1 FINDINGS OF FACT

2 A. Prior Proceedings

3 On September 27, 1979 the Atomic Safety and  
4 Licensing Board issued a partial initial decision dealing  
5 with issues concerning the geology of the Diablo Canyon  
6 site, the adequacy of the seismic design of the Diablo  
7 Canyon plant, potential aircraft or missile crashes into the  
8 plant, and the site security plan. (10 NRC 453) The  
9 partial initial decision did not include conclusions of law  
10 or form of order because of unresolved issues arising from  
11 the accident at the Three Mile Island Plant. Two separate  
12 and independent appeals were taken from the decision. One  
13 of them was filed on behalf of the San Luis Obispo Mothers  
14 for Peace relating to the Licensing Board's findings on the  
15 adequacy of the site security plan. This appeal is being  
16 handled as a completely separate proceeding before a  
17 reconstituted Appeal Board. The other appeal, which is the  
18 subject of these findings of fact, was filed by the San Luis  
19 Obispo Mothers for Peace and certain other intervenors, who  
20 are hereinafter referred to as the Joint Intervenors (J.I.),  
21 and is concerned with the Licensing Board's findings on the  
22 seismic issues in this case.

23 Exceptions to the Licensing Board's decision and  
24 supporting briefs were reviewed by this Board. On March 28,  
25 1980 Joint Intervenors filed a Motion To Reopen to receive  
26 new evidence on, among other things, data developed from an

1 earthquake which occurred in the Imperial Valley in  
2 California and Mexico on October 15, 1979. Briefs and  
3 supporting affidavits in opposition to the motion were filed  
4 by PGandE and the NRC Staff. On June 24, 1980 this Board  
5 issued its decision (ALAB-598, 11 NRC 876) granting in part  
6 Joint Intervenors' motion to reopen and directing the  
7 parties to file written testimony on nine questions set  
8 forth in an appendix to the decision.

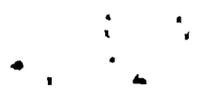

9 In a Memorandum and Order dated August 7, 1980  
10 this Board directed Dr. Mihailo D. Trifunac and Dr. J. Enrique  
11 Luco, witnesses subpoenaed by the Licensing Board in the  
12 proceeding below, to review and comment upon as witnesses of  
13 this Board the testimony furnished by the parties.

14 B. Evidentiary Hearing

15 The evidentiary hearing was held from  
16 October 20 1/ through October 25, 1980. Governor Edmund G.  
17 Brown, Jr. was the only new party to the proceeding, having  
18 been admitted by the Licensing Board as representative of an  
19 interested state pursuant to 10 CFR 2.715(c) (ASLB order  
20 dated November 16, 1979). At the hearing the following  
21 exhibits were numbered for identification and, where  
22 indicated, received into evidence:

23 ///

24 \_\_\_\_\_  
25 1/ The Board originally set September 23, 1980 as the date  
26 for the hearings to commence. However, the absence of  
of the hearing to October 20, 1980.

The order in which testimony was to be received was prescribed in the Appeal Board's Order dated October 6, 1980 as supplemented by its Order dated October 15, 1980. This order of presentation was varied somewhat at the hearing for the convenience of one of the Staff witnesses. In any event the questions propounded in the Appendix to ALAB-598 and the testimony offered in response are set forth following in numerical order:

///

11

1            Question I.     The    October 15, 1979, Imperial  
2 Valley Earthquake (IV-79,  $M_p = 6.4-6.9$ ) provided an  
3 extensive set of strong motion records in the near field of  
4 a rather severe earthquake. The parties should compare the  
5 horizontal peak acceleration values recorded for various  
6 instrument positions with earlier predictions and compila-  
7 tions of such motion, e.g., those contained in the Final  
8 Safety Analysis Report (FSAR) on the Diablo Canyon Nuclear  
9 Power Plant, Amendment 50, Appendix D LL 11B, Figures 2, 3,  
10 and 4; and the United States Geological Survey (USGS)  
11 Circular 795, Figures 4, 24, 47, and 48. Those comparisons  
12 should (if possible) address whether there is magnitude  
13 independence or a saturation effect for ground motion  
14 intensity in the near field of earthquakes.

9            The Imperial Valley earthquake of October 15, 1979  
10 (IV-79 earthquake) yielded an extensive amount of near-field  
11 seismic data. In general the revised and corrected data for  
12 the earthquake give results that are not greater than those  
13 used in nuclear reactor design as exemplified by the design  
14 criteria specified for the Diablo Canyon facility  
15 (Newmark 11; Blume I-1 thru I-5). The new data from the  
16 IV-79 earthquake clearly show that statistical results for  
17 motions recorded at distances greater than ten km should not  
18 be extrapolated linearly to directly determine the peak  
19 accelerations likely to develop in the near-field, and that  
20 there is a clear indication of a saturation effect of peak  
21 ground motion in the near-field with values very near the  
22 fault being no greater than those at a distance of about six  
23 or seven km from the fault (Blume I-5 through I-7; Edwards  
24 VII-1, VII-2; Seed I-1, I-2, Rothman 9). The saturation  
25 effects of interest are two-fold; saturation with decreasing  
26 distance to the fault rupture surface, and saturation with

11

1 increasing magnitude (Smith I-1 thru I-3; Tr. 122, 126,  
2 133-135, 150, 151, 171; Applicant (App.) Ex. R-5, R-6). The  
3 results of the IV-79 earthquake fell within predictions made  
4 by, among others, Drs. Blume, Seed, and Smith and the United  
5 States Geological Survey (USGS) in Circular 795 (Blume I-5,  
6 I-7; Seed I-2, Seed Figure I-2; Smith I-1; Tr. 110, 116,  
7 168, 169). Predictions of peak ground acceleration (PGA)  
8 for conditions at Diablo Canyon demonstrated the  
9 conservatism of the 0.75g reanalysis value (Smith I-1, Tr.  
10 550, 1374, 1375, 1413).

11 Other witnesses (Luco 2-3, Young 20; Tr. 613, 614)  
12 offered predictive correlations based upon defining distance  
13 from a postulated zone of energy release, the epicenter or  
14 hypocenter. Dr. Young could not give a basis for using  
15 epicentral distance to predict peak ground accelerations  
16 (PGA) within 10 kilometers of a fault (Tr. 1069). Dr. Smith  
17 found it very unlikely, both geologically and  
18 seismologically, that the center of energy release is a  
19 point source for a large earthquake, and that the epicenter  
20 or hypocenter is the most probable location for that point  
21 (Tr. 1378). Dr. Smith (Tr. 55-62, App. Ex. R-1) explained  
22 the various distance models and indicated the bases  
23 (statistical, physical intuition and predictive capability)  
24 for preferring normal distance to the fault or distance to  
25 the nearest point of fault rupture or energy release as used

26 ///

11

1 by most experts in the near field of large earthquakes (Tr.  
2 62, 169, 549, J.I. Ex. R-1).

3 A report by TERA Corporation entitled "Final  
4 Report - Evaluation of Peak Horizontal Ground Acceleration  
5 Associated with the Hosgri Fault at Diablo Canyon Nuclear  
6 Power Plant, (Ex. 1 to Smith testimony on Question I),  
7 hereafter referred to as the TERA Report, which incorporates  
8 the IV-79 data, has extended the analysis of horizontal PGA  
9 in the near source region. This analysis supports the  
10 conclusion that PGA does saturate with increasing magnitude  
11 in the near source region. In a conservative analysis,  
12 i.e., when both North American and non-North American  
13 earthquake data are included in a multiple regression  
14 analysis of near source PGA recordings, the predicted median  
15 value for a magnitude 7.5 earthquake at a distance of 5.8 km  
16 is 0.48g for instrumental ground motion. Using only North  
17 American data the figure is .41g. If a regression model is  
18 chosen which assumes complete saturation of PGA with  
19 increasing magnitude (supported on theoretical grounds and  
20 by North American data), the predicted motion for DCNPP is  
21 little influenced by whether the regression analysis is  
22 constrained to require "complete" magnitude saturation.  
23 Because the regression analysis established that the median  
24 plus one-standard-deviation value is 1.52 times the median,  
25 the median plus one-standard-deviation acceleration is 0.62g  
26 (TERA Report 1-3; Smith I-2, I-3; Tr. 380). The similar

1 figure using both North American and non-North American data  
2 is .72g (TERA Report 1-3.)

3 J.I. witness James Brune testified that the  
4 horizontal accelerations for the IV-79 earthquake were in  
5 general agreement with the 70% prediction intervals in USGS  
6 Circular 795 for a M=6.4 earthquake. He stated further that  
7 they represent the average expected, and that other  
8 earthquakes of the same magnitude could be expected to  
9 generate considerably higher and in other cases considerably  
10 lower average accelerations, although he had low confidence  
11 in this conclusion because of lack of sufficient data (Brune  
12 4, 5). He also stated that the data indicate that  
13 acceleration increases with decreasing distance but with a  
14 flattening slope at close distances (Brune 4; Tr. 772, 857).  
15 On the stand Dr. Brune took issue with Dr. Blume's position  
16 that the Imperial fault was considered a vertical plane of  
17 energy release (Tr. 613). Dr. Brune advanced a novel theory  
18 that about 50% of the total energy released by the IV-79  
19 earthquake was released in a zone about ten km in length at  
20 a depth of six to ten km which he called a zone of  
21 "concentrated energy release" (Tr. 613, 843). He  
22 illustrated this zone on J.I. Ex. R-12 and stated it was not  
23 a point source (Tr. 775, 854). However, on  
24 cross-examination he was unable to locate the zone with any  
25 degree of specificity or describe its dimensions (Tr. 776,  
26 778, 779, 788, 854). Further, it developed that Dr. Brune

11

1 had not plotted the data points on J.I. Ex. R-12, was unable  
2 to testify as to what point he had plotted from, and his  
3 testimony on these matters was stricken (Tr. 894, 1201).  
4 Finally he concluded that his zone of concentrated energy  
5 release was not a final result but only a possible fit to  
6 the data, he acknowledged that it should not be used "for  
7 anything other than simply getting a general idea of the  
8 different ways that that would plot," and that he did not  
9 want to "stick [his] neck out" regarding the location of the  
10 zone (Tr. 793, 841, 853, 886). Applicant witnesses Frazier  
11 and Smith saw no evidence of localized high zones of energy  
12 release in the IV-79 records (Tr. 335, 1378).

13 Brown witness George A. Young testified in  
14 comparing the curves of Circular 795 and the IV-79 data that  
15 the Blume curves are low, the Trifunac curves too high, the  
16 Schnabel and Seed curve for magnitude 6.6 plots as an  
17 approximate mean curve to the IV-79 data, and that peak  
18 ground accelerations are magnitude dependent in the near  
19 field (Young 5, 6; Tr. 1054, 1084). Dr. Young also  
20 testified that he would predict a mean peak horizontal  
21 ground acceleration of 1.0 g at the Diablo site for a  
22 magnitude 7.5 earthquake on the Hosgri Fault (Young 15; Tr.  
23 1013). At the hearing Dr. Young testified that he could  
24 name no new project on which he had been given the  
25 responsibility of providing the overall criteria for the  
26 design of the plant (Tr. 609). He also testified that he

1  
2  
3

1 used only 15 stations in comparing Dr. Blume's SAM V  
2 equation and the IV-79 data whereas Dr. Blume had used data  
3 from all the stations (Tr. 740, 972). However, in  
4 discussing the TERA report he stated that all data should be  
5 used unless there are serious questions regarding its  
6 accuracy (Tr. 745, 972, 973). In an exhibit prepared by Dr.  
7 Young (Brown Ex. R-12) when plotted no data points fell  
8 below a mean minus one-standard-deviation, and only one fell  
9 above the mean plus one-standard-deviation, which is  
10 statistically improper (Tr. 979-981).

11 Question II. Response spectra have been devel-  
12 oped from the near-field (1 to 11 km) ground motion records  
13 produced by IV-79. The records contain horizontal peak  
14 acceleration values in the range of 0.81g to about 0.2g.  
15 The applicant calculated a mean peak acceleration of 0.36g  
16 for IV-70 at the 5.8 km site-to-fault distance that  
17 characterizes the Diablo Canyon site (Applicant's Brief).  
18 Despite the fact that the IV-79 peak acceleration values are  
19 generally lower than the 1.15g peak acceleration or 0.75g  
20 zero-period acceleration used as the design basis for the  
21 Diablo Canyon plant (resulting from a postulated 7.5M event  
22 on the Hosgri fault), there are instances (although only  
23 those from the El Centro Arrays are significant) for which  
24 the IV-79 horizontal responses exceed the Newmark Design  
25 Response Spectrum for Diablo Canyon. (See staff brief at  
26 page 9; Brune Affidavit, Attachments A and B.) In view of  
this, the parties should discuss whether the Newmark  
Spectrum is an appropriate and sufficiently conservative  
representation of the 7.5M event at Hosgri. 5/

---

5/ In other words, if the various IV-79 near field  
response spectra were used to generate a smoother,  
average response spectrum for a zero-period accelera-  
tion appropriate to that event (in accordance with  
techniques explained in Blume's testimony fol. Tr. 6099  
at page 6 and pages 39 and 40), and if this spectrum  
were scaled to a 0.75g zero-period acceleration, would  
the resulting response spectrum be bounded by the  
Newmark Spectrum for Diablo Canyon?

11

1           In order to study the characteristics of the  
2 response spectra shapes obtained from the IV-79 records the  
3 24 available horizontal records within eleven km of the  
4 fault were collected and plotted (Blume Figure II-1). The  
5 calculated mean of the 24 horizontal spectra, including the  
6 extremely high spectrum for Bonds Corner, were plotted on  
7 Blume Figure II-2 6/ (Tr. 187, 188). The results clearly  
8 demonstrate the substantial margin between the Diablo design  
9 spectra and the mean Imperial Valley spectrum. Dr. Blume  
10 also prepared a figure showing the peak ground acceleration  
11 of the mean Imperial Valley spectrum normalized to 0.75 g,  
12 and the results showed that the Imperial Valley spectrum  
13 falls within the Diablo Canyon design spectrum within the  
14 periods of interest (Blume II-2; Blume Figure II-3; Tr.  
15 189). Dr. Seed demonstrated that "applying the best  
16 corrections we can to the Imperial Valley data to translate  
17 those records to the Diablo Canyon site, that we in fact  
18 find the resulting spectral shapes will not be greater than  
19 those required by the Newmark-Hosgri spectrum" (Tr. 1415;  
20 App. Ex. R-20). In summary the Newmark and Blume design  
21 response spectra used for the Diablo Canyon Hosgri  
22 reanalysis remain appropriate and conservative in view of  
23 the data obtained from the IV-79 earthquake (Blume II-2;  
24 ///

---

25  
26 6/ The averaging of spectra to arrive at a design spectrum  
is an accepted method (Blume II-2).

1 Newmark 13, 14, 19; Tr. 1353, 1355-1357, 1414, 1415; App.  
2 Exs. R-10, R-20). These results were confirmed by the  
3 modeling work performed by Applicant's witness Frazier  
4 (Frazier VII-4 to VII-13; Frazier Figs. VII-4, VII-5; TERA  
5 Report).

6 Brown witness Young offered testimony on Question  
7 II. He concluded that based on Figure 7 in his testimony  
8 that an appropriate point upon which to anchor his response  
9 spectrum would be 1.4g (Tr. 1007, 1008). The witness could  
10 not name any other building in the world where the design  
11 response spectra was anchored at a level of 1.4g or higher  
12 (Tr. 1009), and that the highest anchor point he knew of was  
13 the 0.75g for Diablo Canyon (Tr. 1010). After testifying  
14 that he expected to see a mean peak horizontal ground  
15 acceleration at the site of 1.0g and that his opinions on  
16 the subject had not changed significantly in the last four  
17 or five years, it developed on cross-examination that he was  
18 the author of a report dated December 1977 concerning  
19 seismic criteria and design concepts for the Point  
20 Conception LNG Import Terminal which recommended that the  
21 peak ground acceleration from the safe-shutdown earthquake  
22 be between .5g and .6g although "Additional study by the  
23 applicant may justify lower values" (App. Ex. R-9, p. x; Tr.  
24 1026, 1030, 1034-1048, 1069, 1070-1078). The earthquake  
25 described as the major seismic hazard to the LNG site was a  
26 magnitude 7.0 to 7.6 assigned to a fault one portion of

1  
2  
3  
4  
5

1 which ran within three miles offshore from the site (App.  
2 Ex. R-9, pp. 38, 39; Tr. 1070). The report also provided as  
3 follows:

4 "It was concluded that the same level of  
5 conservatism in design for safe shutdown  
6 of the plant should be practiced as re-  
7 quired for nuclear power plants . . ."  
8 [App. Ex. R-9, pp. vi, vii.]

