitter does not provide a control signal to other components such as valves or pumps.

30. If several MWRs address similar problems for separate components during relatively short period of time (i.e., weeks), they were further reviewed to ascertain if the failures represent a common-cause failure.

Section E2

EXPOSURE DATA FROM PERFORMANCE AND SURVEILLANCE TESTING

1. Only components located in a major flow path or included in system logic models were examined.

2. An RHR heat exchanger was considered to be tested in a performance test (PT) or surveillance test (ST) if the flow path through the heat exchanger was tested. Should the heat exchanger fail, the applicable failure mode is "failure of the heat exchanger from miscellaneous faults (such as plugging, rupture, leakage, etc.)" (VF).

3. The exposure time relevant to the valve plugging failure mode was calculated as being one-half the test interval assuming that the valve operated successfully during the previous PT/ST if the valve is in the major flow path. This assumption applies only to normally open valves, in which plugging may be caused by internal valve parts coming loose.

4. During a PT/ST, component operability may be tested repeatedly. Even so, only one verification of component operability was assumed for component failure modes that are related to exposure time.

5. Only those components in a direct flow path tested in a given PT/ST were analyzed for exposure-hour-related failure modes. Valves subject to ILRTs were not included unless specifically addressed by the PT/ST.

6. If the test procedure states that 'M' out of 'N' components can be used for testing, then 'M/N' demands were assigned to each of the N components.

7. Manual valve failure modes "manual valve fails to remain open" (OC) and "manual valve fails closed" (PG) were treated as PG failure modes in this study.

8. Cycling a normally-open or normally closed valve results in one demand that the valve open and one demand that it close.

9. Opening a normally closed valve and throttling it collects one open demand if the valve is throttled immediately after opening: problems that occur during initial valve throttling were assumed to represent a failure of the valve to open--a CC failure mode. If, however, the valve was left open--even partially--for some time before throttling, a "valve does not throttle properly" (DN) failure mode was assumed.

10. If a PCV was challenged during a given test, then the operability of the PCV and the flow path through it were tested. Therefore, exposure was accumulated for two PCV failure modes: "does not operate on demand" (DN), and "fails closed, plugged" (PG).

11. Attempts to close a valve that was already closed or to open a valve that was already open are not valid demands on the valve.

12. Partial opening or closing of a valve was counted as full actuation.

13. Gross reverse leakage through check valves represents a failure to close on demand. This failure mode is especially important for multiple-pump trains that are normally in standby. It can occur in any system where pumps with discharge check valves feed a common header (e.g., in the RHR, SWS and CCW systems).

Section E3

EXPOSURE DATA FROM SYSTEM OPERATION

1. Only components in a major flow path or included in system logic models were examined. Thus drain, vent, and manual isolation valves away from the main flow path were not examined.

2. Attempts to close a valve that was already closed or to open a valve that was already open are not valid demands on the valve.

3. When a pump, compressor or fan cooling unit is actuated, it is assumed that the associated manual switch (MSW-DN) and power breaker (CRB-DN) are also actuated.

4. Whenever a pump is started, the associated discharge check valve collects a demand (CKV-CC). However, this demand is collected only for the minimum flow path that is required to operate the pump.

5. If a valve is required to change its position (e.g., to open) when a pump starts or during pump operation, the valve collects a demand.

Section E4

UNAVAILABILITY CALCULATIONS

1. Events were treated as occurring on the date given in the senior reactor operator (SRO) logs or daily summary report (DSR) unless reported differently in the shift supervisor (SS) logs.

2. If only the event start date was found in the SRO logs and no entry was found in the SS log or DSR to identify the event end date, the event end date was taken as the "estimated return to service date" provided in the DSR.

3. SRO and SS logs and DSRs contain data on component, train, and system outages occasioned by scheduled and unscheduled maintenance and tests. Unavailability calculations ignored tests unless they rendered components inoperable.

4. If a plant shut down was commenced in response to a technical specification limiting condition of operation (LCO), it was assumed that the safety systems were no longer required. Unavailability calculations reflect this assumption.

5. Only events with start dates (or estimated time of occurrence) during power operations were included in unavailability calculations. Events that occurred during an outage were excluded.

Section E5

COMPONENT BOUNDARIES

Three major physical interfaces were considered when specifying component boundaries: the mechanical interface (which includes interfaces with lubricating or cooling systems if applicable); the power supply interface; and the command/control interface. For most components, the distinctions between the component and the rest of the system are clear. For some components, however, the interfaces between the component and the rest of the system are not clear and need detailed specification. These components include the batteries, battery chargers, inverters and diesel generators; pumps; motor-, air-, and solenoid-operated valves; cooling units; fans; air compressors; dampers; and gas turbines. The mechanical, power supply, and command/control interface to these components are defined as follows.

Batteries. A battery boundary includes each battery cell, its internal parts (including plates and electrolyte); terminal connections (including cables with lugs or connectors); and any switches or meters required for normal battery operation.

Battery Chargers. The static battery charger boundary includes all components within the charger enclosure and the associated instrumentation, control, and protective devices, including meters, relays, fuses, switches and internal circuit breakers.

Inverters. The inverter boundary includes all components within the inverter unit, the static transfer switch and associated instrumentation, control, and protective devices (including meters, relays, fuses, switches, and circuit breakers).

Diesel Generators. The mechanical boundary of the emergency diesel generator (EDG) encloses the diesel engine and its subsystems. It includes the combustion air path from the intake to the outlet, engine-driven lubrication and fuel oil supplies, and the jacket water cooling system except for the piping and the source of cooling water. The generator and output circuit breaker were excluded from the boundary, because their failures were modeled separately. The control/command boundary includes the entire air-starting system (its accumulators, compressors and the signal input contacts through the starting-air system). The command signals to the signal input contacts lie outside the boundary but local control systems (e.g., governors) and instrumentation are included within it.

Pumps. A pump consists of a pumping unit, driver, and coupling. The mechanical boundary is taken to extend from the pump side of the inlet isolation valve to the pump side of the outlet isolation valve but excludes the valves. The lubrication and cooling boundaries are taken to include local elements of these systems up to the pump but excluding the driving system for cooling water, if it is common to several pumps. The power supply boundary is essentially the same for all electrically driven pumps and is taken to extend from where cables exit the circuit breaker. The circuit breaker and bus in the motor control centers (MCCs) for the pumps were modeled separately. For steam turbine-driven pumps, the power boundary was taken to be the outlet of the steam shutoff valve. Local control systems like the governors are taken to be part of the pump, since a failure of the governor is usually reported as a failure of the pump. The command/control boundaries (including all controls, switches, circuitry, and local instrumentation) for the pump were excluded, since they are modeled as separate basic events in the fault tree model. This boundary definition is consistent with plant maintenance procedures. Each pump was classified as operating in a running or standby mode, or as alternating between running and standby modes.

Air-Operated Valves. The physical boundary of air-operated valves (AOVs) encompasses the valve body, excluding the pilot valve operator, and all fittings, flanges, and seals. The air supply boundary for AOVs is at the point where the air enters inlet to the pilot operator. The command/control boundaries such as solenoid valves, if they exist, are defined as separate components and modeled as such.

Motor-Operated Valves. The physical boundary of motor-operated valves (MOVs) encompasses the valve body, valve operator, the motor, and all fittings, flanges, and seals. The power supply boundary for MOVs is at the point where the power cable exits the circuit breaker. The MCC motor starter contacts were modeled separately. All limit switches or torque switches on the valve also lie outside of valve boundary.

Solenoid-Operated Valves. The physical boundary of solenoid-operated valves (SOVs) encompasses the valve body, valve operator, air actuator (solenoid), and all fittings, flanges, and seals. For solenoid-operated valves, the power supply and control/command boundaries are at the input contacts of the solenoid coil.

Cooling Units. The physical boundary of the cooling unit includes the filters, the cooling coils, and the fan with its driver. The power supply and command/control boundaries are the same as those for the motor-driven pump. If local controls exist (such as hydraulic coupling), they are also defined as falling within the command/control boundary.

Fans. The driving motor, coupling, belt, and blades were defined as falling within the physical boundary of a fan. The power supply and command/control boundaries were assumed to be the same as those for the cooling units.

Air Compressors. The physical boundary of the air compressor includes the compressing unit, driver, and moisture separator. The boundary lies at the intake air filter and the outlet of the moisture separator. The power supply and command/control boundaries were assumed to be the same as those for the cooling units.

PLANT DATA SOURCES

Plant-specific failure data can come from:

- **Maintenance Work Requests (MWRs)**

  MWRs, as described on the maintenance work request cover sheet and work sheets, are the major source of component failure data. A MWR usually identifies the component being maintained and briefly describes the problem, the corrective action taken, and the duration of maintenance. The time of failure can often be extracted as well, but MWRs seldom describe the circumstances under which components fail.

  The MWRs were reviewed in detail to prepare component failure records that were then used directly to calculate the component failure rate or demand probability. Data extracted from MWRs were cross-referenced with two other plant information sources--the licensee event report (LER) database and INPO NPRDS failure reports--to verify the timing of events. Missing or illegible information was verified by cross-checking the shift supervisor (SS) and senior reactor operator (NCO) logs, the daily summary reports (DSRs), monthly reports (MRs), significant occurrence reports (SORs), and SCRAM reports. This cross-checking ensured the completeness of the data and resolved some uncertainties.

  The review process for a MWR is outlined in Figure F1. The failure information was recorded on a plant-specific failure data form (Figure F2) and then compiled into a database (Table F1). It is important to note that subjective judgments were made when the failure mode and severity (i.e., catastrophic, degraded, or incipient) were assigned.

  While reviewing the MWRs, the data analysts consulted with the system analysts to clarify unusual cases. This consultation provided three benefits:

  - The data analysts gained an understanding of how components were modeled
  - The system analysts benefited by understanding how modeled components have failed and been repaired at the plant and adjust the models accordingly
  - The model and component failure data are made consistent.

  The review of MWRs begins by separating them into system and major component categories (i.e., mechanical, electrical, instrumentation and control, and miscellaneous) to help in their handling and tracking. The MWRs were then analyzed in a series of steps:

  [1] Each MWR was screened to determine whether it applies to work performed within the distinct time period selected. Only MWRs within this window were analyzed. MWRs generated within a month of the window were reviewed to find the actual component failure date, since the date of concern in this analysis is the component failure date--not

the work order request date (the "done date").

[2] The failed component addressed in the MWR is identified. MWRs that are not component-specific (e.g., cleaning the turbine room floor) were set aside for later review to determine whether MWRs dealing with system- or plant-level problems should be addressed in the analysis.

[3] MWRs relating to scheduled maintenance or testing were not used to determine failure rates or demand probabilities unless a failed component was repaired under the same work order. These MWRs were to be used, however, to determine the unavailability of components due to maintenance.

[4] The MWRs were reviewed to determine whether the components addressed were modeled in the system fault trees. Particular care was taken to ensure that the component ID shown on the MWR is indeed that of the failed component: frequently this ID is that of the component that manifests the symptoms of failure and not of the component where the failure originated. This is especially true of indicators and alarms, where the actual failure may be of the monitored component.

Delineation of component boundaries is a key issue for data analysts inasmuch as several components are sometimes lumped together for representation in the fault tree model (e.g., a turbine-driven pump containing a turbine, pump, governor, and steam-control and stop valves, is modeled as a single component). However, the maintenance department usually treats such equipment as separate components. The component boundaries assumed are defined in Appendix E.

[5] A failure-severity code--catastrophic, degraded, or incipient--was assigned to the component failure addressed in each MWR. In a catastrophic failure, the component fails so that it cannot function as required. A degraded failure leaves the component functional, but not meeting one or more of its specified operating parameters. An incipient failure occurs when a component remains fully functional within its operational criteria, but shows symptoms of problems that could lead to degraded or catastrophic failure if not repaired.

As only catastrophic failures and some degraded failures--such as valve internal leakage that provides a significant flow path diversion--are modeled, only these failures are relevant to the data analysis.

[6] If a component and its failure severity are found relevant, the actual component failure was compared with the failure modes modeled to determine whether this type of component failure was modeled in the fault tree. Where subjective judgments are made to match modeled failure modes to actual component failures, these judgments were documented on the failure data report form so they can be reviewed later with the system analysts. Consequently, the logic model was sometimes modified to account for

the failure modes identified from the review of MWRs.

[7] Where data are illegible or missing, other plant data sources such as SRO and SS logs were examined. Once the failure report form is completed, selected data are entered into a computer database for final checking to eliminate duplicate component failures and match the failures identified from MWRs with those identified from other plant data sources.

The MWRs were also used to calculate the component demands incurred in post-maintenance testing--it was assumed that if a component is removed from service for scheduled or unscheduled maintenance, it will be tested before being returned to service. Finally, a maintenance database was created. The work orders addressing catastrophic component failures modeled in the system fault trees are compiled with the other MWRs addressing incipient-failures and scheduled-maintenance. The database is used to help determine unavailability as a result of maintenance. This database is shown in Table F2.

- **Licensee Event Reports (LERs)**

  LERs deal with significant events related to the licensee, including organizational and procedural problems. An LER provides, for example, a very detailed description of a given component failure, its effect on the system and plant, the failure date, the corrective action taken, and the failure cause. Since not all failures are reported as LERs, however, they were used only to supplement and cross-check the MWR database.

- **NPRDS Failure Reports**

  INPO can provide detailed failure reports over the period analyzed. Because many failure reports concern degraded or incipient failures that are not within the scope of this study, and because NPRDS failure reports are usually generated from, and are subjective interpretations of, plant MWRs, they were used only to supplement the MWR database.

- **SCRAM Reports**

  These reports provide detailed accounts of all automatic and manual reactor scrams. They were therefore used to identify initiating events. The reports were also helpful in developing a plant operating mode histogram; they contain clues about when certain components or systems malfunctioned.

- **Significant Occurrence Reports (SORs)**

  These reports delineate unusual events that occur at the plant, including some caused by component failures. Because they are not exhaustive, they were used only to supplement the MWR database.

- **Monthly Report (MR)**

  This report summarizes all significant events that occurred during the month and provides such data as the time the plant operated at full power, time spent in shutdown, and number of scrams. Again, it was used to supplement other documentation.

- **Daily Summary Report (DSR)**

  This report describes events significant in the day-to-day plant operation. Out-of-service equipment is often listed, along with its return to service, particularly if this equipment is within the ECCS or if its inoperability represents a LCO. This report is a primary source of data for estimating system unavailability for the ECCS. It also gives daily reactor power levels that can be used to help develop a comprehensive plant operating mode histogram. Care was taken, however, in using the DSR to identify failures because successive periods of system or component unavailability may be occasioned by single failures,.

- **Senior Reactor Operator (SRO) Log or Central Control Room (CCR) Log**

  The SRO log is kept by field operators at the plant. It contains detailed descriptions of events during which equipment is turned on and off, valve line-ups are changed, and components are tagged out for maintenance. Significant equipment failures, system inoperability, plant shutdowns, refueling outages, surveillance testing, and major maintenance activities are logged into the document as one-line entries with time stamps. Data on component demands and operating hours was therefore basically derived from the SRO log making use of the assumptions delineated in Appendix E. The SOR log was also thoroughly reviewed to obtain detailed surveillance testing (ST) data and to help create the system operation logs used to compile performance logs.

  A system operation history table (Table F3) was generated for the modeled systems from the SOR log using the SS logs and other reports to verify and amplify the data. Composites of the total operating procedure demands and operating hours are summarized for each system, as shown in Table F4. This table is then combined with the ST component demand matrix, Table F7, to obtain the total number of demands or operating hours for each component type modeled and its associated failure mode.

- **Shift Supervisor Log (SS Log)**

  This document is a source of plant and system operating history and was used to support and cross-check the SRO log. The SS log was also used to provide information on the time of component failures if this information was missing or illegible in the MWRs. Other information to be extracted during the SS log review included the reactor mode changes and the times of reactor scrams.

- **Surveillance Testing (ST) Procedures**

ST procedures are based on the plant technical specifications. They list the components to be tested and the components utilized during the performance of a given ST. Although each ST procedure specifies a scheduled frequency, the schedules do not accurately represent actual ST performance. To collect more accurate ST performance data, the SRO logs were reviewed and a complete history of the ST performance generated for the period of time studied. The detailed ST log and a summary are presented in Tables F5 and F6, respectively.

The ST procedures were then used to generate a demand matrix for ST procedures and affected components. The ST-demand matrix is shown in Table F7. This table is completed by identifying the normal state for each component and the operation requested by the ST procedure. The corresponding potential failure mode description, failure mode, and demand are listed. The assumptions for compiling the ST-demand matrix and estimating component exposure and operating hours are documented in Appendix E.

- **System Operating Procedures (OPs)**

  These procedures contain instructions for all modes of system operation, including those rarely performed. The procedures were used as a source of background information on component/system operation.

- **Maintenance Procedures**

  Maintenance procedures detail how maintenance is performed. This information was combined with the MWR database to estimate component demands from maintenance activities. Maintenance procedures also provided insight into how certain components are maintained and identify the components associated with each maintenance procedure.

- **Discussions with Plant Staff**

  Discussions with maintenance and operations staff were particularly useful in ensuring that the data compiled reflect the actual component actuation and failure history and in resolving uncertainties in defining component functions or failure modes.

- **Piping and Instrumentation Diagrams (P&IDs), and other plant drawings**

  Plant drawings were used to identify components modeled in the system fault trees, and to understand how components interface with each other.

- **Other Documentation**

  Other plant documentation (such as the FSAR, technical specifications, system descriptions, and vendor documentation) or summaries of the information prepared in the systems analysis were consulted when necessary.

Table F4 Summary Of System Operation Log

NOTES
Based on pump start demands and minimum flow path.
Based on pump start demands.
Based on pump start demands.
Based on pump start demands.
Based on pump start demands.
Not used in final calculation.
Not used in final calculation.
Based on EDG start demands.
Based on EDG start demands.
Based on EDG start demands.
Run hours are only rough estimates. Much of operated duration were assumed as result of missing entries in logs.
Based on pump start demands and minimum flow path.
Based on pump start demands.
Based on pump start demands and minimum flow path.
Based on pump start demands and minimum flow path.
Based on pump start demands.

Table F4 Summary Of System Operation Log

NOTES

Assumed to check the operability of both MS-1's and MS-2's.

These SOVs are the pilot valves for PCV-1214 to 1217.

PWS pump data (number of starts and operated hours) are low due to the lack of entries in the logs.

PWS pump data (number of starts and operated hours) are low due to the lack of entries in the logs.

Based on pump start demands and minimum flow path.

Based on pump start demands.

Based on pump start demands.

Based on pump start demands and minimum flow path.

Based on pump start demands.

Based on pump start demands.

GENERAL ASSUMPTIONS AND NOTES									
1.	Logic model column can have value of YES, NO or NOFM.								
		YES indicates given component and its failure mode is modeled in system fault tree.							
		NO indicates component is not modeled in the system fault tree							
		NOFM indicates component is modeled but specified failure mode for this component is not modeled.							
2.	When evaluating modeled failure modes, the failure modes from ISLOCA were not included in the evaluation at this time.								
	This may be done later, if necessary.								
3.	Following acronyms are used for Initial State column.								
		NC - Normally Closed							
		NO - Normally Open							
		LC - Locked Closed							
		LO - Locked Open							
		LS - Locked Shut							
4.	Following acronyms are used for Requested Action column.								
		VC - Verify Closed							
		VO - Verify Open							
		FX - Flow Check							
		BF - Block Flow

Section H1

CONTROL ROOM INDICATIONS AND CONTROLS

This section describes the control room instrumentation displays, panels, and switches that are important to the human actions addressed in the IP3 IPE. These descriptions are presented according to system. The locations of the displays, panels and switches in the control room are shown in Figure 3.3.3.1. All indicators, recorders, and switches are clearly labeled with nameplates. The lettering and background on these nameplates have contrasting colors and can be read easily.

H1.1 SERVICE WATER SYSTEM (SWS)

The SWS consists of essential and non-essential supply headers each supplied by three service water pumps. Three backup service water pumps are available and normally aligned to the essential header. The pumps designated for service on the essential header are selected using the service water pump select switch on CCR panel SBF-1. Service water pump breaker control switches with running lights are located on CCR panel SJF for all pumps except backup service water pump 38. The controls for the six main service water pumps have four positions (PULLOUT/STOP/AUTO/ START). The controls for backup service water pumps 37 and 39 do not have an auto-start feature.

Discharge flow and pressure indicators for each main service water pump are mounted locally. The backup pump discharge pressures are also monitored locally. Excessively high differential pressure or strainer malfunction actuates a common alarm in the CCR on panel SJF. Essential and non-essential service water header pressure indicators and low- and high-pressure alarms are provided in the CCR from PI-1190/1191, PA-1112A/1111A and PA-1112B/1111B, respectively. Service water flow from the FCUs is monitored by FT-1121/1122/1123/1124/1125 which provide indication and alarm functions on panel SBF-2. An alarm is provided in the CCR if service water flow to the EDGs fall to 1000 gpm.

H1.2 MAIN STEAM SYSTEM

The atmospheric dump valves (ADVs) are normally-closed, air-operated valves designed to fail closed on loss of power or instrument air. The ADVs may be operated manually from the CCR by placing their individual MANUAL/AUTO controller on panel FBF in the CCR. When in AUTO the ADVs will automatically lift at their manual setpoint.

The MSIVs are swing type stop check valves mounted so that reverse flow will assist in closing the valve. The MSIVs can be closed manually in accordance with emergency operating procedures should the auto signal fail. The control switches are located on panel SBF-1.

The condenser steam dump valves are controlled from flight panel FCF. A mode selector switch determines what parameter is to be used for steam dump control (pressure/ temperature/reset). During normal operation, the temperature mode is selected; for plant cool down, the pressure mode is selected. Four red lights on the flight panel indicate open valves, each light representing three valves.

H1.3 COMPONENT COOLING WATER (CCW) SYSTEM

The CCW pumps are controlled from the SGF panel in the CCR. Each pump has a control switch with START, STOP, AUTO and TRIP pullout positions. Red, green and amber lights are associated with these switches: red for ON, green for OFF and amber for over-current trip. CCW header flow indication is provided an CCR panel SGF. High or low levels in either CCW surge tank are alarmed on Panel SGF. Annunciation is provided on CCR panel SGF for low discharge pressure on CCW loop 1 or 2 and low flow to the RHR pumps. In addition, high heat exchanger outlet temperatures are alarmed on CCR panel SGF.

H1.4 PRIMARY WATER MAKE-UP SYSTEM (PWS)

Refilling the RWST is initiated manually. Normally only one primary water pump is selected to run continuously; the second primary water pump is in automatic standby. The pumps can be manually started from central control room (CCR) panel FCF. The make-up control system sends a start signal to both pumps when automatic make-up is required: the pump in operation continues to run and the standby pump starts. Primary water flow controller FIC-111 and primary water flow totalizer YIC-111 can be manually operated from CCR Panel FBF.

H1.5 AUXILIARY FEEDWATER (AFW) SYSTEM

The AFW motor-driven pumps can start automatically or be started by manual actuation--control switches are placed both locally and in the CCR on the condensate and feedwater supervisory panel SCF. The switches in the CCR have three positions : ON/AUTO/TRIP. The steam-turbine-driven pump is a variable speed device, its speed being controlled by remote pneumatic speed charger station HC-1118 located on condensate and feedwater supervisory panel SCF in the CCR. Turbine steam supply to the AFW pump is indicated and alarmed in the CCR.

AFW pump discharge pressure indicators are provided both locally and in the control room on panel FBF. The water level in the steam generators is maintained manually from the CCR by positioning the flow control valves on panel SCF. SG narrow range indicators are provided on panel FBF, while wide range level and flow indicators are provided on panel SCF.

The positions of manual valves CT-6 and CT-64 in the line from the CST to the AFW pumps are displayed and alarmed in the CCR. Redundant level indicators and control room alarms are provided to monitor the condensate storage tank volume. The valve positions for control valves PCV-1187/1188/1189 in the inlet line from the city water supply are also indicated in the CCR.

Pressure switch PC-1355S, located at the nitrogen bottles, will give an annunciated alarm in the control room to warn the operator when the nitrogen bottles need to be changed. Should city water be aligned to provide suction to the AFW pumps, city water supply pressure indication is provided on CCR panel SCF. Low suction flow to the motor-driven AFW pumps is also alarmed in the CCR.

H1.6 HIGH-HEAD SAFETY INJECTION (HHSI) SYSTEM

Manual actuation of the pumps and most of the motor-operated valves is possible from CCR panel SBF-2. Motor-operated valves SI-1810, SI-842 and SI-843, and AOVs SI-1851A/B can be activated manually from CCR panel SBF-1. Position-indicating lights are provided for each valve in the control room. Redundant level monitoring is provided for the RWST to maintain RWST water levels within technical specification requirements: level transmitter LT-920 provides CCR indication of the RWST on panel SBF-1 and level indication controller LIC-921 provides local indication. Should automatic actuation of the HHSI pumps fail, the operator can start them and open motor-operated valves SI-1852A/B and SI-1835A/B from panel SBF-2 in the control room and close the BIT recirculation isolation valves SI-1851A/B from panel SBF-1.

H1.7 LOW-HEAD SAFETY INJECTION (LHSI) / RESIDUAL HEAT REMOVAL (RHR) SYSTEM

The safety injection signal automatically starts all RHR pumps. The pumps can also be manually actuated from CCR panel SGF. The RHR pump control switches in the control room have four positions (PULLOUT/AUTO/STOP/START) with spring return to AUTO. When the pump switch is in the PULLOUT position, the safeguards equipment locked open alarm will be annunciated on panel SGF in the CCR.

The control switches for the MOVs have three positions (CLOSE/ AUTO/OPEN) with spring return to AUTO. Position-indication lights are provided in the control room for each valve. Manual operation of MOV AC-744, AC-745A/B, SI-1869A/B and SI-883 is possible from CCR panel SBF-1. MOV AC-730, AC-731, SI-638, SI-640, SI-746, SI-747 and SI-899A/B can be operated from CCR panel SGF.

H1.8 RECIRCULATION SYSTEM

The recirculation system is in standby during normal plant operation. The operator activates the system upon receipt of a low level (9.2 ft) signal from the RWST, selecting the operating mode and making the appropriate system alignments. To establish flow using the RHR pump, valve line-ups have to be changed from CCR panel SBF-1. Motor-operated valves SI-888A/B can be opened from CCR panel SBF-1 with their own switches or using recirculation switch RS-5. Motor-operated valves SI-856B and SI-856G can be operated from CCR panel SBF-2. Motor-operated valves SI-885A/B can be opened from the safeguards panel SBF-1 but are interlocked with RHR pump suction motor-operated valves AC-730 and AC-731 so that valves SI-885A/B cannot be opened if AC-730 and AC-731 are open.

Level transmitters LT-1251 and LT-1252 send signals to provide recirculation fluid inventory indication on panel FAF to verify long-term performance of the recirculation pumps. Level transmitters LT-1255 and LT-1256 send signals to provide recirculation fluid inventory indication on panel FAF to help monitor long-term operation of ECCS system.

H1.9 ACCUMULATOR SYSTEM

Motor-operated accumulator isolation valves 894A/B/C/D are normally de-energized and open, their positions being shown by indicating lights in the control room. Furthermore, a safety injection signal will also actuate the valve to ensure they are open.

Levels and pressures in the accumulators are monitored during normal operation to assure the readiness of this system. Two water level transmitters (LT-934A/B/C/D and LT-935A/B/C/D) and two pressure transmitters (PT-936A/B/C/D and PT-937A/B/C/D) are provided for each accumulator. Both level transmitters on each accumulator provide signals to indicate levels and actuate high and low- water level alarms in the control room. Similarly, both pressure indicators actuate high- and low-pressure alarms in the control room.

H1.10 CONTAINMENT SPRAY SYSTEM (CSS)

CSS pumps start automatically upon receipt of the high-high containment pressure signal; manual operation from panel SBF-1 in the control room is also possible. The CSS pump control switches in the control room have four positions (PULLOUT/STOP/AUTO/START) with spring return to AUTO. When the pump switch is in the PULLOUT position, the safeguards equipment locked open alarm will be annunciated on panel SBF-1 in the central control room. Should automatic actuation fail, the operator can start the CSS pumps and open the pump motor-operated discharge valves from panel SBF-1 in the control room.

H1.11 480-Vac ELECTRIC POWER SYSTEM

Current and potential transformers on each 480-V bus operate protective relaying to trip circuit breakers under fault, undervoltage, or underfrequency conditions. Controls for non-fire safe shutdown 480-V circuit breakers are present in CCR panel SHF. Most CCR controls for MCC driven pumps and fans consist of two-position maintained contact switches. Three-position, spring return to center, switches are generally used for motor-operated valves and switchgear circuit breakers. Red and green indicating lights show item status on most switch modules. A red light indicates a closed circuit breaker, open valve or running motor. For motor-operated valves, both lights lit simultaneously indicate that the valve is mid-stroke. CCR panel SHF contains 480-V bus voltmeters and undervoltage relay light. In addition, undervoltage on any 480-V safeguards bus is annunciated on panel SBF-2.

H1.12 118-Vac ELECTRIC POWER SYSTEM

The 118-Vac electric power system consist of eight instrument buses and associated load circuit breakers housed in eight individual distribution cabinets in the CCR. Inverters 31,32 and 33 have trouble lights and alarms on each cabinet to indicate abnormal conditions such as reverse polarity, blown fuses, high cabinet temperature, failure of cabinet cooling fans, ac-dc over/under voltage, inability to synchronize with the alternative ac source, and internal circuit breaker status. Inverters 31, 32, and 33 also have individual annunciator windows on CCR panel SGF that alarm should their transfer switches be in the 'reverse' transfer mode.

H1.13 PRIMARY PRESSURE RELIEF (PPR) SYSTEM

The PORVs can be operated manually from flight panel FCF in the CCR. The control switches for the PORV have three positions: CLOSE/AUTO/OPEN. PORV status is indicated by lights on panel FCF. A common alarm on CCR panel SBF will be triggered if either PORV is not seated. The control switches for the motor-operated block valves are also located on flight panel FCF of the CCR. The switches have four positions (PULLOUT/ CLOSE/AUTO/OPEN). Controllers PC-455G/H/K are used to operate spray valves PCV-455A/B in their manual control mode. The controllers are located on CCR flight panel FBF.

Each code safety valve has an RTD installed in its discharge pipe. When the safety valve is open, the RTD indicates a higher temperature on panel FBF in the CCR. High temperature is alarmed when an RTD senses a temperature of 250°F.

H1.14 CONDENSATE SYSTEM (CDS)

Condensate system flow paths A and B use various heat exchangers for cooling and heating water en route to the main boiler feed pumps. If the flow rate in path A decreases to 2400 gpm, the "Gland Steam Condensate Flow Low" alarm annunciates on the SCF panel in the CCR. Common boiler pump suction header PT-408B indicates boiler feed pump suction pressure on panel FAF in the CCR and provides a signal for the boiler feed pump low suction pressure runback.

On the SCF alarm panel, the "Condenser No. 32 Level" common alarm annunciates in response to signals from LC-1159-S (at 11.5 inches above normal), indicating a condenser hotwell No. 32 high level, and LC-1162-S (at 8.5 inches below normal), indicating a condenser hotwell No. 32 low-low level. Condenser No. 32 level is indicated on the SCF panel by level indicator LI-1130. The pneumatic control piping line to LCV-1129 and to LCV-1128 and LCV-1128A each pass through an auto/manual pneumatic loading station (HC-1149/1148) on panel SCF. These two loaders allow the operator to control air pressure to the excess and make-up condensate level control valve operating bellows.

Condensate pump motor bearings are cooled by the turbine hall closed cooling system. The "condensate pump motor bearing cooling water low pressure" alarm on the SCF panel in the CCR annunciates if the cooling water supply pressure drops to 30 psig. The condensate pumps are started and stopped from the feedwater and condensate supervisory panel SCF in the CCR. The condensate pump motor upper, lower, and thrust bearing temperatures are monitored by a bearing alarm located on panel SKF in the CCR. A high (185°F) temperature alerts the operator of abnormal motor bearing temperature using the "bearing monitor" alarm on the panel SEF in the CCR.

Control switches located on panel SCF allow remote operation of city water valves. Pump suction pressures for each of the three auxiliary boiler feed pumps are indicated on panel SCF in the CCR.

H1.15 MAIN FEEDWATER (MFW) SYSTEM

The boiler feedwater pump turbine speed is controlled from the CCR panel FAF to maintain the feedwater header pressure necessary for proper operation of the steam generator feed regulation valves. The low-flow bypass line regulating valves are controlled using a controller mounted on flight panel FBF in the CCR. The motor-operated main feedwater line isolation valves are operated by CLOSE/AUTO/OPEN switches located at the bottom of panel SCF.

H1.16 CHEMICAL AND VOLUME CONTROL SYSTEM (CVCS)

Charging pumps 31, 32, 33, their associated speed controllers SC-141A/B/C, and the control switches for the boric acid transfer pumps 31 and 32 can be operated from CCR panels FBF and FCF. Emergency borate valve MOV-333 is operated from panel SFF.

H1.17 SAFEGUARDS ACTUATION SYSTEM (SAS)

The safeguards actuation system is installed on four racks in the CCR. Operation of the safeguards actuation system is automatic and does not require operator action. The system is reset manually in the CCR. Reactor trip first-out annunciation is provided on flight panel FDF to indicate the cause of the reactor trip (e.g. undervoltage trip, turbine trip) to the operators. Similarly, turbine first-out annunciators are provided on flight panel FAF.

H1.18 6.9-kVac ELECTRIC POWER SYSTEM

Controls for 6.9-kVac circuit breakers are on panel SHF in the CCR and locally on the switchgear.

H1.19 OFFSITE ELECTRIC POWER SYSTEM

Motor operated disconnect switch BK-5 and circuit breaker BT5-6 are controlled from the CCR with power from 125-V dc power panels 31 or 32. Pilot wire, differential, and primary/backup lock-out relays are located in the CCR.

H1.20 EMERGENCY DIESEL GENERATOR ELECTRIC POWER SYSTEM

Engine and generator instrumentation are located at the local control panel in the diesel generator building. In addition, diesel generator output circuit breaker controls are located on panel SHF in the CCR. There are no manual start/stop controls for the diesel generators in the CCR.

H1.21 CONTAINMENT AIR RECIRCULATION COOLING AND FILTRATION SYSTEM

The safety injection signal automatically starts all containment fan cooler units. The units can also be started manually from CCR panel SBF-2. Control switches for the solenoid valves and position indicating lights for the dampers on each fan cooler unit are located on panel SBF-2 in the CCR.

H1.22 REACTOR POWER

Reactor power level and control rod position are indicated on CCR panel FCF. There are two reactor trip buttons, one on panel FCF and the other on panel SBF-2. The rod control mode selector and control switches are located on panel FCF. The main turbine can be manually tripped from flight panel FAF.

Section H2

CALCULATION OF POST-ACCIDENT HUMAN ERROR PROBABILITIES

H2.1 OPERATOR ACTION B--RECOVERY OF AC POWER

SUMMARY

a. Task. The operators restore ac power and establish core cooling in sufficient time to prevent core damage.

b. Success Criteria. The operators restore power to at least one safeguards bus (5A, 6A, or 2A/3A) and initiate safety injection. The inclusion of the initiation of safety injection is conservative because, depending when ac power is recovered, the RCP seal leak rate may still be within the make-up capacity of one charging pump.

c. Scenario/Event Tree(s) Used. Station blackout (SBO) event tree.

ACTION

a. Initial Conditions. The reactor is initially operating at full power. A loss of offsite power occurs. Subsequently, all three emergency diesel generators fail to start or to run.

b. Preceding Operator Actions. The operators will open the turbine-driven AFW pump flow control valves. If ac power recovery is not imminent, the operators will depressurize the steam generators to minimize RCS inventory loss through the RCP seals. The operators will also commence dc load shedding to preserve battery life.

c. Symptoms. All safeguards buses (5A, 6A, and 2A/3A) de-energized.

d. Indications.
"480V Safeguards Bus Undervoltage" annunciator on panel SBF-2.
480-V bus voltmeter on panel SHF.
480-V bus undervoltage relay lights on panel SHF.

e. Procedural Guidance. Upon receipt of a reactor trip, the operators will enter procedure E-0 (Reactor Trip or Safety Injection). If the EDGs fail to start, step 3 of E-0 will direct the operators to enter ECA-0.0 (Loss of All AC Power) if power cannot be restored to at least one safeguards bus. If ac power is lost subsequent to reaching step 3 of E-0, the

operators will be directed to enter ECA-0.0 from the alarm response procedure for 480-V safeguards bus undervoltage (ARP-5).

f. Response.

ECA-0.0 (Rev. 7)

Step 6.a.1 Direct NPO to manually start all emergency diesel generators (EDGs) per SOP-EL-1 (Diesel Generator Operation).

Step 6.a.2 Contact Con Ed and inform them of the extremely urgent need for ac power.

Step 6.a.3 Attempt to energize 480-Vac buses from offsite power as per SOP-EL-5 (Operation of On-Site Power Sources) or EDGs as per SOP-EL-1 (Diesel Generator Operation).

Step 6.e Start Appendix R DG as per SOP-EL-13.

PERFORMANCE SHAPING FACTORS

a. Timing.

Time Available - The time available to recover ac power depends on several factors: time of RCS depressurization; turbine-driven AFW pump availability; dc power availability; stuck-open PORV; and RCP seal leak rate.

Time Needed - The time needed to recover ac power will vary. Section 1.3.2.3 of the IPPSS [1] presents estimates of the probabilities of non-recovery for offsite power and the diesel generators as a function of time. An estimate of the probability of non-recovery of gas turbine #2 was provided by its owner, Consolidated Edison [15]. Once ac power is recovered, the operators must establish safety injection. It was assumed that 30 minutes are required for the operators to diagnose the need for RCS make-up and perform the necessary actions.

b. Competing Actions/Alarms. None.

c. Consequence of Actions.

Success - Success of this action implies that ac power is restored to at least one safeguards bus and that core cooling is established via safety injection. Because the RCP seal leak rate is time-dependent, ECCS make-up requirements will depend on when ac power is restored. Consequently, core damage may still occur even after ac power is restored.

Failure - Failure to restore ac power in time results in the core being uncovered and subsequent core damage.

d. Training/Experience. The operators have simulator training on station blackout sequences.

e. Stress. Moderately to extremely high.

f. Skill/Rule/Knowledge-Based. Rule-based. Each step is proceduralized.

g. Task Complexity. Simple to complex, depending on the cause of ac power failure. For example, recovery of a failed diesel generator may sometimes be achieved by simply resetting the trip relay and locally starting the diesel generator. At other times, however,, recovery may require the use of technical manuals/drawings or making complex adjustments to the control systems.

QUANTIFICATION

AC power can be restored using four different sources of power: diesel generators; offsite power; the gas turbine unit at Indian Point 2; and the Appendix R diesel generator. The operator action tree for restoration of ac power is shown in Figure H2.1.1. The following table describes the quantification of the failure nodes depicted in Figure H2.1.1. Table H2.1.1 shows the results of this quantification for different times.

Failure Node	Median HEP (Error Factor)	Mean HEP	Source
[a] Diesel Generator Recovery			
	----	Evaluated on a cut-set basis	IPPSS [1], Section 1.3.2.3.

Estimates for the probability of non-recovery of a single EDG were taken from Figure 1.3.2.3-1 in Section 1.3.2.3 of the IPPSS [1]. As the time to recover DG failures depends on the cause of failure, recovery of a failed diesel generator was evaluated for individual cut-sets where necessary.

[b] Offsite Power Recovery			
	----	Table H2.1.1	IPPSS, Section 1.3.2.3.

Estimates for the probability of non-recovery of offsite power were obtained using the methodology described in NUREG/CR-5032 [16]. This methodology divides plants into three groups based on their switchyard configuration and the number of sources of offsite power available. IP3 was placed in the group associated with the most conservative estimates of the probability of non-recovery. A point estimate approximation of Equation

23 in NUREG/CR-5032, quantified using lognormal fits to plant-centered, grid, and weather related data sets and weighting factors equal to the fraction of events that fall in a particular data set, was then used to derive mean values for the probability of non-recovery as a function of time. Figure H2.1.2 compares the non-recovery curve used with the empirical data presented in NUREG/CR-5032 and the curve fit to those data.

[c] Operation of Gas Turbine

----	Not credited	Reference 15.

Estimates for the unavailability of the gas turbine, including unavailability caused by hardware failures and maintenance, are presented in Reference [15]. However, no credit was taken for operation of the gas turbine because the estimated probabilities of non-recovery of offsite power may account for such a power source.

[d] Operation of Appendix R Diesel Generator

----	Table H2.1.1	Plant-specific data, NUREG/CR-4772 [17]

The unavailability of the Appendix R diesel generator caused by hardware failures was conservatively estimated to be 0.1. The HEP associated for operation of the Appendix R diesel generator was calculated using the nominal diagnosis model in NUREG/CR-4772 assuming 40 min. are required to align the diesel generator.

The probability of non-recovery of ac power and subsequent core damage were evaluated with and without RCS depressurization. The probabilities of the core being uncovered (and subsequently damaged), given successful ac power recovery and unqualified high temperature RCP seals, were derived from WCAP-10541 [2]. The final results for the quantification are shown in Figure H2.1.3 and Figure H2.1.4 for the case with RCS depressurization and without RCS depressurization, respectively.

The calculated probability of non-recovery of ac power with subsequent core damage for the case in which the RCS is depressurized is 7.1×10^{-3}. For the case where the RCS is not depressurized, the probability increases to 9×10^{-3}. These probabilities represent the recovery factors applied to selected station blackout sequences.

Table H2.1.1. Time-Dependent Probabilities for Non-Recovery of AC Power

Time of AC Power Recovery	Probability of Non-Recovery Of At Least 1 DG [1]	Probability of Non-Recovery of Offsite Power	Probability of Non-Recovery of Gas Turbine [2]	Probability of Non-Recovery of App. R DG	Total Prob. of Non-Recovery of AC Power
1.0 hr	1.00	0.47	1.00	0.13	6.1E-2
2.0 hr	1.00	0.34	1.00 (0.35)	0.1	3.4E-2
3.0 hr	1.00	0.25	1.00 (0.35)	0.1	2.5E-2
4.0 hr	1.00	0.18	1.00 (0.35)	0.1	1.8E-2
5.0 hr	1.00	0.13	1.00 (0.27)	0.1	1.3E-2
6.0 hr	1.00	0.095	1.00 (0.27)	0.1	9.5E-3
7.0 hr	1.00	0.071	1.00 (0.27)	0.1	7.1E-3
8.0 hr	1.00	0.055	1.00 (0.27)	0.1	5.5E-3

[1] No credit was given to recovery of a failed emergency diesel generator.

[2] No credit was given to the use of the Con Ed gas turbines -- use of the gas turbines was assumed to be included in the offsite power recovery curve. The numbers in parentheses indicate the anticipated probabilities for non-recovery if credit is given to the Con Ed gas turbine(s).

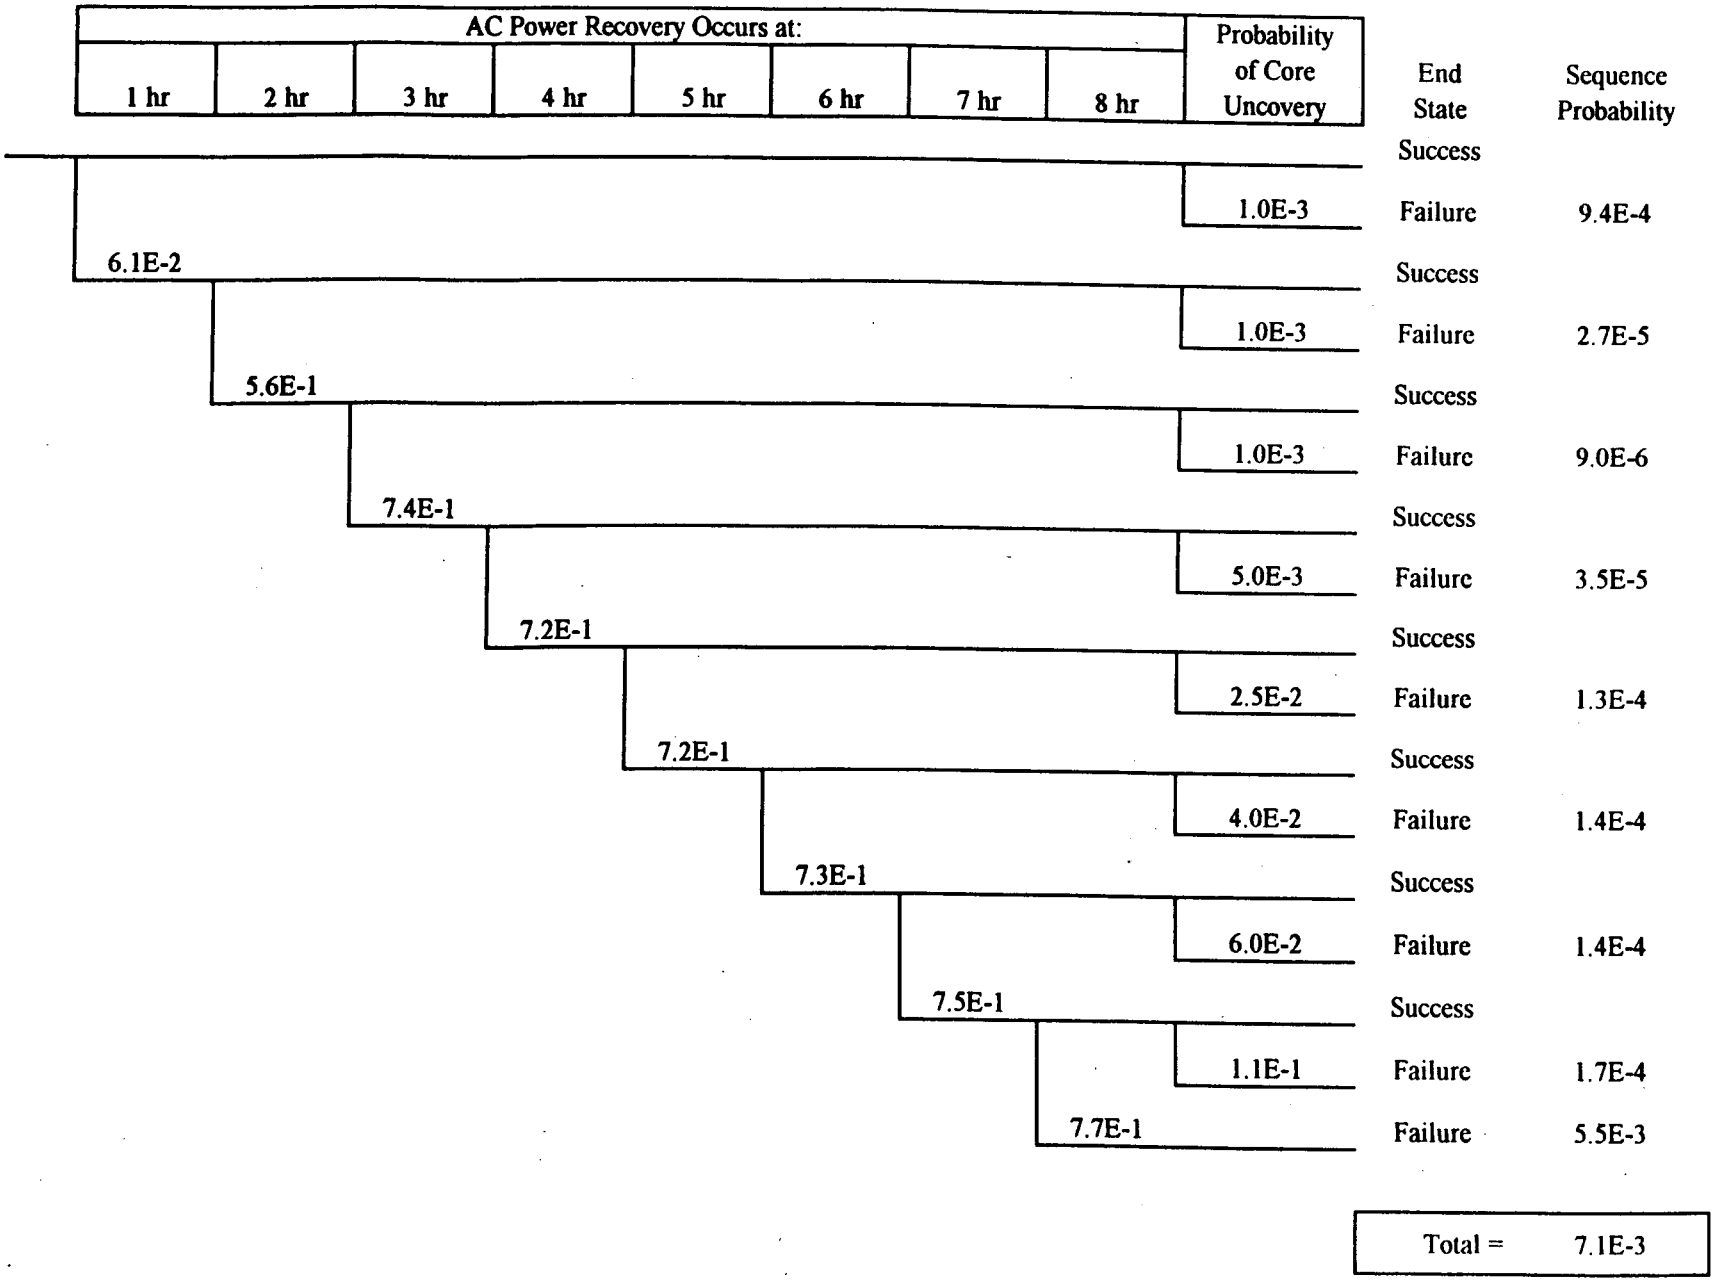

Figure H2.1.4. Sequence Quantification for Recovery of AC Power Without RCS Depressurization

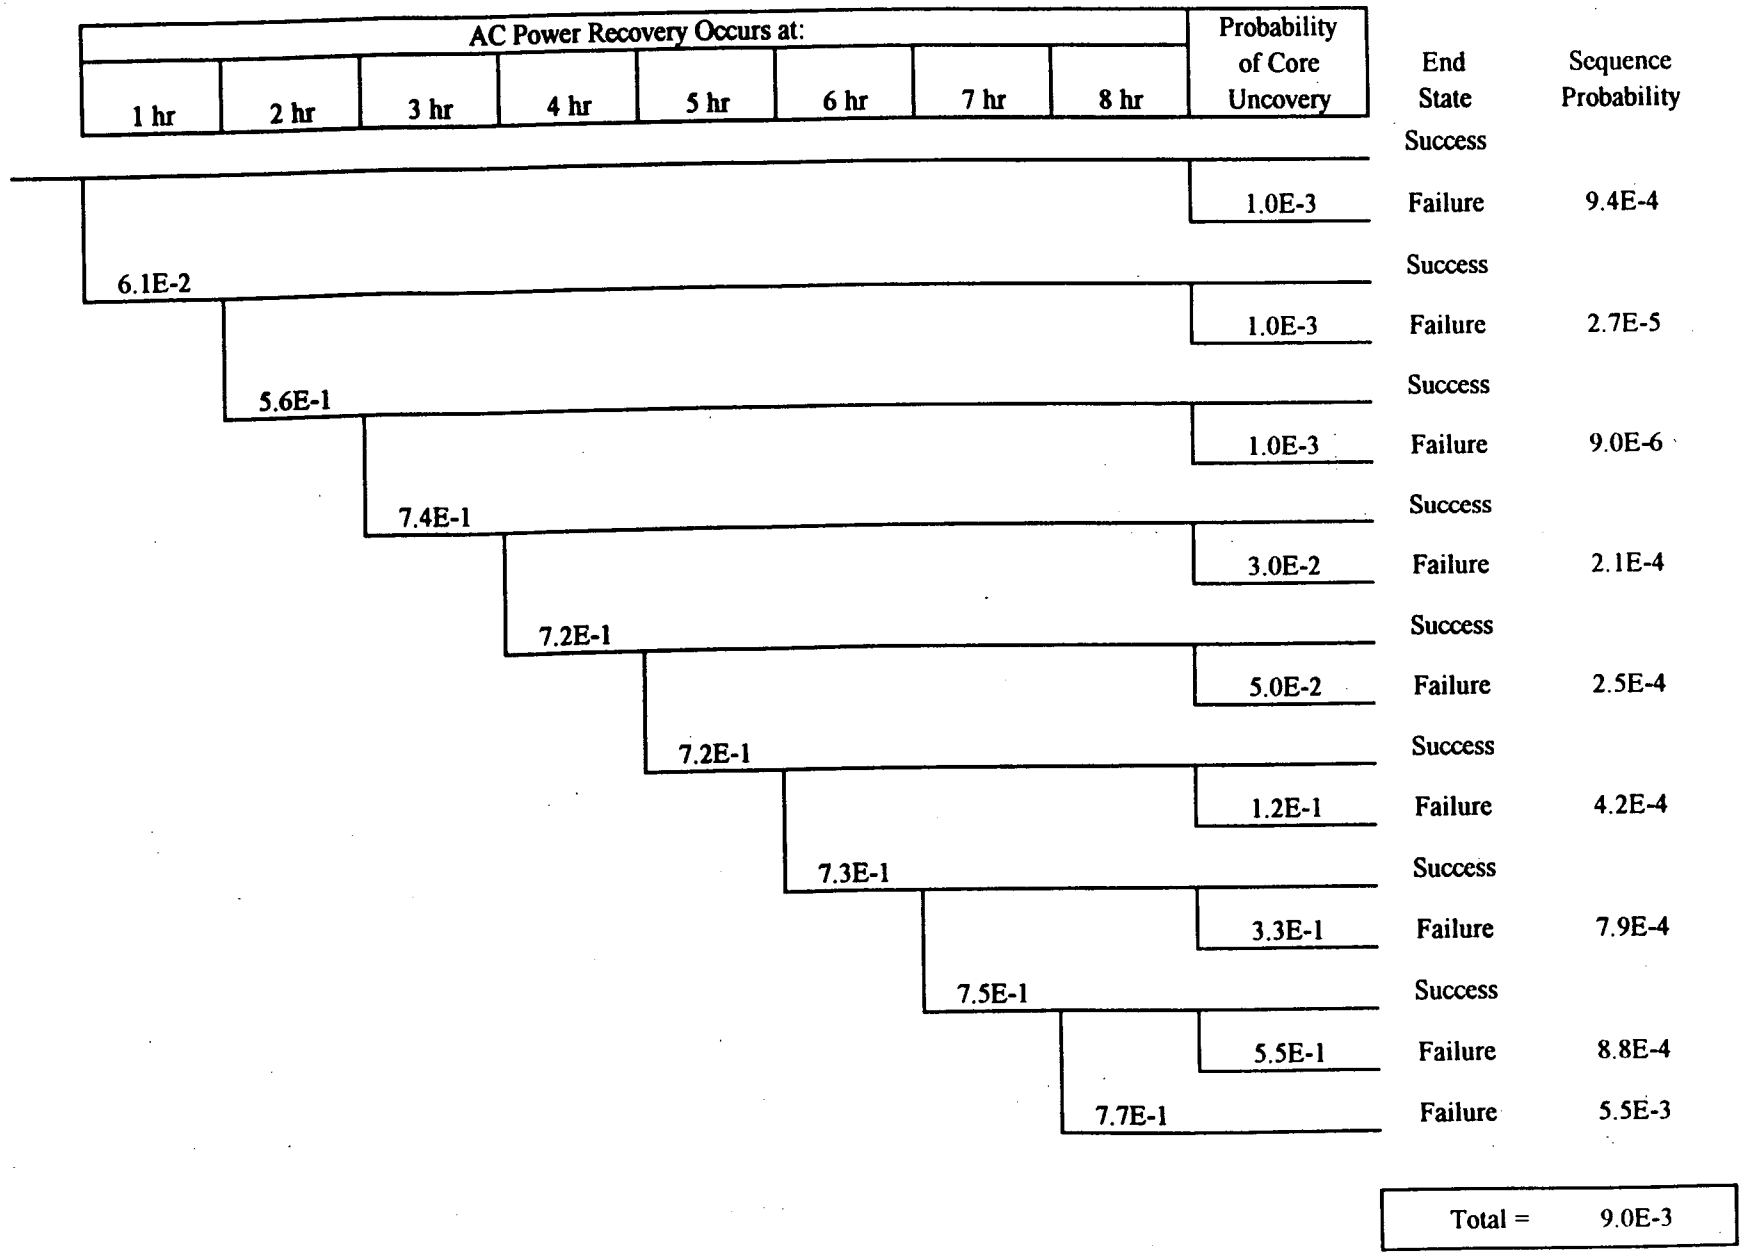


H2.2 OPERATOR ACTION CWRHR--OPERATORS ALIGN BACKUP CITY WATER TO RHR PUMP 31

SUMMARY

a. Task. The operators establish cooling to RHR pump 31 using backup city water.

b. Success Criteria. Sufficient backup city water is supplied to cool RHR pump 31.

c. Scenario/Event Tree(s) Used. Special initiators (TCCW and TSWS).

ACTION

a. Initial Conditions. The reactor is operating at full power. A total loss of component cooling water occurs. A loss of RCS inventory ensues as a result of a loss of RCP seal cooling or a stuck-open PORV.

b. Preceding Operator Actions. The operators will attempt to establish backup city water to the charging pump coolers to provide continued cooling of the RCP seals.

c. Symptoms.
Low component cooling water discharge pressure.
Low RHR pump cooling flow.

d. Indications.
"Component Cooling Pump Loop 1 Discharge Low Pressure" annunciator on panel SGF.
"Component Cooling Pump Loop 2 Discharge Low Pressure" annunciator on panel SGF.
"RHR Pump Cooling Low Flow" annunciator on panel SGF.
CCW flow indicators FI-601A/B on panel SGF.
CCW-to-RHR pump flow indicators FIC-645 and FIC-646 (local indicators).

e. Procedural Guidance.
Alarm response procedure ARP-10 directs the operator to enter procedure ONOP-CC-1. Step 5.9 of ONOP-CC-1 directs the operators to tie in the backup city water cooling to RHR pump 31 using SOP-CC-1B.

f. Response.

ONOP-CC-1 (Rev. 7)

Step 5.9 If component cooling cannot be re-established and the charging or RHR pumps are to be operated, tie in the backup city water to the pumps as per SOP-CC-1B.

SOP-CC-1B (Rev. 11)

Step 4.4.1.a Close valves AC-736A, AC-737A, and AC-1871D (located in RHR pump room--15-ft elevation in PAB).

Step 4.4.1.b Install the city water supply jumper between water supply valve MW-18-16 and the tee immediately downstream of valve AC-736A. Install the drain hose onto the tee immediately downstream of valve AC-1871D. (The city water jumper hose and MW-18-16 are located on the 15-ft elevation in the PAB).

Step 4.4.1.c Open the city water supply valve MW-18-16.

PERFORMANCE SHAPING FACTORS

a. Timing.

Time Available - According to SOP-CC-1B (Step 4.4), the RHR pumps can operate without CCW for 24 hours. However, this assumes that RCS pressure is below the shut-off head of the RHR pumps. If RCS pressure is above the shut-off head of the RHR pumps, functional restoration procedure FR-C.1 cautions that the RHR pumps should not be run for more than 1.75 hours (105 minutes) without component cooling water. The quantification assumed that RCS pressure remains above the shut-off head of the RHR pumps for the first 105 minutes, at which time if city water cooling to RHR pump 31 is not established, RHR pump 31 (together with RHR pump 32) will fail.

Time Needed - 30-35 minutes. This estimate is based on walk-throughs and operator judgement. An operator simulated the task and concluded that, if only one operator were assigned to the task, repeated trips in and out of the RHR pump room would be required. Each trip would require the donning and removal of protective clothing.

b. Competing Actions/Alarms. The operators will be implementing the EOPs when they must make the decision to enter ONOP-CC-1.

c. Consequence of Actions.

Success - Success implies continued operation of RHR pump 31.

Failure - Failure results in failure of both RHR pumps and subsequent core damage.

d. Training/Experience. The operators have been trained on how to respond to a loss of CCW flow to the RHR pumps.

e. Stress. Moderate to high.

f. Skill/Rule/Knowledge-Based. Rule-based. Each step is proceduralized.

g. Task Complexity. Low to moderate

QUANTIFICATION

The operator action tree for CWRHR is shown in Figure H2.2.1. The following table describes the quantification of the failure nodes depicted in Figure H2.2.1. The mean HEP for operator action CWRHR is 3.3×10^{-2}.

Failure Node	Median HEP (Error Factor)	Mean HEP	Source (NUREG/CR-4772)
[a] Operator Diagnoses Need for City Water to RHR Pump 31			
	8.96×10^{-5} (EF=30)	7.6×10^{-4}	Table 8-2, interpolating between item 5 and item 6 (70 minutes)

Assuming that the RHR pumps will fail in 105 minutes given loss of CCW cooling and that 15 minutes is required for the NPO to establish city water cooling to RHR pump 31, diagnosis must occur within 105 - 35 minutes = 70 minutes. Given that low component cooling pump discharge pressure and low RHR pump cooling flow conditions are annunciated, the use of the median joint diagnosis curve in Table 8-2 of the ASEP HRAP to predict the HEP is felt to be conservative.

[b] Operator Performs Required Actions			
	0.02 (EF=5)		Table 8-5, item 3.
	x 5		Five critical actions.
	0.10 (EF=5)	0.161	

The critical post-diagnosis actions are closing valves AC-736A, AC-737A, and AC-1871D; installing the city water supply jumper; and opening MW-18-16. These are step-by-step actions performed under moderately high stress.

[c] Recovery

Failure to align valves properly will be indicated by lack of city water flow through the drain--flow indication (FIC-646) will be lost because of closure of manual valve AC-737A. Even though the only credible recovery action in this case is essentially a check by the operator assigned to perform the action, failure to perform the action will be quite obvious. Therefore, the post-diagnosis HEP calculated above was reduced by a factor of 5, corresponding to the associated error factor in Table 8-5.

COMMENT

It was assumed that diagnosis in operator action CWRHR repeats the diagnosis in operator action SLOCA, the alignment of city water back-up to the charging pumps (Section H2.17) but with less time available. Thus, given diagnostic error in operator action SLOCA, diagnostic error in operator action CWRHR was assumed.

