EXECUTIVE SUMMARY

The objective of this document is to provide traceability and justification for a select few new geochemical data used in the Special Analysis entitled "Special Analysis for the Dose Assessment of the Final Inventories in Center Slit Trenches One through Five" (Collard et al. 2010; SRNL-STI-2010-00760). Most values used in the Special Analysis came from the traditional geochemical data package (Kaplan 2010; SRNL-STI-2009-00473); however, some recent laboratory measurements have made it possible to estimate barium K_d values. Additionally, some recent calculations were made to estimate neptunium K_d values as a function of pH. The assumptions, justifications, and calculations needed to generate these new values are presented in this document, and the values are summarized below.

Rad	Best Sand K_d	Best Clay K_d	High-pH Solution Impact Factor, $f(\text{High-pH})^a$
	(mL/g)	(mL/g)	(unitless)
Ba	15	101	NC ^b
Ra	25	185	NC ^b
Np	NC ^b	NC ^b	20 ^c
Np pH 5.5	3	9	--
Np pH 6	6	18	--
Np pH 6.5	18	54	--
Np pH 7	30	90	--
Np pH 7.5	42	126	--
Np pH 8	50	151	--
Np pH 8.5	55	166	--
Np pH 9	60	180	--
Np pH 10	60	180	--
Np pH 11	60	180	--
Np pH 12	60	180	--
Np pH 12.5	55	166	--

^a $f(\text{High-pH}) = K_{d\text{High-pH}}/K_d$

^b NC = no change in value with respect to the value reported in the original geochemical data package (Kaplan 2010; SRNL-STI-2009-00473)

^c By chemical analogy to Np, Pa as PaO_2^- can be assigned the same "High-pH Solution Impact Factor, $f(\text{High-pH})$ " of 20 (unitless).

1.0 INTRODUCTION

1.1 Objectives

The objectives of this report are twofold.

1. Provide estimates of neptunium (Np) distribution coefficient (K_d) values as a function of pH, which will simulate conditions following *in situ* high-pH injection treatment of a SRS slit trench.
2. Explain sources of new barium (Ba) and radium (Ra) K_d values.

1.2 Np K_d Values as a Function of pH in a High-pH Treated Slit Trench Waste Zone

Np K_d values in SRS sediments were recently measured by Powell et al. (2010a) who reported average values in sandy SRS sediments of 3 mL/g and average values in clayey sediments of 9 mL/g.

Powell (2010) measured Np sorption to an aluminum oxide, boehmite, versus pH (Figure 1-1[A]). Three important features about these data and their implications to SRS data are as follows:

- The NpO_2^+ sorption curve follows the typical behavior of a monovalent in that it had the characteristic sigmoidal curve that showed an increase in sorption with increases in pH; >99% Np sorption was observed between pH 10 and 12.
- A drop in Np sorption is beyond pH 12.4.
- Boehmite is not a common soil mineral, but its sorption behavior relative to metals is similar to that of other iron and aluminum oxyhydroxides (Dixon and Weed 1989). It differs from SRS sediments in the degree of sorption; i.e., the line may shift to the right or left depending on the “point-of-zero-charge” of the solid phase and the height of the sorption maximum. As such, this data must be adjusted for SRS conditions.

The upper plot of Figure 1-1 shows sorption of Np; the experiment was conducted by introducing aqueous Np(V) at various pH conditions to the solid phase, boehmite. Powell has since repeated this Np(V) sorption experiment with boehmite between pH 3.7 and pH 11.0 and under slightly different experimental conditions (Powell et al. 2010b). Though the follow-up study was conducted under slightly different conditions, the results are near identical to those from the original study. The lower plot in Figure 1-1 shows the solubility of Np as a function of pH and was conducted with a solid Np phase. The solubility decreases from pH 6 to 11 and then stabilizes at pH 12, after which it starts to increase.