9 Question III. We are told that IV-79 data are not  
10 relevant to the Diablo Canyon seismic analysis because that  
11 plant is a "rock" site, whereas the Imperial Valley data  
12 were obtained on soil sites. (Rothman - Kuo Affidavit at  
13 page 3; Blume Affidavit, Paragraph 8.) What is the  
14 significance of this difference in view of the conclusion of  
15 the authors of USGS Circular 795 (based on an analysis of  
16 data provided in that document) that, for comparable  
17 earthquake magnitude and distance, there are no significant  
18 differences between peak horizontal accelerations measured  
19 on soil or rock? (USGS Circular 795 at pages 1, 17, and  
20 26.) This question should be considered in light of  
21 statements by applicant's witness Blume to the effect that  
22 acceleration, rather than velocity or displacement, is the  
23 critical parameter in the design of Diablo Canyon (Blume  
24 Affidavit, Paragraph 9; Testimony fol. Tr. 6099, p. 33).

25 The shape of the response spectrum for a soil site  
26 differs from that of a rock site for a given magnitude  
earthquake, the degree of variation depending on the  
frequency range considered. In the high frequency portion  
of the spectrum most experts indicated that there is  
relatively little difference in the spectrum shape between  
soil and rock sites (TERA Report p. 3-4; Blume III-1, III-2,  
Trifunac III.1). In the medium and low frequency portions  
of the spectrum, the difference in spectrum shapes between  
rock and soil sites is more significant. The high frequency  
portion of the response spectrum is predominately influenced

1 by the level of peak acceleration. USGS Circular 795 stated  
2 that "In the distance range used in the regression analysis  
3 (15-100 km) the values of peak horizontal acceleration  
4 recorded at soil sites in the San Fernando earthquake are  
5 not significantly different from the values at rock sites  
6 . . ." This conclusion is supported by examination of near  
7 field ground motion recordings (TERA Report p. 3-5) and the  
8 results of almost three thousand records from point-source,  
9 large underground nuclear explosions in Nevada and  
10 elsewhere, where at short distances from the source the  
11 average accelerations on rock and on alluvium were found to  
12 be about the same (Blume III-1, III-2).

13 The medium and low frequency portions of the  
14 response spectrum are primarily influenced by peak  
15 velocities and displacements, respectively. It is generally  
16 recognized that velocity and displacement are greater in  
17 soft alluvium than on rock. Thus, with regard to the  
18 Imperial Valley, it would be expected that its deep, soft  
19 (low shear velocity) alluvium and high water table would  
20 have a greater velocity and displacement for comparable  
21 earthquake magnitudes than for a rock site such as Diablo  
22 Canyon (Blume III-2; Newmark 17; Tr. 192).

23 Thus, while the high frequency portion of the  
24 response spectrum (dominated by peak accelerations) for a  
25 rock and a soil site for a given magnitude earthquake will  
26 not differ significantly, there will be significant

1  
2  
3  
4  
5

1 differences in the medium to low frequency portions of the  
2 spectrum (Blume III-2).

3           Applicant witness Dr. H. B. Seed is of the opinion  
4 that accelerations on rock would be about 30 percent higher  
5 than accelerations on deep soil (Tr. 234). Others who do  
6 not see this difference do not separate stiff soil sites and  
7 very deep soil sites which give the difference. (Tr. 250,  
8 251).

9           The matter of relative importance of acceleration,  
10 velocity, and displacement in the Hosgri reanalysis of  
11 Diablo Canyon has been addressed. The significant natural  
12 frequencies of the Diablo Canyon structures are all higher  
13 than 2 Hz. As shown on the 4-way log plot spectral diagrams  
14 of Figure 41-A (D-LL 42 of Amendment 53), the velocity  
15 and/or displacement could be arbitrarily increased to a  
16 considerable degree without affecting the design motion for  
17 these rigid, short-period structures and facilities. In  
18 other words, in the high frequency range, as for Diablo  
19 Canyon, acceleration, and not velocity or displacement, is  
20 the critical parameter in design (Blume III-2, III-3).

21           In conclusion, the response of rigid structures,  
22 such as those at Diablo Canyon, is predominantly governed by  
23 acceleration, but since displacement and velocity also  
24 influence the shape of the response spectrum, it is  
25 inappropriate to use data from soil sites to derive response  
26 spectra for rock sites (Blume III-3).

1  
2  
3  
4  
5

1           Question IV. The magnitude of vertical and  
2 horizontal acceleration values measured at IV-79 are  
3 generally comparable. (Mean values calculated at a distance  
4 of 5.8 km from the fault are virtually identical.) The  
5 response spectra developed for vertical motion within 11 km  
6 of the Imperial Fault during IV-79 appear to show generally  
7 equivalent values of vertical and horizontal response for  
8 periods less than about 0.2 seconds (i.e., frequencies in  
9 excess of 5 cps). Finally, in some instances the higher  
10 frequency portions of the IV-79 response spectra for  
11 vertical motion exceed comparable portions of the Diablo  
12 Canyon Design Response Spectrum.

13           Observations made of the IV-79 data and response  
14 spectra appear to be consistent with the criteria set forth  
15 in NRC Regulatory Guide 1.60. These require that vertical  
16 accelerations in the higher frequency range be equal to  
17 horizontal accelerations. As the guide states:

18           It should be noted that the vertical  
19 Design Response Spectra are  $2/3$  those of  
20 the horizontal Design Response Spectra  
21 for Frequencies less than 0.25; for  
22 frequencies higher than 3.5 they are the  
23 same, while the ratio varies between  $2/3$   
24 and 1 for frequencies between 0.25 and  
25 3.5.

26           The references to vertical motion made in the Diablo Canyon  
record, however, indicate that a  $2/3$  ratio between vertical  
and horizontal motion was apparently utilized at all  
frequencies. The parties should address this apparent  
inconsistency and explain it, if possible. Should there be  
substantive and relevant analyses suggesting that vertical  
motion records do not reflect the true vertical motion,  
these should be provided.

          Some vertical accelerations recorded for the IV-79  
earthquake were unusually high in relation to recorded  
horizontal accelerations. These data are presented in  
Frazier Table IV-1 for the strong motion stations positioned  
as shown in Frazier Figure IV-1. At close distances, the  
peak vertical accelerations were as high, on the average, as  
the peak horizontal accelerations. A few of the stations

11  
12  
13  
14

1 recorded vertical peaks that were substantially higher than  
2 the horizontal peaks. While vertical accelerations that  
3 rival or exceed the peak horizontal accelerations are  
4 unusual, they are not without precedent. However, the peak  
5 vertical acceleration of 1.74 g (later corrected to 1.52 g)  
6 recorded for Station 6 is without precedent (Frazier IV-1).

7 Dr. Newmark indicated that high vertical-to-hori-  
8 zontal peak acceleration ratios are caused by instrument  
9 "over-registration" unless firmly attached and could be  
10 discounted (Tr. 426, 427 587-589). As a result Dr. Newmark  
11 stated the two-thirds ratio of vertical-to-horizontal motion  
12 used at Diablo Canyon was justified (Newmark 8, 9, 12). Dr.  
13 Blume also concluded that "vertical recordings are too high"  
14 (Blume IV-5).

15 In interpreting the unusually high vertical  
16 accelerations recorded during the IV-79 event, it is  
17 important to examine the different characteristics of  
18 seismic waves. Acoustic waves in the earth are referred to  
19 as compressional waves or "P waves." The particle motion  
20 for these waves is along the direction of propagation.  
21 Waves with shearing motions, particle motion perpendicular  
22 to the direction of propagation, are referred to as shear  
23 waves or "S waves." The velocity of P waves is always  
24 larger than that of S waves. Hence, the first motions to  
25 occur during an earthquake are due to P waves. Because  
26 these waves emerge steeply, and because the particle motion

1 is along the direction of propagation, P waves appear  
2 principally on vertical recordings. S waves arrive later  
3 and typically provide the preponderance of seismic energy on  
4 both horizontal and vertical recordings of earthquakes. It  
5 is these waves that account for most earthquake damage to  
6 structures (Frazier IV-2; Tr. 255).

7 For typical Southern California earth structures,  
8 vertically polarized shear waves (S waves), and not P waves,  
9 account for the largest vertical accelerations.

10 Furthermore, the vertical-to-horizontal amplitude ratio for  
11 the S waves is typically less than one. This ratio is  
12 controlled by the tangent of the angle of the emerging  
13 S waves with respect to vertical. The angle is small since  
14 material velocities, which increase with depth, cause the  
15 high frequency waves to emerge steeply. Consequently,  
16 vertical accelerations are typically lower than horizontal  
17 accelerations (Frazier IV-2; Tr. 286).

18 In the Imperial Valley, however, the situation is  
19 atypical. The deep sedimentary layering there causes  
20 unusually large P-wave amplitudes. Examination of the  
21 recordings for IV-79 indicate that the large vertical  
22 accelerations resulted from high frequency P waves, not  
23 S waves. The unusually large P waves that appear in the  
24 vertical recordings from IV-79 are due to the uncommon wave  
25 properties of the deep sedimentary basin found in the  
26 Imperial Valley, illustrated in Frazier Figure IV-2.

