2.5 GEOLOGY, SEISMOLOGY, AND GEOTECHNICAL ENGINEERING

2.5.1 Basic Geologic and Seismic Information

The Beaver Valley Power Station - Unit 2 (BVPS-2) site is located on the south bank of the Ohio River in the borough of Shippingport, Pennsylvania, approximately 25 miles northwest of Pittsburgh. As shown on Figure 2.5.1-1, the site lies near the center of the Appalachian Plateau physiographic province. The plant is located upon a terrace of alluvial gravels about 100 feet thick, deposited by higher stages of the Ohio River during the Pleistocene Epoch. The surrounding topography consists of steep-sided, flat-topped hills separated by narrow stream valleys.

Two flat-lying bedrock formations of Pennsylvanian age outcrop in the site vicinity and form the adjacent hills, which rise to el 1,200 feet, as shown on Figure 2.5.1-2. The rocks are unmetamorphosed and show no evidence of major geologic deformation or tectonic activity. Regionally, the site lies near the center of a basin structure of Permian age (Figure 2.5.1-3). The Upper Freeport coal seam lies at el 900 feet, approximately 150 feet above the plant elevation and has been exploited to some extent in the site area. Several thinner coal seams are believed to exist beneath the site between 0 and 200 feet depth, but are not of sufficient extent or quality for commercial development at this time.

Massive sandstones were utilized locally in the past as dimension blocks for use in nearby bridge abutments, retaining walls, and building construction. None of this activity is carried on presently in the site area.

Minor oil and gas production has been realized within 4 miles of the site, drawing mainly from the Pocono Group of Early Mississippian age. There has been neither mining activity nor hydrocarbon extraction beneath the site which could cause ground settlement or collapse, nor is any anticipated.

The regional geologic history of the site region is discussed in Section 2.5.1.1.4, and reveals that the site area has not been subjected to severe diastrophic events at any time since the Precambrian. The area has remained tectonically stable since the Allegheny orogeny, approximately 250 million years ago, with the exception of epeirogenic uplifts, downwarping, and rebound, due to glacial loading.

The site is located in an area of very low seismicity within the Appalachian Plateau tectonic province as shown on Figure 2.5.1-5.

The nearest earthquake of epicentral Intensity V Modified Mercalli (MM), or greater, took place June 27, 1906, at Fairport, Ohio (near Cleveland), 80 miles northwest of the site. Only one earthquake has been reported within 50 miles of the site, reported at Sharon, Pennsylvania, on August 17, 1873, approximately 40 miles north of the site. Limited details have resulted in an estimated intensity of

III-IV (MM). The largest earthquake in the site region is the intensity VII-VIII (MM) event which occurred March 8, 1937, near Anna, Ohio, approximately 200 miles southwest of the site.

Results of geologic mapping in the site area indicate there is no hazard of surface faulting at or near the site. Additionally, no hazard due to ground subsidence is present which could affect the site.

In general, the founding material at the plant site is glacial outwash, overlain locally by thin deposits of silt, sand, and clay deposited during higher stages of the Ohio River. The founding materials for the plant structures are discussed in detail in Section 2.5.4.

Exploratory borings have shown that the bedrock beneath the site is a hard, black shale, and gray sandstone, probably belonging to the Allegheny Formation of Pennsylvanian age. It is estimated to be 350 feet thick in the plant area and shows no indication of extensive weathering, solution cavities, or other deleterious characteristics.

The work described herein was performed by Stone & Webster Engineering Corporation (SWEC), Boston, Massachusetts, with the following exceptions:

- 1. Raymond International, Hackensack, New Jersey, performed subsurface test borings, standard penetration tests, and soil, and rock sampling in the site area under the direction of SWEC.
- 2. Weston Geophysical Engineers, Inc., Westboro, Massachusetts, performed in situ seismic velocity measurements, including seismic refraction profiles and cross-hole, down-hole, and up-hole seismic tests for determining shear moduli of the overburden and bedrock characteristics. They also prepared the original seismicity analysis.
- 3. Pennsylvania Drilling Company, Inc., Pittsburgh, Pennsylvania, performed subsurface test borings, standard penetration tests, soil and rock sampling, and piezometer installations under the direction of SWEC.
- 4. Eger Drilling Company, Inc., Bridgeville, Pennsylvania performed subsurface test borings, standard penetration tests, soil sampling and piezometer installations under the direction of SWEC.

2.5.1.1 Regional Geology

2.5.1.1.1 Regional Physiography

The BVPS-2 site lies on the south bank of the Ohio River within the Appalachian Plateau physiographic province (Figure 2.5.1-1) (Fenneman 1938). This province is characterized by relatively undeformed

Paleozoic sediments which have been gently tilted and extensively dissected, producing the appearance of a rejuvenated peneplain. In Beaver County, the flat hill tops lie at approximately el 1,200 feet above narrow valleys cut 200 to 400 feet below the top of the hills.

Alluvial deposits of varying thickness are found at various elevations on the valley walls, and consist mainly of interbedded sands and gravels. These deposits frequently occur as terraces, and are the result of higher stages of rivers carrying large amounts of glacial outwash during the Pleistocene. The limit of glacial ice has been mapped as being approximately 20 miles north of the site (Shepps et al 1959).

Geologically, the province is a broad, gentle basin whose youngest rocks are the Dunkard Group of Early Permian age. The province is bounded on the west by the Central Lowland province, the boundary being an escarpment of Pennylvanian rocks 1,000 feet high in Tennessee and Kentucky, and a lower escarpment of Mississippian rocks in central southern Ohio. The boundary is somewhat indistinct in central Ohio, but generally follows the limit of glacial till plains. To the northwest and north of the site area, the boundary again follows an escarpment, formed by Silurian and Devonian sandstones, limestones, and Ordovician shales, to their contact with the Precambrian rocks of the Adirondacks (Fenneman 1938). The eastern boundary with the Valley and Ridge province occurs 105 miles east of the site and is marked by an abrupt topographic escarpment as much as 1,500 feet high, called the Allegheny Front. The Valley and Ridge province is characterized by a series of narrow, parallel ridges and valleys; the ridges being limbs of folds composed of resistant rock, and the valleys being the crests and troughs.

A portion of the Central Lowland physiographic province also lies within the site region, the boundary occurring 85 miles to the west. This province is characterized by having a Precambrian basement, or craton, with a veneer of nearly horizontal sedimentary rock of varying thicknesses. The structure is generally controlled by several basins and domes formed by Paleozoic epeirogenic activity. This has produced a diversity of geomorphic features, a large part of which has been extensively modified by Pleistocene glaciation (Eardley 1962).

2.5.1.1.2 Regional Stratigraphy

The distribution of the major geologic units within the site region is shown on Figure 2.5.1-3. A generalized cross section and regional stratigraphic column are given on Figures 2.5.1-4 and 2.5.1-6, respectively. The detailed stratigraphy of the Appalachian basin is thoroughly discussed by Colton (1970) and is summarized subsequently.

2.5.1.1.2.1 Precambrian

Rocks of Precambrian age are exposed in the site region, approximately 180 miles to the southeast in the Blue Ridge anticlinorium. These are a sequence of metasediments and metavolcanics which unconformably overlie what is commonly called Precambrian basement. The basement complex consists of schists, gneisses, and a wide variety of intrusives. The nearly peneplained basement surface has been determined to slope gently to the southeast under the region. Little is known about the stratigraphy of the Precambrian beneath the Appalachian basin.

