Availability of Reference Materials Cited in NRC Publications

Most documents cited in NRC publications will be available from one of the following sources:

1. The NRC Public Document Room, 1717 H Street, N.W.
   Washington, DC 20555
2. The Superintendent of Documents, U.S. Government Printing Office, Post Office Box 37082, Washington, DC 20013-7082
3. The National Technical Information Service, Springfield, VA 22161

Although the listing that follows represents the majority of documents cited in NRC publications, it is not intended to be exhaustive.

Referenced documents available for inspection and copying for a fee from the NRC Public Document Room include NRC correspondence and internal NRC memoranda; NRC Office of Inspection and Enforcement bulletins, circulars, information notices, inspection and investigation notices; Licensee Event Reports; vendor reports and correspondence; Commission papers; and applicant and licensee documents and correspondence.

The following documents in the NUREG series are available for purchase from the GPO Sales Program: formal NRC staff and contractor reports, NRC-sponsored conference proceedings, and NRC booklets and brochures. Also available are Regulatory Guides, NRC regulations in the *Code of Federal Regulations,* and *Nuclear Regulatory Commission Issuances.*

Documents available from the National Technical Information Service include NUREG series reports and technical reports prepared by other federal agencies and reports prepared by the Atomic Energy Commission, forerunner agency to the Nuclear Regulatory Commission.

Documents available from public and special technical libraries include all open literature items, such as books, journal and periodical articles, and transactions. *Federal Register* notices, federal and state legislation, and congressional reports can usually be obtained from these libraries.

Documents such as theses, dissertations, foreign reports and translations, and non-NRC conference proceedings are available for purchase from the organization sponsoring the publication cited.

Single copies of NRC draft reports are available free, to the extent of supply, upon written request to the Division of Technical Information and Document Control, U.S. Nuclear Regulatory Commission, Washington, DC 20555.

Copies of industry codes and standards used in a substantive manner in the NRC regulatory process are maintained at the NRC Library, 7920 Norfolk Avenue, Bethesda, Maryland, and are available there for reference use by the public. Codes and standards are usually copyrighted and may be purchased from the originating organization or, if they are American National Standards, from the American National Standards Institute, 1430 Broadway, New York, NY 10018.

ABSTRACT

This report presents results of analyses of the environmental releases of fission products (source terms) for severe accident scenarios in a pressurized water reactor with a large dry containment. The analyses were performed to support the Severe Accident Risk Reduction/Risk Rebaselining Program (SARRP) which is being undertaken for the U.S. Nuclear Regulatory Commission by Sandia National Laboratories. In the SARRP program, risk estimates are being generated for a number of reference plant designs. The Zion plant has been used in this study as an example of a large dry containment PWR design.

1. INTRODUCTION

This report presents results of analyses of the environmental releases of fission products (source terms) for severe accident scenarios in a pressurized water reactor with a large dry containment. The analyses were performed to support the Severe Accident Risk Reduction/Risk Rebaselining Program (SARRP) which is being undertaken for the U.S. Nuclear Regulatory Commission by Sandia National Laboratories. In the SARRP program, risk estimates are being generated for a number of reference plant designs. The Zion Plant has been used in this study as an example of a large dry containment PWR design.

All of the analyses in this report have been performed with an interim version of the Source Term Code Package[1]. These results supplement analyses reported in BMI-2104 Volume VI[2] using essentially the same codes as in the code package but in their stand-alone forms.

---

* This work was funded under subcontract to Sandia National Laboratories.

2. GENERAL APPROACH

The accident scenarios analyzed in this report were selected as potential contributors to the risk profile of the Zion plant. Based on the results of these scenarios, source term bins* will be developed by Sandia National Laboratories which describe the timing, quantity, and characteristics of the release of fission products to the environment.

The methods of analysis used to predict fission product release and transport behavior are essentially the same as those presented in NUREG-0956, "Reassessment of the Technical Basis for Estimating Source Terms"(3). These computer codes have been assembled as a Source Term Code Package which is scheduled for public release in the spring of 1986. An interim version of the code was used in this study.

2.1 Source Term Code Package

A number of changes have been made in the process of integrating the BMI-2104 source term codes into a Source Term Code Package. Many of these changes merely simplify the use of the codes by streamlining and automating the data transfer between codes. Some of the changes, however, involve actual improvements in the models or in the coupling between models.

Figure 2.1 illustrates the manner in which the codes are grouped in the Source Term Code Package. The MARCH 2(4), CORSOR(5), and CORCON-Mod 2(6) codes are now coupled. The CORSOR-M version of the CORSOR code, which uses an Arrhenius form for the empirical correlation, has been incorporated into MARCH. A consistent treatment can now be made of the release of fission products and the transport of sources of decay heat from the fuel. Based on model improvements suggested by ORNL, the release rates of silver and indium from control rods has been reduced substantially from those in the earlier version of CORSOR. Similarly, CORCON-Mod 2 is now used in the code package to

---

* Each of the accident scenarios identified by the Accident Sequence Evaluation Program (ASEP) and the Severe Accident Risk Reduction/Risk Rebaselining Program (SARRP) is mapped to one of the source term bins in the process of developing the risk profile for the plant.

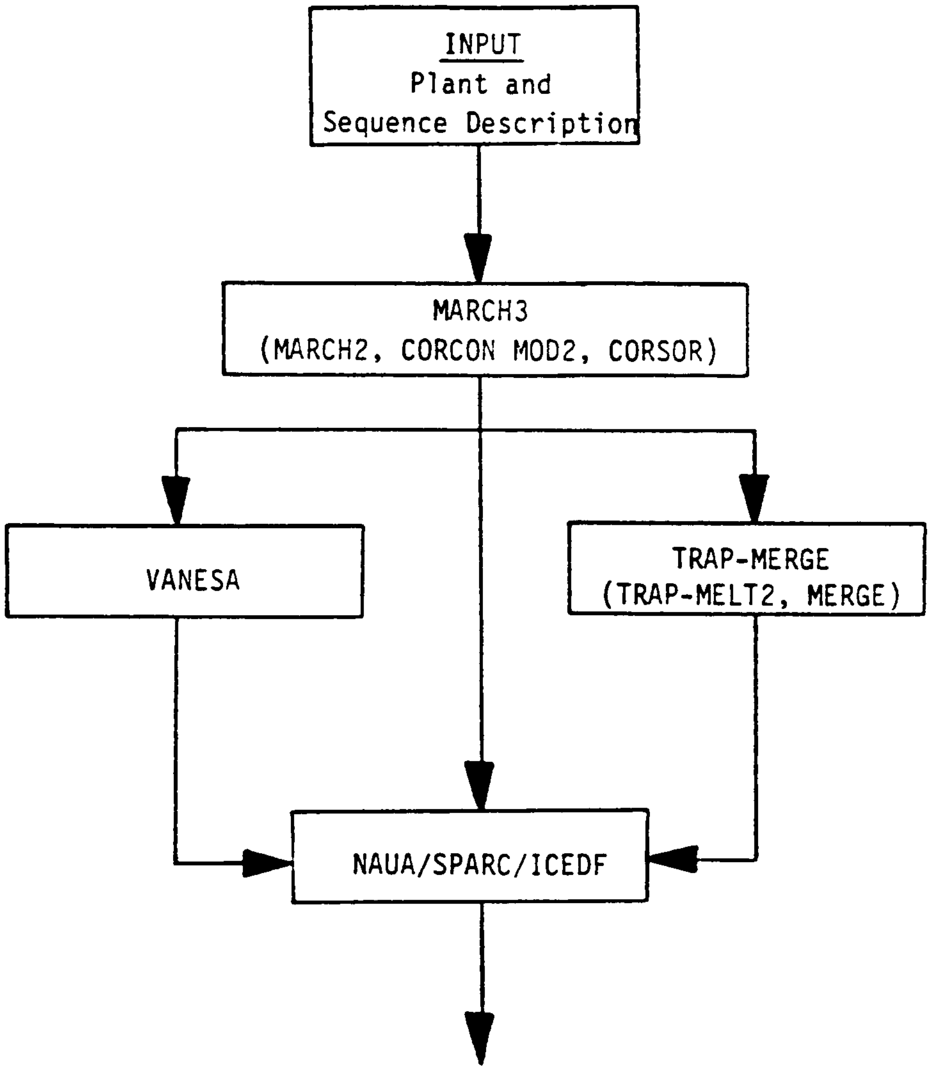

FIGURE 2.1. SOURCE TERM CODE PACKAGE

predict the thermal-hydraulic loads on containment due to core-concrete interactions and as input to the VANESA[7] code to calculate fission product release. In BMI-2104 these processes were treated in a potentially inconsistent manner with two different models, INTER[4] and CORCON-Mod 1[8].

Potentially significant changes also resulted from the intimate coupling of the MERGE[9] and TRAP-MELT[10] codes in the code package. The most important of these are listed below and should be kept in mind when comparing the present results to results presented in BMI-2104 for equivalent accident sequences:

- The decay heat contribution to the thermal hydraulics of the RCS is now considered.

- The fission product transport calculations (TRAP) are nodalized congruently with the thermal hydraulic calculations (MERGE). This includes the use of structures in control volumes that define the boundaries of convective, mixing flow. Previously, distinct structures had to be nodalized as consecutive control volumes.

- Gas properties used in TRAP are those calculated by MERGE and now account for the presence of hydrogen.

- Heat transfer coefficients used in TRAP are supplied by MERGE; mass transfer is based on those using the Chilton-Colburn analogy.

- Aerosol particles are allowed to fall back to upstream volumes if orientation and geometry permit.

- Aerosol particles settling into the melt are instantaneously revaporized by species constituents with condensed vapors revolatilizing as vapors and particles regenerating as particles with nucleation size.

- The treatment of chemisorption on walls now accounts for gas-phase mass transport, which can be limiting for some flows, especially for the highly reactive Te species.

Each of the other codes is run separately in the Code Package. In general, the interfaces between the codes have been automated so that an output file from one code is used as the input file for the next.

2.2 Radionuclide Groups

Initially in the BMI-2104 analyses, four groups of radionuclides were tracked: iodine, cesium, tellurium, and gross aerosols. In order to facilitate ex-plant consequence analyses, the groupings were subsequently changed to the WASH-1400(11) structure: noble gases, iodine, cesium, tellurium, strontium, ruthenium, and lanthanum. In both cases the element named actually represented a group of elements with similar chemical behavior. For the current study, the NRC recommended that two of the WASH-1400 groups (strontium and lanthanum) be further subdivided. Table 2.1 identifies the radionuclide groups used in this study and the additional elements represented by each group. Additionally, the inert aerosols generated in-vessel and those generated ex-vessel are tracked as separate groups. A tracer has also been used in the NAUA(12) calculations to permit a direct heating source term to be assessed at a later date if necessary. A massless source of strength unity is introduced into the containment at the time of vessel failure. The fractional release to the environment of this simulated source is determined as a function of time in the same manner as for the different groups of radionuclides.

3. DESCRIPTION OF PLANT AND ACCIDENT SCENARIOS

The representation of the Zion plant for the present analyses was essentially identical to that previously developed in BMI-2104, Volume VI.

3.1 Accident Scenarios Considered

The accident sequences selected for detailed source term calculations were based on preliminary Accident Sequence Evaluation Program (ASEP) results for accident sequence probabilities and preliminary SARRP containment event tree branching probabilities.

The S2DCr sequence is initiated by rupture of the primary coolant pump seals and is accompanied by failure of the emergency core cooling injection as well as containment spray recirculation systems. The containment fan coolers are initially operable, but are assumed to fail at the time of reactor vessel failure. Late overpressure failure has been selected as the containment failure mode of interest for this sequence. The operation of the containment sprays in the injection mode results in a wet reactor cavity in this sequence; the evaporation of this water by the core debris is the major source of long term containment pressurization.

The S2DCirFir sequence is initiated by primary pump seal rupture and is accompanied by failures of emergency core cooling, containment sprays, as well as containment coolers. Two containment failure modes have been selected for analysis for this sequence: an early containment failure due to hydrogen burning and/or direct heating, and a late failure due to a delayed hydrogen burn or overpressurization.

The TMLU sequence is initiated by a transient and is accompanied by the loss of the power conversion, auxiliary feedwater, and emergency core cooling systems; both the containment coolers and sprays are available in this case. The early containment failure mode selected for analysis is the result of direct heating of the containment atmosphere by the core debris.

3.2 Primary System Flowpaths

The most likely small break initiator has been indicated to be rupture of the primary pump seals; this is the failure mode assumed in the present analyses. Figure 3.1 illustrates the flowpaths for fission products within the primary system for the pump seal LOCA scenarios. The TRAP-MERGE control volume breakdown used for these sequences is illustrated in Figure 3.2.

In the TMLU scenario the primary coolant would be boiled off through the pressurizer relief valve. The primary system fission product flowpath for this sequence is illustrated in Figure 3.3. The TRAP-MERGE control volume breakdown is given in Figure 3.4.

3.3 Containment Flowpaths

The Zion reactor building is treated as a single well mixed volume in these analyses. Thus any fission products released to the containment atmosphere are assumed to mix instantaneously with the contents of the containment. After containment failure airborne activity is calculated to leak out of the containment based on orifice flow. After the initial rapid depressurization the leak rate is largely governed by the available driving forces, i.e., gas and vapor generation.

3.4 Containment Failure Mode and Pressure Level

The Zion containment is a pre-stressed concrete design with post tensioning. A number of analyses have been made of the failure pressure including an evaluation in the utility sponsored PRA[13] and by the Los Alamos National Laboratory in support of the Zion/Indian Point Study[14]. A value of 149 psia was used as the failure pressure in these analyses. An opening size of 7 ft^2 was assumed in calculating leakage to the environment.

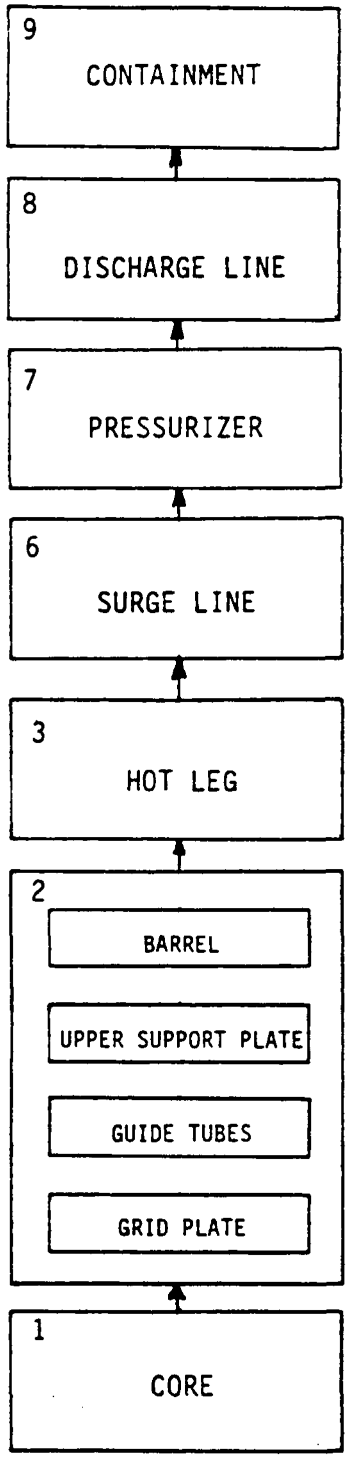

FIGURE 3.4. SCHEMATIC OF TRAP-MERGE CONTROL VOLUMES FOR TMLU SEQUENCE

4. BASES FOR TRANSPORT CALCULATIONS

4.1 Phenomenological Modeling Assumptions

As previously indicated, by far the most likely small break initiator has been identified to be failure of the primary coolant pump seals. Failure of all four pump seals has been predicted to result in a leak rate of 1800 gallons per minute from the primary system. In the MARCH analyses the failed pump seals were represented by a hole 0.0111 square feet in area; this hole size gave the above leak rate of subcooled water at normal reactor operating conditions.