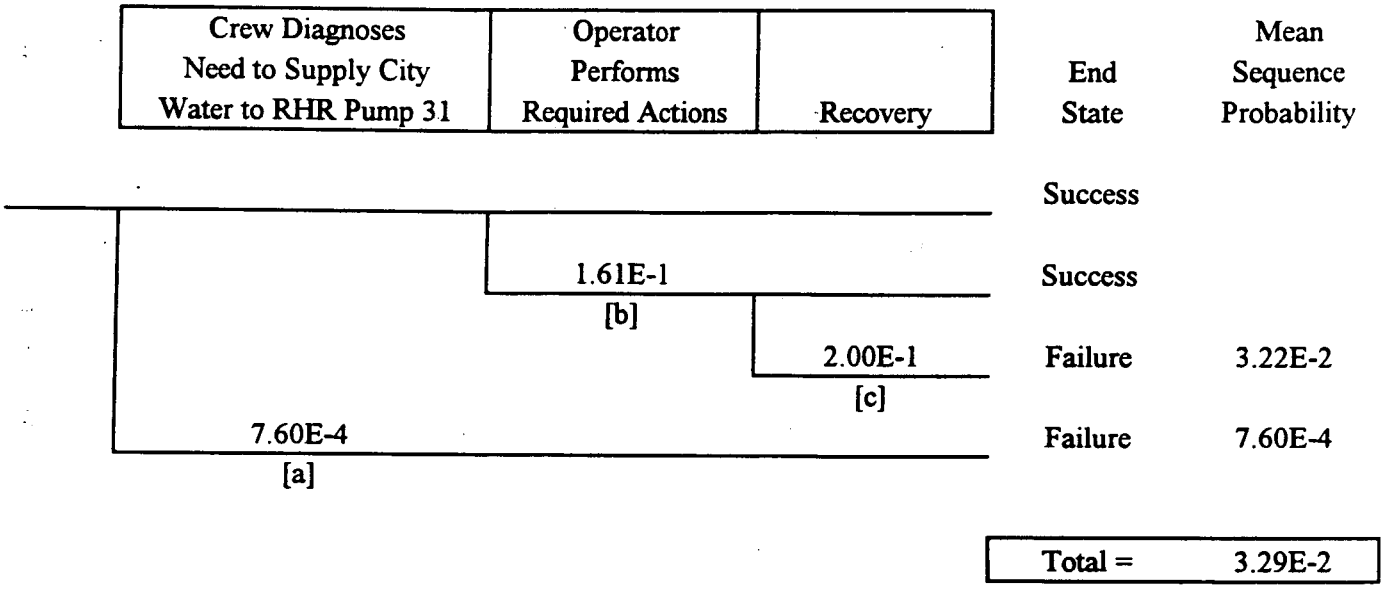
The absence of diagnostic error in operator action SLOCA was not, however, judged to reduce the probability of diagnostic error in operator action CWRHR. Thus, the HEP for operator action CWRHR given the failure of operator action SLOCA can be expressed as

$$SLOCA \times CWRHR|SLOCA = SLOCA \cap CWRHR, \text{ or}$$

$$0.021 \times CWRHR|SLOCA = 6.9\times10^{-4} + (1 - 6.9\times10^{-4})(0.0208)(0.033) = 1.38\times10^{-3}$$

$$\therefore CWRHR|SLOCA = 0.066$$

Figure H2.2.1: Human Action CWRHR - Backup City Water Provided to RHR Pump 31



H2.3 OPERATOR ACTION FB--OPERATOR INITIATES PRIMARY BLEED-AND-FEED COOLING

SUMMARY

a. Task. Operators establish core cooling using bleed and feed.

b. Success Criteria. Bleed-and-feed cooling requires at least one HHSI pump and both PORVs.

c. Scenario/Event Tree(s) Used. MSLB (T4, T5), SBO, SGTR, small LOCA, special initiators (TAC5A, TAC6A, TCCW, TSWGR, TSWS), transients (T1, T2)

ACTION

a. Initial Conditions. The reactor is operating at full power. A reactor trip occurs with subsequent loss of main feedwater. All AFW pumps fail to start or are otherwise unable to deliver sufficient flow to the steam generators.

b. Preceding Operator Actions. The operators will attempt to establish AFW flow from the control room.

c. Symptoms.
Loss of secondary cooling.
"RED" path on critical safety function "HEAT SINK".

d. Indications.
SG narrow range level (LI-417A/B/C, LI-427A/B/C, LI-437A/B/C, LI-447A/B/C) on panel FBF.
SG wide range level (LR-417-1/2, LR-437-1/2) on panel SCF.
AFW flow (FI-1200, FI-1201, FI-1202, FI-1203) on panel SCF.

e. Procedural Guidance. Upon a reactor trip, the operators will enter procedure E-0 (Reactor Trip or Safety Injection). If a safety injection signal is present, Step 20 of E-0 will transfer the operators to FR-H.1 (Response to Loss of Secondary Heat Sink) if total AFW flow is less than 355 gpm. If safety injection has not occurred (and is not needed), the operators will transfer to ES-0.1 (Reactor Trip Response). Once E-0 is exited, the STA is required to monitor the critical safety function (CSF) status trees. The functional restoration procedure for loss of secondary heat sink, FR-H.1, cautions the operators to trip all RCPs and initiate bleed-and-feed cooling immediately if the wide range level in any two SGs is less than 68 percent. Because condensate flow to the SGs cannot be established before the above criteria are met and the limited time available to successfully initiate bleed-and-feed, the operators are trained to initiate bleed-and-feed immediately.

f. Response.

FR-H.1 (Rev. 6)
Step 3 Stop all RCPs [on panel SAF].

Step 8a Manually start 3 HHSI pumps [on panel SBF-2].

Step 9 Verify RCS feed path.

Step 10 Establish RCS bleed path:
- a. Verify power to pressurizer PORV block valves available. If not, dispatch NPO to restore power to block valve RC-MOV-536 at MCC-36A and to RC-MOV-535 at MCC-36B [PAB - 55-ft elevation].
- b. Verify both pressurizer PORV block valves open. If not, open block valves [on flight panel FCF].
- c. Open both pressurizer PORVs [on flight panel FCF].

Step 11 Verify all pressurizer PORVs and block valves open.

PERFORMANCE SHAPING FACTORS

a. Timing.

Time Available - MAAP calculations have shown that if the operators fail to trip the RCPs, bleed-and-feed cooling will not be successful. It was determined that successful bleed-and-feed cooling can be established within 25 minutes of reactor trip provided that the RCPs are tripped 5 minutes after reactor trip. If the RCPs are tripped at 10 minutes, bleed-and-feed must be established before 20 minutes has elapsed after the reactor trip. If the RCPs are tripped at 15 minutes, bleed-and-feed must be initiated within the following 2 minutes.

Time Needed - If power is available to the PORV block valves, primary bleed and feed cooling can be completed within 2 minutes of tripping the RCPs. However, if a PORV block valve is not energized, it is assumed that initiation of bleed-and- feed cooling requires an additional 5 to 10 minutes because an NPO will have to locally energize the block valves at the MCCs. For quantification of the latter case, 10 minutes was assumed.

b. Competing Actions/Alarms. The only competing actions expected are those for restoring feedwater flow to the SGs. However, as the operators have been trained extensively on the importance of promptly establishing bleed-and-feed, the impact of competing actions on operator action FB is expected to be minimal.

c. Consequence of Actions.

Success - Success implies successful core cooling.

Failure - Failure requires secondary heat removal via the condensate system. If the condensate system is unavailable, core damage will occur.

d. Training/Experience. The operators are trained to initiate bleed-and-feed cooling immediately upon entering FR-H.1. Attempts to align condensate flow would be made if bleed-and-feed cooling is unsuccessful.

e. Stress. Moderately high.

f. Skill/Rule/Knowledge-Based. Rule-based. Each step is proceduralized.

g. Task Complexity. Low

QUANTIFICATION

The operator action tree for the initiation of bleed-and-feed cooling is depicted in Figure H2.3.1. The following table describes the quantification of the failure nodes depicted in Figure H2.3.1. The mean HEP for operator action FB was calculated to be 0.012.

Failure Node	Median HEP (Error Factor)	Mean HEP	Source (NUREG/CR-4772)
[a] Both PORV Block Valves Open			
	---	1.0	Estimate of the fraction of time that one or both PORV block valves are closed.

Based on PORV leakage problems, both block valves were assumed to be closed during normal operation.

[b] Both PORV Block Valves Energized			
	---	0.05	Estimate of the time that one or both PORV block valves are de-energized given that they are closed.

Given that a block valve is closed, it was conservatively assumed that there is a 5 percent probability that the block valve is de-energized because of an inoperable, as opposed to

leaking, PORV.

[c] Operator Diagnoses Need for Bleed and Feed (Given Both PORV Block Valves Open or Energized)

2.60×10^{-3} (EF=10)	6.93×10^{-3}	Using the lower bound and interpolating for 15 minutes in Table 8-2.

Because the time available to successfully establish bleed-and-feed is dependent on when the RCPs are tripped, the time available for diagnosis is the latest time at which the RCPs can be tripped and bleed and feed established. With both PORV block valves open (or closed but energized), the time available for diagnosis (beginning with tripping the RCPs) is 15 minutes. Because of the training received by the operators on this action, the lower bound HEP in Table 8-2 was used.

[d] Operators Diagnose Need for Bleed and Feed (Given One or Both Block Valves Closed and De-energized)

10^{-2} (EF=10)	2.66×10^{-2}	Table 8-2 (lower bound).

With one or both PORV block valves closed and de-energized, an NPO must be dispatched to energize the block valve(s) at the MCCs. Since travel time alone could be 5 minutes, the time available for diagnosis (beginning with tripping the RCPs) is reduced from 15 minutes (as explained for node [c]) to 10 minutes. Because of the training received by the operators on this action, the lower bound HEP in Table 8-2 was used.

[e] Operators Trip Reactor Coolant Pumps (Given Both PORV Block Valves Open or Energized)

0.004 (EF=5)	6.46×10^{-3}	Table 8-5, item 3 (lower bound).

Tripping the RCPs is a step-by-step action under moderately high stress. The lower bound value in Table 8-5 was used because frequent simulator training has made control room personnel very familiar with this action.

0.15 (EF=5)	0.24	NUREG/CR-1278, moderate dependence.

SS recovers error by the operator, assuming moderate dependence.

Total [e] = $6.46\times10^{-3} \times 0.24 = 1.55\times10^{-3}$

[f] Operators Trip Reactor Coolant Pumps (Given One or Both PORV Block Valves Closed and De-Energized)

0.004 (EF=5)	6.46×10^{-3}	Table 8-5, item 3 (lower bound).

Same as node [e] except that no credit was given to the SS recovering the failure to trip the RCPs given that one or both block valves are closed and de-energized--the SS was assumed not to be available within the first ten minutes.

[g] Operators Perform Required Actions (Given Both PORV Block Valves Open)

0.004 (EF=5)		Table 8-5, item 3 (lower bound).
x 2		Two critical actions.
0.008 (EF=5)	0.0129	

Moderately high stress was assumed for failure of the operators to start the HHSI pumps or open both PORVs. However, frequent simulator training has made control room operators very familiar with this particular scenario. Therefore, the lower bound value of the HEP was used (see Table 8-1, item 10.f).

0.054 (EF=5)	0.087	NUREG/CR-1278, low dependence.

SRO fails to verify bleed and feed at Steps 9 and 11, respectively, of FR-H.1.

Total [g] = $0.0129 \times 0.087 = 1.12 \times 10^{-3}$

[h] Operators Perform Required Actions (Given One or Both Block Valves Closed But Energized)

0.004 (EF=5)		Table 8-5, item 3 (lower bound).
x 3		Three critical actions.
0.012 (EF=5)	0.0194	

Failure of the operators to start the HHSI pumps, open the block valves, or open both PORVs. Moderately high stress was assumed. However, frequent simulator training has made control room operators very familiar with this particular scenario. Therefore, the lower bound value of the HEP was used (see Table 8-1, item 10.f).

0.054 (EF=5)	0.087	NUREG/CR-1278, low dependence.

SRO fails to verify bleed and feed at Steps 9 and 11, respectively, of FR-H.1.

Total [h] = $0.0194 \times 0.087 = 1.69 \times 10^{-3}$

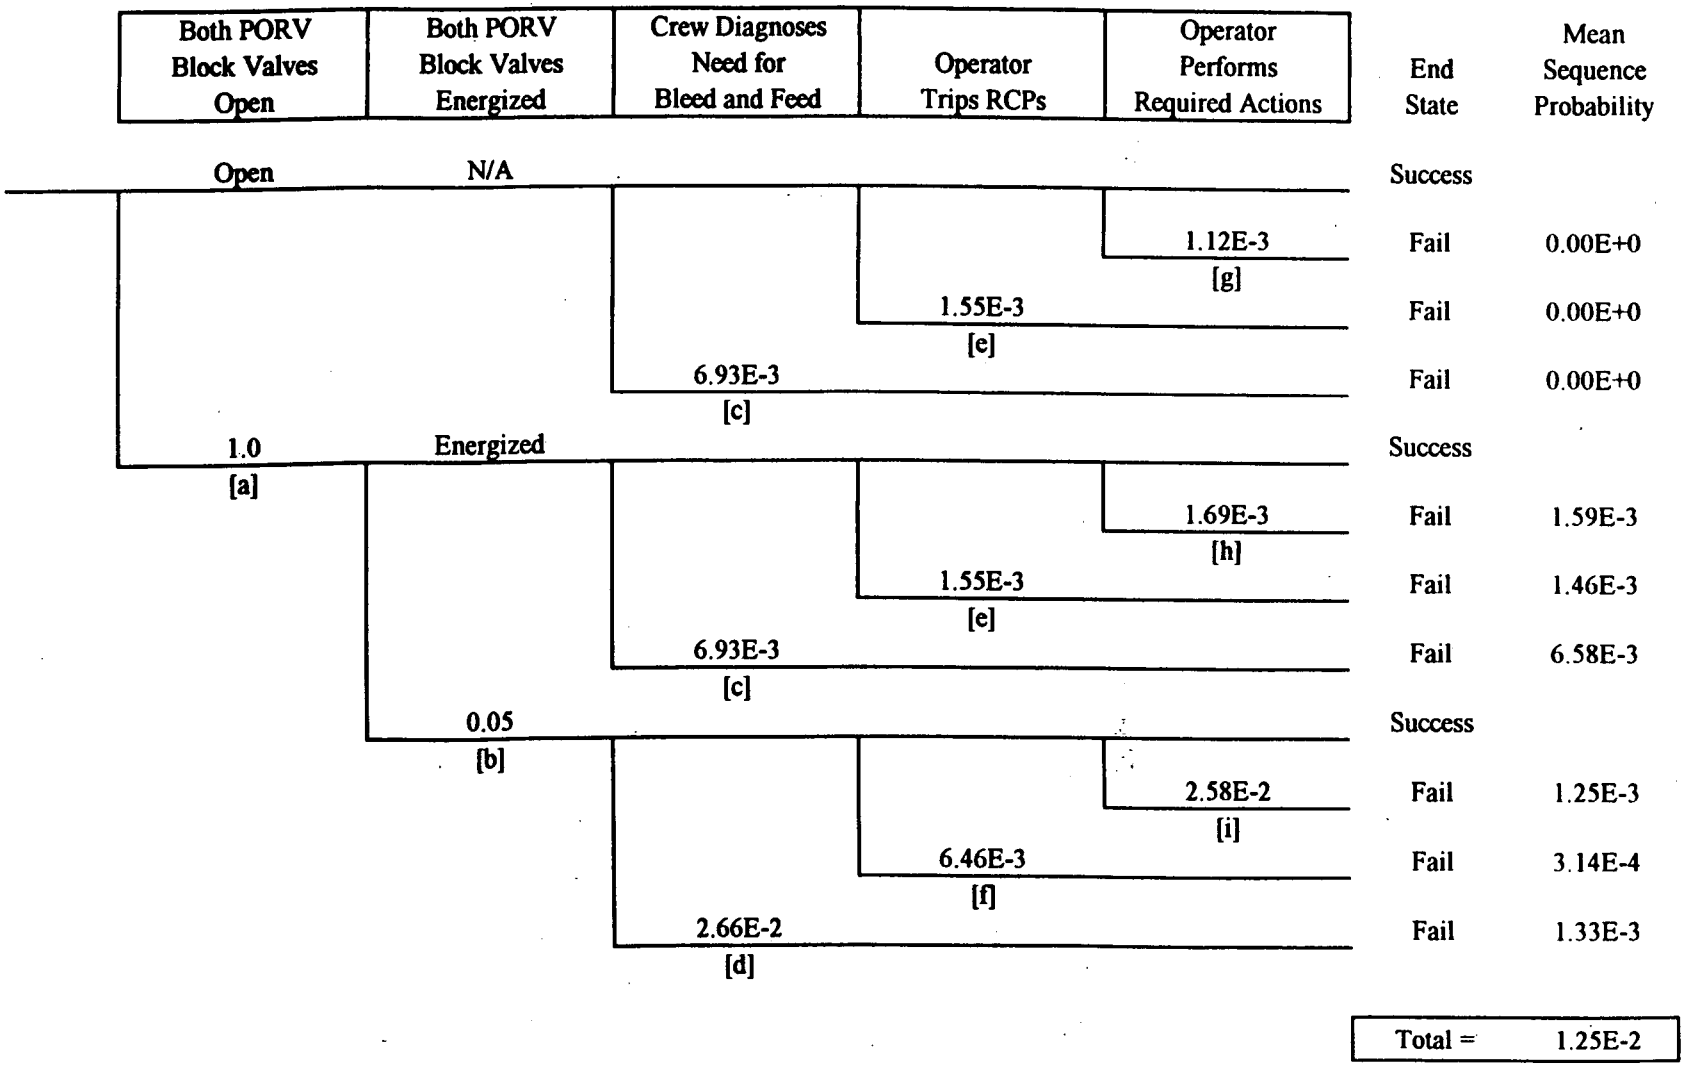
[i] Operators Perform Required Actions (Given One or Both Block Valves De-energized)

0.004 (EF=5)		Table 8-5, item 3 (lower bound).
x 4		Four critical actions.
0.016 (EF=5)	0.0258	

Moderately high stress was assumed for failure of the operators to start the HHSI pumps, energize the block valves, open the block valves, or open both PORVs. However,

frequent simulator training has made control room operators very familiar with this particular scenario. Therefore, the lower bound value of the HEP was used (see Table 8-1, item 10.f). No credit for recovery was taken because of the limited time available to recover errors.

Figure H2.3.1. Human Action FB - Operator Initiates Primary Bleed and Feed Cooling



H2.4 OPERATOR ACTION HLR--HOT-LEG LONG-TERM RECIRCULATION CORE COOLING

SUMMARY

a. Task. 21 hours after the initiating event, operators realign HHSI or RHR/recirculation pumps for hot leg recirculation.

b. Success Criteria. One of two RHR or one of two recirculation pumps deliver flow to one of two hot legs.

c. Scenario/Event Tree(s) Used. Large LOCA.

ACTION

a. Initial Conditions. The reactor is at full power. A break in the RCS occurs which is large enough to reduce RCS pressure to less than the shut-off head of the RHR/ recirculation pumps and to actuate containment spray. The reactor is tripped and SI actuated. At least one RHR/recirculation pump is available. Transfer to cold leg recirculation is successful.

b. Preceding Operator Actions. The operator will have transferred to cold leg recirculation.

c. Symptoms. Not applicable.

d. Indications. Not applicable.

e. Procedural Guidance. After having established cold leg sump recirculation as dictated by ES-1.3 (Transfer to Cold Leg Recirculation), step 54 of ES-1.3 directs the operators to enter ES-1.4 (Transfer to Hot Leg Recirculation) 8 hours after event initiation.

f. Response.

ES-1.3 (Rev. 7)

Step 2 Place recirculation switch 1 [on panel SBF-1] to OFF position.

Step 3 Locally energize valve control circuits:
- a. Hot leg injection line valve 856B at MCC-36B [PAB - 55-ft elevation].
- b. Hot leg injection line valve 856G at MCC-36A [PAB - 55-ft elevation].

Step 4 Align non-BIT hot leg injection valves [on panel SBF-2]:
- a. Close 856J and 856H.

c. Open 856B.

Step 5 Align BIT hot leg injection valves [on panel SBF-2]:
a. Close 856C and 856E.
c. Open 856G.

Step 7 Align recirculation flow to hot legs:
a. Open low-head to high-head valves 888A/B [on panel SBF-1].
b. Open 1869A/B [on panel SBF-1].
c. Open HHSI pump 32 suction valves 887A/7B [on panel SBF-2].
d. Place SI pump suction low pressure alarm block switch to UNBLOCK position.
f. Place recirculation switch 6 to OFF position [on panel SBF-1].
g. Open HHSI pump 32 discharge valve 851A/B and then start all 3 HHSI pumps [on panel SBF-2].
h. Close RHR heat exchanger discharge flow valves HCV-638 and HCV-640 [from panel SGF].
i. Verify minimum core cooling established as indicated by Graph ES14-1.

PERFORMANCE SHAPING FACTORS

a. Timing. Procedures direct the operators to transfer to hot leg recirculation 8 hours after event initiation.

Time Available - The transfer to hot leg recirculation is not required until 21 hours after the initiating event. Therefore, 21 - 8 = 13 hours are available for the operators to complete the transfer to hot leg recirculation.

Time Needed - 30 minutes.

b. Competing Actions/Alarms. None.

c. Consequence of Actions.

Success - Success results in continued core cooling.

Failure - Failure to realign ECCS pump discharge is assumed to result in boron precipitation blocking coolant flow and causing eventual core damage. This assumption is conservative since only breaks of a certain size and at specific locations are expected to require hot leg recirculation.

d. Training/Experience. The operators have been trained in this action.

e. Stress. Normal. The operators will be under high stress initially in reacting to the LOCA. However, by the time transfer to hot leg recirculation is to be made (8 hours), the operators are expected to be at a normal stress level given prior success of equipment and operator actions.

f. Skill/Rule/Knowledge-Based. Rule-based. Each step is proceduralized.

g. Task Complexity. Low.

QUANTIFICATION

A value of 10^{-4} has been assumed for the mean HEP based on the very long time available for this action (several hours), the simple nature of the actions involved, and the indications available to the operators in the event that an error is made. In addition, not all large-break LOCA events will require this action. Failure to realign the recirculation/RHR pumps for hot leg sump recirculation is expected to be dominated by hardware failures.

H2.5 OPERATOR ACTION LTS--LONG-TERM SHUTDOWN VIA EMERGENCY BORATION OF RCS OR LOCAL TRIPPING OF THE REACTOR TRIP BREAKERS/MG SETS

SUMMARY

a. Task. Should the reactor not scram, the operators must establish long-term shutdown by performing emergency boration or, for ATWS events not caused by mechanical failure of the control rods, locally tripping the reactor trip breakers or MG sets.

b. Success Criteria. The operators must perform the above tasks within 10 minutes.

c. Scenario/Event Tree(s) Used. ATWS.

ACTION

a. Initial Conditions. The reactor is operating at full power. A loss of main feedwater occurs, necessitating a reactor trip. However, the reactor fails to trip.

b. Preceding Operator Actions. The operator will attempt to manually trip the reactor. The operator will also verify turbine trip and AFW initiation and perform manual rod insertion (if the control rods are not in AUTO).

c. Symptoms.
Failure of reactor to trip.
"RED" path on critical safety function "SUBCRITICALITY".

d. Indications.
Rod bottom lights not lit.
Reactor trip and bypass breakers not open.
Rod position indicators not at zero.
Neutron flux not decreasing.

e. Procedural Guidance. Upon receiving indications of the need for a reactor trip (e.g., loss of main feedwater, turbine trip, etc.), the operators will enter procedure E-0 (Reactor Trip or Safety Injection). If unable to verify a reactor trip at step 1 of E-0, the operators will enter functional restoration procedure FR-S.1 (Response to Nuclear Power Generation/ ATWS). Long-term shutdown is classified as an immediate action step which the operators are expected to be able to perform from memory.

f. Response.

FR-S.1 (Rev. 4)--Local Tripping of the Reactor Trip Breakers/MG Sets

Step 1 If reactor will not trip, dispatch an NPO to locally open reactor trip breakers, or open the MG set output breakers, or open the MG set motor supply breakers [control building - 33-ft elevation].

FR-S.1 (Rev. 4)--Initiate Emergency Boration of RCS

Step 4.a Verify one charging pump running [on flight panel FBF].
Step 4.b Open emergency borate valve MOV-333 [from panel SFF].
Step 4.c Start both boric acid transfer pumps in high speed [from flight panel FCF].
Step 4.d Transfer operating charging pump to manual control and increase speed to maximum [from flight panel FBF].

PERFORMANCE SHAPING FACTORS

a. Timing.

Time Available - Long-term shutdown is assumed to be required within 10 minutes of the initiating event to prevent the reactor from becoming critical again as the plant cools down. For the loss of main feedwater ATWS, reactor power starts to increase again after about 6 minutes [4]. The time limit of 10 minutes is conservative because the RCS may experience several reactor power transients before core damage occurs.

Time Needed - Two minutes for emergency boration and 5-8 minutes for locally tripping the reactor trip breakers/MG sets.

b. Competing Actions/Alarms. Depending on the initiator, many alarms could be sounding when emergency boration is to be initiated (i.e., within the first 5 minutes). However, the operators will initially focus on performing the immediate action steps in FR-S.1, which include initiating emergency boration and locally tripping the reactor trip breakers/MGs.

c. Consequence of Actions.

Success - Success ensures long-term reactor shutdown (subcriticality).

Failure - Failure is assumed to result in a high pressure core melt.

d. Training/Experience. The operators have had extensive training on this action using the control room simulator.

e. Stress. Extremely high stress is assumed because of the seriousness of an ATWS event and the rapid response required.

f. Skill/Rule/Knowledge-Based. These actions are both skill- and rule-based. The operators have experience performing the actions during simulator exercises, and the action to implement emergency boration is an immediate action step committed to memory (skill-based). The actions are also rule-based because they are proceduralized in FR-S.1.

g. Task Complexity. Low.

QUANTIFICATION

The operator action tree for long-term shutdown is depicted in Figure H2.5.1. The following table describes the quantification of the failure nodes depicted in Figure H2.5.1. The total HEP for Operator Action LTS was estimated to be 2.1×10^{-3}.

Failure Node	Median HEP (Error Factor)	Mean HEP	Source (NUREG/CR-4772)

[a] Operators Diagnose Failure of Reactor Trip

10^{-4}

The probability of the operators failing to diagnose an ATWS event or not performing long-term shutdown in a timely manner is small, especially since these actions constitute immediate action steps and are well-practiced during simulator training.

[b] No Mechanical Failure of Control Rods

0.1 WCAP-11992 [5]

Regardless of the cause of the reactor trip failure, long-term shutdown can be accomplished by performing emergency boration. In addition, the operators can also achieve long-term shutdown for ATWS events caused by signal failures or reactor trip breaker failures by locally tripping the MG sets or reactor trip breakers.

[c] Operators Perform Required Actions for Emergency Boration

0.001 (EF=10)		Table 8-5, item 10.
x 3		Three critical actions.
0.003 (EF=10)	7.99×10^{-3}	

Performing emergency boration is an immediate action step in FR-S.1. No immediate recovery factor by a second person has been applied to this action.

[d] NPO Locally Trips Reactor Trip Breakers or MG Sets

0.098 (EF=5)	0.16	NUREG/CR-1278. Low dependence based on median HEP of 0.05 (step-by-step task performed under extremely high stress).

In addition to emergency boration, long-term shutdown can be accomplished by locally tripping the reactor trip breakers or MG sets, provided that the ATWS was not caused by mechanical failure of the control rods. Low dependence was assumed between the action to perform emergency boration and locally tripping the reactor--the actions are addressed in separate steps of the procedure and are performed by different personnel.

COMMENTS

It was assumed that diagnosis in operator action LTS is part of the same process as diagnosis in operator action MRI (manual rod insertion) but with more time available. This, given diagnostic error in operator action MRI, the probability of diagnostic error in operator action LTS = $10^{-4}/0.5 = 2\times10^{-4}$.

A correct diagnosis in operator action MRI was assumed to preclude diagnostic error in operator action LTS since the correct diagnosis implies that the operator has successfully diagnosed an ATWS event. In addition, operator actions MRI and LTS are affected by the cause of reactor trip failure as mechanical control rod failures preclude manual rod insertion and the local tripping of the reactor trip breakers or MG sets. Assuming 10 percent of all ATWS events are caused by mechanical control rod failures, the HEP for operator action LTS, given failure of operator action MRI, was determined by merging the two models:

$$MRI \times LTS|MRI = MRI \cap LTS$$

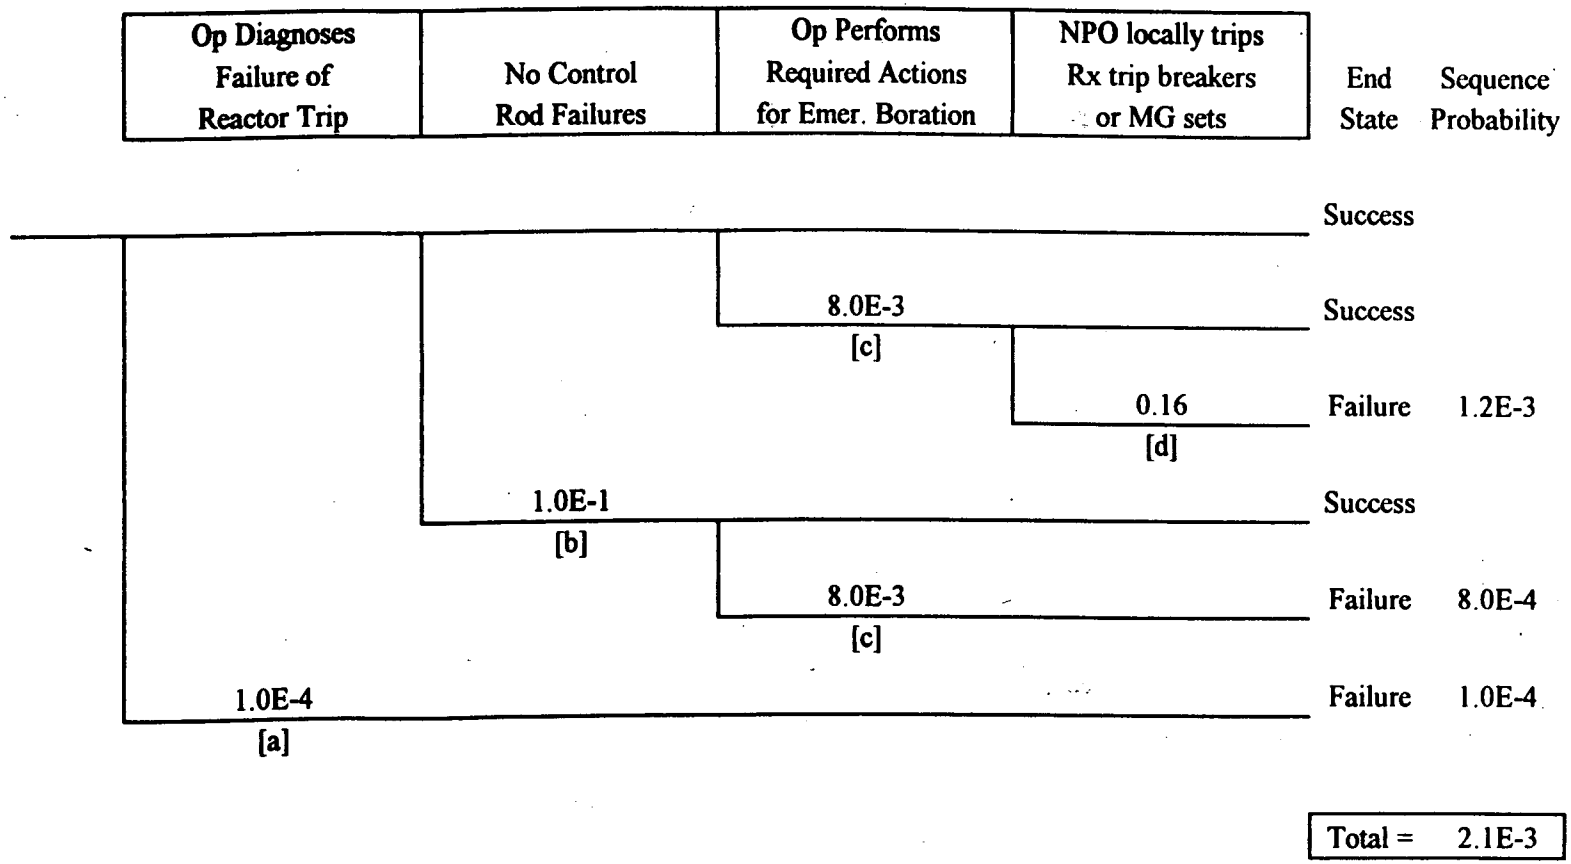
where

$MRI \cap LTS = 9.53\times10^{-4}$, and

$MRI = 0.2$

$\therefore LTS|MRI = 9.53\times10^{-4}/0.2 = 4.8\times10^{-3}$

Figure H2.5.1. Human Action LTS - Long-Term Shutdown Via Emergency Boration or Local Tripping of the Rx Trip Breakers/MG Sets



H2.6 OPERATOR ACTION MRI--MANUAL ROD INSERTION

SUMMARY

a. Task. The operator must manually insert control rods.

b. Success Criteria. The operator manually inserts control rods for one minute prior to RCS peak pressure [6].

c. Scenario/Event Tree(s) Used. ATWS.

ACTION

a. Initial Conditions. While the reactor is at full power, a reactor trip is required. However, both reactor trip breakers fail to open, and the reactor remains at power. The rod control system is in its manual mode.

b. Preceding Operator Actions. The operators will attempt to manually trip the reactor.

c. Symptoms. Failure of the reactor to trip.

d. Indications.
Rod bottom lights not lit.
Reactor trip and bypass breakers not open.
Rod position indicators not at zero.
Neutron flux not decreasing.

e. Procedural Guidance. Upon receiving indications of the need for a reactor trip (e.g., loss of main feedwater, turbine trip, etc.), the operators will enter procedure E-0 (Reactor Trip or Safety Injection). Unable to verify a reactor trip at step 1 of E-0, the operators will enter functional restoration procedure FR-S.1 (Response to Nuclear Power Generation/ATWAS). This action is classified as an immediate action step which the operators are expected to be able to perform from memory.

f. Response.

FR-S.1 (Rev. 4)
Step 1 If reactor will not trip, manually insert control rods [from flight panel FCF].

PERFORMANCE SHAPING FACTORS

a. Timing.

Time Available - Manual (or automatic) rod insertion must be performed for one minute prior to RCS peak pressure. The most limiting ATWS is the total loss of main feedwater, in which RCS pressure peaks at approximately 113 seconds after event initiation [7]. Therefore, for the control rods to be manually inserted for one minute prior to peak pressure, manual rod insertion must begin at (113 - 60) seconds = 53 seconds.

Time Needed - Manual rod insertion is performed by manipulating the rod control lever switch on flight panel FCF. It is assumed that 10 seconds are required to begin manual rod insertion.

b. Competing Actions/Alarms. Many alarms will be sounding when manual rod insertion is expected (i.e., within the first 30 seconds). However, the operators will initially focus on executing the immediate action steps in FR-S.1.

c. Consequence of Actions.

Success - Success reduces the peak RCS pressure following the ATWS and lessens the reliance on the pressurizer PORVs and safety valves to relieve pressure.

Failure - Failure increases reliance on the operation of the pressurizer PORVs and safety valves by increasing the peak RCS pressure following the ATWS.

d. Training/Experience. The operators have had extensive training on this action using the control room simulator.

e. Stress. Extremely high stress is assumed for this action based on the seriousness of an ATWS event and on the quick response required for ATWS-related actions.

f. Skill/Rule/Knowledge-Based. This action is both skill- and rule-based. The operators have experience performing manual rod insertion during ATWS simulator exercises. The action is also rule-based because it is proceduralized in FR-S.1.

g. Task Complexity. Low.

QUANTIFICATION

It was assumed that 10 percent of reactor trip failures result from mechanical failure of the control rods. Such failures preclude manual rod insertion. If the control rods are in AUTO, no operator action is required assuming the control rod system to be available. If the control

rod system is in MANUAL, manual rod insertion is required. Now in four control room simulator sessions, the control rod system was placed in MANUAL prior to the initiating event. In two sessions, the operators failed to perform manual rod insertion before 53 seconds had elapsed after the total loss of main feedwater. Therefore, a mean HEP of 0.5 was assigned to the probability that the operators fail to perform this action. It was conservatively assumed that the probability that the control rods are in manual is 0.2 and that the unavailability for the rod control system is 0.01 when the rods are in AUTO. Therefore, the HEP for operator action MRI is $0.1 + (0.9)(0.2 \times 0.5 + 0.8 \times 0.01) = 0.2$.

H2.7 OPERATOR ACTION MSGI--OPERATORS ISOLATE FAULTED STEAM GENERATOR (MAIN STEAM LINE BREAK)

SUMMARY

a. Task. The operator terminates flow to the faulted steam generator.

b. Success Criterion. Flow to the faulted steam generator is terminated.

c. Scenario/Event Tree(s) Used. Main steam line breaks (T4, T5).

ACTION

a. Initial Conditions. While the reactor is operating at full power, a steam line break occurs which results in a reactor trip and subsequent safety injection signal.

b. Preceding Operator Actions. None are required given success of all automatic actuations.

c. Symptoms.
Any SG pressure decreasing in an uncontrolled manner.
Any SG completely depressurized.

d. Indications. SG pressure (PI-419, PI-429, PI-439, PI-449) on panel FBF.

e. Procedural Guidance. Upon a reactor trip, the operators will enter procedure E-0 (Reactor Trip or Safety Injection). Since a safety injection signal will have been generated, the operators will continue in E-0 until they reach step 28. Step 28 of E-0 directs the operator to go to E-2 (Faulted Steam Generator Isolation) if the above symptoms are observed. In addition, upon exiting E-0 at Step 28, the STA is instructed to monitor the critical safety functions (CSFs). An "ORANGE" or "RED" condition on the "INTEGRITY" CSF status tree may occur. If so, Step 1 of FR-P.1 (or Step 1 of FR-P.2) directs the operator to isolate flow to the faulted steam generator. In addition, if insufficient negative reactivity is inserted by the control rods, an "ORANGE" or "RED" condition may exist on the "SUBCRITICALITY" CSF status tree. If it does, Step 11 of FR-S.1 also directs the operator to isolate flow to the faulted steam generator.

f. Response.

E-2 (Rev. 5)
Step 6b. Isolate AFW flow (to the faulted SG).

PERFORMANCE SHAPING FACTORS

a. Timing.

Time Available - The time available for the operators to isolate the faulted SG(s) is largely determined by the number of steam lines blowing down (i.e., the number of MSIVs which fail to close). Simulator exercises were performed assuming full power operation, end-of-core life conditions, and failure of all four MSIVs. For this case, all SGs depressurize in an uncontrolled manner, and procedures direct the operator to decrease AFW flow to 100 gpm to each SG. These runs showed that approximately 20 minutes are required for RCS cold leg temperatures to decrease to 287°F, which is the maximum temperature at which there is concern for PTS. However, the RCS pressure must exceed 2500 psig at this temperature in order cause imminent PTS conditions. At 1500 psig, the RCS cold leg temperatures must fall to 260°F to cause PTS conditions. Therefore, at least 20 minutes are available to isolate the faulted SG.

Time Needed - The time required to isolate AFW flow is small (less than 1 minute) compared to the time required to reach the steps which direct the operator to isolate flow (approximately 10 - 15 minutes).

b. Competing Actions/Alarms. Numerous alarms are expected to be present when the action is performed. However, the majority of the alarms will indicate the steam line break itself.

c. Consequence of Actions.

Success - Success (along with termination of safety injection) results in a stable plant, with no subsequent PTS-induced challenge to reactor vessel integrity.

Failure - Failure results in a challenge to reactor vessel integrity if high-head safety injection is not controlled.

d. Training/Experience. The operators have extensive training on this action using the control room simulator.

e. Stress. Moderately high because this action is required approximately 20 minutes after the initiating event.

f. Skill/Rule/Knowledge-Based. Rule-based. Each step is proceduralized.

g. Task Complexity. Low.

QUANTIFICATION

The quantification of the operator action to isolate the faulted steam generator is described in the following table. The total HEP for this action is 0.033.

Failure Node	Median HEP (Error Factor)	Mean HEP	Source (NUREG/CR-4772)
[a] Operators Identify Faulted SG			
	0.01 (EF=10)	2.66×10^{-2}	Table 8-2, item 2 (lower bound).

The operators must correctly identify which SG is faulted within 10 minutes. The SG pressure indicators in the CCR (flight panel FBF) will provide the necessary indications. The operators have practiced this event in simulator exercises and know which procedures to follow.

[b] Operators Perform Required Action			
	0.004 (EF=5)	6.46×10^{-3}	Table 8-5, item 3 (lower bound).

The operators must isolate AFW flow to the faulted SG. This is a step-by-step action performed under moderately high stress. The lower bound value of the estimated HEP is used because of frequent simulator training (see Table 8-1, item 10f).

Total HEP = $a + (1-a) \times b = 3.29\times10^{-2}$

H2.8 OPERATOR ACTION ODEP--OPERATOR DEPRESSURIZES RCS FOR LOW-PRESSURE INJECTION

SUMMARY

a. Task. The operator rapidly depressurizes the steam generators (SGs) by opening the condenser dump valves or steam generator atmospheric dump valves (ADVs).

b. Success Criteria. The condenser dump valves or all four SG ADVs are opened to cool and depressurize the RCS to the point where low-pressure injection can begin (i.e., < 275 psig).

c. Scenario/Event Tree(s) Used. Small and intermediate LOCAs, special initiators (TCCW and TSWS), and SGTR.

ACTION

a. Initial Conditions. The reactor is operating at full power. A primary system LOCA occurs and, because the break size is less than 0.2 ft^2, RCS pressure remains above the shut-off head of the LHSI pumps. All HHSI pumps fail to start or run. At least one AFW pump supplies feedwater to the steam generators.

b. Preceding Operator Actions. The operators will attempt to start the HHSI pumps.

c. Symptoms.
Loss of high-head safety injection pumps.
Degraded core cooling (RVLIS full range indication $\leq$ 39% or core exit TCs $\geq$ 700°F).
Inadequate core cooling (core exit TCs $\geq$ 1200°F).
Inadequate core cooling (RVLIS full range indication $\leq$ 39% and core exit TCs $\geq$ 700°F).

d. Indications.
Core exit thermocouples.
RCS subcooling.
RVLIS dynamic head indicator.
RVLIS full range indicator.

e. Procedural Guidance. Upon a reactor trip, the operators will enter procedure E-0 (Reactor Trip or Safety Injection) and proceed through E-0 until step 30. At step 30 of E-0 the operators will transfer to E-1 (Loss of Reactor or Secondary Coolant) on abnormal containment radiation, pressure, or sump level. At step 24 of E-1 the operators are instructed to check if RCS cooldown and depressurization are required. For small

LOCAs (including RCP seal LOCAs), RCS pressure will be greater than 275 psig and the transfer to procedure ES-1.2 (Post-LOCA Cooldown and Depressurization) will be made. For larger size breaks, degraded or inadequate core cooling conditions will preclude the transfer to ES-1.2, and the operators will enter functional restoration procedure FR-C.1 (Response to Inadequate Core Cooling) or FR-C.2 (Response to Degraded Core Cooling), selecting the appropriate procedure by monitoring the critical safety functions (CSFs).

f. Response.

ES-1.2 (Rev. 6) - Small Break LOCA

Step 7 Initiate RCS cooldown to cold shutdown.

- OR -

FR-C.1 (Rev. 6) - Intermediate Break LOCA

Step 11 Depressurize all intact SGs to 95 psig by dumping steam at maximum rate.
Step 12 Close all accumulator isolation valves.
Step 13 Stop all RCPs.
Step 14 Depressurize all intact SGs to atmospheric pressure by dumping steam at the maximum rate.
Step 15 Continue efforts to establish SI flow.

- OR -

FR-C.2 (Rev. 5)

Step 10 Depressurize all intact SGs to 95 psig while maintaining cooldown rate less than 100 deg. F/hr.
Step 11 Verify RHR pumps running. If not, start RHR pumps as necessary.
Step 12 Close all accumulator isolation valves.
Step 13 Stop all RCPs.

PERFORMANCE SHAPING FACTORS

a. Timing. The size of the RCS break determines the time at which degraded or inadequate core cooling is indicated.

For a 1-in. cold leg break, the core is uncovered 2.5 hours after the initiating event, and reactor vessel level decreases to 3.5 feet above the bottom of the active fuel at about 2.9 hours [9]. Core exit temperatures exceed 700°F at about 2.9 hours and 1200°F at 3.0 hours.

For a 4-in. cold leg break, sustained uncovering of the core begins approximately 12 minutes after the initiating event, and reactor vessel level decreases to 3.5 feet above the

bottom of the active fuel at about 20.0 minutes. Core exit temperatures exceed 700°F at about 20.0 minutes and 1200°F at 22.7 minutes.

Time Available - The time available to the operator to complete these actions depends on the capacity of the LHSI pumps and on the size of the break. For smaller break LOCAs, where the operators would be expected to cooldown and depressurize the RCS using procedure ES-1.2, several hours are available before core damage occurs. Regardless of break size, once core cooling is degraded or inadequate, the operators must quickly respond by implementing FR-C.2 or FR-C.1, as appropriate. No credit was taken for continued operation of the RCPs--while core cooling would be enhanced by the operation of the RCPs, the RCPs cannot be expected to run for very long with a highly voided RCS.

Time Needed - It is estimated that approximately 10 minutes are required to perform this action--5 minutes to step through procedure FR-C.1 to Step 14 and 5 minutes thereafter for depressurizing the RCS to below the shut-off head of the RHR pumps.

According to WCAP-9753 [9], opening of the condenser steam dump valves results in RCS depressurization, low head injection, and complete core recovery within 3 minutes after operator action. For cases in which condenser steam dump capability is unavailable, depressurization must be performed using the SG ADVs. According to Westinghouse Owners Group guidelines for Functional Restoration Procedure FR-C.1, opening the ADVs results in RCS depressurization, low head injection, and core recovery within 15 minutes of commencing the operation.

b. Competing Actions/Alarms. During the time when the operators are depressurizing the RCS and accumulator injection occurs, RCS cold leg temperature will decrease significantly, possibly causing a RED path on the "Inventory" critical safety function and prompting a transition to FR-P.1 (Response to Imminent Pressurized Thermal Shock Conditions). However, the "Core Cooling" CSF has priority over the "Inventory" CSF.

c. Consequence of Actions.

Success - Success implies that the RCS has been depressurized and cooled to less than 275 psig, allowing the accumulators and LHSI pumps to inject borated water from the RWST into the RCS cold legs.

Failure - Failure implies that RCS pressure remains above the shut-off head of the LHSI pumps. Because the HHSI pumps are unavailable, core damage will occur.

d. Training/Experience. The operators have been trained on this action.

e. Stress. Extremely high. While a LOCA by itself would produce a relatively high level of stress, indications of inadequate core cooling would create an extremely high level of

stress (threat stress).

f. Skill/Rule/Knowledge-Based. Rule-based. Each step is proceduralized.

g. Task Complexity. The complexity of these actions is low to moderate because of the simple nature of the tasks and the small number of steps required.

QUANTIFICATION

Small LOCA

Diagnosis Error. Because of the time available to perform this action, a screening value of 10^{-3} was assessed.

Post-Diagnosis Error. Because frequent simulator training has made the operators familiar with performing cooldown after small LOCAs, the lower bound HEP in Table 8-5 was used. In addition, moderately high stress levels have been assumed. The median HEP is 0.004 (EF=5), which results in a mean HEP of 6.5×10^{-3}.

Recovery. Assuming moderate dependence between the SS and the operators results in a median HEP of 0.15 (EF=5). The mean HEP is 0.24.

The mean HEP for operator action ODEP (SLOCA) = $10^{-3} + 6.5\times10^{-3} \times 0.24 = 2.6\times10^{-3}$.

Intermediate LOCA

The operator action tree depicting the failure of the operator to depressurize the RCS following an intermediate LOCA is shown in Figure H2.8.1. The quantification of this tree is described below. The total mean HEP for operator action ODEP-S1 was calculated to be 0.0512.

Failure Node	Median HEP (Error Factor)	Mean HEP	Source (NUREG/CR-4772)
[a] Crew Diagnoses LOCA	5.46×10^{-3} (EF=10)	0.0145	Table 8-2, interpolation between items 2 and 3.

The time available for diagnosis of the intermediate LOCA was taken as the time between loss of all high-head injection and the onset of degraded core cooling (i.e., RVLIS full

range ≤ 39 percent or core exit temperatures ≥ 700°F). Based on the analysis performed for WCAP-9753 [9] for a 4-in. cold leg break, 12 min. was assumed to be the time available for diagnosis. Because of extensive simulator training the operators have received on coping with LOCAs, the lower-bound diagnosis HEP was used.

[b] Operators Verify High-Head Safety Injection (HHSI)

10^{-3} (EF=10)	2.66×10^{-3}	Table 8-5, item 10.

Verifying HHSI was classified as an immediate action step in emergency operating procedure E-0.

[c] Inadequate Core Cooling Detected (Given Operator Verifies HHSI)

0.05 (EF=5)	0.0807	Table 8-5, item 5 (lower bound)

Given that the operators have diagnosed the LOCA and verified that HHSI is unavailable, the SRO will anticipate degraded or inadequate core cooling if all attempts to restore HHSI are unsuccessful. Because of the loss of HHSI, extremely high stress levels were assumed. However, the lower bound HEP was assigned because of the extensive training the operators have received.

0.25 (EF=5)	0.403	Table 8-5, item 5

Credit was taken for the STA monitoring the CSF status trees and confirming degraded or inadequate core cooling. The recovery from a failure to detect inadequate core cooling was classified as a dynamic action performed under extremely high stress.

Total [c] = 0.0807 × 0.403 = 0.0325

[d] Inadequate Core Cooling Detected (Given Operator Fails to Verify HHSI)

0.25 (EF=5)	0.403	Table 8-5, item 5

If the operators diagnose the LOCA but fail to monitor HHSI, credit was taken only for the STA detecting degraded or inadequate core cooling--the STA is required to monitor the critical safety functions.

[e] Operators Perform Actions

0.01 (EF=5)	0.0161	Table 8-5, item 4 (lower bound)

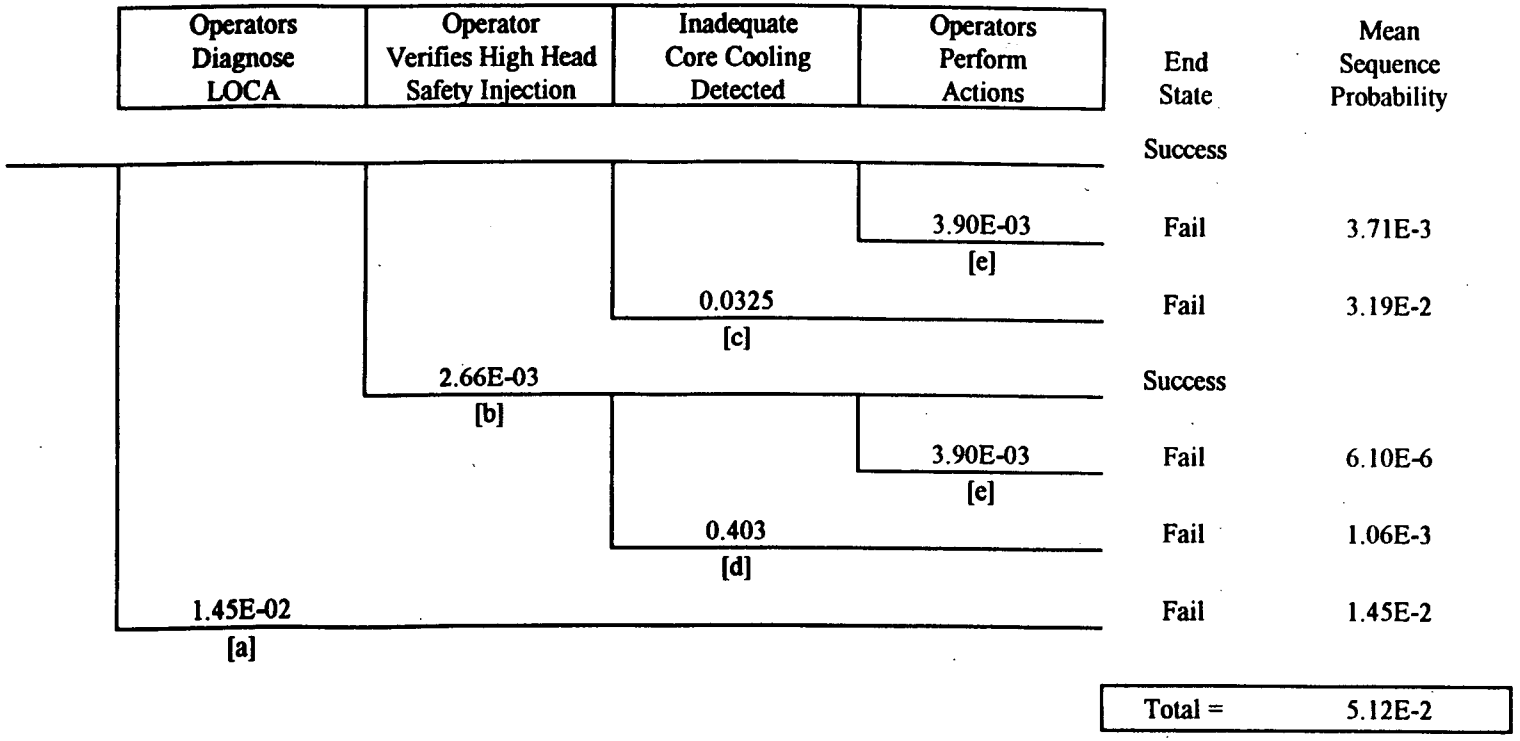
Operator action to depressurize the RCS to establish low-head safety injection flow is proceduralized in functional restoration procedures FR-C.1 and FR-C.2. Therefore, this action was classified as a step-by-step task performed under extremely high stress. However, because of frequent simulator training, the lower bound HEP was used.

0.15 (EF=5)	0.24	Table 20-17, moderate dependency

Failure of the operators to correctly perform the required action can be recovered by the SS. The cue is provided by LHSI unavailability. Moderate dependence was assumed between the SS and the operators.

Total [e] = $0.0161 \times 0.24 = 3.9 \times 10^{-3}$.

Figure 12.8.1. Operator Action ODEP-S1 -- Operator Depressurizes RCS For Low-Head Injection (Intermediate LOCA)



H2.9 OPERATOR ACTION ODEP-SBO--OPERATORS DEPRESSURIZE RCS TO REDUCE RCP SEAL LEAKAGE

SUMMARY

a. Task. The operators depressurize the RCS using the atmospheric steam dump valves (ADVs) to reduce reactor coolant loss through leaking RCP seals.

b. Success Criteria. The operators begin to depressurize the RCS within 2 hours using all four ADVs.

c. Scenario/Event Tree(s) Used. Station blackout event tree (SBO).

ACTION

a. Initial Conditions. The reactor is initially operating at full power. A loss of offsite power occurs; subsequently, all three emergency diesel generators fail. The turbine-driven AFW pump is available.

b. Preceding Operator Actions. The operators will attempt to restore ac power.

c. Symptoms. All safeguards buses de-energized (buses 5A, 6A, and 2A/3A).

d. Indications.
"480V Safeguards Bus Undervoltage" annunciator on panel SBF-2.
480-V bus voltmeter on panel SHF.
480-V bus undervoltage relay lights on panel SHF.

e. Procedural Guidance. Upon receipt of a reactor trip, the operators will enter procedure E-0 (Reactor Trip or Safety Injection). If the EDGs fail to start, step 3 of E-0 will direct the operators to enter ECA-0.0 (Loss of All AC Power) if power cannot be restored to at least one safeguards bus (i.e., bus 5A, 6A, or 2A/3A). If ac power is lost subsequent to reaching step 3 of E-0, the operators will be directed to enter ECA-0.0 from the alarm response procedure for 480-V safeguards bus undervoltage (ARP-5). Step 21 of ECA-0.0 directs the operators to depressurize the intact steam generators to 195 psig.

f. Response.

ECA-0.0 (Rev. 7)
Step 21.a Depressurize intact SGs to 195 psig by manually dumping steam at maximum rate using SG ADVs.

PERFORMANCE SHAPING FACTORS

a. Timing.

Time Available - The time available to begin RCS depressurization depends on the rate of RCS leakage through the RCP seals. Based on the analysis performed in WCAP-10541 [11], it was assumed that RCS depressurization must begin within 2 hours.

Time Needed - Since success for this action has been defined as depressurizing the RCS to minimize the RCP seal leak rate, the time required is simply the time required to step through procedure ECA-0.0 to Step 21 and establish nitrogen backup to the ARVs. One hour was assumed to be required.

b. Competing Actions/Alarms. Procedure ECA-0.0 requires the operator to stop depressurization if SG narrow range level cannot be maintained above 6 percent in any intact SG. Because of this requirement and the fact that only the turbine-driven AFW pump is available to provide make-up to the SGs, depressurization may have to be stopped temporarily to allow SG narrow range levels to increase above 6 percent. This phenomenon has been confirmed by actual observation during simulator exercises but does not have a significant impact on the quantification.

c. Consequence of Actions.

Success - Success delays core damage and, therefore, increases the time available to recover ac power. Alternatively, success decreases the probability of core damage should ac power be restored.

Failure - Failure decreases the time to core damage and, therefore, the time available to recover ac power. Alternatively, failure increases the probability of core damage once ac power is restored.

d. Training/Experience. The operators have ample experience practicing station blackout scenarios on the simulator.

e. Stress. High.

f. Skill/Rule/Knowledge-Based. Rule-based. This action is proceduralized

g. Task Complexity. Moderate. The action to depressurize the RCS using the SGs is straightforward. However, the operator must monitor the SG narrow range levels and is required by procedure to stop depressurization if they all fall below 6 percent.

QUANTIFICATION

Diagnosis. Assuming that the operators are able to step through ECA-0.0 to Step 21 and establish the nitrogen backup to the ARVs within one hour, the time available for diagnosis is 2 - 1 = 1 hour. From Table 8-2 (item 5) of the ASEP HRAP, the median HEP is 1.0^{-4} (EF=30), which yields a mean HEP of 8.5×10^{-4}.

Post-Diagnosis. This action consists of a step-by-step action performed under moderately high stress. Because the operators are well-trained on station blackout scenarios in the simulator, the lower bound of Table 8-5 (item 3) of the ASEP HRAP was chosen. The median value is 0.004 (EF=5), which translates to a mean value of 6.5×10^{-3}.

Recovery. Assuming moderate dependence between the SS and the operators results in a median recovery HEP of 0.15 (EF=5) and a mean recovery HEP of 0.24.

The mean HEP for operator action ODEP-SBO = $8.5\times10^{-4} + 6.5\times10^{-3} \times 0.24 = 2.4\times10^{-3}$

H2.10 OPERATOR ACTION ODEPR--OPERATOR DEPRESSURIZES RCS FOR POST-LOCA COOLDOWN

SUMMARY

a. Task. The operator cools the RCS by opening the atmospheric or condenser steam dump valves and depressurizes the RCS using the pressurizer PORV or spray valves.

b. Success Criteria. The operator depressurizes the RCS to below the shut-off head of the LHSI pumps.

c. Scenario/Event Tree(s) Used. Small-small, small, and intermediate LOCAs.

ACTION

a. Initial Conditions. While the reactor is operating at full power, a primary system break occurs which results in a reactor trip and safety injection. At least one HHSI pump operates in the injection mode. Because of the break size, RCS pressure remains above the shut-off head of the LHSI pumps.

b. Preceding Operator Actions. None required.

c. Symptoms. RCS pressure exceeds the shut-off head of the RHR pumps.

d. Indications. RCS pressure indicators.

e. Procedural Guidance. Upon a reactor trip, the operators will enter procedure E-0 (Reactor Trip or Safety Injection) and proceed through E-0 until step 30. At step 30 of E-0 the operators will transfer to E-1 (Loss of Reactor or Secondary Coolant) on abnormal containment radiation, pressure, or sump level. At step 24 of E-1 the operators are instructed to check if RCS cooldown and depressurization are required. For small LOCAs, RCS pressure will be greater than 275 psig and the transfer to procedure ES-1.2 (Post-LOCA Cooldown and Depressurization) will be made.

f. Response.

ES-1.2 (Rev. 6)

Step 7 Initiate RCS cooldown to cold shutdown using condenser steam dump or ADVs, while maintaining cooldown rate less than 100 deg. F/hr.

Step 11 Depressurize RCS to refill pressurizer using normal spray, one pressurizer PORV, or auxiliary spray.

PERFORMANCE SHAPING FACTORS

a. Timing.

Time Available - The action must be completed before the RWST water level decreases to 9.2 ft. Otherwise, the operators must switch to high-head recirculation cooling. The time available to depressurize the RCS depends on the rate of RWST depletion which, in turn, depends on the break size and number of ECCS pumps running. For a 0.02 ft^2 break, a break size between small and intermediate LOCAs, 9.2 ft in the RWST is reached approximately 3.0 hours after the initiating event. Larger intermediate LOCAs which do not result in RCS depressurization to below the shut-off head of the RHR pumps could reach the 9.2-ft level earlier. However, assuming that the HHSI pumps deliver flow at their maximum flow rate (650 gpm), the low-low RWST level would not be reached sooner than (346,870 - 99,475)/(3 × 650) = 127 minutes, or 2.1 hours.

Time Needed - The time required for the operators to depressurize the RCS to below the shut-off head of the RHR pumps depends on the availabilities of the condenser steam dump or atmospheric dump valves and the pressurizer spray valves or PORVs. In any case, the maximum cooldown rate allowed by procedures is 100 deg. F/hr.

b. Competing Actions/Alarms. None expected.

c. Consequence of Actions.

Success - Success allows use of low pressure sump recirculation.

Failure - Failure requires high pressure sump recirculation.

d. Training/Experience. The operators have ample experience practicing this action on the control room simulator.

e. Stress. Moderate. Core cooling and inventory control is maintained by the HHSI pumps.

f. Skill/Rule/Knowledge-Based. Rule-based--each step is proceduralized.

g. Task Complexity. Low.

QUANTIFICATION

Diagnosis Error. Because of the time available to depressurize the RCS, a screening value of 10^{-3} was assessed.

Post-Diagnosis Error. Because frequent simulator training has familiarized the operators with post-LOCA cooldown during small LOCAs, the lower-bound HEP in Table 8-5 of the ASEP HRAP was used. In addition, moderately high stress levels were assumed. The median HEP is 0.004 (EF=5), which results in a mean HEP of 6.5×10^{-3}.

Recovery. Assuming moderate dependence between the SS and the operators results in a median recovery HEP of 0.15 (EF=5) and a mean recovery HEP of 0.24.

The mean HEP for operator action ODEPR = $10^{-3} + 6.5\times10^{-3} \times 0.24 = 2.6\times10^{-3}$

H2.11 OPERATOR ACTION OHR--OPERATOR INITIATES HIGH-HEAD RECIRCULATION FLOW

SUMMARY

a. Task. The operator aligns the ECCS pumps for cold leg sump recirculation using recirculation or RHR pumps to provide suction to the HHSI pumps.

b. Success Criteria. Success requires that one of four LHSI pumps takes suction from the appropriate sump and discharges to the suction of the HHSI pump.

c. Scenario/Event Tree(s) Used. Small or intermediate LOCAs, SBO, SGTR, special initiators (TAC5A, TAC6A, TCCW, TSWS, TSWGR), transient (T1, T2), and MSLB (T4, T5).

ACTION

a. Initial Conditions. The reactor is at full power. A loss of reactor coolant occurs, resulting in a reactor trip and safety injection actuation. At least one HHSI pump operates in the injection mode.

b. Preceding Operator Actions. None required.

c. Symptoms.
"RWST Low-Low Level" annunciator lit.
Flow to at least two low-head injection lines less than 1200 gpm .

d. Indications.
RWST water level transmitter LT-920.
Low-head injection flow transmitters FT-946A/B/C/D.

e. Procedural Guidance. Upon receipt of a reactor trip and safety injection signal, the operators will enter procedure E-0 (Reactor Trip or Safety Injection). At step 30 of E-0 the operators will transfer to E-1 (Loss of Reactor or Secondary Coolant) on abnormal containment radiation, pressure, or sump level. If at any time (regardless of which procedure is in use) RWST water level falls below 9.2 ft, the operators will transfer to ES-1.3 (Transfer to Cold Leg Recirculation). The criterion for transferring to sump recirculation (9.2 ft in the RWST) is annunciated on panel SBF-2.

f. Response.

ES-1.3 (Rev. 7)

Step 2 Energize the following valve control circuits:
- a) 882 and 1870 at MCC-36B [PAB - 55-ft elevation].
- b) 1810, 743, and 744 at MCC-36A [PAB - 55-ft elevation].
- c) 842 and 843 at SBF-1.

Step 10 Reset SI.

Step 11 Reset containment spray signal.

Step 13 Place recirculation switch 1 to ON position.

This action:
1) Trips HHSI pump 32.
2) Isolates HHSI pump 32 suction valves 887A/B.
3) Trips spray pump 32 if spray pump 31 is running and closes spray pump 32 discharge valve 866B.