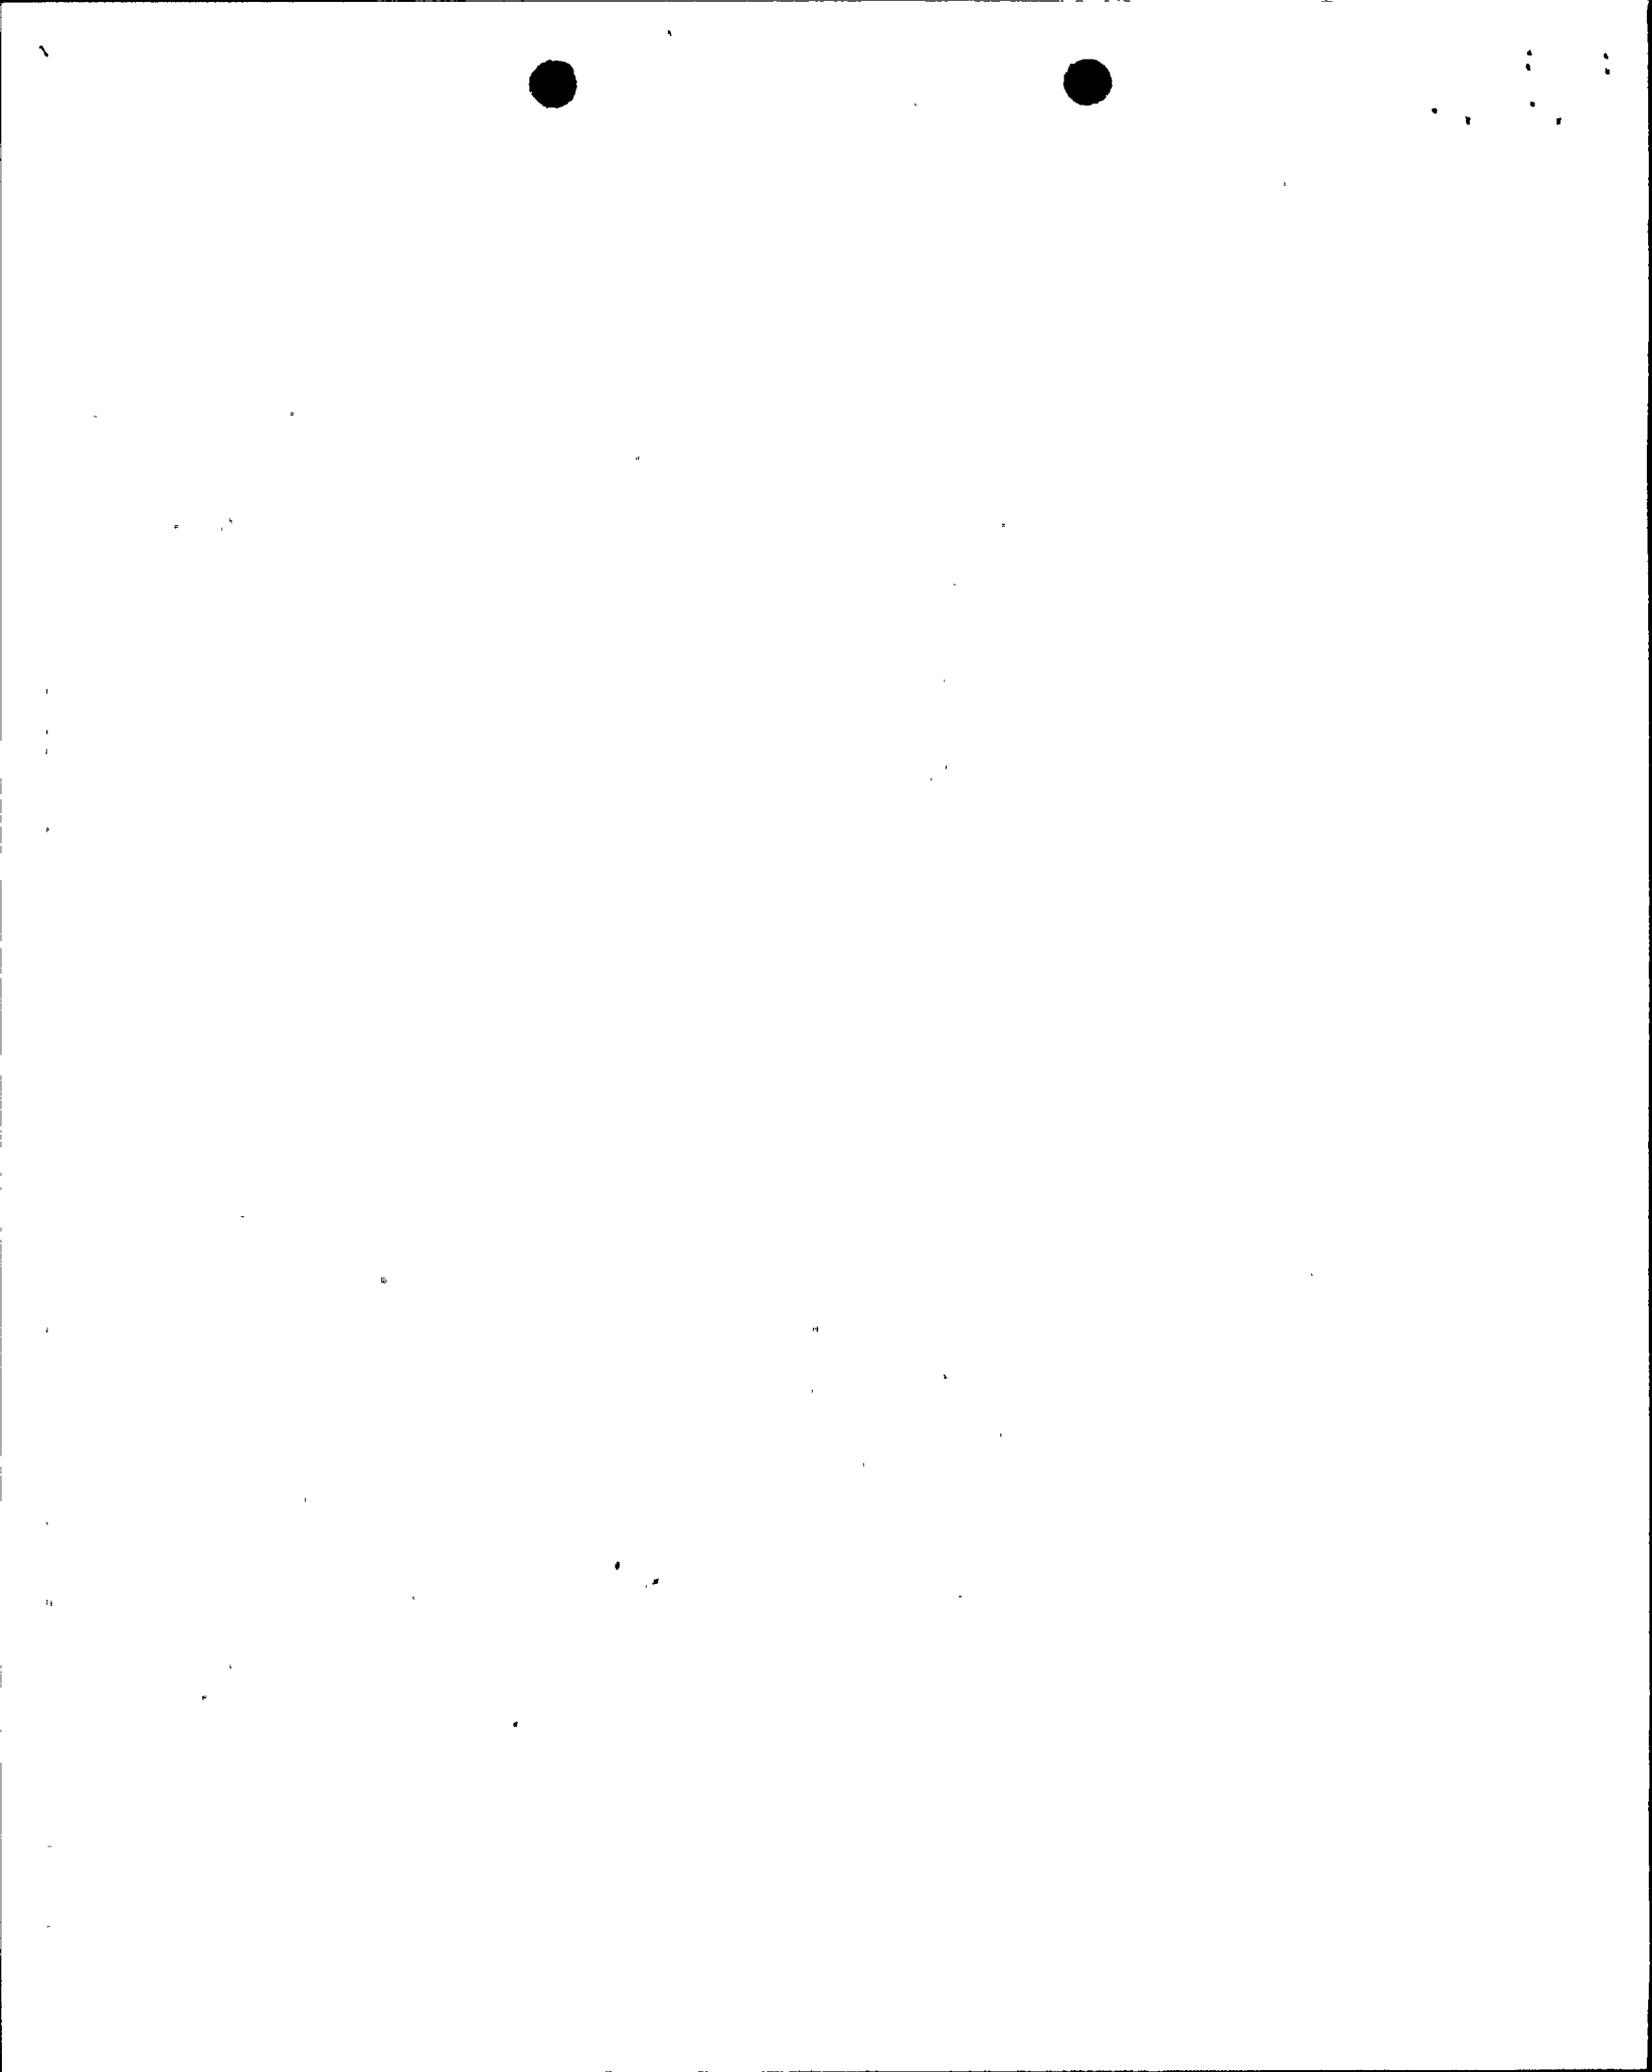

1  
2  
3  
4  
5

1 Material velocities increase nearly linearly with depth from  
2 low values within the 300 meters or so of surface alluvium  
3 to values typical of bedrock at a depth of 6 kilometers.  
4 The properties of this deep sedimentary basin are markedly  
5 different from other regions of California where rock is  
6 encountered within 1 or 2 km of the earth's surface as  
7 illustrated in Frazier Figure IV-2 (Frazier IV-3; Tr. 255,  
8 256).

9           The substantial velocity gradient with depth at  
10 Imperial Valley causes waves to bend (refract) toward the  
11 earth's surface along circular paths in accordance with  
12 Snell's law. The sedimentary basin acts somewhat like an  
13 echo chamber due to the extreme bending of waves toward the  
14 earth's surface. For example, at Imperial Valley only about  
15 10% of the seismic energy (P and S waves) emanating from  
16 earthquake rupture at a depth of 3 km escapes into the  
17 underlying bedrock (e.g. Ray "D" on Frazier Figure IV-3).  
18 The remaining 90% emerges at the earth's surface within an  
19 epicentral distance of 20 km. In a more typical situation,  
20 such as at Diablo Canyon, the energy within 20 km is about  
21 60 percent. Therefore, the unusual echo chamber effect at  
22 Imperial Valley which concentrates seismic energy would not  
23 be expected at Diablo Canyon (Frazier IV-4; Tr. 256, 257,  
24 258, 277, 435, 437, 438).

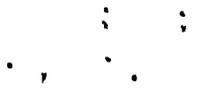

25           While the echo chamber effect at Imperial Valley  
26 would tend to increase both P and S wave amplitudes, the

1 unique velocity profile there (Frazier Figure IV-2)  
2 preferentially amplifies P-wave amplitudes. Due to the  
3 conservation of energy, the amplitude of a seismic wave  
4 increases as it propagates into a medium of decreasing  
5 stiffness. Consequently, the amplitudes of the emerging  
6 waves increase rather dramatically as they approach the  
7 earth's surface. However, high frequency S waves are  
8 severely attenuated in the shallow sediments, thereby  
9 compensating for the amplification of the sedimentary basin.  
10 P waves, on the other hand, can travel efficiently in the  
11 soft surface materials. In the shallow sediments at  
12 Imperial Valley, S waves above 10 Hz can be attenuated by a  
13 factor of ten within one kilometer, while P waves above  
14 10 Hz are attenuated only about 20% over the same distance  
15 (Frazier IV-4; Tr. 257, 258, 287).

16 The large and uniform velocity gradient with depth  
17 in the Imperial Valley preferentially amplifies the P waves  
18 and thus yields higher vertical acceleration peaks than  
19 horizontal peaks. This effect is due to the unique earth  
20 structure at Imperial Valley and since the earth structure  
21 at Diablo Canyon is substantially different, such high  
22 verticals are not expected (Frazier IV-4; Tr. 277).

23 Comparative calculations have been performed to  
24 examine how differences in earth structure between Imperial  
25 Valley and Diablo Canyon lead to differences in surface  
26 motions. Frazier Figure IV-2 illustrates the differences in

1 two earth structures with lower material velocities present  
2 in the Imperial Valley to a depth of about 6 km. Surface  
3 motions have been calculated for small (point) earthquake  
4 ruptures positioned at varying hypocentral depths and  
5 epicentral distances for layered representations of these  
6 two earth structures. The results, termed Green's  
7 functions, include all wave types (including P, S, and  
8 surface waves) over the frequency band from 0 to 20 Hz  
9 (Frazier IV-5).

10 The most notable difference was the ratio of peak  
11 vertical to peak horizontal accelerations. These  
12 vertical-to-horizontal ratios were computed and averaged  
13 over epicentral distances less than 10 km. These ratios,  
14 averaged over the near field, are presented in Frazier Table  
15 IV-2. The vertical-to-horizontal ratio of peak acceleration  
16 is about three to ten times higher for Imperial Valley than  
17 for Diablo Canyon for both strike-slip and dip-slip rupture  
18 over the range of hypocentral depths that were tested.  
19 These results indicate the trend to be expected in actual  
20 earthquake motions, namely, considerably reduced vertical to  
21 horizontal ratios of accelerations at Diablo Canyon as com-  
22 pared to the corresponding ratios recorded for the Imperial  
23 Valley earthquake (Frazier IV-5; Tr. 282, 283, 443).

24 Further discussion of computed ground motions at  
25 Diablo Canyon due to a major hypothesized earthquake along  
26 the Hosgri fault may be found in Dr. Frazier's response to

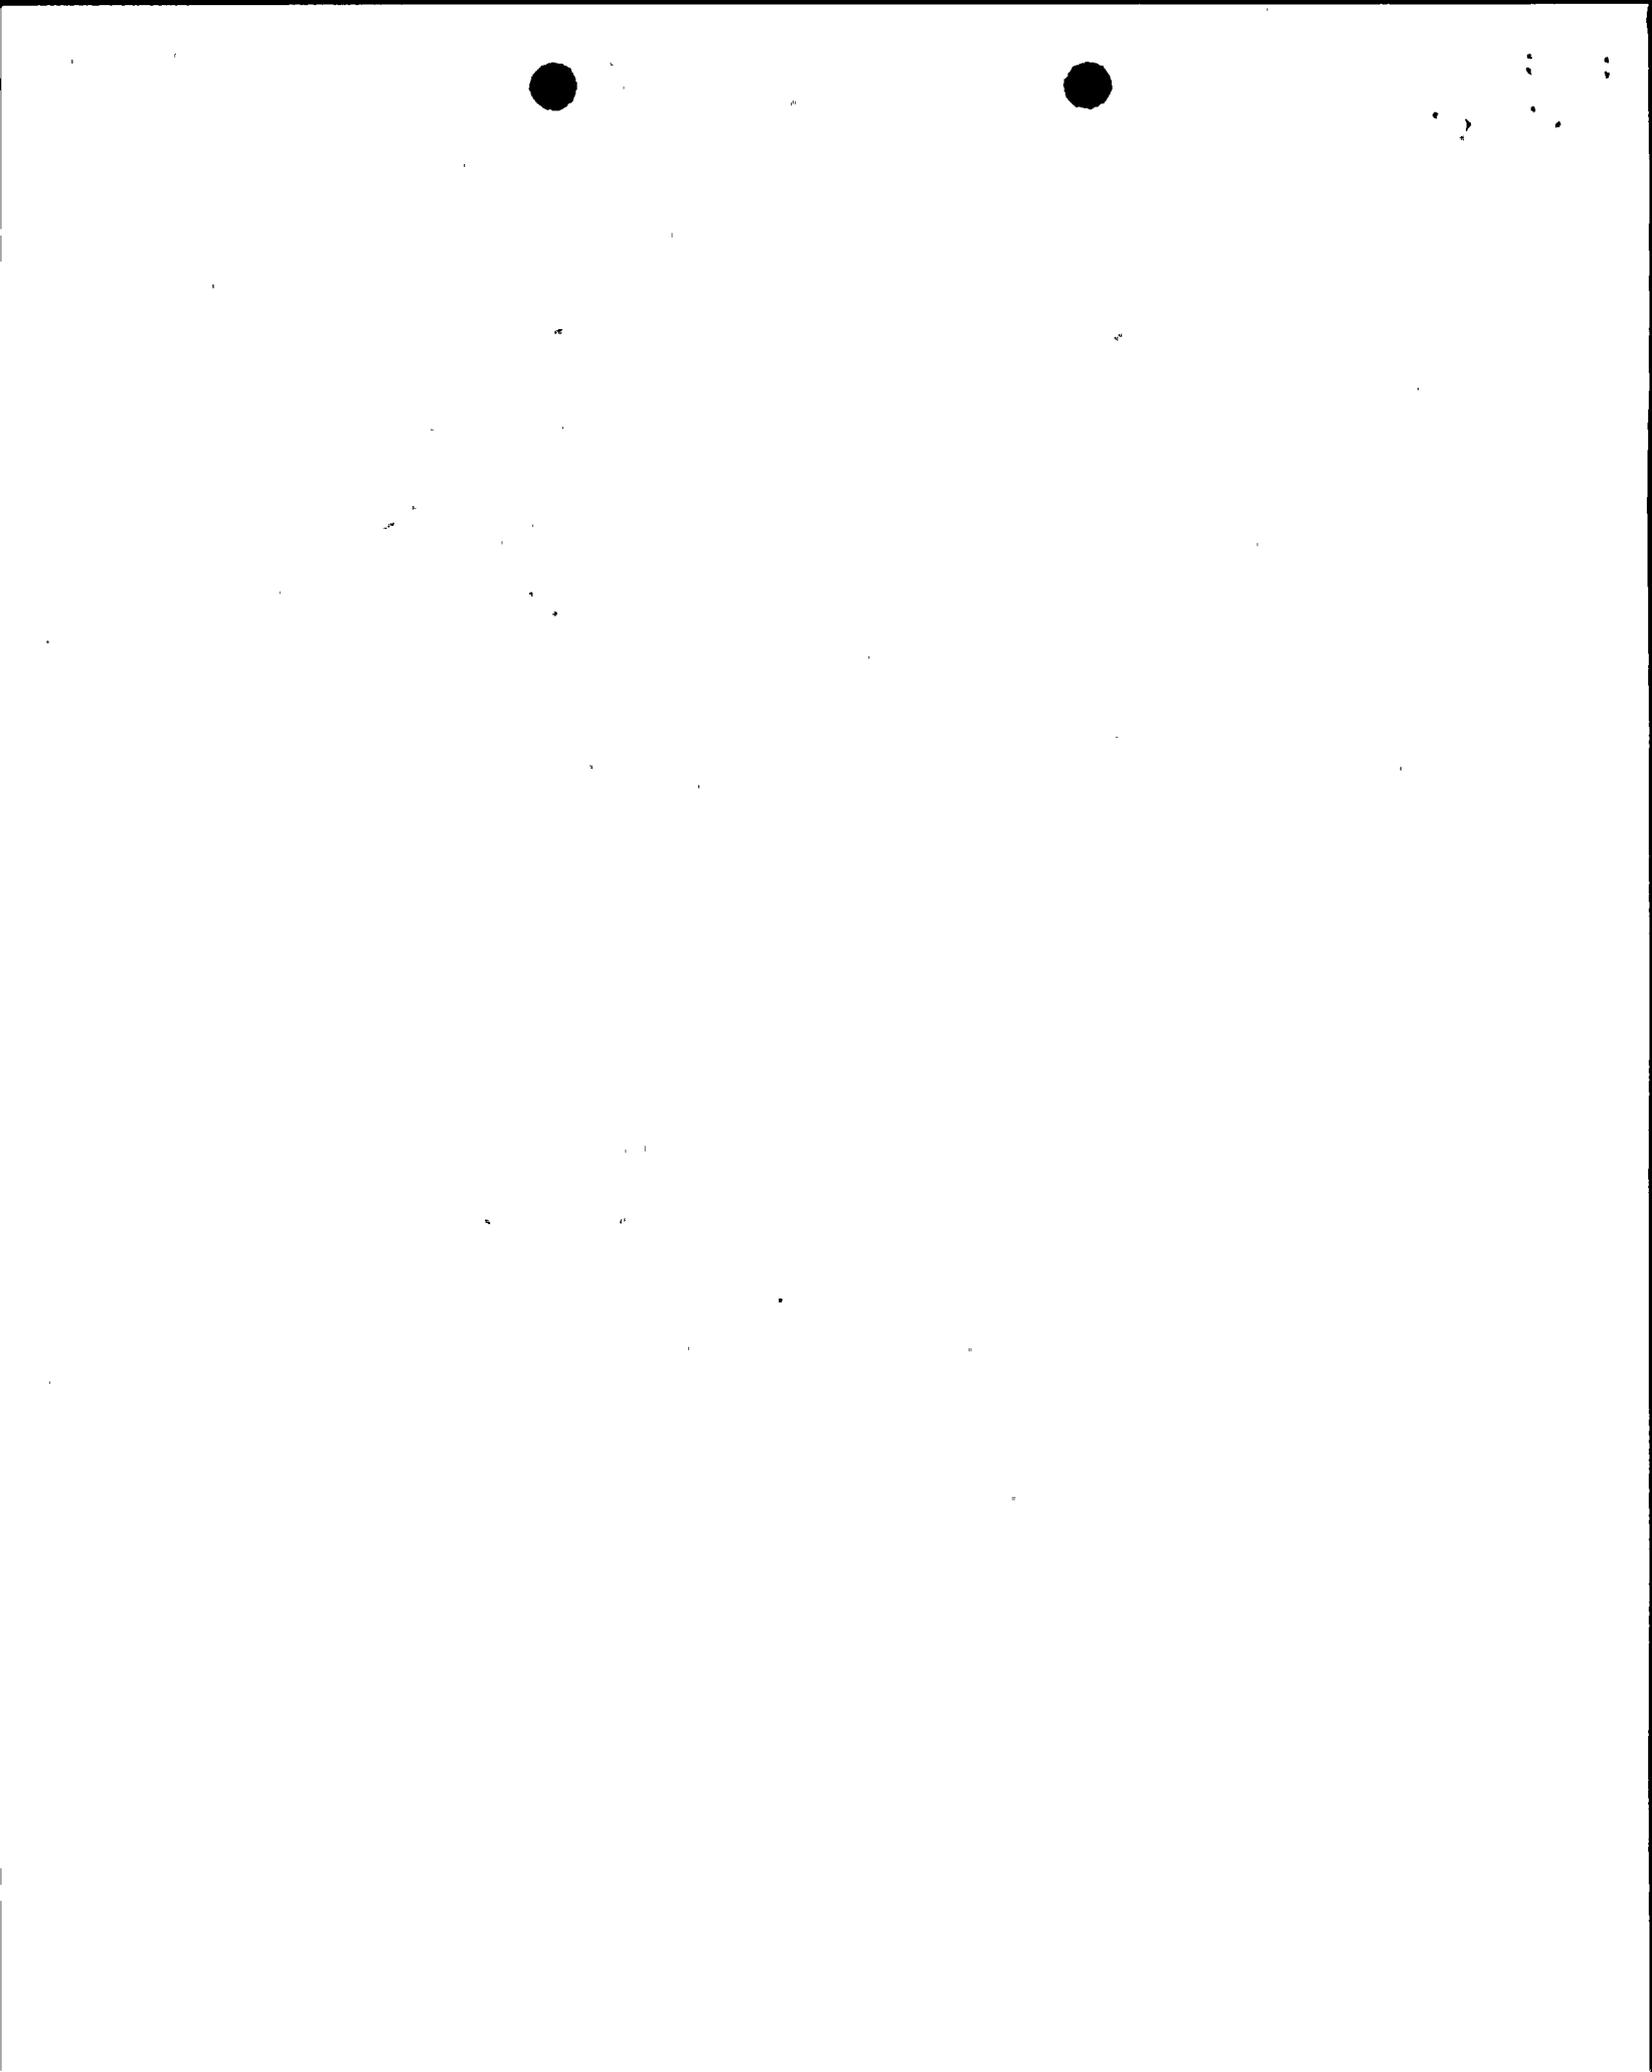

;

1 Question VII. The results of earthquake modeling yield  
2 vertical accelerations less than half the horizontal  
3 accelerations (Frazier IV-6).