2.5.1.1.2.2 Cambrian

Lower Cambrian deposition was concentrated in the southeast part of the Appalachian basin and resulted in a thick clastic wedge sequence, which included the sequence of rocks from the Loudoun to Waynesboro Formations. Equivalent rocks were not deposited on the west limb of the basin. Deposition on the western edge began in the Middle Cambrian with the Mt. Simon, Rome, and Conasauga Formations. The clastic sequence was followed in Middle and Late Cambrian time by basinwide deposition of carbonate rocks. These include the Elbrook Dolomite, Conococheague Limestone, the Lower Ordovician Beekmantown and Middle Ordovician Chambersburg, and Trenton Group rocks.

2.5.1.1.2.3 Ordovician

The carbonate sequence gives way abruptly during the Middle Ordovician to marine clastic deposits, beginning with the Martinsburg Shale. A thick clastic wedge about 8,000 feet thick is believed to have apexed in western Virginia and North Carolina during this time (Eardley 1962). Ordovician clastic sedimentation ended with the deposition of the Oswego Sandstone and Queenston Formation. Evidence exists for a diastrophic event affecting the Upper Ordovician along the east side of the basin, with some units missing, and an angular unconformity being developed (Colton 1970).

2.5.1.1.2.4 Silurian

The Upper Ordovician clastic sequence is overlain by a thin sequence of predominantly clastic rocks, mainly of Early Silurian age, that extends throughout most of the Appalachian basin. It is thickest in the northeast part, and thins to the west, southwest, and north, being totally absent in eastern New York. These rocks include some of the major ridge forming rocks of the Valley and Ridge, and include the Tuscarora Sandstone and Clinton Group.

A carbonate sequence began in the Middle Silurian, and continued into Late Silurian, Early Devonian, and even into the Middle Devonian in some areas. Like the underlying sequences, it is wedge-shaped, being thickest on the east and thinning out to the west and south. The sequence begins with the Lockport Dolomite, and includes the Salina and Bass Islands Group of Late Silurian age, deposited in evaporitic basin conditions, and the Helderberg Group. This sequence is overlain in most parts of the basin by the Oriskany Sandstone.

2.5.1.1.2.5 Devonian

Early Devonian carbonate deposition gave way to predominantly clastic sedimentation in the Middle and Late Devonian throughout most of the basin. The contact is conformable in most places and begins with the Needmore Shale. The sequence includes the Olentangy, Chemung, Catskill, and Bedford formations in the site region and ends before deposition of the Berea Sandstone or Pocono Group.

2.5.1.1.2.6 Mississippian

The Mississippian sequence conformably overlies the Devonian clastic sequence in most areas. The sequence is basically wedge-shaped with modifications due to erosion in eastern Ohio-western Pennsylvania, occurring in the Late Mississippian or Early Pennsylvanian time. The sequence includes the Pocono Group, the Greenbrier Group, and the Mauch Chunk Formation.

2.5.1.1.2.7 Pennsylvanian

Pemsylvanian strata are commonly disconformable on the Mississippian and are distinctly clastic. They include thick sequences of alternating beds of sandstone, shale, and siltstone with lesser amounts of coal and limestone. The Pottsville, Allegheny, Conemaugh, and Monongahela Formations were deposited at this time, and include the great coal-bearing formations of the basin. It has been determined that the Pennsylvanian sequence was originally much thicker, and more extensive, than at present, and nearly 75 percent of the sequence has been eroded since the Paleozoic (Colton 1970).

2.5.1.1.2.8 Permian

Overlying the Monongahela Formation in an oval area in West Virginia, southeast Ohio, and southwest Pennsylvania, is the Dunkard Group, of probable Lower Permian age. The Dunkard Group continued the variable deposition sequence started in the Pennsylvanian. The Allegheny orogeny, occurring progressively from the southeast during the Pennsylvanian and Permian, ended the extensive depositional cycle of the Paleozoic and exposed the sediments of the basin to a long period of erosion which is continuing today.

2.5.1.1.2.9 Triassic

The only rocks found in the site region younger than the Dunkard Group are located approximately 165 miles east of the site in the Gettysburg basin. They belong to the Newark Group and are believed to be Late Triassic or perhaps Early Jurassic in age. They are mainly continental sandstones, arkoses, conglomerates, and fanglomerates deposited in long, narrow, fault-bound basins. Numerous mafic sills and dikes are found associated with these deposits, and are believed to be the result of continental rifting during the Late Triassic and Early Jurassic.

2.5.1.1.2.10 Pleistocene

Unconformably overlying the Paleozoic rocks of northern Pennsylvania and Ohio are the unconsolidated deposits of several episodes of Pleistocene glaciation. Although glacial ice never advanced as far as the site area, the effects of its proximity are evident by the presence of high-level gravel terraces along the Ohio River and its major tributaries. These deposits provide the substrata on which the great majority of the cultural and industrial centers are founded.

Erosion since the retreat of the ice has considerably modified and removed much of the original deposits, but three terraces remain in the site area. The plant is situated on the uppermost terrace and is more fully described in Section 2.5.1.2.

2.5.1.1.3 Regional Structural Geology

The site lies on the west limb of the Appalachian sedimentological basin near the axis of the Appalachian coal basin (Rodgers 1970) or the axis of the Pittsburgh-Huntington basin (Wagner et al 1970). This area is just east of the Central Stable Region of North America and west of the Blue Ridge and Piedmont provinces as indicated on Figure 2.5.1-7.

All Carboniferous rocks in this area dip gently (less than 5 degrees) toward the basin axis, a line through Pittsburgh to Huntington, West Virginia. The basin contains the youngest sedimentary rocks in this part of the country, the Dunkard Group of Lower Permian age, exposed in the axial area 26 miles south of the site. The underlying Middle and Lower Paleozoic strata continue to thicken eastward, so that the axis of deposition is displaced somewhat east of Pittsburgh. The Precambrian surface also continues to dip southeastward under the entire Appalachian basin (Rodgers 1970). East of Pittsburgh, the dip of the Carboniferous strata reverses, and the units are deformed into broad gentle folds. This trend continues eastward into the Allegheny Mountains, until the Allegheny Front is reached at the outermost Carboniferous outcrop. Three anticlines form prominent ridges before the Allegheny Front is reached. These are the Chestnut Ridge, Laurel Hill, and Accident Mountain anticlines. Most of the structures found in the site region are the result of the Allegheny orogeny, which culminated in Late Permian time. No diastrophic events have occurred in the site region since the Early Jurassic.

2.5.1.1.3.1 Structures of the Appalachian Plateau

<u>Foldinq</u>

Major folds within 200 miles of the site are discussed in terms of their history of development, geologic setting, and effects on the geology of the site. The major structural features mentioned herein are shown on Figure 2.5.1-7.

Folds within the site region of the Appalachian Plateau are well displayed southeast of the site between Pittsburgh and the Allegheny

Front. Their wavelengths range from 6 to 12 miles and their structural reliefs vary from 500 to 2,500 feet (Rodgers 1970; Cardwell et al 1968). The three largest of these are the Chestnut Ridge, Laurel Hill, and Accident Mountain anticlines which bring uppermost Devonian rocks to the surface. They are 65, 75, and 85 miles from the site, respectively. Farther east, 150 miles from the site, the higher Deer Park anticline brings to the surface a larger section of Upper Devonian shale. Dips are usually less than 10 degrees and no regularity of plunge of the folds is apparent. Faulting at the surface is rare, but oil and gas drilling has revealed several major faults at depth, mostly in the Devonian section. Evidence indicates that these may be sole thrusts for westward movement of the overlying Plateau rocks (Gwinn 1964). The trend of the folds closely parallels the trend of the major folds in the Valley and Ridge of central Pennsylvania, swinging from northnortheast near Pittsburgh, to east-northeast in north-central Pennsylvania. Two of the Plateau folds can be traced southwestward into West Virginia, where they steepen significantly and increase in amplitude. The Deer Park anticline and the Briery Mountain anticline, the continuation of the Accident Mountain anticline, converge in West Virginia, 100 miles south of the site, and become the Elkins Valley anticline, whose west flank has a structural relief of 9,000 feet and is locally overturned. Thrust faults have been suggested beneath the anticline from well data (Rodgers 1970). All of the anticlines show westward offset across the west-northwest trending Morgantown-Sang Run and Fairmount-Rowlesburg lines. The nature of these features is not clearly understood at this time but may be related to reactivated basement fracture zones along which strike slip movement has occurred (Rodgers 1970; Cardwell et al 1968).

