ABSTRACT (Limit to 1400 spaces. i.e. approximately fifteen single-space typewritten lines) (16) On January 4, 1993, vibration levels began to increase on the 2A1 reactor coolant pump. The 1X (synchronous speed) and 2X (2 times synchronous speed) vibration levels increased at the upper motor, 1X and 2X phase angles wandered, and the orbit exhibited a non-uniform shaft rotation. Overall vibration levels continued to trend upwards. At 2315 on January 12th, a controlled plant shutdown was commenced at a vibration level of 15 mils and increasing. A root cause team was assembled and subsequently developed a detailed inspection plan. Disassembly of the reactor coolant pump and inspection of the pump shaft revealed two cracks just above the hydrostatic bearing. Upon replacement of the pump internals the 2A1 reactor coolant pump was restarted with satisfactory vibration readings. The unit was returned to Mode 1 on April 1, 1993. The cause of the 2A1 reactor coolant pump high vibration was the result of a growing circumferential crack in the pump shaft. The root cause of the crack initiation was the use of seal injection on an idle reactor coolant pump. The corrective actions as a result of this event were: 1) Unit 1 and Unit 2 operating and emergency procedures have been revised to limit the use of seal injection to Design Basis Events and isothermal conditions experienced during reactor coolant system fill and vent. 2) Replaced the motor root assembly on the 2A1 reactor gover radial bearing assembly (shoes, adjusting bolts), upper and lower thrust bearing shoes, reset the upper and lower radial bearing assembly (shoes, adjusting bolts), upper and lower thrust bearing element and seal. 5) The defective pump rotating element was sent to an off-site examination facility for non-destructive examination and subsequent metallurgical examination of the crack area. 6) New

# ANALYSIS OF THE EVENT

This event is not reportable under 10CFR50.73; however, it is being submitted for industry informational purposes.

The Updated Final Safety Analysis Report (UFSAR) addresses decrease in RCS flow rate events in Section 15.3. Concerning Limiting Fault-3 events in this category, the limiting offsite dose event is an RCP shaft seizure with a loss of offsite power (LOOP) as a result of a main generator trip with Technical Specification steam generator tube leakage and a failure to restore offsite power within 2 hours. This worst case event produces offsite doses within acceptance guidelines.

The accident analyses in the UFSAR do not specifically address shaft shearing scenarios. However, Section 15.3.5.1.5.2 of the UFSAR addresses the relationship between a sheared shaft and shaft seizure. A sheared shaft will offer less resistance to flow during the post-LOOP flow coast down phase than a shaft seizure since the shaft is still capable of rotating. During the long term portion of the event, the reverse flow through the affected RCP is greater during the shaft shear event than the shaft seizure event. However, the lower core flow experienced during long term portion of the event has no impact on the minimum Departure from Nucleate Boiling Ratio (DNBR) which has been proven to occur during the first two to four seconds of the transient. It is during this time frame that the shaft seizure event is most limiting due to the lower core flow. Therefore, the margin to design limits is smaller for a shaft seizure event and as a result the shaft shearing event is bounded by the shaft seizure accident analysis.

Based on actual plant conditions at the time of the unit shutdown, a more credible event would have been a loss of flow through one RCP. This event is considered an infrequent type with an insignificant approach to off-site dose limits. Although a partial loss of RCS flow event is not specifically analyzed in the UFSAR, the core and system performance is considered to be no more adverse than a total loss of RCS flow that would occur during a LOOP since, by design, a low RCS flow trip (93% core flow) would automatically initiate a plant trip. In this situation, the minimum DNBR would be higher, due to a lower power to flow ratio, than for a total loss of core flow event. A partial loss of RCS flow through one RCP due to shaft shear is bounded well within the UFSAR accident analysis since 1) There was no existing steam generator tube leakage, 2) a shaft shear event is less limiting than a shaft seizure event, and 3) no LOOP occurred.

The health and safety of the public was not adversely affected by this event.