4 Even accounting for the effects of the unique  
5 earth structure at Imperial Valley, the large vertical  
6 acceleration recorded at Station 6 (1.74 g later corrected  
7 to 1.52 g) during the 1979 Imperial Valley earthquake poses  
8 an enigma. Station 7, which is about 1 km SW of Station 6,  
9 recorded a peak vertical acceleration of .65 g (corrected to  
10 .51 g), and Station 5, which is approximately 3 km NE of  
11 Station 6, recorded a peak vertical of .71 g (corrected to  
12 .44 g). It is clear from field observations that the  
13 Imperial Fault passes between Station 6 and Station 7 and  
14 the Brawley Fault passes between Station 6 and Station 5.  
15 It is important to note that the motion of the wedge-shaped  
16 block, upon which Station 6 is located, is downward relative  
17 to the adjacent blocks (Frazier IV-6).

18 Of significance is the observation that the  
19 S waves at Station 6 were delayed by .5 seconds relative to  
20 Station 7. Station 6 is underlain by material of lower  
21 velocity than is Station 7. The lower velocities may be due  
22 to the down-dropping of the wedge-shaped block between the  
23 Imperial and Brawley Faults upon which Station 6 is located.  
24 This would result in a greater accumulation of lower  
25 velocity sediments beneath Station 6 that would extend  
26 deeper than beneath either Station 7 or 5. However, due to

1 rapid depositional processes, the surface velocities would  
2 likely be similar beneath all of these stations. A  
3 laterally heterogeneous earth structure, which exhibits a  
4 column of low velocity material beneath the vicinity of  
5 Station 6, would trap obliquely emerging waves by refracting  
6 the wave toward the region of lower velocities (i.e., into  
7 the wedge). This is believed to be the cause of the  
8 significant amplification of vertical accelerations recorded  
9 at Station 6. Material attenuation, as cited above,  
10 prevented severe amplification of the high frequency  
11 S waves, which represent the major contributor to the  
12 horizontal ground acceleration (Frazier IV-7, IV-8).

13           Extensive geologic investigations at the Diablo  
14 Canyon site indicate that similar local amplifications of  
15 ground motion should not occur at that site. Therefore,  
16 such unusual recordings as that for Station 6 do not provide  
17 suitable analogs for use in evaluating the seismic criteria  
18 at Diablo Canyon (Frazier IV-8).

19           While some of the peak vertical accelerations  
20 recorded at IV-79 were unusually high, little damage  
21 occurred. This can partially be explained by two facts.  
22 First, the few large vertical pulses are isolated and, while  
23 large in amplitude, they are relatively low in energy.  
24 Second, the P waves with the high peak vertical accelera-  
25 tions arrive well before the onset of the S waves. Thus,  
26 observed recordings of the IV-79 earthquake do not pose as

1  
2  
3  
4  
5

1 severe a threat to structures as their peak accelerations  
2 might suggest due to phase differences in the individual  
3 components (Frazier IV-10).

4 A study of earthquake time histories reveals not  
5 only that the horizontal peaks are usually well separated in  
6 the time domain, but that the vertical peaks are separated  
7 from the horizontal peaks by even more time, up to several  
8 seconds. IV-79 was no exception. The Hosgri reanalysis,  
9 however, required that all three components be considered  
10 simultaneously, with responses combined on a  
11 square-root-of-the-sum-of-the-squares process. In addition,  
12 the Hosgri reanalysis required two equal horizontal  
13 components; in actuality, one horizontal component always  
14 exceeds the other, sometimes substantially. The conclusion  
15 is that the combining procedure for the three earthquake  
16 components, and the assumption of equal horizontal compo-  
17 nents is a conservative procedure (Blume IV-5; Tr. 285,  
18 286).

19 In summary, the vertical accelerations recorded  
20 during the 1979 Imperial Valley earthquake are large due to  
21 the wave properties of the deep sedimentary basin. Such  
22 large vertical accelerations are not likely at Diablo  
23 Canyon. In addition, the required simultaneous combination  
24 of the three components of ground motion for Diablo Canyon  
25 conservatively ignores the actual recorded large phase

26 ///

1 differences between the vertical and horizontal components  
2 (Frazier IV-10).

3 In the Diablo Canyon original design vertical  
4 accelerations were taken at 2/3rds of the horizontal. At  
5 the time Diablo Canyon was designed the 2/3 rule was in  
6 nearly universal effect for nuclear plants. In the opinion  
7 of Applicant witness Blume the two-thirds ratio is appro-  
8 priate for rock sites (Tr. 420). The Diablo Canyon  
9 structures, however, are in fact capable of accommodating  
10 far more than a 2/3 ratio (Blume IV-2; Tr. 419). In the  
11 reanalysis for the Hosgri fault exposure more than 2/3 was  
12 actually used in most cases. The Blume written testimony in  
13 the Licensing Board seismic hearings presented in Figures 8  
14 through 17 to that testimony gives the Hosgri spectra by  
15 Blume and Newmark anchored to 0.50g at zero period without  
16 any tau reduction. The 0.50g was simply 2/3 of the 0.75g  
17 value where tau was zero. A tau reduction could have been  
18 taken as well for the vertical spectra due to the lack of  
19 wave coherence, embedment and other reasons, but it was not.  
20 Using the Newmark horizontal spectrum as an example, the  
21 ratios of the peak vertical effective acceleration to the  
22 peak horizontal are as follows:

23	Miscellaneous Small Structures:	$0.50/0.75 = 0.67$
24	Containment and Intake:	$0.50/0.60 = 0.83$
25	Auxiliary:	$0.50/0.55 = 0.91$
26	Turbine:	$0.50/0.50 = 1.00$

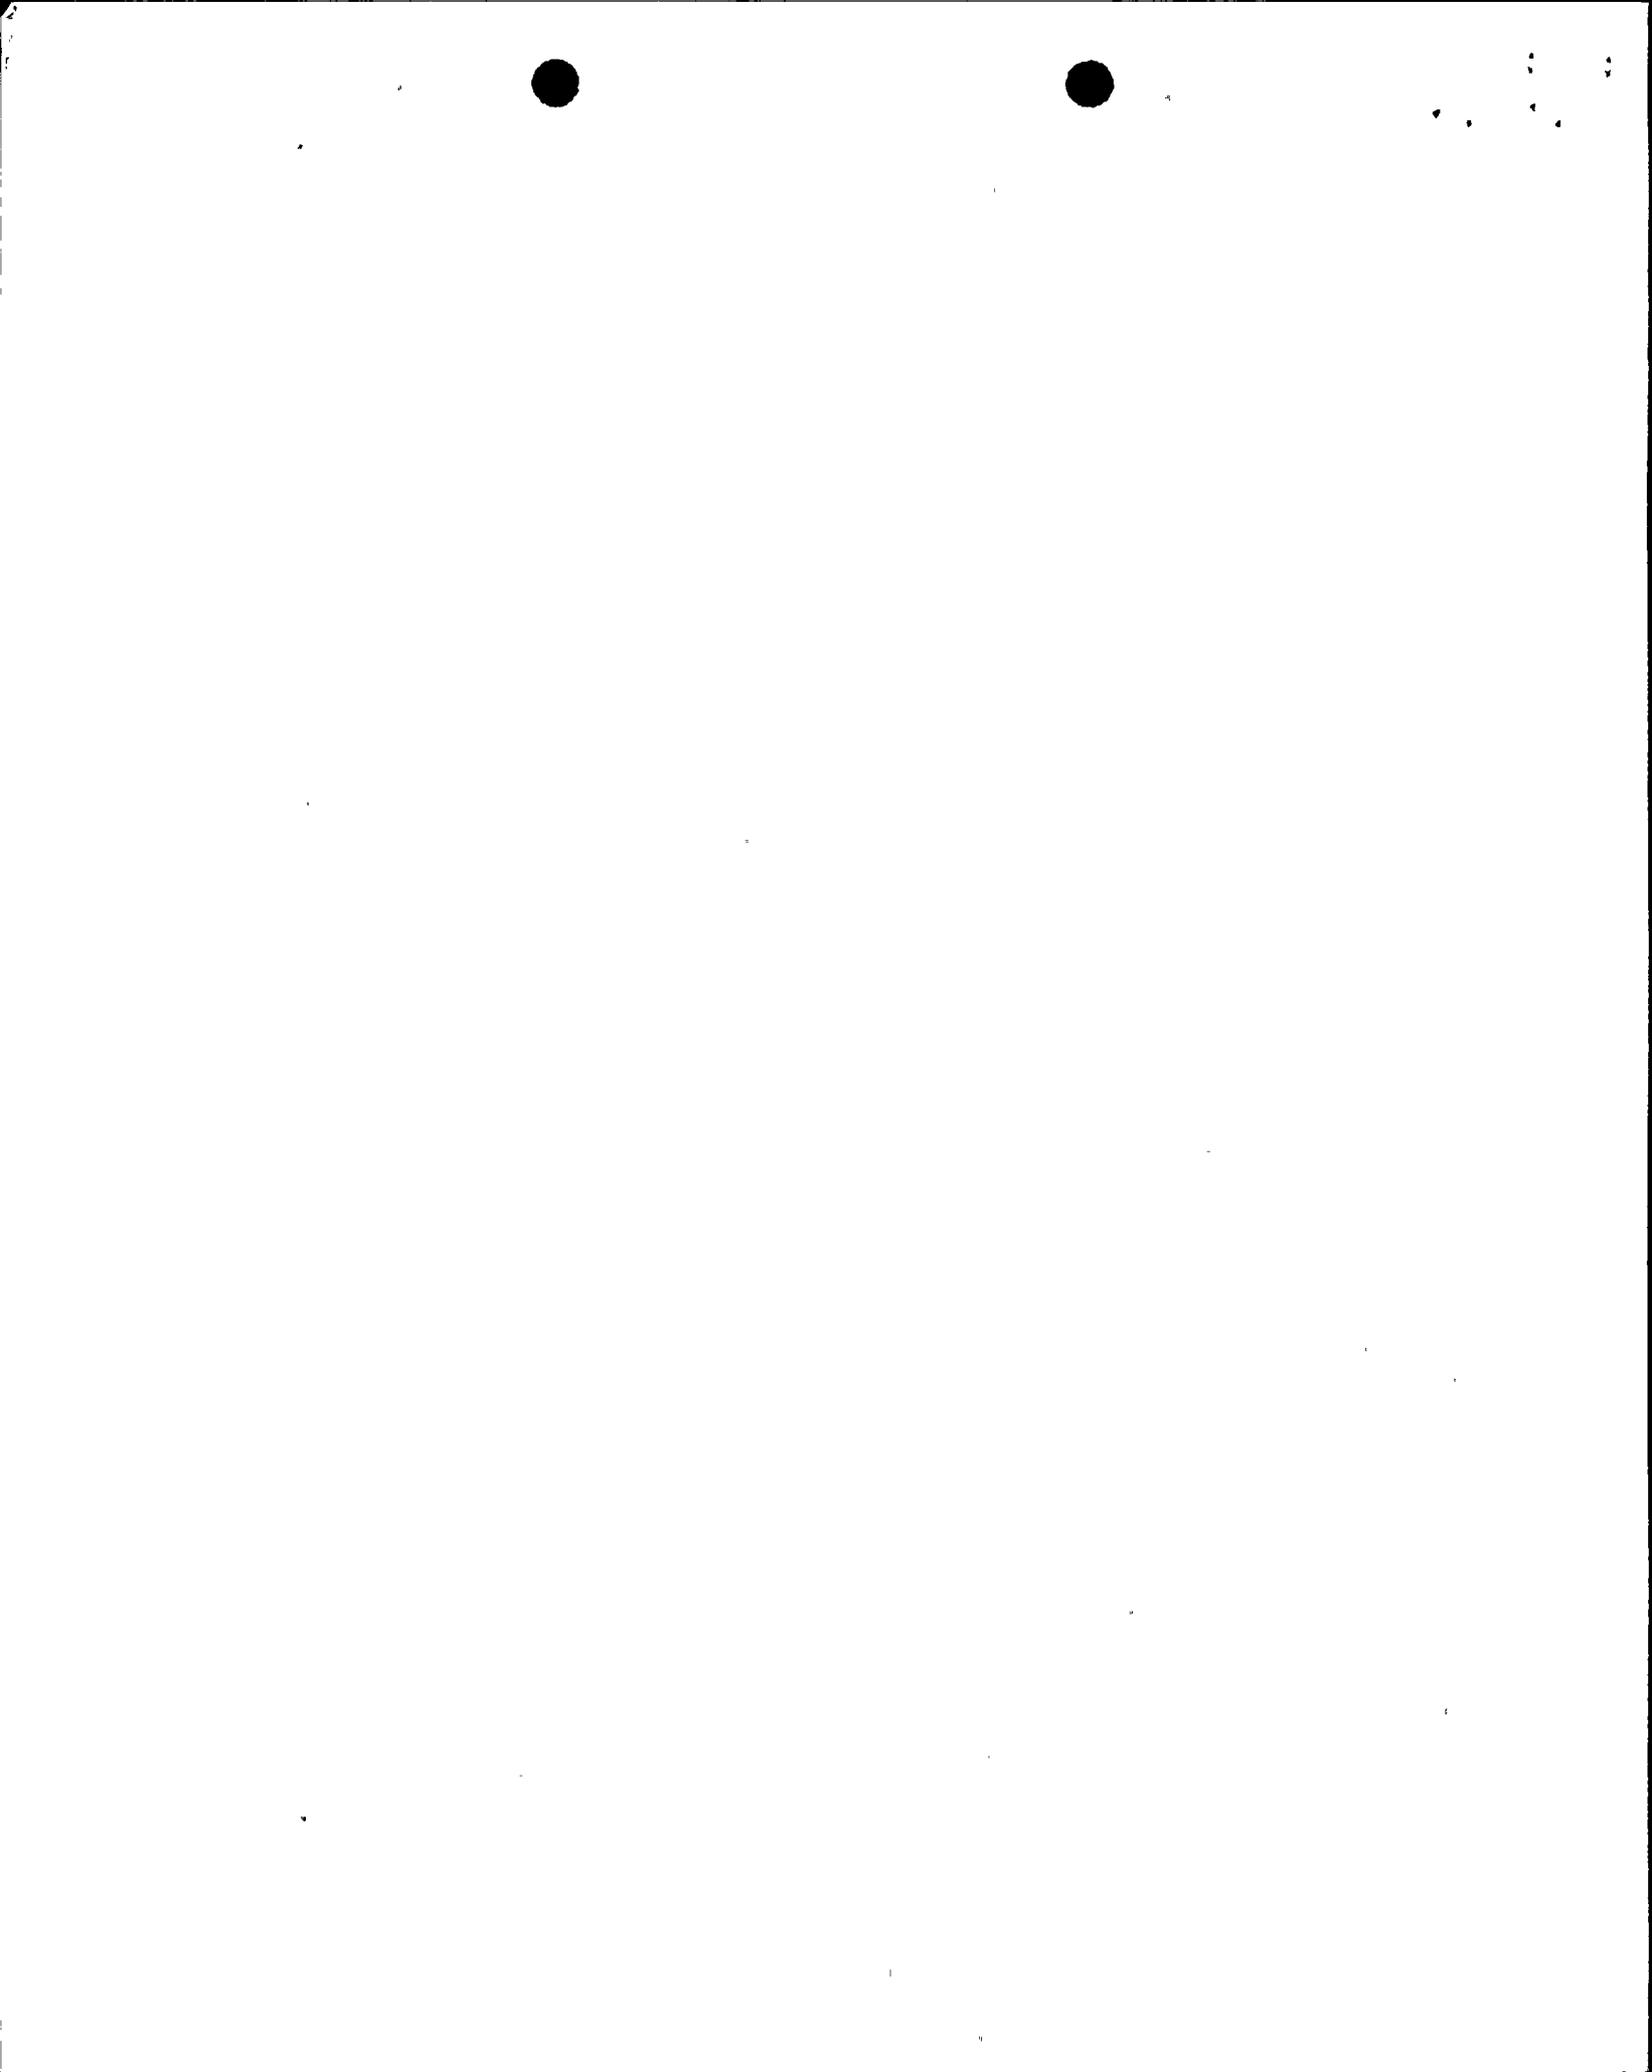

1  
2  
3  
4  
5

1 Thus, for the most important structures, the effective ratio  
2 of peak vertical to peak horizontal acceleration is more  
3 than 0.67 (Blume IV-2, IV-3; Tr. 416, 419).