Step 13c Place HHSI pump 32 in PULLOUT.

Step 14 Place recirculation switch 3 to ON position.

This action:
- a) Trips both RHR pumps 31 and 32.
- b) Closes RHR suction valve 882 and discharge valve 744.

Step 15 Close SWN-FCV-1111 and SWN-FCV-1112. Then start one non-essential SW pump.

Step 17a Open recirculation pump header discharge valves 1802A/B.

Step 17c Start 31 or 32 recirculation pump. If neither recirculation pump can be started, then start an RHR pump.

Step 18 Go to Step 30 for high-head recirculation.

Step 30b Place recirculation switch 5 to ON Position.

This action:
- a) Isolates low-head recirculation header by closing valves 746, 747, 899A, and 899B.
- b) Opens low-head to high-head valves 888A/B.

c) Closes HHSI miniflow valves 842 and 843.
d) Closes RHR miniflow valves 743 and 1870.

Step 33 Place recirculation switch 8 to ON Position.

This action:
a) Closes spray pump test line valve 1813.
b) Closes HHSI suction valve 1810.

Should containment spray need to be aligned for recirculation, the following step in ES-1.3 must be performed.

Step 37b Open spray header valve 889B. If valve 889B will not open, open 889A.

PERFORMANCE SHAPING FACTORS

a. Timing. The cue for performing the switchover to cold leg recirculation is the RWST low-low level alarm (9.2 ft). The time at which this alarm can be anticipated varies with the size of the RCS break.

- *Small LOCA (8×10^{-4} to 0.02 ft^2)* - From MAAP calculations performed for a small LOCA initiator (0.02 ft^2), the low-low RWST water level (9.2 ft) was reached in 181.4 minutes (3 hours). Because this break size is at the high end of the break spectrum for small LOCAs, the switch to sump recirculation will not occur until at least 3 hours have elapsed.

- *Intermediate LOCA (0.02 to 0.2 ft^2)* - From MAAP calculations, the switch to sump recirculation will occur between 51.1 minutes (for a 0.2 ft^2 break with no containment fan coolers operating) and 3 hours (for a 0.02 ft^2 break).

Time Available - The time available to complete the switchover to cold leg recirculation depends on the size of the RCS break. Because the ECCS pumps require a minimum suction head to prevent pump cavitation and subsequent failure, it was assumed that the switch to sump recirculation must be completed before RWST level falls below the minimum required net positive suction head (NPSH).

- *Small LOCA (8.0×10^{-4} to 0.02 ft^2)* - From MAAP calculations performed for the 0.02 ft^2 break (worst case), RWST level decreases from 9.2 ft to 2 ft in 36 minutes, at which point the operators are instructed to stop all ECCS pumps taking suction from the RWST. Insufficient NPSH will occur 10 minutes after the level falls to 2 ft if the pumps are not stopped or sump recirculation has not been completed. The core will be uncovered 1.9 hours after the pumps fail; core exit temperatures will exceed 2200°F approximately 41 minutes after the core is uncovered.

- *Intermediate LOCA (0.02 to 0.2 ft^2)* - The time available to complete the switchover to sump recirculation for intermediate-break LOCAs varies with the size of the break. For 0.02-ft^2 breaks, the timing is identical to that of the small-break LOCA described above. MAAP runs have shown that for intermediate-size breaks (0.2 ft^2) with one or more containment fan cooler units operating, RWST level will decrease from 9.2 ft to 2 ft within 15 minutes. At this level the operators are instructed to stop all ECCS pumps taking suction from the RWST. Insufficient net positive suction head (NPSH) will occur approximately 5 minutes after the level reaches 2 ft, resulting in failure of HHSI, containment spray, and RHR pumps if the operators do not stop them. MAAP also showed that the core is uncovered approximately 2.1 hours (125 minutes) after the ECCS pumps are stopped, and core exit temperatures reach 2200°F approximately 30 minutes thereafter. Therefore, for intermediate-break LOCAs the average time required to deplete the RWST (from the time the low-low level alarm is reached) is (20 + 46)/2 = 33 minutes.

Time Needed - Observations made during simulator exercises indicate that approximately 5 minutes are required to step through procedure ES-1.3 and place RS #1 to the ON position. Another 10 minutes are required to complete the eight-step sequence for switchover to sump recirculation. Therefore, a total of 15 minutes may be required between the time ES-1.3 is entered and sump recirculation completed.

b. Competing Actions/Alarms. None expected for the small LOCA initiators. However, it was assumed that up to five annunciators may be sounding for intermediate LOCAs.

c. Consequence of Actions.

Success - Success implies continued core cooling using the LHSI pumps to supply sump water to the suction of the HHSI pumps.

Failure - Failure results in loss of core cooling.

d. Training/Experience. The operators have ample experience practicing this scenario on the control room simulator.

e. Stress. Moderately high stress levels were assumed for this action because of the time available before the low RWST level (9.2 ft) is reached.

f. Skill/Rule/Knowledge-Based. Rule-based. Each step is proceduralized.

g. Task Complexity. Moderate to high. This action involves a series of steps and requires the operator to monitor flows to determine whether to align the ECCS for low or high-head recirculation.

QUANTIFICATION

Small LOCA

The operator action tree depicting the failure of the operator to initiate high-head recirculation flow for a small LOCA is shown in Figure H2.11.1. The quantification of this tree is described below. The total mean HEP for operator action OHR-SLOCA was calculated to be 4.8×10^{-4}.

Failure Node	Median HEP (Error Factor)	Mean HEP	Source (NUREG/CR-4772)
[a] Crew Diagnoses LOCA			
	Negligible	10^{-5}	

The time available for diagnosis of a small LOCA, based on the time until the low-low RWST level alarm, is at least 3 hours. Because of the long time available, the diagnosis HEP was assumed to be negligible.

[b] Operators Monitor RWST Level			
	0.05 (EF=5)	0.081	Table 8-5, item 4.

Once the LOCA has been diagnosed, the primary operator will be aware of the need to monitor RWST level, as implied by procedures. This constitutes a dynamic task performed under moderately high stress.

[c] Operators Note RWST Low-Low Level (Given Crew Has Diagnosed LOCA and Monitored RWST Level)			
	Negligible	10^{-5}	

Given that the crew has successfully diagnosed the LOCA and monitored the RWST level, the probability that the operators fail to note the RWST low-low level alarm was considered to be negligible.

[d] Operators Note RWST Low-Low Level (Given Crew Has Diagnosed LOCA but Failed to Monitor RWST Level)			
	10^{-4} (EF=10)	2.7×10^{-4}	Table 8-2, interpolating between items 2 and 3 (lower bound).

Once the RWST low-low level alarms, the operators will have 46 - 15 ≈ 30 minutes to diagnose the need for sump recirculation. Because of the extensive training received by the operators on this action, the lower bound diagnosis model was used.

[e] Operators Note RWST Low-Low Level (Given Crew Has Failed to Diagnose LOCA)

0.25 (EF=5)	0.40	Table 8-5, item 5.

If the crew fails to diagnose the LOCA, they will not be expecting the low-low RWST level alarm. Therefore, when this alarm sounds, it is assumed that the operators will be under extremely high stress (threat stress).

[f] Recirculation/RHR Pump Aligned and Started (Given Crew Has Diagnosed LOCA)

0.004 (EF=5)		Table 8-5, item 3 (lower bound).
x 2		Two critical actions.
0.008 (EF=5)	0.0129	

The operator must perform two critical, step-by-step actions: 1) open recirculation pump discharge valves SI-MOV-1802A/B, and 2) start recirculation pump 31 or 32. Complete dependence is assumed between opening the two valves because opening either valve will result in success. Moderately high stress levels have been assumed. Because of extensive training, the lower bound value of the HEP was used.

0.058 (EF=5)	0.094	NUREG/CR-1278, Equation 10-15 in Table 20-17.

The procedure directs the operators to verify minimum core cooling flow upon completion of the eight-step transfer to cold leg recirculation. This satisfies the rules in NUREG/CR-1278 for the assessment of low dependence between the transfer and check.

0.15 (EF=5)	0.24	NUREG/CR-1278, moderate dependence.

SS recovers error, assuming moderate dependence.

Total [f] = $0.0129 \times 0.094 \times 0.24 = 2.9 \times 10^{-4}$

[g] Recirculation/RHR Pump Aligned and Started (Given Initial Failure to Diagnose LOCA)

0.01 (EF=5)		Table 8-5, item 4 (lower bound).
x 2		Two critical actions.
0.02 (EF=5)	0.032	

Same as failure node [f], except extremely high stress levels have been assumed given failure to diagnose the LOCA, and no credit was given to the SRO recovering the error.

[h] Diagnose Need for High-Head Recirculation (Given Crew Has Diagnosed LOCA)

N/A	Negligible

This failure should have a negligible probability compared to the other causes of failure

for this action. Omitting Step 18 of ES-1.3 could cause the operators to proceed directly to Step 19, which instructs the operators to establish low-head injection. Step 18 is a major step and, therefore, very unlikely to be overlooked. In addition, the operators should be aware of RCS pressure at the time of switchover and should realize the need for high-head recirculation. Assuming that the operators perform Step 19, a potential error mechanism could be misreading the flow indications or misinterpreting the criteria for high head injection. However, the flow indications for the low-head injection lines should indicate zero. Therefore, misinterpretation is most unlikely.

[i] Diagnose Need for High-Head Recirculation (Given Crew Has Not Diagnosed LOCA)

0.01 (EF=5)	0.0161	Table 8-5, item 4 (lower bound).

Given failure to diagnose the LOCA and extremely high stress, the operators could potentially misinterpret the need for high-head recirculation (versus low-head recirculation).

[j] RS #5 Placed to ON (Given Crew Has Diagnosed LOCA)

0.004 (EF=5)	6.46×10^{-3}	Table 8-5, item 3 (lower bound).

The operator must place recirculation switch #5 to the ON position. Moderately high stress levels were assumed. Because of extensive training, the lower bound value of the HEP was used.

0.058 (EF=5)	0.094	NUREG/CR-1278, Equation 10-15 in Table 20-17.

The procedure directs the operators to verify minimum core cooling flow upon completion of the eight-step transfer to cold leg recirculation. This satisfies the rules in NUREG/CR-1278 for the assessment of low dependence between the transfer and check.

0.15 (EF=5)	0.24	NUREG/CR-1278, moderate dependence.

SS recovers error, assuming moderate dependence.

Total [j] = $6.46\times10^{-3} \times 0.094 \times 0.24 = 1.5\times10^{-4}$

[k] RS #5 Placed to ON (Given Initial Failure to Diagnose LOCA)

0.01 (EF=5)	0.016	Table 8-5, item 4 (lower bound).

Same as failure node [j], except that extremely high stress levels have been assumed, and no credit was given to the SRO recovering the error.

Intermediate LOCA

The operator action tree depicting the failure of the operator to initiate high-head recirculation flow following an intermediate LOCA is shown in Figure H2.11.2. The quantification of this tree is described below. The total mean HEP for operator action OHR-MLOCA was calculated to be 8.6×10^{-4}.

Failure Node	Median HEP (Error Factor)	Mean HEP	Source (NUREG/CR-4772)
[a] Crew Diagnoses LOCA			
	10^{-4} (EF=10)	2.7×10^{-4}	Table 8-2, item 4 (lower bound).

The time available for diagnosis of the intermediate LOCA, based on the time until the low-low RWST level alarm, is between 51 minutes and 3 hours, depending on the size of the break. For quantification, 30 minutes was conservatively used. Because of extensive training on LOCAs, the lower bound HEP was used.

[b] Operators Monitor RWST Level			
	0.05 (EF=5)	0.081	Table 8-5, item 4.

Once the LOCA has been diagnosed, the primary operator will be aware of the need to monitor RWST level, as implied by procedures. This constitutes a dynamic task performed under moderately high stress.

[c] Operators Note RWST Low-Low Level (Given Crew Has Diagnosed LOCA and Monitored RWST Level)			
	Negligible	10^{-5}	

Given that the crew has successfully diagnosed the LOCA and monitored the RWST level, the probability that the operators fail to note the RWST low-low level alarm is considered to be negligible.

[d] Operators Note RWST Low-Low Level (Given Crew Has Diagnosed LOCA but Failed to Monitor RWST Level)			
	1.4×10^{-3} (EF=10)	3.8×10^{-3}	Table 8-2, interpolating between items 2 and 3 (lower bound).

Once the RWST low-low level alarms, the operators will have 33 - 15 = 18 minutes to diagnose the need for sump recirculation. Because of the extensive training received by the operators on this action, the lower bound diagnosis model was used.

[e] Operators Note RWST Low-Low Level (Given Crew Has Failed to Diagnose LOCA)

0.25 (EF=5)	0.40	Table 8-5, item 5.

If the crew fails to diagnose the LOCA, they will not be expecting the low-low RWST level alarm. Therefore, when this alarm sounds, it is assumed that the operators will be under extremely high stress (threat stress).

[f] Recirculation/RHR Pump Aligned and Started (Given Crew Has Diagnosed LOCA)

Total [f] = 2.9×10^{-4}, as per small LOCA, failure node [f].

[g] Recirculation/RHR Pump Aligned and Started (Given Initial Failure to Diagnose LOCA)

0.01 (EF=5)		Table 8-5, item 4 (lower bound).
x 2		Two critical actions.
0.02 (EF=5)	0.032	

Same as smal LOCA, failure node [f].

[h] Diagnose Need for High-Head Recirculation (Given Crew Has Diagnosed LOCA)

Negligible

Same as small LOCA, failure node [h].

[i] Diagnose Need for High-Head Recirculation (Given Crew Has Not Diagnosed LOCA)

0.01 (EF=5)	0.0161	Table 8-5, item 4 (lower bound).

Given failure to diagnose the LOCA and extremely high stress, the operators could potentially misinterpret the need for high-head (versus low-head) recirculation.

[j] RS #5 Placed to ON (Given Crew Has Diagnosed LOCA)

Total [j] = 1.5×10^{-4}, as per small LOCA, failure node [j].

[k] RS #5 Placed to ON (Given Initial Failure to Diagnose LOCA)

0.01 (EF=5)	0.016	Table 8-5, item 4 (lower bound).

Same as failure node [j], except that extremely high stress levels have been assumed, and no credit was given to the SRO recovering the error.

COMMENTS

Small LOCA Initiator (S2)

It was assumed that diagnosis of the LOCA in operator action OHR-S2 is part of the same process as diagnosis of the LOCA in operator action ODEPR. Thus, given diagnostic error in operator action ODEPR, the probability of error in the diagnosis of a LOCA in operator action OHR-S2 = 10^{-5} /10^{-3} = 10^{-2}. Conversely, successful diagnosis in operator action ODEPR guarantees successful diagnosis of the LOCA in operator action OHR-S2. With this logic, the HEP for operator action OHR-S2 given the failure of operator action ODEPR can be determined by merging operator action trees for the two actions. A value of 2.2×10^{-3} was calculated.

Intermediate LOCA Initiator (S1)

The dependency between error in diagnosing a LOCA in operator actions ODEPR and OHR-S1 is similar to that between ODEPR and OHR-S2 except that the time available to diagnose the LOCA is less for the intermediate LOCA. The HEP for operator action OHR-S1 given the failure of operator action ODEPR was calculated as 0.046.

Recirculation Pump Unavailability

The quantification performed above for operator action OHR assumed that the recirculation pumps were available for low pressure recirculation. However, should the recirculation pumps be unavailable, the operators must align the RHR pumps to take suction from the containment sump and deliver flow to the suction of the HHSI pumps. This aspect impacts the quantification of the HEP in the following manner:

1. Turning recirculation switch #3 to the ON position becomes a critical action if the need for sump recirculation is not diagnosed in sufficient time to allow the switchover before the RWST empties.

2. Returning recirculation switch #3 to the OFF position is also a critical action, since this action allows the operator to re-open the RHR pump discharge valve 744.

3. The operators must re-open the RHR pump discharge valve 744.

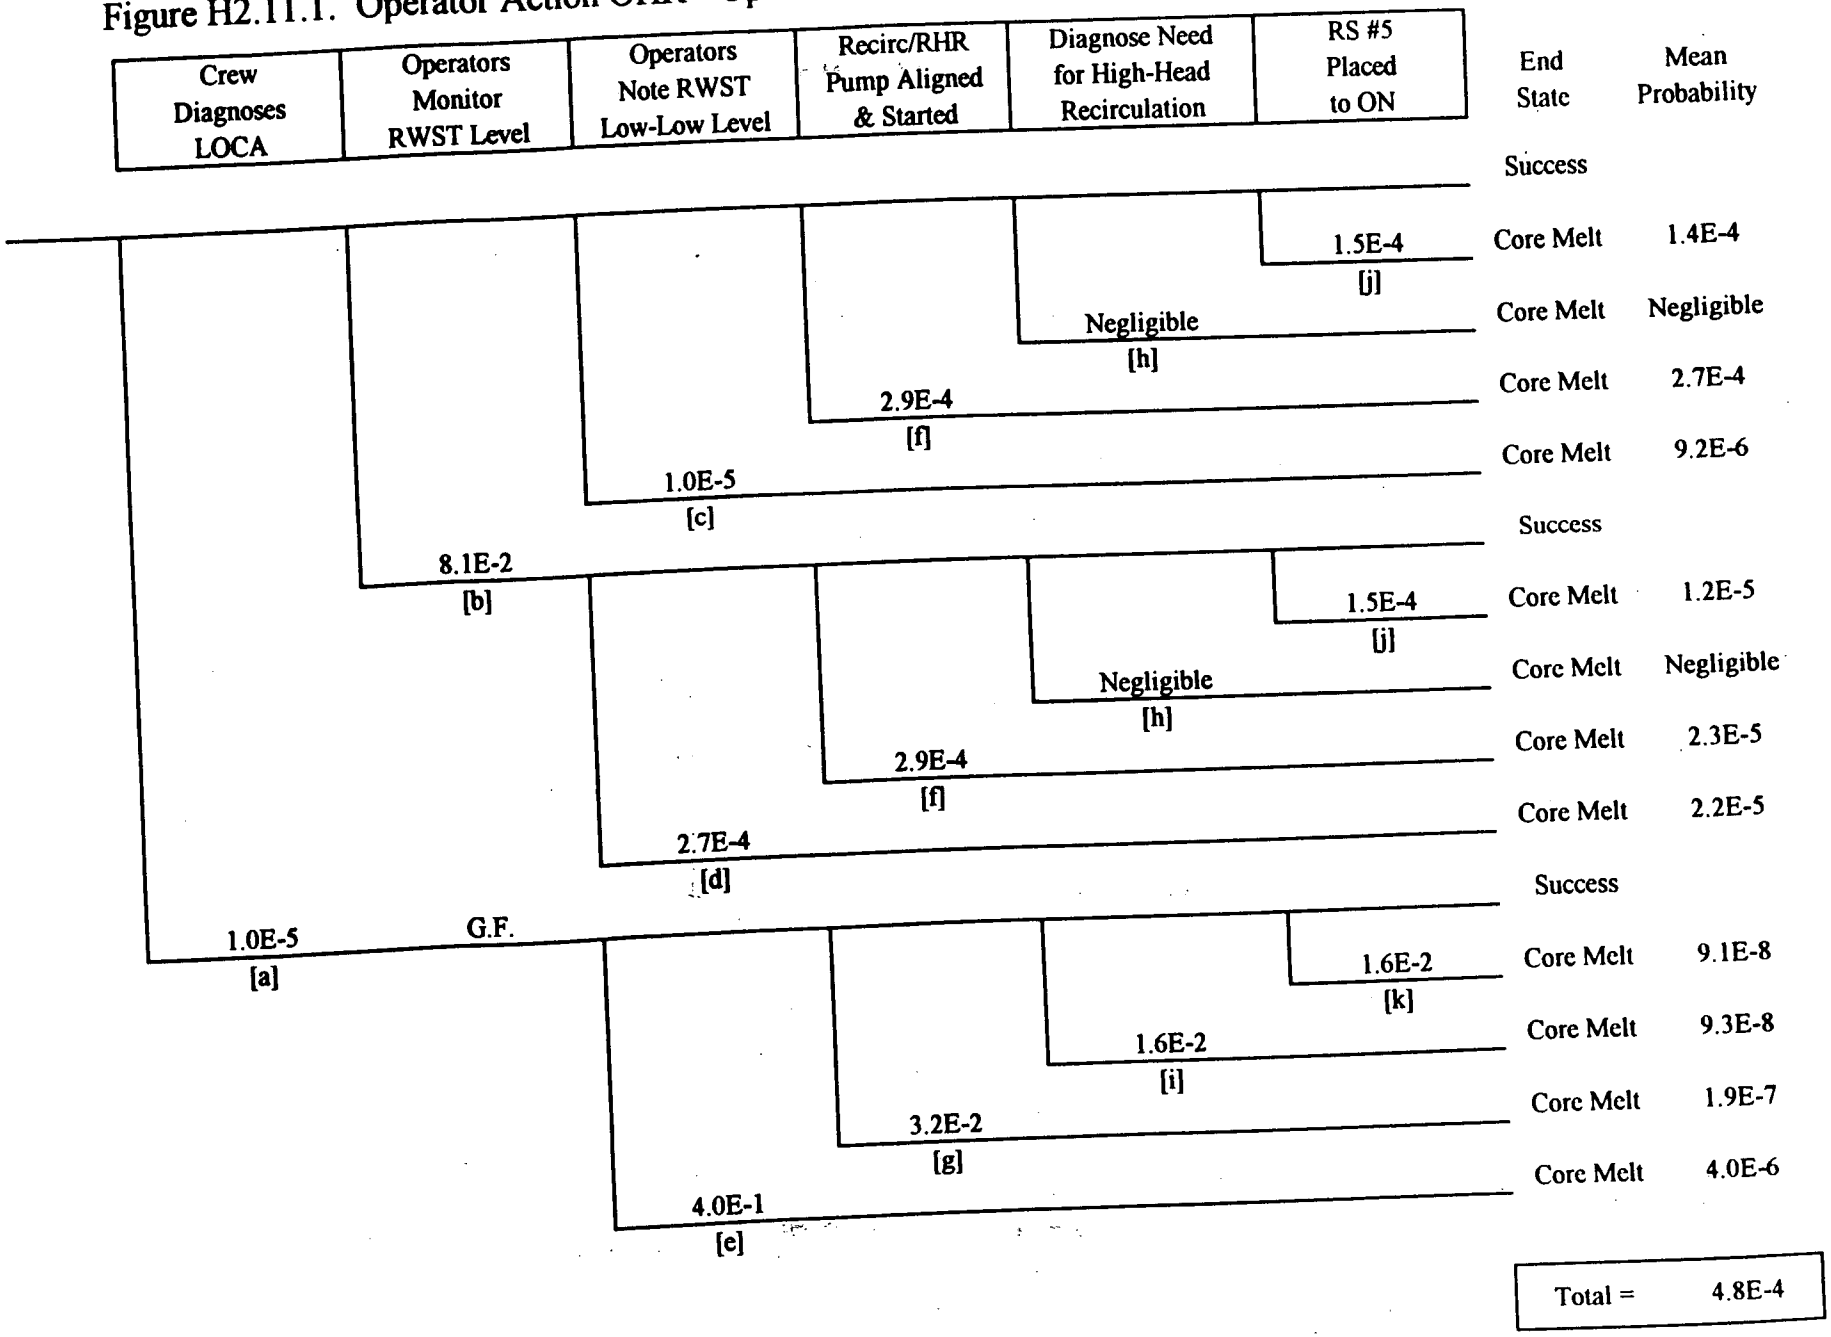
4. The operators must open the RHR pump containment sump suction valves.

5. The operators must start the RHR pump(s).

6. The operators must re-open HCV-638 or HCV-640 to establish flow through the RHR heat exchangers.

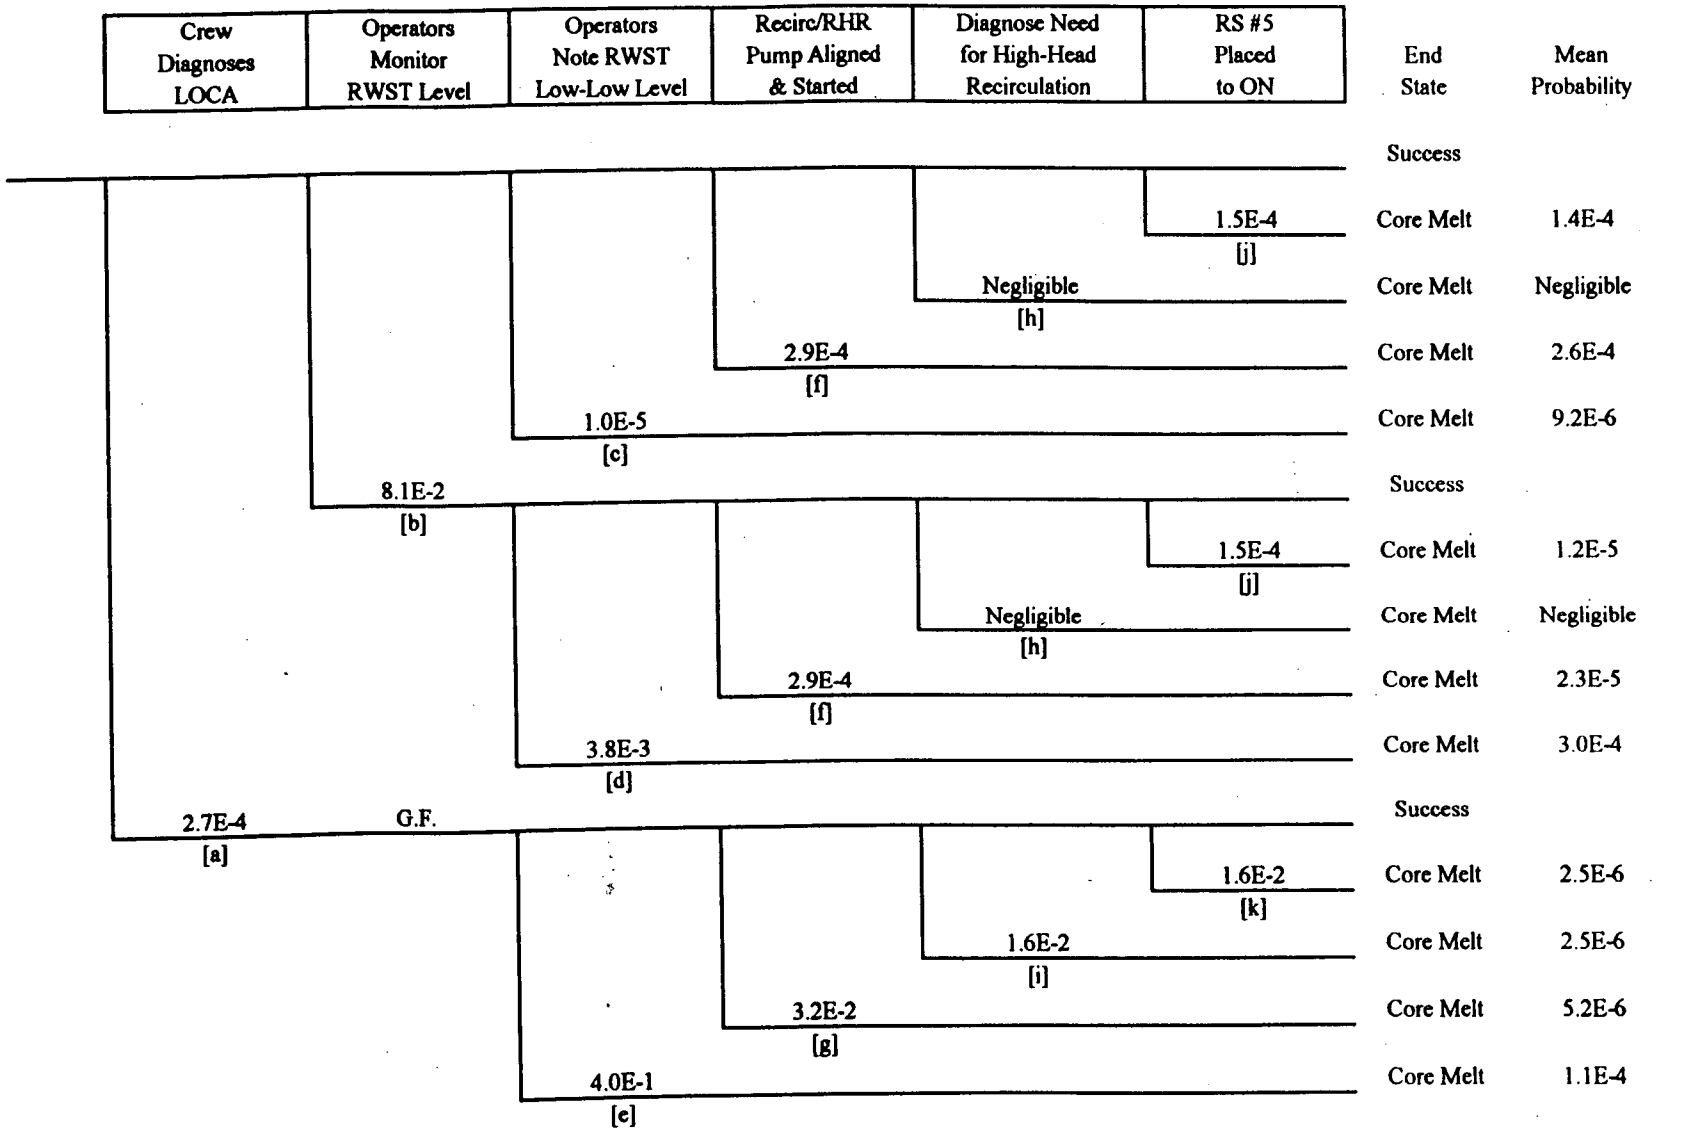
The overall effect of the above modifications to operator action OHR is shown in Table H2.12.1 of Section H2.12.

Figure H2.11.1. Operator Action OHR - Operator Initiates High-Head Recirculation Flow (Small LOCA)



G.F. = Guaranteed Failure

Figure H2.11.2. Operator Action OHR - Operator Initiates High-Head Recirculation Flow (Intermediate LOCA)



G.F. = Guaranteed Failure

H2.12 OPERATOR ACTION OLR--OPERATOR INITIATES LOW-HEAD RECIRCULATION FLOW

SUMMARY

a. Task. The operator aligns the LHSI pumps to take suction from the containment/recirculation sump.

b. Success Criteria. Success requires that flow to one of four cold legs be delivered by one of two recirculation pumps, taking suction from the recirculation sump, or by one of two RHR pumps, taking suction from the containment sump.

c. Scenario/Event Tree(s) Used. Small, intermediate, and large LOCAs, special initiators (TCCW and TSWS), and SGTR.

ACTION

a. Initial Conditions. The reactor is at full power. A loss of reactor coolant occurs, resulting in a reactor trip and safety injection signal. Subsequent plant response is conditional on the initiating event:

Large LOCAs - At least one RHR pump or two of three HHSI pumps inject RWST water into the RCS cold legs.

Small and Intermediate LOCAs - At least one of three HHSI pumps injects RWST water into the RCS cold legs. One recirculation or RHR pump is available. The operator depressurizes the RCS to below the shut-off head of the recirculation/RHR pumps.

The other initiating events were assumed to be bounded by the small LOCA case.

b. Preceding Operator Actions. For small and intermediate-break LOCAs, the operator depressurizes the RCS to below the shut-off head of the RHR pumps. For large-break LOCAs, no operator actions are required prior to sump recirculation provided automatic actions are successful.

c. Symptoms.
"RWST Low-Low Level" annunciator lit.
Greater than 1200 gpm to at least two low-head injection lines.

d. Indications.
RWST water level transmitter LT-920.
Low-head injection flow transmitters FT-946A/B/C/D.

e. Procedural Guidance. Upon receipt of a reactor trip and safety injection signal, the operators will enter procedure E-0 (Reactor Trip or Safety Injection). At step 30 of E-0 the operators will transfer to E-1 (Loss of Reactor or Secondary Coolant) on abnormal containment radiation, pressure, or sump level. If at any time (regardless of which procedure is in use) RWST water level falls below 9.2 ft, the operators will transfer to ES-1.3 (Transfer to Cold Leg Recirculation). The criterion for transferring to sump recirculation (9.2 feet in the RWST) is annunciated on panel SBF-2.

f. Response.

ES-1.3 (Rev. 7)

Step 2 Energize the following valve control circuits:
- a) 882 and 1870 at MCC-36B [PAB - 55-ft elevation].
- b) 1810, 743, and 744 at MCC-36A [PAB - 55-ft elevation].
- c) 842 and 843 at SBF-1.

Step 10 Reset SI.

Step 11 Reset containment spray signal.

Step 13 Place Recirculation Switch 1 to ON position.

This action:
- a) trips HHSI pump 32.
- b) isolates HHSI pump 32 suction valves 887A/B.
- c) trips spray pump 32 if spray pump 31 is running and closes spray pump 32 discharge valve 866B.

Step 13c Place HHSI Pump 32 in PULLOUT.

Step 14 Place recirculation switch 3 to ON position.

This action:
- a) Trips both RHR pumps 31 and 32.
- b) Closes RHR suction valve 882 and discharge valve 744.

Step 15 Close SWN-FCV-1111 and SWN-FCV-1112. Then start one non-essential SW pump.

Step 17a Open recirculation pump header discharge valves 1802A/B.

Step 17c Start recirculation pump 31 or 32. If neither recirculation pump can be started, then start an RHR pump.

Step 19 Place recirculation switch 6 to ON position.

This action trips all HHSI pumps.

Step 21 Place recirculation switch 8 to ON position.

This action:
a) Closes spray pump test line valve 1813.
b) Closes HHSI suction valve 1810.

Should containment spray be needed for recirculation, the following step in ES-1.3 must be performed.

Step 37b Open spray header valve 889B. If valve 889B will not open, open 889A.

PERFORMANCE SHAPING FACTORS

a. Timing. The cue for the switchover to cold leg recirculation is an alarm at a 9.2 ft level in the RWST. The time at which this alarm is anticipated varies with the size of the RCS break and operator action to depressurize the RCS.

- *Small LOCA* - From MAAP calculations performed for a small LOCA initiator (0.02 ft^2), the low-low RWST water level (9.2 ft) will be reached in 181.4 minutes (3 hours). Because this break size is at the high end of the break spectrum for small LOCAs, the switchover to sump recirculation will not be made until at least 3 hours have elapsed.

- *Intermediate LOCA Without Containment Spray Actuation* - Intermediate LOCAs were analyzed assuming that the break is in the high end of the spectrum (0.2 ft^2). A large break size increases the rate of RWST depletion and, therefore, decreases the time available for the operators to switch to sump recirculation. In addition, for sequences with one or more containment fan cooler units operating, MAAP runs have shown that containment spray will not be actuated (i.e., containment pressure remains below 37.2 psia). The low-low RWST level is reached in 69 minutes.

- *Intermediate LOCA With Containment Spray Actuation* - Without containment fan coolers operating, containment spray will be actuated at 14 minutes, causing the low-low RWST level to be reached in 51 minutes.

- *Large LOCA* - Assuming that the HHSI, RHR, and containment spray pumps deliver their design flow rates (400 gpm, 3000 gpm, and 3120 gpm, respectively), the low-low RWST level will be reached in (346,870 - 99,475)/(3 × 400 + 2 × 3000 + 2 × 3120) = 18 minutes. However, for large LOCAs, the design pump flow rates may be

exceeded, resulting in more rapid RWST depletion. To obtain a more realistic estimate of time to depletion, calculations were performed using the MARCH code. These results showed that the low-low RWST level is reached at approximately 16 minutes after the initiating event, which is comparable to the hand calculation.

Time Available - The time available to complete the switchover to cold leg recirculation depends on the size of the RCS break.

- *Small LOCA with Depressurization* - The time available for this scenario differs from the small LOCA scenario requiring high-pressure recirculation (Operator Action OHR) in that depressurization of the RCS to below the shut-off head of the RHR pumps will deplete the RWST more rapidly. Although the operators are instructed to shut off the RHR pumps in E-1 (Step 20) prior to depressurization if RCS pressure is stable or increasing, once RCS pressure is below the shut-off head of the RHR pumps, the operators will restart the pumps. Therefore, at the low-low RWST level, the rate of RWST depletion in this scenario will be greater than for the small LOCA scenario without RCS depressurization. For this reason, this action was conservatively modeled using the HEP derived for the intermediate LOCA without containment spray actuation (see below).

- *Intermediate LOCA Without Containment Spray Actuation* - MAAP runs have shown that for intermediate-size breaks (0.2 ft^2) with one or more containment fan cooler units operating, RWST level will decrease from 9.2 ft to 2 ft within 15 minutes, at which time the operators are instructed to stop all ECCS pumps taking suction from the RWST. Should they fail to do so, insufficient net positive suction head (NPSH) and failure of the HHSI, containment spray, and RHR pumps will occur approximately 5 minutes after the level reaches 2 ft. MAAP runs also showed that the core is uncovered approximately 2.1 hours (125 minutes) after the ECCS pumps are stopped, and core exit temperatures reach 2200°F approximately 30 minutes thereafter. To be conservative, it was assumed that recirculation must be established before the core is uncovered. Therefore, the operators have 15 + 125 = 140 minutes to establish sump recirculation assuming that the pumps are stopped when RWST level reaches 2 ft. If the operators do not stop the ECCS pumps, the RHR pumps will fail and only the recirculation pumps will be available for sump recirculation.

- *Intermediate LOCA With Containment Spray Actuation* - MAAP runs have shown that for intermediate-size breaks (0.2 ft^2) with no containment fan cooler units operating, RWST level will decrease from 9.2 ft to 2 ft within 10.7 minutes, at which time the operators are instructed to stop all ECCS pumps taking suction from the RWST. Should they fail to do so, insufficient net positive suction head (NPSH) and failure of the HHSI, containment spray, and RHR pumps will occur approximately 3.1 minutes after the level reaches 2 ft. MAAP runs also showed that the core is uncovered approximately 2.0 hours (118 minutes) after ECCS pumps are stopped, and core exit temperatures reach 2200°F approximately 26 minutes

thereafter. To be conservative, it was assumed that recirculation must be established before the core is uncovered. Therefore, the operators have 11 + 118 = 129 minutes to establish sump recirculation assuming that the pumps are stopped when RWST level reaches 2 ft. If the operators do not stop the ECCS pumps, the RHR pumps will fail and only the recirculation pumps will be available for sump recirculation.

- *Large LOCA* - Assuming that the HHSI, RHR, and containment spray pumps deliver their maximum flow (650 gpm, 5500 gpm, and 3120 each, respectively), the empty level (0 ft, or 13,902 gallons) will be reached in 85,573/(3 × 650 + 2 × 5500 + 2 × 3120) = 4.5 minutes from the time at which the 9.2-ft level is reached. If the operator does not stop the pumps taking suction from the RWST at this time, those pumps will cavitate and fail. MARCH predicts that core melt will begin approximately 34 minutes later.

Time Needed - Observations made during simulator exercises indicate that approximately 5 minutes are required to step through procedure ES-1.3 and place RS #1 to the ON position. Another 10 minutes are required to complete the eight-step sequence for switchover to sump recirculation. Therefore, a total of 15 minutes may be required between entry into ES-1.3 and the completion of sump recirculation.

b. Competing Actions/Alarms. It was assumed that up to five annunciators could be sounding at the time of sump switchover for large LOCA initiators. In addition, the operators may be prompted to make a transition to FR-P.1 (Response to Imminent Pressurized Thermal Shock Conditions). However, if a low-low RWST level occurs, ES-1.3 takes precedence over FR-P.1.

c. Consequence of Actions.

Success - Success results in continued core cooling and RCS make-up with the recirculation/RHR pumps taking suction from the appropriate sumps and delivering flow to the RCS cold legs.

Failure - Failure results in a loss of core cooling.

d. Training/Experience. The operators have ample experience practicing this scenario on the control room simulator.

e. Stress. For large-break LOCAs, extremely high stress levels were assumed. For small and intermediate-break LOCAs, moderately high stress levels were assumed because of the longer time available before the RWST low level (9.2 ft) is reached.

f. Skill/Rule/Knowledge-Based. Rule-based. Each step is proceduralized.

g. Task Complexity. Moderate to high. This action involves a series of steps and requires

the operator to monitor flows to determine whether to align the ECCS for low-head or high-head recirculation.

QUANTIFICATION

Small LOCA With Depressurization

For the reasons described above, this action was conservatively assigned the HEP calculated for the intermediate LOCA. The operator action tree depicting the failure of the operator to initiate low-head recirculation during a small LOCA is shown in Figure H2.12.1.

Intermediate LOCA

The operator action tree depicting the failure of the operator to initiate low-head recirculation during an intermediate LOCA is shown in Figure H2.12.1. Error in the diagnosis of a LOCA was not depicted in the tree as operator action OLR follows operator action ODEPR which itself requires successful diagnosis of a LOCA. The total HEP for operator action OLR was calculated to be 3.0×10^{-4}.

Failure Node	Median HEP (Error Factor)	Mean HEP	Source (NUREG/CR-4772)
[a] Operators Monitor RWST Level	0.05 (EF=5)	0.081	Table 8-5, item 4.
[b] Operators Note RWST Low-Low Level (Given Crew Has Monitored RWST Level)	Negligible	10^{-5}	
[c] Operators Note RWST Low-Low Level (Given Crew Failed to Monitor RWST Level)	2×10^{-6} (EF=30)	1.7×10^{-5}	Table 8-2 (lower bound).

Once the LOCA has been diagnosed, the primary operator will be aware of the need to monitor RWST level, as implied by procedures. This constitutes a dynamic task performed under moderately high stress.

Given that the crew has successfully diagnosed the LOCA and monitored the RWST level, the probability that the operators fail to note the RWST low-low level alarm is considered to be negligible.

With a recirculation pump available, the time available to establish low-head recirculation

cooling is equal to the time required to deplete the RWST (15 minutes) plus the time to core uncovery (125 minutes). Therefore, the total time available to diagnose the need for low-head sump recirculation is 15 + 125 - 15 = 125 minutes. The lower bound diagnosis HEP was used because of the extensive training received by the operators on this action.

[d] Recirculation/RHR Pump Aligned and Started

0.004 (EF=5)		Table 8-5, item 3 (lower bound).
x 2		Two critical actions.
0.008 (EF=5)	0.0129	

The operator must perform two critical, step-by-step actions: 1) open recirculation pump discharge valves SI-MOV-1802A/B, and 2) start recirculation pump 31 or 32. Complete dependence between opening the two valves was assumed because opening either valve will result in success. Moderately high stress levels have been assumed. Because of extensive training, the lower bound value of the HEP was used.

0.058 (EF=5)	0.094	NUREG/CR-1278, Equation 10-15 in Table 20-17.

The procedure directs the operators to verify minimum core cooling flow upon completion of the eight-step transfer to cold leg recirculation. This satisfies the rules in NUREG/CR-1278 for the assessment of low dependence between the transfer and check.

0.15 (EF=5)	0.24	NUREG/CR-1278, Equation 10-16 in Table 20-17.

SS recovers error, assuming moderate dependence between the SS and the operators.

Total (d) = $0.0129 \times 0.094 \times 0.24 = 2.9 \times 10^{-4}$.

Large LOCA

The operator action tree depicting the failure of the operator to initiate low-head recirculation following large LOCAs is shown in Figure H2.12.3. The quantification of this tree is described below. The total mean HEP for this action was calculated to be 4.4×10^{-3}.

Failure Node	Median HEP (Error Factor)	Mean HEP	Source (NUREG/CR-4772)
[a] Crew Diagnoses LOCA			
	2.1×10^{-3} (EF=10)	5.6×10^{-3}	Table 8-2 (lower bound).

The time available for diagnosis was based on the time at which the low-low RWST level is reached, approximately 16 minutes.

[b] Operators Monitor RWST Level

0.25 (EF=5)	0.40	Table 8-5, item 5.

Once the LOCA has been diagnosed, the primary operator will be aware of the need to monitor RWST level, as implied by procedures. This constitutes a dynamic task performed under extremely high stress. (Extremely high stress was assigned based on Table 8-1, item 10.e).

[c] Operators Note RWST Low-Low Level (Given Crew Has Diagnosed LOCA and Monitored RWST Level)

Negligible	10^{-5}

Given that the crew has successfully diagnosed the LOCA and monitored the RWST level, the probability that the operators fail to note the RWST low-low level alarm is considered to be negligible.

[d] Operators Note RWST Low-Low Level (Given Crew Has Diagnosed LOCA but Failed to Monitor RWST Level)

10^{-3} (EF=10)	2.7×10^{-3}	Table 8-2, item 3 (lower bound).

With a recirculation pump available, the time available to establish low-head recirculation cooling is equal to the time required to deplete the RWST (4.5 minutes) plus the time to core uncovery (30 minutes). Therefore, the total time available to diagnose the need for low-head sump recirculation is 5 + 30 - 15 = 20 minutes. The lower bound diagnosis HEP was used because of the extensive training received by the operators on this action.

[e] Operators Note RWST Low-Low Level (Given Crew Has Failed to Diagnose LOCA)

0.25 (EF=5)	0.40	Table 8-5, item 5.

If the crew fails to diagnose the LOCA, they will not be expecting the low-low RWST level alarm. Therefore, when this alarm sounds, it is assumed that the operators will be under extremely high stress (threat stress).

[f] Recirculation/RHR Pump Aligned & Started (Given Crew Has Diagnosed LOCA)

0.01 (EF=5)		Table 8-5, item 4 (lower bound).
x 2		Two critical actions.
0.02 (EF=5)	0.0323	

The operator must perform two critical, step-by-step actions: 1) open recirculation pump discharge valves SI-MOV-1802A/B, and 2) start recirculation pump 31 or 32. Complete

dependence is assumed between opening the two valves because opening either valve will result in success. Extremely high stress levels were assumed due to the presence of a large LOCA. Because of extensive training, the lower bound value of the HEP was used.

0.069 (EF=5)	0.111	NUREG/CR-1278, Equation 10-15 in Table 20-17.

The procedure directs the operators to verify minimum core cooling flow upon completion of the eight-step transfer to cold leg recirculation. This satisfies the rules in NUREG/CR-1278 for the assessment of low dependence between the transfer and check.

0.16 (EF=5)	0.26	NUREG/CR-1278, Equation 10-16 in Table 20-17.

SS recovers error, assuming moderate dependence between the SS and the operators.

Total [f] = $0.0323 \times 0.111 \times 0.26 = 9.3 \times 10^{-4}$.

[g] Recirculation/RHR Pump Aligned & Started (Given Initial Failure to Diagnose LOCA)

0.01 (EF=5)		Table 8-5, item 4 (lower bound).
× 2		Two critical actions.
× 2		Doubling rule for time stress.
0.04 (EF=5)	0.065	

Same action as failure node [f], except no credit was taken for recovery and the HEP was doubled to account for time stress.

A summary of the quantitative results for operator actions OLR and OHR (from Section H2.11) are shown in Table H2.12.1.

COMMENTS

The quantification of operator action OLR was performed assuming that the recirculation pumps are available for low pressure recirculation. However, should the recirculation pumps be unavailable, the operators must align the RHR pumps to take suction from the containment sump. This aspect changes the quantification of the human error probability in the following manner:

1. Turning recirculation switch #3 to the ON position, or stopping the RHR pumps before the RWST depletes, becomes a critical action.

2. Returning recirculation switch #3 to the OFF position also is a critical action, since this

action allows the operator to re-open the RHR pump discharge valve 744.

3. The operators must re-open the RHR pump discharge valve 744.

4. The operators must open the RHR pump suction valves (from the sump).

5. The operators must start the RHR pump(s).

6. The operators must re-open HCV-638 and/or HCV-640 to establish flow through the RHR heat exchanger(s).

The net effect of the above modifications to operator action OLR is shown in Table H2.12.1.

Figure H2.12.1. Operator Action OLR - Operator Initiates Low-Head Recirculation Flow (Small or Intermediate LOCA)

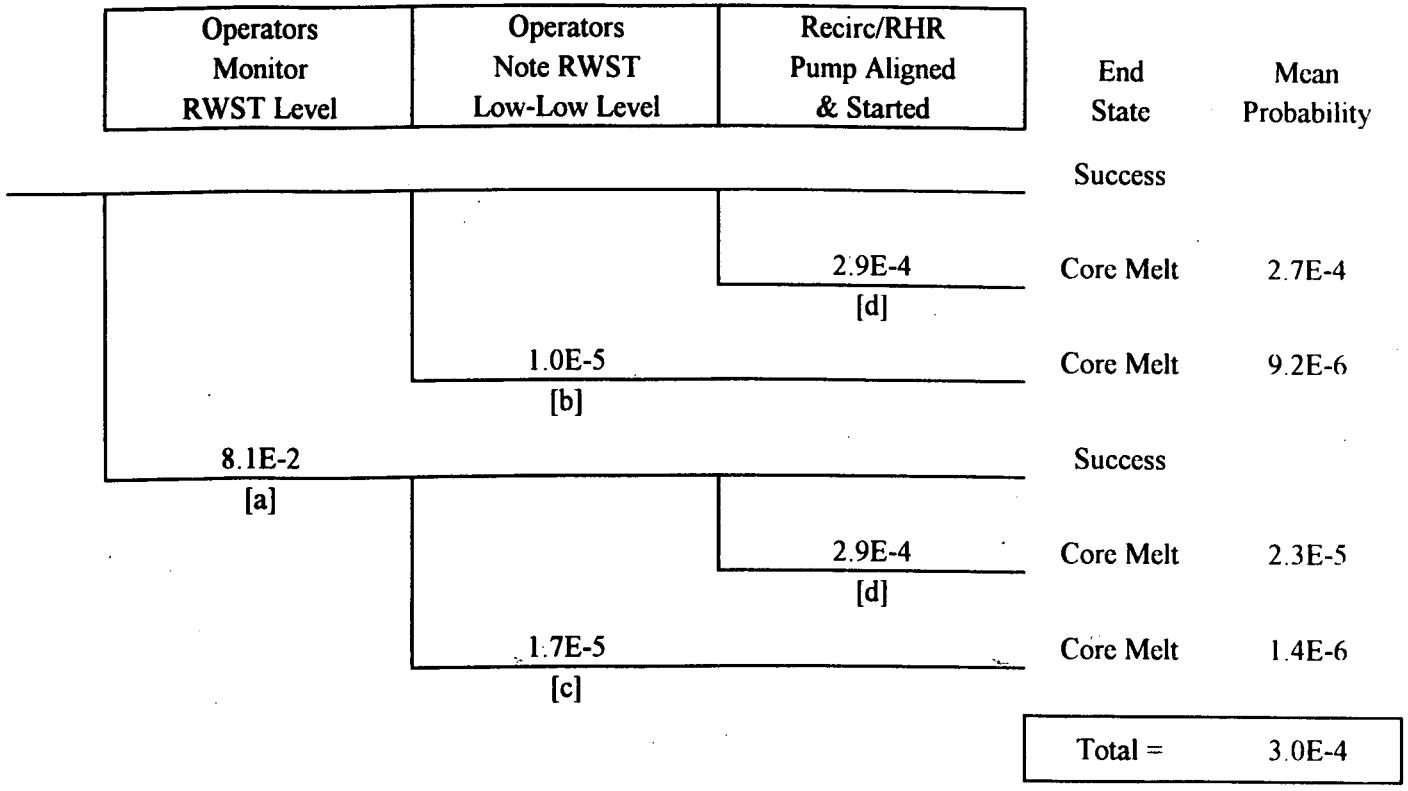


Figure H2.12.2. Operator Action OLR - Operator Initiates Low-Head Recirculation Flow (Large LOCA)

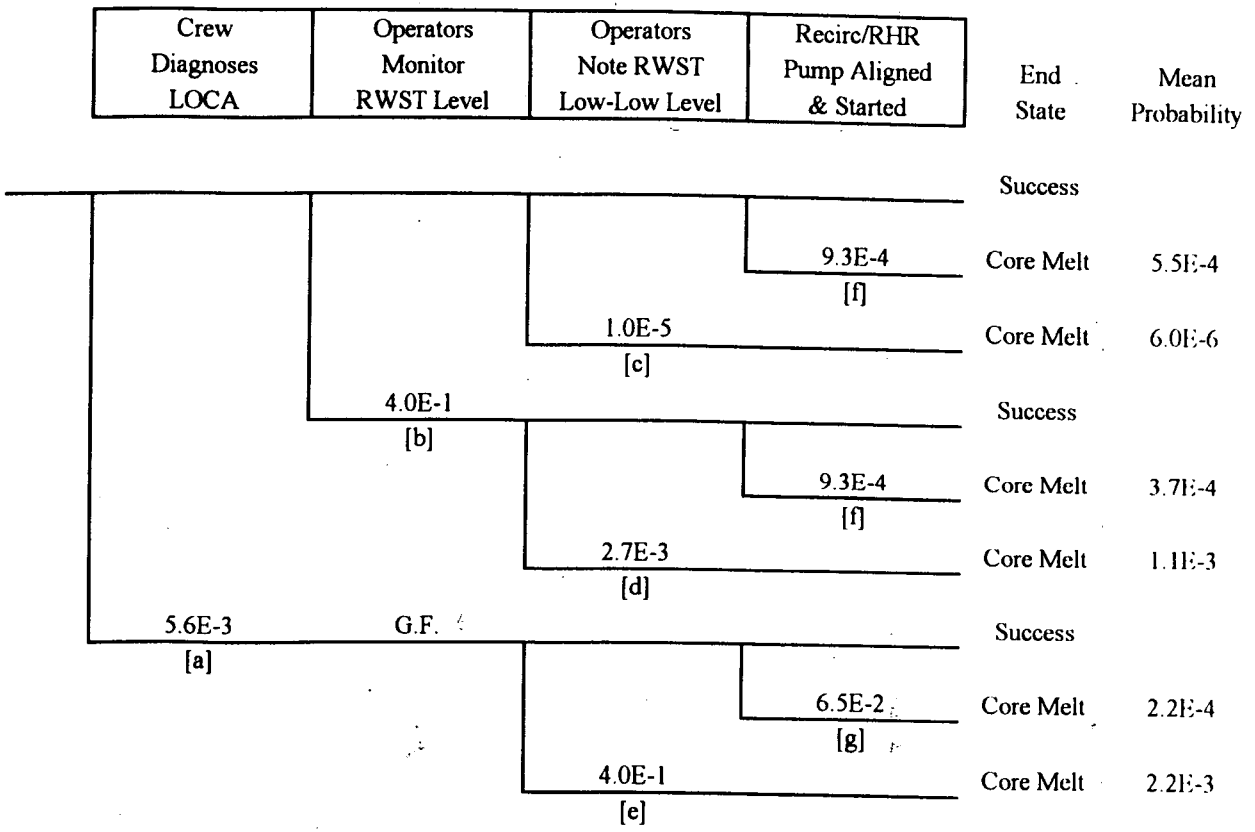

G.F. = Guaranteed Failure

Table H2.12.1. Summary of Results for Switchover to Sump Recirculation

Scenario	Recirculation and RHR Pump Status			Total Mean HEP [1]
	Recirc & RHR Pumps Available	Only Recirc Pumps Available	Only RHR Pumps Available	
HHR - SLOCA	4.8E-4	4.8E-4	2.2E-3	4.8E-4
HHR - MLOCA	8.6E-4	8.6E-4	2.3E-3	8.6E-4

H2.13 OPERATOR ACTION ORCS--OPERATOR PERFORMS EARLY (ORCS-E) OR LATE (ORCS-L) RCS COOLDOWN AND DEPRESSURIZATION

SUMMARY

a. Task. The operators depressurize the RCS using the intact steam generators to reduce and eventually terminate flow into the faulted steam generator.

b. Success Criteria. The operators reduce RCS pressure to a value at or below the pressure of the faulted steam generator.

c. Scenario/Event Tree(s) Used. SGTR.

ACTION

a. Initial Conditions. While the reactor is operating at full power, a steam generator tube ruptures.

b. Preceding Operator Actions. The operators will isolate flow to and from the faulted steam generator.

c. Symptoms. RCS pressure greater than faulted SG pressure.

d. Indications.
Core exit thermocouples.
SG pressure indicators.
RCS pressure indicators.

e. Procedural Guidance. Upon receipt of a reactor trip and safety injection signal, the operators will enter procedure E-0 (Reactor Trip or Safety Injection). Step 29 of E-0 will transfer the operators to E-3 (Steam Generator Tube Rupture) on indication of abnormal condenser air ejector, SG blowdown, or main steam line radiation.

f. Response.

E-3 (Rev. 7)
Step 20 Initiate RCS cooldown.
- a. Determine required core exit temperature (based on ruptured SG pressure).
- b-c. Dump steam to condenser (or atmosphere) from intact SGs at maximum achievable rate until core exit temperatures are less than the required temperature from Step 20.a.
- d. Stop RCS cooldown.

e. Maintain stable RCS temperature.

Step 24 Depressurize RCS to minimize break flow and refill pressurizer using pressurizer spray. If spray not available, perform Step 25.

Step 25 Depressurize RCS using pressurizer PORV to minimize break flow and refill pressurizer.

PERFORMANCE SHAPING FACTORS

a. Timing: MAAP code runs were performed for a SGTR to determine the time available to the operators to successfully cool down and depressurize the RCS. The following conditions were analyzed:

- AFW Flow Isolated - The MAAP code predicts that if the operators isolate AFW flow to the faulted steam generator at 20 minutes after reactor scram, the faulted SG will overfill 12 minutes thereafter.

- AFW Flow Not Isolated (High-Head Safety Injection Available) - MAAP predicts that should the operator fail to isolate feedwater flow to the faulted SG, the faulted SG will overfill 22 minutes after reactor scram. Alternatively, if the operators successfully isolate flow to the faulted SG but do not cool and depressurize the RCS in a timely manner, SG overfill will also occur, resulting in the release of water through the secondary safety valves. It was assumed that should this occur, the valves will fail to reclose and leakage can only be terminated if the RCS is cooled down and depressurized to cold shutdown conditions before RWST depletion. MAAP code runs showed that for an initial leak rate of 400 gpm through the ruptured tube, RWST depletion occurs at 8 hours.

- High-Head Safety Injection Unavailable - Should HHSI be unavailable, the operator must initiate RCS cooldown using the intact steam generators to allow the accumulators to inject coolant and ensure adequate core cooling until low-head injection is possible. MAAP predicts that core damage will occur at 7 hours. The timing for core damage is taken from a MAAP run in which a 400 gpm RCS break and no emergency core cooling were assumed.

Time Needed -

- AFW Flow Isolated - The time required to cooldown and depressurize the RCS is based upon exercises conducted using the control room simulator. These exercises show that with RCPs tripped, the time required to cool and depressurize the RCS to below the ruptured SG pressure is approximately 12 minutes. Tripping the RCPs requires use of a pressurizer PORV for depressurization, since the spray valves are

inoperable. Should the RCPs trip, the time required for depressurization is less. With the RCPs running, cooldown can be accomplished more rapidly, while use of the spray valves instead of the PORV results in a longer time to depressurization. The net effect, however, is that cooldown and depressurization can be accomplished more quickly (< 12 minutes) with the RCPs running. For conservatism, 12 minutes was assumed to be the time required.

- AFW Flow Not Isolated (High-Head Safety Injection Available) - It is assumed that the operators need 2 hours to bring the RCS to RHR entry conditions (assuming a cooldown rate of 100 deg. F/hr) and an additional 3 hours to bring the reactor to cold shutdown (assuming a cooldown rate of 50 deg. F/hr). Therefore, the operator must initiate cooldown within 8 - 2 - 3 = 3 hours after reactor scram to terminate RCS leakage before RWST depletion.

- High-Head Safety Injection Unavailable - At least one hour is needed for RCS cooldown to 650 psig, the pressure at which the accumulators will inject coolant into the RCS. Once the accumulators have injected, it was assumed that an additional hour is required to bring the RCS to below the shut-off head of the RHR pumps. Therefore, the latest time at which cooldown can be initiated is 7 - 1 - 1 = 5 hours (assuming a cooldown rate of 100 deg. F/hr).

b. Competing Actions/Alarms. None expected.

c. Consequence of Actions.

Success - Success terminates RCS flow into the faulted steam generator.

Failure - Failure results in continued leakage of RCS inventory into the faulted steam generator. The steam generator will eventually overfill, causing a direct release into the environment through the atmospheric dump or safety valves. The RWST will eventually deplete and, with no alternative source of water for the ECCS pumps, core damage will result.

d. Training/Experience. The operators have substantial experience practicing this scenario on the control room simulator and are well aware of the need to perform this action in a timely manner.

e. Stress. Moderately stress levels are assumed.

f. Skill/Rule/Knowledge-Based. Rule-based. Each step is proceduralized.

g. Task Complexity. Moderate.

QUANTIFICATION

Operator Action ORCS-E

Diagnosis. Diagnosis was modeled in the quantification of operator action SGISO, which assumes that feed flow to the faulted SG must be isolated within 20 minutes of the reactor trip. The 20-minute time window is based on 32 minutes required to overfill the SG and 12 minutes to cooldown and depressurize the RCS. For sequences in which the operators are unsuccessful in preventing overfill, it was assumed that the operators must cool and depressurize the RCS to cold shutdown conditions to terminate RCS leakage into the faulted SG. Because the time available to diagnose and perform this action is very long (at least 7 hours), the diagnosis HEP was considered to be negligible.

Post-Diagnosis. Post-diagnosis human error was quantified using Table 8-5 (item 3)--performing a critical step-by-step task under moderately high stress. The median HEP is 0.02 with an error factor of 5. However, because the operators have been well-trained on this action, the lower bound of the HEP (0.004) was assigned. The resultant mean HEP is 6.5×10^{-3}.

Recovery. Assuming high dependence between the SRO and the board operator and moderate dependence between the SS and board operator, the median recovery HEPs are 0.5 (EF=5) and 0.15 (EF=5), respectively. The mean recovery HEPs for the SRO and SS are 0.81 and 0.24, respectively.

The mean HEP for operator action ORCS-E = $6.5\times10^{-3} \times 0.81 \times 0.24 = 1.3\times10^{-3}$.

Operator Action ORCS-L

- *Faulted SG Isolated (Operator Action SGISO Successful With Subsequent Failure of Operator Action ORCS-E).* If operator action SGISO is successful, diagnosis in operator action ORCS-E was also assumed to be successful. Thus, failure of operator action ORCS-E was presumed to be caused by post-diagnosis human error. This failure has the same result as a failure of operator action SGISO--the faulted steam generator is overfilled and water is released through the secondary side safety valve. Although there is some dependency between the failures of early and late cooldown/depressurization, because much more time is available for late cooldown/depressurization and recovery is possible even after steam generator overfill, low dependency between early and late cooldown/depressurization was assumed. Equation 10-15 in Table 20-17 yields a non-recovery probability of $(1+19 \times 1.3 \times 10^{-3})/20 = 0.05$. Therefore, the probability that the operators fail to perform both early and late cooldown/depressurization given successful isolation of flow to the faulted steam generator is:

  ORCS-E x ORCS-L (given SGISO success) = $1.3\times10^{-3} \times 0.05 = 6.5\times10^{-5}$.

- *Faulted SG Overfilled (Operator Action SGISO Failed).* Diagnosis failure in operator action SGISO was assumed to increase the likelihood of diagnosis failure in operator action ORCS-L. The time available for diagnosis of the SGTR in ORCS-L is 3 hours, or 180 minutes. The lower bound median diagnosis HEP from Table 8-2 of NUREG/CR-4772 is 4.6×10^{-6} (EF=30), which results in a mean diagnosis HEP of 3.9×10^{-5}. The post-diagnosis HEP is the same as that for ORCS-E (i.e., 1.3×10^{-3}). The mean HEP for operator action ORCS-L (given failure to isolate flow to the faulted steam generator) is:

  $$\text{ORCS-L (given SGISO failed)} = [3.9\times10^{-5} + (2.7\times10^{-3})(1 - 3.9\times10^{-5}/2.7\times10^{-3})(1.3\times10^{-3}) + (1 - 2.7\times10^{-3})(1.25\times10^{-3})(1.3\times10^{-3})] \div 3.9\times10^{-3} = 0.01$$

H2.14 OPERATOR ACTION RHR-SD--DECAY HEAT REMOVAL PROVIDED BY RHR SHUTDOWN COOLING

SUMMARY

a. Task. The operator establishes RHR operation for normal shutdown cooling by opening the hot leg suction isolation valves, adjusting the flow control valves downstream of the RHR heat exchangers, and starting an RHR pump.

b. Success Criteria. Success requires that one RHR pump take suction from the RCS hot leg and discharge to one of four RCS cold legs.

c. Scenario/Event Tree(s) Used. Small-small LOCA and SGTR. This action is modeled for sequences in which the operator has cooled and depressurized the RCS to less than 450 psig and 350°F, with support to at least one RHR pump available.