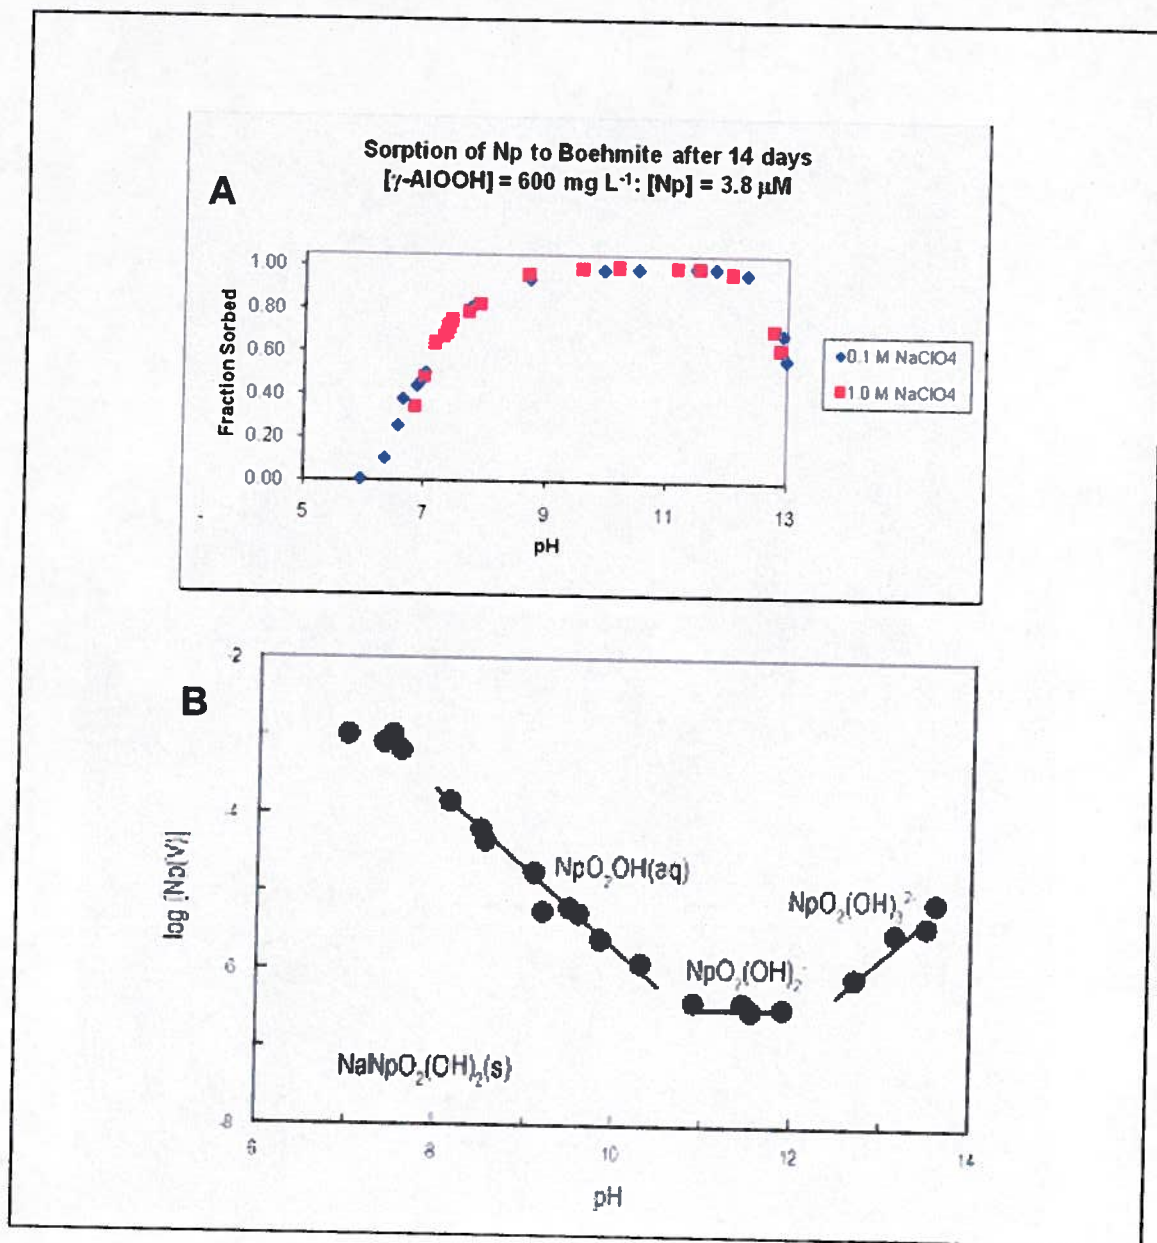

Figure 1-1. (A) Fraction of Aqueous Np(V) Sorbed to Boehmite as a Function of pH, I = 0.1 and 1.0 M NaClO₄, (B) Concentration of Aqueous Np(V) as a Function of pH with NpO₂OH(s) in Solution

Note: Figure 1A from Powell 2010
Figure 1B from Rao et al. 2006

Wong et al. (2009) recently conducted a literature review of Np sorption to cementitious materials. A list of data is presented in Table 1-1. All data seem to indicate that uptake of neptunium on cement materials increases with contact time and is relatively independent of the redox conditions of the experiments. Hoglund et al. (1985) and Bayliss et al. (2000) found that cement/concrete composition had little influence on K_d values.

Sylwester et al. (2000) provided spectroscopic evidence that Np(V), the mobile form of neptunium, is first sorbed on cement followed by reduction to Np(IV), the far less mobile form of neptunium. The mechanism responsible for reduction of neptunium was unclear (no reducing agents were added in the experiments and reducing capacity of the cement is not known). But a very important discovery made was only about six months was required for about half of the Np(V) to be reduced (immobilized) to Np(IV). This same research group published very similar results with a little extra data in a second manuscript by Zhao et al. (2000).

When time is not limiting sorption, neptunium K_d values are typically >1000 mL/g (Table 1-1). This behavior is certainly more characteristic of stronger sorbing Np(IV) than that of Np(V) and is consistent with the spectroscopic findings of Sylwester et al. (2000) and Zhao et al. (2000) that demonstrated that Np(V) reduces to Np(IV).

The above studies link Np reduction to sorption on cementitious solids. However, the transition to more stable Np species is a function of pH, irrespective of the solid phase. Np(IV) is thermodynamically more stable at high pH under the equilibrium redox conditions found in the SRS subsurface. Redox potential in the SRS environment typically ranges from 0.2 to 0.4 volts in pH ~5 groundwater. Figure 1-2 is an Eh-pH diagram of