4           When the ratio of vertical to horizontal is  
5 studied on a spectral basis, we see that the ratio varies  
6 depending on the period of vibration. Blume Figures IV-1  
7 and IV-2 show the ratio of vertical design spectrum to  
8 horizontal design spectrum for the Blume and Newmark Hosgri  
9 spectra, respectively. The figures demonstrate that within  
10 the period range of interest (less than 0.5 sec) only the  
11 ratios for the miscellaneous structures approach two-thirds.  
12 The primary Category 1 structures are designed to ratios  
13 greater than two-thirds, and in the case of the Turbine  
14 Building the ratio approaches 1.4 at about 0.10 seconds for  
15 the Blume spectrum. The ratio specified by NRC Reg. Guide  
16 1.60 is also shown on the figures for reference. Thus,  
17 while the Hosgri reevaluation criteria specified a  
18 two-thirds ratio of vertical to horizontal, the facts are  
19 that the primary structures and components have been  
20 analyzed for ratios greater than two-thirds (Blume IV-3).

21           Dr. Smith showed that the incoherence of high  
22 frequency motion was such that the vertical PGA across a  
23 building could be reduced in a manner similar to the  
24 included in the "tau effect" for horizontal PGA (Tr.  
25 1391-6). Such a reduction was not included for Diablo

26 ///

1 Canyon and therefore an additional element of conservatism  
2 is present (Blume IV-2).

3 Question V. Peak horizontal acceleration values  
4 measured at the base of the Imperial Valley Services  
5 Building during IV-79 exceed those measured in the free  
6 field 103 meters away from the building. The motion records  
7 are described as showing similar amplitudes but greater low  
8 frequency motion in the building than in the free field. No  
9 response spectra for the two recording locations have been  
10 provided. The acceleration data, however, may be taken to  
11 indicate that no reduction in building motion due to the tau  
12 effect was realized in this instance.

13 Based on these observations, intervenors question  
14 the validity of the tau concept as well as its use to reduce  
15 the higher frequency portions of the Diablo Canyon Design  
16 Spectrum. The staff and the applicant answer that, because  
17 the Imperial County Services Building was supported on piles  
18 in a deep soil structure, these observations are irrelevant  
19 to the use of a tau effect in the seismic reanalysis of  
20 Diablo Canyon, which is built on a rock site. Staff witness  
21 Newmark, however, used recorded earthquake motions at the  
22 Hollywood Storage Building to demonstrate the use of a tau  
23 effect analysis. The Hollywood Storage Building itself is  
24 built on piles in soil. Thus, the "build-on-piles"  
25 rationale appears insufficient to explain why no tau effect  
26 was evident at the Imperial Valley Services Building.

16 One feature distinguishing the two buildings that  
17 no party commented upon is that the Hollywood Storage  
18 Building has a basement and the Services Building does not.  
19 Intervenors' witness, Dr. Luco, used this fact to explain in  
20 part why he believes the Hollywood building should have a  
21 large tau value. Rojahn and Ragsdale's discussion implies  
22 that to some extent ground level instrumental responses  
23 within the Imperial Valley Services Building may have been  
24 influenced by the response (and failure) of the building  
25 itself.

21 In any event, given the apparent similarities  
22 between the structural foundations of the two buildings, the  
23 explanations provided thus far for a seeming lack of a tau  
24 effect at the Imperial Valley Services Building are  
25 inadequate. The parties should provide additional  
26 information on this point and relate their analyses to both  
geologic and structural conditions prevailing at the Diablo  
Canyon site.

Geology

Applicant's geological witness Douglas Hamilton described the differences between the Imperial Fault and the Hosgri Fault. His testimony included three tables which presented comparisons of the faults on three bases: character of the crust in the region of each fault; character of the fault itself; and character of sites near each fault. The information contained in the three tables indicates that, except for the facts the two faults have roughly comparable lengths, and each has a component of right-lateral strike slip in its sense of offset, the faults are dissimilar in nearly all respects. Sites located between five and six km (as well as over a much wider range of distances) from the fault traces also are highly dissimilar. He therefore concluded that the geological conditions which gave rise to the ground response effects recorded during the IV-79 earthquake do not exist at the Diablo Canyon site (Hamilton V-11 through V-15).

Structures

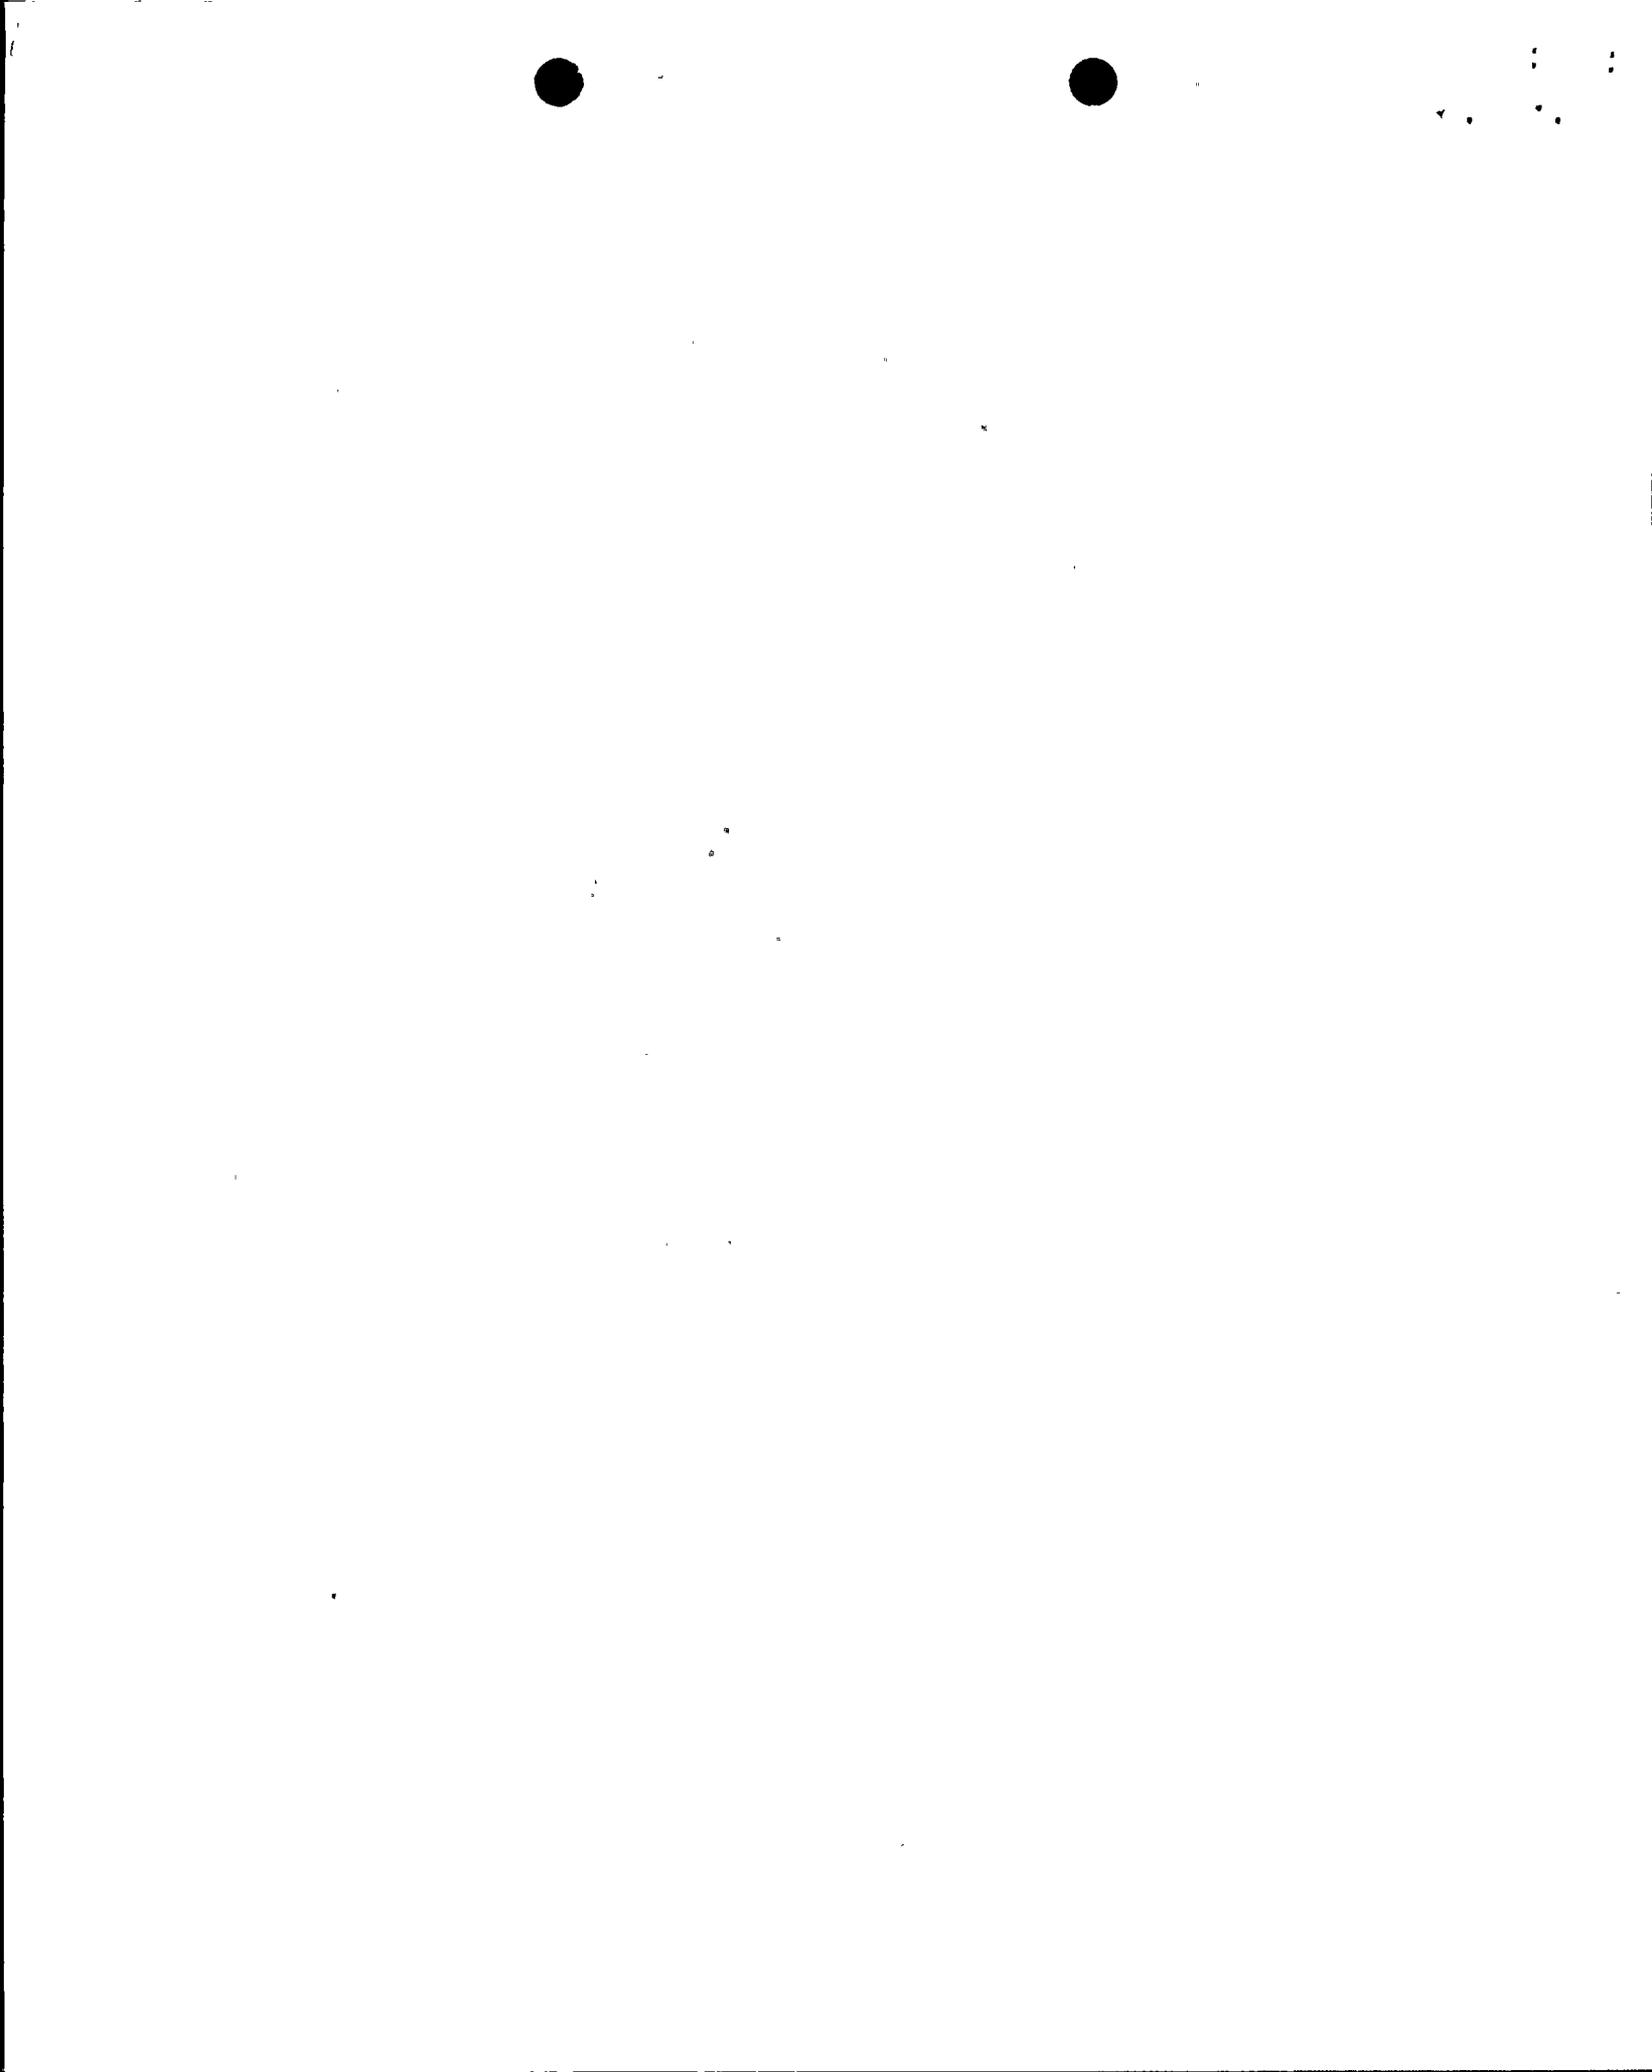

There are major structural and foundation differences between the Hollywood Storage Building ("HSB"), the Imperial County Services Building ("ISCB") and the Diablo Canyon structures. The HSB has a basement with heavy and continuous basement walls and it has a full-area concrete base slab extended to these walls. Thus its base in effect constitutes a rigid horizontal plate girder with a

1 1  
1 1  
1 1

1 web (slab) and flanges (walls). The base of this structure  
2 is very stiff horizontally. Moreover, there is passive  
3 resistance of the soil against the basement walls  
4 (Blume V-2).

5           The ICSB, on the other hand, has no basement; it  
6 has only one short segment of wall at its first story  
7 perimeter, and its base slab does not extend to either line  
8 of foundations in the longitudinal direction. There are  
9 small ties between the pile caps but these have little  
10 rigidity to act as a horizontal rigid frame. The connection  
11 of the slab to the few interior first-story wall segments is  
12 minimal. Moreover, the connection of the ICSE slab to the  
13 structure is not such as to make even this minor rigidity  
14 effective. Therefore, the ICSB does not have adequate  
15 lateral stiffness at its base to develop much, if any, "tau  
16 effect," whereas the HSB has sufficient stiffness. The ICSB  
17 is founded on much softer and deeper soil than the HSB. The  
18 ICSB also has relatively long (45 ft to 60 ft) piles which  
19 do not reach to a significantly harder material. The shear  
20 velocity of the soil in which these relatively flexible ICSB  
21 piles are embedded is only in the range of 400 to 700 fps  
22 and the material below the pile tips does not reach 1050 fps  
23 velocity until a depth of over 200 feet. At the HSB the  
24 piles are relatively short (12 ft to 30 ft) and thus  
25 stiffer, and since they extend into a much firmer layer of  
26 material the lateral stiffness of the two buildings differs

1 greatly. The size and shape of the two buildings vary as  
2 well, so the buildings are not comparable in size or  
3 proportion. Further, the HSB has much more total pile  
4 capacity per square foot of building area than the ICSB  
5 because it is higher and is designed for heavy storage  
6 loading (Blume V-3).