ACTION

a. Initial Conditions. While the reactor is at full power, a loss of reactor coolant occurs. The loss is sufficient to initiate an SI signal, but not enough to actuate containment spray. The reactor is tripped and SI actuated. The RCS pressure remains above the shut-off head of the RHR pumps. At least one HHSI pump starts and injects RWST water, and at least one RHR pump starts and runs in minimum flow.

b. Preceding Operator Actions. The operator has cooled and depressurized the RCS to less than 450 psig and 350°F.

c. Symptoms. RCS pressure $\leq$450 psig and RCS temperature $\leq$350°F.

d. Indications.
Flow indication (FI-638 and FI-640).
Temperature indication (TE-639 and TE-641).
RCS temperature and pressure indication.

e. Procedural Guidance. Upon a reactor trip, the operators will enter procedure E-0 (Reactor Trip or Safety Injection) and proceed through E-0 until step 30. At step 30 of E-0 the operators will transfer to E-1 (Loss of Reactor or Secondary Coolant) on indication of abnormal containment radiation, pressure, or sump level. At step 24 of E-1, the operators are instructed to check if RCS cooldown and depressurization are required. For small LOCAs or SGTRs, RCS pressure will be greater than 275 psig and the transfer to procedure ES-1.2 (Post-LOCA Cooldown and Depressurization) will be made. Step 25 of ES-1.2 will instruct the operators to check if the RHR system can be placed in service.

If RCS temperature is less than 350°F and RCS pressure is less than 450 psig with adequate power available to at least one RHR pump, then the RHR system will be placed in service as dictated by system operating procedure SOP-RHR-1 (Residual Heat Removal System).

f. Response.

SOP-RHR-1 (Rev. 10)

Step 4.2.4 Open component cooling water valves (822A for RHR pump 31; 822B for RHR pump 32).

Step 4.2.10 Isolate the RHR loop from the RWST by closing valve 882.

Step 4.2.11 Unlock and open the manual containment isolation valve AC-732 (located at the 55-ft elevation in the PAB piping penetration area). Energize and open motor-operated RHR pump suction valves AC-730 and AC-731 (at MCC-36A and 36B, respectively--55-ft elevation in the PAB).

Step 4.2.12 Close the RHR heat exchanger discharge hand flow control valves HCV-638 and 640.

Step 4.2.13 Start an RHR pump.

Step 4.2.18 Adjust the RHR heat exchanger discharge hand flow control valves HCV-638 and HCV-640 to give the desired RCS cooldown rate.

PERFORMANCE SHAPING FACTORS

a. Timing.

Time Available - Considerable time is available for aligning RHR for normal cooldown since the AFW System can maintain RCS pressure and temperature at RHR cut-in conditions. However, the operators must establish RHR cooling before a low level (9.2 ft) is reached in the RWST.

Time Needed - The alignment to normal RHR cooldown can be accomplished within 30 minutes.

b. Competing Actions/Alarms. None expected.

c. Consequence of Actions.

Success - Success implies successful long-term RHR shutdown cooling.

Failure - Failure requires switchover to cold leg recirculation when the RWST water level reaches the low-low setpoint.

d. Training/Experience. This action is performed during normal plant trips in which the plant is brought to cold shutdown conditions and during refuelling outages.

e. Stress. Normal. While the stress levels could initially be high, by the time normal RHR cooldown is to be performed (> 4 hrs), the operators will be under considerably less stress with the plant in a stable condition. Because this action is part of the normal operating procedures, there would be very little reluctance to perform it.

f. Skill/Rule/Knowledge-Based. This action is both rule- and skill-based. The operators have experience in performing the action, and each step is proceduralized.

g. Task Complexity. This action has moderate complexity. However, the operators have considerable experience in performing it.

QUANTIFICATION

Quantification of operator action RHR-SD is described below. The total mean HEP for this action was calculated to be 9.3×10^{-4}.

Median HEP (Error Factor)	Mean HEP	Source (NUREG/CR-4772)
Diagnosis Error		
Negligible due to the long time available for this action.		
Post-Diagnosis Error		
0.004 (EF=5)		Table 8-5, item 3 (lower bound).
x 6		6 critical actions.
0.024 (EF=5)	0.039	

Recovery

Should the operators make a error in aligning the RHR system for shutdown cooling, sufficient time will be available for the operators to identify the error. The indications of a loss of shutdown cooling are increasing RCS temperature and pressure. A recovery factor of 0.0614 (EF=5) was used for recovery at a subsequent step in the procedure, assuming low dependence. The mean recovery factor is 0.099. In addition, assuming moderate dependence between the SS and the others gives a median HEP of 0.15 (EF=5) and a mean HEP of 0.24.

The mean HEP for operator action RHR-SD = $0.039 \times 0.099 \times 0.24 = 9.3\times10^{-4}$

H2.15 OPERATOR ACTION RV--OPERATOR STOPS SAFETY INJECTION FLOW TO PREVENT PRESSURIZED THERMAL SHOCK

SUMMARY

a. Task. The operators terminate safety injection flow.

b. Success Criteria. Safety injection flow is terminated.

c. Scenario/Event Tree(s) Used. MSLB (T4, T5).

ACTION

a. Initial Conditions. While the reactor is operating at full power, a main steam line breaks. The RCS cools down. Subsequently, an SI signal is generated.

b. Preceding Operator Actions. No operator actions are required if all other systems operate as designed.

c. Symptoms. "RED" Path on Critical Safety Function "INTEGRITY".

d. Indications.
RCS cold leg temperature indicators.
RCS pressure indicators.

e. Procedural Guidance. Upon a reactor trip, the operators will enter procedure E-0 (Reactor Trip or Safety Injection). Since a safety injection signal will have been generated, the operators will continue in E-0 until they reach step 28. Step 28 of E-0 directs the operator to go to E-2 (Faulted Steam Generator Isolation) if any SG depressurizes in an uncontrolled manner or is completely depressurized. Upon exiting E-0, the STA is instructed to monitor the critical safety functions (CSFs). An "ORANGE" or "RED" condition on the "INTEGRITY" CSF status tree will cause the operators to enter functional restoration procedure FR-P.1 (Response to Imminent Pressurized Thermal Shock Conditions). If the SI termination criteria are met (i.e., RCS subcooling greater than 70°F and RVLIS full range level greater than 62 percent), the HHSI pumps will be stopped as dictated by step 12 of FR-P.1.

f. Response.

FR-P.1 (Rev. 5)
Step 7 Reset SI.
Step 12 Stop SI pumps and place in AUTO.

PERFORMANCE SHAPING FACTORS

a. Timing.

Time Available - 30 minutes.

Time Needed - 10 minutes, including time required to reach Step 12 of FR-P.1 and stop SI pumps.

b. Competing Actions/Alarms. All anticipated actions/alarms are related to this action.

c. Consequence of Actions.

Success - Success precludes a challenge to reactor vessel integrity by pressurized thermal shock (PTS).

Failure - Failure results in a challenge to reactor vessel integrity by PTS.

d. Training/Experience. The operators are well trained in this action.

e. Stress. Moderately high.

f. Skill/Rule/Knowledge-Based. Rule-based. Each step is proceduralized.

g. Task Complexity. Low.

QUANTIFICATION

Diagnosis Error. The time available for diagnosis is 30 - 10 = 20 minutes. The median HEP was estimated using Table 8-2 (item 3) of NUREG/CR-4772. Because the operators are well-trained on this action, the lower bound median HEP (0.001) was used. The mean HEP is 2.7×10^{-3}.

Post-Diagnosis Error. Terminating high-head safety injection is a step-by-step action performed under moderately high stress. In addition, because frequent simulator training has made control room operators very familiar with this action, the lower bound of the estimated HEP in Table 8-5 (item 3) was used. The mean HEP is 6.5×10^{-3}.

Recovery. Assuming moderate dependence between the SS and the other operators gives a median HEP of 0.15 (EF=5) and a mean HEP of 0.24.

The mean HEP for operator action RV = $2.7\times10^{-3} + 6.5\times10^{-3} \times 0.24 = 4.3\times10^{-3}$.

COMMENTS

For steam line break accident sequences, diagnosis in operator action RV was assumed to be part of the same process as diagnosis to isolate flow to the faulted SG (operator action MSGI) but with more time available. Thus, given diagnostic error in operator action MSGI, the probability of diagnostic error in operator action RV =

$$2.73\times10^{-3} \div 2.66\times10^{-2} = 0.103$$

However, the absence of diagnostic error in operator action MSGI was not held to diminish the probability of diagnostic error in operator action RV.

Thus, the HEP for operator action RV given the failure of operator action MSGI is

$$MSGI \times RV|MSGI = MSGI \cap RV, \text{ or}$$

$$0.0329 \times RV|MSGI = 2.73\times10^{-3} + (2.66\times10^{-2})(1 - 0.103)(1.6\times10^{-3}) + (1 - 2.66\times10^{-2})(6.5\times10^{-3})(4.3\times10^{-3}) = 2.80\times10^{-3}$$

$$\therefore RV|MSGI = 0.085$$

H2.16 OPERATOR ACTION SGISO--OPERATORS ISOLATE RUPTURED STEAM GENERATOR (SGTR)

SUMMARY

a. Task. The operators isolate flow to and from the faulted steam generator.

b. Success Criteria. The operators isolate feedwater flow to the faulted steam generator and close the associated main steam isolation valve (MSIV) and atmospheric dump valve (ADV).

c. Scenario/Event Tree(s) Used. SGTR.

ACTION

a. Initial Conditions. While the reactor is operating at full power, a steam generator tube rupture occurs.

b. Preceding Operator Actions. None.

c. Symptoms.
Condenser air ejector radiation abnormal.
SG blowdown radiation abnormal.
Increasing level in one SG.
Decreasing pressurizer level and pressure.

d. Indications.
"Process Monitor High Radiation" annunciator on panel SBF-2.
"R15 Condenser Air Ejector" alarm on the radiation monitoring control cabinet.
"R19 Steam Generator Blowdown" alarm on the radiation monitoring control cabinet.
Condenser air ejector radiation monitor RM015.
Steam generator blowdown radiation monitor RM019.
Main steam radiation monitors RM062A, B, C, and D (one per SG).[1]

e. Procedural Guidance. Upon receipt of a reactor trip and safety injection signal, the operators will enter procedure E-0 (Reactor Trip or Safety Injection). Step 29 of E-0 directs the operators to implement E-3 (Steam Generator Tube Rupture) if condenser air ejector, SG blowdown, or main steam line radiation is abnormal.

---

[1] According to Alarm Response Procedure ARP-40 (Rev. 6), the alarm is not presently connected to the main steam radiation monitors.

f. Response.

E-3 (Rev. 7)

Step 4 Isolate flow from ruptured SG(s).

a. Adjust faulted SG ADV controller to 1040 psig.
b. Close faulted SG MSIV and MSIV bypass valve.
c. Close faulted SG ADV. If ADV cannot be closed, locally isolate valve.
d. Locally close steam supply valve from faulted SG to turbine-driven AFW pump.
e. Verify blowdown isolation valve(s) on faulted SG closed [on panel SCF].
f. Locally isolate faulted SG steam traps upstream of MSIVs.

Step 5 Stop feed flow to ruptured SGs.

PERFORMANCE SHAPING FACTORS

a. Timing. MAAP code runs performed for a SGTR to determine the time available to the operators to successfully cool and depressurize the RCS predicted that if the operators isolate AFW flow to the faulted SG within 20 minutes of reactor scram, the time to SG overfill is 32 minutes after reactor scram. Failure to isolate feedwater flow to the faulted SG results in the SG overfilling at 22 minutes after reactor scram.

Time Available - Because the operator must also cool and depressurize the RCS to terminate leakage, it was assumed that AFW flow to the faulted SG must be isolated within 20 minutes of the reactor trip to ensure that the operator has sufficient time to cool and depressurize the RCS before SG overfill.

Time Needed - One minute to isolate the flow control valve feeding the ruptured steam generator. Fifteen minutes are estimated to be required for isolating the flow from the faulted SG, since some of the actions must be performed locally. However, local isolation of the SG steam traps and AFW turbine steam supply valve are not critical with respect to the time available to prevent SG overfill. Therefore, the limiting action is flow isolation to the faulted SG.

b. Competing Actions/Alarms. None expected.

c. Consequence of Actions.

Success - Success, in conjunction with RCS depressurization, prevents the direct release of reactor coolant into the environment through the faulted steam generator and open relief valves.

Failure - Failure results in steam generator overfill and release of RCS inventory through the atmospheric dump valve (ADV) or safety valves.

d. Training/Experience. The operators have substantial experience practicing this scenario on the simulator.

e. Stress. Moderate.

f. Skill/Rule/Knowledge-Based. Rule-based. Each step is proceduralized.

g. Task Complexity. Low.

QUANTIFICATION

Diagnosis Error. The time available for diagnosis is 20 minutes. The median HEP was estimated using Table 8-2 (item 3) of NUREG/CR-4772. Because the operators are well-trained on this action, the lower bound median HEP (10^{-3}) was used. The mean HEP is 2.7×10^{-3}.

Post-Diagnosis Error. Isolating feedwater flow to the faulted steam generator is a step-by-step action performed under moderately high stress. In addition, because frequent simulator training has made control room operators very familiar with this action, the lower bound of the estimated HEP in Table 8-5 (item 3) was used. The mean HEP is 6.46×10^{-3}.

Recovery. Assuming high dependence between the SRO and the board operator and moderate dependence for the SS results in median recovery HEPs of 0.5 (EF=5) and 0.15 (EF=5), respectively. The mean HEPs for the SRO and SS are 0.81 and 0.24, respectively.

The mean HEP for operator action SGISO = $2.7\times10^{-3} + 6.5\times10^{-3} \times 0.81 \times 0.24 = 3.9\times10^{-3}$.

H2.17 OPERATOR ACTION SLOCA--OPERATOR ALIGNS BACKUP CITY WATER TO CHARGING PUMP COOLERS

SUMMARY

a. Task. The operators supply backup city water to the charging pump coolers.

b. Success Criteria. Backup city water flow is established to at least one charging pump cooler.

c. Scenario/Event Tree(s) Used. Special initiators (TCCW, TSWS).

ACTION

a. Initial Conditions. While the reactor is operating at full power, a total loss of component cooling occurs.

b. Preceding Operator Actions. The operators trip the reactor coolant pumps.

c. Symptoms. Component cooling water low discharge pressure.

d. Indications.
"Component Cooling Pump Loop 1 Discharge Low Pressure" annunciator on panel SGF.
"Component Cooling Pump Loop 2 Discharge Low Pressure" annunciator on panel SGF.
Charging pump fluid drive cooler local flow indicator FI-637.
CCW flow indicators FI-601A/B on panel SGF.

e. Procedural Guidance.
Alarm response procedure ARP-10 directs the operator to enter procedure ONOP-CC-1. Step 5.9 of ONOP-CC-1 (Loss of Component Cooling) directs the operators to tie in backup city water cooling to the charging pumps if component cooling cannot be re-established, as dictated by SOP-CC-1B (Component Cooling System Operation).

In addition, for initiating events which result in an SI signal, Step 23 of E-0 directs the operators to locally align city water to the charging pumps if component cooling is unavailable.

f. Response.

SOP-CC-1B (Rev. 11)

Step 4.3.1.a Close telltale drain valves MW-681 and MW-684 on the city water supply line.
Step 4.3.1.b Close manual CCW inlet and outlet isolation valves AC-756A/B.
Step 4.3.1.c Open city water isolation valve MW-26 and city water backup supply valve AC-701A.
Step 4.3.1.d Remove the flange next to the city water backup drain valve AC-701B and then open the valve.

Note: Valves MW-681, MW-684, AC-756A/B, MW-26, AC-701A/B are located close to each other on the 55-ft elevation in the PAB. A phone is adjacent to the valves.

PERFORMANCE SHAPING FACTORS

a. Timing.

Time Available - Backup city water must be supplied to a running charging pump within 20 minutes of losing CCW to prevent overheating and subsequent failure of the charging pump. Should the running charging pump fail, the standby charging pumps are available to provide RCP seal cooling. Procedure SOP-CC-1B directs the operators not to operate any charging pump unless cooling water is supplied to the charging pump coolers. It was assumed that the operators will trip the running charging pump on loss of CCW flow to the coolers. (This assumption is conservative because tripping the charging pump hastens the RCP seal LOCA). Once the operators trip the charging pumps, one hour is available for the operators to align backup city water to the charging pump coolers and start the charging pumps before the RCP seal leak rate exceeds 24 gpm/pump or the capacity of the charging pumps.

Time Needed - 10-15 minutes. This estimate was based on walk-throughs with plant operators.

b. Competing Actions/Alarms. The operators will implement the EOPs once the reactor has been tripped. Therefore, procedure ONOP-CC-1 may be performed concurrently with the EOPs.

c. Consequence of Actions.

Success - Success maintains cooling of the RCP seals.

Failure - Failure results in a loss of RCP seal cooling and a primary system LOCA.

d. Training/Experience. The operators have been trained in how to respond to a loss of CCW flow to the charging pumps.

e. Stress. High stress levels are assumed based on the severity of the consequences of losing cooling to the RCP seals.

f. Skill/Rule/Knowledge-Based. Rule-based. Each step is proceduralized.

g. Task Complexity. Moderate.

QUANTIFICATION

Diagnosis Error. Assuming that the operators trip the running charging pumps on loss of CCW, 60 minutes are available to align backup city water to the charging pump coolers before RCP seal failure. Assuming that 15 minutes are required to perform the alignment, 45 minutes are available for diagnosis. Using Table 8-2 of the ASEP HRAP yields a median HEP of 2.60×10^{-4} and an error factor of 10. This results in a mean HEP of 6.9×10^{-4}.

Post-Diagnosis Error. Four critical valve manipulations must be performed by the operator. Assuming a moderate level of stress, a median HEP of $4 \times 0.02 = 0.08$ was assumed (with an error factor of 5) using Table 8-5. The associated mean HEP is 0.13. However, failure to make a proper valve alignment will be indicated by the absence of city water draining to the floor. As a result, it was decided to use the lower bound value for the post-diagnosis HEP calculated above, yielding an HEP of 0.026.

Recovery. Failure of the operator to align city water to the charging pumps will result in failure of the running charging pump. This failure should prompt the SRO to send an operator to verify proper alignment of city water to the charging pump coolers. Dependence between recovery error and post-diagnosis error will be high, however. Table 8-5 (item 7) gives a median HEP of 0.5, with an error factor of 5. The resulting mean HEP is 0.8.

The mean HEP for operator action SLOCA = $6.9\times10^{-4} + (0.026 \times 0.8) = 0.021$.

H2.18 OPERATOR ACTION VISO--OPERATOR ISOLATES INTERFACING SYSTEMS LOCA BREAK

SUMMARY

a. Task. The operators mitigate the interfacing systems LOCA by isolating the break.

b. Success Criteria. The operators close valves and isolate the break.

c. Scenario/Event Tree(s) Used. ISLOCA (V).

ACTION

a. Initial Conditions. While the reactor is operating at full power, a piping failure occurs in a system which interfaces with the RCS, causing a LOCA outside containment.

b. Preceding Operator Actions. None.

c. Symptoms. Decreasing RCS pressure and level with abnormal radiation in the plant auxiliary building (PAB).

d. Indications.
RCS pressure indicators.
Pressurizer level indicators.
Radiation monitors.

e. Procedural Guidance. The operators will enter E-0 on a reactor trip or safety injection signal. At Step 36, the operators will transfer to ECA-1.2 (LOCA Outside Containment) on PAB abnormal radiation levels.

f. Response.

ECA-1.2 (Rev. 4)

Step 4a Sequentially close and open the following valves while monitoring for an RCS pressure increase or other indication of break isolation. Leave closed any valve that, when closed, indicates break isolation.

1) 31 RHR heat exchanger outlet valve 747 [panel SGF].
2) 32 RHR heat exchanger outlet valve 746 [panel SGF].
3) HHSI cold leg injection line valve 856C [panel SBF-2].
4) HHSI cold leg injection line valve 856E [panel SBF-2].
5) HHSI cold leg injection line valve 856H [panel SBF-2].

6) HHSI cold leg injection line valve 856J [panel SBF-2].
7) RHR heat exchanger outlet to HHSI valves 1869A/B [panel SBF-1].

PERFORMANCE SHAPING FACTORS

a. Timing.

Time Available - The time available for the operators to isolate the break depends on its size and location.

Time Needed - The operators are instructed to identify the break by trial-and-error, closing valves and monitoring the resulting RCS pressure. Assuming one minute to close a valve and one minute while the operator waits for the pressure response, it will take the operators approximately 20 minutes to exercise all the valves in Step 4a of ECA-1.2.

b. Competing Actions/Alarms. No competing actions or alarms that will distract the operators from implementing the EOPs are expected.

c. Consequence of Actions.

Success - Success terminates the LOCA.

Failure - Failure results in an unisolated LOCA which bypasses the containment building.

d. Training/Experience. The operators have had training on this action.

e. Stress. High stress was assumed.

f. Skill/Rule/Knowledge-Based. This action involves a combination of rule- and knowledge-based actions. Although this action is proceduralized (rule-based), the operators must recognize the appropriate valve to close and isolate the LOCA based on RCS response (i.e., pressure).

g. Task Complexity. Low.

QUANTIFICATION

An initial screening value of 0.1 was used for the HEP of the operator failing to isolate an interfacing system LOCA.

H2.19 OPERATOR ACTION WRWST--RWST REFILLED FOR CONTINUED CORE COOLING

SUMMARY

a. Task. The operators provide make-up to the RWST using the primary water system so that, for 24 hours, sufficient water is maintained in the RWST to allow high pressure injection in the absence of cold leg recirculation capability (e.g., no/insufficient sump water inventory or loss of all recirculation and RHR pumps). Depending on the RCS conditions, the operator may have to reduce ECCS flow to match RWST make-up flow.

b. Success Criteria. At least one primary water make-up pump (150 gpm) provides make-up to the RWST.

c. Scenario/Event Tree(s) Used. SGTR. This action is taken in sequences involving a loss of reactor coolant outside containment, where the RWST is the only supply of water to the ECCS pumps.

ACTION

a. Initial Conditions. The reactor is at full power. A steam generator U-tube ruptures, resulting in the generation of an SI signal. Two scenarios may result requiring operator action to refill the RWST:

   a) If the operators are unable to depressurize the RCS to terminate leakage from the RCS, a low-low RWST water level alarm will occur at approximately 9 hours [13].

   b) If the operators depressurize the RCS but RHR shutdown cooling fails, RCS temperature and pressure will rise. RCS leakage into the secondary side will recommence, and a low-low RWST water level alarm will eventually result.

b. Preceding Operator Actions. The operators are directed by procedure to identify and then isolate the faulted steam generator (see operator action SGISO, Section H2.16). They will then attempt to depressurize the RCS to terminate leakage from the RCS to the secondary (see operator action ORCS, Section H2.13).

c. Symptoms.
Loss of internal and external recirculation capability.
Insufficient containment level (< 48' 2").
RHR shutdown cooling unavailable.
RCS depressurization not possible.
Low RWST level.

d. Indications.
"Refuel Water Storage Tank Low-Low Level" annunciator on panel SBF-2.
RWST level indicator LI-920 on panel SBF-1.
Containment sump level indicators LI-940 and LI-941 on panel SBF-1.
Recirculation sump level indicators LI-938 and LI-939 on panel SBF-1.

e. Procedural Guidance. The anticipated sequence of events leading to the operator diagnosing the need to refill the RWST is as follows. When RWST level falls below 9.2 ft, the operator is instructed to go to ES-1.3 (Transfer to Cold Leg Recirculation). At Step 1b of ES-1.3, the operators will transfer to ECA-1.1 (Loss of Emergency Coolant Recirculation) because containment level will be less than 48 ft 2 in. At Step 2 of ECA-1.1 the operators are instructed to commence make-up to the RWST.

f. Response.

ES-1.3 (Rev. 7)
Step 1b If containment level is not greater than 48 ft 2 in., go to ECA-1.1.

ECA-1.1 (Rev. 6)
Step 2 Add make-up to RWST as necessary to maintain RWST level greater than 2 feet. Refer to SOP-SI-2.

SOP-SI-2 (Rev. 5)
Step 4.1 Close manual valve CH-297, and open valves CH-295 and CH-350 (located at the 73-ft elevation in the PAB).
Step 4.2 Set the Boric Acid and Primary Water flow control valves to give the desired boron concentration.
Step 4.3 Initiate a manual blended make-up in accordance with SOP-CVCS-3.

SOP-CVCS-3 (Rev. 7)
Step 4.1.2 Place the BA transfer pump speed selector switches [on flight panel FCF] in the SLOW position.
Step 4.1.3 Place both boric acid transfer pumps [on flight panel FCF] in the AUTOMATIC position and one primary water pump in the START position.
Step 4.1.4 Place the flight panel boric acid flow controller in AUTOMATIC.
Step 4.1.5 Adjust the flight panel boric acid flow controller auto setpoint to match the RCS and blender output boron concentrations.
Step 4.2.2 Place the RCS make-up mode selector switch [on flight panel FCF] to MANUAL. Switch to START on the make-up control switch, then return switch to NORMAL.

ECA-1.1 (Rev. 6)
Step 18 If SI termination criteria cannot be met, an NPO must be dispatched to locally throttle the operating HHSI pump discharge valves to achieve the

required minimum SI flow from Figure ECA11-1.

PERFORMANCE SHAPING FACTORS

a. Timing.

Time Available - The cue for performing this action is low-low RWST water level. MARCH code runs show that, for an initial rupture leak rate of 600 gpm, RWST depletion occurs at 9 hours [13], the core is uncovered 1 hour after RWST depletion, and core damage occurs 1.5 hours thereafter. Therefore, to prevent core damage, the operator should begin to refill the RWST within 2 hours of receiving a low-low RWST water level signal. Note that this estimate is conservative because the technical support center should recognize the need for RWST make-up before the low RWST level alarm, even if the control room operators do not.

It should also be noted that the volume of water available in the RWST between the low-low level (9.2 ft) and the "empty" level (2 ft) is approximately 67,500 gallons [12] . If it is assumed that safety injection flow offsets the tube leak rate at the time of low-low RWST level and that the initial tube leak rate is 600 gpm, the RWST will deplete in approximately 1.9 hours.

Time Needed - 30 minutes from the time the decision is made to make-up the RWST. Walk-thoughs with plant operators showed that local valve manipulations can be performed within 15 minutes, including travel time. Another 15 minutes was assumed to be required for control room actions and stepping through the procedures.

b. Competing Actions/Alarms. None.

c. Consequence of Actions.

Success - Success allows core cooling to be continued by high head safety injection.

Failure - Failure results in core melt due to the eventual depletion of the RWST and loss of suction to the HHSI pumps.

d. Training/Experience. The operators have experience refilling the RWST during normal plant operations.

e. Stress. Moderate. This action is not required until several hours after the initiating event, at which time the operators will have established decay heat removal and RCS make-up.

f. Skill/Rule/Knowledge-Based. Rule- and skill-based. Each action is proceduralized. In addition, the operators have experience refilling the RWST during normal plant operations.

g. Task Complexity. Moderate.

QUANTIFICATION

The quantification of operator action WRWST is described below and depicted in Figure H2.19.1. The total mean HEP for Operator Action WRWST was estimated to be 0.18.

Failure Node	Median HEP (Error Factor)	Mean HEP	Source (NUREG/CR-4772)
[a] Operators Diagnose Need for Refilling RWST			
	0.0001 (EF=30)	8.48×10^{-4}	Table 8-2, item 5.
	The cue for performing this action is low-low RWST water level and the subsequent inability to transfer to cold leg sump recirculation. Once the operators receive the cue, it is conservatively assumed that the operators must diagnose the need for RWST refill within one hour.		
[b] NPO Performs Local Valve Alignments			
	0.02 (EF=5)		Table 8-5, item 3.
	x 3		Three critical actions
	0.06 (EF=5)	0.0968	
	The NPO must close manual valve CH-297 and open manual valves CH-295 and CH-350. These are step-by-step actions performed under moderately high stress.		
[c] Operators Perform Required Actions			
	0.004 (EF=5)	6.46×10^{-3}	Table 8-5, item 3.
	The operators must initiate a manual blended make-up.		
	0.5 (EF=5)	0.807	Table 8-5, item 7.
	The SRO will verify that the RWST is being refilled. However, there is high dependence between recovery error and previous errors.		

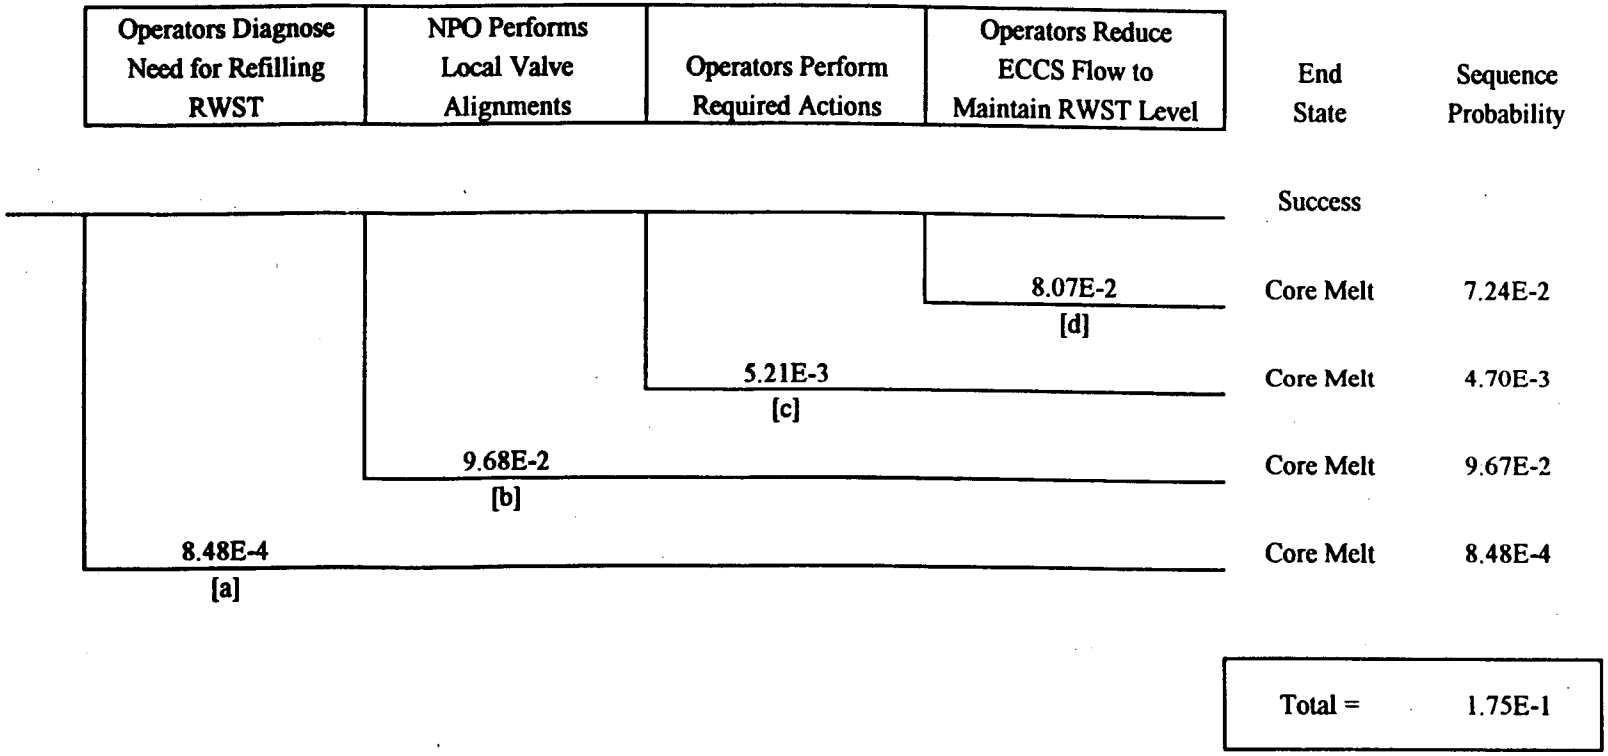
Total [c] = $6.46\times10^{-3} \times 0.807 = 5.21\times10^{-3}$

[d] Operators Reduce ECCS Flow to Maintain RWST Level

0.05 (EF=5)	0.0807	Table 8-5, item 4.

This action has been classified as a dynamic action performed under moderately high stress. Although the action to reduce ECCS flow is proceduralized, the operators must monitor ECCS flow and periodically adjust flow as necessary. Therefore, this action is classified as dynamic.

Figure H2.19.1. Human Action WRWST - RwST Refilled for Continued Core Cooling



H2.20 OPERATOR ACTION HHI-XHE-FO-898--OPERATORS OPEN MANUAL VALVE SI-898

This action was modeled in the high-head safety injection fault tree. The action is conditional on failure of the normal suction supply to the HHSI pumps. However, because it is very unlikely that the operators will diagnose the loss of suction before the HHSI pumps fail, no credit was taken for this action (HEP = 1.0).

H2.21 OPERATOR ACTION MFW--OPERATORS RE-ESTABLISH MAIN FEEDWATER SYSTEM OPERATION

SUMMARY

a. Task. The operators re-establish MFW to the steam generators.

b. Success Criteria. Main feedwater established to at least one steam generator.

c. Scenario/Event Tree(s) Used. Transient (T3), special initiators (TAC5A and TAC6A).

ACTION

a. Initial Conditions. While the reactor is operating at full power, a reactor trip occurs which results in the feed regulator valves closing. However, the main boiler feed pumps continue to run in recirculation mode. Subsequently, all AFW pumps fail to start or deliver flow to the steam generators.

b. Preceding Operator Actions. The operators will attempt to manually start the AFW pumps.

c. Symptoms. No AFW pump running.

d. Indications.
SG narrow range level (LI-417A/B/C, LI-427A/B/C, LI-437A/B/C, LI-447A/B/C) on panel FBF.
SG wide range level (LR-417-1/2, LR-437-1/2) on panel SCF.
AFW flow (FI-1200, FI-1201, FI-1202, FI-1203) on panel SCF.

e. Procedural Guidance. Upon a reactor trip, the operators will enter procedure E-0 (Reactor Trip or Safety Injection). Because an SI signal has not been generated, the operators will transfer to procedure ES-0.1 (Reactor Trip Response). Step 3 of ES-0.1 then instructs the operators to establish main feedwater flow if no auxiliary boiler feed pump can be started.

f. Response.

ES-0.1 (Rev. 7)
Step 3.c If no AFW pump can be started, then:
1) Block in TC-412M relays in safeguards initiation rack 1-2 and 2-2.
2) Attempt to establish main feed via low flow bypass valves [on panel SCF].

PERFORMANCE SHAPING FACTORS

a. Timing.

Time Available - 39 - 52 minutes, based on the time until steam generator dryout. If the reactor coolant pumps are not tripped, the steam generator inventory will be depleted in approximately 39 minutes after the reactor trip. On the other hand, if the reactor coolant pumps are tripped one minute after the reactor trip, the time before the steam generator inventory is depleted will be extended by 13 minutes.

Time Needed - 10 minutes. This is a conservative estimate of the time required to reach Step 3.c in ES-0.1 and perform the actions.

b. Competing Actions/Alarms. The operators will be monitoring SG water level. When SG narrow range level decreases below 6 percent, the operators are instructed to enter FR-H.1 (Response to Loss of Secondary Heat Sink).

c. Consequence of Actions.

Success - Success results in decay heat removal using the steam generators.

Failure - Failure requires the use of the condensate system or bleed-and-feed to remove decay heat.

d. Training/Experience. The operators have had training on this action.

e. Stress. Moderate.

f. Skill/Rule/Knowledge-Based. Provided no SI signal is generated, this action is proceduralized in ES-0.1 (rule-based). However, FR-H.1 does not contain explicit instructions to re-establish MFW flow (knowledge-based).

g. Task Complexity. Moderate.

QUANTIFICATION

No credit was taken for this action due to the lack of explicit direction in FR-H.1 to re-establish main feedwater.

H2.22 OPERATOR ACTION OAC4--OPERATOR RESETS MCCS AFTER SI/LOSP

An initial screening value of 0.1 was used for the HEP of the operators failing to reset the MCCs after a safety injection signal or loss of offsite power.

H2.23 OPERATOR ACTION OAFW2--OPERATOR ALIGNS TURBINE-DRIVEN AFW PUMP

SUMMARY

a. Task. The operator opens the turbine-driven AFW pump flow control valves to supply auxiliary feedwater to the steam generators. The operator must also reset the overspeed trip should such a trip have occurred.

b. Success Criteria. Total feedwater flow rate greater than 355 gpm to the steam generators(s).

c. Scenario/Event Tree(s) Used. These actions are modeled in the auxiliary feedwater system fault tree as basic events AFW-XHE-FO-HC405 and AFW-XHE-FO-TDP32.

ACTION

a. Initial Conditions. While the reactor is operating at full power, a reactor trip occurs with subsequent loss of main feedwater. Subsequently, SG water level falls below the setpoint for AFW actuation.

b. Preceding Operator Actions. None expected.

c. Symptoms. Reactor trip.

d. Indications.
SG narrow range level (LI-417A/B/C, LI-427A/B/C, LI-437A/B/C, LI-447A/B/C) on panel FBF.
SG wide range level (LR-417-1/2, LR-437-1/2) on panel SCF.
AFW flow (FI-1200, FI-1201, FI-1202, FI-1203) on panel SCF.

e. Procedural Guidance. Upon a reactor trip, the operators will enter procedure E-0 (Reactor Trip or Safety Injection). If a safety injection signal is present, the operators will verify that the AFW pumps are running and that the total AFW flow exceeds 355 gpm. If total AFW flow is less than 355 gpm, the operators will manually start the AFW pumps and align the valves as necessary. If no safety injection signal is present, the operators will transfer to procedure ES-0.1 (Reactor Trip Response) at Step 4 of E-0 and adjust the AFW flow control valves as necessary to establish a total AFW flow greater than 355 gpm as directed in Step 3.d of ES-0.1.

f. Response.

E-0 (Rev. 7)--Reactor Trip or Safety Injection

Step 10b. Verify turbine-driven pump running.

Step 20. Verify total AFW flow exceeds 355 gpm. If no response obtained and narrow range level indicator shows less than 6 percent in all SGs, manually start pumps and align valves as necessary. If total AFW flow exceeding 355 gpm cannot be established, go to FR-H.1 (Response to Loss of Secondary Heat Sink).

ES-0.1 (Rev. 7)--Reactor Trip Response

Step 3d. Verify total AFW flow exceeds 355 gpm. If no response obtained, adjust AFW flow control valves as necessary.

FR-H.1 (Rev. 6)--Response to Loss of Secondary Heat Sink

Step 2.a.6 Locally check the AFW flow control valves.

Step 2.b Try to restore AFW flow.

Step 2.c If total AFW flow to the SGs is less than 355 gpm, dispatch NPO to restore AFW flow locally.

PERFORMANCE SHAPING FACTORS

a. Timing.

Time Available - 52 minutes, based on the time at which the steam generator inventory is depleted.

Time Needed - Two minutes to open the AFW flow control valves from the control room. Less than 15 minutes, including travel time, to reset the turbine overspeed trip.

b. Competing Actions/Alarms. None.

c. Consequence of Actions.

Success - Success results in secondary decay heat removal.

Failure - Failure of this action, combined with failure of the two motor-driven AFW pumps, requires an alternative method of decay heat removal to be implemented--bleed-and-feed, main feedwater restoration, or condensate feed to the SGs.

d. Training/Experience. The operators have extensive training and actual experience in establishing secondary decay heat removal using the turbine-driven AFW pump.

e. Stress. Low if one motor-driven AFW pump is available. Moderate if both motor-driven AFW pumps are unavailable.

f. Skill/Rule/Knowledge-Based. Skill-based--the operators are experienced and trained on the response to low SG water level or flow. Rule-based--opening the AFW flow control valves is proceduralized. Knowledge-based--the action to reset the overspeed trip, should it be necessary, requires some diagnosis by the operator.

g. Task Complexity. Low.

QUANTIFICATION

Operator Opens AFW Flow Control Valves

Diagnosis Error. The time available for diagnosis was assumed to be 50 minutes. The lower bound median diagnosis HEP is 8.1×10^{-6} (EF=25), which results in a mean HEP of 5.5×10^{-5}.

Post-Diagnosis Error. Because the operators are very familiar with the action to open the turbine-driven AFW pump flow control valves, the lower bound of the HEP (assuming moderately high stress) in Table 8-5 (item 3) was used. The corresponding mean HEP is 6.5×10^{-3}. Assuming high dependence between the SRO and the operator and moderate dependence for the SS, the median recovery HEPs are 0.5 (EF=5) and 0.15 (EF=5), respectively. The mean recovery HEPs for the SRO and SS are 0.81 and 0.24, respectively. Therefore, the total mean HEP for failing to open the flow control valve is $6.5\times10^{-3} \times 0.81 \times 0.24 = 1.26\times10^{-3}$.

The total HEP is $5.5\times10^{-5} + 1.26\times10^{-3} = 1.3\times10^{-3}$.

Operator Resets Turbine Overspeed Trip

Diagnosis Error. The time available for diagnosis is 52 - 15 = 37 minutes. The median nominal diagnosis HEP is 5.0×10^{-4} (EF=16), which results in a mean HEP of 2.1×10^{-3}.

Post-Diagnosis Error. This action constitutes a dynamic action performed under moderately high stress because the operator must diagnose the cause of AFW pump failure. The use of item 4 in Table 8-5 yields a median HEP of 0.05 (EF=5) and a mean HEP of 0.081. Assuming high dependence between the SRO and the operator and moderate dependence for the SS, the median recovery HEPs are 0.5 (EF=5) and 0.19 (EF=5), respectively. The mean recovery HEPs for the SRO and SS are 0.81 and 0.30, respectively. Therefore, the total mean HEP for failing to reset the AFW turbine overspeed trip is $0.081 \times 0.81 \times 0.30 = 2.0\times10^{-2}$.

The total HEP is $2.1\times10^{-3} + 2.0\times10^{-2} = 0.022$.

H2.24 OPERATOR ACTION OBSWS--OPERATOR STARTS BACKUP SERVICE WATER PUMPS

No credit was given to the operators starting the backup service water pumps.

H2.25 OPERATOR ACTION OCOND--OPERATORS ALIGN CONDENSATE SYSTEM FOR SECONDARY COOLING

SUMMARY

a. Task. The operators depressurize the steam generators and establish condensate flow to them.

b. Success Criteria. The operators depressurize at least one steam generator to less than 570 psig and establish flow using at least one main condensate pump.

c. Scenario/Event Tree(s) Used. Transient (T2).

ACTION

a. Initial Conditions. While the reactor is operating at full power, a plant trip occurs with subsequent loss of main feedwater. All three AFW pumps fail to start or deliver sufficient flow to the steam generators.

b. Preceding Operator Actions. The operators will attempt to establish AFW flow. However, once the operators enter FR-H.1, they will proceed to initiate bleed-and-feed cooling based on low SG level.

c. Symptoms. Loss of main and auxiliary feedwater.

d. Indications.
SG narrow range level (LI-417A/B/C, LI-427A/B/C, LI-437A/B/C, LI-447A/B/C) on panel FBF.
SG wide range level (LR-417-1/2, LR-437-1/2) on panel SCF.
AFW flow (FI-1200, FI-1201, FI-1202, FI-1203) on panel SCF.
MFW flow (FI-418, FI-428, FI-438, FI-448).

e. Procedural Guidance. Upon receipt of a reactor trip, the operators will enter procedure E-0 (Reactor Trip or Safety Injection). If a safety injection signal is present, Step 20 of E-0 will transfer the operators to FR-H.1 (Response to Loss of Secondary Heat Sink) if total AFW flow is less than 355 gpm. If safety injection has not occurred (and is not needed), the operators will transfer to ES-0.1 (Reactor Trip Response). Once E-0 is exited, the STA is required to monitor the critical safety function (CSF) status trees. The functional restoration procedure for loss of secondary heat sink is FR-H.1. Step 5 of FR-H.1 directs the operator to depressurize the SGs and establish feed flow from the condensate system. It should be noted, however, that the criteria for initiating bleed-and-feed will be met before condensate flow can be established. Therefore, this action will

not begin until after attempts to establish decay heat removal via bleed-and-feed have failed.

f. Response.

FR-H.1 (Rev. 6)

Step 3 Stop all RCPs.

Step 4.a-c Depressurize RCS to 1850 psig using auxiliary spray or one PORV.

Step 4.e Block low pressurizer pressure SI actuation.

Step 5.c Depressurize at least one SG to less than 570 psig by dumping steam to condenser at the maximum rate. If condenser steam dump is unavailable, dump steam from SGs using atmospheric dump valves (ADVs).

Step 5.d Establish condensate flow:

1) Start one main condensate pump.
2) Reset MBFP trips.
3) Open BFP discharge valves BFD-2-31 and BFD-2-32.
4) De-energize BFD-2-31 in open position at MCC-36A.
5) De-energize BFD-2-32 in open position at MCC-36B.
6) On safeguards initiation racks G-4 and G-6 place feedwater isolation defeat key witches to the DEFEAT position.
7) Open feedwater low flow bypass valve(s) as required.

PERFORMANCE SHAPING FACTORS

a. Timing.

Time Available - 39 - 52 minutes, based on the time until steam generator dryout. If the reactor coolant pumps are not tripped, the steam generator inventory will be depleted in approximately 39 minutes after the reactor trip. On the other hand, if the reactor coolant pumps are tripped one minute after the reactor trip, the time before the steam generator inventory is depleted will be extended by 13 minutes.

Time Needed - 20 minutes was assumed to be the time required to establish condensate flow to the SGs.

b. Competing Actions/Alarms. Bleed-and-feed cooling will be attempted prior to the initiation of condensate flow. It was assumed in the quantification that the attempt to initiate bleed-and-feed cooling will consume 10 minutes.

c. Consequence of Actions.

Success - Success results in decay heat removal using the steam generators.

Failure - Since this action is taken only after attempts to establish AFW flow and bleed-and-feed cooling have failed, failure results in loss of decay heat removal and subsequent core damage.

d. Training/Experience. The operators have been extensively trained on the use of functional restoration procedure FR-H.1 (Response to Loss of Secondary Heat Sink).

e. Stress. Extremely high, since this action follows failed attempts to establish AFW flow and bleed-and-feed cooling.

f. Skill/Rule/Knowledge-Based. Rule-based (steps are proceduralized).

g. Task Complexity. Moderate.

QUANTIFICATION

Diagnosis Error. The time available for diagnosis is 47 minutes (time to SG dryout given RCPs tripped at 15 minutes) - 20 minutes (time required to align condensate) = 27 minutes. However, because the criteria for initiating bleed-and-feed will be satisfied before condensate flow can be established, the operators have been trained to immediately initiate bleed-and-feed upon entering FR-H.1. It was assumed that the operators will try to initiate bleed-and-feed cooling for 10 minutes. Therefore, the time available for diagnosis is 27 - 10 = 17 minutes. Interpolating between items 2 and 3 in Table 8-2 yields a lower bound median diagnosis HEP of 1.7×10^{-3}, with an error factor of 10. The mean diagnosis HEP is 4.6×10^{-3}.

Post-Diagnosis Error. This action constitutes a step-by-step task performed under extremely high stress. The critical actions to be performed are 1) tripping the RCPs, 2) depressurizing the SGs, and 3) establishing condensate flow. Because of the training received by the operators, the lower bound HEP was used. The lower bound median HEP for performing a step-by-step critical action under extremely high stress is 0.01 (EF=5), which yields a mean HEP of 0.016. The total mean HEP is $3 \times 0.016 = 0.048$.

Recovery. Failure to perform the required actions correctly can be recovered by the SRO at Step 6 of FR-H.1, which directs the operators to verify narrow range SG level exceeds 6 percent. Assuming low dependence between the original error and the verification step results in a median recovery HEP of 0.079 (EF=5) and a mean recovery HEP of 0.13. In addition, assuming moderate dependency between the SS and the others gives a median non-recovery probability of 0.15 (EF=5) and a mean probability of 0.24.

The total mean HEP for operator action OCOND = 4.6×10^{-3} + 0.048 × 0.13 × 0.24 = 6.1×10^{-3}

COMMENTS

The failure of the operators to establish bleed-and-feed will impact the probability that the operator also fail to align condensate flow to the steam generators in the following ways. First, failure to timely diagnose the loss of secondary heat sink is common to both, and failure to timely diagnose the need for bleed and feed will increase the probability that the operators also fail to diagnose the need for condensate flow. Secondly, failure of the operators to trip the RCPs during bleed and feed reduces the time available to align condensate flow. With this logic, the HEP for operator action OCOND given failure of operator action FB can be determined by merging the models for the two actions. A mean value of 0.37 was calculated for OCOND|FB.

$$\therefore \text{OCOND}|\text{FB} = 0.37.$$

H2.26 OPERATOR ACTION OCST--OPERATOR OPENS CITY WATER SUPPLY VALVE TO PROVIDE ALTERNATIVE AFW PUMP SUCTION

SUMMARY

a. Task. The operator provides an alternative source of water supply to the AFW pumps by opening valves PCV-1187, 1188, and/or 1189 to align the city water supply.

b. Success Criterion. An alternative supply of water is provided to at least one AFW pump.

c. Scenario/Event Tree(s) Used. The action is modeled as a recovery action for sequences involving plugging of CST isolation valve CT-6 or CT-64.

ACTION

a. Initial Conditions. The reactor is operating at full power. A reactor trip occurs with subsequent loss of main feedwater. One or more AFW pumps operate initially, supplying sufficient flow to the steam generators. Subsequently, the AFW pumps trip on low suction flow.

b. Preceding Operator Actions. None.

c. Symptoms.
Loss of secondary cooling.
"RED" path on critical safety function "HEAT SINK".

d. Indications.
SG narrow range level (LI-417A/B/C, LI-427A/B/C, LI-437A/B/C, LI-447A/B/C) on panel FBF.
SG wide range level (LR-417-1/2, LR-437-1/2) on panel SCF.
AFW flow (FI-1200, FI-1201, FI-1202, FI-1203) on panel SCF.
"Aux. Boiler Feed Low [Suction] Flow" alarm on panel SCF.

e. Procedural Guidance. Currently the EOPs do not address loss of CST suction to the AFW pumps (other than low CST level). However, the procedures are being revised to address plugging or inadvertent closure of CST isolation valve CT-6 or CT-64.

f. Response. The revised procedure will contain explicit instructions for the operators to align backup city water to the suction of the AFW pumps should low suction flow be indicated.

PERFORMANCE SHAPING FACTORS

a. Timing.

Time Available - The minimum time available to re-establish AFW pump operation is approximately 39 minutes. This time is based on the time in which the steam generator will be emptied should the reactor coolant pumps not be tripped.

Time Needed - The AFW pumps can be aligned to the city water supply from the control room. The necessary actions can be taken in two minutes.

b. Competing Actions/Alarms. The competing actions/alarms are expected to involve restoring secondary heat removal or establishing decay heat removal using bleed-and-feed cooling.

c. Consequence of Actions.

Success - Success results in availability of the AFW pumps and secondary decay heat removal.

Failure - Failure requires that secondary cooling be established using the main feedwater or condensate system, or that primary cooling be established using bleed-and-feed cooling.

d. Training/Experience. Since procedural guidance for this scenario has not yet been implemented, no training or experience exists. However, it was assumed that operators will receive training on this scenario once the procedures are revised.

e. Stress. Moderately high stress levels were assumed.

f. Skill/Rule/Knowledge-Based. Rule-based--the action will be proceduralized.

g. Task Complexity. Simple.

QUANTIFICATION

Diagnosis Error. The time available to perform this action was conservatively estimated as 30 minutes. Assuming that all the operators will receive training on this action once the procedures are in place, the nominal diagnosis HEP was used. The median nominal diagnosis HEP from Table 8-2 (item 4) is 0.001 (EF=10); the mean HEP is 0.0027.

Post-Diagnosis Error. Two critical actions must be performed: opening the city water supply valves (PCV-1187, 1188, and/or 1189), and restarting the AFW pumps. Assuming moderately high stress levels, the median HEP is $2 \times 0.02 = 0.04$, with an error factor of 5. The resulting mean HEP of 0.065. For recovery, moderate dependence was assumed between the SS and the others, giving a median recovery HEP of 0.16 (EF=5) and a mean HEP of 0.26. The total post-diagnosis HEP is, therefore, $0.065 \times 0.26 = 0.017$.

$\therefore$ OCST = 0.0027 + 0.017 = 0.02

H2.27 OPERATOR ACTION OESWS--OPERATORS RESTART ESSENTIAL SERVICE WATER PUMPS

SUMMARY

a. Task. The operator restarts an essential service water pump if it trips.

b. Success Criteria. Pump restarted.

c. Scenario/Event Tree(s) Used. This action was modeled as a recovery action for selected sequences.

ACTION

a. Initial Conditions. While the reactor is at full power, a loss of offsite power occurs. Subsequently, one or more essential service water pumps trip.

b. Preceding Operator Actions. None expected.

c. Symptoms.
Low essential service water pressure.
Insufficient cooling to components serviced by SW.
480-V switchgear motor trip.

d. Indications.
"Service Water Header [Essential] High Low Pressure" alarm.
"Containment Vent Fan Cooling Water Low Flow" alarm (common) during SI actuation.
"480 V Swgr. Motor Trip (Common)" alarm.

e. Procedural Guidance. Emergency Operating Procedure E-0 (Reactor Trip or Safety Injection) and Off-Normal Operating Procedure ONOP-RW-1.

f. Response.
If the loss of offsite power is accompanied by an SI signal, Step 8 of E-0, which is classified as an immediate action step, directs the operator to verify that the essential service water pumps are running. If they are not, the operator is instructed to identify and manually start the pumps aligned to the essential header. If no SI signal is present following the loss of offsite power, the operators will transfer to procedure ES-0.1 (Reactor Trip Response) and at Step 7 of ES-0.1 will verify that the essential service water pumps are running.

In addition to Step 8 of E-0 and Step 7 of ES-0.1, ONOP-RW-1 (Step 4.1 in the immediate operator actions) directs the operator to start service water pumps in the affected header if service water pressure is low.

PERFORMANCE SHAPING FACTORS

a. Timing.

Time Available - Emergency diesel generators (EDGs) and containment fan cooler units (FCUs) are critical loads supplied by the essential service water header during a safety injection actuation or loss of offsite power. It was assumed that these components will fail if service water is not re-established within 10 minutes.

Time Needed - 1 minute.

b. Competing Actions/Alarms. The competing actions/alarms depend on the initiating event. However, regardless of the event, the priority will be to implement the EOPs. These call for starting the essential SW pumps if they are not running.

c. Consequence of Actions.

Success - Success results in continued and sufficient flow to the essential service water header.

Failure - Failure results in loss of (or insufficient) flow to the essential service water header.

d. Training/Experience. The operators have been trained on the need to verify adequate essential service water flow during implementation of the EOPs.

e. Stress. Moderately to extremely high stress, depending on the cause of the reactor trip (i.e., on plant response).

f. Skill/Rule/Knowledge-Based. Rule-based. Each step is proceduralized.

g. Task Complexity. Simple.

QUANTIFICATION

No credit was given to the operators restarting the essential service water pumps given that they are tripped and fail to restart automatically.

H2.28 OPERATOR ACTION OMCC312A--OPERATORS ALIGN ALTERNATIVE SAFE SHUTDOWN EQUIPMENT TO MCC-312A

SUMMARY

a. Task. The operators establish RCP seal cooling by aligning and operating the alternative safe shutdown equipment from MCC-312A.

b. Success Criteria. Following failure of the 480-V safeguard buses, RCP seal cooling is restored within one hour by providing seal injection from charging pump 31 or 32 or thermal barrier cooling from component cooling pump 32. In both cases, the ultimate heat sink is provided by service water pump 38. To restore RCP seal cooling, the charging pump or component cooling pump and service water pump 38 must be aligned to MCC-312A, which is normally energized by offsite power from 6.9kv switchgear bus 1.

c. Scenario/Event Tree(s) Used. Internal flooding--initiating event TCTL-15.

ACTION

a. Initial Conditions. While the reactor is at full power, a pipe break occurs in the control building that results in the loss of all 480-Vac safeguard buses (i.e., buses 2A, 3A, 5A and 6A).

b. Preceding Operator Actions. The operators will enter procedure E-0 (Reactor Trip or Safety Injection) upon a reactor trip and open the turbine-driven AFW pump flow control valves.

c. Symptoms. All safeguard buses deenergized.

d. Indications.
"480V Safeguards Bus Undervoltage" annunciator on panel SBF-2
480-V bus voltmeter on panel SHF
480-V bus undervoltage relay ;lights on panel SHF.

e. Procedural Guidance. Upon a reactor trip, the operators will enter procedure E-0 (Reactor Trip or Safety Injection). If unable to restore power to at least one safeguards bus, the operators will transfer to ECA-0.0 (Loss of All AC Power). At step 6 of ECA-0.0, the operators are directed to restore power to the 480-Vac safeguard buses. Currently, there are, however, no explicit instructions in the EOPs that direct the operators to align alternative safe shutdown equipment to MCC-312A. While procedure SOP-EL-12 contains the necessary instructions, this procedure is used only for fire-related

events.

f. Response.

SOP-EL-12 (Rev. 8)

Step 4.1 Energize Service Water Pump 38:

1) Remove loads from bus 312 (by deenergizing MCC "E-1" feeder and all loads from PDP-TG-1 except 30A breaker, or MCC "A" and "C" feeders).

2) Close the disconnect switch for service water pump 38 on MCC-312A.

3) Start service water pump 38 at MCC-312A by pushing in and turning the key switch to the "Start" position.

Step 4.2 Energize Component Cooling Pump 32:

1) Remove loads from bus 312 (by deenergizing MCC "E-1" feeder and all loads from PDP-TG-1 except 30A breaker, or MCC "A" and "C" feeders).

2) Visually verify that the component cooling pump is not running.

3) Verify at the transfer switch that all eight indicating lights are extinguished.

4) At the transfer cabinet located adjacent to component cooling pump 32 in the PAB, place the switch in the alternative feed position by rotating in clockwise.

5) Close the disconnect switch on MCC-312A for component cooling pump 32.

6) Start component cooling pump 32 at MCC-312A by pushing in and turning the key switch to the "Start" position.

Step 4.3 Energize Charging Pump 32:

1) Remove loads from bus 312 (by deenergizing MCC "E-1" feeder and all loads from PDP-TG-1 except 30A breaker, or MCC "A" and "C" feeders).

2) Visually verify that charging pump 32 is not running.

3) Verify at the transfer switch that all eight indicating lights are extinguished.

4) Verify that the bulldog switch is open the 31 charging pump room.

5) At the transfer cabinet located adjacent to charging pump 32, place the switch in the alternative feed position by rotating in clockwise.

6) Close the disconnect switch on MCC-312A for charging pump.

7) Start charging pump 32 at MCC-312A by pushing in and turning the key switch to the "Start" position.

PERFORMANCE SHAPING FACTORS

a. Timing.

Time Available - 60 minutes were assumed to be available to re-establish RCP seal cooling. After 60 minutes, the RCP seal leak rate exceeds the capacity of one charging pump.

Time Needed - Approximately 30 minutes are needed to align and start service water pump 38, component cooling pump 32, and charging pump 31 or 32 from MCC-312A. While priorities can be established for aligning and starting the pumps, these priorities are not reflected in SOP-EL-12. These priorities are based on the facts that a failure to align service water pump 38 is less limiting (because of the large heat capacity of the service water system and thus the additional time available to recognize and recover the loss of service water flow) and that component cooling pump 32 is needed for both seal injection (cooling the charging pumps) and thermal barrier cooling.

b. Competing Actions/Alarms. The operators will continue in their efforts to restore the 480-Vac safeguard buses.

c. Consequence of Actions.

Success - Success results in decay heat removal by the turbine-driven AFW pump and limited reactor coolant loss from RCP seal leaks.

Failure - Failure results in excessive RCP seal leakage and subsequent uncovering of the core and core damage.

d. Training/Experience. The operators have had no training to deal with this scenario.

e. Stress. Extremely high stress levels were assumed.

f. Skill/Rule/Knowledge-Based. Although the actions are rule-based in that they are proceduralized, the operators must identify the correct procedure to implement. This

latter is a knowledge-based action.

g. Task Complexity. High. Several key actions must be performed and their execution requires a coordinated effort in the main control room, turbine building, and PAB.

QUANTIFICATION

Diagnosis Error. With 30 minutes available for diagnosis, the nominal diagnosis HEP from Table 8-2 of NUREG/CR-4772 was used. This yields a median HEP of 0.001 with an error factor of 10. The resulting mean diagnosis HEP is 2.7×10^{-3}.

Post-Diagnosis Error. Post-diagnosis error results from a failure to align or start service water pump 38 and component cooling pump 32 or charging pump 31 or 32. The median HEP for these actions was calculated as 0.05 (EF=5) using Table 8-5 (item 4) of NUREG/CR-4772 and assuming step-by-step actions performed under extremely high stress. The resulting mean HEP is 0.081.

Recovery. Indicating lights on MCC-312A should alert the operator to any failure to perform the required actions correctly. In addition, inadequate RCP seal cooling (e.g., low bearing/thermal barrier cooling flow and high bearing/thermal barrier cooling return temperatures) will be annunciated in the control room. Therefore, the annunciator response model was used to estimate a non-recovery probability for post-diagnosis actions. Conservatively assuming the presence of ten unrelated alarms, Table 8-4 (item 10) of NUREG/CR-4772 assigns a median HEP of 0.05 with an error factor of 10. The resulting mean non-recovery HEP is 0.13.

Therefore, assuming revised procedures,

$$\text{OAPPR} = 0.0027 + 0.081 \times 0.13 = 0.013.$$

H2.29 OPERATOR ACTION OAFW-HVAC--OPERATOR PROVIDES ALTERNATIVE AFW PUMP ROOM VENTILATION

SUMMARY

a. Task. The operator must provide auxiliary boiler feed pump (ABFP) room ventilation should normal room ventilation fail.

b. Success Criterion. ABFP room roll-up garage door opened before ABFP room temperature reaches 160°F.

c. Scenario/Event Tree(s) Used. This action is demanded should normal ABFP room ventilation system fail after a reactor trip.

ACTION

a. Initial Conditions. While the reactor is operating at full power, a reactor trip occurs. The main feedwater pumps are tripped, and one or more AFW pumps deliver flow to the steam generators. Concurrently or subsequently, a total loss of ventilation to the ABFP room occurs.

b. Preceding Operator Actions. The operators will enter procedure E-0 (Reactor Trip or Safety Injection) upon the reactor trip and continue through E-0 if a safety injection signal is present. If no safety injection signal is present, the operators will transfer to procedure ES-0.1 (Reactor Trip Response).

c. Symptoms.
High ABFP room temperature.

d. Indications.
"Aux Feed Pump Room Hi Temp" annunciator on panel SDF.

e. Procedural Guidance. Until recently, no explicit procedural guidance was provided to direct the operators to open the roll-up door in the ABFP room. However, Alarm Response Procedure ARP-7 is being revised to direct the operators to open the roll-up door if the room temperature exceeds 120°F.

f. Response.