Of significantly different trend from these folds is the Burning Springs anticline in west-central West Virginia, about 100 miles southwest of the site. It trends nearly north-south across the center of the coal basin with a structural relief of 1,650 feet. The limbs dip very steeply, and the fold structure terminates rather abruptly at either end. Its existence has been interpreted to be due to several repetitions of the Devonian section along imbricate thrust surfaces, possibly facilitated by the presence of Salina Group salt beds (Rodgers 1970).

The folds of the Plateau are so parallel to those in the adjacent Valley and Ridge, that no one doubts their formation at the same time and by the same forces. The difference in complexity and degree of deformation between the two areas indicates that the stress levels were considerably lower in the Plateau, or the rocks responded to the force differently because of an anisotropic property of the rocks. Thin-skinned tectonics, with movement occurring along zones of salt or weak shales, seems to be the best explanation for the origin of structures found in the Appalachian Plateau of the site region (Rodgers 1963, 1970; Gwinn 1964).

Recent seismic reflection profiling in the southern Appalachians appears to confirm large scale decollement movement of rocks in the Appalachian Plateau and Valley and Ridge. Movement was generally to the northwest and occurred mainly during the Allegheny orogeny (Cook et al 1979, 1980).

Other folds of note exist in the Appalachian Plateau section of eastern Ohio. The Parkersburg-Lorain syncline is the westernmost fold of the western Appalachian basin, and can be traced from Parkersburg, West Virginia, to Lorain County on Lake Erie. The syncline is a structural trough trending N10W and is nearly 5 miles wide in the Marietta region, approximately 80 miles west of the site (Lemborn 1951). The Cambridge arch is the anticlinal counterpart of the Parkersburg-Lorain syncline, and parallels it to the east. It can be traced from the Ohio River in Washington County, Ohio, northwestward into Summit County. The structure has a relief of 450 feet in Washington County, but becomes less well defined northward (Lamborn 1951). Both of these folds are known to affect the Devonian shale sequence above the Onondaga Formation. The folds are underlain by pinchouts of bedded salt, and their location may be due to movements along this zone during the Allegheny orogeny.

<u>Faults</u>

The Clarendon-Linden fault zone is a major tectonic feature in the Appalachian Plateau and Central Stable Region of western New York. Ιt trends north-south for over 60 miles from near Lake Ontario to northern Allegheny County. The Clarendon-Linden fault is postulated to be not a single fault but instead, a zone consisting of several parallel basement faults which become surface flexures (Van Tyne 1976). Most of the movement is believed to be confined to those formations below the Silurian deposits. Movement is believed to have been downthrown to the east, reversing later to become downthrown to the west. A significant amount of seismic activity has taken place in the area of Attica, New York, in close proximity to the Clarendon-Linden structures (Sbar and Sykes 1977; Pomeroy et al in press). Recent low-level seismic activity has been correlated with highpressure fluid injection operations in brine fields which are developed in the area, and it is believed to be relieving stress along the fault system. For this reason, the fault must be considered an active feature. The south end of the fault zone is about 160 miles northeast of the BVPS-2 site. The seismicity of the Clarendon-Linden fault zone is discussed in Section 2.5.2. The Intensity VIII (MM) event in 1929 near Attica is the largest event to occur in western New York and has been correlated with the Clarendon-Linden structure.

Recent work in south-central Pennsylvania has resulted in a proposed fault zone near latitude 40°N called the Transylvania fault (Root and Hoskins 1977). This zone is believed by the authors to be a fundamental fracture of the continental plate, end has been traced from the Blue Ridge, across the Appalachian Plateau a few miles south of the BVPS-2 site. The fault is believed to have been active prior to the opening of the Atlantic and was rejuvenated at that time. No seismic activity is now associated with the zone, and it probably has been inactive at least since the Jurassic. The existence of the zone in the Appalachian Plateau is somewhat conjectural, based only on anomalous aeromagnetic patterns (Popenoe et al 1964; Beck and Mattick 1964) and a proximity to one of Wagner and Lytle's (1976) zones of structural discontinuity.

Other investigators have recently proposed the existence of similar geologic features beneath the Appalachian Plateau. Wagner (1976) hypothesizes "growth faults" based on the confined subsurface distribution of certain rock units of Cambrian and Lower Ordovician age. The faults were to have been active during the Cambrian and Ordovician periods. Root (1978) proposes similar down-to-the-east basement faults recurrently active during the Paleozoic and Mesozoic eras. Parrish and Lavin (1982) propose that kimberlite intrusions of Mississippian to mid-Jurassic age were emplaced at the intersection of basement faults along the edge of the Rome Trough with crossstructural lineaments. These cross-structural lineaments were identified from gravity and magnetic anomaly terminations, pronounced magnetic gradients, changes in gravity patterns, structural discontinuities and satellite imagery. The basement faults are believed to be Triassic to Jurassic in age. Harris (1978) proposes border faults to the Rome Trough in Kentucky and West Virginia as being active during early and middle Paleozoic time.

There appears to be no correlation between the Transylvania faults, Wagner or Root's growth faults, or those faults and lineaments proposed by Parrish and Lavin. All of the features described above are believed to be at least Mesozoic in age, show no history of seismic activity, and pose no threat to the safety of the BVPS-2 site.

Other investigators have recently proposed the existence of similar geologic features beneath the Appalachian Plateau. Wagner (1976) hypothesizes "growth faults" based on the confined subsurface distribution of certain rock units of Cambrian and Lower Ordovician The faults were to have been active during the cambrian and age. Ordovician periods. Root (1978) proposes similar down-to-the-east basement faults recurrently active during the Paleozoic and Mesozoic. Parrish and Lavin (1982) proposal that kimberlite instrusions of Mississippian to mid-Jurassic age were emplaced at the intersection of basement faults along the edge of the Rome Trough with cross structural lineaments. These cross structural lineaments were identified from gravity and magnetic anomaly terminations, pronounced magnetic gradients, changes in gravity patterns, structural discontinuities, and satellite imagery. The basement faults are believed to be Triassic to Jurassic in age. Harris (1978) proposes border faults to the Rome Trough in Kentucky and West Virginia as being active during early and middle Paleozoic time. There appears to be no correlation between the Transylvania fault, Wagneror Root's growth faults or those faults and lineaments proposed by Parrish and Lavin. All of the features described above are believed to be at least Mesozoic in age, show no history of seismic activity, and pose no threat to the safety of the BVPS-2 site.

Ver Steeg (1944) describes several minor faults in eastern Ohio. Between Wilkesville and Clarion in Vinton County, there is a northsouth striking fault with a throw of 7 feet; in Harrison County, a north-northeasterly striking reverse fault has a throw of 1.5 feet. He also describes a vertical fault with a throw of 15 feet dipping to the west at 45 to 50 degrees. The age of these minor faults is not known, but they may be related to Alleghenian folding. They occur 140 and 42 miles southwest of the site, respectively.