The early containment failure modes identified for source term analyses represent very low probability outcomes for these sequences. The loadings required to fail the Zion containment are considered to be unlikely. However, direct interaction between dispersed hot core debris and the containment atmosphere is believed to be a possible mechanism for achieving such loadings. MARCH 3 does not contain models for the direct interaction of the core debris with the containment atmosphere. In order to calculate containment loads and containment conditions that would be consistent with the postulated failure of the Zion containment, the control parameters for the reactor cavity and hydrogen combustion models in MARCH were selected to enhance hydrogen and steam generation as well as to promote hydrogen combustion. The parameters selected served to approximate the high temperatures and pressures that would be encountered in the event of direct heating; these model input choices should not be construed as being representative of most likely or expected behavior.

4.2 Results of Thermal Hydraulic Analyses

4.2.1 S_2DC_r Sequence

In this sequence, as it has been considered here, the accident is initiated by the failure of the primary coolant pump seals and is accompanied by failure of emergency core cooling injection and containment spray recirculation systems. The containment building coolers are initially operational but are assumed to fail at the time of reactor vessel failure; the latter would be an accident induced failure. The accident event times as calculated by MARCH 3 are given in Table 4.1. Core and primary system conditions at key times in the accident sequence are presented in Table 4.2; containment conditions are summarized in Table 4.3.

Figure 4.1 illustrates the primary system pressure response for this sequence. The corresponding primary system leak rates and water inventories are given in Figures 4.2 and 4.3, respectively. The primary system pressure drops rapidly from the normal operating level to saturated conditions and is maintained essentially constant at that level as long as the break (pump seal) is water covered. When sufficient inventory is lost to uncover the break the leak flow switches to steam; the latter is clearly reflected by the change in the calculated leak rate. Due to the relatively small opening in the system, the pressure remains at high levels throughout the entire in-vessel portion of the accident. The changes in the leak flow are reflected in the time dependent water inventory illustrated in Figure 4.3.

The maximum and average core temperatures for this sequence are illustrated in Figure 4.4. Initially the core temperatures drop from their operating levels to near the water temperature. At decay heating levels all the heat generation can be removed from the water covered core with only small temperature differences. As the core uncovers the temperatures begin to rise. The maximum temperature in the core is seen to arrest at the input specified effective liquidus temperature, except for brief excursions due to metal-water reactions as molten fuel relocates within the core. The average temperature of the core is seen to increase monotonically up to the point of core collapse. Beyond that point the individual core node temperatures are no longer defined. The fractions of cladding reacted and core melted are illustrated in Figure 4.5.

The average temperature of the gases leaving the core and that leaving the primary system during this sequence as calculated by MARCH 3 are illustrated in Figure 4.6. It is noteworthy that by the time the hot gases reach the break in the primary system and enter the containment their temperature is quite low. The temperature histories of some of the primary system structures are illustrated in Figure 4.7. Based on the MARCH modeling, only the first structure immediately above the core experiences high

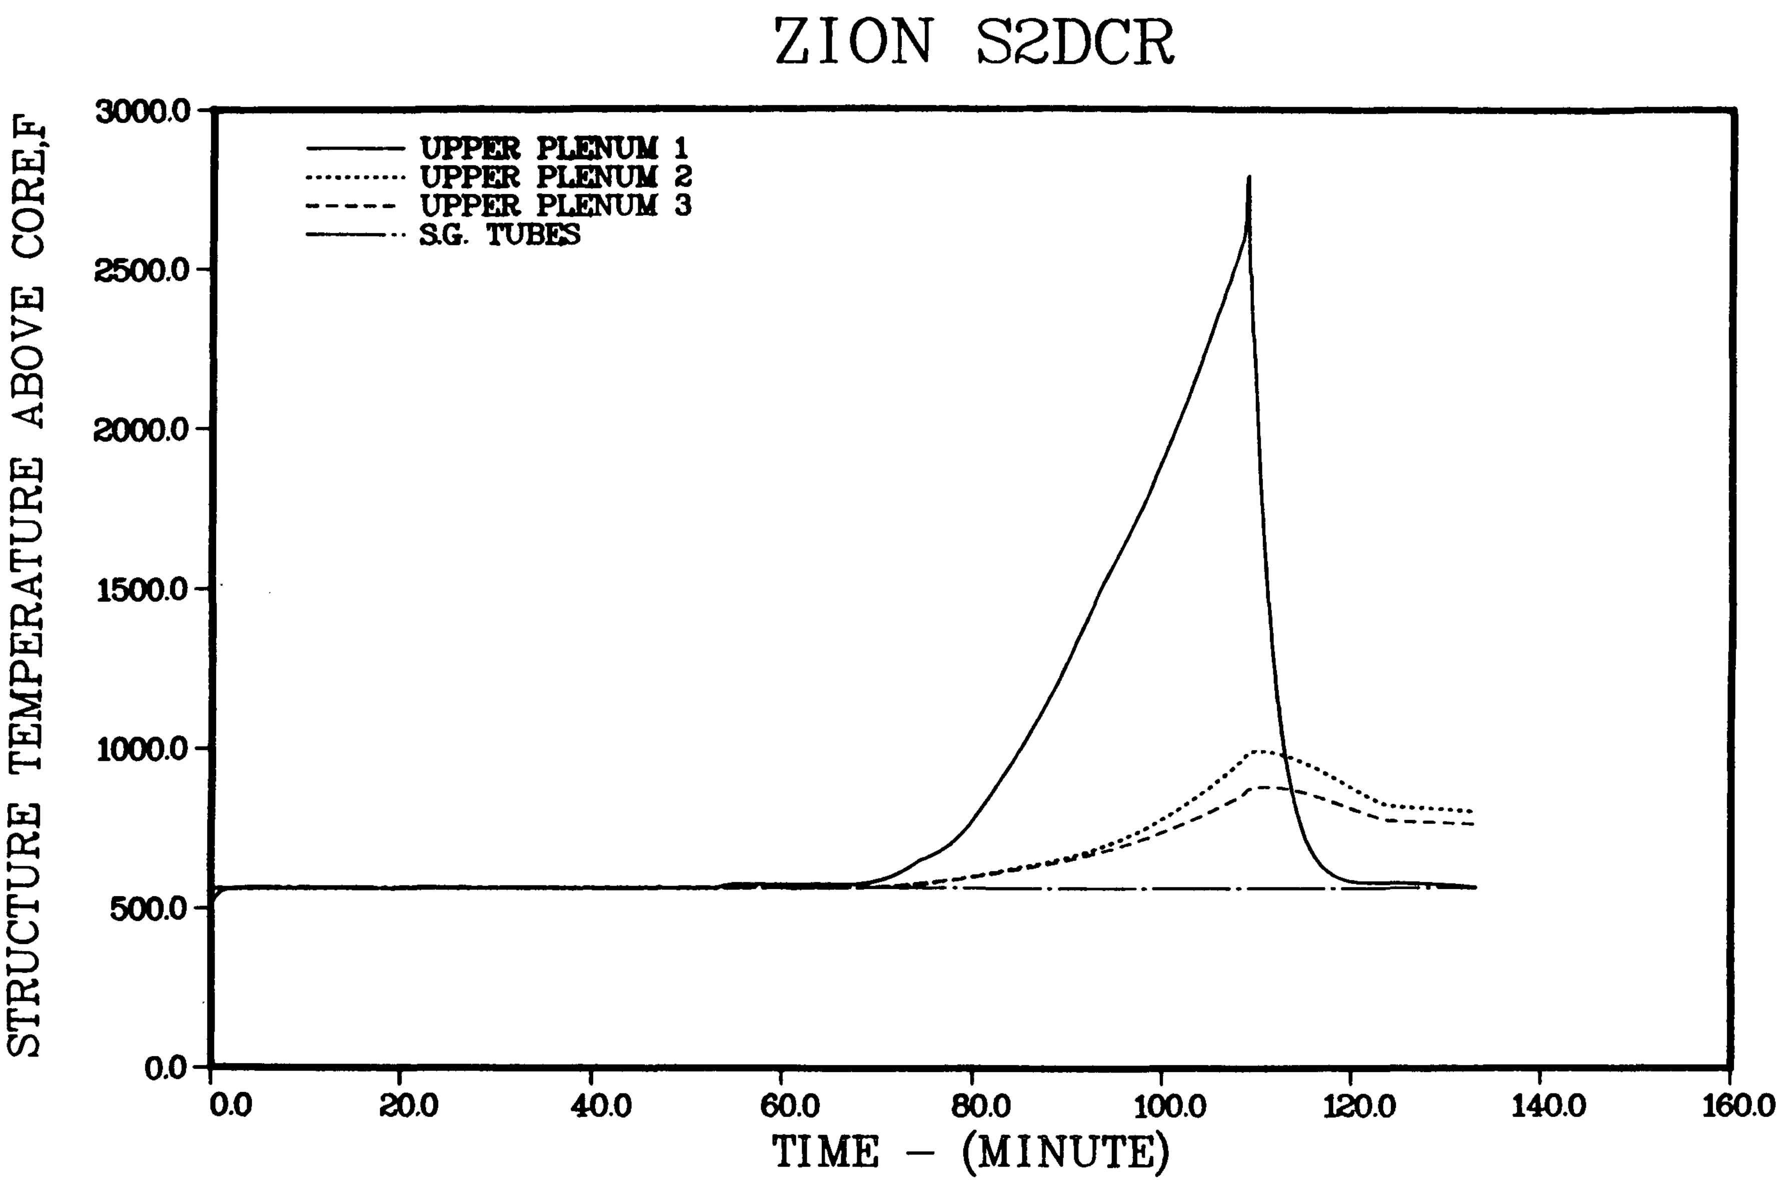

FIGURE 4.7 PRIMARY SYSTEM STRUCTURE TEMPERATURES FOR S_2DC_R

temperatures, with structures further downstream of the core experiencing only modest heating. The steam generator tubes in this sequence remain water filled and do not see any temperature increase. The MARCH 3 modeling of the primary system is based on once-through flow of gases and does not attempt to take into account possible recirculation of hot gases within the primary system. While such recirculation has been postulated to be important in certain transient events, it is doubtful that such recirculation flows could be established in this scenario with its continuing blowdown of the primary system inventory.

The containment pressure and temperature responses for this sequence are illustrated in Figures 4.8 and 4.9; the containment sump and reactor cavity water inventories and temperatures are given in Figures 4.10 and 4.11, respectively. The initial operation of the containment coolers in this sequence maintains the containment pressure below the assumed spray initiation setpoint of 25 psia until the time of vessel failure. Vessel failure is followed by the assumed failure of the building coolers and the initiation of the containment sprays. Thus only a small containment pressure rise is predicted immediately after vessel failure. A subsequent larger pressure excursion is predicted due to hydrogen combustion, but this pressure increase is quickly reduced by the containment sprays. The operation of the containment sprays is also reflected in the containment sump and reactor cavity water inventories illustrated in Figure 4.10.

At early times in the sequence the inventory of water in the sump originates from blowdown water from the primary system and condensate from the containment coolers. As the water on the containment floor builds up it begins to overflow into the reactor cavity, but up to the time of vessel failure the total quantity of water in the containment is limited. The actuation of the containment sprays following vessel failure together with the accumulator discharge result in the flooding of the reactor cavity and a rapid increase in the quantity of water on the containment floor. The sprays fail upon switchover to the recirculation mode. As the water in the reactor cavity is boiled off by the core debris, the reactor cavity is kept full by overflow from the containment sump; this is illustrated by the continuing decrease in the sump inventory following spray failure. As can be seen in Figure 4.11, the sump water remains relatively cold while that in the reactor cavity is

heated to saturation. Following containment failure the cavity water temperature decreases due to flashing.

The predicted progression of concrete attack is illustrated in Figure 4.12. The total volume of gases leaked from the containment is illustrated in Figure 4.13. The time dependent containment leak rates used as input in the NAUA analyses of containment fission product transport are given in Table 4.4. The MARCH 3 calculated distribution of the noble gases during this sequence is illustrated in Figure 4.14.

4.2.2 $S_2DC_{ir}F_{ir}$ Sequence

The $S_2DC_{ir}F_{ir}$ sequence is initiated by the failure of the primary coolant pump seals and is accompanied by failures of emergency core cooling injection and both the containment sprays and coolers. The primary system behavior for this sequence is identical to that of the preceding S_2DC_r sequence and the discussion will not be repeated. Two containment failure modes have been examined for this sequence; these are described below.

The early containment failure considered for this sequence (designated by S_2DCF_1) is assumed to be the consequence of a combination of hydrogen combustion and direct heating of the containment atmosphere by the core debris. The accident event times for this scenario are summarized in Table 4.1. Core and primary system conditions at key times can be found in Table 4.2, and containment conditions are summarized in Table 4.3.