ARP-7 (Rev. 12) - "Aux Feed Pump Room Hi Temp" alarm on panel SDF
If the temperature in the ABFP room exceeds 120°F, open the roll-up door to provide ventilation.

PERFORMANCE SHAPING FACTORS

a. Timing.

Time Available - The time available to restore ventilation to the ABFP room depends upon the number of AFW pumps operating and the initial temperature of the room. Assuming conservatively that all three AFW pumps are operating and the initial room temperature is 90°F, the room temperature will increase from 120°F (alarm setpoint) to 160°F (qualification temperature of the motor-driven AFW pumps) in 103 minutes.

Time Needed - This action, including travel time to the ABFP room, can be accomplished within 15 minutes assuming there are no heat stress-induced delays.

b. Competing Actions/Alarms. None expected.

c. Consequence of Actions.

Success - Success results in continued operability of the AFW pumps.

Failure - Failure results in the loss of all AFW pumps, requiring alternative methods to remove decay heat.

d. Training/Experience. Since the procedural guidance for this scenario has not yet been implemented, no training or experience currently exists. However, it was assumed that operators will receive training on this scenario once the procedures are revised.

e. Stress. Moderate to extremely high stress levels were assumed. Since the alarm setpoint for high ABFP room temperature is 120°F and five to ten minutes may elapse before the operator enters the ABFP room, actual room temperature on entry will be higher. Consequently, heat stress could cause extremely high stress levels.

f. Skill/Rule/Knowledge-Based. Rule-based--this action will be proceduralized.

g. Task Complexity. Simple.

QUANTIFICATION

The operators will have 103 - 15 = 88 minutes to diagnose the high temperature condition (greater than 120°F) in the ABFP room. However, the time available was conservatively assumed to be 60 minutes based on the fact that there may be delays in establishing natural air circulation. Using the nominal diagnosis model in NUREG/CR-4772, the median diagnosis HEP from Table 8-2 (item 5) is 10^{-4}, with an error factor of 30. The corresponding mean HEP is 8.5×10^{-4}. Post-diagnosis errors were considered to be negligible given

successful diagnosis.

In addition to the human error contribution for failure to establish ABFP room ventilation, failure of the annunciator module was also considered, since such a failure will preclude detection of high room temperature condition. From IEEE Standard 500-1984, the recommended failure rate for annunciator modules is 1.02×10^{-6}/hr. Operation of the annunciator is verified every refuelling outage during testing of the ABFP room temperature indicators. Therefore, the hardware contribution to failure was estimated to be 1.02×10^{-6}/hr $\times$ (1.5 $\times$ 8760 hrs)/2 = 6.7×10^{-3}.

Combining the contributions of human and hardware failures (8.5×10^{-4} and 6.7×10^{-3}, respectively), the total failure probability is 7.6×10^{-3}.

$\therefore$ OAFW-HVAC = 7.6×10^{-3}.

H2.30 OPERATOR ACTION OCTL15-HVAC--OPERATORS PROVIDE ALTERNATIVE SWITCHGEAR ROOM VENTILATION

SUMMARY

a. Task. The operator must provide 480-Vac switchgear room ventilation should normal room ventilation fail.

b. Success Criterion. Alternative room cooling established by opening doors and using a portable fan to circulate air.

c. Scenario/Event Tree(s) Used. The action is addressed in sequences which involve a failure of the 480-Vac switchgear room ventilation system.

ACTION

a. Initial Conditions. While the reactor is operating at full power, a reactor trip occurs. Concurrently or subsequently, a failure occurs which results in inadequate ventilation in the 480-Vac switchgear room.

b. Preceding Operator Actions. The operators will enter procedure E-0 (Reactor Trip or Safety Injection) upon the reactor trip and continue through E-0 if a safety injection signal is present. If there no safety injection signal is present, the operators will transfer to procedure ES-0.1 (Reactor Trip Response).

c. Symptoms.
High 480-Vac switchgear room temperature.

d. Indications.
A modification will be installed to provide a control room alarm on high control building - 15-ft elevation (480-Vac switchgear room) ambient temperature.

e. Procedural Guidance. A night order directs that the double doors to the turbine building be blocked open to allow sufficient air to circulate through the room to cool the 480-Vac switchgear and allow resetting of any breakers that may trip because of high temperatures. Prior to plant startup, this night order will be replaced with an alarm response procedure which will specify the response to increasing switchgear room ambient temperature and maintain the temperature below the design value of 104°F.

f. Response.

The alarm response procedure has not yet been developed to address a high temperature in the 480-V switchgear room. However, the new procedure will direct the operator to open the double doors to the turbine building and align a portable fan. The requirements for the portable fan, however, have yet to be determined.

PERFORMANCE SHAPING FACTORS

a. Timing.

Time Available - Equipment qualifications show that the ambient room temperature in the switchgear room must reach 117°F to trip the 480-Vac switchgear breakers. With one fan operating during a normal transient event, calculations show that the maximum room temperature will be 113°F. Therefore, no operator action is required. However, should both fans be inoperable during a transient event (or one fan inoperable during a LOCA), room temperatures will rise fairly rapidly to 117°F, requiring the operators to establish alternative ventilation and possibly reset tripped breakers.

Time Needed - The double doors to the turbine building can be opened within ten minutes (including travel time to the switchgear room); a further five minutes may be required to set up the portable fan.

b. Competing Actions/Alarms. None expected.

c. Consequence of Actions.

Success - Success results in continued operation of buses 2A, 3A, 5A, and 6A and essential equipment supplied by those buses.

Failure - Failure results in loss of all 480-Vac safeguards buses (2A, 3A, 5A, and 6A).

d. Training/Experience. Since the procedural guidance for this scenario has not yet been implemented (except in the night orders), no training or experience currently exists. However, it was assumed that each operator will receive training on this scenario once the alarm response procedures are revised.

e. Stress. Moderate to extremely high stress levels were assumed.

f. Skill/Rule/Knowledge-Based. Rule-based--this action will be proceduralized.

g. Task Complexity. Simple.

QUANTIFICATION

A modification is currently being implemented which will provide a control room alarm on high switchgear room ambient temperature. In addition, an alarm response procedure is being developed to provide guidance for establishing alternate ventilation of the switchgear room. For conditions in which normal ventilation is unable to maintain the ambient room temperature below 117°F, it was assumed that the breakers will have to be reset. Because of the time available to establish alternate room ventilation, a screening value of 0.1 was used for failure to perform the action.

$\therefore$ OCTL15-HVAC = 0.1

INTRODUCTION

This appendix describes the results of the analyses performed to predict the progression of severe accident sequences determined to be dominant contributors to core damage. These analyses sought to predict the containment pressure profile and the time at which the containment fails to help characterize source term releases.

The thermal-hydraulic behavior of IP3 was analyzed using version 3.0B, Revision 16, of the Modular Accident Analysis Program for Pressurized Water Reactors (MAAP/PWR)[1].

The following scenarios were analyzed to provide insight into the phenomena and mechanisms pertinent to a severe accident progression.

[1] A long-term station blackout scenario in which sufficient dc power is available to operate the AFW steam-turbine-driven pump and atmospheric dump valves for 4 hours. No RCP seal LOCA occurs. After 4 hours, battery depletion is assumed to occur, stopping AFW flow to the steam generators.

[2] A short-term station blackout scenario in which the AFW steam-turbine-driven pump is unavailable for secondary-side cooling.

[3] A large LOCA scenario in which ECCS injection is successful until switch-over to long-term recirculation core cooling is attempted.

[4] A long-term station blackout scenario with RCP seal failure after 30 minutes. The AFW system steam-turbine-driven pump is assumed to fail after 4 hours because of battery depletion.

[5] A long-term station blackout scenario in which dc power is available to operate the AFW steam-turbine-driven pump and atmospheric dump valves for 4 hours and in which no RCP seal LOCA occurs. After 4 hours, battery depletion is assumed to stop AFW flow to the steam generators. AC power is restored 90 minutes after vessel breach.

[6] A large LOCA scenario in which ECCS injection is successful until switch-over to long-term recirculation core cooling is attempted. No containment heat is removed by the containment fan coolers, containment spray system, or RHR heat exchangers.

---

[1]Fauske & Associates, Inc., "MAAP 3.0B Users manual," prepared for The Electric Power Research Institute, March 16, 1990.

[7] A small LOCA scenario in which ECCS injection and recirculation core cooling are unavailable. No containment heat is removed by containment fan coolers or RHR heat exchangers. However, containment sprays operate.

[8] A long-term station blackout scenario in which dc power is available to operate the AFW steam-turbine-driven pump and atmospheric dump valves for 4 hours and in which no RCP seal LOCA occurs. After 4 hours, battery depletion is assumed to occur, stopping AFW flow to the steam generators. AC power is restored 90 minutes after vessel breach. To provide a more realistic coolant heat flux, the MAAP/PWR default parameter for flat plate critical heat flux was lowered from 0.14 to 0.015. This change reduces heat loss to the coolant and so allows core-concrete interaction to occur.

[9] A short-term station blackout scenario in which the AFW steam-turbine-driven pump is unavailable for secondary-side cooling. No RCP seal LOCA occurs. After steam generator dryout, RCS boiloff results in core melt and vessel breach, followed by core-concrete interactions that will slowly pressurize the containment until it fails. Containment depressurization through a containment rupture area of 1 ft^2 follows.

[10] A long-term station blackout scenario in which dc power is available to operate the AFW steam-turbine-driven pump and atmospheric dump valves for 4 hours. No RCP seal occurs. After 4 hours, battery depletion occurs, stopping AFW flow to the steam generators. Subsequent RCS boiloff results in core melt and vessel breach, followed by core-concrete interactions that will slowly pressurize the containment until it fails. Containment depressurization through a containment rupture area of 1 ft^2 follows. AC power is restored 90 minutes after vessel breach.

Section K2

RESULTS

K2.1 ACCIDENT SCENARIO 1 -- LONG-TERM STATION BLACKOUT WITHOUT AC POWER RECOVERY

This accident scenario is initiated by a loss of offsite power. Subsequently, onsite emergency power is also lost. RCS integrity remains intact because no RCP seal LOCA occurs. AFW flow to the steam generators is initially provided by the steam-turbine-driven AFW pump. Make-up to the steam generators continues until, after 240 minutes, the dc batteries are completely depleted. Subsequently, the steam generators boil dry at 370 minutes (Figure K2.1.1). Because no heat can be removed from the RCS to the secondary-side, RCS pressure increases from slightly below 2250 psia to 2470 psia (Figure K2.1.2). At an RCS pressure of 2470 psia, further RCS pressure increases are limited by steam flow through the pressurizer safety relief valves. With RCS pressure cycling about the PORV setpoint, rapid RCS boil-off ensues (Figure K2.1.3) and the core is uncovered at 433 minutes. Once uncovered, the core starts to heat up and the metals within it interact with steam, producing hydrogen.

Debris from the core melt progression will relocate and accumulate on the core support plate until, at 585 minutes, the plate fails. Subsequently, continued debris relocation into the lower region of the reactor vessel leads to vessel failure via a failed instrument penetration at 593 minutes.

The containment pressure during this accident sequence is shown in Figure K2.1.4. The containment pressure rises after the primary relief tank disk ruptures at 386 minutes. A second containment pressure rise occurs after vessel breach, a rapid containment rise from 35.1 psia to 51.2 psia being predicted by MAAP/PWR. Sustained core-concrete interactions from decay heat will then slowly pressurize the containment until containment failure results at 47 hours. Containment depressurization through a containment leak area of 0.1 ft^2 follows.

Hydrogen production history is depicted in Figure K2.1.5: about 1140 lbs of hydrogen are produced in-vessel and about 1260 lbs is produced ex-vessel (during core-concrete interactions). However, the hydrogen does not burn because the containment atmosphere is steam inerted and, in the absence of ac power, no ignition sources are present.

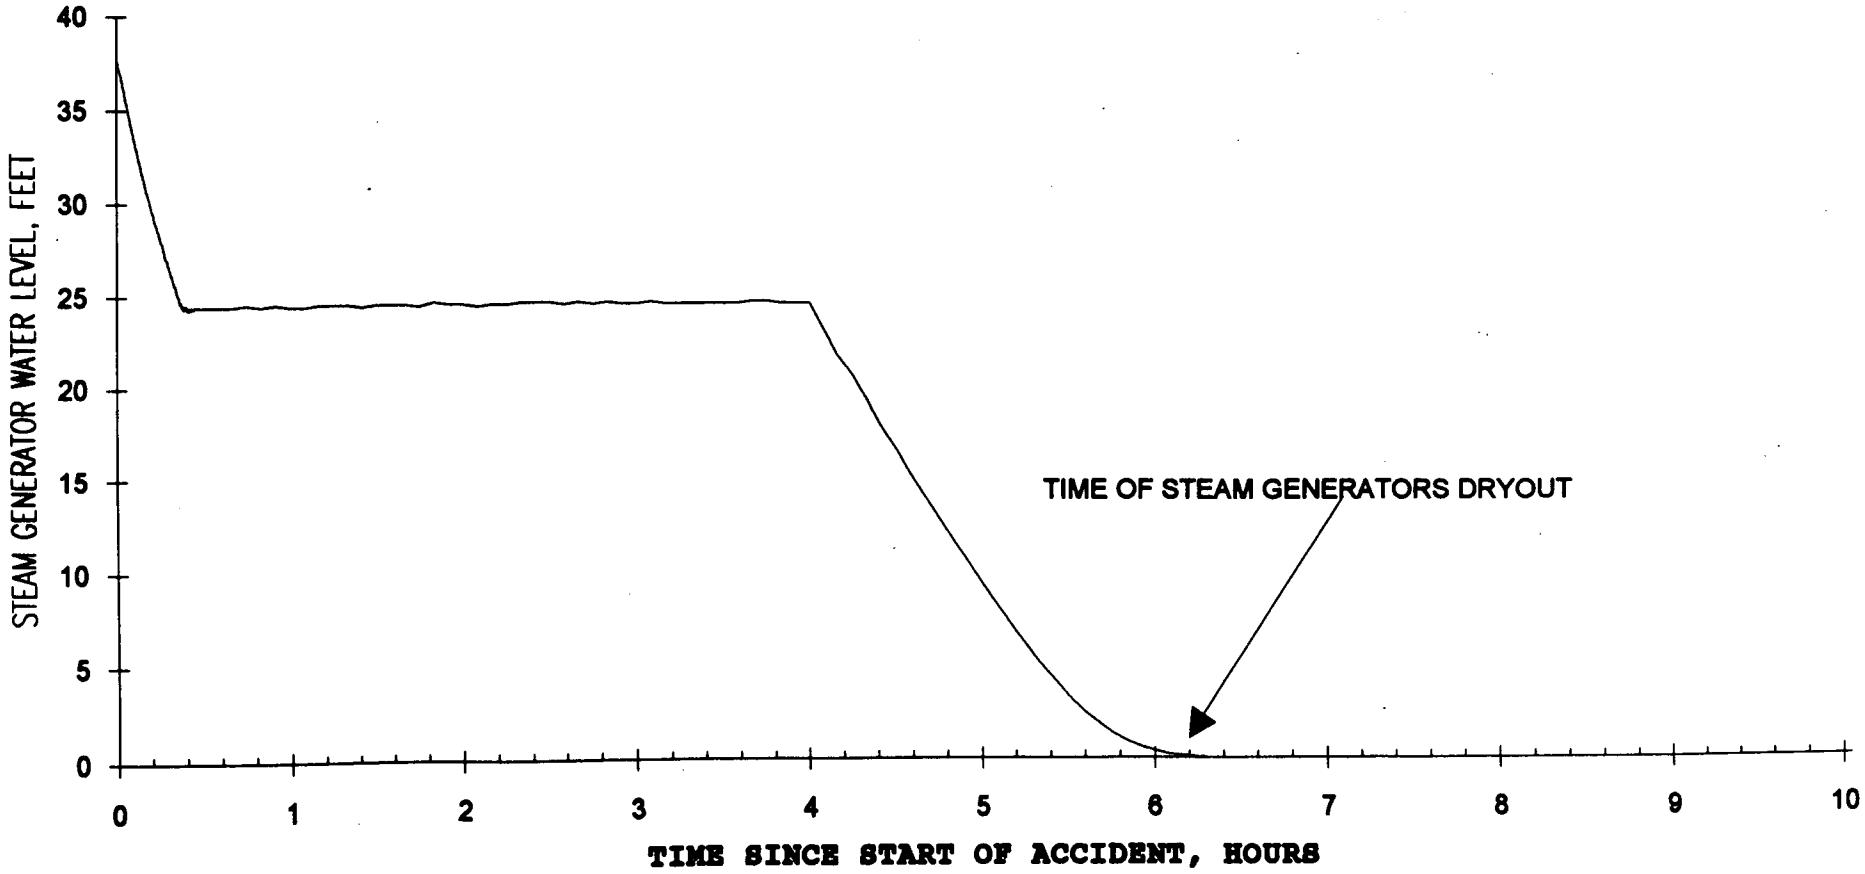

Figure K2.1.2 Accident Scenario 1 -- RCS Pressure

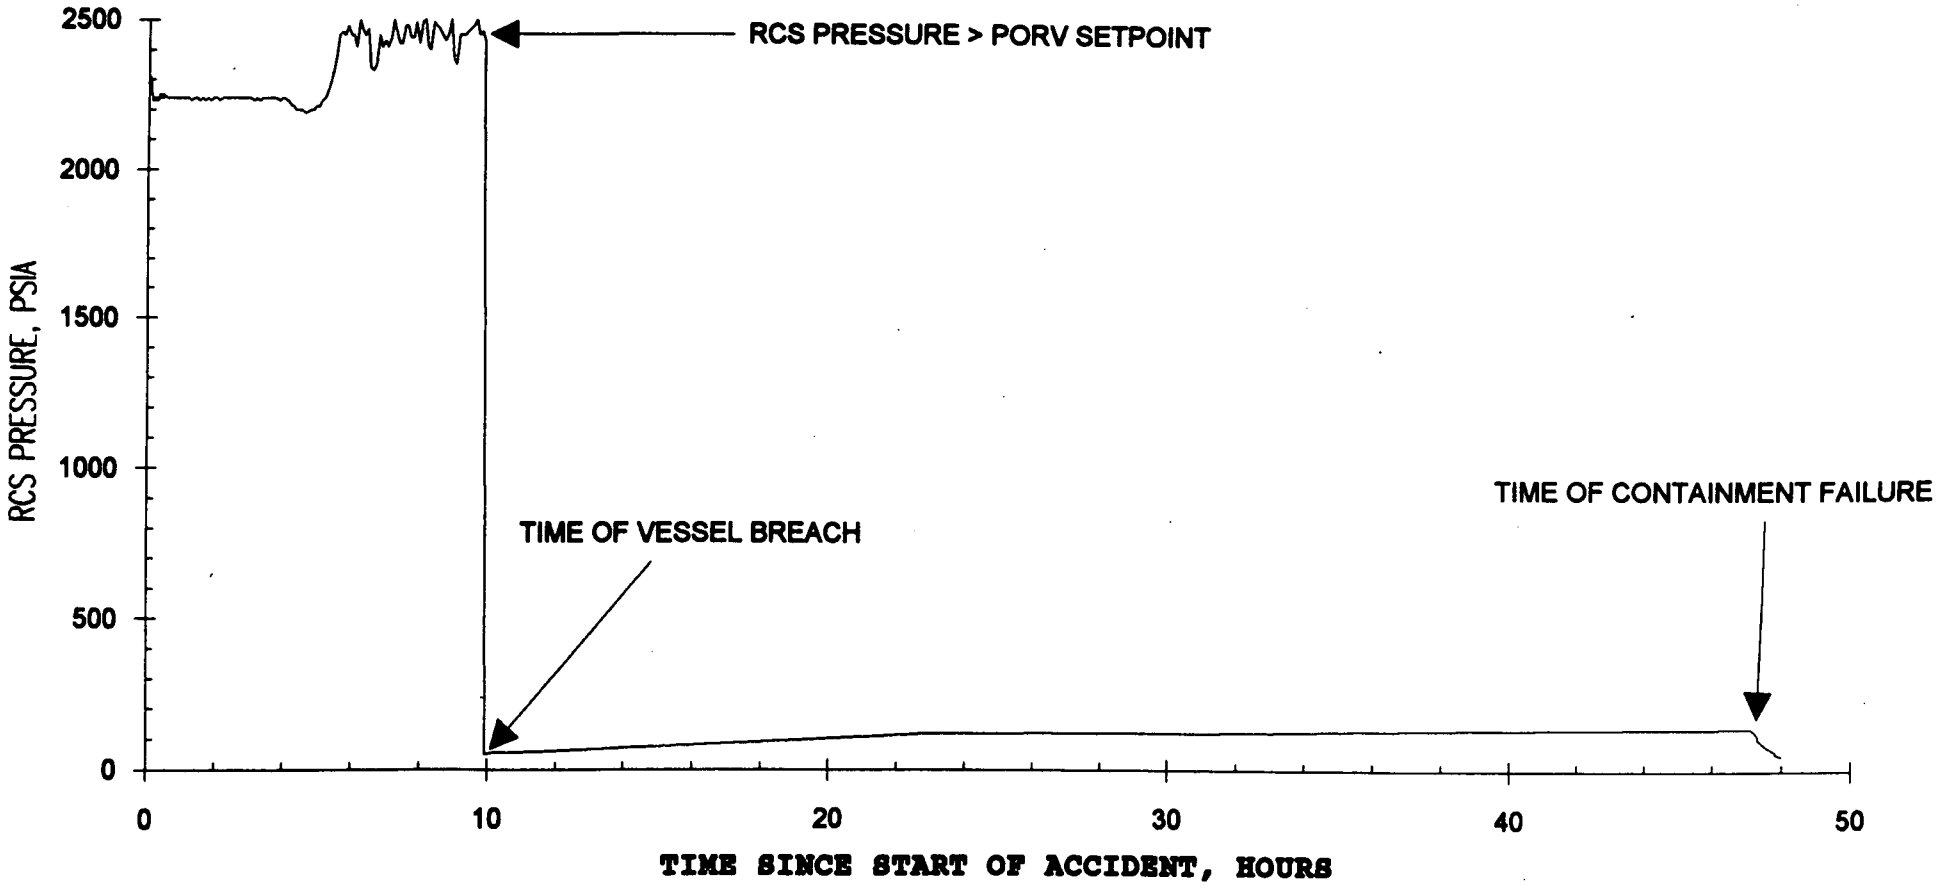

Figure K2.1.3 Accident Scenario 1 -- RCS Water Level

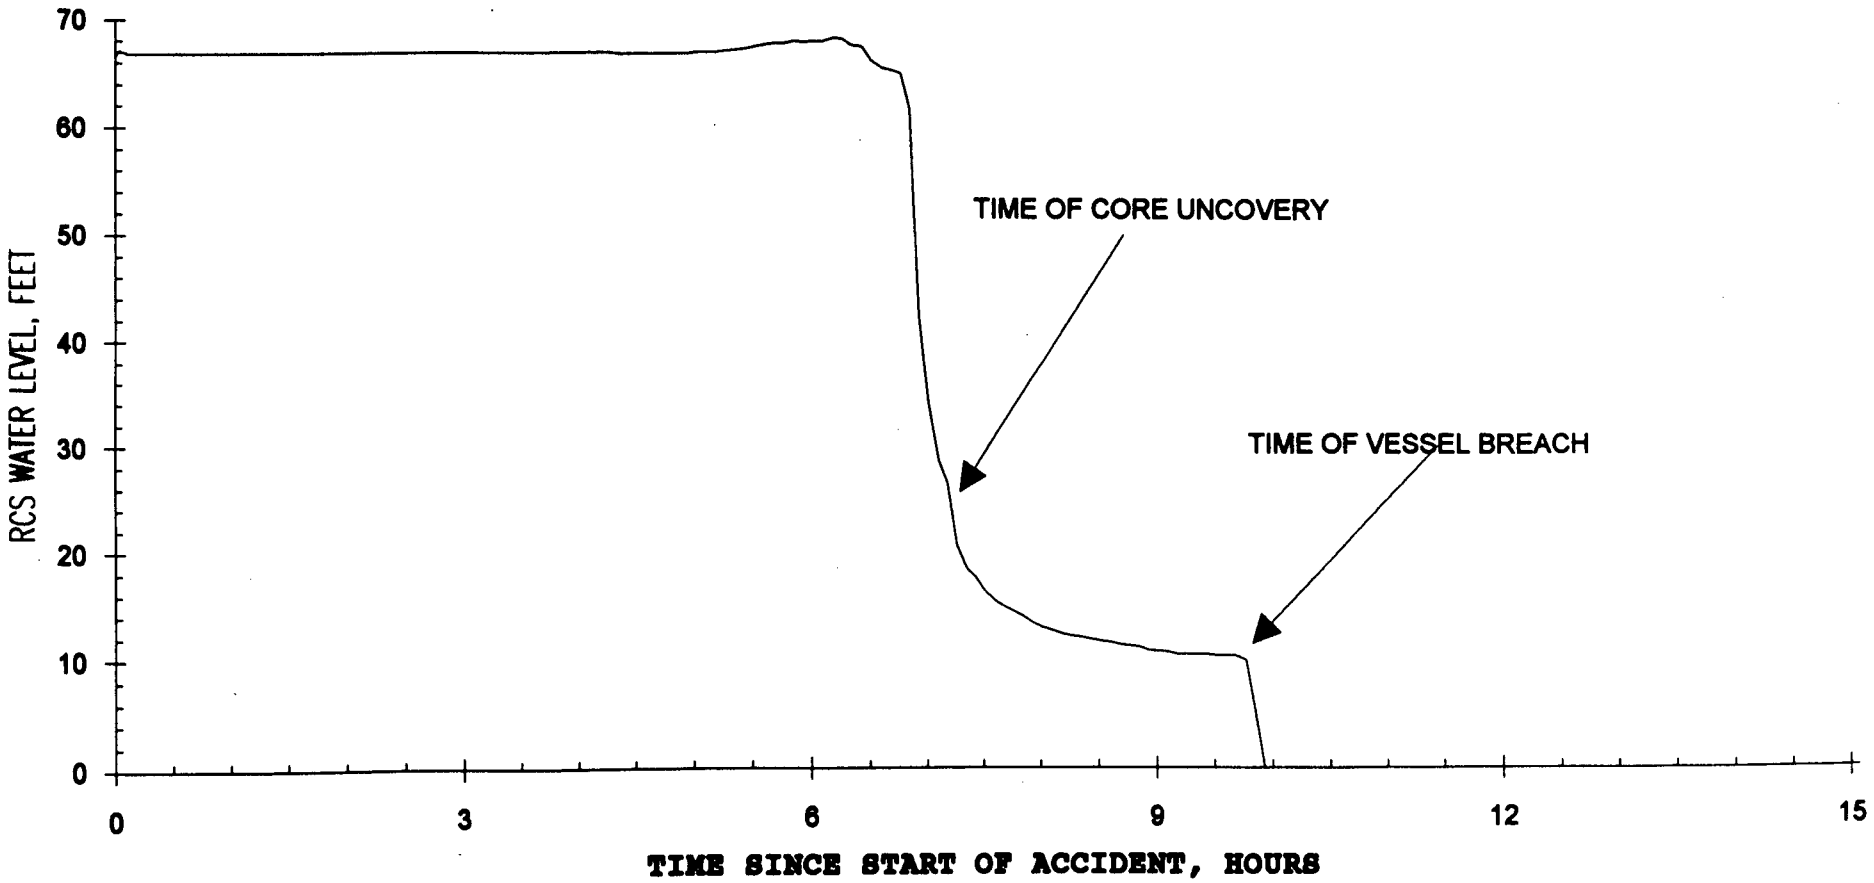

Figure K2.1.4 Accident Scenario 1 -- Containment Pressure

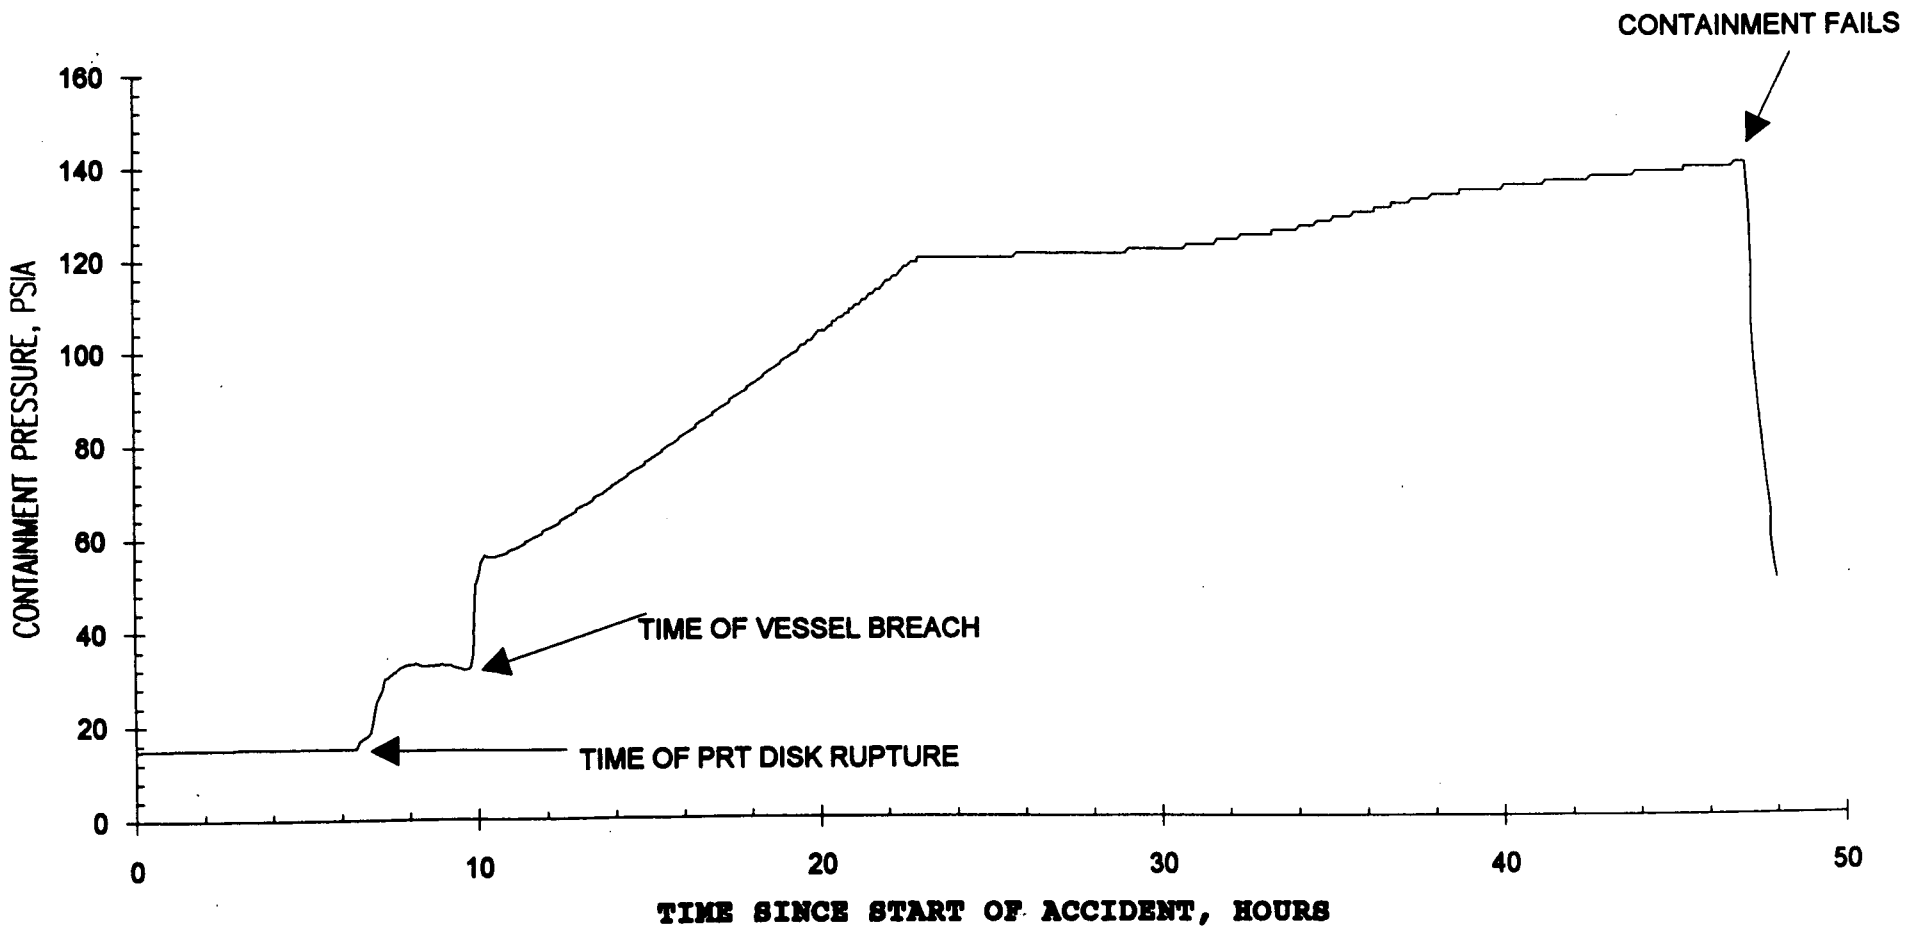

Figure K2.1.5 Accident Scenario 1 -- Hydrogen Production

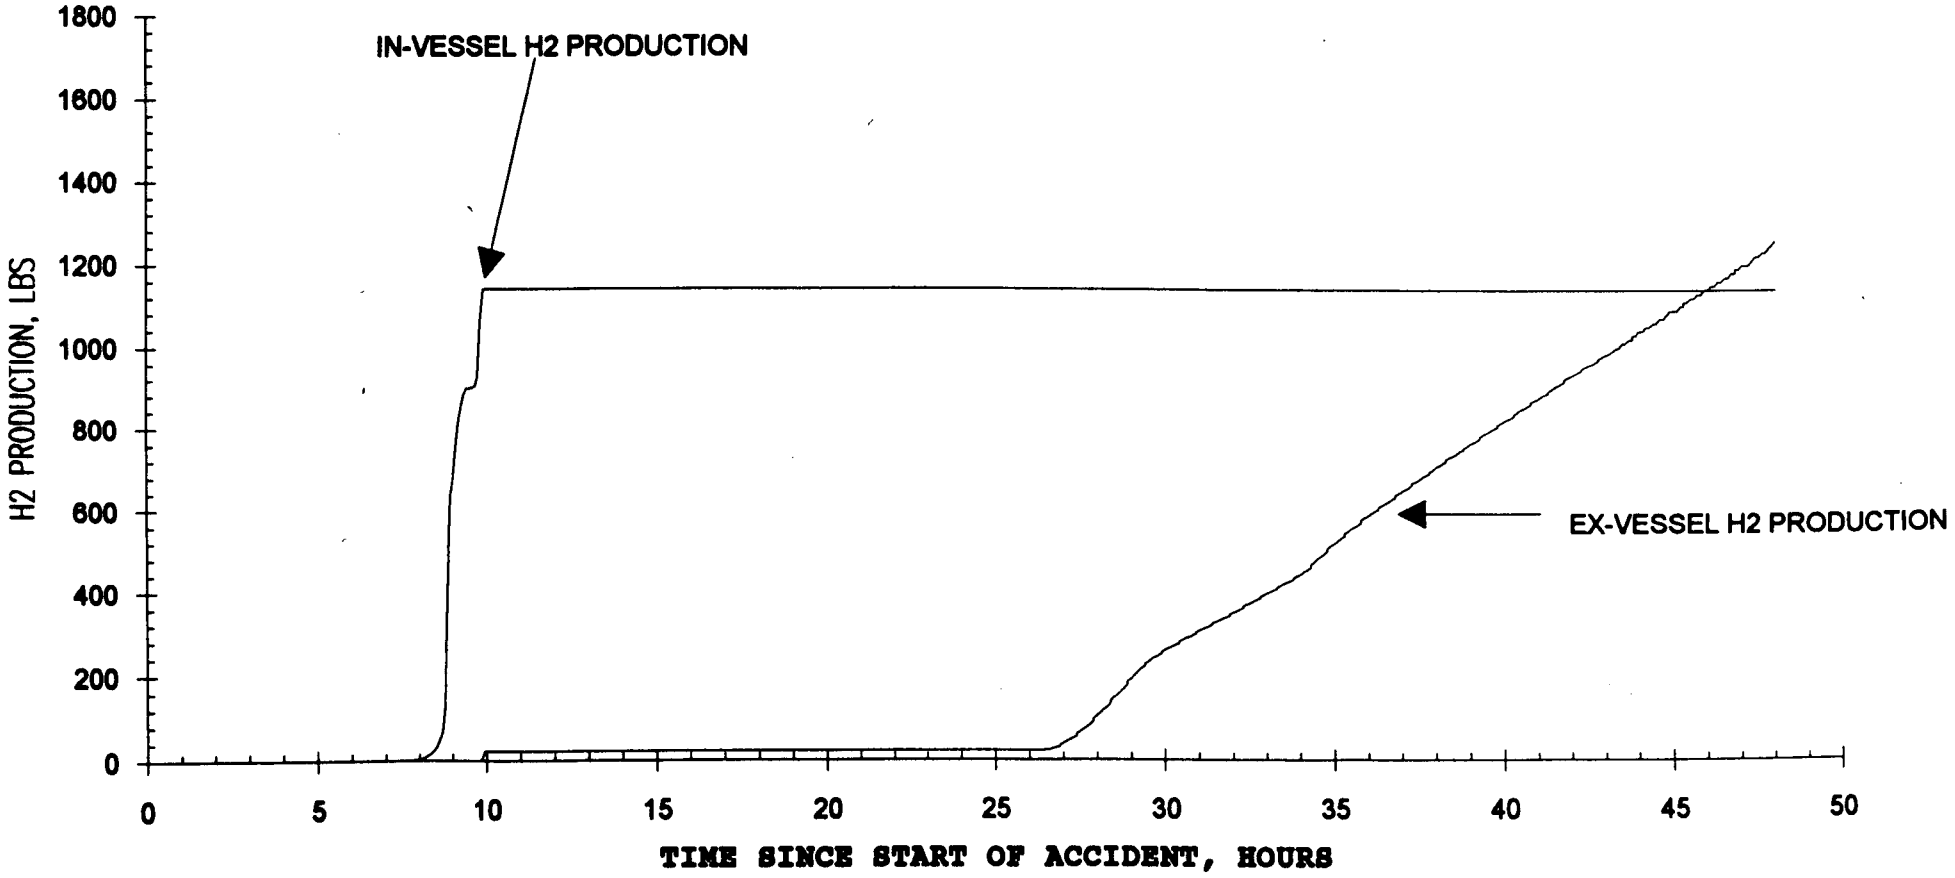

K2.2 ACCIDENT SCENARIO 2 -- SHORT-TERM STATION BLACKOUT WITHOUT AC POWER RECOVERY

In terms of steam generator, RCS and containment behavior, this accident scenario differs from Accident Scenario 1 only in event timing. Steam generator level, RCS pressure and water level, containment pressure, and hydrogen production history are shown in Figures K2.2.1 - K2.2.5.

Figure K2.2.1 Accident Scenario 2 -- Steam Generator Water Level

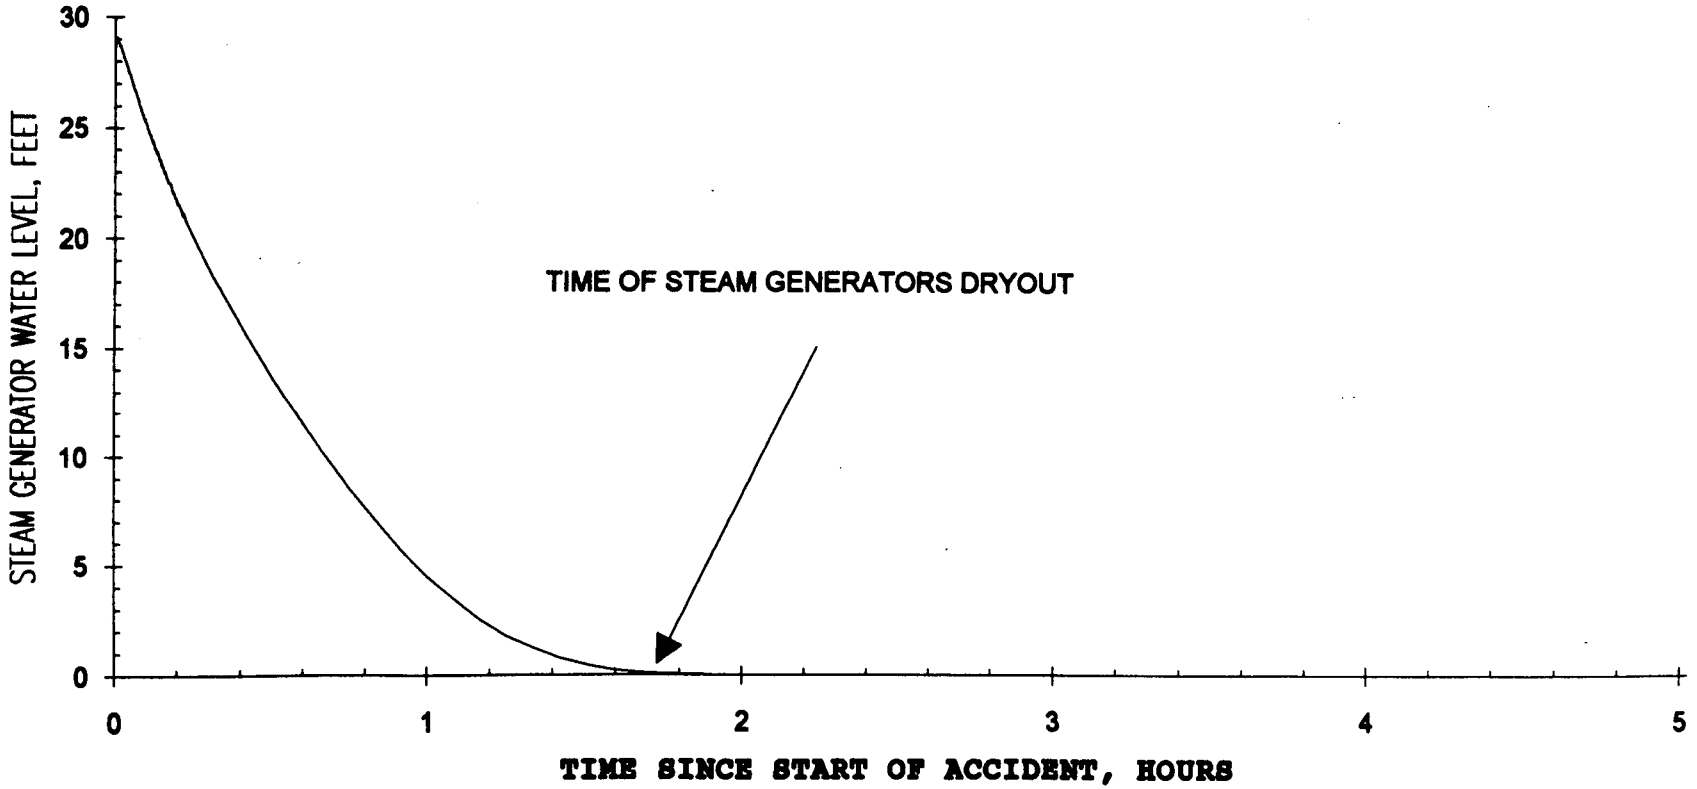

Figure K2.2.2 Accident Scenario 2 -- RCS Pressure

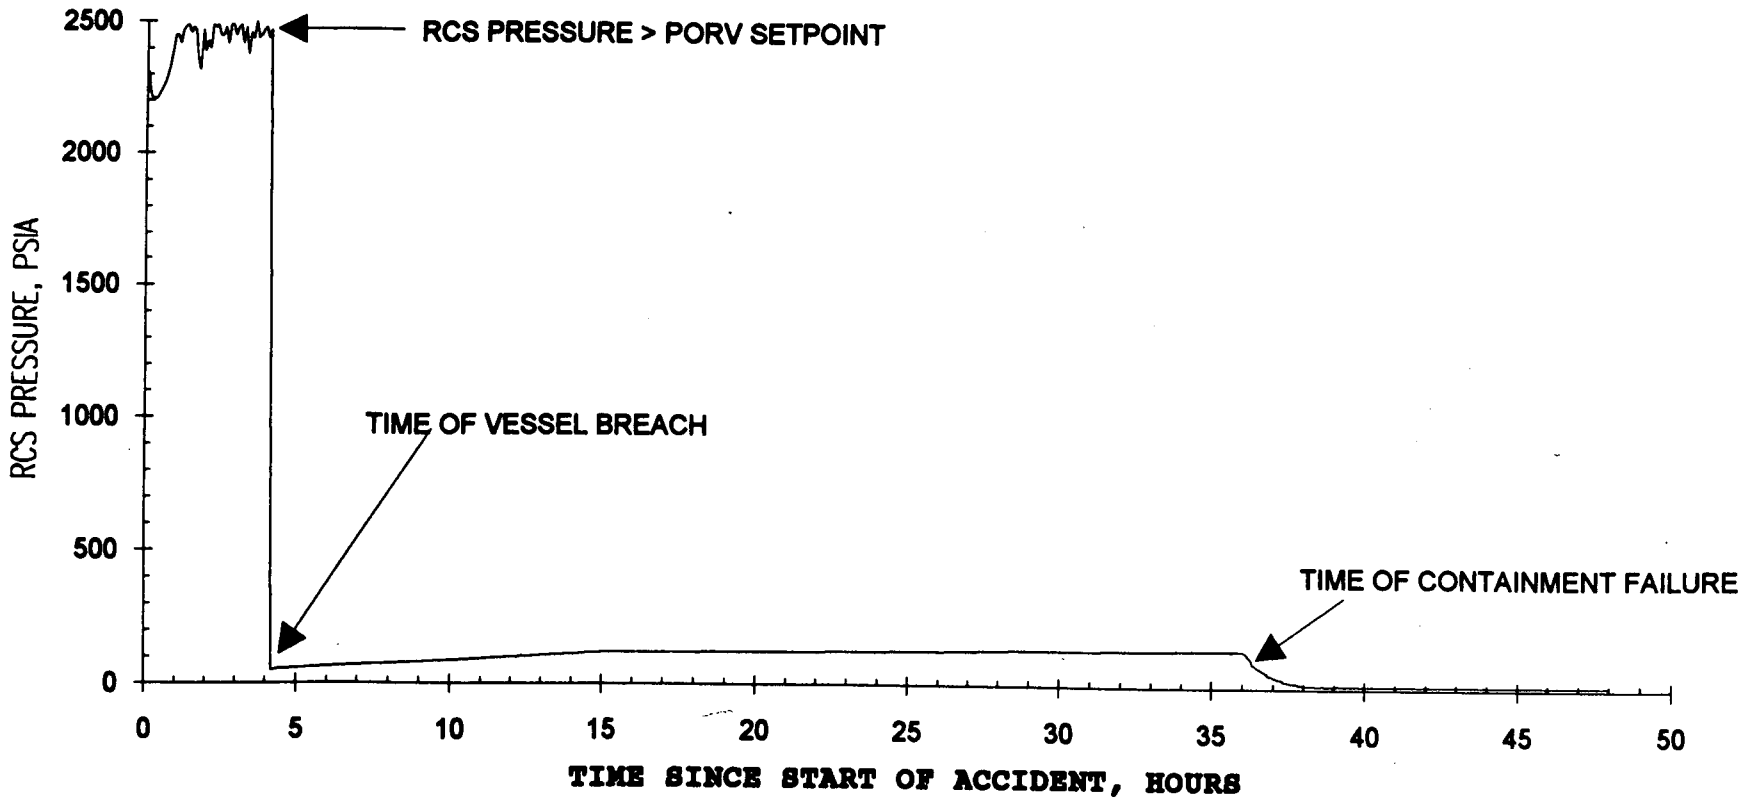

Figure K2.2.3 Accident Scenario 2 -- RCS Water Level

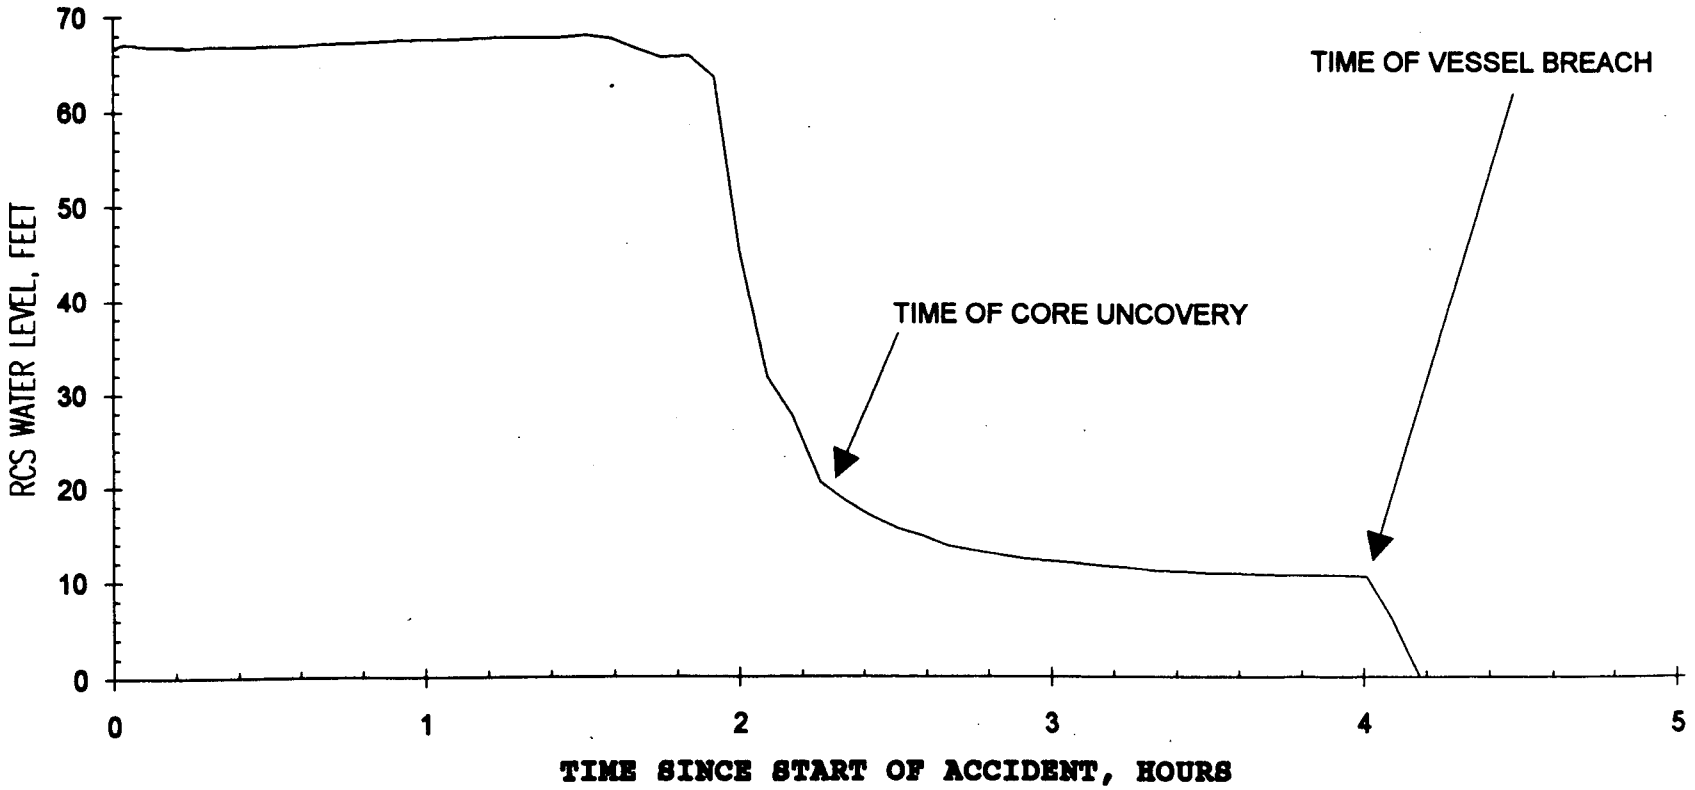

Figure K2.2.4 Accident Scenario 2 -- Containment Pressure

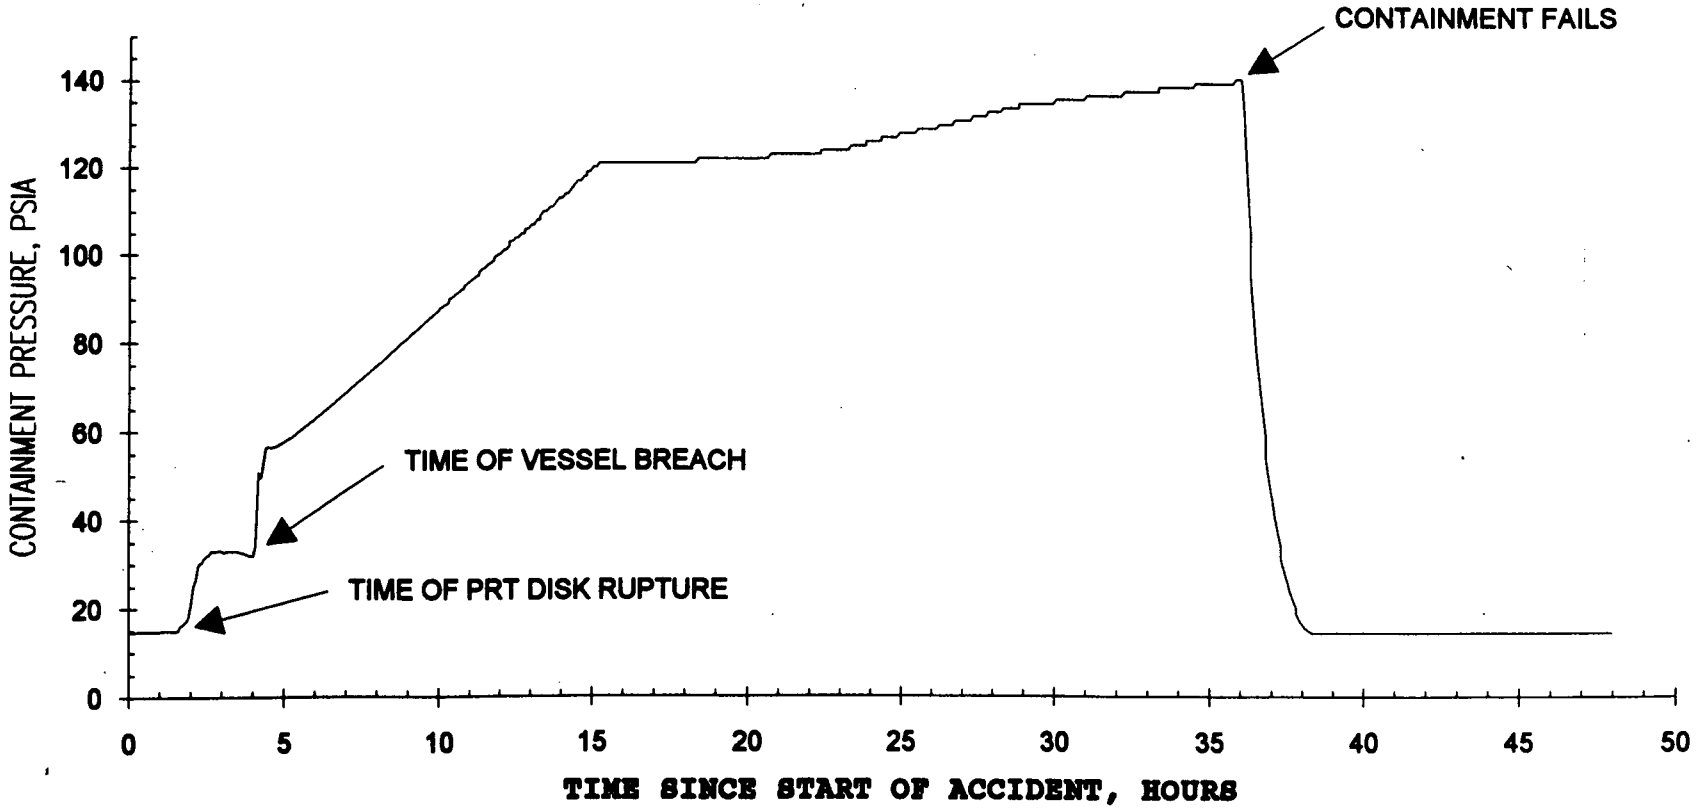

Figure K2.2.5 Accident Scenario 2 -- Hydrogen Production

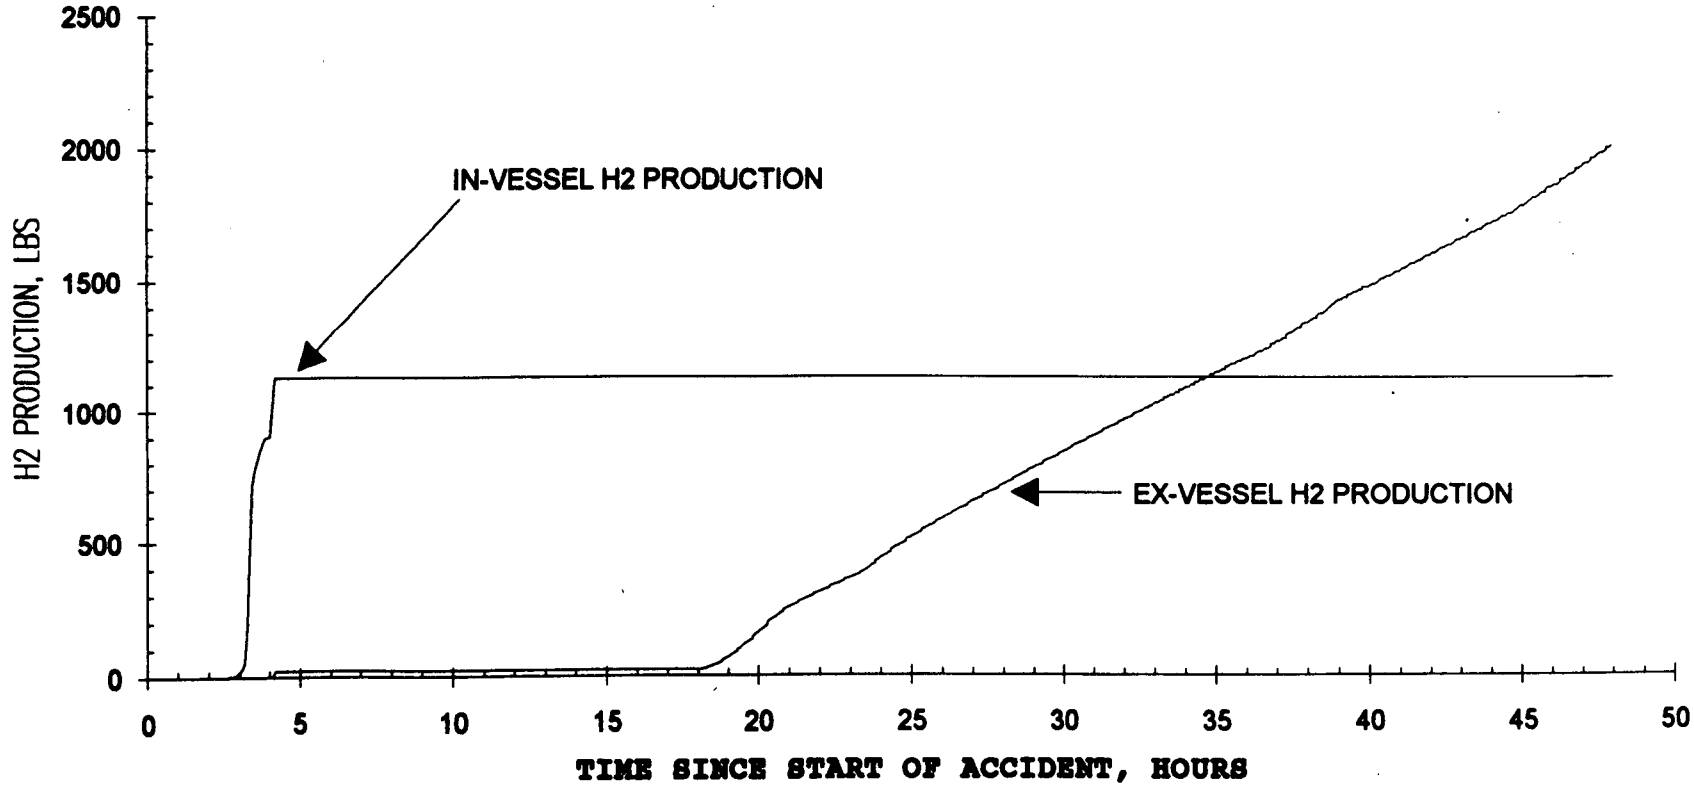

K2.3 ACCIDENT SCENARIO 3 -- LARGE LOCA WITH RECIRCULATION CORE COOLING FAILURE

A large LOCA is initiated by a reactor coolant hot leg pipe rupture at the 67-ft elevation (34 feet from the bottom of the reactor vessel head). Because of the size of rupture, the RCS depressurizes very rapidly (Figure K2.3.1). Low RCS pressure (<675 psia) causes the accumulators to discharge, the accumulators emptying in 54 seconds. Because pressurizer water level decreases rapidly, both high- and low-head safety injection systems initiate to provide adequate core cooling, maintaining RCS water level at the break elevation. Upon RWST depletion, switch-over to long-term recirculation fails and is considered non-recoverable. The ensuing RCS boil-off (Figure K2.3.2) leads to the core being uncovered and core damage. Because of metal-water reactions, hydrogen is produced.

Support plate failure is predicted to occur at 273 minutes because of debris relocation and accumulation on the core support plate. Lower head vessel failure occurs 8 minutes later.

Containment pressure to this accident sequence is shown in Figure K2.3.3. The containment pressure rises to 42 psia after the initial RCS blowdown and then decreases to 17 psia, because of containment fan cooler and spray operation and steam condensation on the containment concrete structures. After the failure of recirculation core cooling at 59 minutes, the ensuing core boil-off generates sufficient steam and hydrogen to raise the containment pressure to 23 psia. After RCS boil-off, steam and hydrogen generation rates decrease, allowing the containment fan coolers to lower the containment pressure to 20 psia. A final containment pressure rise from 20 psia to 28 psia occurs at vessel breach as the core debris reacts with water in the reactor pit. The reactor pit water level drops rapidly from 25 feet to 0.12 feet over a 5 minute period after vessel breach (Figure K2.3.4).

The hydrogen production history predicted by MAAP/PWR is depicted in Figure K2.3.5. The total amount of hydrogen produced in-vessel is about 872 lbs. Ex-vessel hydrogen production, however, is only about 15 lbs because the core debris inside the reactor pit is quenched by water present at the time of vessel breach. MAAP/PWR also predicts that no hydrogen burns will occur at vessel breach.