Janssens et al (1976) report overthickened Salina units and folding of the younger sediments in Guernsey County, Ohio, approximately 60 miles from the site. They postulate thrusting above the E salt unit of about 1 mile toward the northwest, with parallel folding of the preceding units. They also postulate a major tear fault in eastcentral Washington County, Ohio, similar to others found in the Appalachian basin associated with movement along salt beds during the Allegheny orogeny, approximately 95 miles from the site. (Janssen 1977, personal communication)

2.5.1.1.3.2 Structures of the Central Stable Region

<u>Folds</u>

The Cincinnati arch is the dominant basement structure in the Central Stable region of Ohio. This feature marks the change in dip from the easterly component of the Appalachian basin to the westerly component of the Michigan and Illinois basins. It served to divide the basins into separate depositional environments as well as to separate the mobile Appalachian basin from the stable intra-cratonic interior.

The Cincinnati arch is the northern extension of the Nashville-Jessamine dome, located in Tennessee and Kentucky. At its northern end, the arch bifurcates into the northwesterly trending Kankakee arch, and the north-easterly trending Findlay arch. The earliest development of the arch took place near the end of the Early Ordovician, with evidence of erosion of the Lower Ordovician and Upper Cambrian in northern Ohio. A complex sequence of uplift, stability, and subsidence relative to the basins followed, continuing into post-Permian to pre-Late Triassic time when the final uplift occurred (Janssens 1967, 1973). The arches represent Precambrian basement structural highs which have remained inactive since approximately the beginning of the Mesozoic.

The arch system continues into Canada and extends to the Canadian Shield as the Algonquin axis. A cross structure, the Chatham sag, separates the Findlay arch from the Algonquin axis. The feature in Canada is believed to have a similar, related history. The arch system is believed to have served as the anvil during lateral compression of the Paleozoic sediments from the southeast and east during the Allegheny orogeny (Rodgers 1970).

Faults

Ver Steeg (1944) describes a minor fault in Delaware County, Ohio, within the Central Stable Region. It strikes N2OE and dips 58 degrees to the east with a displacement of 8.5 feet. Jacoby (1969) reports two minor faults in the International Salt Mine in Cleveland. Both are nearly vertical gravity faults striking N7OW, and dipping to the north. The throws on the faults are 4 to 4.5 feet and 47 feet. The origin of the faulting is unknown.

Owens (1967) reports a small displacement, north-south trending, gravity fault, downthrown to the east on the Precambrian surface in Clinton-Fayette-Pickaway Counties, Ohio. The fault is based on an east-west seismic cross section. He also states the feature may be the result of erosion on the Precambrian surface.

Two other faults in Ohio were recognized during site investigations for Perry Nuclear Power Plant - Unit 1 and Unit 2, Lake County, Ohio, approximately 90 miles northwest of the site. The Warners Creek and Hell Hollow faults were found to be relatively small features, probably younger than 35,000 years and related to slumping of rock masses along joint planes or thrust faults which resulted from loading effects and ice movements during the Pleistocene (Cleveland Electric Illuminating Company 1974). Evidence for deep-seated faulting in the area was not present. The largest fault known in Ohio is the Bowling Green fault, approximately 180 miles from the BVPS-2 site. It is a high angle reverse fault and trends north-northwest across the top of the Cincinnati arch through Hancock, Wood, and Lucas Counties into Michigan. It displaces the Trenton oil horizon some 200 feet. The fault is believed to become a monocline at both ends (Ver Steeg 1944; Janssens 1973). The bedrock surface across the fault was leveled by erosion during the Mesozoic and Cenozoic eras, and it appears that no movement has occurred on the fault since about the end of the Paleozoic (Woodward-Moorhouse and Associates, Inc. 1974). The majority of structural features in northwestern Ohio lie in a northwest-southeast direction paralleling the trends in the Michigan basin, to which they are probably related.

Several faults have been identified in Ontario in the vicinity of the Chatham sag. They include the Electric fault, the Dawn fault, the Clearville fault, the Kimball-Colinville fault, and the Willey fault (Brigham 1972). These faults are 140 miles from the site at their nearest known location and are believed to be Ordovician to Devonian in age, with no evidence of post-Devonian activity.

2.5.1.1.3.3 Structures of the Valley and Ridge Province

Sedimentary strata of the Valley and Ridge have been deformed into a close succession of anticlines and synclines, each several miles across. Most folds are asymmetrical and have been overturned or steepened on the northwest limb. Progressive deformation has resulted in southeast dipping thrust faults developing along the overturned limb in places. Faulting is common in the Valley and Ridge of Virginia and Tennessee, while folding dominates in Pennsylvania. The deformation has been related to thin-skinned tectonics which took place during the Allegheny orogeny (Gwinn 1964, 1970; Rodgers 1963, 1970).

Some of the larger structures closest to the site are the Wills Mountain anticline, Broad Top syncline, and the Nitanny anticline, 110 to 125 miles southeast of the site. All of these structures have been shown to be the result of folding and thrusting along relatively shallow, weak stratigraphic units during the Allegheny orogeny. The Birmingham and Sinking Valley thrusts are exposed 115 miles southeast of the site, and are associated with development of the Nitanny anticlinorium. A major fault, the Little North Mountain thrust, is present 150 miles southeast of the site where it coincides with the mid-province structural front, the zone of vertical and overturned beds (Rodgers 1970). It is just one of several thrusts in the Valley and Ridge of Virginia and Maryland, which developed approximately in the same manner and at the same time. 2.5.1.1.3.4 Structures of the Blue Ridge and Piedmont Provinces

A small part of the Blue Ridge and Piedmont provinces lies within 200 miles of the BVPS-2 site. The history and geologic structures of the two provinces are similar and are discussed together.

The Blue Ridge and Piedmont provinces are characteristically composed of metamorphosed Precambrian and Lower Cambrian eugeosynclinal sediments, which have been intensely folded and faulted. Involvement during two deformations distinguishes these provinces from the Valley and Ridge to the west. Major features of the northern end of the provinces, within 200 miles of the site, are the South Mountain-Blue Ridge anticlinorium and the Catoctin Border fault. The former is the major anticlinal feature of the Blue Ridge, and exposes metamorphosed Precambrian basement rocks in its core with volcanic rocks unconformably overlying them. Plate tectonic theory and interpretation of recent seismic profiling indicate that the Blue Ridge and Piedmont rocks are allochthonous, having been thrust a minimum of 35 miles over Valley and Ridge sedimentary rocks. Deformation and westward transport is believed to have started during the Ordovician Taconic orogeny and culminated in the Pennsylvania to Permian, Allegheny orogeny. Orogenic compressive stresses ceased with the initiation of continental rifting during the Triassic and Jurassic, creating the present Atlantic Ocean basin (Cook 1983; Cook et al 1979; Harris and Bayer 1979; Cook, Brown, and Oliver 1980.)

The Catoctin Border fault forms the western boundary of the Piedmont province in Pennsylvania, Maryland, and northern Virginia. It is a normal fault, downthrown to the east, and borders the Gettysburg-Culpepper basin of Triassic age.

2.5.1.1.3.5 Lineaments Within the Site Region

Several studies have included the identification and analysis of lineaments in the area surrounding the BVPS-2 site (Gwinn 1964; Wagner and Lytle 1976; Kowalik and Gold 1976; Briggs and Kohl 1976; Saunders and Hicks 1976; Bench et al 1977; Colton 1977). Some studies were based on satellite imagery, while others used subsurface geologic information. Several lineaments were identified in the immediate site vicinity, but none are believed to correspond to bedrock fault traces. Most lineaments can be shown to correspond to topographic features and segments of rivers and streams. Many lineaments which represent valley traces are parallel or normal to fold axes. Joint patterns in this area also tend to be parallel or normal to these axes (Briggs and Kohl 1976). Although the relationship between joints and straight stream valleys is still in question, the valley lineaments do suggest some relation to Allegheny orogeny folding. Most, if not all, lineaments identified in Pennsylvania can be shown to have originated before the Cenozoic. The very low level of seismic activity in the area precludes development of any lineaments as a result of recent fault movement.