7 In summary as to the comparison of the two  
8 buildings, they are not at all alike in spite of both having  
9 piles. The ICSB is much more flexible in soil and/or pile  
10 movement horizontally and since the horizontal rigidity of  
11 the ICSB structure at its base level is only a fraction of  
12 that of the HSB it is considered inadequate to support a  
13 "tau effect." To state that these two buildings are alike  
14 because they both have piles is similar to stating that they  
15 are alike because both have walls and roofing (Blume V-4).

16 The Diablo Canyon structures are obviously a great  
17 deal more rigid laterally than the HSB for the following  
18 reasons:

- 19 ° They are based on rock
- 20 ° They are embedded in the rock
- 21 ° They are large
- 22 ° They are massive
- 23 ° Their base slabs and walls are very thick

24 In short, the Diablo Canyon plant is far better suited for  
25 the tau concept than even the HSB or for that matter any  
26 building in Los Angeles or San Francisco (Blume V-4, V-5).

ICSB Record

The acceleration records in the ICSB show higher values than the records of free-field motions and thus could lead to the conclusion that tau-effect is not realized in this instance. Such a conclusion is not warranted, however, on the basis of this data. At least two good explanations exist for the apparent absence of a tau-effect in this case:

1. Since there is invariably some scatter in observed levels of peak acceleration at nearby locations in the free-field, the record of free-field peak acceleration values is not necessarily representative of the general free-field conditions in the region surrounding the ICSB. Thus if additional free-field records had been obtained at other locations nearer to or on other sides of the building, they are likely to have shown peak acceleration values different from those of the single free-field station installed about 300 feet from the building. The occurrence of scatter within a limited area may easily result in motions that vary by a factor of 1.5 or more. The ICSB free-field record is lower than several other records at greater distances from the fault. Thus the average free-field motions in the vicinity of the ICSB may easily have been as high as 0.33 g (0.22 x 1.5) at other surrounding points in the free-field. In fact they may have been even higher since the motions shown by the single recording in the free-field near the ICSB were unusually low

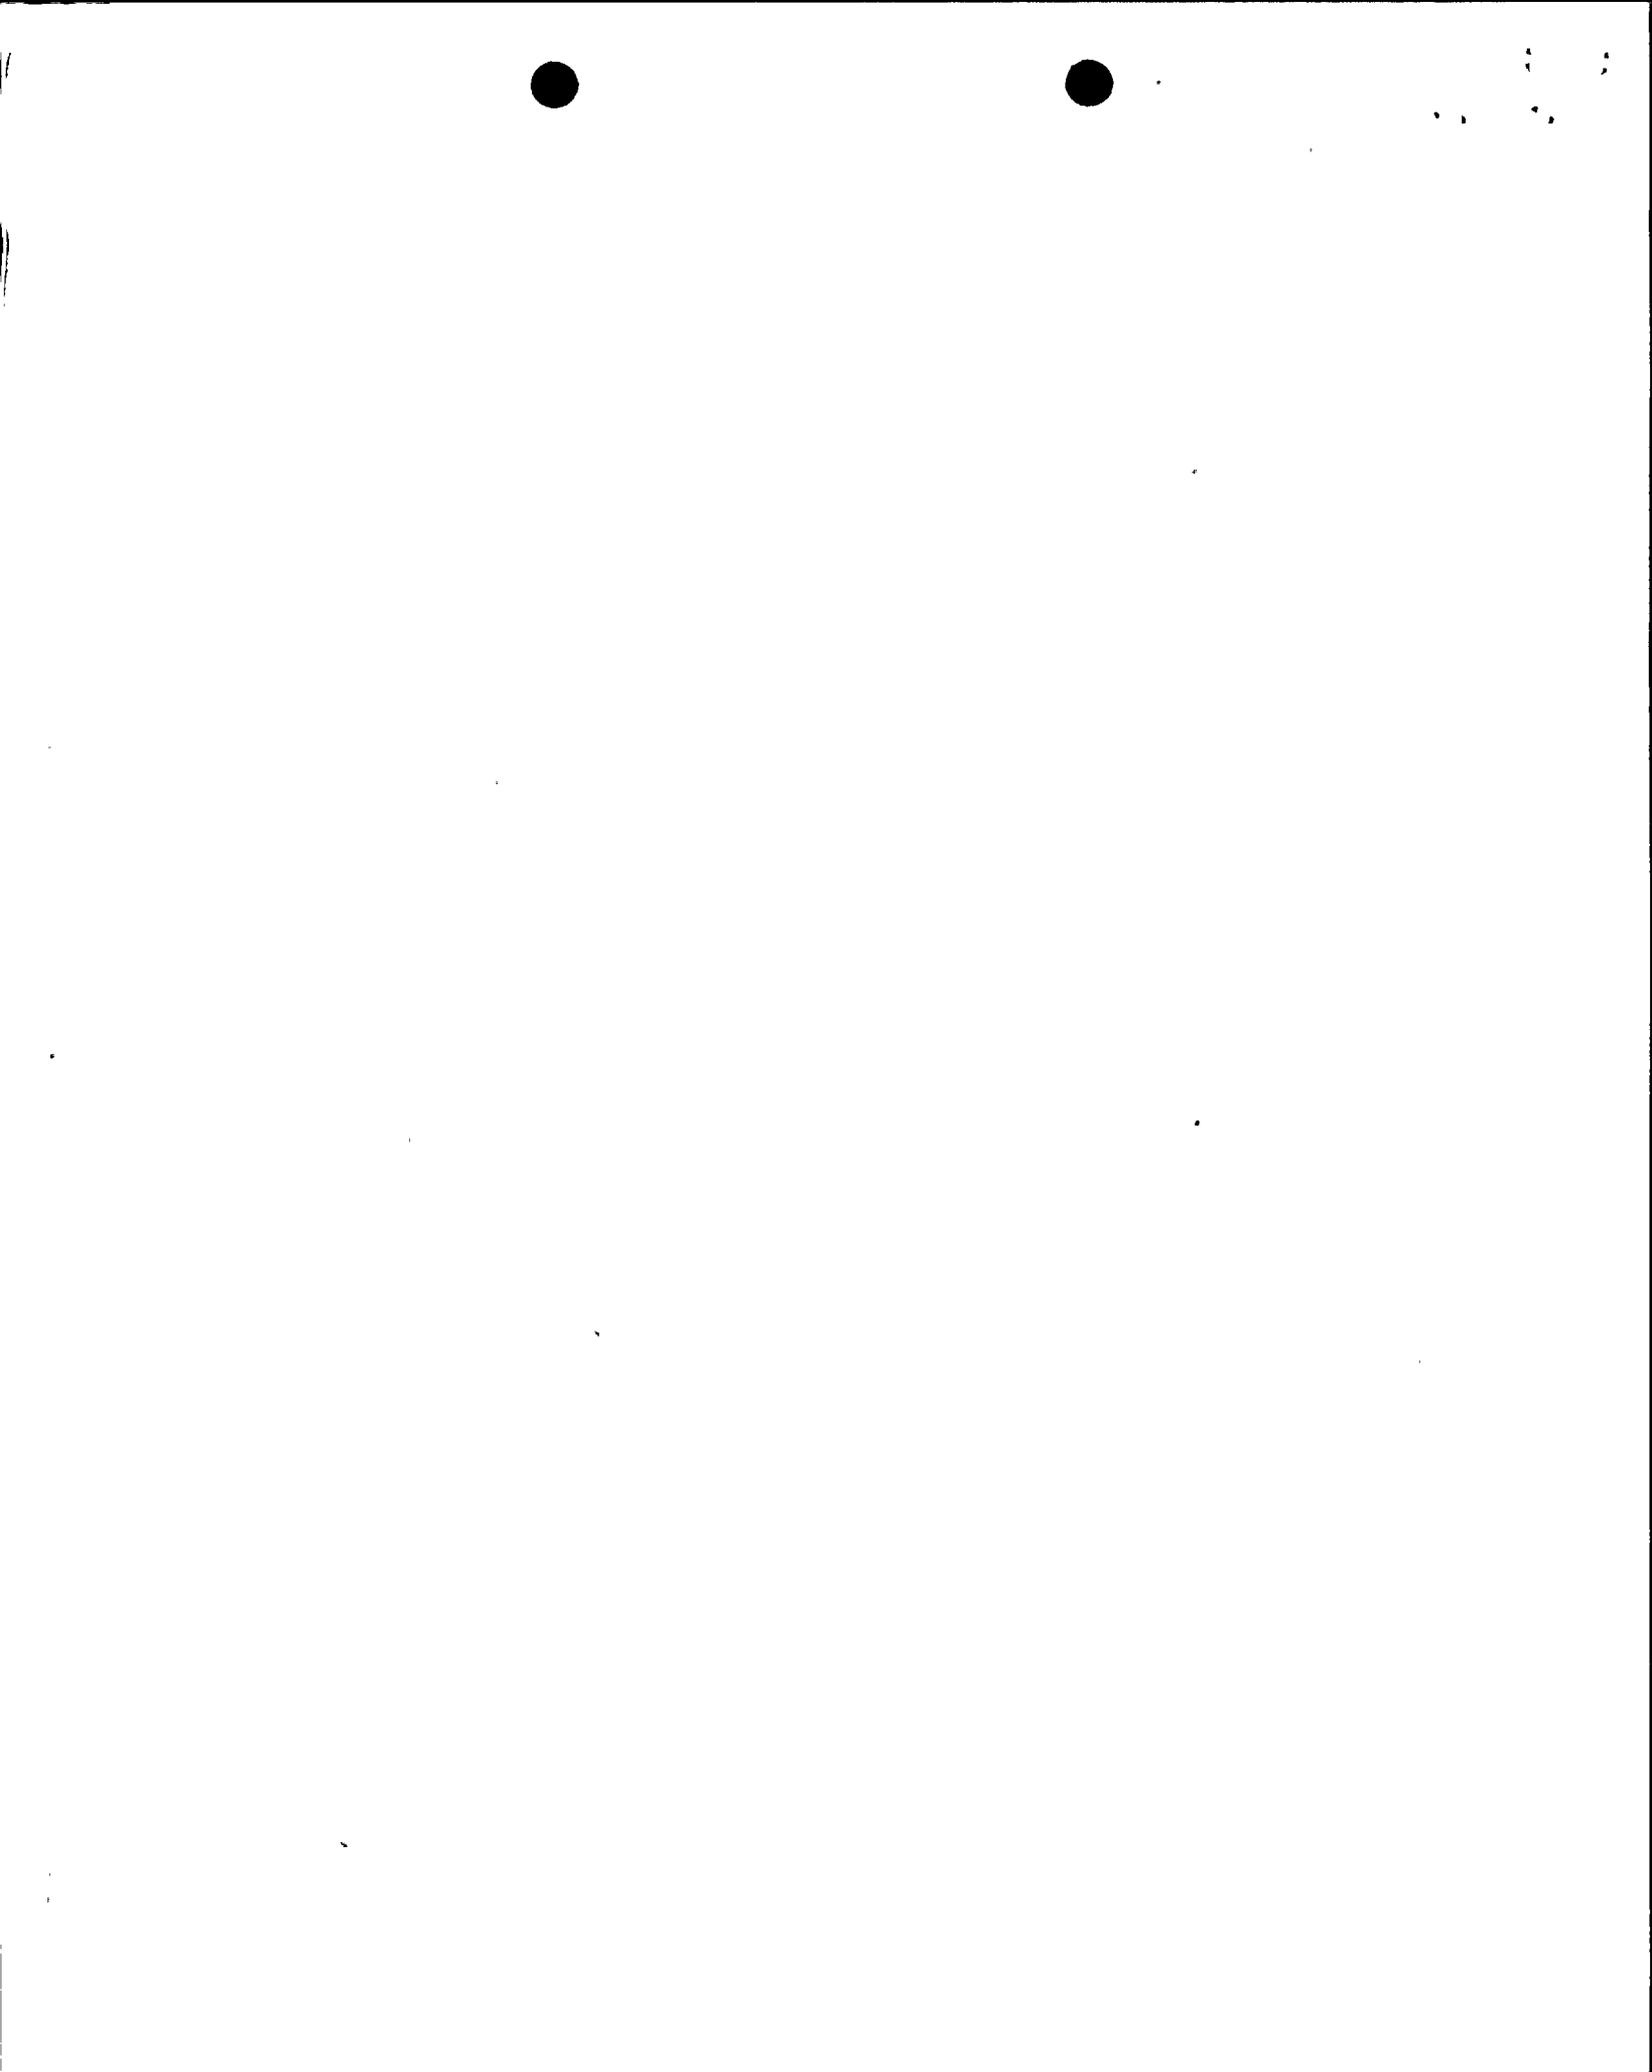

1 as compared to other recordings at comparable distances.  
2 Based on the entire set of data available the average  
3 acceleration at a distance of 7-1/2 km from the fault was  
4 about 0.34 g, also suggesting that higher values might have  
5 been developed in some locations in this general area. More  
6 importantly it suggests that the motions within the building  
7 were apparently about the same as the average for the  
8 free-field. This still shows no apparent tau-effect for  
9 this building -- and this is to be expected because other  
10 factors which might cause differential base motions at other  
11 sites would not be expected to be significant at the ICSB.

12 e.g., (a) Because of the deep soil layer overlying the  
13 entire area around the building, incoming  
14 waves are likely to be essentially vertical.  
15 This fact, combined with the limited dimen-  
16 sion of the ICSB would cause differential  
17 times of arrival due to inclined wave effects  
18 to be negligible in this case.

19 (b) Because of the relative homogeneity of the  
20 deep soil layer, significant differential  
21 times of arrival due to non-homogeneity would  
22 not be expected.