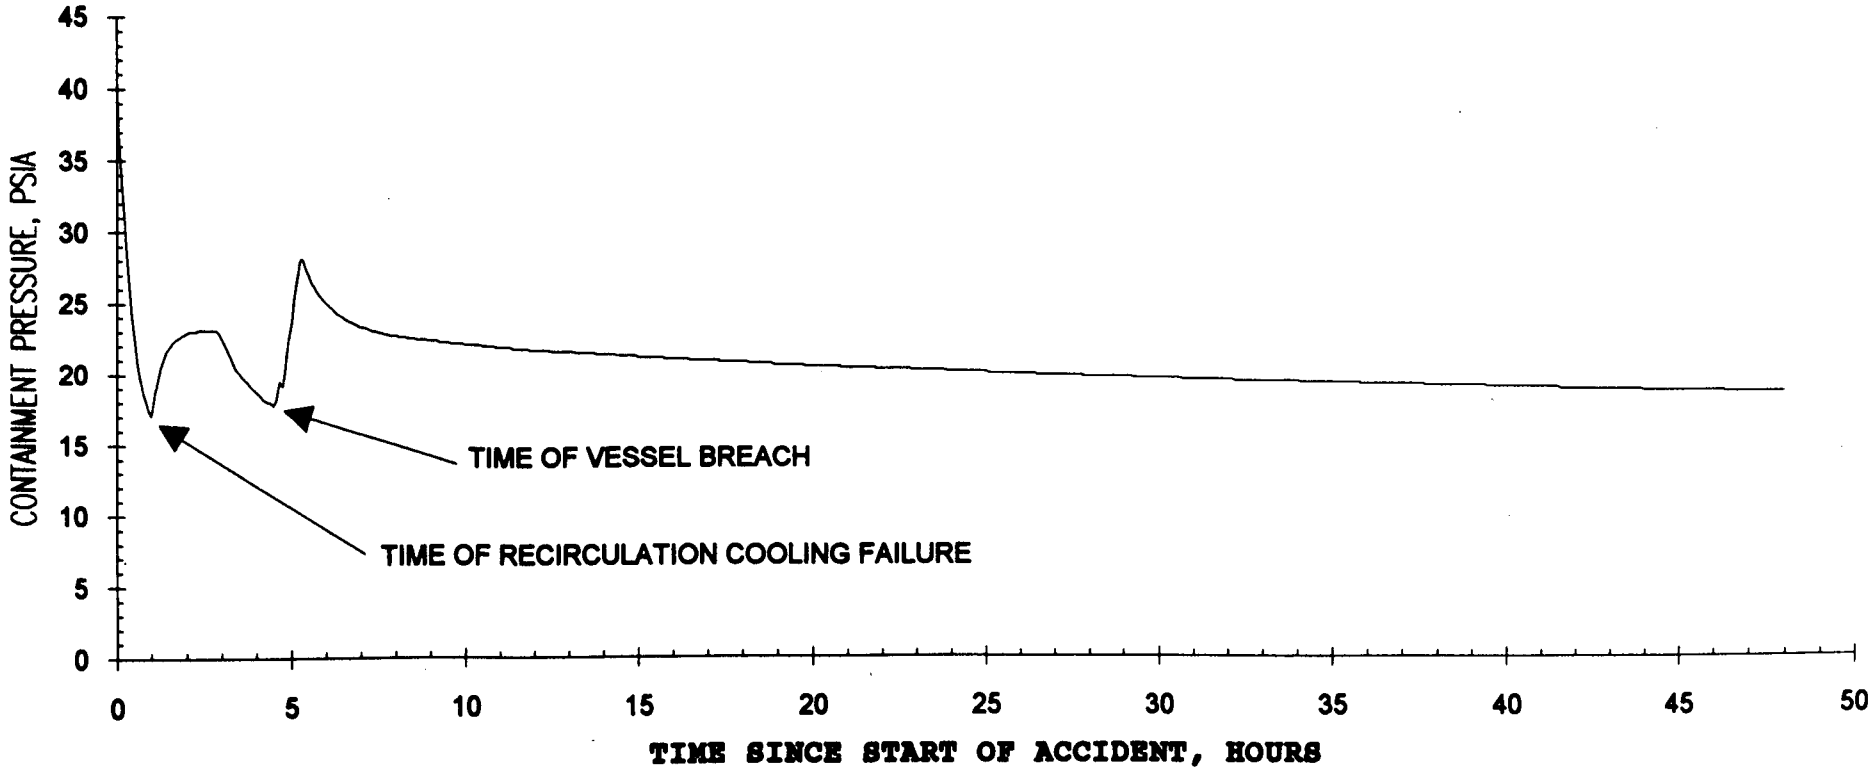

Figure K2.3.4 Accident Scenario 3 -- Reactor Pit Water Level

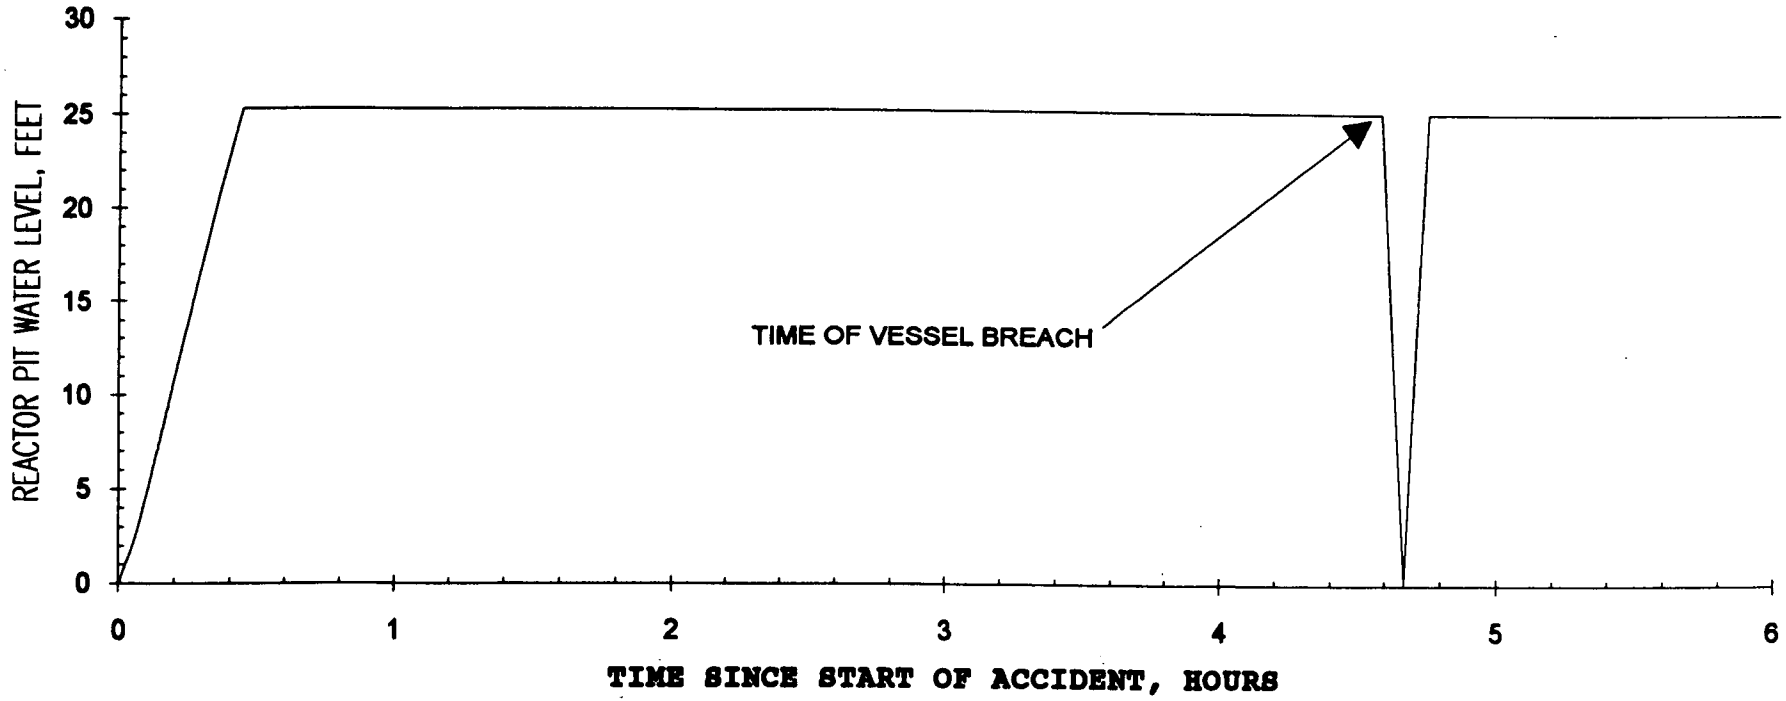

Figure K2.3.5 Accident Scenario 3 -- Hydrogen Production

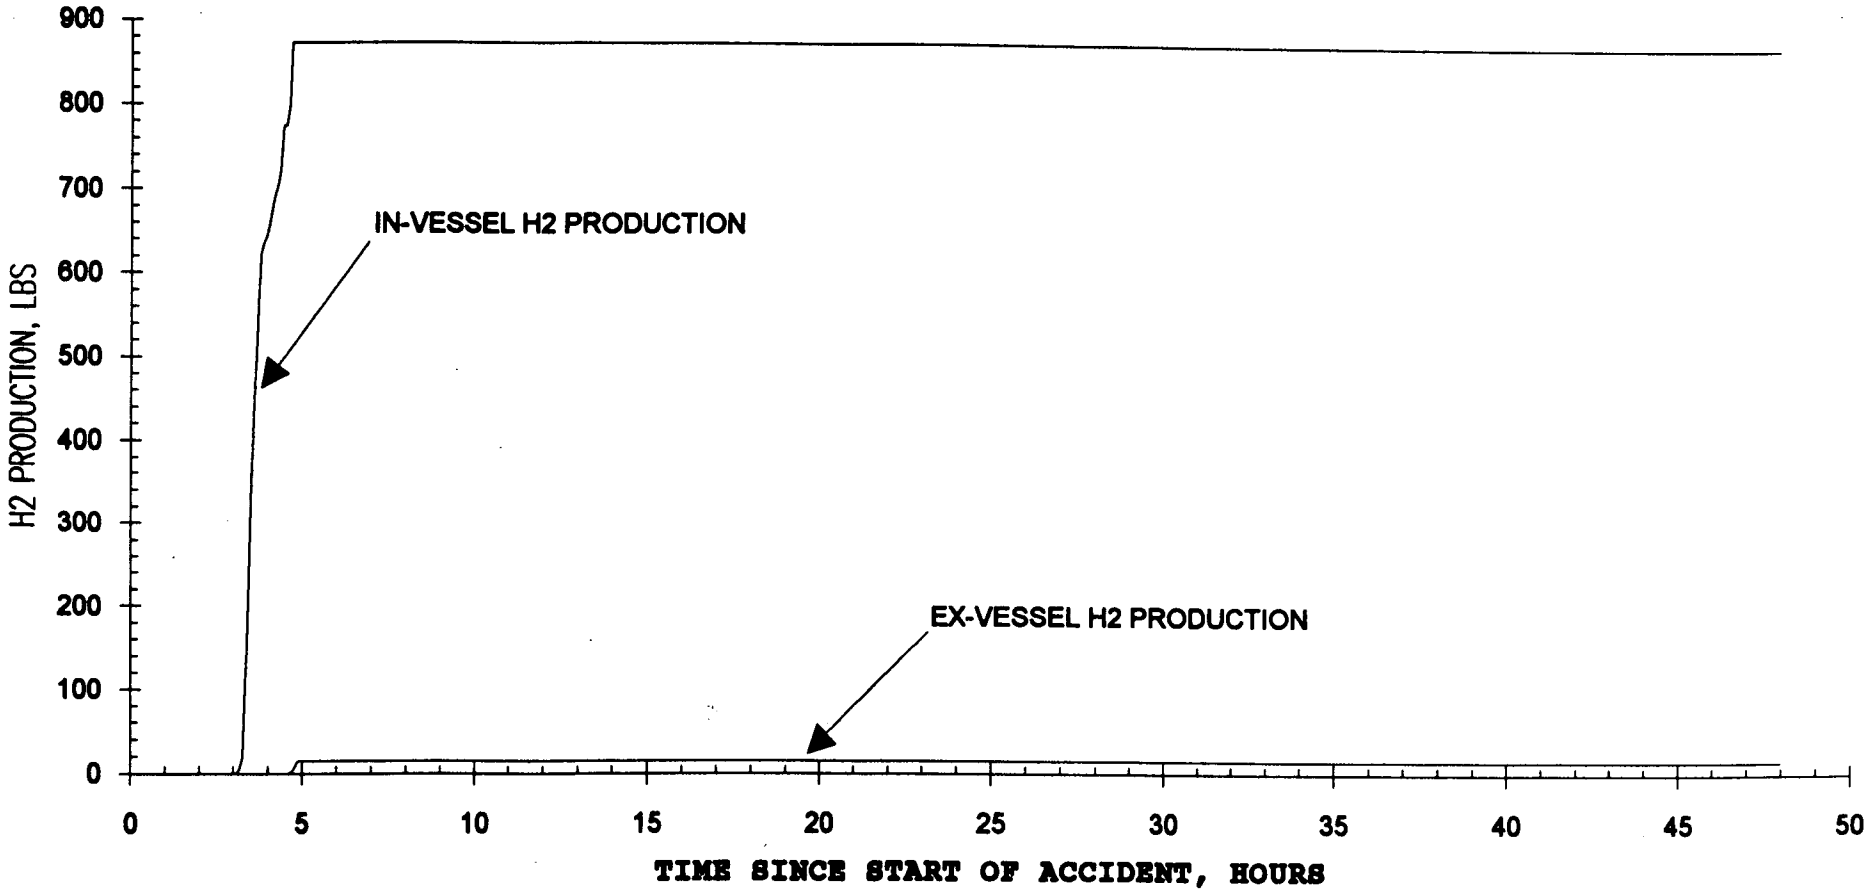

K2.4 ACCIDENT SCENARIO 4 – LONG-TERM STATION BLACKOUT WITH RCP SEAL LOCA AND NO AC POWER RECOVERY

This accident scenario is initiated by loss of offsite power with a subsequent loss of onsite emergency power. AFW flow to the steam generators is provided by the steam-turbine-driven AFW pump. RCS integrity is breached because of RCP seal failure after 30 minutes. Make-up to the steam generators continues until, after 240 minutes, the dc batteries are completely depleted. For the first 30 minutes, RCS pressure is similar to that predicted for Accident Scenario 1. After RCP seal failure, however, RCS pressure falls to 700 psia. (Figure K2.4.1). Because the SBO renders all core make-up systems unavailable, RCS inventory will decrease (Figure K2.4.2) and the core is uncovered at 165 minutes (or 135 minutes after RCP seal failure). Once the core is uncovered, it starts to heat up and the metals within it interact with the steam, producing hydrogen.

Debris from the core melt progression will accumulate on the core support plate such that, at 326 minutes, the plate fails. Upon plate failure, RCS pressure increases from 700 psia to 1050 psia. Continued debris relocation into the lower region of the reactor vessel leads to vessel failure, via a failed instrument penetration, at 335 minutes.

The steam generator water level response is depicted in Figure K2.4.3. Although the AFW steam-turbine-driven pump is assumed to fail upon battery depletion, rapid steam generator boil-off does not occur because the RCP seal LOCA removes sufficient heat from the RCS to lessen heat transfer from the primary to secondary-side. MAAP/PWR predicts steam generator dryout after 41.8 hours.

Containment pressure during this accident sequence is shown in Figure K2.2.4. Containment pressure slowly increases from the onset of the SBO event until vessel breach, at which time a pressure spike from 30.9 psia to 42.0 psia is predicted by MAAP/PWR. Sustained core-concrete interactions from decay heat will slowly pressurize the containment until containment failure results at 40 hours. Containment depressurization follows through a containment leak area of 0.1 ft^2.

The hydrogen production history is depicted in Figure K2.4.5. About 942 lbs of hydrogen is produced in-vessel and about 680 lbs of hydrogen is produced ex-vessel during core-concrete interactions. However, the hydrogen does not burn because the containment atmosphere is steam inerted and, without ac power, no ignition sources are present.

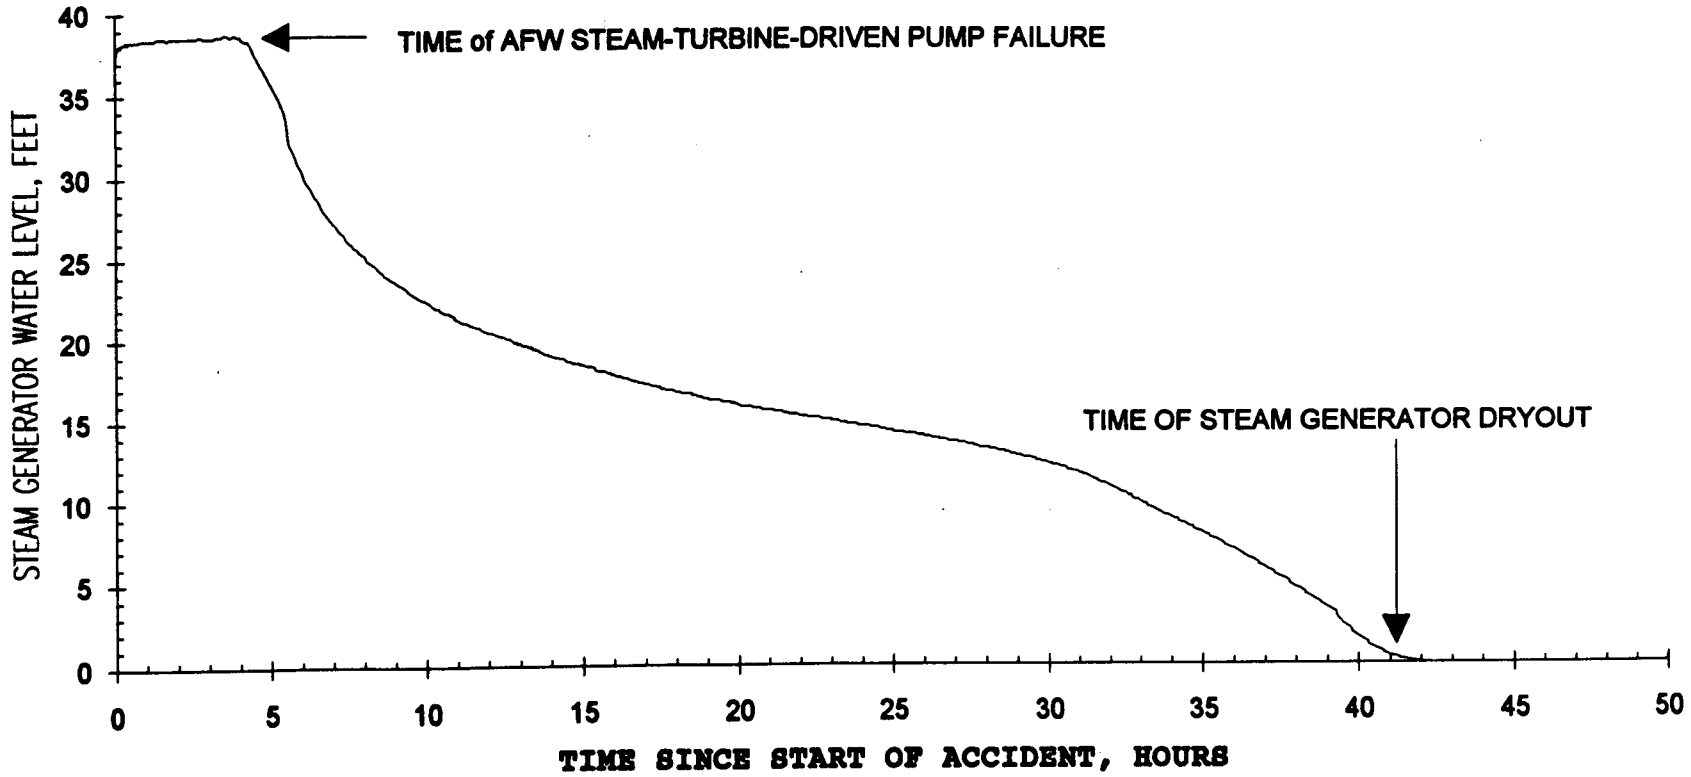

Figure K2.4.4 Accident Scenario 4 -- Containment Pressure

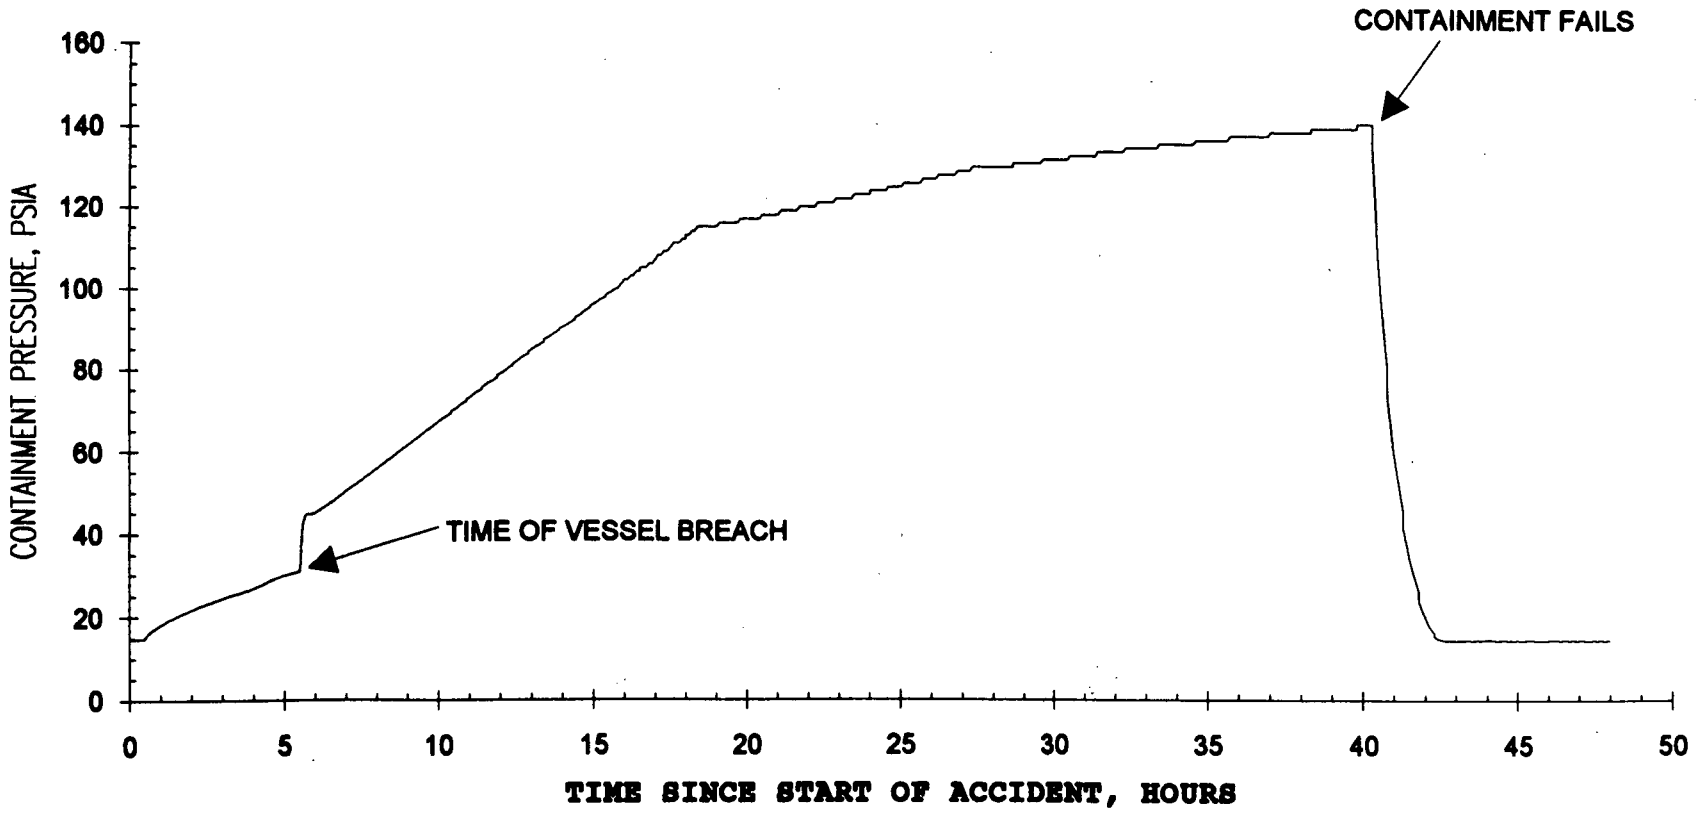

Figure K2.4.5 Accident Scenario 4 -- Hydrogen Production

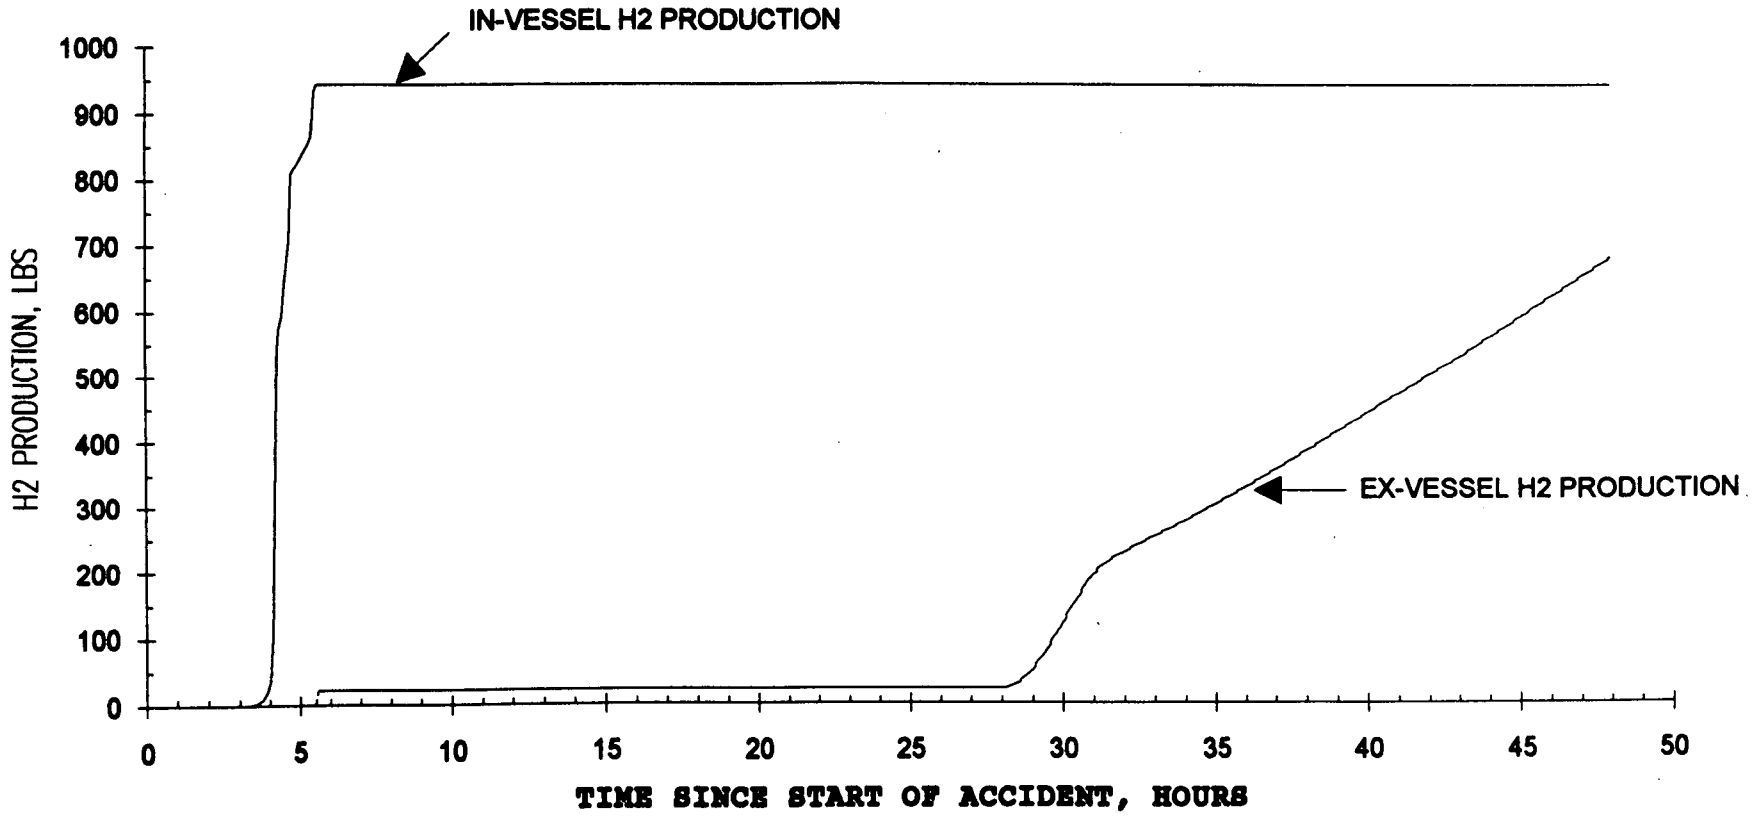
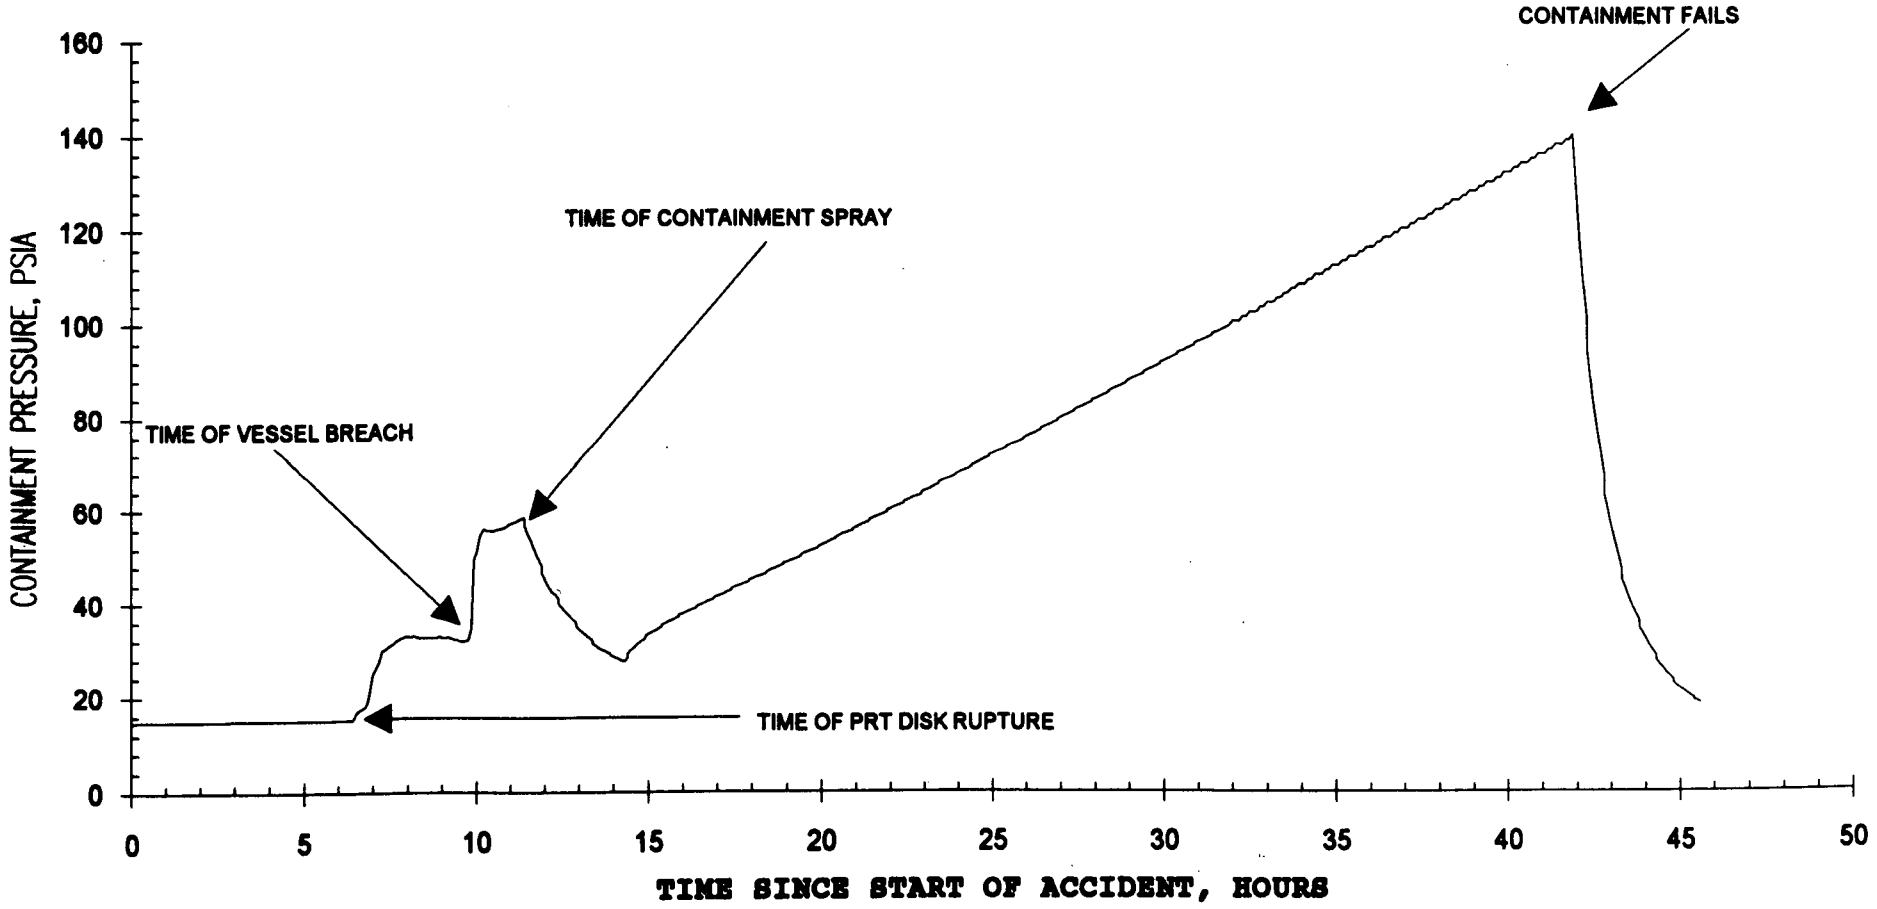


K2.5 ACCIDENT SCENARIO 5 -- LONG-TERM STATION BLACKOUT WITH AC POWER RECOVERY AFTER VESSEL BREACH

In terms of RCS and containment behavior, this accident scenario is essentially identical to Accident Scenario 1 until after vessel breach. However, 90 minutes after vessel breach (712 minutes from accident initiation), ac power is restored and containment sprays start to operate in their injection mode. Initially, the RWST provides the water inventory; after RWST depletion, containment recirculation spray is aligned through the RHR heat exchangers with the containment sumps as the source of water. Other ECC or containment heat removal systems are not restored, however.

Containment pressure during this accident sequence is shown in Figure K2.5.1. The containment pressure rises after the primary relief tank disk ruptures at 417 minutes. A second rapid containment pressure rise from 35.1 to 51.2 psia occurs after vessel breach. After restoration of ac power and actuation of the containment spray system at 712 minutes, containment pressure decreases to 27.4 psia. Following RWST depletion, containment spray recirculation is aligned by 843 minutes. However, without containment heat removal (no RHR heat exchangers or fan coolers are available), containment pressure increases until containment failure results at 43 hours. Containment depressurization through a containment leak area of 0.1 ft^2 follows.

Figure K2.5.1 Accident Scenario 5 -- Containment Pressure

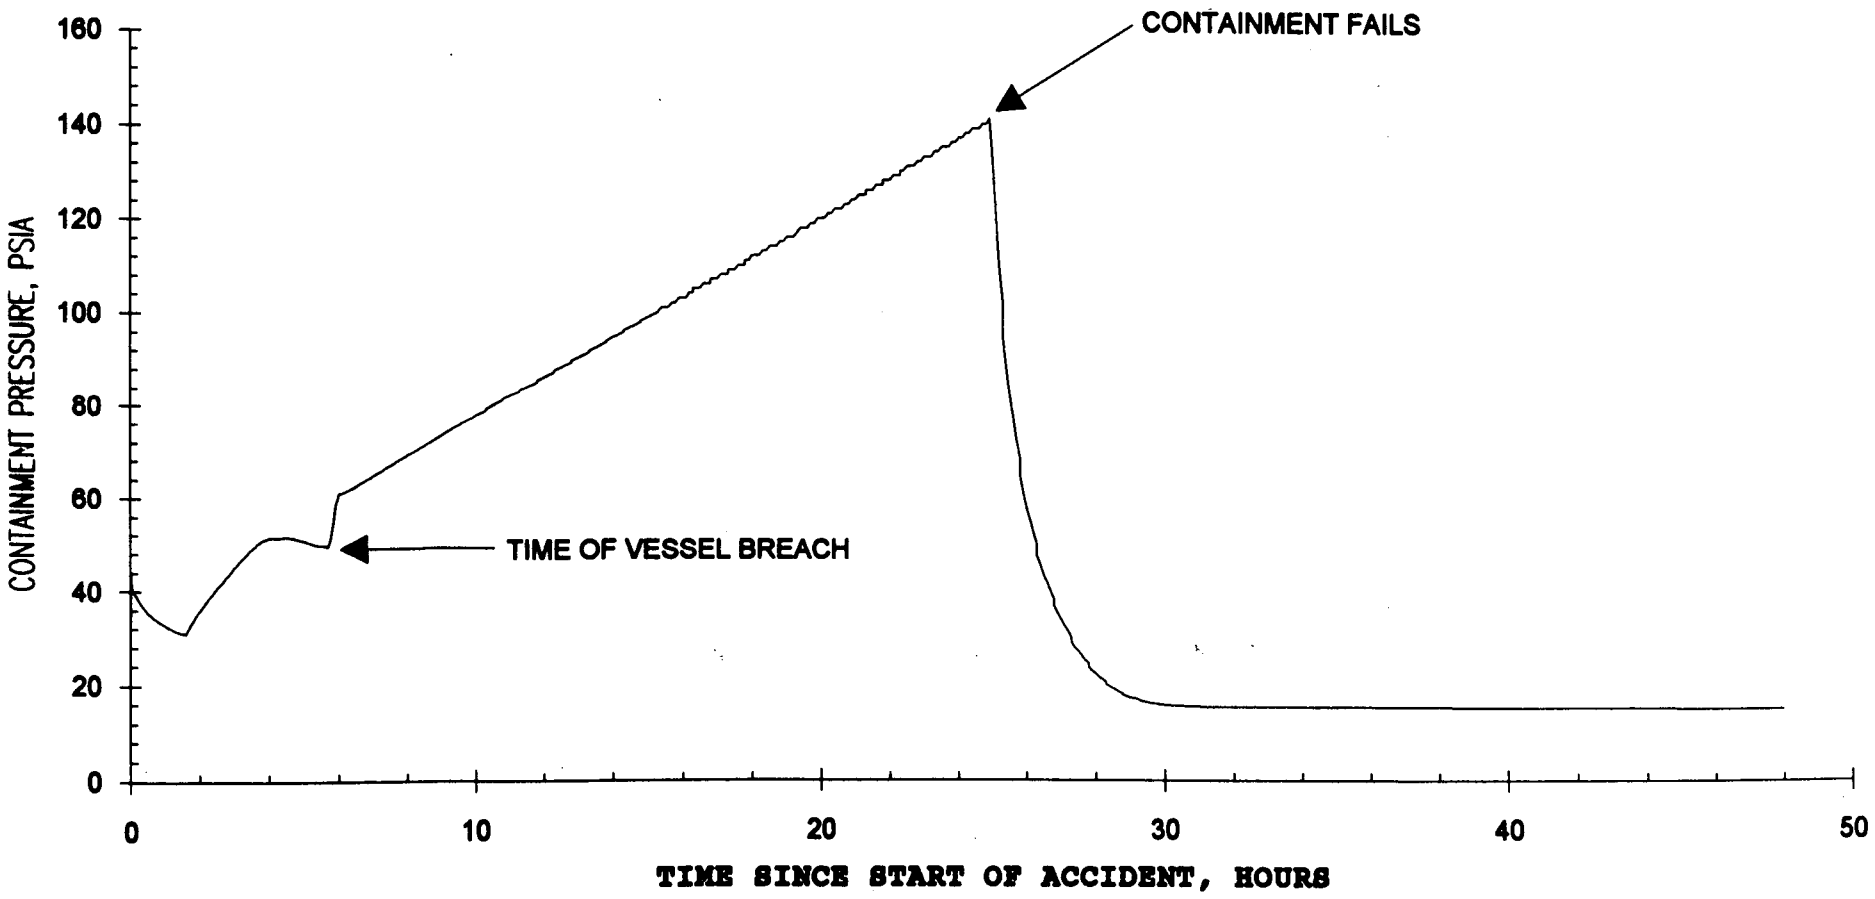


K2.6 ACCIDENT SCENARIO 6 -- LARGE LOCA WITH RECIRCULATION CORE COOLING AND CONTAINMENT HEAT REMOVAL FAILURES

In terms of early RCS and containment behavior, this accident scenario is similar to Accident Scenario 3 (Section K2.3), except that containment heat removal is unavailable. Thus, unlike Accident Scenario 3, late containment overpressurization failure occurs.

Containment pressure during this accident sequence is shown in Figure K2.6.1. Containment pressure rises to 44 psia after the initial RCS blowdown and then decreases to 31 psia, because of steam condensation on the containment concrete structures. After recirculation core cooling failure at 88 minutes, the ensuing reactor coolant boil-off and core melt generates sufficient steam and hydrogen to raise the containment pressure and cause it to fail at 25 hours. Containment depressurization through a containment leak area of 0.1 ft^2 follows.

Figure K2.6.1 Accident Scenario 6 -- Containment Pressure



K2.7 ACCIDENT SCENARIO 7 -- SMALL LOCA WITH ECCS FAILURE

A small LOCA is initiated by a reactor coolant hot leg pipe break at the 67-ft elevation. The RCS depressurizes slowly (Figure K2.7.1). Operation of the AFW system provides secondary-side cooling (Figure K2.7.2) and augments RCS depressurization. As pressurizer pressure decreases, both high- and low-head safety injection systems receive an initiation signal for core cooling. However, no injection or recirculation core cooling is available. The ensuing boil-off of reactor coolant leads to the core being uncovered at 49 minutes (Figure K2.7.3) and subsequent core damage. Because of metal-water reactions, hydrogen is produced.

Support plate failure is predicted to occur at 137 minutes because of debris relocation and accumulation on the core support plate. The lower head of the vessel fails 8 minutes later.

The containment response during this accident sequence is shown in Figure K2.7.4. Containment pressure rises slowly because of the evolution of steam and hydrogen that accompany the leakage of reactor coolant into the containment and reactor coolant boil-off in the core. At vessel breach, containment pressure is 36 psia. Following vessel breach, as the core debris reacts with water in the reactor pit, containment pressure rises to 39 psia. The resulting pressure spike will actuate the containment spray system (containment pressure >37.6 psia), which will lower containment pressure to 26 psia. After RWST depletion, containment recirculation spray is aligned, but, because the RHR heat exchangers are unavailable for decay heat removal, continued steam and hydrogen generation will raise the containment pressure until containment failure results at 29 hours. Containment depressurization through a containment leak area of 0.1 ft^2 follows.

The hydrogen production history predicted by MAAP/PWR is depicted in Figure K2.7.4. About 799 lbs of hydrogen is produced in-vessel and about 486 lbs of hydrogen is produced ex-vessel during core-concrete interactions.

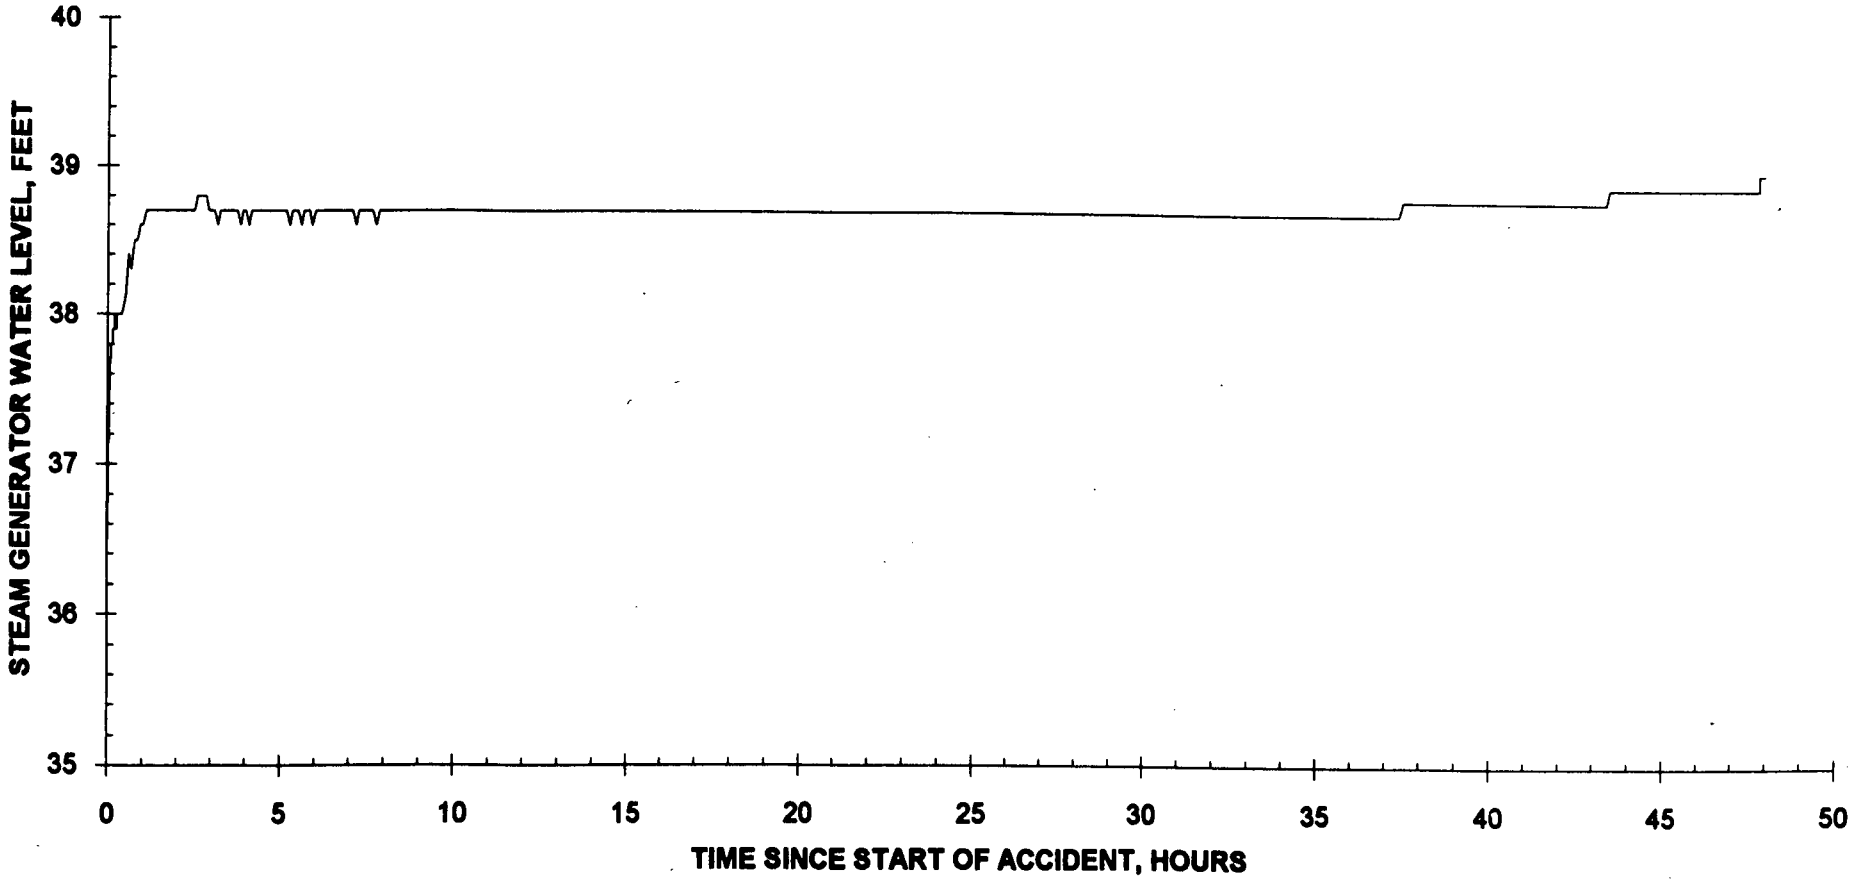

Figure K2.7.3 Accident Scenario 7 -- RCS Water Level

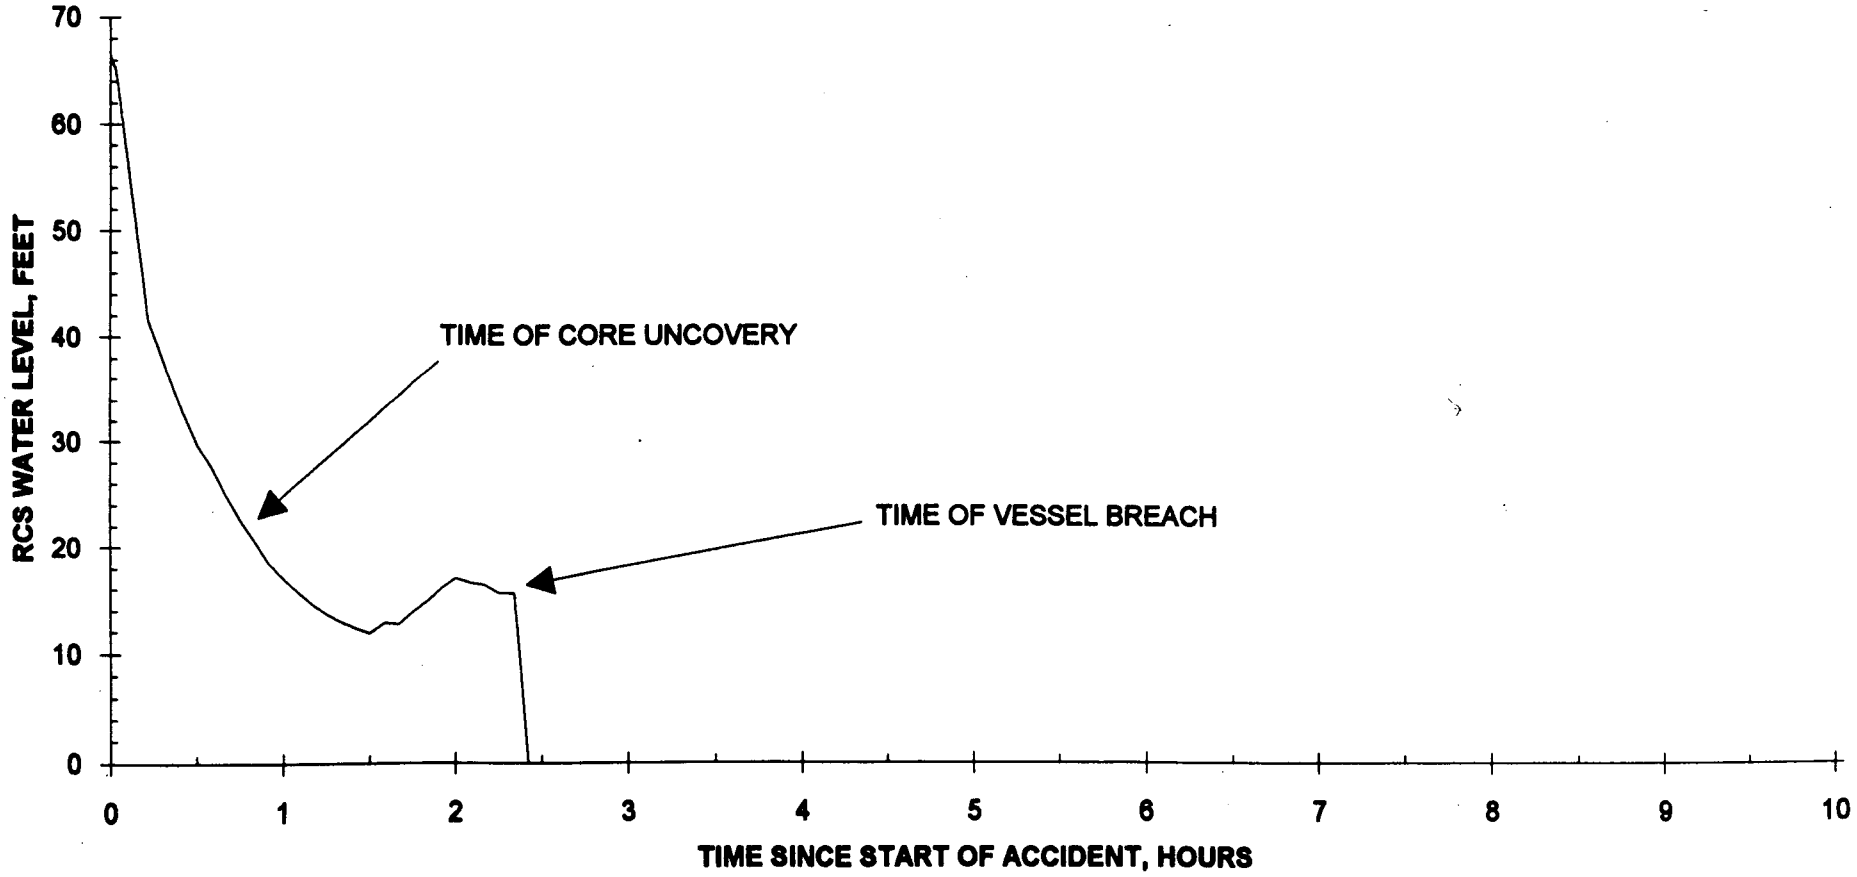

Figure K2.7.4 Accident Scenario 7 -- Containment Pressure

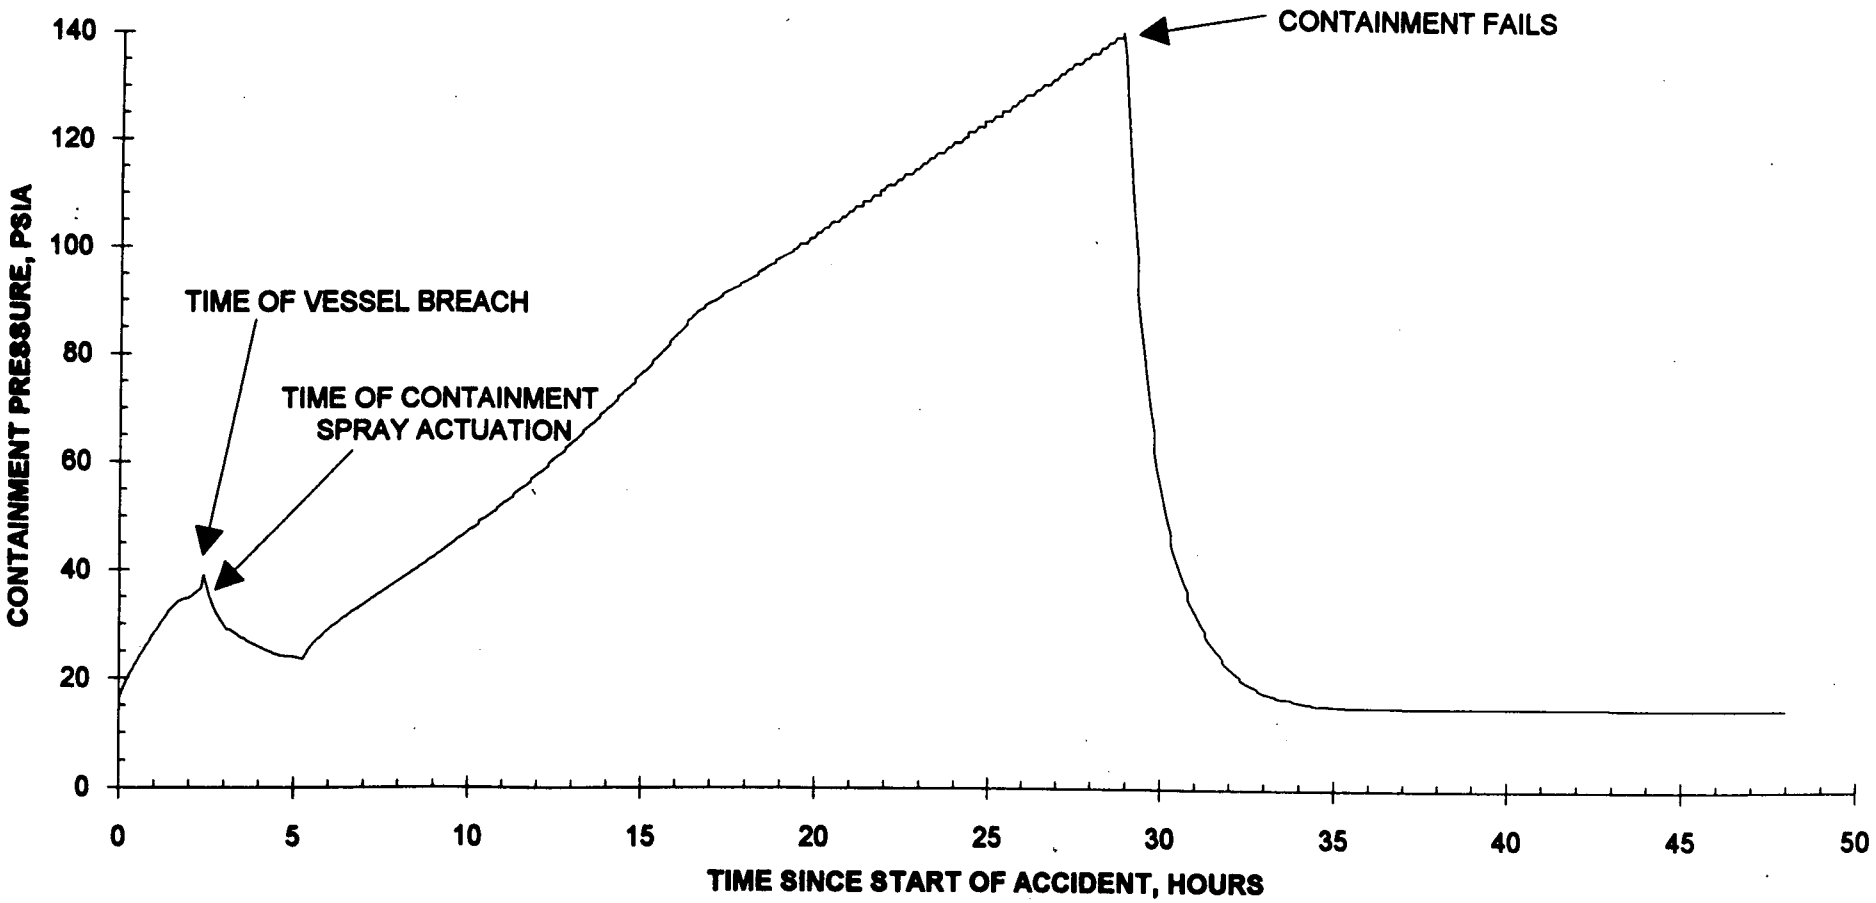

Figure K2.7.5 Accident Scenario 7 -- Hydrogen Production

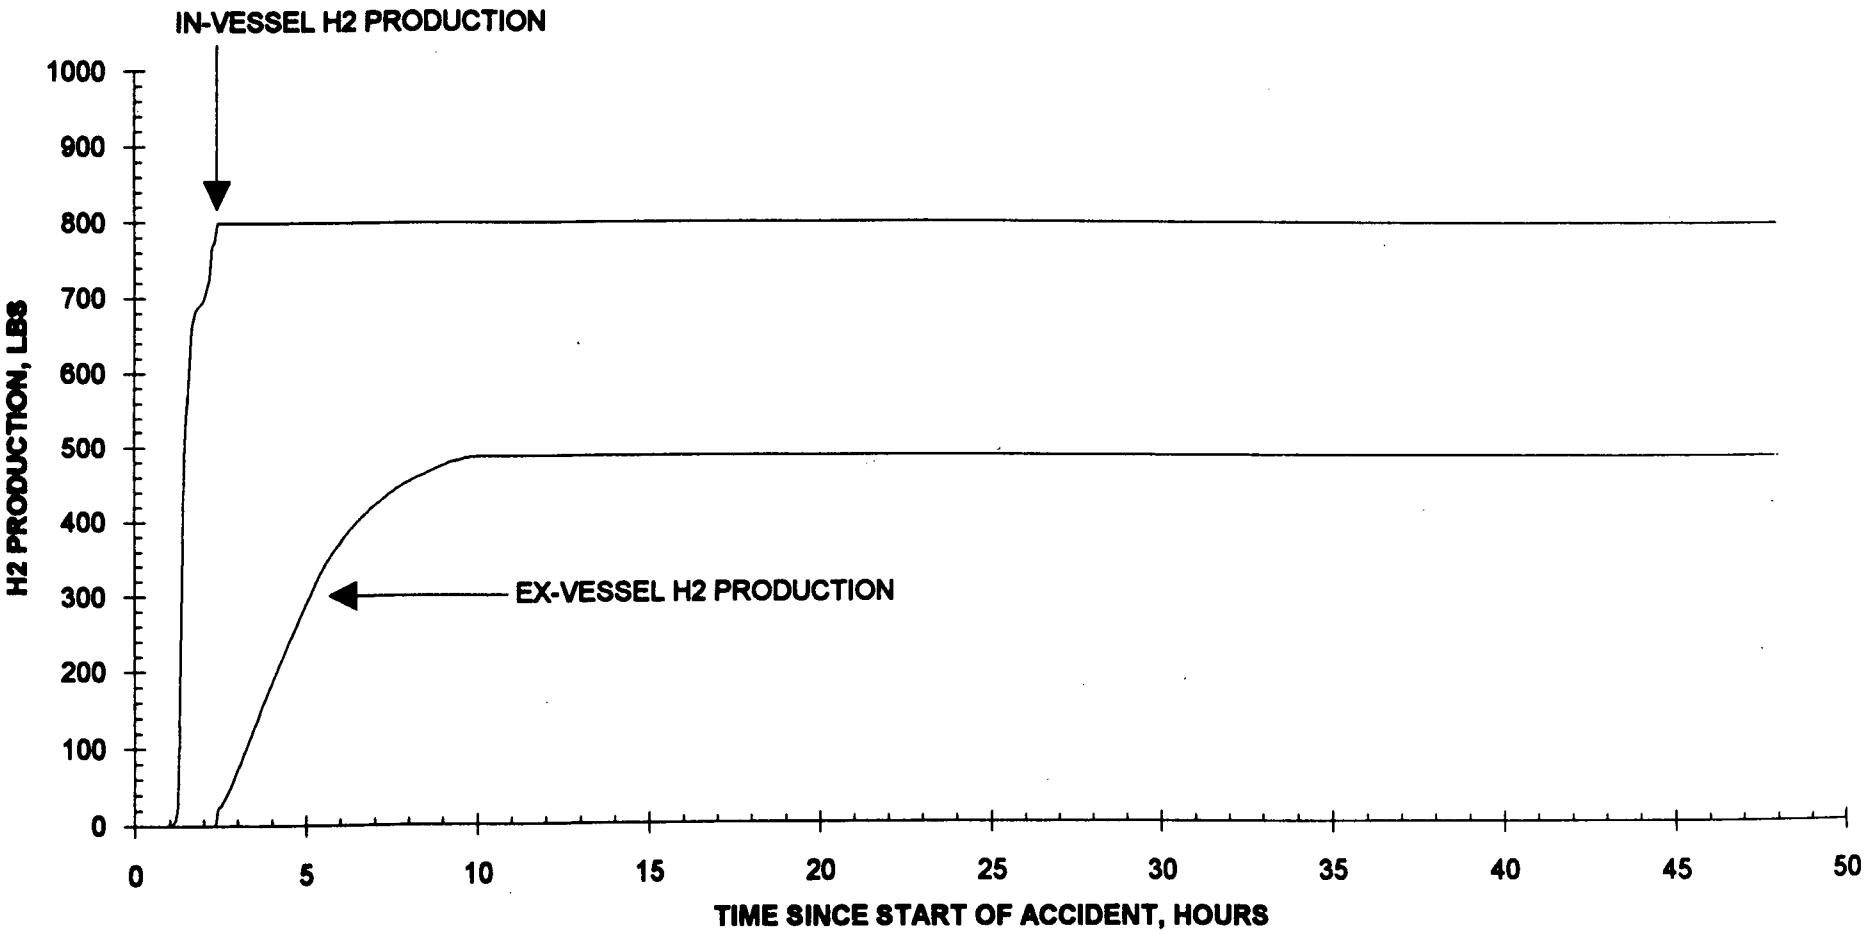

K2.8 ACCIDENT SCENARIO 8 -- LONG-TERM STATION BLACKOUT WITH AC POWER RECOVERY AFTER VESSEL BREACH AND LOWER FLAT PLATE CRITICAL HEAT FLUX

This accident scenario differs from Accident Scenario 5 only in that the coolant heat flux parameter for flat plat critical heat flux (FCHF) is reduced from 0.14 for Accident Scenario 5 to a more realistic 0.015 here. This change reduces heat loss to the coolant and so allows core-concrete interactions to occur. The occurrence of core-concrete interactions impacts fission product release. However, the overlaying water pool provided by containment spray operation will provide some decontamination.