2.5.1.1.4 Regional Geologic History

The geologic history of the region about the site can best be understood by tracing the history of development of the central Appalachian basin. The Appalachian basin is an elongated sedimentary basin which extends from the Canadian Shield in southern Quebec and Ontario southwestward to central Alabama. It includes here the area of typical Valley and Ridge structures, as well as the rocks of the Appalachian Plateau. Most of the site region (200-mile radius) falls within this area, except for a small section of Blue Ridge and Piedmont rocks to the southeast.

The general configuration and character of the Precambrian basement beneath the basin is fairly well known from oil and gas exploration activities and gravity and aeromagnetic data. Rocks of the Canadian Shield are believed to continue as a peneplain surface beneath the Paleozoic cover, and slope at a very low angle to the south and southeast (Beck and Mattick 1964; King 1977; Kulander and Dean 1978). The depth to the basement is generally equal to the thickness of the overlying sediments and ranges from 2,000 feet over the Cincinnati arch to about 35,000 feet in the geosynclinal portion of the Appalachian basin. The basement surface reflects a long period of erosion which began in Late Precambrian time, and continued into the Middle Cambrian. It resulted in a marked angular unconformity between the metamorphic and igneous complex of the basement, and the sedimentary pile within the basin. Subsidence of the basement in the late Middle Cambrian and Late Cambrian initiated deposition of marine sediments, consisting mostly of sandstone and sandy dolomite, the basal clastic sequence. The sequence is wedge-shaped with the greatest thickness being along the eastern edge of the basin, indicating transgression from the southeast. This sequence was followed by an episode of carbonate deposition during the Late Cambrian and Early Ordovician during a prolonged period of crustal quiescence. Evidence suggests that the carbonate deposits ended abruptly southeastward at a continental shelf bordering the eugeosyncline (Rodgers 1968). This sequence ended after deposition of the Trenton Limestone.

Gentle epeirogenic uplift during the early Middle Ordovician resulted in an erosional disconformity in the upper part of the Cambrian-Ordovician carbonate section in some parts of the basin. Clastic sediments of Late Ordovician to Middle Silurian age conformably overlie the Trenton, although in many areas this episode began in the Middle Ordovician (King 1959). They were derived from erosion of emergent land to the southeast and southwest (Eardley 1962; King 1959). The first part of the later clastic deposits forms the Middle and Upper Ordovician Normanskill and Martinsburg Formations of New York and Pennsylvania, considered to be flysch deposits (King 1977). Evidence exists for a major deformation in Late Ordovician time, mostly from the northeastern part of the basin. The Taconic orogeny left its imprint in central and eastern Pennsylvania as a distinct angular unconformity between highly deformed Upper Ordovician rocks, only slightly deformed Lower Silurian rocks. A thick wedge of elastic sediments, centered in east-central Pennsylvania, began to accumulate in Late Ordovician time, and continued through the Silurian and Devonian, with the greatest development during the Silurian and Devonian. The source of these sediments is believed to have been an upland to the east which was developing as a result of continental plate convergence (King 1977).

Early Silurian clastics were followed by a thick carbonate and shale sequence during the Middle Silurian. Overlying these are the evaporites of the Salina Group and the Bass Islands carbonates. The top of the Bass Islands is a widespread Early Devonian unconformity, while the top of the overlying Helderberg Formation is a widespread regional unconformity. This unconformity was overlain by the transgressive sequence of the Oriskany and Bois Blanc Formations and was followed by carbonate deposition (Onondaga). This was followed by a thin sequence of clastics with intermittent carbonates up to the end of the Devonian, known as the Catskill Delta. Deposition of the Pocono Sandstone and Mauch Chunk Shale followed conformably on top of the marine Catskill deposits in some areas, but unconformably in most of the basin during the Early Mississippian. They indicate thickening toward the eastern geosynclinal trough which coincided with the Valley and Ridge province.

Another gentle uplift occurred in Late Mississippian or Early Pemsylvanian time in the northwest part of the basin and resulted in an erosional disconformity between the Mississippian and Pennsylvanian (Colton 1970). The Pennsylvanian strata are distinctly clastic, and include the great coal-bearing formations of the Appalachian Plateau and Valley and Ridge provinces, deposited in a restricted basin. The Pottsville, Allegheny, Conemaugh, and Monongahela Formations in the site vicinity were deposited at this time.

Conformably overlying the Monongahela in an oval area of southwest Pennsylvania, eastern Ohio, and West Virginia, is the Dunkard Group of Early Permian age. It is composed of shale, sandstone, and a few thin coal beds.

The age of deformation of this area is not clearly defined, but, presumably, it was later than the youngest rocks present, and before deposition of Late Triassic sediments in the Newark-Gettysburg basin, 165 miles east of the site. The Allegheny orogeny completely changed the character of the Appalachian basin from a predominantly depositional environment into an emergent mountain range and plateau.

The basin can be separated into two structural provinces, the Appalachian foldbelt on the east, and the Appalachian Plateau on the west. The boundary between the two closely coincides with the Allegheny Front. The foldbelt was subjected to intense deformation during the Allegheny orogeny which resulted in folding and faulting and generation of the Valley and Ridge mountains in central Pennsylvania and Virginia. Intensity of deformation decreases rapidly west of the Allegheny Front.

The Appalachian Plateau was also subject to the lateral compressive forces of this orogenic episode, and shows mild deformation within the higher stratigraphic units. The presence of Salina salt beds underlying a large portion of the area apparently had a major effect on controlling the deformation in this area. The salt beds greatly reduced the resistance to the lateral compressive stresses, and facilitated thin-skinned tectonic movements over a large area (Gwinn 1964; Rodgers 1963). In some parts of the Plateau, it can be shown that other weak sedimentary units may have acted in a similar manner (Rodgers 1970). These deposits were the major influence for lateral, northwestern thrusting of the orogenically-disturbed sequences, folding, and faulting of strata above the weak zones, and plastic flow and decollement deformations within the zones. Most of the folds are asymmetrical and steepest on the northwest flank. Thrust faults are the dominant structure in the southern Appalachians, but die out in southern Pennsylvania in a belt of anticlines and synclines.

The tectonic forces which resulted in the Allegheny orogeny are believed by many to be a continuation of earlier Paleozoic continental collision. The forces have been extinct since Late Paleozoic-Early Mesozoic time when, it is believed, the continental plates were rifted apart and generated the present Atlantic Ocean basin. Since that time, the Appalachian basin area has been subjected to moderate epeirogenic movements, which have provided the relief necessary to produce the geomorphologic dissection present today.

Outside the Appalachian basin, but within the site region in eastern Pennsylvania, is an area of Mesozoic deformation and sedimentation. The Newark-Gettysburg-Culpepper basin is a series of long, narrow, fault-bound basins of Late Triassic and Early Jurassic deposits, which developed as a result of continental rifting. The deposits are chiefly clastic, and predominantly red in color, being fanglomerates, conglomerates, sandstones, arkoses, and mudstones. Basalt flows, and diabase dikes and sills are voluminous within the deposits. The total thickness of the deposits is about 20,000 feet, believed to be derived from granitic and gneissic terrain to the southeast (Eardley 1962). The faulting that marked the beginning of the basin deposition indicates the beginning of the Palisades orogeny. It started in late Triassic time, and probably ended before the Early Jurassic (Rodgers 1970).

The final phase in the geologic history of the site region was that of the Pleistocene glaciations, which covered the entire northern half of the region. The tectonic results of the glaciations were down-warping of the area overlain by and adjacent to ice, followed by rebound after removal of the ice load. The low-level seismic activity that still occurs in the northeastern United States and eastern Canada is traditionally attributed to this rebound. Periglacial events, associated with the development of outwash terraces along the Ohio River, are as yet incompletely understood.