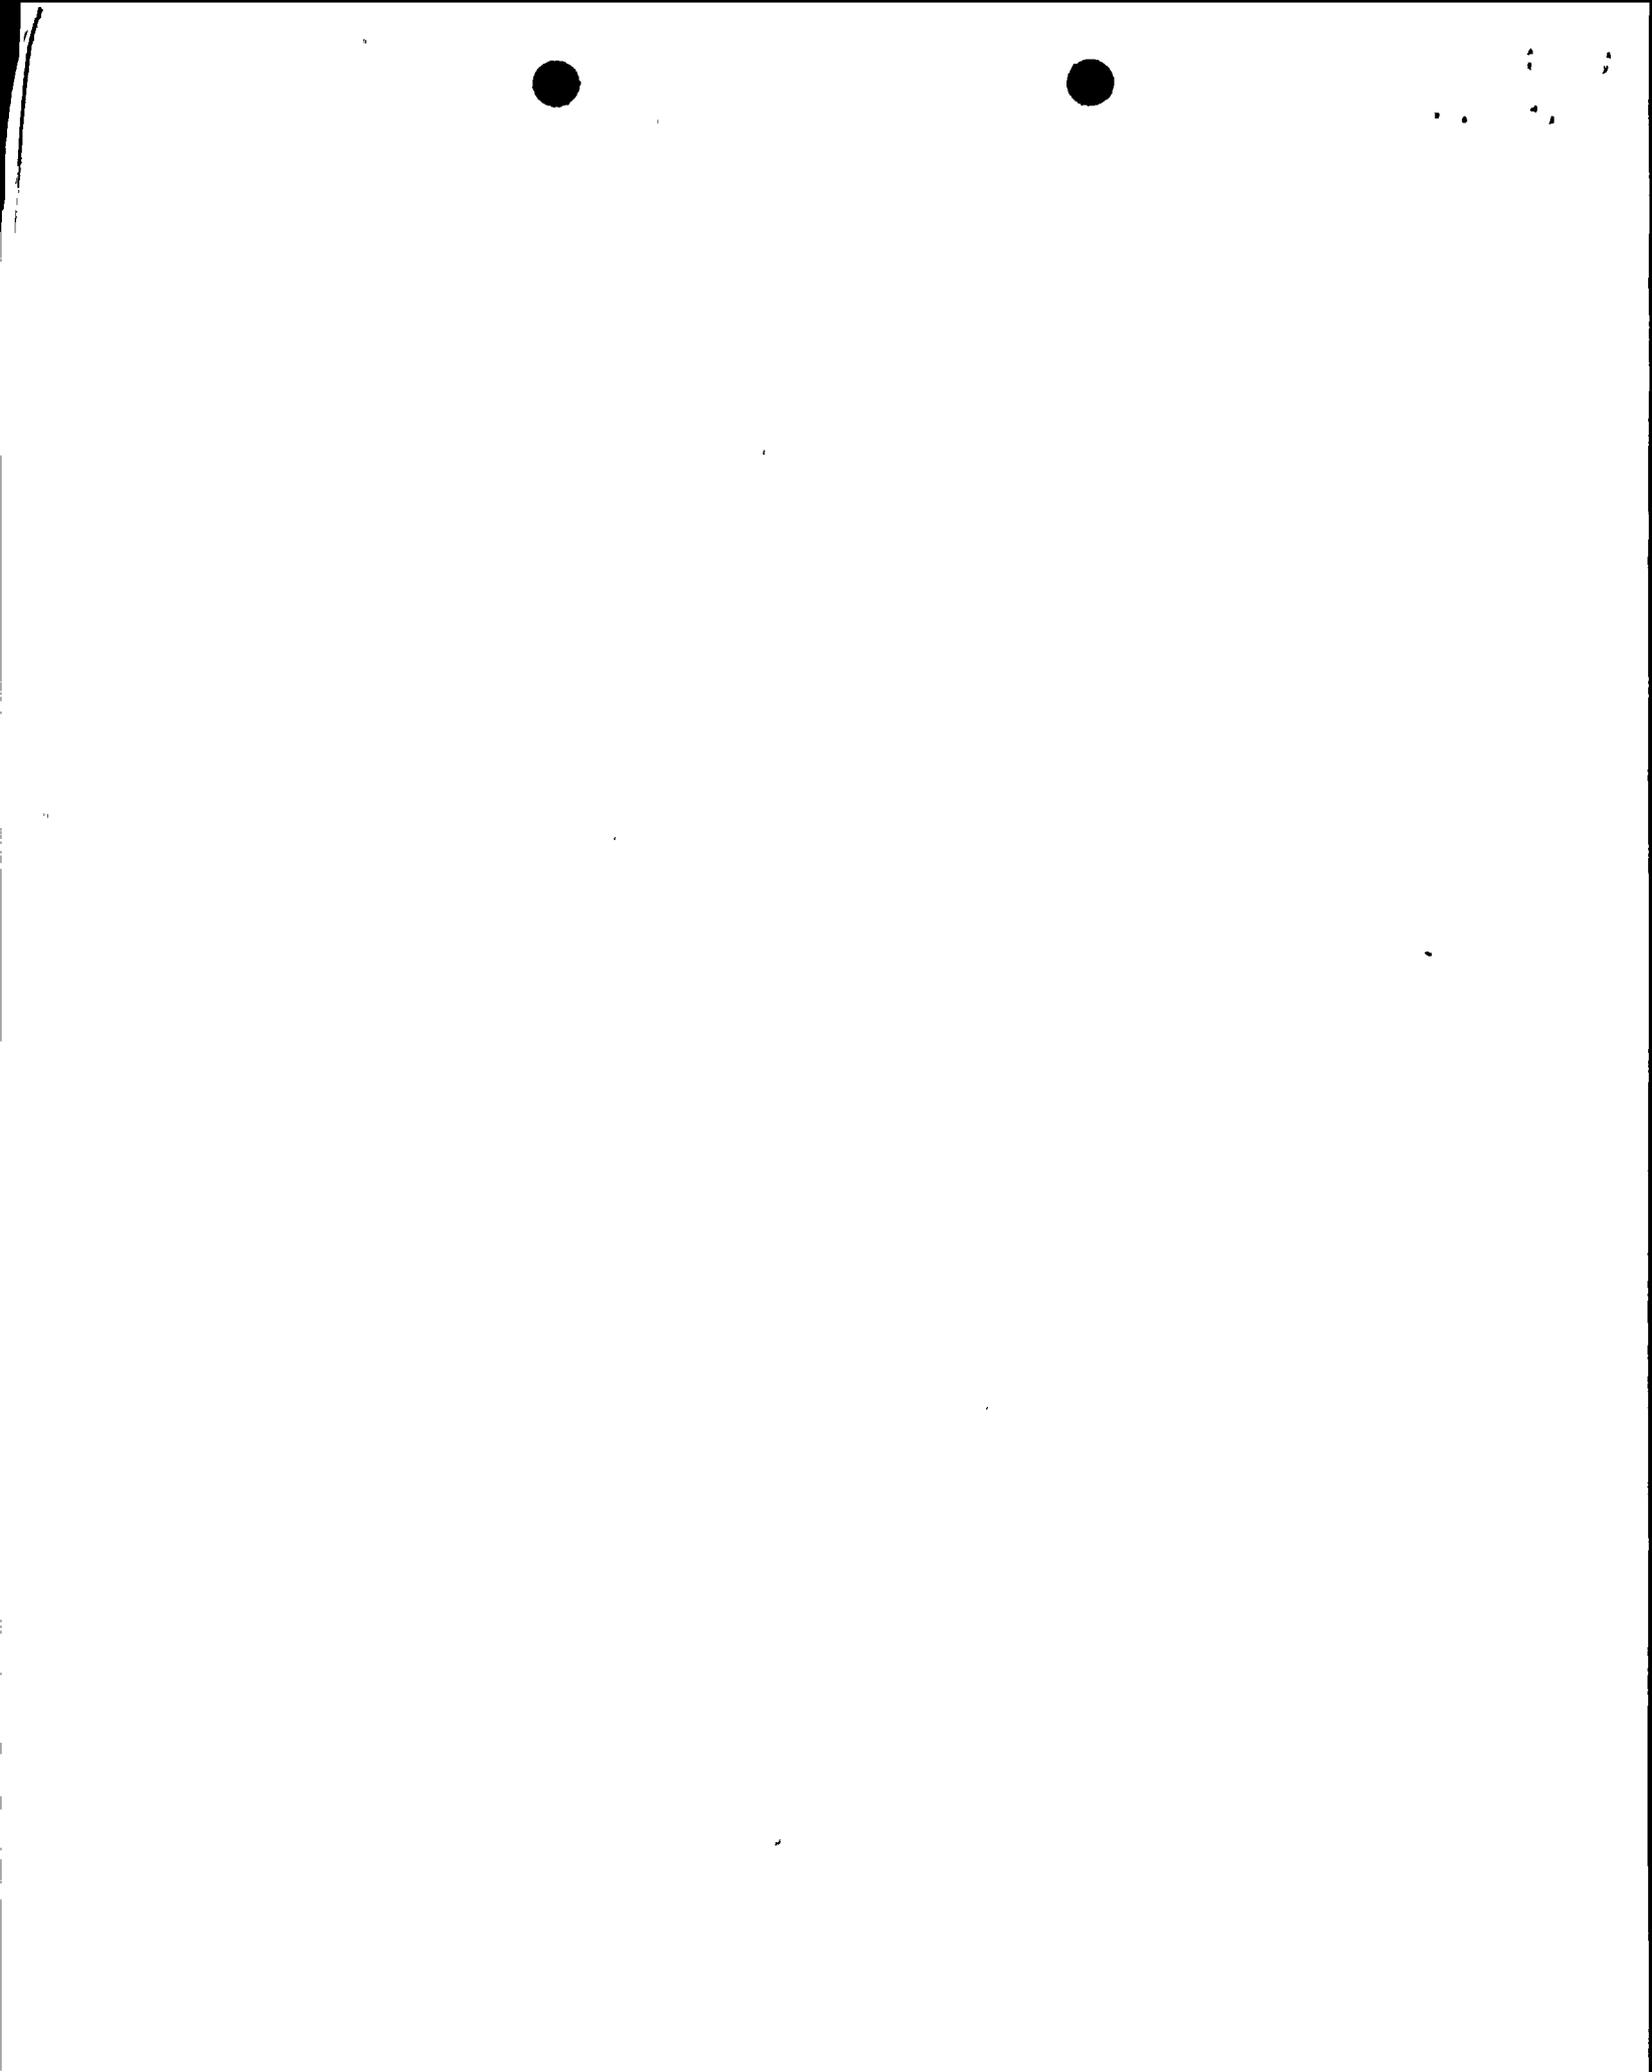

23 (c) Because of the light weight of the building,  
24 the influence of soil-structure interaction  
25 on the building would be expected to be very  
26 low, provided it were firmly embedded on the  
ground surface.

1 Thus a tau-effect (or a base slab averaging effect)  
2 producing lower motions inside the building than  
3 representative free-field values would be expected to be  
4 very low in this case (Blume V-9, V-10; Newmark 7, 8; Seed  
5 V-1 through V-4; Smith V-1, V-2).

6 There is also a good possibility that the  
7 configuration of the base of the ICSB and the instrument  
8 locations on the base may have caused some amplification of  
9 free-field motions for this particular building. If the  
10 soil had settled away only slightly from the base of the  
11 pile caps, as sometimes occurs, the response of the  
12 pile/pile cap/ and overlying six feet of fill could be very  
13 complex leading to some amplification of the ground motions  
14 by the time they reached the base slab, two feet above the  
15 ground surface. Furthermore, the motions recorded at the  
16 ground floor of the building could have been increased by  
17 torsional effects since they were located near the edges,  
18 where torsion could affect the response of the building.  
19 Thus there are valid reasons why the motions recorded in the  
20 building could have been amplified so that they were higher  
21 than those in the free-field and this would have nothing to  
22 do with the presence or absence of a tau-effect (Blume V-11,  
23 VI-2, VI-3; Seed V-5, V-6; VI-5, VI-6).

24 In summary therefore, there are good reasons why  
25 tau-effects should not be expected at this poorly designed  
26 building, or why the accelerations recorded on the base slab

1 of the building might even be amplified over the motions in  
2 the underlying soil. It should also be noted that one can  
3 not ascribe any value to measurements that are made in a  
4 building that is failing (Tr. 688). This situation does not  
5 exist at the Diablo Canyon site, however. At Diablo Canyon  
6 motions are likely to have much greater non-coherence  
7 because of the non-homogeneity of the underlying rock  
8 foundation, non-verticality of waves approaching the  
9 foundation, and soil-structure effects which instead of  
10 amplifying adjacent rock motions would cause some  
11 attenuation of these motions. Accordingly, the data from  
12 the Imperial County Services Building showing an absence of  
13 tau-effects should in no way reflect on the appropriateness  
14 of incorporating the tau-effect in the design of the Diablo  
15 Canyon plant (Seed V-5, V-6, V-7; Tr. 687, 688).

16 Tau-Effect - El Centro Array

17 In the case of large foundations, seismic wave  
18 motion may vary significantly from one part of the founda-  
19 tion to another. Three separate and complex base averaging  
20 effects have been recognized and described collectively as  
21 the tau effect. Processes which may contribute to  
22 variations in ground motion across a foundation include  
23 non-vertically incident waves, random fluctuations in motion  
24 due to non-homogeneities along the path of wave propagation,  
25 and soil-structure interaction. When a foundation is  
26 subjected to accelerations that are not simultaneous, as for

11  
12  
13

1 example when the wave motion is trying to move the ends of  
2 the foundation upward and the middle downward, the massive  
3 and rigid nature of the foundation will average such motion  
4 and thus attenuate it by some factor (Smith V-3).

5           The USGS Differential Array in the Imperial Valley  
6 provides some new information on the spatial variation in  
7 the ground motion over distances comparable with large  
8 foundations. Since the instruments are located in a  
9 free-field situation, the data can only address the  
10 questions of angle of incidence, and fluctuations due to  
11 inhomogeneities. Although no information on soil structure  
12 interaction is available, some important inferences about  
13 the other base averaging effects can be made (Smith V-3).

14           Simple ray tracing from the earthquake source  
15 shows that the waves approach the array at an oblique angle  
16 such that the total delay across the array is only 20-30  
17 milliseconds (2-3 samples, since the sample rate is  
18 100/second). In this situation, which corresponds to nearly  
19 vertical wave incidence, base averaging effects due to the  
20 angle of incidence could not be very significant (Smith  
21 V-4).

22           The degree of incoherence in the Differential  
23 Array ground motions due to non-homogeneities is  
24 investigated in two ways. First, the response spectrum of  
25 the array average ground motion for stations 1-3, separated  
26 by a maximum distance of 55 meters, was compared to the

4 4  
4 4

1 average spectrum of the individual recordings. This  
2 comparison requires that the recordings be put on an  
3 absolute time basis, which is believed to have been done to  
4 an accuracy of 1/200 to 1/400 of a second. The results of  
5 this analysis indicate that the reduction due to incoherence  
6 is about 20% for vertical motions and at least 10% for  
7 horizontal motions at frequencies of 20 to 30 hertz. (Tr.  
8 1391-1392).

9 Another technique, which does not require absolute  
10 time, is covariance analysis. In this method the maximum  
11 correlation between the ground motion filtered to represent  
12 various frequency bands, for each pair of stations was  
13 computed and plotted versus separation distance. Although  
14 the peak correlation was 100% for the closest stations, for  
15 the 5 to 15 hertz frequency range the peak correlation drops  
16 to about 80% at a distance of 50 meters, and for the 15 to  
17 25 hertz frequency range, the peak correlation drops to only  
18 60% at 20 meters (Tr. 1395).

19 In conclusion, high frequency components of ground  
20 motion, particularly above 10 to 15 hertz, are significantly  
21 incoherent over distances of 50 to 100 meters -- the  
22 reduction in ground motion at these frequencies being at  
23 least 10% to 20% for both vertical and horizontal components  
24 (Tr. 1395-1396; Smith V-4 to V-6; App. Exs. R-13 through  
25 R-16).

26 ///

11 11

1           Question VI. Throughout the Licensing Board  
2 hearings, parties stressed the role of soil-structure  
3 interactions as a mechanism that would reduce the magnitude  
4 of structure motion relative to ground motion (e.g., Tr.  
5 8878; 8947-46). Staff and applicant's arguments (in  
6 response to intervenors' suggestion of the apparent lack of  
7 tau effect during IV-79) point to soil structure  
8 interactions as the reason for building motion exceeding  
9 that of the ground (Blume Affidavit, Paragraph 10; Rothman -  
10 Kuo Affidavit, page 7). (a) Describe and explain the  
11 circumstances in which soil-structure interactions produce  
12 enhanced or reduced structural response. (b) Discuss the  
13 relevance and applicability for such interactions to the  
14 seismic response assumed for Diablo Canyon.

15           Soil-structure interaction is a complex phenomenon  
16 which is generally understood to mean the effect of physical  
17 interaction between the building and the adjacent soil or  
18 rock on both the response of the structure and the motions  
19 developed in the base of the structure. However, many  
20 engineers have considered the subject to have a broader  
21 context and to include such additional effects as

- 22           1. The development of strong structural response  
23           because of the similarity between the natural  
24           period of a building and the characteristic period  
25           of the soil formation on which it is constructed.
- 26           2. The effects of non-coherence of ground motions at  
            the base of a structure and the homogenizing of  
            these motions by a rigid base slab in a structure.
3. The variations of ground motions with depth and  
            the effects of this variation on structure  
            response (Blume VI-1; Seed VI-1).

///

11  
12  
13

1           In the testimony presented at the Licensing Board  
2 seismic hearing, the term soil-structure interaction was  
3 generally used in the more restrictive sense mentioned  
4 above. Possible effects of similarities in periods of  
5 buildings and site were not given any special terminology,  
6 the non-coherence of ground motions at the base of a  
7 building was generally referred to as the tau-effect, and  
8 variations of motions with depth were not considered because  
9 the structures under consideration are relatively near the  
10 ground surface (Seed VI-2).

11           Physical soil-structure interaction of the type  
12 discussed above has been investigated extensively over the  
13 past 20 years and in general it would appear that the  
14 magnitude of the effects depends on

- 15           (1) the relative medium on which it rests, and  
16           (2) the physical size or mass of the structure  
17           involved.

18 Thus for example, soil structure interaction effects  
19 increase as the ratio of building stiffness to soil  
20 stiffness increases, and the effects are greater for massive  
21 structures such as nuclear power plants than for more  
22 conventional buildings (Seed VI-2).

23           Where a conventional building is firmly founded on  
24 a soil or rock deposit, it seems to be generally agreed that  
25 soil-structure interaction effects tend to reduce the  
26 response developed at the base of a building compared with

100

1 those developed assuming rigid base conditions. The  
2 magnitude of this reduction in conventional buildings  
3 generally ranges from zero to a few tens of percent. For  
4 nuclear power plants soil structure interaction may be  
5 significantly larger, ranging from about 10 to 50 percent  
6 (Seed VI-2, VI-3).

7           The influence of soil-structure interaction at the  
8 Diablo Canyon facility was studied by Professors Seed and  
9 Lysmer who concluded that the effects would be small (for  
10 nuclear power plants). Typical results of the Diablo Canyon  
11 study are shown on Seed Figure VI-1 and show that  
12 soil-structure interaction would reduce the spectral  
13 accelerations for the base slab motions by about 20 percent  
14 below those of the free-field motions for frequencies above  
15 4 or 5 Hz. It is in this range of frequencies that the  
16 tau-effect has its major influence (Seed VI-3, VI-4).