K2.9 ACCIDENT SCENARIO 9 -- SHORT-TERM STATION BLACKOUT WITHOUT AC POWER RECOVERY AND CONTAINMENT RUPTURE FAILURE

This accident scenario is essentially identical to Accident Scenario 2 until containment failure. However, this accident scenario postulates a rupture containment failure mode with a leak area of 1.0 ft^2. The resulting containment depressurization is depicted in Figure K2.9.1.

K2.10 ACCIDENT SCENARIO 10 -- LONG-TERM STATION BLACKOUT WITH AC POWER RECOVERY AFTER VESSEL BREACH AND CONTAINMENT RUPTURE FAILURE

This accident scenario is essentially identical to Accident Scenario 5 until containment failure. However, this accident scenario postulates rupture as the containment failure mode with a leak area of 1.0 ft^2. The resulting containment depressurization is depicted in Figure K2.10.1.

Figure K2.9.1 Accident Scenario 9 -- Containment Pressure

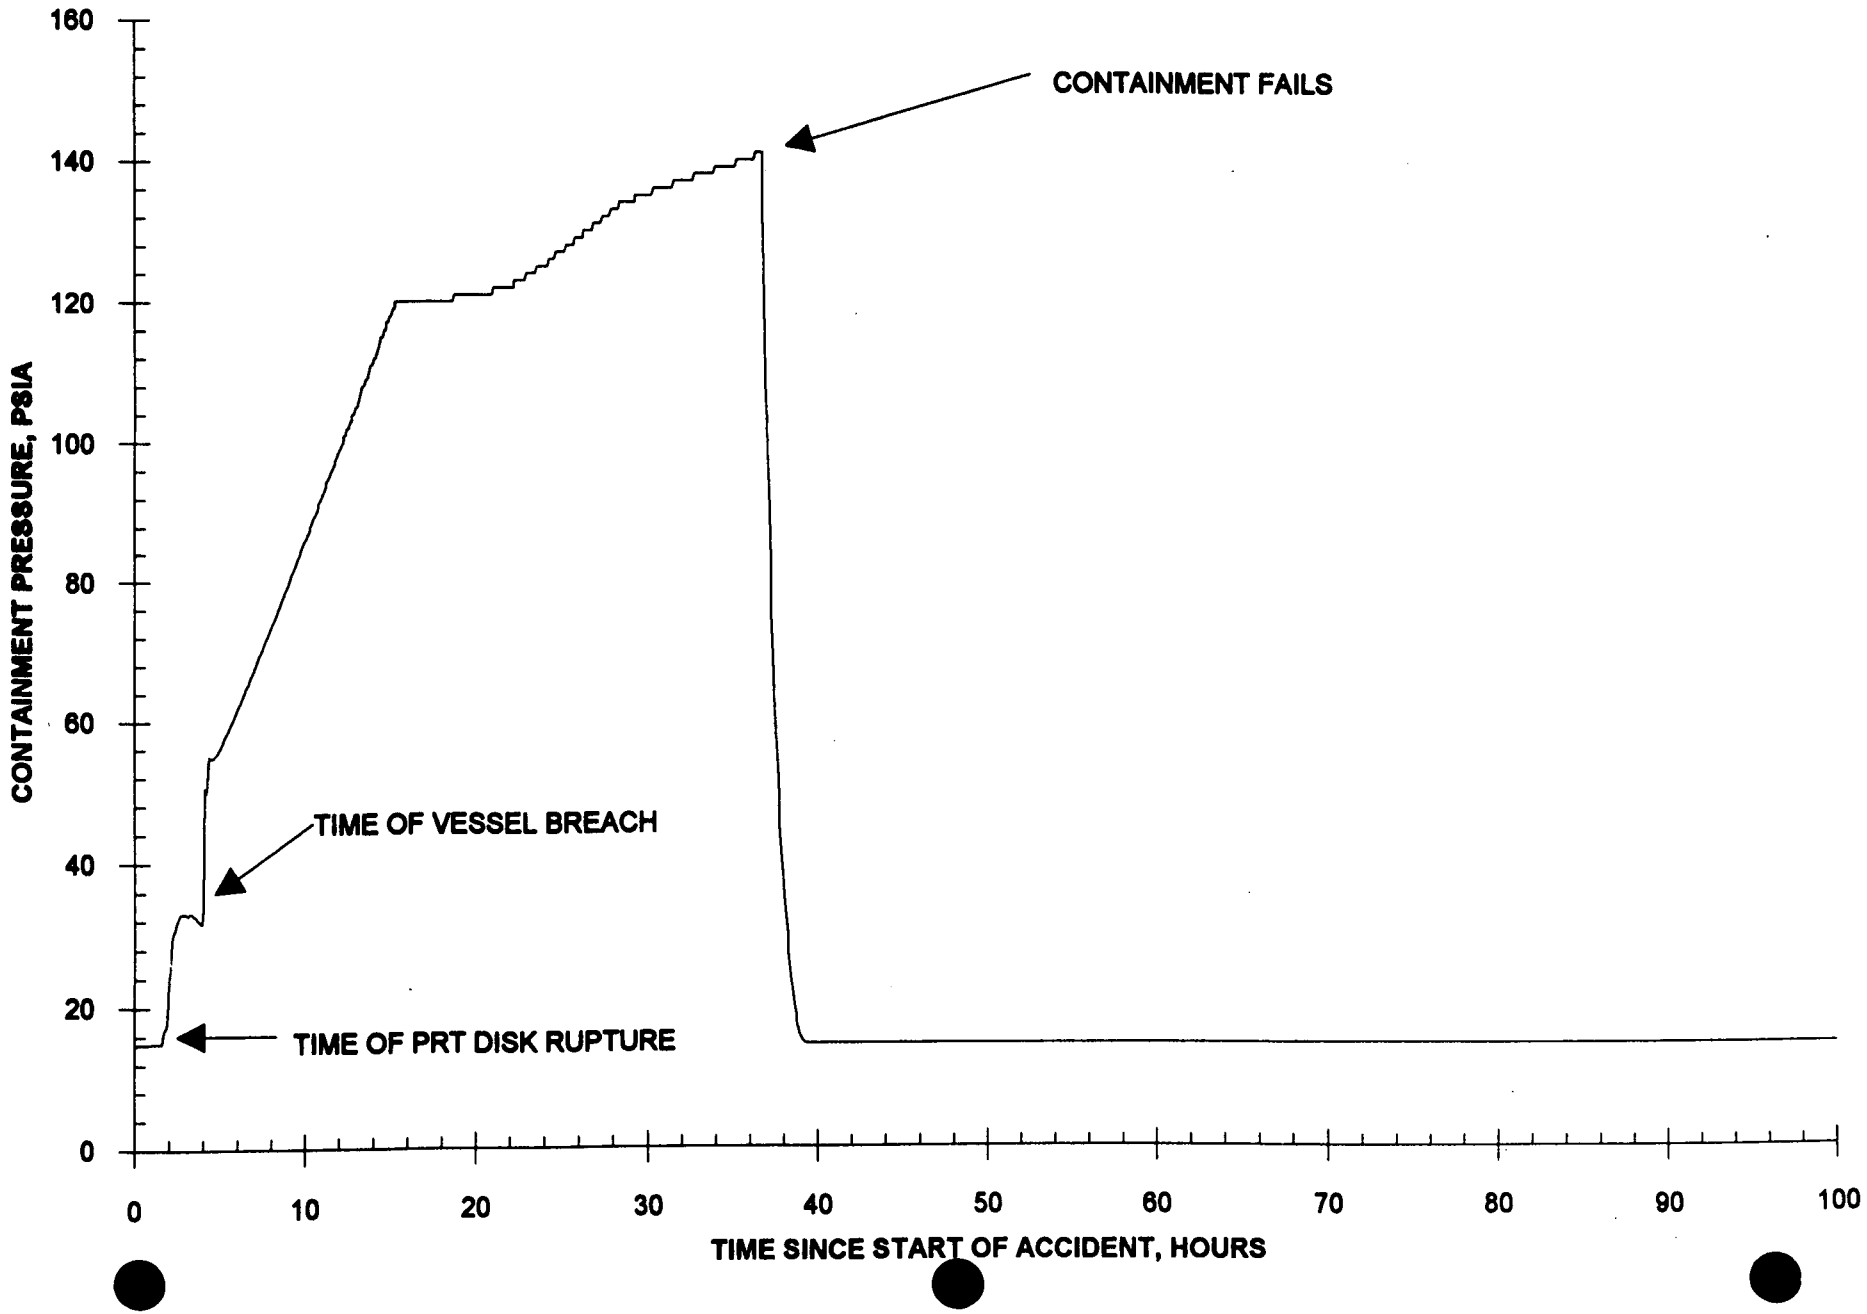

Figure K2.10.1 - Accident Scenario 10 -- Containment Pressure

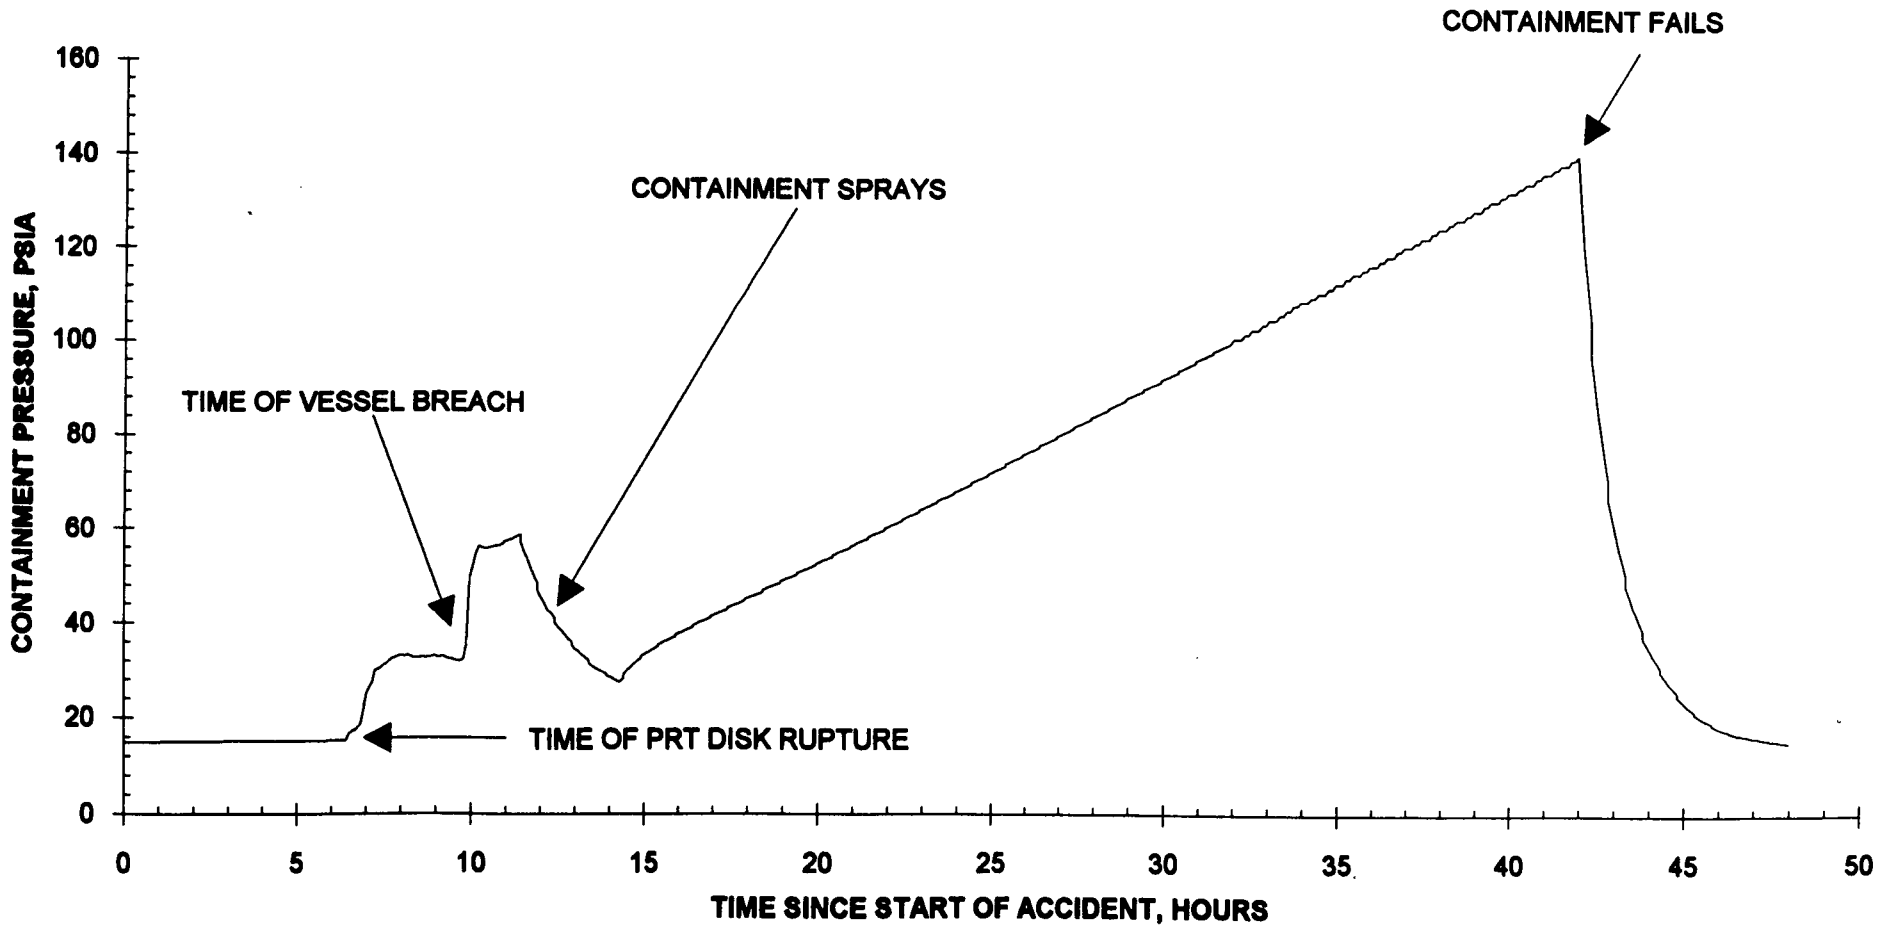

K2.11 SUMMARY OF RESULTS

The predicted response to postulated accident scenarios determined to be significant contributors to the core damage frequency is summarized in Tables K2.11.1 and K2.11.2.

APPENDIX L

CALCULATION OF SOURCE TERM PARAMETERS FROM MAAP CALCULATIONS

Table of Contents

L1	Introduction	L-1
L2	Input Data	L-2
L3	Assumptions	L-4
L4	Analysis Methods and Calculations	L-5
L5	Results and Conclusions	L-8

Section L1

INTRODUCTION

The methodology and terms used in the source term algorithm are described in Section 4.8. In this appendix, the calculation of source term parameter values from MAAP calculations is described.

Section L2

INPUT DATA

The input data for the calculation of the source term algorithm parameter values are the output files from the MAAP runs [1,2]. The specific runs are as follows:

Scenario #2

- Station blackout
- High RCS pressure at the onset of core damage
- AC power not recovered
- Sprays unavailable
- Containment heat removal unavailable.
- Leak failure of containment.

Scenario #5

- Station blackout
- Auxiliary feedwater available
- High RCS pressure at the onset of core damage
- AC power recovered before containment failure
- Sprays available.
- Containment heat removal unavailable.
- Leak failure of containment.

Scenario #6

- Large break LOCA
- Low RCS pressure at the onset of core damage
- Sprays unavailable
- Containment heat removal unavailable
- Leak failure of containment.

Scenario #7

- Small break LOCA
- Low-high RCS pressure at the onset of core damage
- Sprays available
- Containment heat removal unavailable
- Leak failure of containment
- Critical heat flux (FCHF) above the debris in the cavity

lowered to 0.015 MW/m^2.

Scenario #8

- As scenario #5 except that critical heat flux (FCHF) above the debris in the cavity lowered to 0.015 MW/m^2.

Scenario #9

- Short term station blackout
- High RCS pressure at the onset of core damage
- AC power not recovered
- Sprays unavailable
- Containment heat removal unavailable
- Containment ruptures (i.e., a break of 1 ft^2 area).

Scenario #10

- As scenario #5 except that containment fails by rupture (i.e., break of 1 ft^2).

Section L3

ASSUMPTIONS

The assumptions made in calculating the source term algorithm parameter values are:

- The release of in-vessel fission products is complete before vessel failure.
- The DF for most aerosols is not specific to fission product (i.e., the DF for tellurium is applicable to cesium, etc.).
- Late and early events are defined relative to the time of vessel failure. Containment failure or spray operation at or before vessel failure is defined as an early event. Containment failure or spray operation after vessel failure is defined as a late event. No absolute time references are used.
- Consequences of natural deposition and sprays decontamination mechanisms are very difficult to distinguish. Therefore, approximations must be made to determine the range of the values possible for a given calculation.

Section L4

ANALYSIS METHODS AND CALCULATIONS

RFs and DFs are calculated in a manner consistent with their definitions: RFs are calculated by dividing the release by the initial mass; DFs are calculated by dividing the mass entering a volume by the mass leaving that volume (e.g., DF_{VSL} is the ratio of released mass in-vessel to the mass in the containment at vessel failure). This method for calculating RFs and DFs from the MAAP output data is described for each source term algorithm parameter.

In-vessel Release Fraction (RF_{IV})

$$RF_{IV} = \frac{\text{Inv Rel}_f}{\text{Initial}_f}$$

where,

Inv Rel_f = The final isotope mass in-vessel release,

Initial_f = The initial isotope.

Decontamination Factor for the RCS (DF_{VSL})

$$DF_{VSL} = \frac{\text{Inv Rel}_v}{\text{Cont}_v}$$

where,

Inv Rel_v = The isotope mass in-vessel release at vessel failure,

Cont_v = The isotope mass in the containment at vessel failure.

Ex-vessel Release Fraction (RF_{CCI})

$$RF_{CCI} = \frac{\text{Exv Rel}_f}{\text{Initial}_f}$$

where,

Exv Rel_f = The final isotope mass ex-vessel release.

Revolatilization Release Fraction (RF_{IV})

$$RF_{REV} = \frac{Ps_v - Ps_f}{Ps_v}$$

where,

Ps_f = The final isotope mass in the primary system,

Ps_v = The isotope mass in the primary system at vessel failure.

Decontamination Factor for the Overlying Pool (DF_{POOL})

$$DF_{POOL} = \frac{\sum \text{Exv Rel}_f}{\sum \text{Exv Rel}_f - \text{Total FP in pool}}$$

where,

total FP in pool = The total fission product removal for the containment water pool.

Decontamination Factor for Containment and Sprays for Ex-vessel Releases (DF_{LCON} and DF_{LSPY})

$$DF_{LCONTANDLSPRY} = \frac{\text{Exv Rel}_f}{\text{From Ct}_f}$$

where,

from Ct_f = The final isotope mass released to the environment.

Decontamination Factor for Containment and Sprays for In-vessel Releases (DF_{ECON} and DF_{ESPY})

If no ex-vessel release has occurred:

$$DF_{ECONTANDESPRY} = \frac{Inv\ Rel_f}{From\ Ct_f}$$

If ex-vessel release has occurred:

[1] Calculate the revolatilization release to the environment (R_{REV}).

[2] Calculate the ex-vessel release to the environment (R_{cci}).

[3] Calculate the in-vessel release to the environment as follows:

$$R_{IV} = \frac{From\ Ct_f}{Initial_f} - R_{REV} - R_{CCI}$$

[4] Calculate the combined DF due to sprays and the containment as follows:

$$DF_{ECONTANDESPY} = \frac{RF_{IV}}{DF_{VSL} * R_{IV}}$$

Section L5

RESULTS AND CONCLUSIONS

For each MAAP run, a description of the accident scenario, a summary of the key events, and an excerpt of results from the MAAP output are presented. Following this, the calculations of the RFs and DFs for each MAAP run are presented. All RFs were calculated for the fission product species represented in the CET. The DFs were calculated using several fission product species, but predominately CsI and CsOH. The values of the source term algorithm parameters, estimated for each accident scenario modeled using MAAP, were used to quantify the CET.

Results:

NG $\frac{336.4988}{336.5000} = 1$ CsI $\frac{26.91473}{29.82595} = 0.902$ TeO2 $\frac{0}{20.9033} = 0$

CsOH $\frac{177.0525}{196.2022} = 0.902$ SRO $\frac{0.27401}{71.18863} = 0.004$

DF_{vsl}

After Vessel Failure:

CsI $\frac{26.91473}{2.50095} = 10.762$ CsOH $\frac{177.0525}{13.67131} = 12.951$ SRO $\frac{0.2741}{0.02446} = 11.206$

RF_{mcci}

Results:

CsI $\frac{1.71286}{(29.82595 - 26.91473)} = 0.588$ TeO2 $\frac{20.899}{(20.9033 - 0.0)} = 1$

CsOH $\frac{18.37296}{(196.2022 - 177.0525)} = 0.959$ SRO $\frac{0.01134}{(71.1886 - 0.27401)} = 1.599 \cdot 10^{-4}$

RF_{rev}

From final results and results immediately after vessel failure:

CsI $\frac{24.41388 - 23.96885}{24.41388} = 0.018$ CsOH $\frac{163.3813 - 158.3557}{163.3813} = 0.031$

DF_{pool}

Results:

No fission product removal due to overlying pool.

$DF_{Lcont\ and\ Lspry}$

Finally:

No late sprays, so spray DF = 1.0

TE02 $\frac{20.89902}{4.3079} = 4.851$ UO2 $\frac{0.07480}{0.0122} = 6.131$

DF_{econt} and espry

Assume DF_{Icont} applies to CsI and CsOH

No early sprays so spray DF = 1.0

CSI

$$Rrev := \left[0.902 \cdot \left(1 - \frac{1}{10.762}\right)\right] \cdot \frac{0.018}{(4.851 \cdot 1 \cdot 1)} \qquad Rrev = 0.003$$

$$Rmcci := (1 - 0.902) \cdot \frac{0.588}{(4.851 \cdot 1 \cdot 1)} \qquad Rmcci = 0.012$$

$$Riv := \frac{0.9195}{29.82595} - 0.003 - 0.012 \qquad Riv = 0.016$$

$$DFiv := \frac{0.902}{0.016} \qquad DFiv = 56.375$$

$$DFecont := \frac{56.375}{(10.762 \cdot 1)} \qquad DFecont = 5.238$$

CSOH

$$Rrev := \left[0.902 \cdot \left(1 - \frac{1}{12.951}\right)\right] \cdot \frac{0.031}{(4.851 \cdot 1 \cdot 1)} \qquad Rrev = 0.005$$

$$Rmcci := (1 - 0.902) \cdot \frac{0.959}{(4.851 \cdot 1 \cdot 1)} \qquad Rmcci = 0.019$$

$$Riv := \frac{8.77516}{196.2022} - 0.005 - 0.019 \qquad Riv = 0.021$$

$$DFiv := \frac{0.902}{0.021} \qquad DFiv = 42.952$$

$$DFecont := \frac{42.952}{(12.951 \cdot 1)} \qquad DFecont = 3.317$$

Caculation of RF's and DF's for IP3 MAAP Runs
Accident Progression Scenario # 5

Description of Sequence

- Long Term Station Blackout event
- High RCS pressureat the onset of core damage
- AC power is not recovered
- Containment sprays are available late
- Containment heat removal is not available

Key Results of Calculation

- Aux feedwater off 240 min
- Core uncovery 433 min
- Support plate failure 585 min
- Reactor vessel failure 593 min
- Sprays on 608 min
- Containment failure (Leak) 42 hrs

TOTAL FP REMOVAL (KG) DUE TO DECONTAMINATION IN CONTMT WATER POOLS IS 0.0000E+00
0SUMMARY OF FISSION PRODUCT REMOVAL IN ICE CONDENSER:
TOTAL FP REMOVAL DUE TO GRAV. SET. IN ICE COND. IS 0.0000E+00 KG; REMOVAL DUE TO CONDENSATION IS 0.0000E+00 KG
TOTAL FP REMOVAL DUE TO IMPACTION IN ICE COND. IS 0.0000E+00 KG

Caculation of RFs and DFs

RF_{iv}

Results:

NG $\frac{336.499}{336.5000} = 1$ CsI $\frac{25.26259}{29.82595} = 0.847$ TeO2 $\frac{0}{20.9033} = 0$

CsOH $\frac{166.1832}{196.2022} = 0.847$ SRO $\frac{0.28079}{71.18863} = 0.004$

DF_{vsl}

After Vessel Failure:

CsI $\frac{25.26259}{1.60452} = 15.745$ CsOH $\frac{166.1832}{9.59516} = 17.319$ SRO $\frac{0.28079}{0.04149} = 6.768$

RF_{mcci}

Results:

CsI $\frac{0.0}{(29.82595 - 25.26259)} = 0$ TeO2 $\frac{0.0}{(20.9033 - 0.0)} = 0$

CsOH $\frac{0.0}{(196.2022 - 166.1832)} = 0$ SRO $\frac{0.0}{(71.1886 - 0.28079)} = 0$

RF_{rev}

From final results and results immediately after vessel failure:

CsI $\frac{23.65815 - 23.52735}{23.65815} = 0.006$ CsOH $\frac{156.5887 - 155.512}{156.5887} = 0.007$

DF_{pool}

No fission product removal due to overlying pool.

$DF_{Lcont\ and\ Lspry}$

Finally:

Late CCI releases, therefore late DFs cannot be calculated.

DF_{econt} and espry

Finally:

The values represent the multiplication of DF_{econt} and DF_{espry}

CsI $\frac{25.26259 - 23.52735}{0.00016} = 1.085 \cdot 10^4$ CsOH $\frac{166.1832 - 155.512}{0.00253} = 4.218 \cdot 10^3$

To seperate out the DFs the value of one of the DFs must be assumed. Based on the results from scenario #2, the value for DF_{econt} for a late containment failure with a leak is approximately 5 but may be as high as 100.

Therefore;

CsI DFespry $\frac{1.085 \cdot 10^4}{5} = 2.17 \cdot 10^3$ to $\frac{1.085 \cdot 10^4}{100} = 108.5$

CsOH DEespry $\frac{4.218 \cdot 10^3}{5} = 843.6$ to $\frac{4.218 \cdot 10^3}{100} = 42.18$

Calculation of RF's and DF's for IP3 MAAP Runs
Accident Progression Scenario # 6

Description of Sequence

- Large LOCA event
- Low RCS pressure at the onset of core damage
- Containment sprays are unavailable
- Containment heat removal is unavailable

Key Results of Calculation

- Reactor vessel failure 5.5 hrs
- Containment failure 25 hrs

Caculation of RF's and DF's

RF_{iv}

Results:

NG $\frac{336.5007}{336.5000} = 1$ CsI $\frac{29.53941}{29.82595} = 0.99$ TeO2 $\frac{0}{20.9033} = 0$

CsOH $\frac{194.3177}{196.2022} = 0.99$ SRO $\frac{1.02664}{71.18863} = 0.014$

DF_{vsl}

After Vessel Failure:

CsI $\frac{29.53941}{22.1155} = 1.336$ CsOH $\frac{194.3177}{146.0022} = 1.331$ SRO $\frac{1.02664}{0.68549} = 1.498$

RF_{mcci}

Results:

CsI $\frac{0.01592}{(29.82595 - 29.53941)} = 0.056$ TeO2 $\frac{0.0}{(20.9033 - 0.0)} = 0$

CsOH $\frac{0.37766}{(196.2022 - 194.3177)} = 0.2$ SRO $\frac{0.03145}{(71.1886 - 1.02664)} = 4.482 \cdot 10^{-4}$

RF_{rev}

From final results and results after vessel failure:

CsI $\frac{7.4394 - 5.81199}{7.4494} = 0.218$ CsOH $\frac{48.69029 - 35.09732}{48.69029} = 0.279$

DF_{pool}

Final fission product mass released ex-vessel:

$23.144 + .016 + 0.031 + 0.378 + 0.014 + 0.023 + 0.079 + 1.919 + 0.170 = 25.774$

$DFpool := \frac{25.774}{(25.774 - 25.769)}$ $DFpool = 5.155 \cdot 10^{3}$

DF_{Lcont} and Lspry

From final results:

No late sprays so spray DF = 1.0

Total Late DF based on Te2 $\frac{1.91889}{0.00019} = 1.01 \cdot 10^{4}$

DFlcont $\frac{1.01 \cdot 10^{4}}{\left[1 \cdot \left(5.155 \cdot 10^{3}\right)\right]} = 1.959$

DF_{econt} and espry

Assume DF_{Icont} applies to CsI and CsOH

No early sprays so spray DF = 1.0

CSI $Rrev := \left[0.99 \cdot \left(1 - \frac{1}{1.336}\right)\right] \cdot \frac{0.218}{(1.959 \cdot 1 \cdot 1)}$ $Rrev = 0.028$

$Rmcci := (1 - 0.99) \cdot \frac{0.056}{(1.959 \cdot 5155 \cdot 1)}$ $Rmcci = 5.545 \cdot 10^{-8}$

$Riv := \frac{1.41741}{29.82602} - 0.028 - 0.0$ $Riv = 0.02$

$DFiv := \frac{0.99}{0.02}$ $DFiv = 49.5$

$DFecont := \frac{49.5}{(1.336 \cdot 1)}$ $DFecont = 37.051$

CSOH $Rrev := \left[0.99 \cdot \left(1 - \frac{1}{1.331}\right)\right] \cdot \frac{0.279}{(1.959 \cdot 1 \cdot 1)}$ $Rrev = 0.035$

$Rmcci := (1 - 0.99) \cdot \frac{0.2}{(1.959 \cdot 5155 \cdot 1)}$ $Rmcci = 1.98 \cdot 10^{-7}$

$Riv := \frac{11.6807}{196.2022} - 0.035 - 0.0$ $Riv = 0.025$

$DFiv := \frac{0.99}{0.025}$ $DFiv = 39.6$

$DFecont := \frac{39.6}{(1.331 \cdot 1)}$ $DFecont = 29.752$

Caculation of RF's and DF's for IP3 MAAP Runs
Accident Progression Scenario # 7

Description of Sequence

- Small LOCA event
- Low-high RCS pressure at the onset of core damage
- Containment sprays are available
- Containment heat removal is unavailable
- CHF of overlying pool reduced to 0.015 MW/m2

Key Results of Calculation

- Reactor vessel failure 145 min
- Containment failure 28 hrs

Caculation of RF's and DF's

RF_{iv}

From final results:

NG $\frac{336.4998}{336.5000} = 1$ CsI $\frac{28.4098}{29.82595} = 0.953$ TeO2 $\frac{0}{20.9033} = 0$

CsOH $\frac{186.8864}{196.2022} = 0.953$ SRO $\frac{0.58754}{71.18863} = 0.008$

DF_{vsl}

After Vessel Failure:

CsI $\frac{28.4098}{19.07114} = 1.49$ CsOH $\frac{186.8864}{127.52390} = 1.466$ SRO $\frac{0.58754}{0.50367} = 1.167$

RF_{mcci}

From final results:

CsI $\frac{1.40412}{(29.82595 - 28.4098)} = 0.992$ Te2 $\frac{27.93127}{(31.04062 - 0.0)} = 0.9$

CsOH $\frac{9.31091}{(196.2022 - 186.8864)} = 0.999$ SRO $\frac{1.07131}{(71.1886 - 0.58754)} = 0.015$

RF_{rev}

From final results and results after vessel failure:

CsI $\frac{9.51957 - 9.23803}{9.51957} = 0.03$ CsOH $\frac{63.1816 - 61.07836}{63.1816} = 0.033$

DF_{pool}

Total final fission product mass released ex-vessel:

$1661.696 + 1.404 + 1.071 + 9.31 + 0.517 + 0.871 + 3.879 + 013 + 27.931 + 6.463 = 1.726 \cdot 10^3$

$DFpool := \frac{1.726 \cdot 10^3}{\left(1.726 \cdot 10^3 - 1.712 \cdot 10^3\right)}$ $DFpool = 123.286$

$DF_{Lcont\ and\ Lspry}$

From final results:

Total Late DF based on Te2 $\frac{27.93127}{0.00025} = 1.117 \cdot 10^5$

$DF_{lcont\text{-}lspry} = \frac{1.117 \cdot 10^5}{((123.286))} = 906.023$

The value for the late DF of the containment varies between 5 and 100

Therefore;

DFspry $\frac{906.023}{5} = 181.205$ to $\frac{906.023}{100} = 9.06$

DF_{econt} and espry

Assume DF_{Icont} applies to CsI and CsOH

CSI $\quad Rrev := \left[0.953 \cdot \left(1 - \frac{1}{1.49}\right)\right] \cdot \frac{0.03}{(906.023)} \qquad Rrev = 1.038 \cdot 10^{-5}$

$$Rmcci := (1 - 0.953) \cdot \frac{0.992}{\left(1.117 \cdot 10^{5}\right)} \qquad Rmcci = 4.174 \cdot 10^{-7}$$

$$Riv := \frac{0.00043}{29.82602} - 1.038 \cdot 10^{-5} - 4.174 \cdot 10^{-7} \qquad Riv = 3.62 \cdot 10^{-6}$$

$$DFiv := \frac{0.953}{3.62 \cdot 10^{-6}} \qquad DFiv = 2.633 \cdot 10^{5}$$

$$DFecont\_espy := \frac{2.633 \cdot 10^{5}}{(1.49 \cdot 1)} \qquad DFecont\_espy = 1.767 \cdot 10^{5}$$

The value for the early DF of the containment varies between 5 and 100

Therefore;

DFspry $\quad \frac{1.767 \cdot 10^{5}}{5} = 3.534 \cdot 10^{4}$ to $\frac{1.767 \cdot 10^{5}}{100} = 1.767 \cdot 10^{3}$

The higher value for DF_{Icont} is more probable, suggesting that the DFspry has a value near 1000.

Caculation of RF's and DF's for IP3 MAAP Runs
Accident Progression Scenario # 8

Description of Sequence

- Long Term Station Blackout event
- High RCS pressureat the onset of core damage
- AC power is not recovered
- Containment sprays are available late
- Containment heat removal is unavailable
- CHF reduced to 0.015 MW/m2

Key Results of Calculation

- Aux feedwater off 240 min
- Core uncovery 434 min
- Reactor vessel failure 598 min
- Sprays on 688 min
- Containment failure 42 hrs

TOTAL FP REMOVAL DUE TO GRAV. SET. IN ICE COND. IS 0.0000E+00 KG; REMOVAL DUE TO CONDENSATION IS 0.0000E+00 KG
TOTAL FP REMOVAL DUE TO IMPACTION IN ICE COND. IS 0.0000E+00 KG

Caculation of RF's and DF's

RF_{iv}

From final results:

NG $\frac{336.499}{336.5000} = 1$ CsI $\frac{25.26717}{29.82595} = 0.847$ TeO2 $\frac{0}{20.9033} = 0$

CsOH $\frac{166.21280}{196.2022} = 0.847$ SRO $\frac{0.28313}{71.18863} = 0.004$

DF_{vsl}

After Vessel Failure:

CsI $\frac{25.26717}{1.71057} = 14.771$ CsOH $\frac{166.2128}{9.4920} = 17.511$ SRO $\frac{0.28313}{0.03227} = 8.774$.

RF_{mcci}

From final results:

CsI $\frac{0.06612}{(29.82595 - 25.26717)} = 0.015$ Te2 $\frac{0.51093}{(31.0406 - 0.0)} = 0.016$

CsOH $\frac{1.53779}{(196.2022 - 166.2128)} = 0.051$ SRO $\frac{0.00258}{(71.1886 - 0.28313)} = 3.639 \cdot 10^{-5}$

RF_{rev}

From final results and results after vessel failure:

CsI $\frac{23.5567 - 23.3272}{23.5567} = 0.01$ CsOH $\frac{156.722 - 155.1219}{156.722} = 0.01$

DF_{pool}

Total final fission product mass released ex-vessel:

$32.658 + 0.066 + 0.003 + 1.538 + 0.002 + 0.001 + 0.511 = 34.779$

$DFpool := \frac{34.779}{(34.779 - 33.353)}$ $DFpool = 24.389$

$DF_{lcont\ and\ lspry}$

From final results:

Total Late DF based on Te2 $\frac{0.51093}{0.00019} = 2.689 \cdot 10^{3}$

$DF_{lcont\text{-}lspry} = \frac{2.689 \cdot 10^{3}}{24.389} = 110.255$

The value for the late DF of the containment varies between 5 and 100
Therefore;

DFspry $\frac{110.255}{5} = 22.051$ to $\frac{110.255}{100} = 1.103$

DF_{econt} and espry

Assume DF_{Icont} applies to CsI and CsOH

CSI $Rrev := \left[0.847 \cdot \left(1 - \frac{1}{14.771}\right)\right] \cdot \frac{0.01}{(110.255)}$ $Rrev = 7.162 \cdot 10^{-5}$

$Rmcci := (1 - 0.847) \cdot \frac{0.015}{(110.255 \cdot 24.389)}$ $Rmcci = 8.535 \cdot 10^{-7}$

$Riv := \frac{0.00015}{29.82595} - 7.162 \cdot 10^{-5} - 8.535 \cdot 10^{-7}$ $Riv = -6.744 \cdot 10^{-5}$

A negative value is non-physical, therefore it must be assumed that using the late DF of TE2 for CsI was a bad approximation.

Caculation of RF's and DF's for IP3 MAAP Runs
Accident Progression Scenario # 9

Description of Sequence

- Station Blackout event
- High RCS pressureat the onset of core damage
- AC power is not recovered
- Containment sprays are unavailable
- Containment heat removal is unavailable
- Containment failure size increase to 1 ft2 (i.e rupture)

Key Results of Calculation (Assumed the same as scenario #2)

- Steam generators dryout 103 min
- Core uncovery 134 min
- Support plate failure 241 min
- Reactor vessel failure 249 min
- Containment failure 36 hrs

$DFecont := \frac{43.429}{(12.486 \cdot 1)}$ $DFecont = 3.478$

Caculation of RF's and DF's for IP3 MAAP Runs
Accident Progression Scenario # 10

Description of Sequence

- Long Term Station Blackout event
- High RCS pressureat the onset of core damage
- AC power is not recovered
- Containment sprays are available late
- Containment heat removal is unavailable
- Containment failure size = 1 ft2 (rupture)

Key Results of Calculation

- Aux feedwater off	240 min
- Core uncovery	433 min
- Reactor vessel failure	593 min
- Sprays on	683 min
- Containment failure	42 hrs

DF_{vsl}

After Vessel Failure:

CsI $\frac{27.6371}{2.858828} = 9.667$ CsOH $\frac{181.8042}{12.71012} = 14.304$ SRO $\frac{0.36158}{0.02343} = 15.432$

RF_{mcci}

From final results:

CsI $\frac{0.0}{(29.82595 - 25.26259)} = 0$ TeO2 $\frac{0.0}{(20.9033 - 0.0)} = 0$

CsOH $\frac{0.0}{(196.2022 - 166.1832)} = 0$ SRO $\frac{0.0}{(71.1886 - 0.28079)} = 0$

RF_{rev}

From final results and results after vessel failure:

CsI $\frac{24.77893 - 24.49337}{24.77893} = 0.012$ CsOH $\frac{169.0938 - 166.9665}{169.0938} = 0.013$

DF_{pool}

No fission product removal due to overlying pool.

$DF_{lcont\ and\ lspry}$

From final results:

No late MCCI releases, therefore late DFs cannot be calculated.

DF_{econt} and espry

From final results:

The values represent the multiplication of DF_{econt} and DF_{espry}

CsI $\frac{27.63712 - 24.49337}{0.00004} = 7.859 \cdot 10^4$ CsOH $\frac{181.8042 - 166.9665}{0.00043} = 3.451 \cdot 10^4$

To seperate out the DFs the value of one of the DFs must be assumed. Based on the results from scenario #2 the value for DF_{econt} for a late containment failure with a leak is approximately 5 but may be as high as 100.

Therefore;

CsI DFespry $\frac{7.859 \cdot 10^4}{5} = 1.572 \cdot 10^4$ to $\frac{7.859 \cdot 10^4}{100} = 785.9$

CsOH DEespry $\frac{3.451 \cdot 10^4}{5} = 6.902 \cdot 10^3$ to $\frac{3.451 \cdot 10^4}{100} = 345.1$

Section M1

INTRODUCTION

A major objective of an IPE is the quantitative evaluation of containment performance by estimating fission product source terms for a wide range of postulated severe accidents. Because the stochastic behavior of system performance in response to postulated accident initiating events and numerous uncertainties related to severe accident behavior require a probabilistic treatment, a probabilistic logic model for containment performance assessment was used--a containment event tree (CET).

The CET is an event tree with top events (or questions) that represent the principal factors influencing the magnitude and timing of fission product release to the environment. These questions are rather complex and require an elaborate supporting logic structure to consider the wide spectrum of factors that can contribute to their answers. The CET includes two types of top events:

- Logical events: where the answer to a question is certain given the specific conditions represented by the question.

- Basic events: where the answer is uncertain due to stochastic behavior or inadequate knowledge of the governing phenomena.

In this appendix, the basic events are examined and a probability (i.e. split fraction) is asigned to each possibility.

Several information sources were used in the quantification (or assignment) of probabilities to basic events. These include:

- Human error probability (HEP) quantification

- System fault trees used in the Level 1 analysis

- Industry and published data

- Plant-specific thermal hydraulic analyses.

When examining industry and published data and plant-specific thermal hydraulic analyses, a systematic and consistent method was established to translate quantitative data (such as numerical probabilities) as well as qualitative information (event descriptions such as likely and possible) into probabilities. These guidelines for quantification are presented in Appendix M-B. They indicate the appropriate split fractions assigned to a basic event for varying levels

of confidence in a particular outcome.

Section M2

QUANTIFICATION OF BASIC EVENTS

For each basic event, a short description of the event is given, and the evaluation of the probability follows. All assumptions that were made with respect to the individual basic events are noted in the calculation.

BASIC EVENT: AC_POWER_E

CET QUESTION NUMBER: 23

DESCRIPTION: AC power recovered prior to vessel failure in station blackout scenarios

This basic event addresses whether AC power will be recovered after the onset of core damage, but prior to vessel breach in Station Blackout (SBO) scenarios.

QUANTIFICATION:

The probability of ac power recovery can be determined directly from an ac power recovery (or non-recovery) probability curve for IP3. Quantification of all ac power recovery basic events for IP3 were based on the offsite ac power recovery probability curve provided in Appendix H. This curve provides the probability of off-site ac power recovery as a function of time for up to 9 hours. For the purposes of basic event quantification, it was assumed that the curve is "flat" beyond 9 hours. This assumption is conservative and will only affect late ac power recovery basic events.

Because level 1 PDSs are defined at the onset of core damage, the probability of off-site ac power recovery prior to core uncovery is already considered in the frequency of the SBO PDSs. Therefore, quantification of this basic event is performed by normalising the probability of offsite ac power recovery at vessel failurewith respect to the ac power non-recovery probability at the time the core is uncovered. This prevents double counting of the frequency already considered in the level 1 analysis. Basic event AC_POWER_E1 represents the early ac power recovery probability for short term SBOs while AC_POWER_E2 represents the early AC power recovery probability for long term SBOs.

Based on calculations using the Modular Accident Analysis Program (MAAP), performed as part of accident progression model development, the times associated with uncovering the core and vessel failure were determined to be approximately 2 and 4 hours respectively for short-term SBOs. The offsite ac power recovery probability at these times are:

Time (hr)	Cumulative Offsite AC Power Recovery Probability
2	0.75
4	0.87

Therefore, the value for basic event AC_POWER_E1 is

AC_POWER_E1 = (0.87-0.75) / (1.0-0.75)

or

AC_POWER_E1: E_Ac = 0.48, nE_AC = 0.52

Based on MAAP calculations, the time associated with uncovering the core and vessel failure were determined to be approximately 7.75 and 10 hours respectively for long-term SBOs. The offsite ac power recovery probability at these times are:

Time (hr)	Cumulative Offsite AC Power Recovery Probability
7.75	0.92
10	0.93

Therefore, the value for basic event AC_POWER_E2 is

AC_POWER_E2 = (0.93-0.92) / (1.0-0.92)

or

AC_POWER_E2: E_AC = 0.13, nE_AC = 0.87

BASIC EVENT: AC_POWER_L

CET QUESTION NUMBER: 60

DESCRIPTION: AC power recovered after vessel failure, but prior to the onset of mcci in station blackout scenarios

This basic event addresses whether ac power will be recovered after vessel failure, but prior to the onset of MCCI in station blackout scenarios.

QUANTIFICATION:

This basic event was quantified in a manner similar to that used in the quantification of basic event AC_POWER_E: quantification was performed by evaluating the probability of off-site ac power recovery at the onset of core-concrete unteractions (CCIs), and normalising the value by dividing by the ac power non-recovery probability at vessel failure. The onset of MCCI represents a significant time late in the accident progression because of its impact on the evolution of fission products. Basic event AC_POWER_L1 represents the late ac power recovery probability for short-term SBOs while AC_POWER_L2 represents the late ac power recovery probability for long-term SBOs.

Based on MAAP calculations, the times associated with vessel failure and the onset of MCCI in the short-term SBO scenarios were determined to be approximately 4 and 18 hours respectively. The off-site ac power recovery probability at these times are:

Time (hr)	Cumulative Offsite AC Power Recovery Probability
4	0.87
18	0.93

Therefor the value for basic event AC_POWER_L1 is

AC_POWER_L1 = (0.93-0.87) / (1.0-0.87)

or

AC_POWER_L1: L_AC = 0.46, nL_AC = 0.54

Because the offsite ac power recovery probability curve is assumed to be flat beyond the time of 9 hours, the quantification of the basic event AC_POWER_L2 results in a value of 0.0. The time of vessel failure in long-term station blackout scenarios is approximately 10 hours and the onset of CCI occurs some time later.

AC_POWER_L2: L_AC = 0.0, nL_AC = 1.0

BASIC EVENT: ALPHA

CET QUESTION NUMBER: 43

DESCRIPTION: Does alpha mode failure occur?

This basic event addresses whether, given an in-vessel fuel-coolant interaction, the vessel and the containment will fail (i.e., alpha mode failure).

QUANTIFICATION:

The logic structure of the CET precludes alpha mode failure unless an in-vessel fuel-coolant interaction (FCI) occurrs. In the NUREG-1150 studies for Surry [1] and Zion [2], the values for alpha mode failure were based on the work of the Steam Explosion Review Group (SERG). The probability of alpha mode failure at low pressure was 0.008. As this value includes the probability of having in-vessel FCIs, and we consider an FCI probability in a separate question, this value must be corrected to give only the alpha mode failure probability, given that an FCI has occurred.

Using the quantification guidelines described in Appendix M-A, the NUREG-1150 results indicate that the entire alpha mode failure process (FCI to VF to CF) at low RCS pressure is considered to be extremely unlikely (i.e. 0.01). The probability of a low pressure fuel-coolant interaction was quantified here as 0.1 (see basic event FCI_IV). Therefore, the probability of an alpha mode failure is 0.1.

ALPHA: Alpha = 0.1, nAlpha = 0.9

BASIC EVENT: BURN_EARLY

CET QUESTION NUMBER: 37

DESCRIPTION: Does an early h2 burn occur?

This basic event addresses whether an early hydrogen burn will occur.

QUANTIFICATION:

A low hydrogen concentration (see basic event H2_EARLY) was defined as being below the lower flammability limit. Therefore, low hydrogen concentrations are precluded from burning. For medium and high hydrogen concentrations, two types of burns are considered:

- E_Def - Large deflagration burns, that will challenge the containment.
- E_Diff - Small deflagration burns, a series of small deflagrations, or diffusion burns. These burns represent no containment challenge.

Detonations were considered in a separate question.

In the Surry and Zion NUREG-1150 studies, early hydrogen burns were not considered; however, they were considered in the Grand Gulf study [3]. The results indicate that if ignition sources or ac power are available, then hydrogen burns always occur.

In the Grand Gulf study [3], several probabilities for burns without ignition sources are provided for hydrogen concentrations that vary from 4 percent to 16 percent. The probabilities that a burn will occur vary from 0.21 to 0.38. Based on the quantification guidelines, the probability of a burn occurring with a medium or high hydrogen concentration and no ignition sources was assigned a value of 0.5.

The type of burn needs also to be considered. It was assumed that if ac power is available, small deflagrations and diffusion burns will be considered likely (probability = 0.9). If no ignition sources are available, an intermediate split between the two cases was assumed (probability = 0.5). The final probabilities for burns are obtained by multiplying the base probability of having a burn by the probability of the burn type. Basic event BURN_EARLY_1 represents the burn probability for sequences where ignition sources are available.

BURN_EARLY_1: nE_Burn = 0.0, E_Def = 0.1, E_Diff = 0.9

Basic event BURN_EARLY_2 represents the burn probability for sequences where ignition sources are not available.

BASIC EVENT: BURN_LATE

CET QUESTION NUMBER: 71

DESCRIPTION: Is there a late h2 burn?

This basic event addresses whether a late hydrogen burn will occur in the containment.

QUANTIFICATION:

The following assumptions were used in the quantification of late burns:

- If a burn occurred early or at vessel breach, then an ignition source is available to ignite any hydrogen produced late (by CCI). Late burns were assumed to be diffusion burns that will not challenge the containment.
- If ac power is available early, all late burns will be diffusion burns.
- If debris is not coolable (CCIs occur), high concentrations of combustible gases (i.e. H_2, CO) will occur (i.e., equivalent to 2200 lbm H_2 or greater).

The results of BURN_EARLY and DETONATION_EARLY were used to quantify BURN_LATE. The cases to be examined for BURN_LATE are as follows:

Case 4) High hydrogen or CCIs, ac power is recovered late in SBO scenarios (BURN_LATE_1).

Case 5) High hydrogen or CCI, ac power is not recovered in SBO scenarios (BURN_LATE_2).

Case 6) Medium hydrogen, no CCI, ac power is recovered late in SBO scenarios (BURN_LATE_3).

Case 7) Medium hydrogen, no CCI, ac power is not recovered in SBO scenarios (BURN_LATE_4).

Case 4

Because ac power is recovered late with a high combustible gas concentration in containment, it was assumed that the burn will either be a deflagration or a detonation. The quantification of the DETONATION_EARLY basic event indicated a probability of 0.1 (for detonation) for this same scenario should it occur early. Therefore the same probability will be assigned for this case (detonation 0.1, deflagration 0.9, diffusion burn 0.0).

BURN_LATE_1: L_Det = 0.1, L_Def = 0.9, nL_Diff = 0.0

Case 5

The probability of ignition when no ac power is present was 0.5. Since there is a high combustible gas concentration in the containment, all of these burns are large deflagrations or detonations-- based on the probabilities from DETONATION_EARLY, 10 percent will be detonations. Thus, the overall probability of detonation will be 0.05, of deflagration 0.45, and of diffusion/no burn 0.50.

BURN_LATE_2: L_Det = 0.05, L_Def = 0.45, nL_Diff = 0.5

Case 6

Because ac power is recovered late with a deflagrable (not detonable) concentration of hydrogen in the containment, it was assumed that a deflagration will occur. Therefore, the probabilities are: detonation 0.0, deflagration 1.0, diffusion burn 0.0

BURN_LATE_3: L_Det = 0.0, L_Def = 1.0, nL_Diff = 0.0

Case 7

Case 7 is like case 5, except that detonations are precluded since the hydrogen level is only medium. Therefore the probabilities are; detonation 0.0, deflagration 0.5, diffusion burn/no burns 0.5.

BURN_LATE_4: L_Det = 0.0, L_Def = 0.5, nL_Diff = 0.5

BASIC EVENT: BURN_VF

CET QUESTION NUMBER: 51

DESCRIPTION: Does an H_2 burn occur at vessel failure?

This basic event addresses whether a hydrogen burn will occur at vessel failure.

QUANTIFICATION:

The following assumptions are taken when quantifying this basic event:

- No burns occur prior to vessel failure
- Medium or high hydrogen levels are present in the containment (combustible concentrations)
- If ignition sources are available (i.e., ac power is available), then hydrogen burns always occur.

Detonations are considered in a separate question.

Basic event BURN_VF_1 addresses whether a burn occurs at vessel failure, given a medium hydrogen concentration early, no early burns, and DCH. As DCH will cause ignition at vessel failure, the split fraction simply indicates the likelihood that the burn will be a deflagration rather than a diffusion burn. Just as with the early burn basic events (BURN_EARLY_2), an even split between deflagrations and diffusion burns was assumed.

BURN_VF_1: nE_Burn = 0.0, E_Def = 0.5, E_Diff = 0.5

Basic event BURN_VF_2 addresses whether no burn, a deflagration, or a diffusion burn occur at vessel failure given that the early hydrogen concentration is high and DCH does not occur. Just as with the early burn basic events, an even split was assumed between burn and no burn, and, should a burn occur, it was assumed to be a deflagration.

BURN_VF_2: nE_Burn = 0.5, E_Def = 0.5, E_Diff = 0.0

Basic event BURN_VF_3 addresses whether a burn will occur at vessel failure, given a medium hydrogen concentration and no DCH. Once again, an even split is assumed between burn and no burn, and just as with the early burn basic events, an event split was assumed between deflagrations and diffusion burns for the medium hydrogen concentration cases.

BURN_VF_3: nE_Burn = 0.5, E_Def = 0.25, E_Diff = 0.25

BASIC EVENT: CFE_BURN

CET QUESTION NUMBER: 39

DESCRIPTION: Does the containment fail due to an early H_2 burn?

This basic event addresses whether an early hydrogen burn will fail the containment due to overpressure.

QUANTIFICATION:

The probability of containment failure as a result of a hydrogen burn depends on the type of burn (e.g., diffusion burn, deflagration, or detonation) and the resulting containment pressure. It was assumed that if a detonation occurs, then the containment will fail. For deflagrations, the pressure rise resulting from the burn is calculated. Once the pressure is known, the probability of containment failure can be calculated using the curve for static overpressurization failure in Appendix B. The adiabatic isochoric complete combustion (AICC) correlation was used to estimate the pressure increase for deflagrations. The pressure estimate using the AICC correlation is shown in below.

Given:

Containment free volume:	$V = 2.61E6\ ft^3$
Universal gas constant:	R = 1545.3 ft-lbf/lbmole/R [4]
Molecular weight of air	M_a = 28.964 lbm/lbmole [5]
Molecular weight of hydrogen	M_b = 2.016 lbm/lbmole [5]
Heat of combustion (hydrogen)	q = 104,084 Btu/lbmole [6]
Specific heat of air	C_v = 0.173 Btu/lbm/R [4]
Nominal containment O_2 concentration	X_{O2} = 0.20946 [5]

Assumed:

Initial containment pressure	P = 14.7 psia or 37.7 psia
Initial containment temperature	T = 90 F = 550 R
Containment atmosphere is ideal gas	PV = NRT
Complete combustion at constant vol.	AICC correlation

Calculations:

Using the assumptions that the atmosphere is an ideal gas, and noting that the combustion process is at constant volume, the following equation can be written:

where,

$$P_f = P_o * \frac{N_f}{N_o} * \frac{T_f}{T_o}$$

P_f = containment pressure following combustion.
P_o = containment pressure prior to combustion.
N_f = total moles of gas following combustion.
N_o = total moles of gas prior to combustion.
T_f = containment temperature following combustion.
T_o = containment temperature prior to combustion.

Let:

N_a = number of moles of air in the containment prior to combustion.
N_b = number of moles of hydrogen in the containment prior to combustion.

Therefore, $N_o = N_a + N_b$

Assuming complete combustion, the following equation applies:

$$O_2 + 2H_2 \text{ --> } 2H_2O$$

From this, it can be seen that $N_f = N_a + N_b/2$.

The AICC Correlation gives the temperature response to combustion:

$$T_f = T_o + \frac{N_b * q}{C_v * N_a * M_a}$$

To account for increase in containment pressure due to the generation of non-condensible gas prior to combustion, a weighting fraction of (N_o/N_a) is multiplied into the equation for P_f. In addition, Reference [6] shows that the pressure rise from a hydrogen deflagration as calculated using the AICC correlation is approximately a factor of two greater than that shown by experimental data becxause the assumption that the combustion process is complete is overly-conservative. Therefore, the final temperature as calculated by the AICC correlation will be corrected using a weighing factor of two to account for this discrepancy. Hence:

$$P_f = P_o * \frac{N_o}{N_a} * \frac{N_a + \frac{N_b}{2}}{N_a + N_b} * \frac{T_o + \frac{N_b * q}{2C_v * N_a * M_a}}{T_o}$$

Four cases were examined:

- High hydrogen, base containment pressure 37.7 psia
- Medium hydrogen, base containment pressure 37.7 psia
- High hydrogen, base containment pressure 14.7 psia
- Medium hydrogen, base containment pressure 14.7 psia.

High Hydrogen

The definition of high hydrogen is 2200 lbm (representing 112 percent core oxidation). Using this mass and the above equation, P_f can be determined. The probability of containment failure can then be obtained from Appendix B.

high base containment pressure,

P_o = 37.7 psia
P_f = 140.3 psia (or 125.6 psig)
Containment failure probability = 0.30

CFE_BURN_1: H2_CFE = 0.30, H2nCFE = 0.70

low base containment pressure,

P_o = 14.7 psia
P_f = 127.0 psia, 112.3 psig
Containment failure probability = 0.07

CFE_BURN_2: H2_CFE = 0.07, H2nCFE = 0.93

Medium Hydrogen

Since medium hydrogen concentrations refer to a mass of between 600 lbm to 2200 lbm (i.e. 31 to 112 perecent core oxidation), a range of probabilities must be determined. First the probability at midpoint of the range (1400 lbm) is determined.

low base containment pressure,
P_o = 14.7 psia
P_f = 82.5 psia (or 67.8 psig)
Containment failure probability = 0.001

CFE_BURN_3: H2_CFE = 0.001, H2nCFE = 0.999

high base containment pressure,
P_o = 37.7 psia
P_f = 101.6 psia (or 86.9 psig)
Containment failure probability = 0.001

CFE_BURN_4: H2_CFE = 0.001, H2nCFE = 0.999

The amount of hydrogen generation necessary to raise the probability of containment failure to 0.01 with medium hydrogen concentrations was also investigated.

low base containment pressure,
From Appendix B, $P_f \approx$ 102 psig (or or 116.7 psia)
Solving N_b for by trial and error, hydrogen mass $\approx$ 2020 lbm represening 103 percent oxidation.

high base containment pressure,
From Appendix B, $P_f \approx$ 102 psig (or 116.7 psia)
Solving N_b for by trial and error, Hydrogen Mass $\approx$ 1720 lbm represnting 88 percent oxidation.

From reference [7], Table 5-6, (and basic event H2_EARLY), an expert elicitation on core oxidation provides a distribution for the oxidation of zirconium in the core. This distribution indicates that zirconium oxidation in the range from 88 to 103 percent oxidation is extremely unlikely. Therefore, no credit was given to the possibility that medium hydrogen will be sufficiently large to have a containment failure probability exceeding the value calculated at the midpoint of the medium hydrogen range.

BASIC EVENT: CFE@VF

CET QUESTION NUMBER: 54

DESCRIPTION: Containment failure results from pressure rise at vessel failure

There are ten possible combinations of events at vessel failure that may cause a significant pressure rise in containment. The probability that each of these event combinations will produce containment failure must be quantified for both high and low containment base pressures. Thus, twenty basic events are quantified below.

QUANTIFICATION:

BASIC EVENT CFE@VF_1

This basic event addresses whether containment failure occurs, given that, at vessel failure:

- The containment base pressure is high (23 psig, 37.7 psia)
- DCH occurs
- The hydrogen concentration in containment is high (See H2_EARLY)
- A hydrogen deflagration occurs in containment.

From the quantification of CFE_BURN_1, it can be seen that the containment pressure reaches 140.3 psia (125.6 psig) given the deflagration of high hydrogen concentrations and a high base pressure. Assuming an additional containment pressure increase of approximately 100 psi [8] from DCH, the final containment pressure given the above conditions is approximately 240.3 psia (225.6 psig). From Appendix B, this pressure corresponds to a containment failure probability of 0.999.

CFE@VF_1: VF_CFE = 0.999, nVF_CFE = 0.001

BASIC EVENT CFE@VF_2

This basic event addresses whether containment failure occurs given that, at vessel failure:

- The containment base pressure is high (23 psig, 37.7 psia)
- The reactor pit is dry
- DCH occurs
- The hydrogen concentration in containment is Medium (See H2_EARLY)
- A hydrogen deflagration occurs in containment.

The quantification of CFE_BURN_2 shows that the containment pressure reaches 101.6 psia (86.9 psig) given hydrogen deflagration in the presence of medium hydrogen concentrations and a high base pressure. Assuming an additional containment pressure increase of approximately 100 psi [8] because of DCH, the final containment pressure for the above conditions is approximately 201.6 psia (186.9 psig). From Appendix B, this pressure corresponds to a containment failure probability of 0.997.

CFE@VF_2: VF_CFE = 0.997, nVF_CFE = 0.003

BASIC EVENT CFE@VF_3

This basic event addresses whether containment failure occurs given that, at vessel failure:

- The containment base pressure is low (0 psig, 14.7 psia)
- DCH occurs
- The hydrogen concentration in containment is High (See H2_EARLY)
- A hydrogen deflagration occurs in containment.

The quantification of CFE_BURN_3 predicts that the containment pressure reaches 127.0 psia (112.3 psig) given hydrogen deflagration in the presence of high hydrogen concentrations and a low base pressure. Assuming an additional containment pressure increase of approximately 100 psi [8] because of DCH, the final containment pressure for the above conditions is approximately 227.0 psia (212.3 psig). From Appendix B, this pressure corresponds to a containment failure probability of 0.999.

CFE@VF_3: VF_CFE = 0.999, nVF_CFE = 0.001

BASIC EVENT CFE@VF_4

This basic event addresses whether containment failure occurs given that, at vessel failure:

- The containment base pressure is low (0 psig, 14.7 psia)
- The reactor pit is dry
- DCH occurs
- The hydrogen concentration in containment is Medium (See H2_EARLY)
- A hydrogen deflagration occurs in containment.

The quantification of CFE_BURN_4 predicts that the containment pressure reaches 82.5 psia (67.8 psig), given hydrogen deflagration in the presence of medium hydrogen concentrations and a low base pressure. Assuming an additional containment pressure increase of approximately 100 psi [8] because of DCH, the final containment pressure given the above conditions is approximately 182.5 psia (167.8 psig). From Appendix B, this pressure corresponds to a containment failure probability of 0.97.