Since MARCH 3 does not have explicit modeling of the direct interaction of the core debris with the containment atmosphere, the conditions arising from such interactions were approximated by use of existing debris-water interaction and hydrogen combustion models, notably by inputs to these models designed to enhance containment pressure generation. Specifically, a very small debris particle size was used for the debris-water interaction in the reactor cavity, and the steam inerting criterion for hydrogen-oxygen recombination in the containment atmosphere was removed. The results of these input choices are conceptually consistent with those expected from the dispersal of a large fraction of the core into the containment atmosphere. While attack of the concrete has been assumed in these analyses, it is also

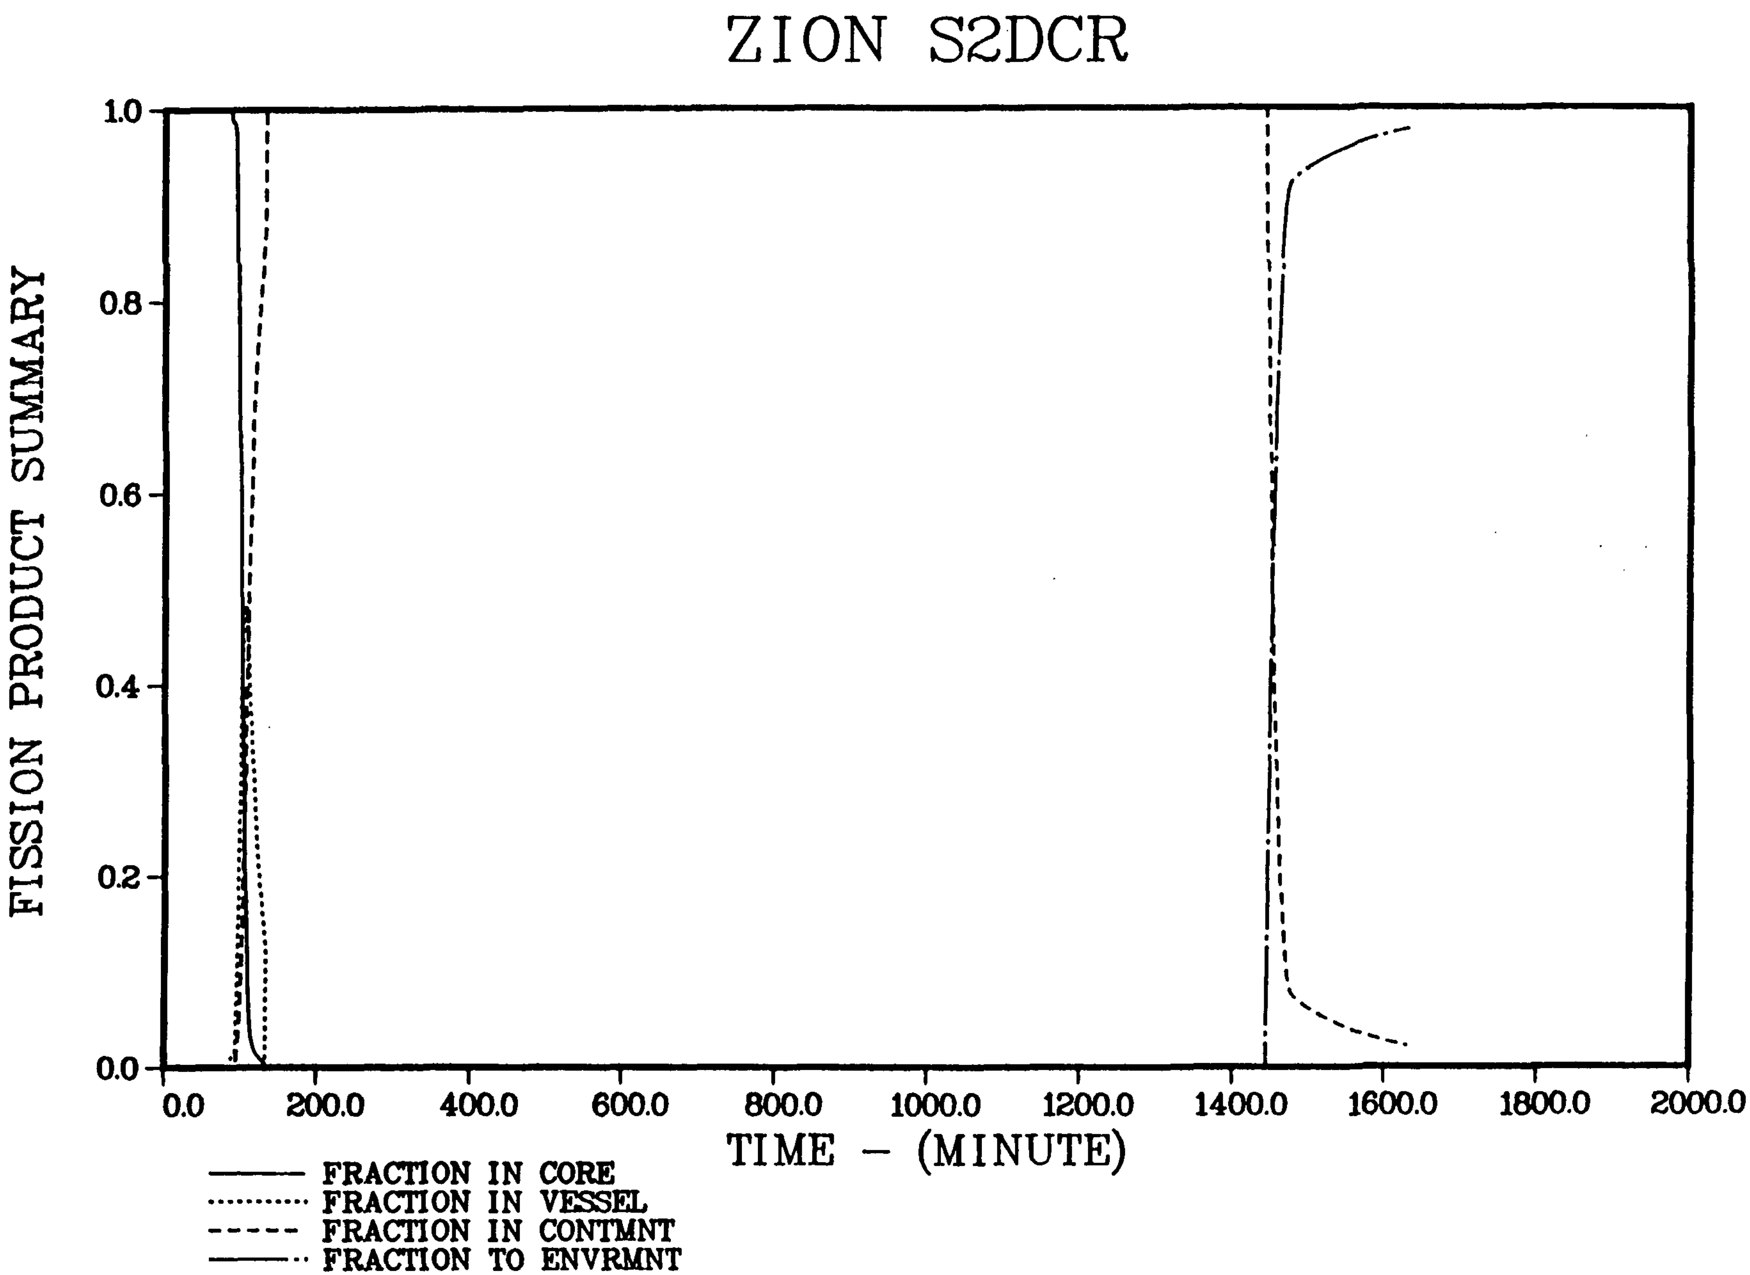

FIGURE 4.14. NOBLE GAS DISTRIBUTIONS FOR S_2DC_R SEQUENCE

possible that the widespread dispersal of the core debris throughout the containment implied for this scenario would preclude significant corium-concrete interactions.

The calculated containment pressure and temperature responses associated with early containment failure for this sequence are illustrated in Figures 4.15 and 4.16. The combination of a large steam spike together with hydrogen-oxygen recombination raises the containment pressure beyond the nominal failure level.

The containment sump and reactor cavity water inventories and temperatures are illustrated in Figures 4.17 and 4.18. Because of the inoperability of both the emergency core cooling as well as spray injection systems in this scenario the total quantity of water in the containment is limited to that initially in the primary system and the accumulators. Up to the time of reactor vessel failure the amount of water in the reactor cavity is quite limited. Accumulator discharge following head failure leads to a rapid increase in reactor cavity water, but most of this water is evaporated in the ensuing interaction with the core debris. The quantity of water evaporated rapidly is limited by the stored energy in the core debris, and complete boiloff of cavity water is delayed until the debris reheat. Similarly, the attack of the concrete is delayed until the debris reheat, as is illustrated in Figure 4.19.

The total volume of gases leaked from the containment for this scenario is illustrated in Figure 4.20. The time dependent leak rates used as input to the containment fission product transport analyses are given in Table 4.4. The MARCH 3 calculated noble gas distributions are illustrated in Figure 4.21.

The late containment failure mode initially selected for analysis for the $S_2DC_{ir}F_{ir}$ sequence (designated as S_2DCF_1) was based on the assumption of a late hydrogen burn. The latter presupposed buildup of a high concentration of hydrogen and the condensation of sufficient steam to permit combustion late in the accident sequence. Initial MARCH 3 analyses of such a scenario did not support the hypothesis of a large delayed hydrogen burn, indicating that combustion would be precluded by continuing high partial pressures of steam. As the steam in the containment atmosphere condensed on containment structures it would run down to the containment sump. Since the