Np. The speciation of Np under high pH conditions in SRS soils is approximately represented by the region within the blue rectangle. Note that redox potential decreases as pH is increased, leading to the reduced Np(IV) form becoming the more stable species. Given these conditions, it is recommended that Np K_d values be increased under high pH conditions.

2.0 RESULTS

2.1 Estimating Neptunium K_d Values as a Function of pH

The following assumptions were made in deriving an estimate of Np K_d values as a function of pH:

1. **The measured K_d for SRS sandy sediment of 3 mL/g and Clay K_d of 9 mL/g (measured in Powell et al. 2010) serves as the lower bound estimate under natural background conditions.**
2. **The upper range K_d 's in a high-pH solution environment are assumed to be 20x greater than the lower bound set at 3 mL/g for sandy sediment and 9 mL/g for clayey sediment. The "20x" value was selected to produce a maximum K_d value of 60 and 180 in sandy and clayey sediments, respectively, to reflect the large increase in sorption observed when Np enters a high pH environment. These values are lower than all values reported in the literature and are therefore conservative for most modeling scenarios (Figure 1-1 and Table 1-1).**
3. **Np sorption to SRS soils is assumed to be similar to boehmite.** Experimental sorption data of Np(V) onto boehmite (α -AlOOH) by Powell (2010) at 0.1 and 1.0 M NaClO₄ (Figure 1-1) were used to provide fraction sorbed as a function of pH. In Figure 1-1, Powell shows essentially complete sorption between pH 10–12.4. This is reinforced by additional experimental data in Powell et al. (2010b) which is provided in Appendix B. Starting with the lower bound K_d measurements (i.e., 3 mL/g for sandy sediment and 9 mL/g for clayey sediment) the maximum sorption at high pH (10 – 12.4) was assumed to be 20x these values (i.e., 60 mL/g for sandy sediment and 180 mL/g for clayey sediment). The K_d 's at other pH values were obtained by scaling these maximum values by the fraction sorbed from the Powell et al. (2010a) data. The resulting K_d data are shown in Figure 2-1 and Table 2-1.