CFE@VF_4: VF_CFE = 0.97, nVF_CFE = 0.03

BASIC EVENT CFE@VF_5

This basic event addresses whether containment failure occurs, given that, at vessel failure:

- The containment base pressure is high (23 psig, 37.7 psia)
- High pressure blowdown occurs
- The hydrogen concentration in containment is High (See H2_EARLY)
- A hydrogen deflagration occurs in containment.

The quantification of CFE_BURN_1 predicts that the containment pressure reaches 140.3 psia (125.6 psig) given hydrogen deflagration in the presence of high hydrogen concentrations and a high base pressure. There is an additional pressure increase in containment caused by high pressure blowdown from the vessel. This pressure increase would be similar to the pressure spike in containment associated with a large-break LOCA and is approximately 50 psi [9]. With this additional containment pressure increase, the final containment pressure is approximately 190.3 psia (175.6 psig). From Appendix B, this pressure corresponds to a containment failure probability of 0.99.

CFE@VF_5: VF_CFE = 0.99, nVF_CFE = 0.01

BASIC EVENT CFE@VF_6

This basic event addresses whether containment failure occurs, given that, at vessel failure:

- High pressure blowdown occurs :
- The containment base pressure is high (23 psig, 37.7 psia)
- The hydrogen concentration in containment is medium (See H2_EARLY)
- A hydrogen deflagration occurs in containment.

The quantification of CFE_BURN_2 predicts that the containment pressure reaches 101.6 psia (86.9 psig) given hydrogen deflagration in the presence of medium hydrogen concentrations and a high base pressure. An additional 50-psi pressure increase in containment results from high pressure blowdown from the vessel. The final containment pressure given the above conditions is approximately 151.6 psia (136.9 psig). From Appendix B, this pressure corresponds to a containment failure probability of 0.57.

CFE@VF_6: VF_CFE = 0.57, nVF_CFE = 0.43

BASIC EVENT CFE@VF_7

This basic event addresses whether containment failure occurs, given that, at vessel failure:

- The containment base pressure is low (0 psig, 14.7 psia)
- High pressure blowdown occurs
- The hydrogen concentration in containment is High (See H2_EARLY)
- A hydrogen deflagration occurs in containment.

The quantification of CFE_BURN_3 predicts that the containment pressure reaches 127.0 psia (112.3 psig) given hydrogen deflagration in the presence of high hydrogen concentrations and a low base pressure. An additional 50-psi pressure increase in containment results from high pressure blowdown from the vessel. The final containment pressure given the above conditions is approximately 177.0 psia (162.3 psig). From Appendix B, this pressure corresponds to a containment failure probability of 0.95.

CFE@VF_7: VF_CFE = 0.95, nVF_CFE = 0.05

BASIC EVENT CFE@VF_8

This basic event addresses whether containment failure occurs, given that, at vessel failure:

- The containment base pressure is low (0 psig, 14.7 psia)
- High pressure blowdown occurs
- The hydrogen concentration in containment is Medium (See H2_EARLY)
- A hydrogen deflagration occurs in containment.

The quantification of CFE_BURN_4 predicts that the containment pressure reaches 82.5 psia (67.8 psig) given hydrogen deflagration in the presence of medium hydrogen concentrations and a low base pressure. An additional 50-psi pressure increase in containment results from high pressure blowdown from the vessel. The final containment pressure is approximately 132.5 psia (117.8 psig). From Appendix B, this pressure corresponds to a containment failure probability of 0.15.

CFE@VF_8: VF_CFE = 0.15, nVF_CFE = 0.85

BASIC EVENT CFE@VF_9

This basic event addresses whether containment failure occurs, given that, at vessel failure:

- The containment base pressure is high (23 psig, 37.7 psia)
- The reactor pit is dry
- DCH occurs.

Assuming a containment pressure increase of approximately 100 psi [8] from DCH, the final containment pressure is approximately 137.7 psia (123 psig). From Appendix B, this pressure corresponds to a containment failure probability of 0.24.

CFE@VF_9: VF_CFE = 0.24, nVF_CFE = 0.76

BASIC EVENT CFE@VF_10

This basic event addresses whether containment failure occurs, given that, at vessel failure:

- The containment base pressure is low (0 psig, 14.7 psia)

- The reactor pit is dry
- DCH occurs.

Assuming a containment pressure increase of approximately 100 psi [8] from DCH, the final containment pressure is approximately 114.7 psia (100 psig). From Appendix B, this pressure corresponds to a containment failure probability of 0.01.

CFE@VF_10: VF_CFE = 0.01, nVF_CFE = 0.99

BASIC EVENT CFE@VF_11

This basic event addresses whether containment failure occurs, given that, at vessel failure:

- The containment base pressure is high (23 psig, 37.7 psia)
- The hydrogen concentration in containment is high (See H2_EARLY)
- A hydrogen deflagration occurs in containment.

The quantification of CFE_BURN_1 predicts that the containment pressure reaches 140.3 psia (125.6 psig). From Appendix B, this pressure corresponds to a containment failure probability of 0.30.

CFE@VF_11: VF_CFE = 0.30, nVF_CFE = 0.70

BASIC EVENT CFE@VF_12

This basic event addresses whether containment failure occurs, given that, at vessel failure:

- The containment base pressure is high (23 psig, 37.7 psia)
- The hydrogen concentration in containment is medium (See H2_EARLY)
- A hydrogen deflagration occurs in containment.

The quantification of CFE_BURN_2 predicts that the containment pressure reaches 101.6 psia (86.9 psig). From Appendix B, this pressure corresponds to a containment failure probability of 0.001.

CFE@VF_12: VF_CFE = 0.001, nVF_CFE = 0.999

BASIC EVENT CFE@VF_13

This basic event addresses whether containment failure occurs, given that, at vessel failure:

- The containment base pressure is low (0 psig, 14.7 psia)
- The hydrogen concentration in containment is high (See H2_EARLY)
- A hydrogen deflagration occurs in containment.

The quantification of CFE_BURN_3 predicts that the containment pressure reaches 127.0 psia (112.3 psig). From Appendix B, this pressure corresponds to a containment failure probability of 0.07.

CFE@VF_13: VF_CFE = 0.07, nVF_CFE = 0.93

BASIC EVENT CFE@VF_14

This basic event addresses whether containment failure occurs, given that, at vessel failure:

- The containment base pressure is low (0 psig, 14.7 psia)
- The hydrogen concentration in containment is Medium (See H2_EARLY)
- A hydrogen deflagration occurs in containment.

The quantification of CFE_BURN_4 predicts that the containment pressure reaches 82.5 psia (67.8 psig). From Appendix B, this pressure corresponds to a containment failure probability

of 0.001.

CFE@VF_14: VF_CFE = 0.001, nVF_CFE = 0.999

BASIC EVENT CFE@VF_15

This basic event addresses whether containment failure occurs, given that, at vessel failure:

- The containment base pressure is high (23 psig, 37.7 psia)
- High pressure blowdown occurs.

Assuming a 50-psi pressure increase in containment due to high pressure blowdown, the final containment pressure is approximately 87.7 psia (73 psig). From Appendix B, this pressure corresponds to a containment failure probability of 0.001.

CFE@VF_15: VF_CFE = 0.001, nVF_CFE = 0.999

BASIC EVENT CFE@VF_16

This basic event addresses whether containment failure occurs, given that, at vessel failure

- The containment base pressure is low (0 psig, 14.7 psia)
- High pressure blowdown occurs.

Assuming a 50-psi containment pressure increase from high pressure blowdown, the final containment pressure is approximately 73.7 psia (50 psig). From Appendix B, this pressure corresponds to a containment failure probability of 0.001.

CFE@VF_16: VF_CFE = 0.001, nVF_CFE = 0.999

BASIC EVENT CFE@VF_17

This basic event addresses whether containment failure occurs, given that, at vessel failure:

- The containment base pressure is high (23 psig, 37.7 psia)
- The reactor pit contains water
- DCH occurs
- The hydrogen concentration in containment is medium (See H2_EARLY)

- A hydrogen deflagration occurs in containment.

The quantification of CFE_BURN_2 predicts that the containment pressure reaches 101.6 psia (86.9 psig). Assuming an additional containment pressure increase of approximately 120 psi [8] from DCH with water in the pit, the final containment pressure is approximately 221.6 psia (206.9 psig). From Appendix B, this pressure corresponds to a containment failure probability of 0.999.

CFE@VF_17: VF_CFE = 0.999, nVF_CFE = 0.001

BASIC EVENT CFE@VF_18

This basic event addresses whether containment failure occurs, given that, at vessel failure:

- The containment base pressure is low (0 psig, 14.7 psia)
- The reactor pit contains water
- DCH occurs
- The hydrogen concentration in containment is Medium (See H2_EARLY)
- A hydrogen deflagration occurs in containment.

The quantification of CFE_BURN_4 predicts that the containment pressure reaches 82.5 psia (67.8 psig). Assuming an additional containment pressure increase of approximately 120 psi from DCH with water in the pit [8], the final containment pressure is approximately 202.5 psia (187.8 psig). From Appendix B, this pressure corresponds to a containment failure probability of 0.997.

CFE@VF_18: VF_CFE = 0.997, nVF_CFE = 0.003

BASIC EVENT CFE@VF_19

This basic event addresses whether containment failure occurs, given that, at vessel failure:

- The containment base pressure is high (23 psig, 37.7 psia)
- The reactor pit contains water
- DCH occurs.

Assuming a containment pressure increase of approximately 120 psi from DCH with water in the pit [8], the final containment pressure is approximately 157.7 psia (143 psig). From Appendix B, this pressure corresponds to a containment failure probability of 0.70.

CFE@VF_19: VF_CFE = 0.70, nVF_CFE = 0.30

BASIC EVENT CFE@VF_20

This basic event addresses whether containment failure occurs, given that, at vessel failure:

- The containment base pressure is low (0 psig, 14.7 psia)
- The reactor pit contains water
- DCH occurs .

Assuming a containment pressure increase of approximately 120 psi [14] from DCH with water in the reactor pit, the final containment pressure is approximately 134.7 psia (120 psig). From Appendix B, this pressure corresponds to a containment failure probability of 0.18.

CFE@VF_20: VF_CFE = 0.18, nVF_CFE = 0.82

BASIC EVENT: CFE_EX_FCI

CET QUESTION NUMBER: 55

DESCRIPTION: Do ex-vessel FCIs fail containment?

This basic event addresses whether the containment will fail, given an ex-vessel fuel-coolant interaction has occurred.

QUANTIFICATION:

The Surry and Zion studies [1, 2] both calculated a probability of containment failure using a fast pressure rise algorithm embedded into a user function; therefore, actual numbers could not be obtained. Furthermore, other steam explosion studies are, in general, too specific to be applied to IP3. However, this event is typically considered to be almost impossible because of the strength of large dry containments and the cavity configuration of Pressurized Water Reactors (PWRs). Therefore, based on the quantification guidelines in Appendix A, this probability was assumed to be 0.001.

CFE_EX_FCI: FCI_CFE = 0.001, FCInCFE = 0.999

BASIC EVENT: CFL_BMMT

CET QUESTION NUMBER: 73

DESCRIPTION: Does the core melt through the basemat?

Given that CCIs occur and the debris is not dispersed, this basic event addresses whether core debris in the reactor cavity will melt-through the concrete containment basemat.

QUANTIFICATION:

This basic event considers two possible accident scenarios:

1) A wet cavity with water above the debris (CFL_BMMT_1)

2) A dry cavity (CFL_BMMT_2).

The Surry containment has a 10 ft. thick basemat that is largely siliceous in composition [1]; at Zion the containment has a 9 ft. thick basemat. At Surry [1], the probabilities for these case were 0.25 and a 0.4, respectively. At Zion [2], 0.4 and 0.8, respectively.

Current industry thinking on the probability of basemat melt-through is that the values used for Surry and Zion are overly conservative, and that melt-through is unlikely, even in a dry cavity. Furthermore,, the large floor area in the cavity and keywayat IP3 provides for relatively shallow debris bed depths. Based on the quantification guidelines in Appendix A, a value of 0.1 was assigned to the case where water is present above the debris bed.

CFL_BMMT_1: BMMT = 0.1, nBMMT = 0.9

While current thinking is that basemat melt-through is unlikely, there is considerable uncertainty associated with the case where the cavity is dry. Therefore, based on quantification guidelines, this basic event was assigned a value of 0.5.

CFL_BMMT_2: BMMT = 0.5, nBMMT = 0.5

BASIC EVENT: CFL_BURN

CET QUESTION NUMBER: 72

DESCRIPTION: Does the containment fail late due to a burn?

This basic event addresses whether a late combustible gas burn will fail the containment.

QUANTIFICATION:

The quantification of this basic event is similar to quantifying basic event CFE_BURN. Late containment failures from combustible gas burns can only result from a detonation or deflagration. Late burns are precluded if there is a high steam concentration in containment. Therefore, all late burn pressure rise calculations assume that the containment base pressure is low (i.e., 14.7 psia). However, three cases are examined for late burn failures:

- Deflagrations where CCIs are the source of combustible gas
- Deflagrations from high hydrogen sources
- Deflagrations from medium hydrogen sources.

Detonations were assumed to alays result in containment failure.

Deflagrations following CCI

CCIs were assumed to produce the highest combustible gas concentrations. Using the distribution of hydrogen generation from [7], the maximum amount of hydrogen possible is approximately 125 percent of that derived from the core zirconium inventory (see basic event H2_EARLY). This represents approximately 2456 lbm of hydrogen equivalent combustible gases. Using a base pressure of, P_o = 14.7 psia, the pressure calculated by the AICC curve is, P_f = 142.2 psia or 127.5 psig. This produces a containment failure probability of 0.33.

CFL_BURN_1: L_CGCFL = 0.33, nL_CGCFL = 0.67

Deflagrations with High Hydrogen

This case is identical to CFE_BURN_2.

CFL_BURN_2: L_CGCFL = 0.07, nL_CGCFL = 0.93

Deflagrations with Medium Hydrogen

This case is identical to CFE_BURN_3.

CFL_BURN_3: L_CGCFL = 0.001, nL_CGCFL = 0.999

BASIC EVENT: CFL_SOP

CET QUESTION NUMBER: 74

DESCRIPTION: DOES THE CONTAINMENT FAIL LATE DUE TO STATIC OVERPRESSURIZATION?

This basic event represents the probability that late steam/non-condensible gas production will cause static overpressurization of the containment.

QUANTIFICATION:

Four cases are considered for this basic event and are as follows:

1) Debris cooled and no containment heat removal.
2) Debris cooled and containment heat removal.
3) CCI and containment heat removal.
4) CCI and no containment heat removal.

The overpressurization of the containment late is viewed essentially as problem of energy balance. Energy is added to the containment atmosphere from decay heat and potentially from CCI. A hand calculation was performed to determine the amount of steam necessary to fail the containment. The hand calculation is based on the equation of state for ideal gases (i.e PV=nRT). Basic values for the hand calculation are taken from the data in basic event H2_EARLY. The hand calculation is as follows:

From containment fragility curve failure at 0.999 probability = 195 psig or 210 psia
Saturation temperature @ 210 psia = 385 F or 845 R
lbmols = [(210 psia) (144 in2/ft2) (2.61E6 ft3)]/(1545.3 ft-lbf/lbmole/R * 845 R)
lbmols = 60,433
lbmass = 60,433 * 18 lbs/lbmole = 1,087,974 lbs
volume = 1,087,974 / 8.33 lb/gal ≈ 130,600 gals or 37% of RWST inventory

Only 37% of the RWST inventory must be boiled away and remain non-condensed to cause almost certain containment failure. The integrated decay heat necessary to boil this inventory away is easily obtained in time frames less than 24 hours. Therefore in the absence of containment heat removal, containment failure is almost certain. Thus, both cases with no containment heat removal, cases 1 and 4, are given a 0.999 probability of failing containment.

CFL_SOP_1: CFL = 0.999, nCFL = 0.001
CFL_SOP_4: CFL = 0.999, nCFL = 0.001

If containment heat removal is present, it can remove approximately 112 MW of energy. This value is far greater than the decay energy generated late (less than 20 MW). Therefore, it will be assumed that if the debris is cooled and decay heat is the only heat source to the containment, that the containment will not failed. Thus the probability for failing containment for case 2 is given a value of 0.0.

CFL_SOP_2: CFL = 0.0, nCFL = 1.0

If CCI is occurring late, this may add up to twice the energy of decay heat due to the chemical energy generated during CCI. The total energy added to the containment is still less than the capacity of containment heat removal. Therefore, this basic event is given an extremely unlikely chance of failing containment and the containment failure probability for case 3 is assigned a value of 0.01.

CFL_SOP_3: CFL = 0.01, nCFL = 0.090

EVENT: CHR_EARLY

CET QUESTION NUMBER: 40

DESCRIPTION: Operator fails to operate fan coolers:

This basic event addresses whether the operator fails to initiate operation of the fan coolers in recovered blackouts.

QUANTIFICATION:

Quantification of this event includes two elements. One element is failure of the operator to initiate operation of the fan coolers once ac power is recovered. This human error probability is 0.052 as discussed in the quantification of SPRAY_LATE. The other element is the probability that the fan coolers would fail to operate due to a hardware failure should the operator attempt to initiate operation. This probability, 6.3×10^{-7}, is negligible compared to the human error probability and was therefore ignored.

CHR_EARLY: E_CHR = 0.948, nE_CHR = 0.052

BASIC EVENT: CM>20%

CET QUESTION NUMBER: 35

DESCRIPTION: CORE MELT GREATER THAN 20%

This basic event represents the probability that core melt will be greater than 20% given that AC power has been recovered, the vessel can be depressurized.

QUANTIFICATION:

The definition of this basic event has changed from it's earlier definition. It is now assumed that only station blackouts can have core melt less than 20%. This assumption is less conservative than NUREG-1150 in which it was assumed that all initiators would proceed to full core melt.

For a station blackout to have less that 20% core melt, it is assumed that; 1) AC power has been recovered; and 2) there is sufficient time left before 20% of the core has melted for the reactor vessel to be depressurized. Two MAAP cases were important in determining the probability for this basic event, MAAP run No. 1 and MAAP run No. 5.

For some SBO sequences, AC power was recovered prior to the onset of core damage (but not in time to completely prevent core damage). In these cases, the probability that less than 20% of the core melted is assumed to be 1.0.

CM<20% = 1.0, CM>20% = 0.0 (Case 3)

MAAP run No. 1 was a short term station blackout. Core uncovery occurs at approximately 2.2 hours and vessel failure occurs at approximately 4.2 hours. It is estimated from the MAAP results that severe core melting (i.e. greater than 20% core melt) has occurred in less than one hour after core uncovery. Therefore, the reactor vessel must be depressurized in this sequence in less than one hour for the sequence to be considered recoverable. However, at approximately 3 hours from scram, the steaming rate from the core is only slightly less than the flow rate out of the PORVs. Thus all short term blackouts are considered unrecoverable.

CM<20% = 0.0, CM>20% = 1.0 (Case 6)

MAAP run No. 5 was a long term station blackout. Core uncovery occurs at approximately 7.2 hours and vessel failure occurs at approximately 10 hours. It is estimated that the time from core uncovery to severe core melting is approximately 1.5 hours. The PORVs are more than adequate to depressurize the vessel at the decay heat levels at 7 hours from scram.

Two basic events were defined for long term SBOs:

- Given AC power recovery, a long term sequence, and medium to low RCS pressure, what is the probability of core melt proceeding to full core melt (i.e. greater than 20%).
- Given AC power recovery, a long term sequence, and high RCS pressure, what is the probability of core melt proceeding to full core melt (i.e. greater than 20%).

For the first case all the criteria have been met for core melt progression to be stopped. However, some uncertainty exists as to whether this will occur. Based on the criteria for quantification, CM>20% is considered unlikely and is therefore given a probability of 0.1.

CM<20% = 0.9, CM>20% = 0.1 (Case 4)

The second case meets all the criteria, except the vessel is at high pressure, and must be depressurized. Therefore, for this event the analysis is inconclusive and it is assigned a probability of 0.5.

CM<20% = 0.5, CM>20% = 0.5 (Case 5)

BASIC EVENT: CTMT_BASE_PRESS

CET QUESTION NUMBER: 30

DESCRIPTION: Containment base pressure at vessel failure

This basic event addresses whether the containment base pressure will have reached the containment spray actuation setpoint of 23 psig after the onset of core damage, but prior to vessel failure.

QUANTIFICATION:

It was assumed that if the base pressure meets or exceeds 23 psig, a containment spray actuation signal will be sent. The MAAP calculations performed for accident progression model development were analyzed to identify wht accident scenarios that might lead to a high containment base pressure after the onset of core damage, but prior to vessel breach. Few of the scenarios analyzed indicated a high containment base pressure--vaporizing the entire RCS inventory over 1 to 2 hours is insufficient to increase the containment pressure to the spray initiation set point. While the large break LOCA scenario did result in a high containment pressure prior to core damage, this initiator was considered in basic event SPRAY_VE).

The only accident scenario that could be postulated that might result in a high containment base pressure is one in which the RCS inventory was vaporized along with a substantial fraction of the RWST inventory. (Non-condensible gas generation is too low to significantly increase containment base pressure). To achieve this, the accident scenario would have no containment fan coolers, some sort of RCS breach or leak where the initial RCS inventory was lost, and successful (and controlled) RWST injection to the RCS after the onset of core damage and before vessel breach. Recovery of injection after the onset of core damage, but before vessel breach is considered only for SBOs with early ac power recovery and transients where the operator depressurizes during core damage. For the SBO scenarios, both fan coolers and auxiliary feedwater will likely be recovered with the recovery of AC power. If fan coolers are recovered, the steam challenge to the containment will be alleviated; if auxiliary feedwater is recovered, the need to relieve pressure through the PORVs (for transients) will be eliminated. For these reasons, this basic event was assigned a value of 0.0.

CTMT_BASE_PRESS: CP>23 = 0.0, CP<23 = 1.0

BASIC EVENT: DCH

CET QUESTION NUMBER: 50

DESCRIPTION: Does DCH occur?

This basic event addresses whether direct containment heating occurs, given that high pressure melt ejection has occurred previously.

QUANTIFICATION:

Given high pressure melt ejection (HPME) has occurred, DCH may follow resulting in a significant pressure rise in containment. As the data available in the literature regarding DCH are minimal and significant uncertainty exists, this basic event was assigned a value of 0.5.

DCH: DCH = 0.5, nDCH = 0.5

BASIC EVENT: DISPERSAL

CET QUESTION NUMBER: 57

DESCRIPTION: IS THE DEBRIS DISPERSED?

This basic event represents the probability that debris is dispersed and cooled following an alpha, HPME or ex-vessel steam explosion event.

QUANTIFICATION:

For this basic event, dispersal is defined to be debris that is dispersed to such an extent that it is coolable by radiative and natural convection only. To evaluate this basic event, the depth of the debris bed given full core melt is calculated as follows.

Given:

Mass of UO2 in core	221,600 lbs [8]
Mass of zircaloy in core	44,450 lbs [8]
Mass of other core components (assumed to be steel)	17,950 [8]
Density of UO2	684 lbs/ft^3 [9]
Density of zircaloy	406 lbs/ft^3 [9]
Density of steel	495 lbs/ft^3 [9]
Area of cavity	477 ft^2 [8]

$$\text{Depth} = [(221{,}600/684) + (44{,}450/406) + (17{,}950/495)]/477 \approx 1 \text{ ft}$$

Typically, calculations for debris coolability by radiation and convection with an adiabatic lower surface have debris bed maximum thicknesses of approximately 1 to 2 inches. Therefore, this basic event represents the probability that debris is dispered such that the maximum debris bed thiskness is less than 2 inches. As this would require a substantial fraction of the core to be ejected from the reactor cavity, it is considered unlikely that dispersal wil occur.

DISPERSAL: Disp = 0.1, nDisp = 0.9

BASIC EVENT: DETONATION_EARLY

CET QUESTION NUMBER: 38

DESCRIPTION: Does an early H_2 detonation occur?

This basic event addresses whether an early hydrogen deflagration, in the presence of a detonable concentration, is actually a detonation.

QUANTIFICATION:

Based on the definitions of low, medium and high hydrogen concentrations, (see basic event H2_EARLY), a detonation can only occur for high hydrogen concentrations. It was also assumed that a detonation can only occur if the criteria for an early burn (see basic event BURN_EARLY) have also been met.

The early detonation of hydrogen was considered in the Grand Gulf study [3]. The probability of hydrogen detonation with hydrogen concentrations between 12 and 16 percent was 0.22; for concentrations above 16 percent, it was 0.25. Based on these values, the probability of a hydrogen detonation is relatively unlikely. Therefore, based on our quantification guidelines, this basic event is assigned a value of 0.1 for a detonation and 0.9 for a deflagration.

DETONATION_EARLY: E_DET = 0.1, nE_DET = 0.9

BASIC EVENT: DETONATION_VF

CET QUESTION NUMBER: 52

DESCRIPTION: Is the H_2 burn at vessel failure a detonation?

This basic event addresses whether a hydrogen burn at vessel failure will be a detonation.

QUANTIFICATION:

This basic event was assumed to be very similar to basic event DETONATION_EARLY. The following assumptions were made:

- A deflagration burn occurrs at vessel failure
- A high concentration of hydrogen exists in the containment
- Sprays do not operate.

As with basic event DETONATION_EARLY, this basic event was considered unlikely and is assigned a value of 0.1.

DETONATION_VF: VF_DET = 0.1, nVF_DET = 0.9

BASIC EVENT: DP_PORV

CET QUESTION NUMBER: 24

DESCRIPTION: The rcs is depressurized during core damage by opening the PORVS

This basic event addresses whether the RCS can be depressurized prior to vessel breach by opening the PORVs.

QUANTIFICATION:

This basic event has two cases:

- Short-term sequences, in which the time to core damage is less than approximately 2 hours.
- Long-term sequences, in which the time to core damage is much greater than 2 hours.

There are three sources of information available to quantify this event: a MAAP calculation; a hand calculation; and data from the NUREG-1150 study. The hand calculation applies to the short term sequences; the MAAP calculation and NUREG-1150 data apply to the long-term sequences.

Short-Term Sequences

Since data were not available to indicate the time when it is physically possible to have the PORVs depressurize the vessel, a hand calculation was made to estimate this value. The calculation assumes that the RCS is at the PORV setpoint and that the coolant is saturated.

Known Values

Normal reactor power		3025 MW [6]
PORV setpoint	2325 psia	16.1 MPa
PORV capacity (single PORV)	179,000 lb/hr	22.55 kg/s
Heat of vaporization H_{fg} @ 2325 psia		925,990 J/kg [5]

Energy Removal Rate for 2 PORVs

E_{rem} = 925900 J/kg * 2 * 22.55 kg/s = 4.176E7 J/s = 41.76 MW

Energy Removal Rate as a Fraction of Total Power

E_{rem} / P_o = 41.76 MW / 3025 MW = 0.0138

Time at Which Decay Heat Equals Energy Removal Rate

The decay heat of the reactor as a fraction of total power is given as follows:

$$\frac{P}{P_o} = 0.1[(\tau - T_o + 10)^{-0.2} - 0.87(\tau - T_o + 2x10^7)^{-0.2}]$$

where,

$\tau - T_o$ = the time from scram in seconds

By iteration, the time at which the decay heat equals the heat removal rate is approximaely 2 hours. Therefore, the minimum time at which the PORVs could begin to depressurize the RCS is also approximately 2 hours. This indicates that the likelihood of depressurizing the RCS using two PORVs is low for short-term sequences. Based on the quantification guidelines, the hand calculation results indicates that a value of 0.1 be assigned to successful depressurization for short term events.

DP_PORV_1: DP_PORV = 0.1, nDP_PORV = 0.9

Long Term Sequences

A single MAAP calculation applies to this case. Scenario 4 described in Appendix K is a long term station blackout that has ac power restored after the core is uncovered, but prior to vessel breach. The calculation indicates that the PORVs, which were opened approximately 8 hours after scram, would depressurize the RCS before the vessel failure.

Different values were obtained for this probability for the Surry and Zion plants. While neither analysis indicated whether the data applied to long- or short-term sequences, it was assumed that the values were meant for longer term sequences. The probability for Surry is from pg A.1.1-23 [1] and is 0.9 for successful depressurization of the RCS. The value for Zion is from pg. A-14 [2] and is 0.5 for successful depressurization of the RCS.

There are uncertainties in this event, since the time at which the operator will reach this step in the procedures, and the time available for depressurization before vessel breach are not clearly defined. The Surry value is in better agreement with the MAAP value (i.e unity), but

a value of unity cannot be justified given the uncertainties. This event is therefore considered likely, and using the quantification guidelines, a value of 0.9 is assigned to successful depressurization.

DP_PORV_2: DP_PORV = 0.9, nDP_PORV = 0.1

BASIC EVENT: FCI_EX

CET QUESTION NUMBER: 55

DESCRIPTION: Do ex-vessel FCIs occur?

This basic event addresses whether an ex-vessel fuel-coolant interaction will occur at vessel failure.

QUANTIFICATION:

The conditions under which ex-vessel FCIs can occur are:

- There is water in the containment cavity
- The debris is highly molten (see basic event SLUMP)
- The debris leaves the failed reactor vessel by gravity pour (i.e. this can be through a penetration or gross failure, but not by HPME).

These conditions are similar to those under which FCI was considered in the Surry and Zion studies. Given the high degree of uncertainty with regard to ex-vessel FCIs, using the quantification guidelines in Appendix A, this basic event was assigned a value of 0.5.

FCI_EX: Ex_FCI = 0.5, nEx_FCI = 0.5

BASIC EVENT: FCI_IV

CET QUESTION NUMBER: 42

DESCRIPTION: Do in-vessel fuel-coolant interactions occur?

This basic event addresses whether a fuel-coolant interaction will occur inside the reactor vessel.

QUANTIFICATION:

The primary assumption when quantifying this basic event is that water exists in the lower head of the reactor vessel. It is further assumed that steam explosions are only possible should the debris be highly molten and slump into the lower head (i.e., a large amount of molten debris relocating simultaneously as opposed to a small amount of melt "trickling down" into the lower head). Therefore, it was assumed that the basic event SLUMP must be true, before an in-vessel FCI can occur.

Basic event FCI_IV directly impacts the alpha mode failure (see basic event ALPHA) in which an in-vessel steam explosion causes vessel failure that in turn causes containment failure.

The NUREG-1150 study did not consider steam explosions separately from the complete process of alpha mode failure. Therefore, this basic event was quantified in conjunction with the quantification of alpha mode failure. The values used by the Surry [1] and Zion [2] studies are based on the work of the SERG. The probability of alpha mode failure (the complete process) at low pressure was 0.008. The probability of alpha mode failure at high pressure was 0.0008 (i.e. 1 order of magnitude smaller).

The probabilities from NUREG-1150 were divided between the fuel-coolant interaction basic event and the alpha mode failure basic event for the IP3 CET. Three cases were examined for this basic event: low, medium and high RCS pressure.

Low RCS Pressure

The NUREG-1150 results indicate that the alpha mode failure (FCI to VF to CF) at low RCS pressure is considered to be extremely unlikely (i.e. 0.01). Since, alpha mode failure was quantified with a probability of 0.1, then low pressure fuel-coolant interactions will be assigned a probability of 0.1.

FCI_IV_3: IV_FCI = 0.10, nIV_FCI = 0.90

High RCS Pressure

Consistent with NUREG-1150, the probability of fuel-coolant interactions occurring at high pressure are considered to be an order of magnitude lower than at low pressure. Therefore, the probability is 0.01.

FCI_IV_1: IV_FCI = 0.01, nIV_FCI = 0.99

Medium RCS Pressure

The value for medium pressure was chosen to fall in between the values for high and low pressure. It was given a value of 0.05.

FCI_IV_2: IV_FCI = 0.05, nIV_FCI = 0.95

BASIC EVENT: H2_EARLY

CET QUESTION NUMBER: 36

DESCRIPTION: Amount of early hydrogen production

This basic event addresses whether in-vessel hydrogen production will be high, medium or low.

QUANTIFICATION:

To quantify this basic event, the low, medium and high hydrogen production values must be defined. Historically, the amount of hydrogen produced is expressed in terms of the fraction of total zirconium oxidized in the core.

Hydrogen from Core

The total zirconium mass at IP3 is 44,450 lbm. Using the chemical reaction for zirconium,

$$Zr + 2H_2O \text{ --> } 2H_2 + ZrO_2$$

the total amount of hydrogen produced if all the zirconium is oxidized is as follows:

Molecular weight of zirconium = 91.22 lbm/lbmole [10]
Molecular weight of hydrogen = 2.016 lbm/lbmole [10]

Number of lbmoles of Zr = 44,450 lbm / 91.22 lbm/lbmole = 487.3 lbmole
Number of lbmoles of H_2 (using chemical reaction) = 487.3 * 2 = 974.6 lbmole
Mass of hydrogen produced = 974.6 lbmoles * 2.016 lbm/lbmole = 1964.8 lbmole

Therefore, the fraction of hydrogen is based on 1964.8 lbm.

Low Hydrogen

The low hydrogen production upper bound is defined as the minimum amount required to achieve a burn. Based on analytical burn calculations [6], the amount of H_2 needed to achieve burn is 4.1 percent by mole fraction. Therefore minimum hydrogen is calculated as follows:

Definitions:

H_2 frac = N_b / (N_b + N_a)

where,

N_b = Number of moles of hydrogen
N_a = Moles of air in containment

Given:

Containment free volume:	V = 2.61E6 ft^3 [6]
Universal gas constant:	R = 1545.3 ft-lbf/lbmole/R [12]

Assumed:

Initial containment pressure	P = 14.7 psia
Initial containment temperature	T = 90°F or 550 R
Containment atmosphere is ideal gas	PV = NRT

Calculations:

N_a = [(14.7 psi)*(144 in^2/ft^2)*(2.61E6 ft^3)] / [(1545.3 ft-lbf/lbmole/R)*(550 R)]
N_a = 6500 lbmole

If H_2 frac = 0.041, then

N_b = 0.041/(1 - 0.041) * N_a
N_b = 0.041/(1 - 0.041) * 6500 lbmole = 278 lbmole

Mass of H_2 = 278 lbmole * 2.016 lbm/lbmole = 560 lbm
For simplicity, this value was rounded up to 600 lbm
As a fraction of the core, 600 lbm / 1964.8 lbm = 31%

Therefore, 600 lbm is the upper limit of low hydrogen production for IP3. This mass represents the oxidation of 31 percent of the zirconium in the core.

High Hydrogen

High hydrogen production is defined to be the amount of hydrogen needed for detonation--a mole fraction of 13.8 percent [6]. Using the same equations as for low hydrogen, the mass is calculated as follows:

Calculations:

If H_2 frac = 0.138, then

$N_b = 0.138/(1 - 0.138) * N_a$
$N_b = 0.138/(1 - 0.138) * 6500$ lbmole = 1041 lbmole

Mass of H_2 = 1041 lbmole * 2.016 lbm/lbmole = 2098 lbm
For simplicity, this value was rounded up to 2200 lbm
As a fraction of the core, 2200 lbm / 1964.8 lbm = 112%

Therefore, the 2200 lbm lower limit of high hydrogen production for IP3 represents 112 percent of the hydrogen drived from zirconium in the core. It is possible to have hydrogen generation that exceeds 100 percent of core zirconium oxidation, since steel structures in the core may also be oxidized.

Medium Hydrogen

Medium hydrogen is defined as any amount of hydrogen between 600 lbm and 2200 lbm (i.e. between 31% and 112% of zirconium oxidized).

Quantification

MAAP calculations performed for IP3 and the results of the NUREG-1150 study were used to quantify the amount of hydrogen produced during a core melt: . The MAAP calculations included several station blackouts (cases #1, #5, #1', #5' and #5''), a small LOCA (case #2), and a large LOCA (case #12) (Appendix...) and covered a wide range of pressures inside the vessel during core damage. None of the calculations considered had injection or recirculation to the core during core damage. The results for the cases were all very consistent, and range from 42 to 55 percent of the core zirconium oxidized.

The values for NUREG-1150 for Surry [1] and Zion [2] used the mean value of the aggregate distribution from the expert elicitation [7]. The experts examined 10 cases, that had various ranges of pressure and some had injection (in this case the discharge of the accumulators) before, after, or during core melt. The mean values for the cases used by Surry and Zion were closely grouped together and ranged from 32 to 52 percent. Pressure did not seem to be as important to the amount of zirconium oxidized as did the time of accumulator discharge. Accumulator discharge during core melt produced the highest values of oxidation. These are only the mean values for the distributions produced by the experts. The range of values varied from a low value of 6% at the cumulative 1% probability level to a high value of 125% at the 99% probability level.

Full core melt, all pressures, with early injection or recirc

Based on the MAAP and NUREG-1150 data, once a full core melt has occurred, the most likely amount of zirconium oxidation will be in the medium range (i.e. between 31% and 112%). However, the high range of zirconium production cannot be completely ruled out, although it is considered almost impossible. The low range of hydrogen production (after the probabilities for high and medium are subtracted from unity) must therefore be considered unlikely. This produces value of 0.9 for medium, 0.001 for high and 0.099 for low. These values were assumed to have no dependence on the system pressure.

H2_EARLY_1: 0.099 LOW, 0.9 MEDIUM, 0.001 HIGH

Full core melt, all pressures, no early injection or recirc

The amount of hydrogen produced here will be less than in those sequences where injection or recirculation is available. However, no data are readily available to quantify this basic event (MAAP calculations were injection is recovered always quench the debris and terminate core melt progression). Therefore, based on the quantification guidelines in Appendix A, an even split will be assigned between low and medium hydrogen production values.

H2_EARLY_2: 0.5 LOW, 0.5 MEDIUM, 0.0 HIGH

BASIC EVENT: H2O_PIT

CET QUESTION NUMBER: 45

DESCRIPTION: Water in the reactor vessel cavity

This basic event addresses whether water will flow to the reactor vessel cavity given: (1) the RWST inventory is within the containment, and (2) the RWST contents were injected to the containment by some means other than containment sprays.

QUANTIFICATION:

This basic event addresses whether the RWST inventory, if located in the sumps at the 46-ft level, will flow to the reactor vessel cavity. The presence of water in the cavity may impact severe accident progression significantly by cooling molten debris within the vessel via ex-vessel heat transfer, terminating the accident progression. Shoild the vessel fail, the water my quench the debris or cause ex-vessel FCIs or exacerbate the effects of DCH.

Given some breach of the RCS and successful injection of the RWST inventory to the containment, the ultimate location of the water may affect the accident progression. If the RWST inventory is injected to the containment by containment sprays, it was assumed that water will fill the reactor pit, as the annulus between the RCS and the shield wall would create a direct flow path from the spray header to the pit. However, if the RWST inventory is injected to the containment and fills the sumps at the 46-ft level, some flow path from that level to the reactor pit is required for the water to fill the pit [2]. Two possibilities are the man-way hatch that provides worker access from the 46-ft level to the pit, and backflow from the containment sump via the waste disposal system piping [8]. Investigation of the both possibilities has been inconclusive. It is not clear whether the man-way hatch is water tight (or if not water tight, what the leakage flow rate would be around it), or if the waste disposal system piping has isolation or check valves that would prohibit backflow. Based on the quantification guidelines listed in Appendix M-A, the value assigned to this basic event is 0.5.

H2O_PIT: H2O_PIT = 0.5, H2OnPIT = 0.5

BASIC EVENT: HEAT_TRANS_EX

CET QUESTION NUMBER: 46

DESCRIPTION: Does ex-vessel heat transfer cool the debris?

This basic event addresses whether ex-vessel heat transfer will cool the debris in the lower head, thereby preventing vessel failure.

QUANTIFICATION:

Experimental and analytical investigations into the cooling of core debris inside the lower head has been conducted by Fauske and Associates [3]. The basic assumption to this work is that if the water in the containment cavity is higher than the bottom of the reactor vessel, then nucleate boiling heat transfer on the outside of the lower head may be sufficient to cool the debris. This work is relatively new and has been criticized. Therefore, this event should be considered possible, since no data exists to indicate its likelihood. Thus, a probability of 0.5 is used to quantify this event.

HEAT_TRANS_EX: Ex_Hx = 0.5, nEx_Hx = 0.5

BASIC EVENT: HLSL

CET QUESTION NUMBER: 27

DESCRIPTION: The hot leg/surge line remains intact

This basic event addresses whether the hot leg/surge line will remain intact during the accident.

QUANTIFICATION:

After much of the core is uncovered, the upper portion of the vessel and the piping connected to it will be subjected to temperatures well above the design temperature. The core will be above 2000°F, so temperatures higher than 1000°F are possible in the vicinity of the hot leg nozzles and the surge line. Should the RCS remain at high pressure during degradation, the hoop stress on the hot leg and the surge line will be high, and the elevated temperatures will weaken the metal considerably. It is possible, therefore, that the piping may fail before vessel breach.

Several experts were consulted for the NUREG-1150 study of this phenomenon. The experts examined three cases:

- A high pressure case (i.e. at the PORV setpoint)
- A medium pressure case (pressure between 1200 and the PORV setpoint)
- A low pressure case (pressure less than 1200 psia).

The mean value of the distribution for the three cases was used to quantify this basic event for both Surry and Zion. The probability of the hot leg/surge line remaining intact for each case are as follows:

high pressure	0.28
medium pressure	0.966
low pressure	1.0 (failure impossible)

Using the NUREG-1150 data and the guidelines for quantification this, basic event was quantified as follows:

medium pressure -- failure is unlikely, value = 0.1

HLSL_1: HLSLOK = 0.9, nHLSLOK = 0.1

high pressure -- failure is possible, value = 0.5

HLSL_2: HLSLOK = 0.5, nHLSLOK = 0.5

BASIC EVENT: HPME

CET QUESTION NUMBER: 49

DESCRIPTION: Does high pressure melt ejection occur?

This basic event addresses whether HPME will occur.

QUANTIFICATION:

Three conditions are necessary for HPME to occur:

- The vessel pressure must exceed 200 psi [7]. In this IPE, this corresponds to a low, medium or high pressure.
- The debris must have a high molten fraction (see basic event SLUMP).
- The vessel failure mode must be a penetration failure (see basic event VF_SIZE).

The occurrence of HPME was discussed in the NUREG-1150 study [7], Issue 6, of the in-vessel expert elicitations. The aggregate results assuming an RCS pressure of 2500 psi were that HPME occurred 91 percent of the time (i.e. 79 out of 87 percent penetration failures, see basic event VF_SIZE). The aggregate results assuming an RCS pressure of 2000 psi were that HPME occurred 69 percent of the time. These results indicate that for the medium or high pressure conditions, HPME is considered likely. Thus for medium or high pressure, this basic event is given a probability of 0.9.

HPME_2: HPME = 0.9, nHPME = 0.1

The results for pressure's between 200 psi and 1200 psi were identical to 2000 psi, 69% of the failures were HPME. However, for IP3, the upper end of the low pressure range is 600 psi. As the lower pressure range overlaps the "cutoff" pressure for HPME, it is uncertain whether or not HPME will occur. Based on the quantification guidelines provided in Appendix A, this basic event was assigned a value of 0.5.

HPME_1: HPME = 0.5, nHPME = 0.5

BASIC EVENT: INJ_EARLY

CET QUESTION NUMBER: 29

DESCRIPTION: Is injection initiated early?

These basic events address whether injection will fail to initiate early given AC power is available and the RCS pressure is sufficiently low to avoid pump deadheading.

QUANTIFICATION:

The quantification for INJ_EARLY_1 assumes that the RCS is at medium pressure, but that is below the high-head injection shutoff head. The scenario considered is recovery from a blackout, so the injection systems were not previously challenged. Since the LHF system is needed to draw suction from the RWST, the probability of failure to inject is equal to the probability that either HHF or LHF fail.

From [13], this probability is:

$$P_f = P_f(HHF) + P_f(LHF) - [P_f(HHF) * P_f(LHF)]$$

The probabilities of failure to initiate low- and high-head injection are supplied by Level 1 type fault trees, which model the systems and their associated automatic initiation logic. These probabilities are 0.003 and 0,00018 for low- and high-head flow, respectively [8]. Therefore, the total failure probability of injection for INJ_EARLY_1 is 0.00318.

INJ_EARLY_1: INJ = 0.9968, nINJ = 0.0032

The quantification for INJ_EARLY_2 assumes that the RCS is at low pressure. The scenario considered is recovery from a blackout, so the injection systems were not previously challenged. Since the LHF system is needed to draw suction from the RWST, no credit was taken for HHF availability. Therefore the probability of failure to inject is equal to the probability that LHF fails. As stated above, this probability is 0.003.

INJ_EARLY_2: INJ = 0.997, nINJ = 0.003

BASIC EVENT: INJ_LATE

CET QUESTION NUMBER: 61

DESCRIPTION: Is injection initiated late?

This basic event addresses whether injection will fail to initiate late given ac power is available and the injection systems were not challenged early.

QUANTIFICATION:

The quantification for INJ_LATE assumes that the RCS is at low pressure (by definition, vessel failure has occurred). The scenario considered is late recovery from a blackout, so the injection systems were not previously challenged. Since the LHF system is needed to draw suction from the RWST, no credit was taken for HHF availability. Therefore the probability of failure to inject is equal to the probability that LHF fails.

The probability of failure to initiate low head injection is supplied by Level 1 type fault trees, which model the system and its associated automatic initiation logic. This probability is 0.003 [8].

INJ_LATE: L_INJ = 0.997, nL_INJ = 0.003

BASIC EVENT: QUENCH

CET QUESTION NUMBER: 63

DESCRIPTION: IS THE DEBRIS QUENCHED?

This basic event represents the probability that debris is quenched immediately after vessel failure.

QUANTIFICATION:

Two cases are considered in the basic event quench and are examined below:

- Debris falls into a cavity full of water;
- Debris falls into a dry cavity and then water is added.

Case 1 - Cavity Full of Water

When molten core debris initially contacts water, rapid steam generation at the debris/coolant interface causes course debris fragmentation. This, is turn, exposes a greater debris surface area to coolant which further enhances heat transfer. The confidence one can have that debris fragmentation will result in fully-quenched debris increases as the depth of the pool increases. In particular, experiments and analyses performed at Argonne National Laboratory to address the issue of steam spike [10] indicate highly efficient melt quenching in pools deeper than approx. 0.5 m if particle sizes are sufficiently small (i.e., nominal diameter less than 1 mm). Deeper pools (3 to 5 m) were required to fully quench larger melt particles (up to 10 mm). Based on a review of several international research programs, the Swedish Nuclear Power Inspectorate concluded that "water depths of no less than 4 to 5 meters should be sufficient to make sure that the melt will fragment and quench before reaching the containment floor" [11]. Based on this data and that water in the IP3 cavity will produce deep pools, this basic event is considered likely and given a probability of 0.9.

QUENCH_1: Quench = 0.9, nQuench = 0.1

Case 2 - Water Added to Debris in Dry Cavity

There is no data directly applicable to this case. But it is not believed that fragmentation will be as large for this case, as for the cavity full of water case and therefore may not be as likely to quench. Therefore the probability of this basic event should be lower than for case 1 and was assigned a value of 0.5

QUENCH_2: Quench = 0.5, nQuench = 0.5

BASIC EVENT: RECIRC_EARLY

CET QUESTION NUMBER: 34

DESCRIPTION: Does the operator initiate recirculation early?

This basic event addresses whether the operator fails to initiate recirculation to the RCS prior to vessel failure given that there is water in the containment and recirculation sumps and that power is available.

QUANTIFICATION:

The probability of failure to initiate recirculation prior to vessel failure, given the above conditions, is dominated by the failure of the operator to correctly perform the action under high stress conditions. Using the HEP methodology discussed in the quantification of SPRAY_LATE, the human error probability is 0.052.

RECIRC_EARLY: E_Recrc = 0.948, nE_Recrc = 0.052

BASIC EVENT: RECIRC_FAIL

CET QUESTION NUMBER: 64

DESCRIPTION: Are the recirculation pumps or piping failed by severe accident phenomena?

QUANTIFICATION:

No data exist to quantify this basic event. Detonations in containment, high pressure melt ejection (HPME), and ruptures of the containment were each assigned indeterminate probabilities of failing the recirculation pumps.

Detonations and HPME

RECIRC_FAIL_1: RCRC_Fl = 0.5, RCRCnFl = 0.5

CFE Ruptures

RECIRC_FAIL_2: RCRC_Fl = 0.5, RCRCnFl = 0.5

HPME Event

RECIRC_FAIL_3: RCRC_Fl = 0.5, RCRCnFl = 0.5

BASIC EVENT: RECIRC_LATE

CET QUESTION NUMBER: 65

DESCRIPTION: Does the operator initiate recirculation late?

This basic event addresses whether the operator fails to initiate recirculation to the RCS late, given that power is available, water is in the containment and recirculation sumps, and it was not possible for the operator to initiate recirculation early.

QUANTIFICATION:

The probability of failure to initiate recirculation following vessel failure, given the above conditions, is dominated by the failure of the operator to correctly perform the action under high stress conditions. Using the HEP methodology discussed in the quantification of SPRAY_LATE, the human error probability is 0.052.

RECIRC_LATE: L_Recrc = 0.948, nL_Recrc = 0.052

BASIC EVENT: ROCKET

CET QUESTION NUMBER: 53

DESCRIPTION: Does the vessel act as a rocket and fail the containment?

This basic event addresses whether the vessel will act like a rocket at vessel failure and fail the containment.

QUANTIFICATION:

The conditions necessary for the vessel to act like a rocket include gross failure of the vessel lower head at a high vessel pressure. Both the Surry [1] and the Zion [2] studies assigned a probability of 0.001 to this event. This results indicates that the event is almost impossible, but cannot be ruled out. The same probability was used here.

ROCKET: ROCKET = 0.001, nROCKET = 0.999

BASIC EVENT: SGTR_EARLY

CET QUESTION NUMBER: 26

DESCRIPTION: Do high temperatures induce SGTR?

This basic event addresses whether high gas temperatures in the steam generator will induce a tube rupture.

QUANTIFICATION:

Steam generator tube ruptures can occur in high pressure sequences where hot gases enter the steam generator. Several experts were consulted for the NUREG-1150 study [7]. The experts examined sequences where the RCS pressure was at or near the PORV setpoint and the secondary side of the steam generators was dry. The experts assumed defective tubes in the steam generator were very likely.

The NUREG-1150 results for the probability of an SGTR have a distribution that ranges from 10^{-5} to 0.1208 with a mean value of 0.018. This value was used in both the Zion [2] and Surry [2] PRAs for the probability of tube ruptures occurring, suggesting that an SGTR is extremely unlikely. Therefore, based on our quantification guidelines, a value of 0.01 is assigned to the probability of an SGTR.

SGTR_EARLY_2: E_SGTR = 0.01, nE_SGTR = 0.99

For station blackout scenarios where ac power is recovered early, there is a high likelihood that the operator will initiate auxiliary feedwater, thus precluding an SGTR. For this basic event, the likelihood of the operator failing to initiate auxiliary feedwater is considered with the likelihood of an SGTR occurring. The probability is simply the product of the HEP (see basic event SPRAY_EARLY) of 0.052and the probability of an SGTR, (i.e., 0.052 * 0.01 = 0.0005).

SGTR_EARLY_1: E_SGTR = 0.0005, nE_SGTR = 0.9995

BASIC EVENT: SLUMP

CET QUESTION NUMBER: 41

DESCRIPTION: Does the core slump to the lower head?

This basic event addresses whether the core will slump to the lower head as a large mass, instead of smaller amounts relocating at different times.

QUANTIFICATION:

A basic assumption of the IPE is that if core damage is greater than 20 percent, then all of the core becomes degraded and eventually relocates to the lower head. This basic event describes how the core is relocated to the lower head. A slump of the core implies that the core relocates as a single mass almost simultaneously, with an implicit assumption that the core debris has a high molten fraction. Conversely, no core slump means that the core relocates in a piece-wise fashion and has a low molten fraction.

The way in which the core relocates has a significant impact on other events in the CET. In-vessel steam explosions and HPME were assumed to occur only if the core slumps, since both phenomena are very dependent on the existence of high core molten fractions.

The NUREG-1150 study for the Surry, Zion or Seqouyah PWRs did not address this question completely. The question is only partially addressed by the Peach Bottom study. The Grand Gulf study [3] contains a similar question that asks whether the debris in the lower head has high or low molten fraction. The probability that the debris would have a high molten fraction for situations where injection was provided to the vessel was 0.025. The probability that the debris would have a high molten fraction with no injection was 0.10.

This basic event is divided into three cases, one that has recirculation (SLUMP_1), one that has injection (SLUMP_2), and one that has neither (SLUMP_3). The probabilities for all cases were based on the Grand Gulf data. Core slump with injection or recirculation is assumed to be extremely unlikely. Core slump without injection or recirculation was assumed to be unlikely. Therefore the IPE values are quantified using the Appendix A guidelines as:

Early Recirculation

SLUMP_1: SLUMP = 0.01, nSLUMP = 0.99

Early Injection

SLUMP_2: SLUMP = 0.01, nSLUMP = 0.99

SLUMP_3: SLUMP = 0.1, nSLUMP = 0.9

BASIC EVENT: SORV_EARLY

CET QUESTION NUMBER: 25

DESCRIPTION: Does a PORV stick open while cycling prior to vessel breach?

This basic event addresses whether a PORV will stick open while cycling prior to the breach of the reactor vessel.

QUANTIFICATION:

The primary assumption for this basic event is that the RCS pressure is at the PORV setpoint. Sequences that have either medium or low RCS pressures, or that have the RCS depressurized, or already have a stuck-open PORV were assumed not to challenge (i.e., cycle) the PORVs.

The probability of a PORV sticking open assumed to be 0.025 per challenge. MAAP calculations were examined to determine the number of times the PORVs cycle during blackouts and high pressure transients. This is somewhat difficult, since the plot timestep is not fine enough to always capture the cycling of a PORV. However, the number of cycles is believed to be in the range from about 5 to 50 cycles during most high pressure sequences. This would give a failure probability of approximately 0.1 to 0.5. Since the number of cycles is difficult to determine, and therefore introduces a significant uncertainty, this event was assigned a value of 0.5.

SORV_EARLY: E_SORV = 0.5, nE_SORV = 0.5

EVENT: SPRAY_EARLY

CET QUESTION NUMBER: 31

DESCRIPTION: Do the containment sprays initiate early?

This basic event addresses whether containment sprays initiate during the in-vessel phase of the accident given that containment pressure exceeds the automatic initiation setpoint of 23 psig, ac power is available, and containment spray actuation was not required prior to core damage.

QUANTIFICATION:

The probability of failure to initiate sprays is supplied by a Level 1 type fault tree, which models the containment spray system and its associated automatic initiation logic. This probability is 3.6×10^{-5} [8].

SPRAY_EARLY: E_Spry = 0.999964, nE_Spry = 3.6×10^{-5}

EVENT: SPRAY_LATE

CET QUESTION NUMBER: 69

DESCRIPTION: Operator fails to initiate containment sprays late:

These basic events address whether containment sprays fail to actuate late because of operator error or equipment failure are occasioned by severe accident phenomena. It is assumed that containment pressure exceeds the automatic initiation setpoint of 23 psig and ac power is available.

QUANTIFICATION:

It was assumed that containment sprays following vessel failure would only be available in recirculation mode. This is a modeling assumption, since late injection was given precedence over containment sprays if the RWST inventory was still in the tank. Therefore, operator action would be required to initiate containment sprays.

The probability of failure to initiate is obtained through a human error probability (HEP) calculation using the NUREG/CR-4772 methodology [14]. Following this methodology, and conservatively ignoring credit for operator shift changes, advice from the emergency director, etc., an HEP can be calculated using the following equation:

$$HEP_{TOT} = HEP_D * M_D + \{HEP_{RO} * M_{RO} * HEP_{SRO} * M_{SRO}\}$$

where:

HEPD	Probability of failure to diagnose
HEPRO	Probability of failure to originally complete the task
HEPSRO	Probability of failure of SRO to verify completion of task
M	Multipliers based on error factors corresponding to the above failure probabilities. These multipliers are bases on values suggested in the methodology reference. The multipliers convert failure probabilities from median values to mean values.

For Level 2 analyses, all HEP calculations assume that the operator is under high stress, since core damage has occurred. For step-by-step actions, such as those an operator would perform when following a procedure, the values for HEP_{RO}, M_{RO}, HEP_{SRO}, and M_{SRO} are 0.05, 1.65, 0.5, and 1.25, respectively [14]. In addition, the values for HEP_D and M_D create "Failure to Diagnose" probabilities that are one to two orders of magnitude lower than are created by the

failure of the operator to perform the required action. Therefore, for simplicity, the "Failure to Diagnose" term was ignored. Thus, a constant HEP will be used for all Level 2 analyses. This value is:

HEP = 0.05 * 1.65 * 0.5 * 1.25 = 0.052

The quantification of SPRAY_LATE_1 is for sequences in which the containment reaches 23 psig, which is the level for which spray initiation is required. In addition, either no containment failure occurred or the containment failure was only a leak. Since containment pressure/temperature did not rupture the containment, it was assumed that the containment spray piping and recirculation pumps were not affected by severe accident phenomena. Therefore the probability of failure to initiate sprays is simply the HEP.

SPRAY_LATE_1: L_Spry = 0.948, nL_Spry = 0.052

The quantification of SPRAY_LATE_2 considers the probability that the containment spray piping was ruptured at the same time a containment rupture occurred. Therefore, either a human error or rupture of the piping could prevent spray initiation. It is our judgement that spray piping rupture due to an early containment failure is unlikely. However, since there are no supporting calculations, the quantification guidelines suggest a failure probability of 0.1. Since there are two trains leading to the spray headers, the total failure probability occasioned by containment rupture is the product of the failure probability for each individual train. That is:

0.1 * 0.1 = 0.01.

Since either a human error failure or a "phenomena" failure could cause failure to initiate the sprays, the total failure probability is:

0.052 + 0.01 - (0.052 * 0.01) = 0.061

SPRAY_LATE_2: L_Spry = 0.939, nL_Spry = 0.061

BASIC EVENT: VF

CET QUESTION NUMBER: 47

DESCRIPTION: Does the reactor vessel fail?

This basic event addresses whether the core debris is not cooled in-vessel, and fails the lower head.

QUANTIFICATION:

This basic event can be divided into three cases:

- Injection is provided to the core and less than 20 percent of the core has been degraded.
- In excess of 20 percent of the core has been degraded and ex-vessel heat transfer and containment heat removal occurs.
- In excess of 20 percent of the core has been degraded and either no ex-vessel heat transfer or containment heat removal occurs.

Core Melt < 20%, Injection

No data exits for this case. However, the fact that less than 20 percent of the core has been melted indicates that most of the core has been cooled. Therefore, only a small portion of the core is available to attack the lower head. It was assumed therefore that the likelihood of vessel failure is very low and the probability of failure was assigned a value of 0.05.

VF_1: VF = 0.05, nVF = 0.95

Core Melt > 20%, Ex-vessel heat transfer and containment heat removal

VF_2: VF = 0.0, nVF = 1.0

Core Melt > 20%, no Ex-vessel heat transfer or containment heat removal

VF_2: VF = 1.0, nVF = 0.0

BASIC EVENT: VF_SIZE

CET QUESTION NUMBER: 48

DESCRIPTION: Is vessel failure a gross or penetration failure?

This basic event addresses whether if the vessel fails the failure will either be a gross failure of the lower head or the failure will be in a single lower head penetration.

QUANTIFICATION:

The primary assumption for this question is that vessel failure (if not caused by an alpha mode failure) is due to molten core debris attacking the lower head.

Lower head failure was the subject of expert eliciation in the NUREG-1150 study [3], Issue 6. There was a wide difference of opinion among the experts on the mode of vessel breach. One expert was certain that vessel failure would always be by failure of a penetration. Another expert was the only one who thought that gross bottom head failure was possible. The aggregate results were that gross lower head failure occurred only 13% of the time. Therefore for this basic event, gross failure is considered unlikely and penetration failure likely.

VF_SIZE: VF_Gr = 0.1, VF_Pen = 0.9, nVF = 0.0

APPENDIX M-B

Guidelines for Assigning Conditional Probabilities to CET Events

VALUE	DESCRIPTION
1.	The indicated outcome is certain given the conditions defined for the case in question. Usually this value is reserved for logical outcomes not requiring analysis to support them. Analysis or calculations that are needed to support a certain outcome use only methods appearing in textbooks or peer-reviewed journals. The results of the analysis demonstrate the indicated outcome to be appropriate considering all relevant uncertainties. Other analytical approaches have been considered and these yield the same result or are not applicable. No debate as to the outcome would be expected from individuals who are informed as to the specifics of the case and the associated phenomena.
(1. - 0.001) i.e., 0.999	The indicated outcome is almost certain. Detailed analysis has been performed which addresses all relevant phenomena and has been subjected to independent review. At least one other independent reviewer who has analyzed the situation agrees that the outcome is almost certain. Separate analysis exists that supports this outcome. Consideration of all identified uncertainties has been made and none has been found to have a credible effect on the outcome.
(1. - 0.01) i.e. , 0.99	The indicated outcome is extremely likely. Either detailed analysis has been performed and subjected to independent review or a significant body of directly applicable experimental data published in the technical literature, support this position. The indicated outcome is obtained for all credible assumptions as to the values of parameters in supporting analysis. Arguments against this position are not supported by either analysis or data.

VALUE	DESCRIPTION
(1. - 0.05) i.e., 0.95	The indicated outcome is very likely. Either detailed analysis has been performed and reviewed for completeness or a significant body of relevant experimental data supports this position. Arguments against this position are obviously flawed or data exist that contradict in some measure the arguments presented.
0.9	The indicated outcome is likely. It is supported by analysis or the preponderance of experimental evidence. Arguments against this position are apparently flawed and the technical basis for disagreement with the counter argument has been established. Alternatively, no analysis has been performed but there is general agreement between two or more independent experts that the indicated outcome is appropriate.
0.5	The indicated outcome is fully possible. Either no analysis has been performed or existing analysis is inconclusive. Inconclusive analysis includes that for which no concurrence from an independent party can be gained. Experimental data do not clearly indicate this outcome to be more likely or experiments are obviously no directly pertinent.
0.1	The indicated outcome is unlikely. It cannot be supported by incontrovertible analysis or a preponderance of data. It is, however, a credible outcome when attendant uncertainties are considered.
0.05	The indicated outcome is very unlikely. While analysis cannot rule it out completely, arguments in favor of this outcome are not supported by the available data. At most, a few experiments suggest that this outcome could occur.
0.01	The indicated outcome is extremely unlikely. Uncertainties in the available analysis that show the outcome not to occur can be identified. Consideration of these uncertainties might lead to this outcome but no analytical or experimental support can be found.

VALUE	DESCRIPTION
0.001	The indicated outcome is almost impossible. It has credibility only if a number of unsupported (but not demonstrably incorrect) assumptions are made. No analysis is available to support this result event when relevant uncertainties in the parameters of the analysis are considered.
0.	The indicated outcome is impossible. It is either ruled out by the physical situation or a large body of analysis and experiment support alternate outcomes.

APPENDIX M-C

Probability of Containment Failure Due to Static Over-Pressure

The containment failure curve was generated using data from the EQE overpressure capacity report[1]. The data was used to produce a normal distribution using Lotus 123. The Lotus 123 data is shown below and is shown in Graph form in Figure B1.

LINER TEAR @ MAIN STEAM & FEEDWATER PENETRATIONS (800 F)

Mean Failure Pressure	134 psig
Log Standard Deviation	0.12

Pressure (psig)	Failure Probability	Leak Area* (sq in)	Z	Phi(-Z)
1	0.001	0	-40.815	0.999
50	0.001	0	-8.215	0.999
84.4	0.001	0	-3.852	0.999
90	0.001	0	-3.317	0.999
95	0.002	0	-2.866	0.998
99	0.006	0	-2.523	0.994
100	0.007	0.83	-2.439	0.993