17           The Hosgri reanalyses of the structures at Diablo  
18 Canyon are based on the assumption that the structures are  
19 founded on a rigid base. This neglects completely any  
20 soil-structure interaction effects of the type discussed  
21 above and illustrated in Seed Figure VI-1 and thus in this  
22 respect is conservative. It leads to the result that the  
23 base motions are the same as those in the free-field and  
24 thus to the use of horizontal base spectral accelerations at  
25 frequencies above 4 or 5 Hz which are about 20 percent  
26 higher (the actual amount varying with frequency as shown in

1  
2  
3  
4

1 the figure) than those which would be computed with  
2 allowance for soil-structure interaction effects due to  
3 foundation compliance. Other types of soil-structure  
4 interaction -- such as the base slab averaging effect due to  
5 the non-coherence of ground motions over the area of the  
6 slab -- would reduce the design motions still further,  
7 perhaps by as much as an additional 20 percent. Thus there  
8 are ample grounds to justify the magnitude of the base  
9 motions used for the Hosgri reanalysis of the Diablo Canyon  
10 NPP structures. While the main justification for using a  
11 tau-factor to reduce motions in this case was developed on  
12 the basis of non-coherence of ground motions, consideration  
13 of all types of soil-structure interaction could have led to  
14 even greater reductions than those used (Seed VI-4).

15 Question VII. Intervenors (Brune Affidavit,  
16 page 5) and the applicant (Frazier Affidavit, Paragraph 3)  
17 have suggested that the strong motion data obtained from  
18 stations along the direction of the Imperial Fault evidence  
19 the "focusing" of earthquake motion. Yet, when the acceler-  
20 ation data of two such stations, El Centro Array Numbers 6  
21 and 7, are plotted as a function of distance from the fault  
22 (e.g., Blume Affidavit, Figures 1 and 2), the horizontal  
23 acceleration values fall well below the regression line mean  
24 for the 1 km distance. The vertical acceleration values are  
25 also lower than the mean on such a plot.

21 To the extent possible, the parties should analyze  
22 the seismic records for the IV-79 earthquake as they pertain  
23 to the focusing phenomenon and relate the results of such  
24 analyses to the likelihood that, in the event of an earth-  
quake anywhere along the Hosgri Fault, focusing might result  
in amplified seismic motion at Diablo Canyon.

25 Hypotheses which account for changes in the  
26 character of the radiation pattern of a point dislocation

1  
2  
3  
4  
5

1 strike-slip source due to rupture propagation usually  
2 conclude that of the three components of motion associated  
3 with the source (transverse, longitudinal, and radial), the  
4 transverse component is generally considered the one most  
5 strongly affected by rupture propagation, followed in  
6 importance by the radial and longitudinal components,  
7 respectively. These intensifications of amplitude of motion  
8 in the direction of propagation may be loosely termed  
9 "rupture focusing" (Edwards VII-1; Frazier VII-1 through  
10 VII-3; Tr. 448).

11 In his testimony at the ASLB seismic hearing, Dr.  
12 James Brune stated that the simplest theoretical representa-  
13 tions of the phenomenon of rupture focusing suggest that  
14 enhanced high frequency accelerations might be produced in a  
15 narrow "beam" ( $\pm 5^\circ$ ) in the direction of rupture propagation  
16 under special conditions. A  $\pm 5^\circ$  "beam" in the direction of  
17 rupture emanating from the epicenter includes stations 6 and  
18 7 of the El Centro array. If the simple predictions based  
19 on Brune's testimony are taken literally, then we must  
20 conclude that any rupture propagating on the fault from the  
21 epicenter toward stations 6 and 7 would result in focusing  
22 being observed at those stations. However, the records from  
23 stations 6 and 7 provide no such evidence, according to the  
24 data presented in Edwards Figures VII-1 and VII-2 (Edwards  
25 VII-2; Frazier VII-4; Tr. 452).

26 ///

4 4  
2 2

1           Both Drs. Brune and Frazier agree that the IV-79  
2 records show no strong evidence of focusing (Tr. 626;  
3 Frazier VII-4). Dr. Brune thought this might be caused by  
4 the earthquake having been a series of multiple events  
5 rather than a continuous rupture (Tr. 627). However,  
6 focusing accompanies all earthquakes to a greater or lesser  
7 degree. The rough equivalence of the transverse and  
8 longitudinal PGA values within a few kilometers of the  
9 Imperial fault is not inconsistent with some focusing  
10 effect. However, such focusing, if it occurred, did not  
11 result in abnormally high PGA values. It seems most  
12 significant that any focusing which might exist does not  
13 appear to alter the broader tendency toward saturation of  
14 PGA values in the near-field. Applicant witness Robert  
15 Edwards testified that the rupture focusing phenomenon is  
16 not relevant to the Diablo Canyon site in light of the fact  
17 that the portion of the Hosgri fault trace which may be  
18 "lined-up" with the Diablo Canyon site ( $\pm 5^\circ$ ) is so far from  
19 the site (nearest approach is about 27 km) that any  
20 amplification by high frequency focusing would be eliminated  
21 through material damping of the high frequency radiation  
22 (Edwards VII-3, VII-4; Frazier VII-12; Tr. 294, 295, 453).

23           PGandE witness Dr. Gerald Frazier presented  
24 extensive testimony on a computer model he developed and  
25 tested for simulating earthquake processes to provide  
26 additional information on ground accelerations and the

1 effects of focusing at Diablo Canyon. The earthquake model  
2 simulates effects due to site specific earth structure,  
3 complex rupture sequences, radiation pattern, focusing and  
4 stress drop. Stringent tests have been and are currently  
5 being performed to simulate near-field recordings from past  
6 earthquakes. These tests indicate that the earthquake model  
7 is suitable for predicting ground motion close to large  
8 magnitude earthquakes, albeit conservatively predicting  
9 higher than real peak ground accelerations directly in the  
10 maximum beam of focusing (Frazier VII-5, VII-8 thru VII-12;  
11 J.I. Exs. R-6 thru R-9; Tr. 302-313, 505, 506, 509, 518).

12 Frazier described site specific simulations which  
13 were performed at Diablo Canyon to examine effects of  
14 rupture along the Hosgri Fault focused toward the site in a  
15 manner consistent with geologic data. After conducting and  
16 analyzing the tests, Frazier concluded as follows:

- 17 (a) The effects of rupture focusing are much less  
18 apparent for frequencies of interest at the Diablo  
19 Plant. Furthermore, the Diablo Canyon site is not  
20 positioned for significant focusing from rupture  
21 along the Hosgri. Therefore, adverse effects due  
22 to rupture focusing are highly unlikely at the  
23 Diablo Canyon Site. Dr. Brune did not agree with  
24 this conclusion because he believes that the  
25 parameters used by Dr. Frazier are such that the

26

effects of focusing are not as apparent as they were in the San Onofre study (Tr. 630).

(b) The largest accelerations produced by the earthquake model originated from hypothetical rupture along the northern extent of the Hosgri fault, which was beamed directly at the site, did not contribute significantly to the peak levels of acceleration. The conclusion is drawn that focused rupture along the Hosgri fault cannot produce unusually high levels of ground acceleration at the site.

(c) The computed levels of ground motion are relatively independent of the length of rupture. Consequently, peak acceleration at Diablo Canyon should be basically insensitive to increases in magnitude for magnitudes greater than about 6.5.

(d) The mean values of peak acceleration were well below design levels. Furthermore, calculated free-field response spectra are uniformly below that used in the reanalysis. Thus, the earthquake modeling studies indicate that the Hosgri reanalysis spectrum is substantially conservative even when comparing free-field predictions with actual reanalysis criteria.

(e) The earthquake model when properly applied predicts earthquake motion at least as well as

1 1  
1 1

1           alternate methods (Frazier VII-5 through VII-13;  
2           Tr. 1374, 1375).

3           Dr. Brune, while agreeing that computer modeling  
4           is important to understand strong ground motion, was  
5           critical of the Frazier model study on the ground the  
6           parameters chosen by Dr. Frazier were not conservative  
7           enough or that he (Dr. Brune) did not understand them (Tr.  
8           631-633, 637, 647-649, 652, 653, 821, 823)

9           J.I. counsel produced a fault map, later  
10          withdrawn, purporting to show a strand from the Hosgri Fault  
11          pointing straight toward the Diablo plant site. Applicant  
12          witness Frazier testified that the strand was taken into  
13          account in his modeling in the sense that the data base used  
14          takes into account how these features have acted in past  
15          earthquakes (Tr. 313). He stated that as the rupture  
16          proceeds down the main trend of the fault it "hopscoches"  
17          around a bit on these splays or strands but they would not  
18          independently be capable of generating more than a magnitude  
19          3 earthquake (Tr. 314-317). J.I. witness Brune testified  
20          that the splay could lead to a maximum of focused energy  
21          toward the Diablo facility (Tr. 648). However, the official  
22          USGS map of the area (J.I. Ex. 11) does not show the splay  
23          shown on J.I. Ex. 10 (withdrawn) (Tr. 939). The USGS  
24          witness testified that he doubted the splay existed (Tr.  
25          940). Applicant witness Hamilton testified that he did not  
26          believe that features such as the splay in question have

4  
4  
4

1 large amounts of movement on them and would not likely  
2 participate in any significant way in a major earthquake  
3 along the Hosgri (Tr. 322-324).

4 Question VIII. We have received preliminary  
5 reports of the effect of IV-79 on the El Centro Steam Power  
6 Station. (Board Notification December 17, 1979, Levin and  
7 Martore Observations; Rothman - Kuo Affidavit, page 12). In  
8 many respects, the structures and systems of that facility  
9 resemble those of the Diablo Canyon plant. Their response  
to a severe, well instrumented seismic event can be analysed  
to help confirm or refute analytical techniques and assump-  
tions used in the Diablo Canyon seismic analysis. The  
parties should prepare and submit such an analysis.

10 The El Centro Steam Plant is a 4-unit electric  
11 generating facility of the Imperial Irrigation District  
12 located approximately 5 km from the Imperial fault. Each  
13 unit of the facility contains three distinct structures: a  
14 steel frame and concrete turbine building, containing  
15 mechanical and electrical equipment as well as piping  
16 systems; a concrete pedestal supporting the turbine and  
17 located within, but structurally separated from, the turbine  
18 building; and a boiler structure which is a braced steel  
19 frame supporting a hanging boiler and structurally connected  
20 to the turbine building (Blume VIII-1).

21 Each unit of the plant is structurally  
22 independent, and since Unit 4 is the most recent unit  
23 (constructed in 1968) it was selected by PGandE witness Dr.  
24 John A. Blume for detailed study. A USGS strong motion  
25 accelerograph is located less than 1 km southeast of the  
26 plant (USGS No. 5164 El Centro Differential Array), and its

1 recorded trace was used to derive time histories and  
2 response spectra for the plant analyses.

3 Dr. Blume outlined the results of his study, which  
4 was based upon analytical methods similar to those used in  
5 the Diablo Canyon reanalysis. The study results showed that  
6 although the plant and its equipment were subjected to  
7 seismic accelerations considerably above those for which it  
8 had been designed actual damage was minor. These results  
9 demonstrate the inherent conservatism in seismic design  
10 analytical methods similar to those used in the Diablo  
11 reevaluation (Blume VIII-1 through VIII-10).

12 Dr. Newmark testified that the building was over-  
13 loaded by a factor of three and suffered no damage (Tr. 711,  
14 712).

15 Westinghouse also did a study of the El Centro  
16 plant's piping and supports, by means of a computer model  
17 generated by the same methods used in the generation of  
18 computer models for Diablo Canyon and other nuclear  
19 projects. Significant reductions in the input seismic  
20 excitation still conservatively predict the results in the  
21 piping system due to the additional conservatism in the  
22 piping analysis itself. This study also demonstrated that  
23 the analytical methods and assumptions used by Westinghouse  
24 in the evaluation of piping systems at Diablo Canyon contain  
25 significant conservatisms (Gangloff VIII-1 through VIII-9).

26 ///

4 1 4

1            Significant reductions in the input seismic  
2 excitation still conservatively predict the results in the  
3 piping system due to the additional conservatisms in the  
4 piping analysis itself. It can, therefore, be concluded  
5 that the evaluations performed on Diablo Canyon are conser-  
6 vative and provide substantial margin (perhaps a factor as  
7 high as five on stress and deflection) to the results that  
8 would be expected from an actual seismic event (Gangloff  
9 VIII-1 through VIII-9).

10            A study conducted for the NRC Staff by Lawrence  
11 Livermore National Laboratory was designed to analytically  
12 estimate the equipment response which, when compared to  
13 actual observation, will indicate the levels of actual  
14 equipment capacity. They confirmed, among other things, the  
15 low level of damage observed at the plant (Staff Ex. R-1).  
16 The study concluded that the inherent seismic resistance of  
17 engineered structures, piping and equipment is greater than  
18 has been assumed. When even the most modest attention is  
19 paid to design significant capability is rendered. Because  
20 they are subject to strict and rigorous design procedures,  
21 the report concluded that nuclear power plants contain even  
22 higher inherent margins than other structures (Staff Ex.  
23 R-1, pp. 39-41; Tr. 713, 721, 1340-1342).

24            Dr. Newmark summarized the significance of these  
25 comparisons during the hearing. He stated "The issue is  
26 primarily that we can learn about earthquakes from buildings

1 2  
3 4

1 that survive as much as we can from instruments that measure  
2 earthquake motions and that this is not a negligible factor  
3 in our experience. And this is one of the points that leads  
4 me to believe that what we have done with the [Diablo  
5 Canyon] design or strengthening is such that we can be  
6 assured that even should a major overload occur because of  
7 an earthquake considerably larger than that which we have  
8 provided for, the structure would not be in a situation that  
9 would cause any hazard at all" (Tr. 713).

10 Question IX. In addition to answering our ques-  
11 tions about information from the Imperial Valley earthquake,  
12 we would like the parties to address Paragraph E on page 6  
13 of the McMullen affidavit (included with the Staff Response  
14 to Joint Intervenors' Motion to Reopen). That paragraph  
15 states that, "in its geologic and seismologic review of the  
16 Point Conception LNG site, the USGS reported that 'Existing  
17 evidence favors association of the 4 Nov., 1927 (M 7.3)  
18 Lompoc earthquake with an east dipping reverse fault such as  
19 the Offshore Lompoc or similar reverse fault 10 km to the  
20 south that offsets the seafloor.'" Does this USGS statement  
21 reflect either evidence not presented in the Diablo Canyon  
22 hearing or a change in the USGS position based on evidence  
23 already in the record? In any event, discuss that state-  
24 ment's implications for this case.

18 The evidence adduced at the hearing clearly  
19 indicated a significant shift in the USGS position as to the  
20 likely source of the 1927 Lompoc earthquake. The position  
21 taken by the USGS in 1976 was that "The 1927 earthquake,  
22 therefore, cannot be unequivocally located on any one of  
23 these faults" (McMullen 4). The USGS recognized that any of  
24 the candidate faults could be the source, or put another  
25 way, the Hosgri was at least as likely to be the source as  
26 any other fault. In contrast to this relative anonymity of

11  
12  
13  
14

1 the identity of the fault, the USGS now clearly favors the  
2 Lompoc fault (Tr. 932) and believes that the probability  
3 that it could have been the Hosgri has been lowered (Tr.  
4 934, 951). In other words, the residuum of uncertainty that  
5 remains as to the fault identity can only sustain a bounding  
6 contingency that "does not exclude" (Tr. 933) the Hosgri.  
7 This shift in emphasis has been generated by increased  
8 knowledge of the Lompoc fault itself. The USGS has changed  
9 its mind in regard to the length of the Lompoc fault such  
10 that it is now compatible with the magnitude of the 1927  
11 earthquake (Tr. 931) and has identified the existence of sea  
12 floor offset, an effect that would also be attributable to  
13 the 1927 earthquake (Tr. 952). In fact the USGS witness  
14 stated that with the possible exception of a 4.8 magnitude  
15 earthquake in May, 1980, he knew "of no others that we can  
16 associate [with the Hosgri fault] with any degree of  
17 certainty" (Tr. 937).

18           The significance of this to the seismic evaluation  
19 of the Diablo Canyon site is to reaffirm and reinforce the  
20 high degree of conservatism of the assumption of a 7.5' M  
21 earthquake capability for the Hosgri fault. Or, as  
22 characterized by Dr. Buck in a question to the USGS witness,  
23 the supposition would be "extremely conservative" (Tr. 953).  
24 The USGS's conservative assumption in 1976 of an earthquake  
25 of that size was undoubtedly colored by its view, at that  
26 time, that an historic earthquake of 7.3 M had likely

2000

1 occurred on the Hosgri. With the probability of this so  
2 diminished, the conclusion is unavoidable that, in fact, the  
3 7.5 M assumption is more representative of a hypothetical  
4 limit.

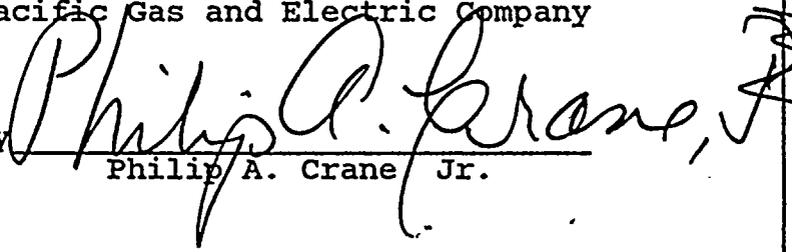

5 Respectfully submitted,