2.5.1.2 Site Geology

2.5.1.2.1 Site Physiography

The site is located on the south bank of the Ohio River in the town of Shippingport, 0.5 mile southeast of the town of Midland, Pennsylvania, and adjacent to Beaver Valley Power Station - Unit 1 (BVPS-1). It is situated near the center of the Appalachian Plateau physiographic province as outlined by Fenneman (1938). As previously described in Section 2.5.1.1.1, this province is characterized as an extensively dissected peneplain underlain by nearly flat-lying, undeformed Paleozoic sediments. The dissected topography has been somewhat subdued beneath several glacial drifts beginning about 20 miles north of the site and extending northward.

The site is situated on the uppermost Pleistocene outwash terrace of the Ohio River, which has an average elevation of approximately 735 feet in the main plant area (Figure 2.5.4-1). A younger terrace exists between the upper terrace and the present flood plain of the Ohio at an elevation of approximately 688 feet. The mean pool elevation of the river at the site is approximately 664 feet 6 inches. The upper terrace rises gently southward for a distance of approximately 1,500 feet before ending abruptly against a series of steep-sided, flat-topped hills with a top elevation of approximately 1,200 feet. The Ohio River is between 1,000 feet to 1,400 feet wide near the site, including the present flood plain.

Figure 2.5.4-50 is a top of rock contour map. As indicated on Figure 2.5.1-2, flat-lying sedimentary rocks of the Allegheny Group of Pennsylvanian age immediately underlie the 100-foot thick terrace. The Allegheny Group consists of a sequence of interbedded shales, sandstones, coal seams, underclays, and a limestone bed. It is estimated to be 350 feet thick in the site area, and contains one minable coal bed, the Upper Freeport coal, which outcrops above plant grade at approximately el 900 feet. No coal seam has been mined in the plant area at elevations below that of the plant, and no seam is considered to have commercial potential beneath the plant (Patterson 1963). The site is drained by a small northwesterly flowing stream, Peggs Run, which enters the Ohio River near the east end of the site. The stream was diverted in conjunction with construction of BVPS-1, and is now culverted or lined for its entire run through the site.

In the immediate area, there are no surface features indicative of actual or potential landsliding, or surface or subsurface subsidence, due to mining or cavernous conditions.

2.5.1.2.2 Site Stratigraphy

The area within 5 miles of the site is underlain by predominantly flat-lying, or gently-dipping sedimentary rocks, varying in age from the Middle Cambrian to the Late Pennsylvanian. Formation descriptions are from Gray (et al 1960), Wagner (et al 1975), and Fettke (1950).

2.5.1.2.2.1 Precambrian

Crystalline Precambrian rock is believed to unconformably lie beneath the thick Paleozoic sequence. Little is known about the rocks which comprise the basement complex as none are exposed within the area, nor have they been encountered in drill holes. From other areas, they have been found to be composed of various metamorphosed sedimentary and igneous materials, which have been intruded by various other igneous bodies. Beck and Mattick (1964) indicate that the basement may be between 10,000 and 11,000 feet deep in the site area, based on an aeromagnetic survey. The eroded basement surface is believed to dip southeasterly, averaging 85 ft/mile.

2.5.1.2.2.2 Cambrian

Early and Middle Cambrian stratigraphy in the site area is incompletely known from a few deep wells located in adjacent states. Stratigraphic relations indicate a sea transgressing from the southeast during this time which deposited a thick clastic wedge on the Precambrian surface. The westward extent of this wedge is not fully known, and it is somewhat speculative whether Lower and early Middle Cambrian rocks are represented beneath the site. Deposition may have begun in late Middle Cambrian with the Pleasant Hill and Warrior Formations, or even the Potsdam sandstone, but is definitely known to have occurred by the Late Cambrian with the Gatesburg Formation. The Gatesburg is known from a deep well in Butler County, Pennsylvania, to be a fine-grained, crystalline, light brownish gray dolomite, sandy dolomite, or dolomitic sandstone in excess of 350 feet thick (Fettke 1950).

2.5.1.2.2.3 Ordovician

Carbonate sedimentation continued in the Early and Middle Ordovician with deposition of Beekmantown Group rocks, composed of fine- to medium-grained, crystalline, light gray dolomite. The thickness of the Beekmantown varies in western Pennsylvania from 0 to 200 feet. A major unconformity occurs at the base of the Middle Ordovician section and is nearly basinwide in extent with the magnitude increasing to the northwest (Colton 1970). Approximately 4,500 feet of Lower Ordovician strata, present in central Pennsylvania, are missing in western Pennsylvania. It is not known to what extent rocks beneath the site were affected.

A sequence of predominantly noncalcareous clastic sedimentation began in the Middle Ordovician and continued into the Early Silurian. The Utica Formation, Reedsville Shale, Oswego Sandstone, and Queenston Shale are believed to exist beneath the site. The Utica is a black shale 100 to 300 feet thick while the Reedsville is a gray shale between 700 and 800 feet thick in western Pennsylvania. The Oswego Sandstone is a very-fine-grained, gray sandstone 0 to 60 feet thick, and the Queenston is a red shale, in part silty and sandy, and may be between 850 and 1,200 feet thick.

2.5.1.2.2.4 Silurian

Clastic deposition continued through the Early and Middle Silurian with deposition of the Tuscarora and Rose Hill Formations, the Keefer Sandstone, the Rochester Shale and the McKenzie Formation. The Tuscarora is a white-to-gray, fine-grained sandstone, conglomeratic in part, and may be 500 to 700 feet thick. The Rose Hill Formation is a reddish purple-to-greenish gray, fossiliferous shale with some hematitic sandstone lenses, and may be up to 875 feet thick. The overlying Rochester Shale is dark gray and calcareous and may be from 0 to 60 feet thick. Moderate gas and minor oil production has been realized from the Tuscarora Formation in northwestern Pennsylvania, Ohio, and West Virginia. The McKenzie Formation is a greenish gray shale interbedded with gray, fossiliferous limestone, and may be up to 330 feet thick.

Upper Silurian rocks were also predominantly clastic comprising the Bloomsburg, Wills Creek, and Tonoloway Formations. The Bloomsburg is a red interbedded shale and siltstone with lenses of sandstone and limestone. The unit varies in thickness from a few hundred to over 1,500 feet thick. The Wills Creek Formation is typically a greenish gray, fissile shale with local limestone and sandstone lenses. It may be up to 475 feet thick. The Tonoloway Formation is a gray, laminated, argillaceous limestone up to 575 feet thick. Deposition of the Keyser Formation marked the completion of the shift to carbonate sedimentation. The Keyser is a dark gray, fossiliferous, crystalline to nodular limestone and may be up to 300 feet thick.

2.5.1.2.2.5 Devonian

Carbonate deposition continued into Early Devonian time beginning with the Coeymanns Limestone, New Scotland Formation, and the Mandata Shale. The Coeymanns Limestone is a dark gray, crystalline limestone which may be sandy and shaly in places with some chert nodules. The thickness varies from 0 to 75 feet. The New Scotland Formation is a dark gray, cherty, fossiliferous limestone with some sandstone lenses and may be between 25 and 80 feet thick. The Mandata is a dark gray, calcareous shale between 20 and 150 feet thick. Overlying these are the Shriver Chert and the Ridgeley Sandstone. The Shriver is a dark gray, cherty limestone with some interbeds of shale and sandstone and may be up to 165 feet thick. The Ridgeley Sandstone (Oriskany) is a white to brown, partly calcareous, fossiliferous sandstone from 0 to 110 feet thick. There has been some production of gas in Beaver County from the Ridgeley Sandstone.