^a Powell (2010)

^b Measured values

2.2 Barium and Radium K_d Values

In the past, the SRS performance assessments have always assumed all IIA elements in the periodic table had the same K_d values as Sr, for which SRS has several good measurements. SRS made this assumption because no actual measurements had been made with the other elements, Be, Mg, Ca, (Sr), Ba, and Ra, listed in increasing atomic weight and, assumed, sorptive strength to soil. As noted in this list, barium exists between Sr and Ra in the periodic table, and based on known first principles of chemical behavior related to its periodicity (where it exists on the periodic chart in relation to other elements), SRS can assume that sorption behavior of Ba will be between that of Sr and Ra (Sr, Ba, and then Ra are directly on top of one another on the periodic chart). Kaplan (2010) reported Sr K_d values of 5 mL/g and 17 mL/g for sand and clay, respectively. Powell et al. (2010a) recently measured similar values. They also measured new Ra K_d values (Table 2-2). From the Sr and Ra K_d values, Ba values were estimated assuming their magnitude were in the middle of the K_d values of Sr and Ra. The result was a Ba sandy sediment K_d value of 15 mL/g and Ba clayey sediment K_d value of 101 mL/g (Table 2-2).

Table 2-2. Recommended K_d Values Based on These Experimental Results Compared with Previously Recommended K_d Values Used in SRS Performance Assessments (Kaplan 2010)

Rad	Recommended Values Based on this Study		Existing Geochemical Data Package SRNL-STI-2009-00473		Comment
	Sand K_d (mL/g)	Clay K_d (mL/g)	Sand K_d (mL/g)	Clay K_d (mL/g)	
Sr	5	17	5	17	No change recommended; K_d 's are highly dependent on ionic strength (Kaplan 2010).
Ba	15	101	5	17	Estimated based on Sr and Ra measured K_d values. Ba K_d values were estimated to be midway between Sr and Ra K_d values.
Ra	25	185	5	17	Ra K_d (ionic strength, ~0.02 M, which approximates that of SRS groundwater) (Powell et al. 2010a)

3.0 CONCLUSIONS

Some new geochemical parameters have been identified in this document. The geochemical values are new to this document or were issued since the writing of the last geochemical data package (Kaplan et al. 2010). The database used to build the sediment K_d table in the geochemical data package (Kaplan et al. 2010) has been updated with this new information (Geochem Data Package 09 v2c.xls) and inserted into Appendix A.

^b New data from this document

APPENDIX B: Figure of Np(V) Sorption to Boehmite as a Function of pH 3.7 to 11.0 (Powell et al. 2010b)

Figure of Sorption of Pu(V) (■,□) and Np(V) (▲) on boehmite after ten days in the absence of α-Hydroxyethane-1,1-diphosphonic Acid (HEDPA). Open symbols represent boehmite-free control solutions. Background solution was 1M NaCl (■) or 1M NaClO₄ (□). The bold arrow indicates the boehmite point-of-zero-salt-effect. Additional solution conditions: $[\gamma\text{-AlOOH}] = 660\text{mgL}^{-1}$; $[\text{Pu(V)}] = 2.1\text{ }\mu\text{M}$; $[\text{Np(V)}] = 10.6\text{ }\mu\text{M}$.