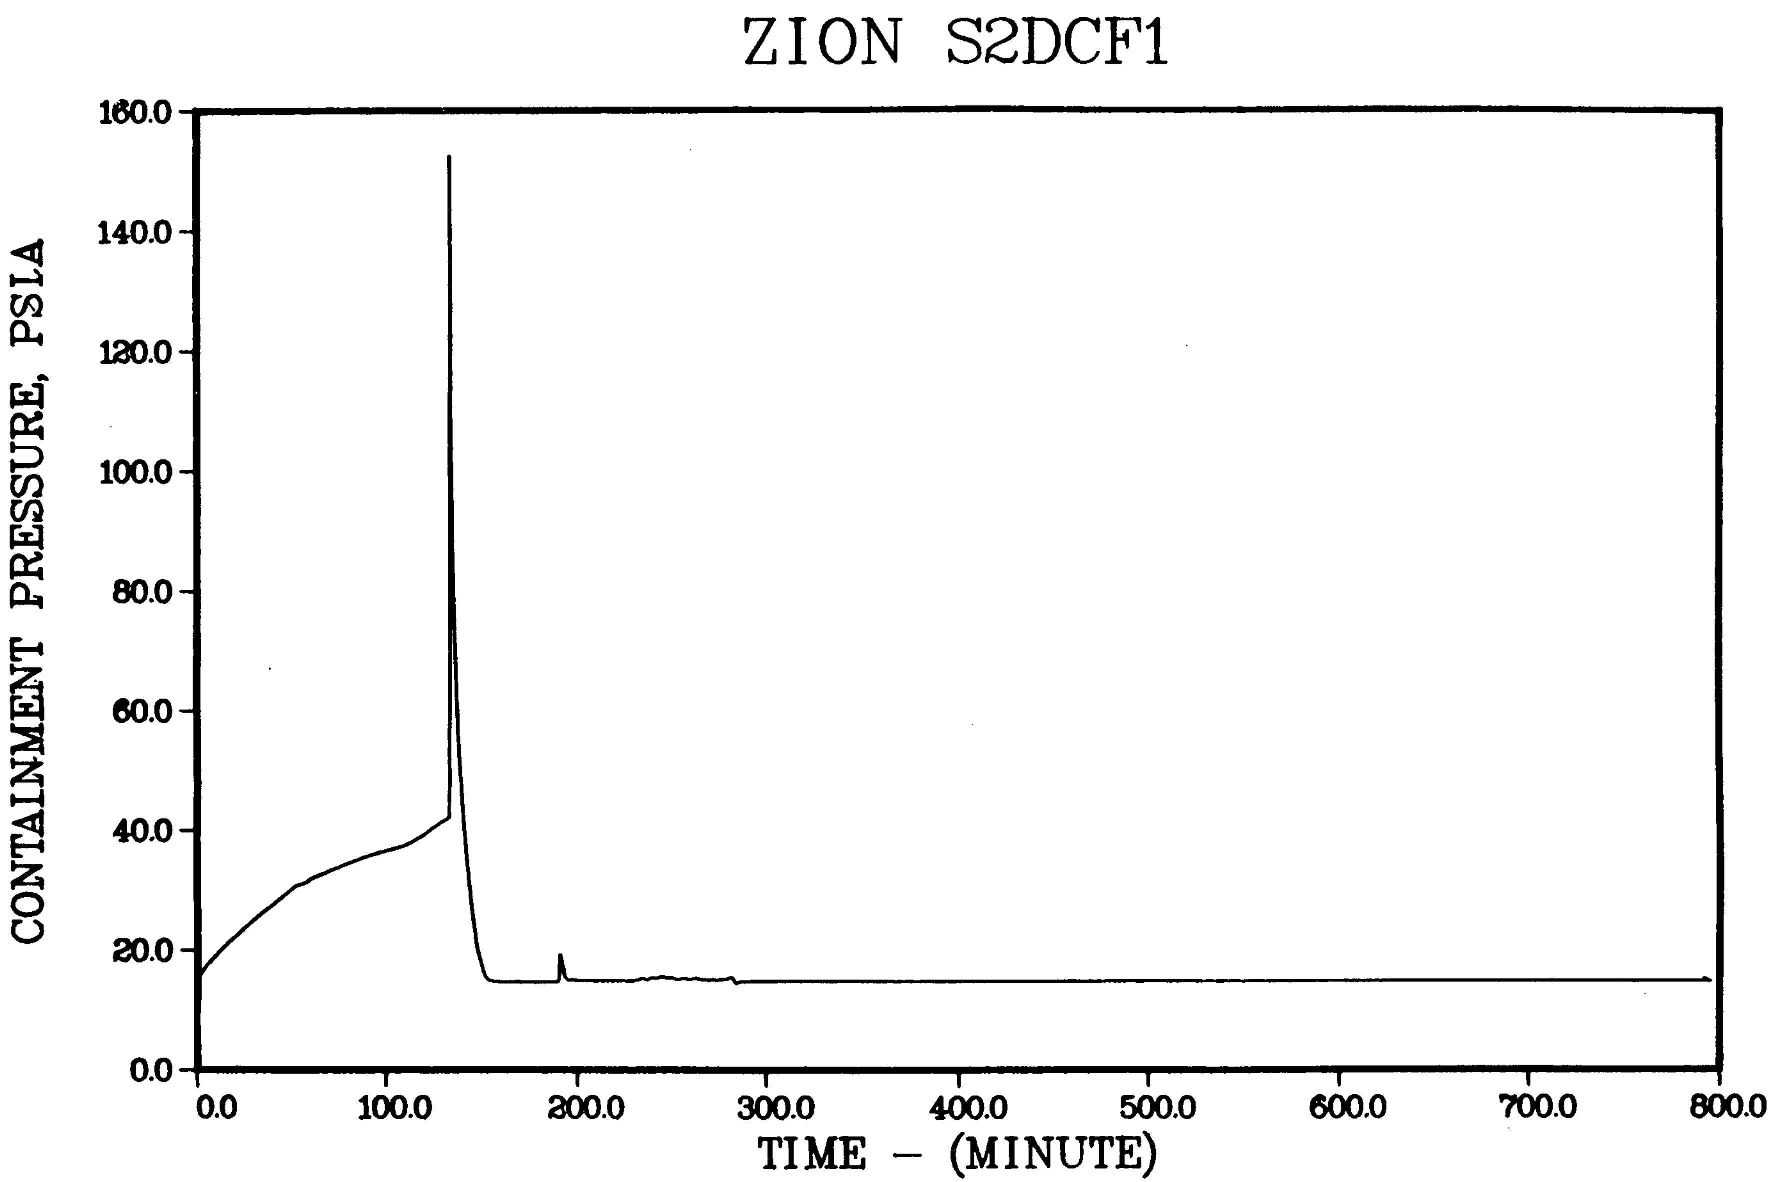

FIGURE 4.15. CONTAINMENT PRESSURE RESPONSE FOR S_2DCF SEQUENCE WITH EARLY CONTAINMENT FAILURE

WITH EARLY CONTAINMENT FAILURE

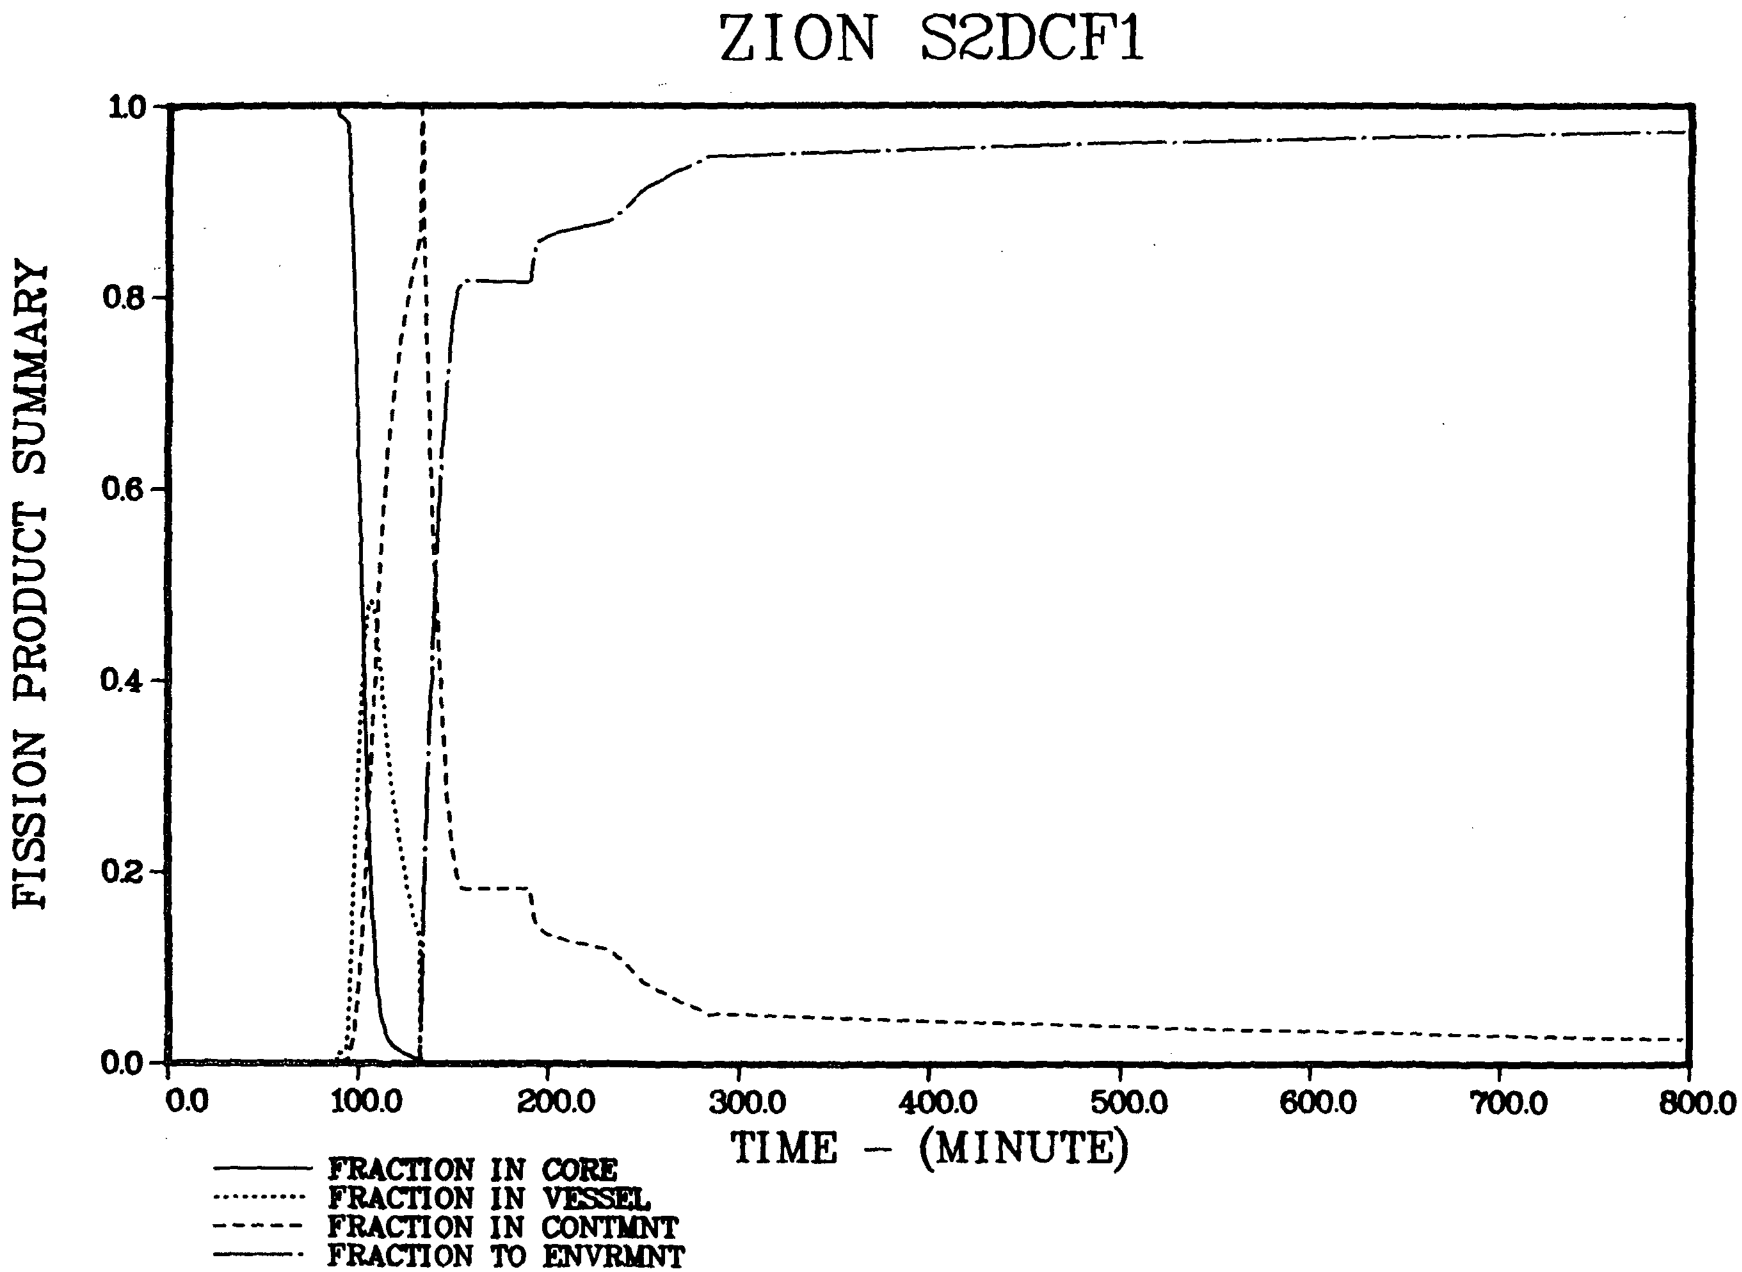

FIGURE 4.21. NOBLE GAS DISTRIBUTIONS FOR S_2DCF SEQUENCE WITH EARLY CONTAINMENT FAILURE

containment floor, including the sump, can only hold a limited quantity of water without overflow into the reactor cavity, some of the condensed water would return to the cavity to be reevaporated. Thus a high partial pressure of steam in the containment atmosphere was indicated for prolonged periods of time. Also, since all the water in the containment did not come into contact with the core debris in the reactor cavity, not all of it could be evaporated. Thus the predicted pressure rise in the containment was limited to well below the nominal failure level for this containment for an extended period of accident time. This conclusion is quite consistent with the results for the TMLB scenario in BMI-2104.

To satisfy the identified need for a late containment failure for this sequence the MARCH 3 calculation was set up assuming that all the water on the containment floor could enter the reactor cavity. This may be regarded as an approximation of the situation in which a significant fraction of the core debris is expelled from the reactor cavity and can thus boil the water on the containment floor. It will be recalled that MARCH does not provide a capability for explicitly distributing the core debris to various parts of the containment. Another way of achieving the desired late containment failure would have been to assume that the containment sprays or coolers were recovered at some time late in the accident; the condensation of steam by sprays or coolers would have brought the containment atmosphere into the flammable range.

The accident event times for the late containment failure scenario as described above are given in Table 4.1. Core and primary system conditions are again the same as for S_2DC_r and are given in Table 4.2. The containment conditions at key times during the accident sequence are summarized in Table 4.3.

The predicted containment pressure and temperature responses for the $S_2DC_{ir}F_{ir}$ sequence with late containment failure are illustrated in Figures 4.22 and 4.23. The containment sump and reactor cavity water inventories and water temperatures are given in Figures 4.24 and 4.25, respectively. As noted above, for the time period after reactor vessel failure it was assumed that the core debris would come into contact with all the water on the containment floor; this is reflected in Figure 4.24 as the sump water flowing into the reactor cavity. The essentially constant decrease in the containment water