Middle Devonian rocks are predominantly clastic, and include the Needmore Shale, Selinsgrove Limestone, Marcellus Formation, and Mahantango Formation. The Needmore Shale is a greenish blue, thin bedded shale, and the Selinsgrove is a blue to black, medium bedded limestone. The Marcellus Formation is a black, carbonaceous shale, while the Mahantango is a brown to olive shale with interbedded sandstones and may be highly fossiliferous. The four units comprise the Hamilton Group, which varies from 140 to 2,000 feet thick in western Pennsylvania.

Late Middle and Upper Devonian rocks are represented by the Tully Limestone, Harrell Shale, Brallier, Chemung, Canadaway, Conneaut, Cattaraugus, and Oswayo Formations. The Tully is an argillaceous limestone 0 to 150 feet thick. The Harrell is a dark gray to black shale, while the Brallier Formation consists of interbeds of gray shale, siltstone, and sandstone. The Chemung is an irregularlybedded gray siltstone, sandstone, and shale, displaying abundant primary sedimentary features. The Canadaway consists of alternating gray shales and brown sandstones, and the Conneaut consists of alternating gray, brown, greenish, and purplish shales and siltstones. Red, gray, and brown shales and sandstones make up the Cattaraugus Formation, while the uppermost Devonian Oswayo Formation consists of greenish gray to gray shales, siltstones, and sandstones. The thickness of the Upper Devonian section, from the Harrell Shale through the Oswayo Formation, is between 3,000 and 6,000 feet from northwest to southeast Pennsylvania.

2.5.1.2.2.6 Mississippian

Pocono Group rocks of Early Mississippian age are predominantly gray, massive, cross-bedded sandstones and conglomerates with minor amounts of shale. They are between 570 and 900 feet thick in western Pennsylvania, and are important oil and gas reservoirs. The overlying sandy Loyalhanna Limestone is between 0 and 80 feet thick. The Upper Mississippian Mauch Chunk Formation consists of red shales with brownto-greenish gray, flaggy sandstones and is 0 to 100 feet thick.

2.5.1.2.2.7 Pennsylvanian

An erosional unconformity separates the Upper Mississippian and Lower Pennsylvanian systems in western Pennsylvania. The Pottsville Group probably rests on the Mauch Chunk in the site area. The Pottsville is typically a light gray-to-white, coarse-grained sandstone and conglomerate with minor shale beds. It is between 120 and 230 feet thick in the site area and contains some minable coal beds. The Middle Pennsylvanian, Allegheny Group, overlies the Pottsville, and is the subsurface bedrock at the site. It is also the dominant rock unit exposed in the site area. The Allegheny consists of cyclic sequences of sandstone, shale, limestone, and coal.

Differentiating the several coal beds has been accomplished by utilizing the distinctive Vanport Limestone. The type locality is approximately 6 miles northeast of the site, in the town of Vanport.

This limestone has been described as having abundant fossils, being very brittle, and breaking into irregular fractures. It is gray to blue in color, and interbedded with calcareous shale. Its total maximum thickness is 19 feet (Woolsey 1905). Above the Vanport Limestone is an interval which includes several coal beds, beginning with the Lower, Middle, and Upper Kittanning. Their respective thicknesses have been reported as 0 to 36 inches, 14 to 24 inches, and generally less then 6 inches (Patterson 1963).

The Lower and Upper Freeport Coal occur above the Upper Kittanning Coal, and have been or are currently mined within the site area. The thickness of the lower Freeport coal seam is 14 to 48 inches, while the upper seam thickness averages 36 inches. They are separated by approximately 45 feet of sandstone and shale.

The Lower Freeport coal is presently being open cut, auger mined, at Kelly Mine No. 1 in a 41-inch bed along Wolf Run in Industry. The

Upper Freeport has been both strip mined and underground mined along Peggs Run in a 48-inch average thickness bed. This coal seam also serves as the boundary between the Allegheny and Conemaugh Groups.

The Upper Pennsylvanian Conemaugh Group outcrops in the site area and continues the cyclic sedimentation sequence begun in the Allegheny. The Conemaugh Group has been divided into two mappable formations in the site area, the Glenshaw and the Casselman Formations (Wagner et al 1975). The Glenshaw contains cyclic sequences of red shales, sandstones, thin coal beds, and several thin marine limestones. The Ames Limestone, which forms the boundary between the two formations, is the most distinctive marker horizon within the Conemaugh Group. The weathered surface, where exposed, is covered with numerous projections of crinoid stems. It is a very persistent bed with an average thickness of 3 feet (Woolsey 1905). Where exposed, it is light brownish gray, being dark bluish gray on a fresh surface.

Between the Ames Limestone and the Morgantown Sandstone (the probable upper limit of rock types found in the site area) are approximately 40 feet of variegated shale or shaly limestone, and a thin coal seam (Woolsey 1905). The Casselman also contains cyclic sequences of red sandstones and shales with thin limestones and coal beds. The Glenshaw is 300 to 350 feet thick in the site vicinity, while the Casselman varies between 200 and 400 feet thick. Rocks younger than the Conemaugh do not outcrop within the site area, but are found 10 miles south of the site. They belong to the Upper Pennsylvanian Monongahela Group and continue the cyclic sedimentation sequences.

2.5.1.2.2.8 Pleistocene

Pleistocene deposits in the site area exist as terraces above the larger streams, and consist of unconsolidated sand and gravel deposits with varying amounts of clay and silt. Thicknesses of greater than 150 feet are known. The terrace on which the plant is situated averages 100 feet in thickness. It resulted from the ancestral Ohio River depositing enormous volumes of glacial outwash which was being carried away from the ice margins during the Late Pleistocene. The terrace at the site has not been correlated with any one of the seven known ice advances into Pennsylvania, but is probably the product of several of them.

Recent alluvial materials exist in the site area as floodplain deposits, primarily adjacent to the present Ohio River, but also mantling the intermediate terrace. The intermediate terrace is the result of flood control projects which lowered the river level during the 1930s.

2.5.1.2.3 Site Structure

The site area geologic investigation consisted of field-checking the existing published geologic literature within approximately 7 miles of the site. The original work, upon which all later information is based, was performed by L. H. Woolsey between 1902 and 1905, and was

published as the Beaver Folio. Coal, oil, and gas explorations since 1905 have only slightly modified Woolsey's original interpretations.

The field verification took place over a 2-week period in the fall of 1978 and relied primarily on recent road cuts, coal mining activities, and cliff exposures. The results of our investigation are presented subsequently, and are in complete agreement with the efforts of Woolsey (1905) and of Wagner (et al 1975) which indicate that the bedrock in the area is relatively flat-lying and undeformed. No offsets of stratigraphic marker beds were detected, based on exposures several miles apart, and no bedrock faults were identified within 5 miles of the site.

2.5.1.2.3.1 Structure as Determined from Coal Mining

The Peggs Run Coal Company Mine No. 2 is located approximately 8,500 feet south of the BVPS-2 site. The mine was operated in the Upper Freeport Coal seam, with an average thickness of 48 inches and ranged in elevation between 939 and 906 feet. The dip of the seam has been calculated from mine elevations to be less than 1 degree (33 /4,000 feet) to the northeast in one area, to less than 0.25 degree (13 /3,000 feet) to the southwest in another area. A strip mine operated by Peggs Run Coal Company, and located 2,600 feet southeast of the site, removed Upper Freeport Coal at an average elevation of 920 feet.

A similar example of the local structural dip variation (deviation from the regional southwest dip) has been extracted from Woolsey (1905). He had reported a 30-foot decrease in elevation of the Upper Freeport between the two adjacent towns of Vanport (el 938 feet) and Beaver (el 908 feet) located at least 10 miles to the northeast of the Peggs Run mine referenced previously. Based on both the absolute value and range of elevations at the two locations, the regional dip is found to be imperceptible over a 10-mile distance.

The Lower Kittanning Coal seam was also observed to maintain a nearly imperceptible dip from one side of the Ohio River to the other at Midland.