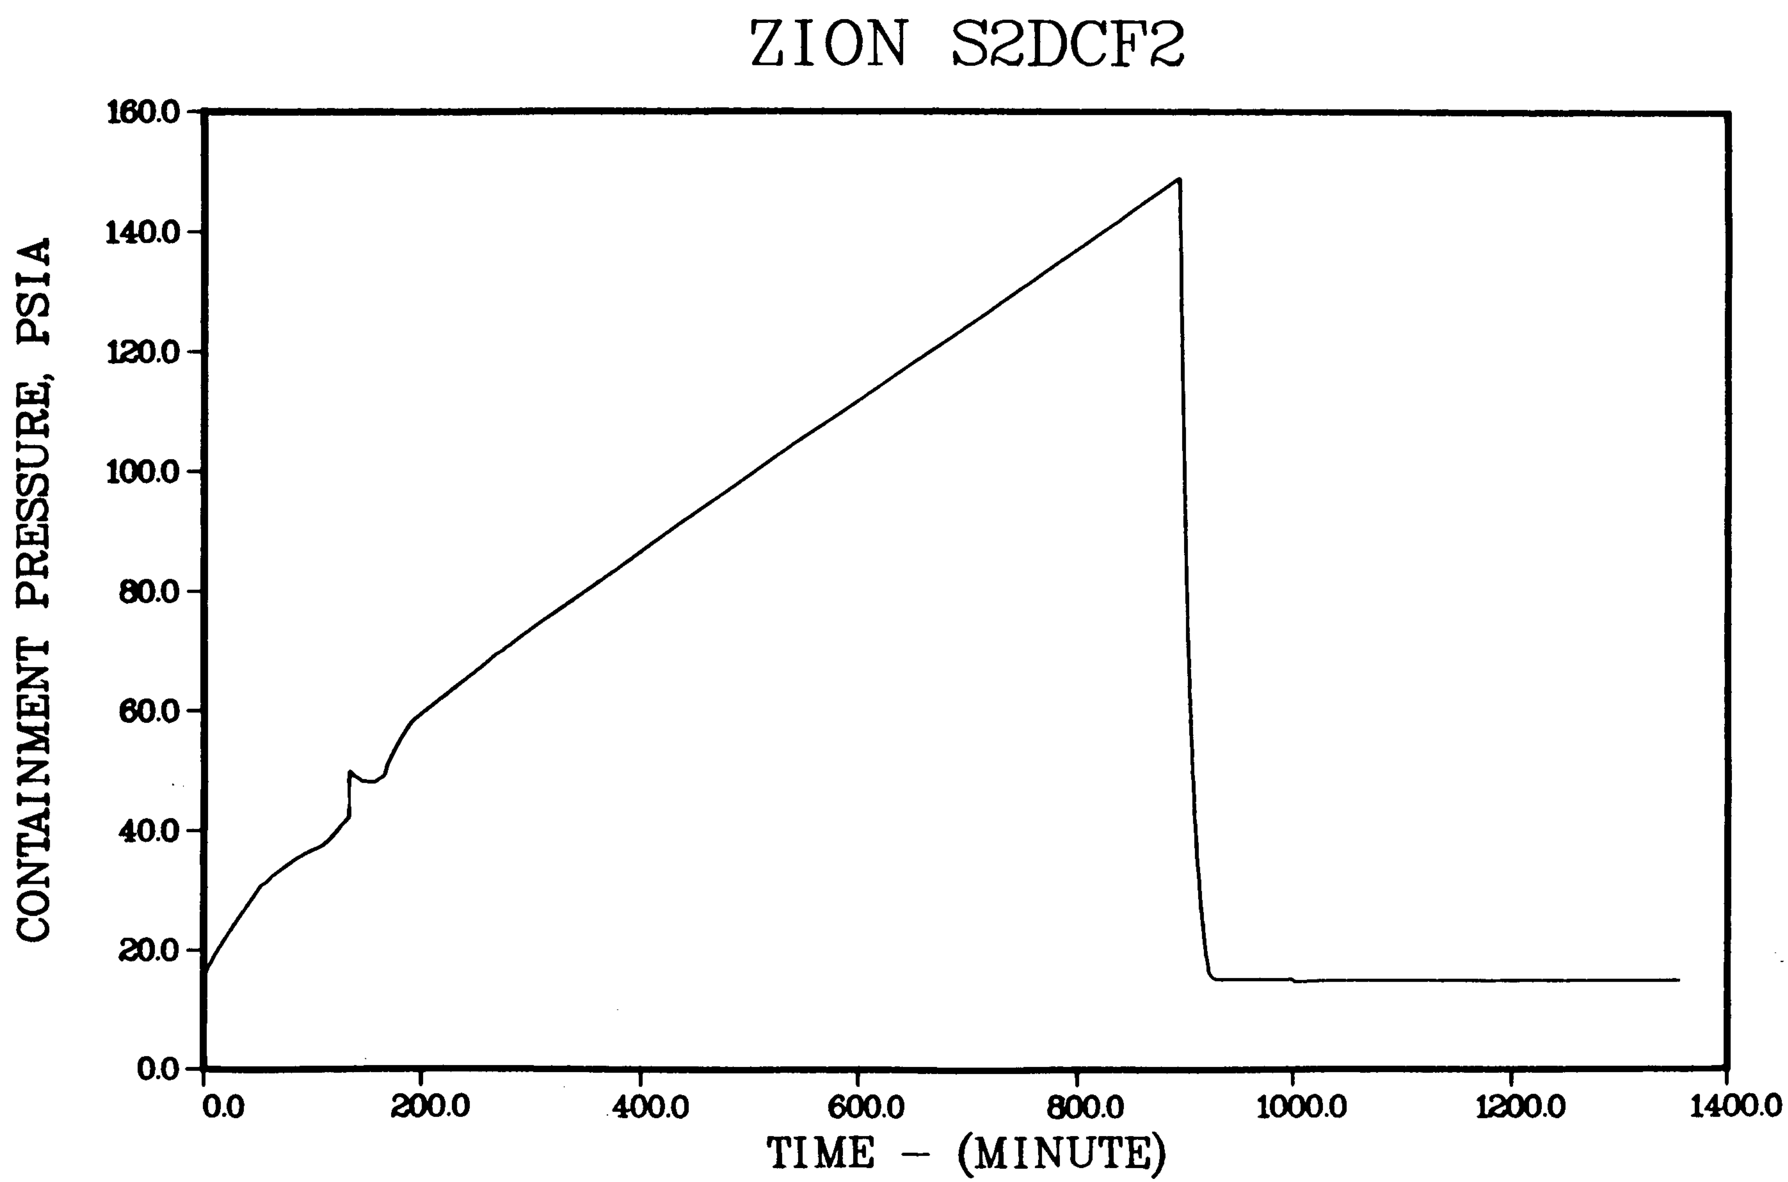

FIGURE 4.22. CONTAINMENT PRESSURE RESPONSE FOR S_2DCF SEQUENCE WITH LATE CONTAINMENT FAILURE

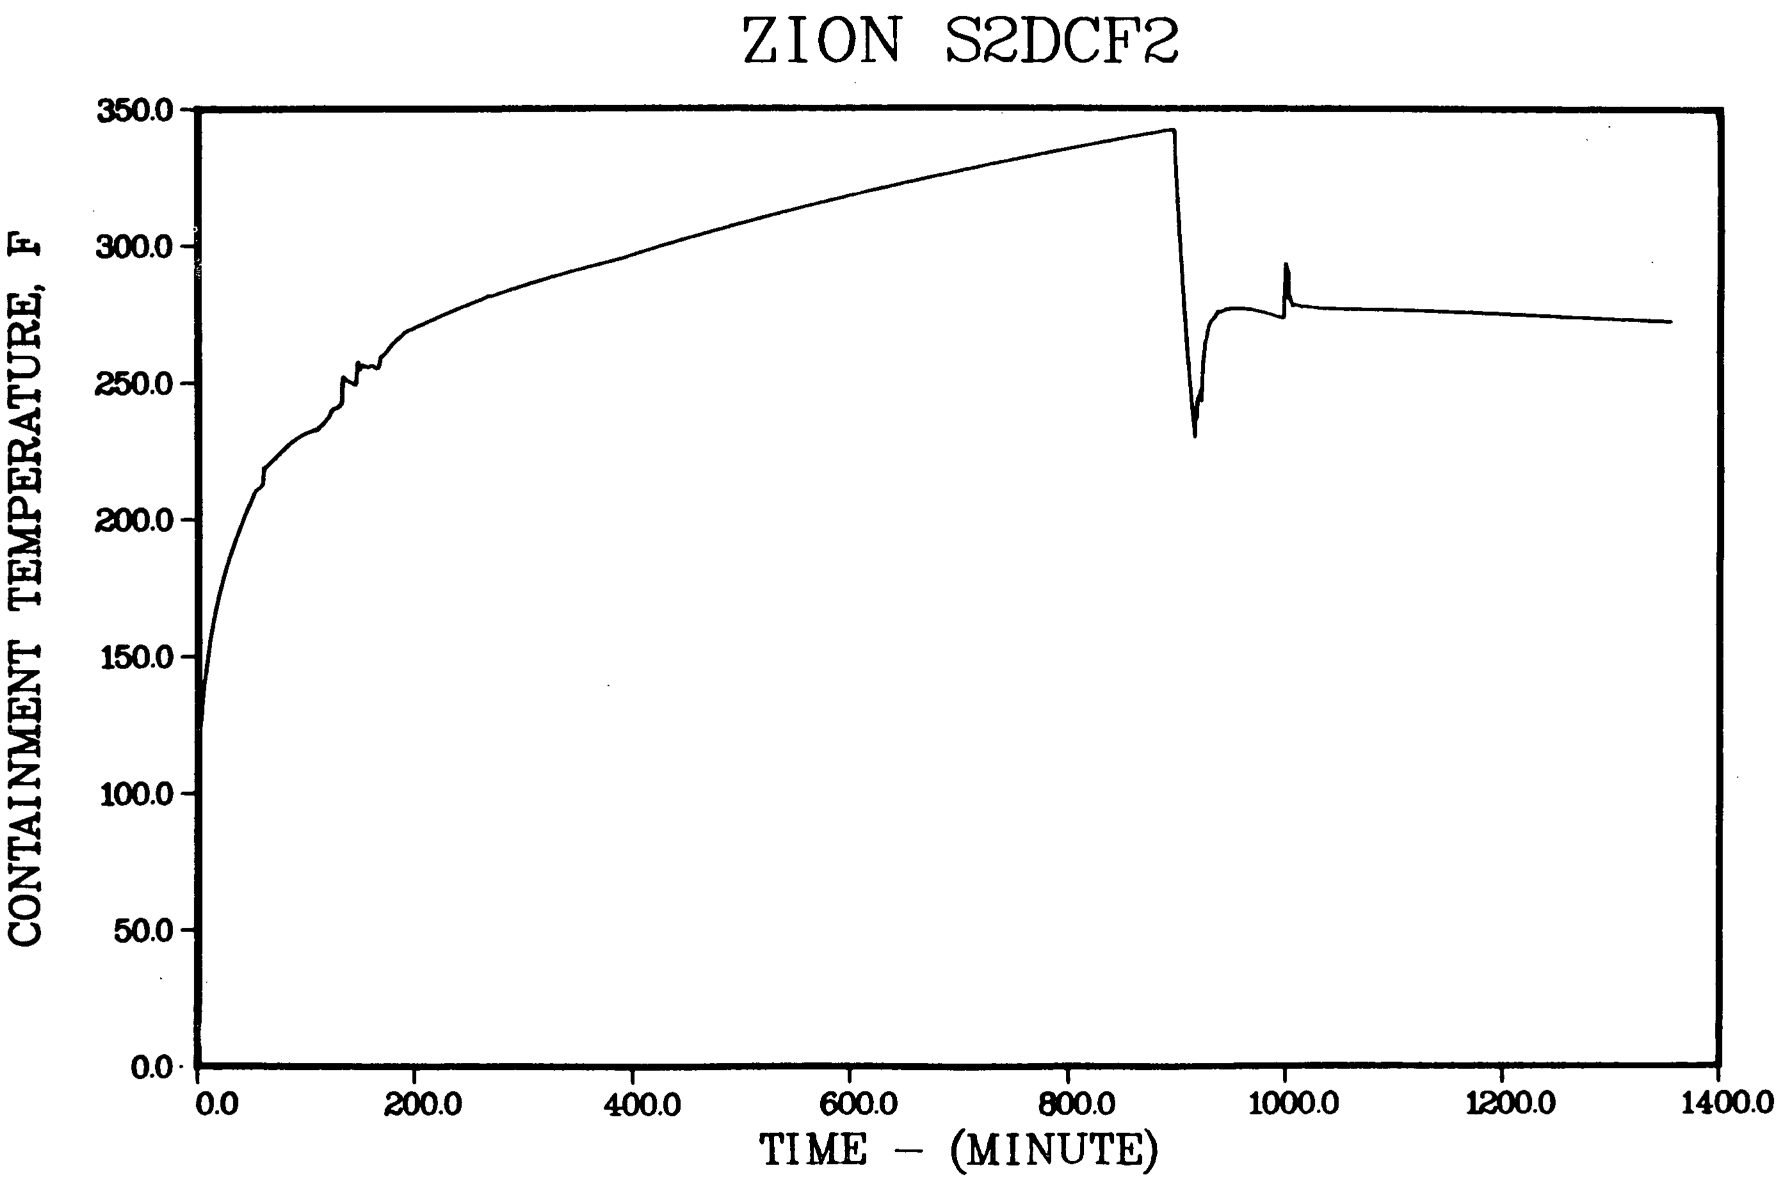

FIGURE 4.23. CONTAINMENT TEMPERATURE RESPONSE FOR S_2DCF SEQUENCE WITH LATE CONTAINMENT FAILURE

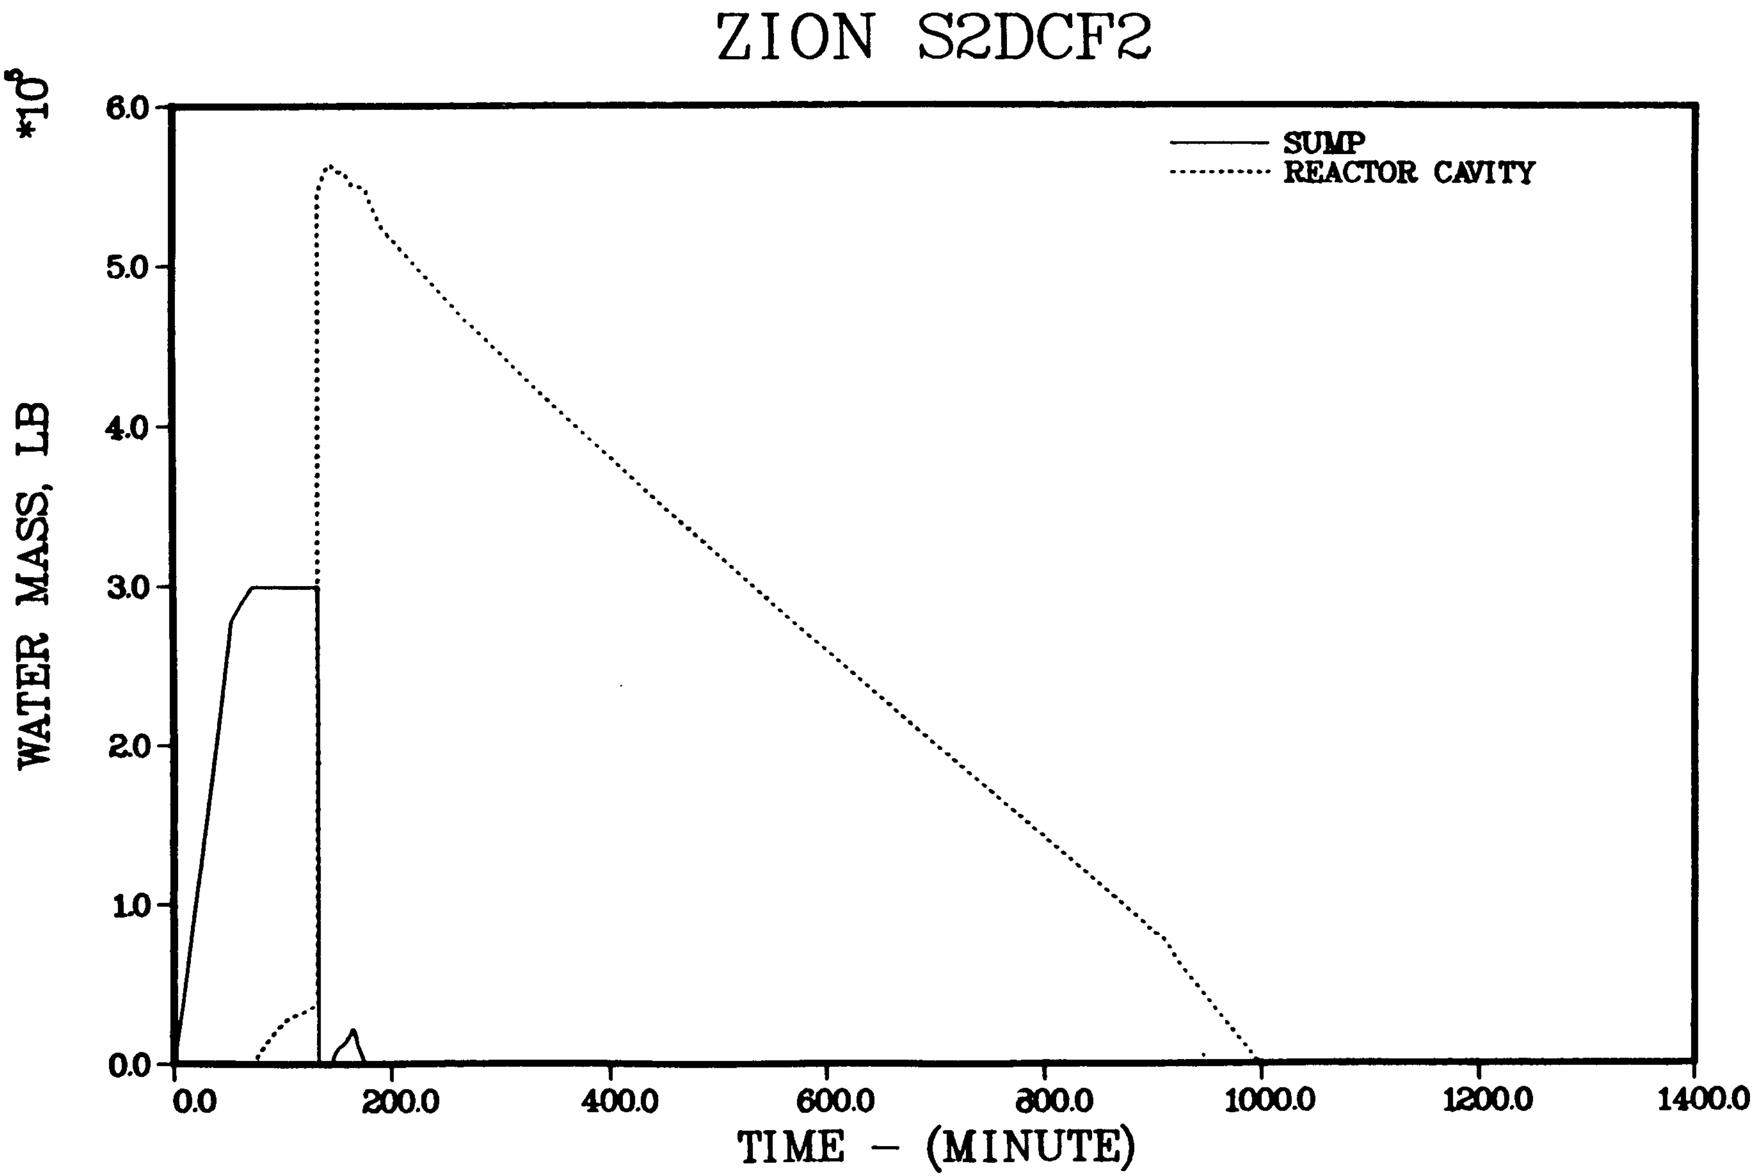

FIGURE 4.24. CONTAINMENT SUMP AND REACTOR CAVITY WATER INVENTORIES FOR S_2DCF SEQUENCE WITH LATE CONTAINMENT FAILURE

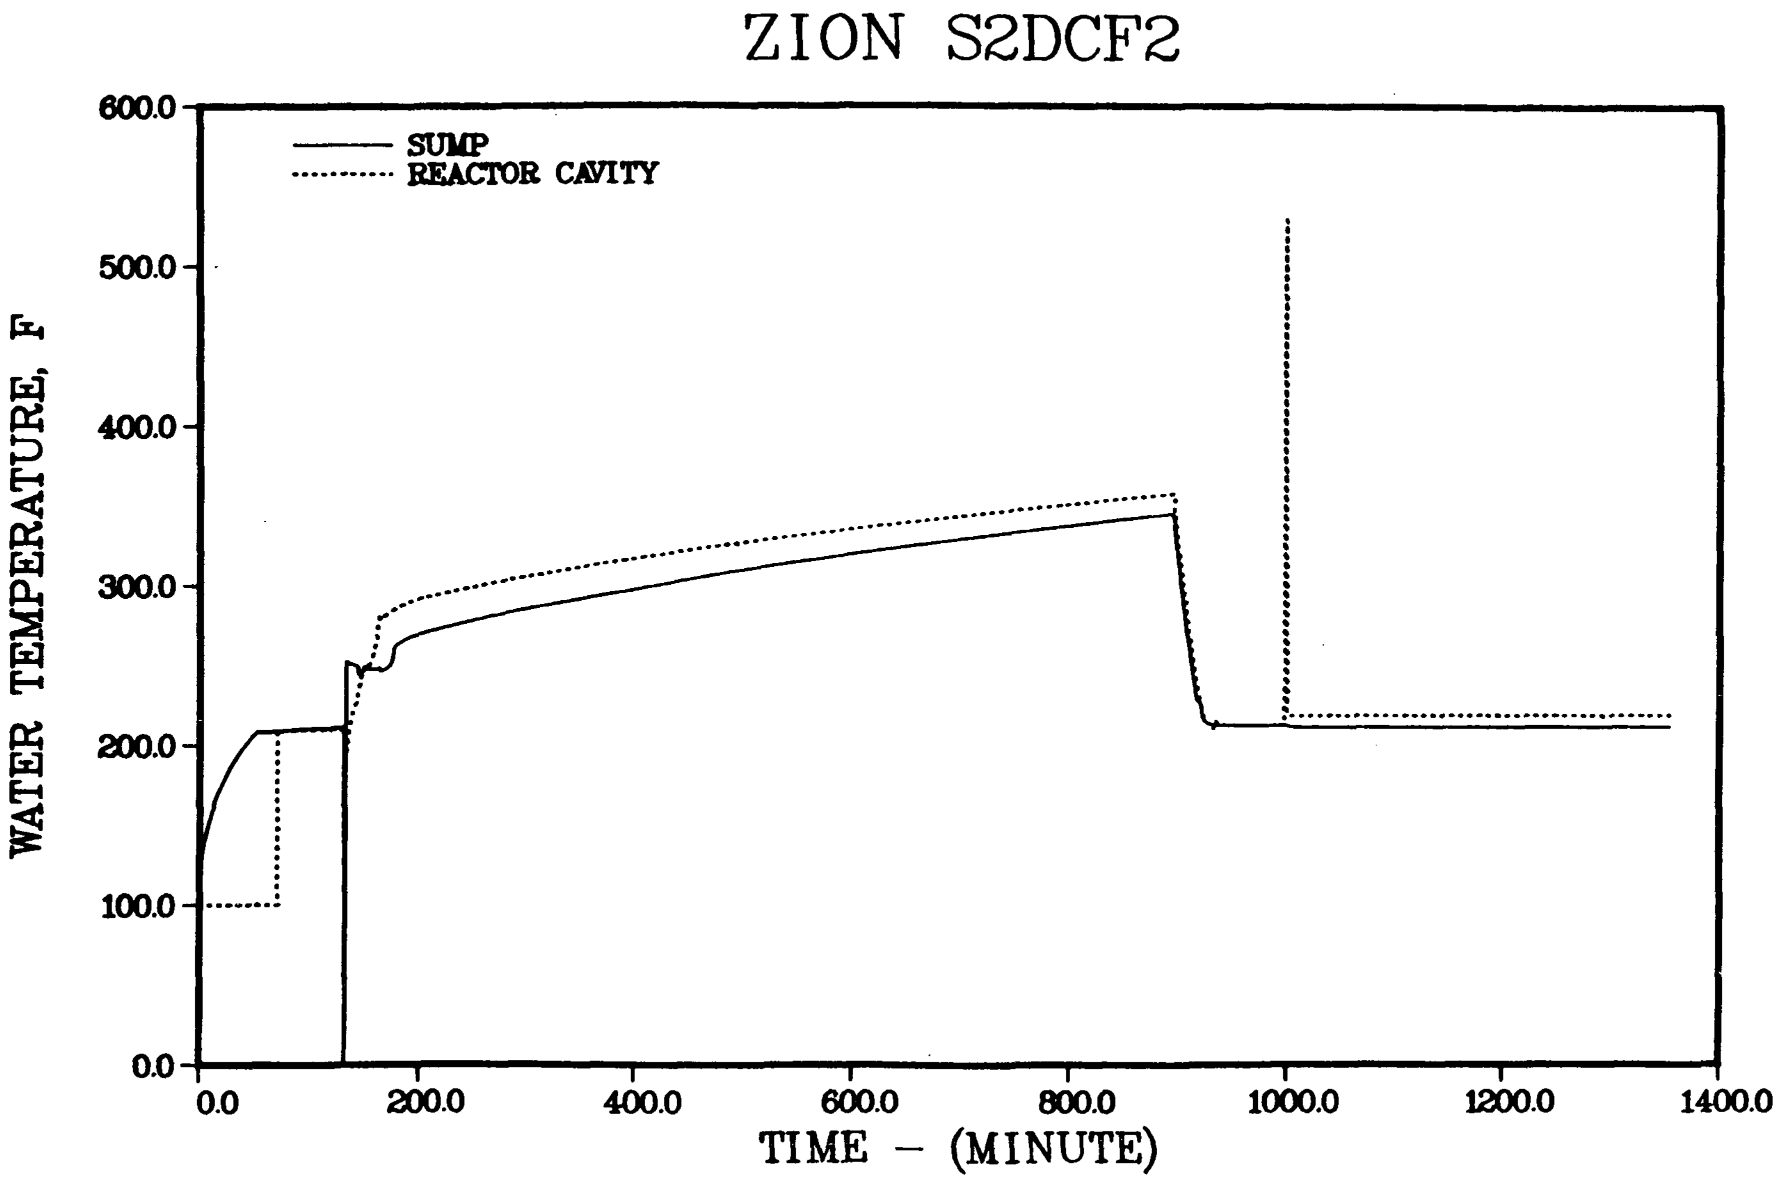

FIGURE 4.25. CONTAINMENT SUMP AND REACTOR CAVITY WATER TEMPERATURES FOR S_2DCF SEQUENCE WITH LATE CONTAINMENT FAILURE

inventory is manifested as essentially a constant rate of containment pressure increase up to the assumed failure level. All the water on the containment floor is predicted to be boiled off about an hour after containment failure. The time required to boil off all this water can be quite variable and would depend, among other factors, on the fraction of the core which comes into contact with the water. In the present analyses the entire core was assumed to simultaneously attack the concrete basemat as well as boiling water at the top surface. The rate of heat loss to the water was limited by film boiling and radiation from a flat surface. If less than the entire core comes into contact with the water in the containment, (is expelled from the cavity) the rate of boiloff could be slower. On the other hand, fragmentation of the core debris upon contact with water could result in more rapid boiloff. If the core debris should form a coolable bed on the containment floor the attack of the concrete could be delayed until after the time that all the water is boiled off.

The predicted progression of concrete attack is illustrated in Figure 4.26. It should again be recognized that these results are based on the simultaneous attack of the concrete and boiloff of water by the entire mass of the core debris, with no substantial initial quenching of the debris by the water in the cavity.

The total volume of gases leaked from the containment for this scenario is illustrated in Figure 4.27. The time dependent leak rates used as input to the containment fission product transport analyses are given in Table 4.4. The MARCH 3 calculated distributions of the noble gases are illustrated in Figure 4.28.

4.2.3 TMLU Sequence

The TMLU sequence is initiated by a transient and is accompanied by the failures of the power conversion, auxiliary feedwater, and emergency core cooling systems. Both the containment coolers and sprays are available during this sequence.

The early containment failure mode selected for analyses for this sequence is a very low probability outcome and is based on the assumption of the direct interaction between the core debris and the containment atmosphere. As noted previously, MARCH does not have explicit models for treating direct

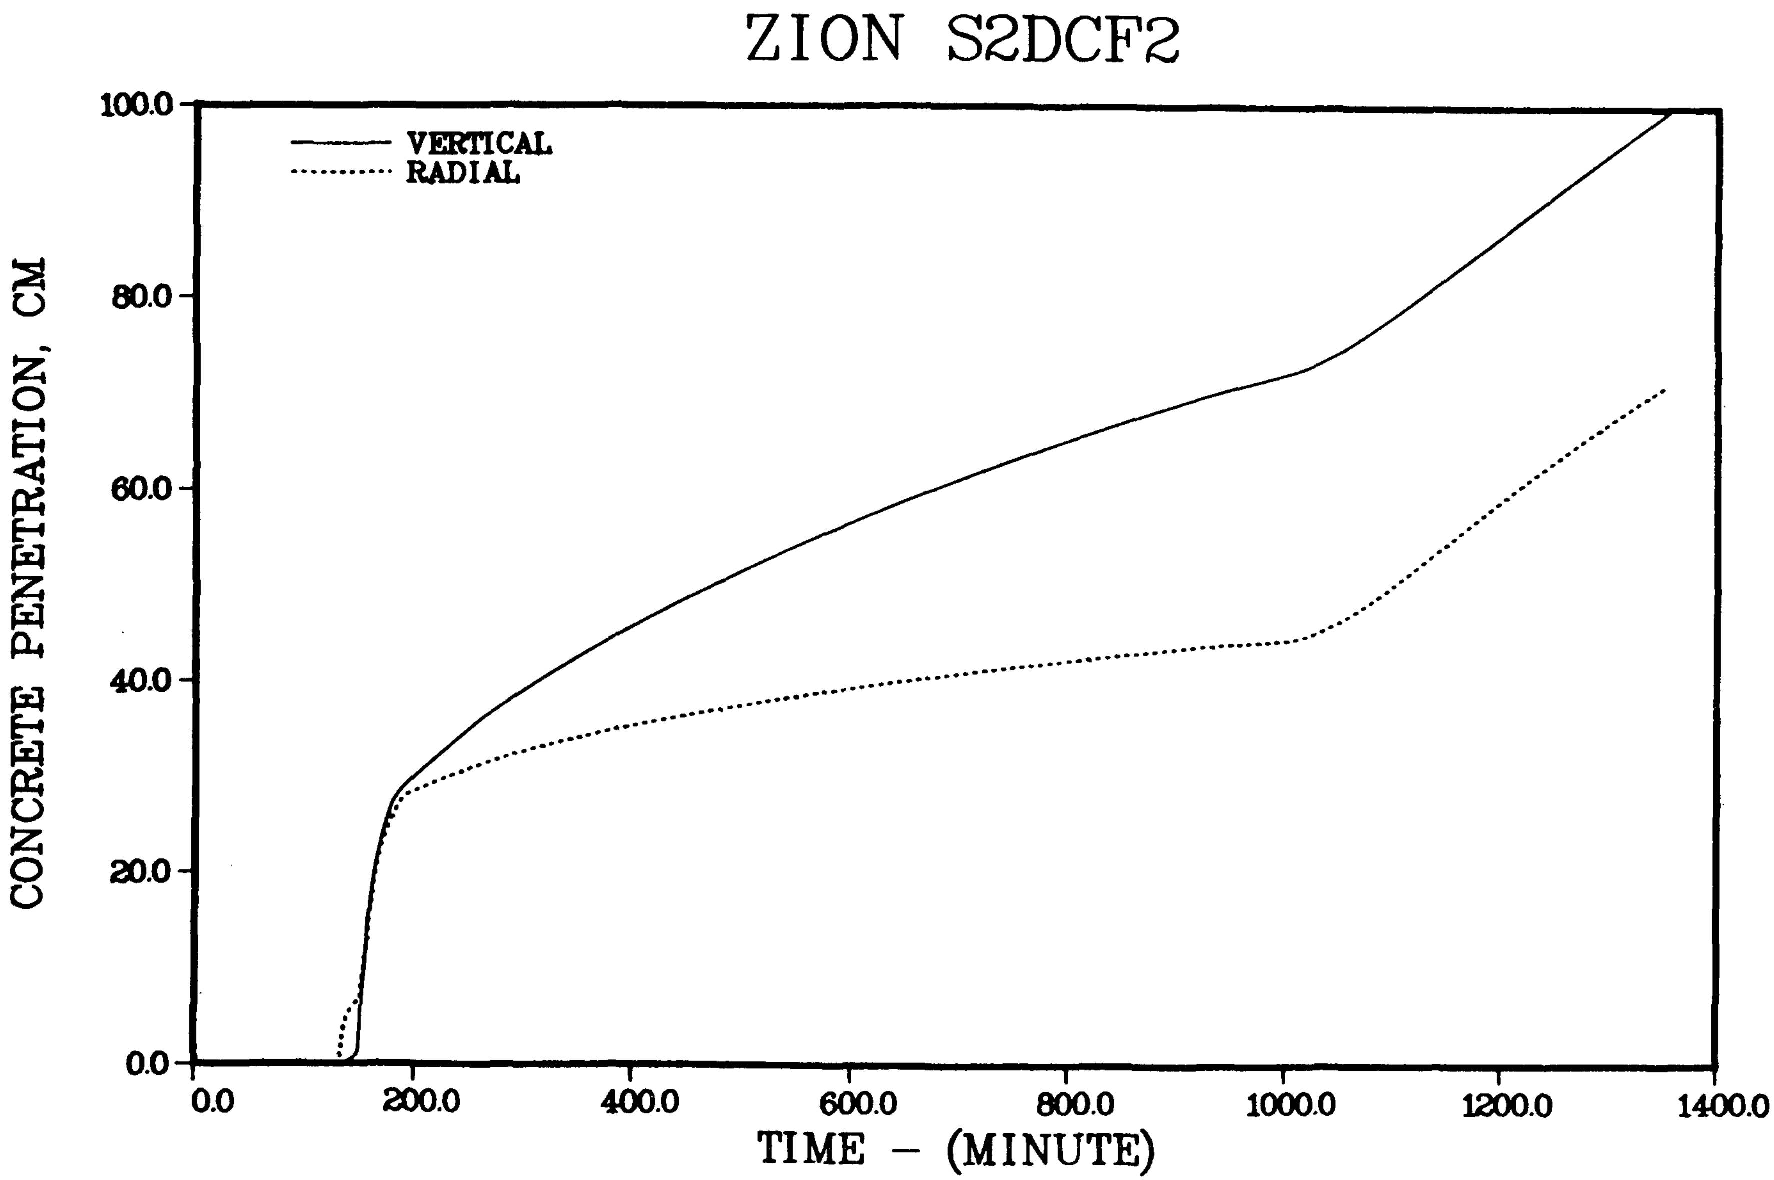

FIGURE 4.26. PROGRESSION OF CONCRETE ATTACK FOR S_2DCF SEQUENCE WITH LATE CONTAINMENT FAILURE

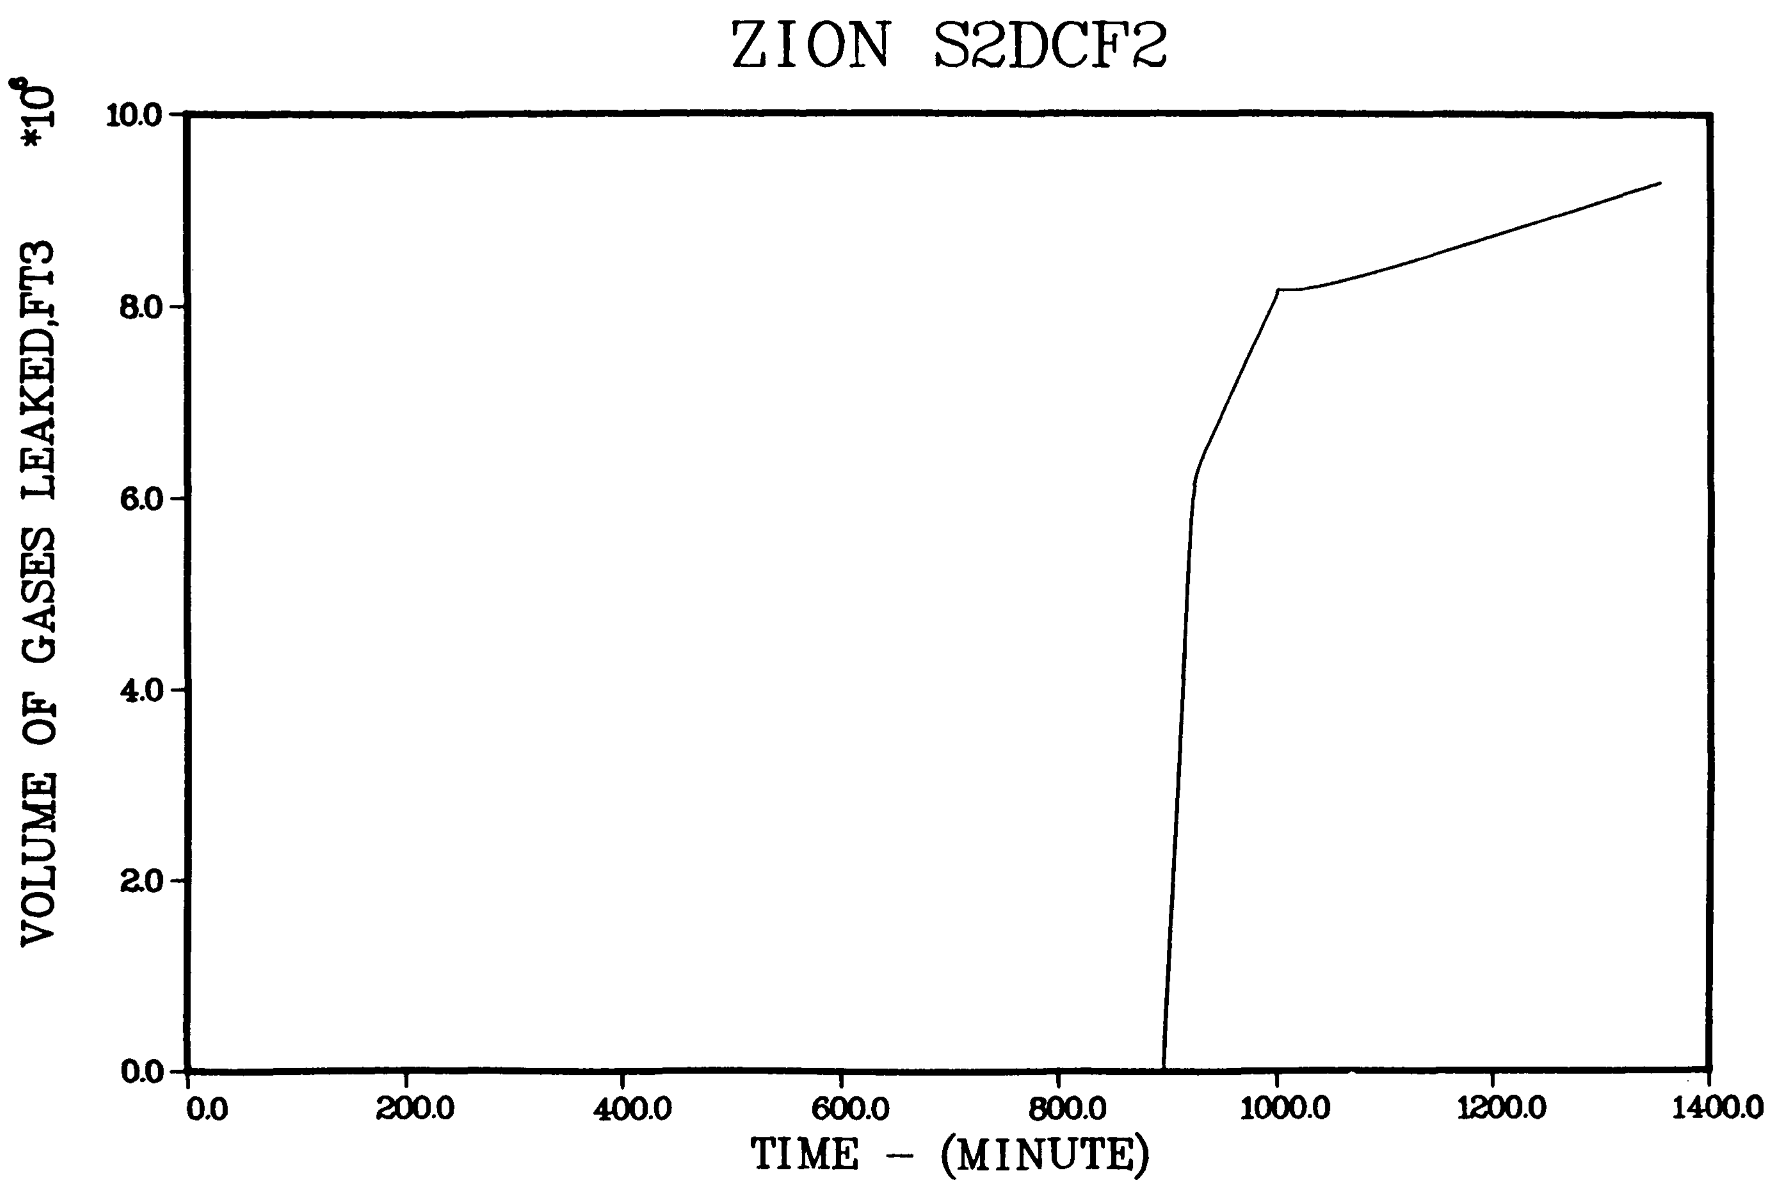

FIGURE 4.27. TOTAL VOLUME OF GASES LEAKED FOR S_2DCF SEQUENCE WITH LATE CONTAINMENT FAILURE

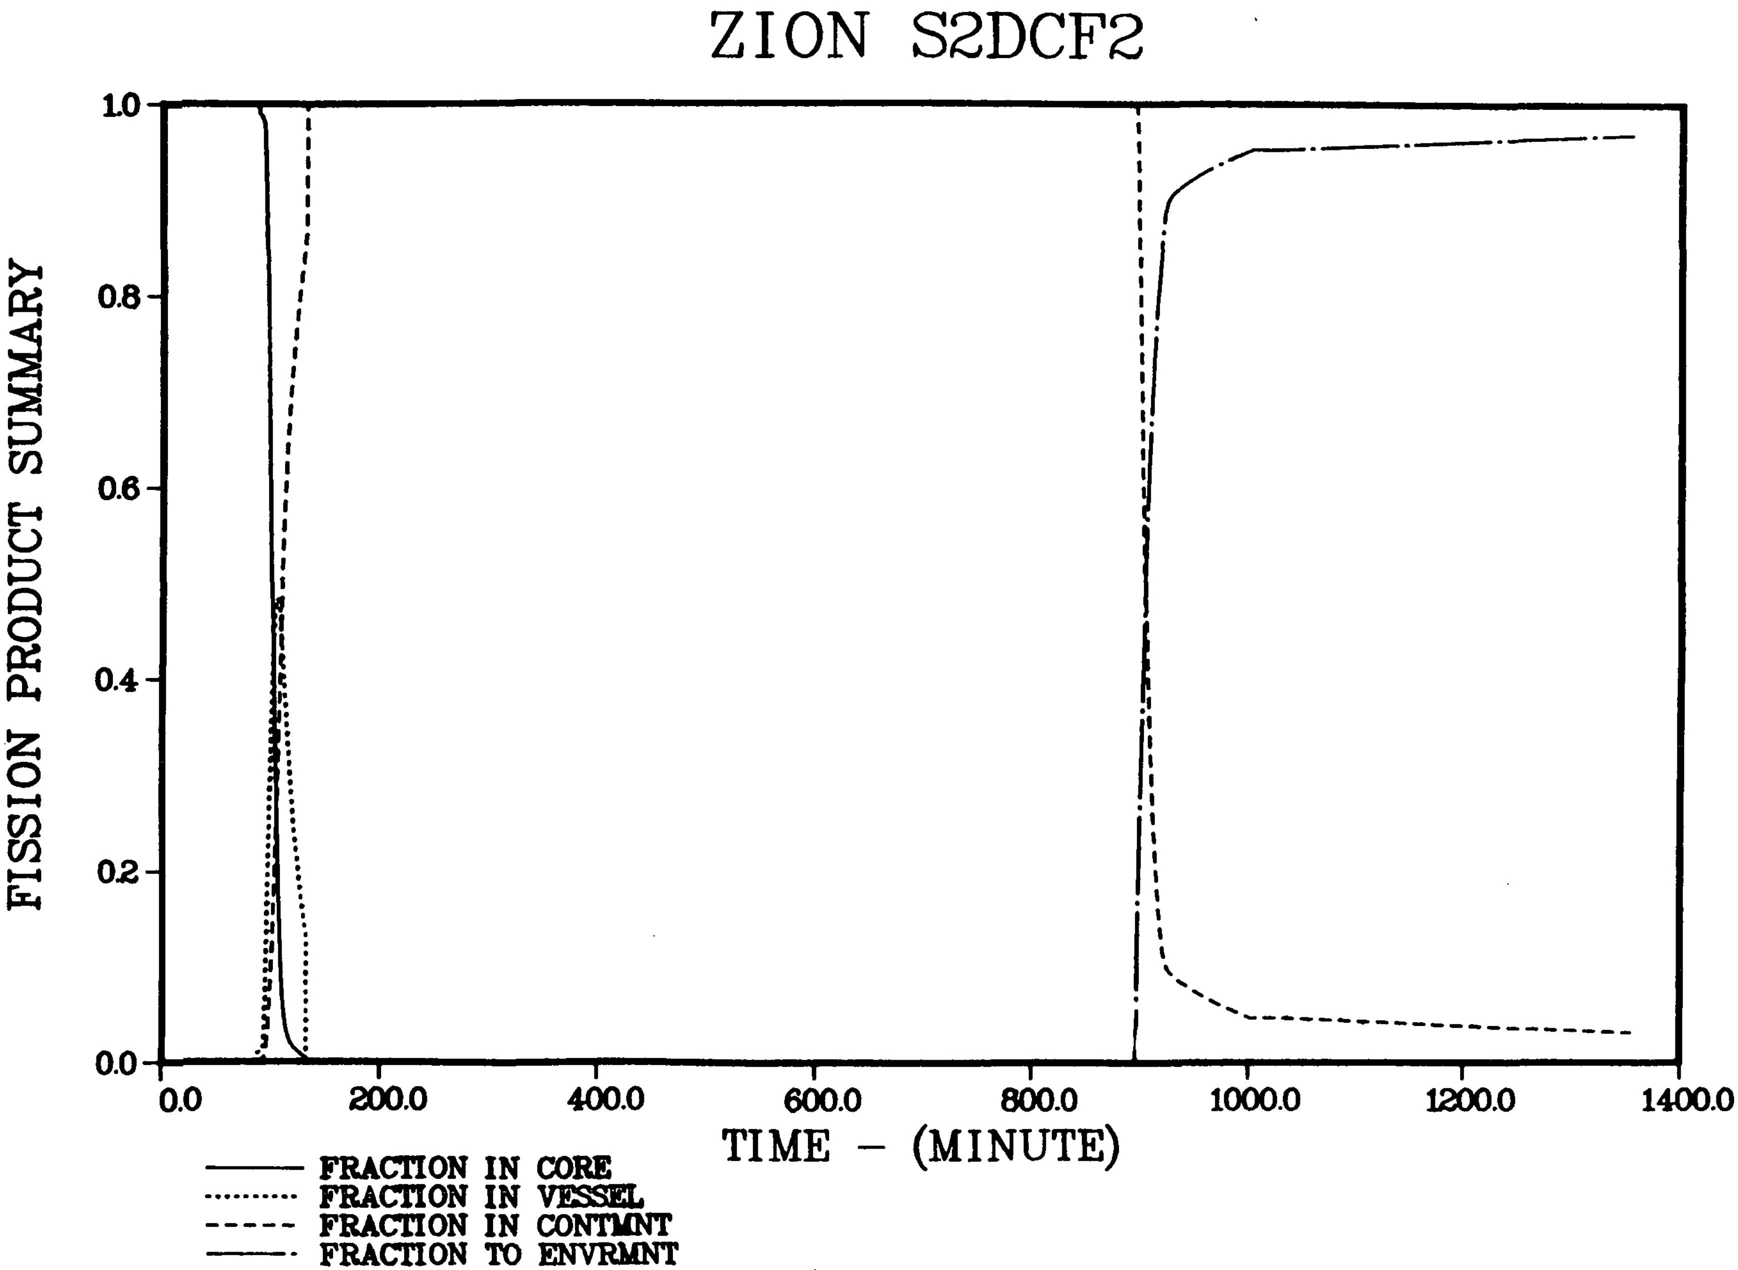

FIGURE 4.28. NOBLE GAS DISTRIBUTIONS FOR S_2DCF SEQUENCE WITH LATE CONTAINMENT FAILURE

heating; as before, the loadings and containment conditions that would be associated with such phenomena were simulated by selected choice of inputs to the debris-water interaction and hydrogen combustion models.

The accident event times for the TMLU sequence are again summarized in Table 4.1. The core and primary system conditions at key times during the sequence are summarized in Table 4.2; containment conditions are given in Table 4.3.

Figure 4.29 illustrates the predicted primary system response for this sequence. During the initial portion of the transient, while the steam generators are providing an effective heat sink, the primary system pressure is reduced below normal operating levels. As the steam generators begin to dry out and lose their effectiveness, the primary system pressure rises to the safety/relief valve setpoint. The steam generator secondary side water inventory is illustrated in Figure 4.30. The combined steam and water leak rates from the primary system are illustrated in Figure 4.31, with the primary system water inventory shown in Figure 4.32. After the initial transient which results in the expulsion of a small amount of the primary coolant inventory through the pressurizer relief valve, all the decay heat is removed through the steam generators. As the steam generators approach dryout the primary system pressure rises and expulsion of primary coolant starts at about 65 minutes. The rate of primary coolant loss is nearly constant until the inventory becomes saturated; at that point the rate of coolant loss increases significantly, as can be seen in Figure 4.31. The uncovery of the pressurizer surge line at about 105 minutes changes the leak flow from liquid to steam, with a substantial decrease in the rate of coolant loss. The steam boiloff rate remains relatively constant until the time of core uncovery; from there the rate of boiloff decreases. The final rapid increase in coolant boiloff is associated with the collapse of the core into the vessel head. The maximum and average core temperatures for this scenario are illustrated in Figure 4.33. The fractions of cladding reacted and core melted are illustrated in Figure 4.34. The behavior illustrated is typical of what has been seen for a variety of accident scenarios.

The temperatures of the gases leaving the top of the core and leaking to containment are illustrated in Figure 4.35. The abrupt drop in the core exit temperatures is not real but correspond to a period of no flow

through the core. As in similar cases, it is noteworthy that while very high temperatures are predicted at the top of the core, the temperature of the gases leaving the primary system is relatively low. The temperatures of some of the primary system structures are illustrated in Figure 4.36. Again it is interesting to note that only the first structure immediately above the core is predicted to experience very high temperatures; structures further downstream experience only limited heating. It should be noted that these results are based on the once-through flow of the gases from the core to where they exit to the containment. There is no provision in MARCH to model the internal recirculation of hot gases within the primary system; the latter have been postulated to have potentially significant effects on the course of accidents like the sequence considered here.

The predicted containment pressure and temperature responses for the TMLU scenario with early containment failure are illustrated in Figures 4.37 and 4.38. The rapid pressure increase to the containment failure level immediately after reactor vessel failure was based on a very small particle size in the debris-water interaction model as well the removal of the steam inerting inhibition to hydrogen-oxygen recombination in the containment atmosphere. These selected inputs were used as a simulation for the conditions that may result from the direct interaction of the core debris with the containment atmosphere.

Since the containment sprays are operating in this sequence there is a large quantity of water potentially available for interaction in the reactor cavity; if all the water is included in the interaction, the core debris would be quenched with minimal steam production. As part of the simulation of direct heating, the amount of water that was assumed to participate in the debris-water interaction in the reactor cavity was restricted to that in the accumulators. The containment sump and reactor cavity water inventories and temperatures are illustrated in Figures 4.39 and 4.40, respectively. The reactor cavity is kept filled by overflow from the containment sump. The cavity water is continually boiled off and thus maintained at the saturation temperature while the sump water remains relatively cold.

The predicted progression of concrete attack for this sequence is illustrated in Figure 4.41. These results are based on the assumption that concrete attack is initiated as soon as the debris reheat after the initial quenching, and that concrete attack and boiloff of cavity water occur

simultaneously. Several other courses are also possible for the scenario being considered. In view of the direct containment heating assumption, it is possible that the debris could be sufficiently dispersed to preclude significant concrete attack. Or, the debris could form a coolable bed and remain quenched as long as there is water on the containment floor.

The total volume of gases leaked from the containment is illustrated in Figure 4.42. The time dependent leak rates used as input to the containment fission product transport analyses are given in Table 4.4. The MARCH calculated noble gas distributions for this sequence are illustrated in Figure 4.43.

4.3 Radionuclide Sources

4.3.1 Source Within Pressure Vessel

The inventory of fission products used for these analyses is the same as in Volume VI of BMI-2104. Table 4.5 provides the inventories for each of the key fission product, actinide, and structural elements. These values are based on ORIGEN calculations for a PWR reactor with a three region model in which the maximum burnup corresponds to 33,000 MW days/tonne. In Table 4.6 these elements are collected into the elemental groups used in this study.

4.3.2 Sources Within the Containment

Release from Reactor Coolant System

Radionuclides enter the containment as they are transported through the primary system. After melt-through of the reactor pressure vessel, material still suspended in the RCS is assumed to be transported into the containment as the RPV and containment pressures are equalized.

Release from Core-Concrete Interaction

The VANESA code was used to predict aerosol and gas release rates and compositions as functions of time. Composition of the core materials contacting the concrete was determined with the CORSOR module. These compositions for the various sequences are given in Table 4.7. The concrete

5. RADIONUCLIDE RELEASE AND TRANSPORT

5.1 S_2DC_r Sequence

5.1.1 Transport in the Reactor Coolant System

In the S_2DC_r sequence, primary system pressures and temperatures are intermediate in value, ranging roughly between 700 and 1350 psia (48 to 92 atmospheres) and 640 F and 1340 F (610 K to 1000 K), respectively. Flows are intermediate, also. Under these conditions, the predicted progression with time of release from fuel and of deposition within the RCS of the three volatile fission product species CsI, CsOH, and Te, and of the structural and fuel material aerosol, is as shown in Table 5.1. 72.4 percent of CsI, 72.3 percent of CsOH, 52.6 percent of Te, and 69.2 percent of aerosol released from the fuel during this period are retained in the RCS. Table 5.1 also shows that little additional deposition of any of these species occurs after the beginning of core slump (6505 sec) despite continued, if reduced, release from fuel. This can be traced to the following circumstances: with core slumping, the RCS surface temperatures exceed those of the cooled gas and the volatile fission products condense largely on aerosol particles. Sorption is not competitive with this process. Vapor pressures at the cooled gas temperatures are so low that little transport occurs in the vapor phase. Aerosol release from the melt is reduced by the lower melt temperature to the point where less agglomeration takes place in the core region and smaller particles transport through the system with lower residence time. Aerosol retention is therefore significantly reduced. Since the volatile fission products are condensed on the aerosols, the extent of their retention is similarly reduced.

Table 5.2 gives the total quantities of material released from the fuel and retained on RCS surfaces at the end of the in-vessel release period for each of the elemental release groups.

Figures 5.1 through 5.4 provide a more detailed view of the transport behavior of the volatile fission products and of structural material aerosols in the RCS as a function of time. Each curve shows the mass of the given species that has been transported beyond the specified control volume

and is therefore no longer subject to capture by that control volume or control volumes upstream of it. It is clear from the curves that little flow holdup occurs--the releases from each of the indicated volumes closely track the release from fuel (solid line). With melt quenching after core collapse, release rates are much reduced and this is reflected by the sharp decrease of slope for the aerosol release from fuel curve (Figure 5.4). The corresponding curves for these volatile fission products show a gentler transition because their release rates continually diminish with fuel inventory depletion. Note that most retention occurs in the upper plenum and the steam generator.

5.1.2 Transport in Containment for the S_2DC_r Sequence

In this sequence, the containment fails almost 22 hours after vessel failure, thus allowing the radionuclides considerable time to deposit in the containment. Table 5.3 summarizes the various sources of radionuclides to the containment atmosphere. The time-dependent size distribution of airborne particles in the containment is shown in Table 5.4, and the fraction of core inventory released from the containment as a function of time is listed in Table 5.5. Table 5.6 presents the locational distribution of the radionuclides at the end of the accident. The core inventory fractions listed as captured in cavity water are those predicted by the VANESA code.

In addition to the long residence time for deposition before the containment fails, the deposition by diffusiophoresis is enhanced by condensation early in the accident. As a result, releases to the environment are low with the maximum being about 0.2 percent of core inventory for Te.

5.2 $S_2DC_{ir}F_{ir}$ Sequence

5.2.1 Transport in the Reactor Coolant System

The $S_2DC_{ir}F_{ir}$ sequence is identical to the S_2DC_r sequence for phenomena pertaining to the RCS. The latter was described already in 5.1.1.

5.2.2 Transport in Containment for the S_2DCF1 Scenario

Table 5.7 provides a summary of the sources of radionuclides to the containment atmosphere for the S_2DCF1 scenario. Although the releases from the reactor coolant system are the same as for S_2DC_r, the ex-vessel release is higher.

In this scenario, the containment fails subsequent to reactor vessel failure due to hydrogen combustion and direct heating. The time-dependent size distribution of airborne particles in the containment is shown in Table 5.8, and the fraction of core inventory released from the containment as a function of time is listed in Table 5.9. Table 5.10 presents the locational distribution of the radionuclides at the end of the accident.

The radionuclide release to the environment is high for this sequence due to the complete abseance of containment engineered safety features as well as a very short residence time of fission products in the containment. The fractional releases for Cs, I, and Te are 0.22, 0.22, and 0.32, respectively. The major removal mechanism in this sequence is sedimentation. Condensation onto particles occurs only near the end of the accident, so it contributes very little to the removal of radionuclides.

5.2.3 Transport in Containment for the S_2DCF2 Scenario

Table 5.11 provides a summary of the source terms to the containment for the S_2DCF2 scenario. In this scenario the containment fails 14 hours after the reactor vessel fails. The time-dependent size distribution of airborne particles in the containment is shown in Table 5.12, and the fraction of core inventory released to the environment as a function of time is listed in Table 5.13. Table 5.14 presents the locational distribution of the radionuclides at the end of the accident.

The relatively long time between the time the core starts to melt to the time the containment fails allows sedimentation and diffusion processes to remove the majority of the radionuclides from the containment air space. As a

result, only a few percent of the volatile and lesser amount of the nonvolatile radionuclides are predicted to be released to the environment.

5.3 TMLU Sequence

5.3.1 Transport in the Reactor Coolant System

The TMLU sequence is characterized by high, 2,370 psia (161 atmospheres), primary system pressure and temperatures, 800 F to 1825 F (700 K to 1270 K), and relatively low flow rates. For these conditions, the predicted progress with time of the release from fuel and of deposition within the RCS of the three volatile fission product species CsI, CsOH, and Te, and of the structural and fuel material aerosol is as shown in Table 5.15. These data are characterized by monotonically increasing depositions which, however, experience a jump increase during the period of core slumping (between 10,639 and 10,762 seconds). This jump can be traced to the surge in steam flow accompanying slumping and the resultant transfer of material out of the core region and into regions (such as the upper plenum and pressure relief line) of the RCS with high deposition efficiency. Beyond the core collapse period deposition is diminished for the same reasons as those given for the S_2DC_r sequence. Table 5.15 shows that 77.6 percent of CsI, 81.1 percent of CsOH, 52.7 percent of Te and 78.3 percent of aerosol released from the fuel during this period are retained in the RCS.

Table 5.16 gives the total quantities of material released from the fuel and retained on RCS surfaces at the end of the in-vessel release period for each of the elemental release groups.

Figures 5.5 through 5.8 give a more detailed view of transport behavior of the volatile fission products and of structural material aerosols in the RCS as a function of time. As for the S_2DC_r sequence, each curve gives the mass of the given species that has been transported beyond the specified control volume and is thus no longer subject to capture by that control volume or control volumes upstream of it. Unlike the case for the S_2DCr sequence, significant holdup occurs before the beginning of core slumping. Indeed, the large amount of retention indicated before about 10,400 seconds for CsI in Figure 5.5 in the core region (difference between the solid curve and the

dashed curve of the core), is seen to be entirely due to holdup since the fuel and core curves merge later in time. If natural convection between the core region and the upper plenum were taken into account, it is likely that fission products would move out of the core region and be subject to deposition in the upper plenum earlier in the scenario than indicated. In the TMLU sequence it is again the upper plenum that plays a major role in retention of all species.

5.3.2 Transport in Containment for the TMLU Sequence

In this sequence the containment fails at the time of vessel failure. The containment sprays operate until the containment fails. Table 5.17 summarizes the sources of radionuclides to the containment atmosphere from the reactor coolant system and from the interaction of molten fuel debris with concrete. The time-dependent size distribution of airborne particles in the containment is given in Table 5.18, and the fraction of core inventory released from the containment as a function of time is listed in Table 5.19. Table 5.20 presents the locational distribution of the radionuclides at the end of the accident.

The sprays during the in-vessel release period are quite effective at removing the airborne particles. Therefore, the majority of the I, Cs, and Te released to the containment is retained in the containment. In general, the radionuclide release to the environment is low for this sequence with the highest percentage being 4 percent of the Te.

5.4 Noble Gas and Energy Release to the Environment

The release of noble gases to the environment is calculated by the MARCH 3 code rather than the fission product transport codes TRAP and NAUA since the noble gases are assumed to be transported with the bulk flow of gases without attenuation. The energy associated with gases escaping the containment is also calculated in the MARCH 3 code. The environmental releases of noble gases and energy are tabulated in Table 5.21. The heat of vaporization of the steam in the escaping gases is not included in the tabulated energies.

6. SUMMARY AND CONCLUSIONS

This report presents results of source term analyses for several accident sequences for the Zion large dry containment PWR supplementing those given in Volume VI of BMI-2104. The current analyses have focused on the more likely core melt accident sequences as identified by the Accident Sequence Evaluation Program (ASEP). The containment failure modes considered include some occurring late in time as well as some assumed to take place relatively early in the course of the accident sequences. The latter failure modes are believed to be of very low probability for the large volume, high strength containment being considered.

Among the insights arising from the results of present analyses are the following:

1. All the accident scenarios considered indicate significant retention of the volatile fission product species on reactor coolant system surfaces. The possible long-term revaporization of these species has not been included in the present analyses.
2. The predicted environmental fission product releases for delayed containment failure, even in the absence of active engineered safety features, are quite low.
3. For early containment failure in the absence of any engineered safety feature operation, the predicted environmental releases of the volatile fission products are considerable; the releases of some of the less volatile species may also be of concern.
4. For the assumed early containment failure mode with initial availability of the containment sprays, the predicted environmental source terms are generally low, with the tellurium release from corium-concrete interactions at about 4 percent being the highest.

The source term analyses presented in this report were performed as input to a broader study aimed at developing updated risk profiles for a number of reference plant designs. The results presented should not be viewed in isolation but consideration should be given to the relative probabilities of the accident sequences as well as the containment failure modes.

13. ABSTRACT (200 words or less)

This report presents results of analyses of the environmental releases of fission products (source terms) for severe accident scenarios in a pressurized water reactor with a large dry containment. The analyses were performed to support the Severe Accident Risk Reduction/Risk Rebaselining Program (SARRP) which is being undertaken for the U.S. Nuclear Regulatory Commission by Sandia National Laboratories. In the SARRP program, risk estimates are being generated for a number of reference plant designs. The Zion Plant has been used in this study as an example of a large dry containment PWR design.