2.5.1.2.3.2 Structure as Determined from Limestone Horizons

The Vanport Limestone was verified at Merrill along Fourmile Run at el 720 feet, as reported by Woolsey (1905).

In addition, the Ames Limestone was found both north of the site in Midland, and south of the site near Hookstown. The two exposures of the Ames in Midland were noted as loose, detached blocks, at approximately el 1,200 feet, as indicated by Woolsey's Areal Geology map (1905).

Along U.S. Route 30, 1.4 miles west of the State Route 151 junction, the Ames Limestone outcrops at approximately el 1,200 feet, once again consistent in elevation and location, as reported by Woolsey.

These two limestone marker beds nearly bound the exposure of the Allegheny and Conemaugh Groups in the site area.

2.5.1.2.3.3 Jointing and Bedding

Four joint sets were identified from outcrops within the 5-mile radius of the site; two sets strike roughly northeast and two strike northwest; all are near vertical. This is in fair agreement with the results of Bench (et al 1977) in this area, which indicated the joints are the result of tectonic stresses, and subsequent stress adjustments produced during the erosion and unloading that affected the Plateau. The two dominant joint systems, which strike N76W and N57W, are believed to be the bedrock expression of the principal stress trends, and possibly relate to a structural weakness which resulted from the Allegheny folding and thrusting.

2.5.1.2.3.4 Faulting

No bedrock faulting was identified within 5 miles of the BVPS-2 site. A fault was identified, however, about 0.25 mile outside the radius at the Stewart Hill road cut along U.S. Route 30 in West Virginia. The fault strikes N35E and dips 17 degrees northwest and appears to be a gravity fault. The amount of displacement is indeterminable, as an 18-inch marker coal seam (Elk Lick coal) does not outcrop west of the fault, but presumably occurs beneath the ground surface.

The time of last movement has been determined stratigraphically by an overlying, horizontal sandstone bed, which appears to be continuous across the fault plane at the top of the exposure. Slumping of sediments along the fault plane during deposition resulted in upturned beds being overlain by the horizontal sandstone, as seen at the west end of the exposure. A portion of the fault is shown on Figure 2.5.1-8.

A similar example of deformation during sedimentation is cited by Wagner (et al 1970) and occurs in a railroad cut in the Casselman Formation near McKeesport. Here, a faulted sandstone is overlain by a claystone which is not offset.

The shallow dip angle of the fault in West Virginia is indicative of near-surface failure, probably as a submarine slump of semiconsolidated material. The upper surface of the slumped block was then eroded, leveled, and subsequently overlain by the thick sand layer during the Pennsylvanian.

2.5.1.2.4 Site History

The geologic history of the site area is similar to the history of the Appalachian basin discussed in Section 2.5.1.1.4 and is briefly summarized here.

An extended period of erosion on the Precambrian basement complex, which began during the Late Precambrian, ended during the Middle or Late Cambrian when a sea, transgressing from the southeast, deposited

a basal clastic sequence in the site area. This was followed throughout most of the Paleozoic Era by an alternating sequence of carbonate and clastic sedimentation, punctuated by three orogenic events: 1) the Taconic during the Middle Ordovician, 2) the Acadian during the Middle Devonian, and 3) the Alleghenian during the Permian. The latter had the most significant effect in the site area by producing a series of very gentle folds within the Paleozoic strata, and ended the sedimentation cycle. The site lies on the west limb of a troughlike basin, known as the Pittsburgh-Huntington basin. Dips of strata into the basin are gentle, usually less than 3 degrees, and are nearly imperceptible in the site area. Obviously, diastrophic deformation has not played a major role in the history of the site area. Tectonic forces have been inactive in the site area probably since the end of the Allegheny orogeny, 250 million years ago. Periodic epeirogenic uplifts, isostatic adjustments, and erosion since the Paleozoic have produced the well-dissected plateau present in the site area today.

2.5.1.2.5 Plot Plan

Location plans of borings performed at the site are shown on Figures 2.5.4-10, 2.5.4-13 and 2.5.4-15. Plant structures are superimposed upon these figures.

2.5.1.2.6 Geologic Profiles of Plant Foundations

Geologic profiles are presented in Section 2.5.4.

2.5.1.2.7 Extent of Backfill and Excavation

Excavation end backfill at the site are discussed in Section 2.5.4.5.

2.5.1.2.8 Engineering Geology Evaluation

2.5.1.2.8.1 Dynamic Behavior During Prior Earthquakes

Site investigations show no features or conditions indicative of disturbance during prior earthquakes, such as flow structures, fissures, or slumps in the unconsolidated deposits.

2.5.1.2.8.2 Description and Evaluation of Deformational and Weathered Zones

No zones of severe weathering, structural deformation, or lithologic weakness were identified in the site area based on core borings, seismic velocity measurements, and site area geologic reconnaissance. Seismic refraction studies indicate that hard, intact rock with compressional wave velocities of 12,000 feet per second (fps) underlies the site. No low velocity or anomalous zones were indicated.

The underlying rock is slightly weathered for the first few feet, with weathering effects decreasing rapidly with depth. All

structures are founded on select granular fill or natural soil deposits, with bedrock lying at least 55 feet deep.

Pomeroy (1979) mapped recent and older landslides and identified areas most susceptible to sliding within Beaver County, Pennsylvania. It was noted that most landslides that had been observed occurred in colluvial soils and weathered rock derived from mudstone, claystone, shale, and siltstone. It was further noted that most recent landslides had been generated by construction activities. The site topography is shown on Figure 2.5.4-13. While not specifically identified as an area of potential instability, the steep slopes to the south of the BVPS plant site are colluvial in nature. They are, however, sufficiently removed from the main plant area to present no potential safety problem in the event of a landslide. The stability analysis of the colluvial slopes to the south of the emergency outfall structure (EOS), located at the far western end of the site, is described in a summary report submitted separately (SWEC 1983). It was concluded that although there may be a potential for movement of the upper portion of the colluvial slope above el 780 ft, any slope movements would not affect the EOS.

2.5.1.2.8.3 Unrelieved Residual Stresses in Rock

Unrelieved residual stresses in rock were considered to have no influence on the design and operation of the plant due to the thickness of founding overburden.

2.5.1.2.8.4 Evaluation and Description of Natural Soils

The characteristics of the in situ surficial materials are described in Section 2.5.4.2 and the Soil Densification Program Report (DLC 1976).

2.5.1.2.8.5 Description of Man's Activities at the Site

Some oil and natural gas have been recovered within 5 miles of the site, mostly from the Pocono Group of Mississippian age. No wells have been drilled within the site boundary, nor are any anticipated. Extraction of natural gas or oil is not likely to produce consolidation and subsequent surface subsidence of the well lithified rocks beneath the site. The rocks in the site area are Permian or older and have not been susceptible to consolidation upon withdrawal of fluids from them.

Coal has been recovered at several locations within 5 miles of the site by underground and surface mining methods, mostly from the Upper Freeport coal seam.

No coal mining has taken place beneath the site nor is any anticipated. The limited quantity, low quality, and depth below the surface of the underlying coal seams precludes development during the expected lifetime of the plant. Maps indicating the areas underlain by coal deposits, and oil and gas, are presented on Figures 2.5.1-9 and 2.5.1-10, respectively.

Withdrawal of groundwater in the site area is discussed in Section 2.4.13.

2.5.1.2.9 Site Ground-water Conditions

The ground-water conditions in the site area are discussed in detail in Sections 2.4.13 and 2.5.4.6.

2.5.2 Vibratory Ground Motion

The site region is characterized by a low level of earthquake activity. The Ohio River Valley in which the site is located has been well settled since the early 1800's. During the past 180 years, there have been few earthquakes within 200 miles of the site and only three within 50 miles. There are two centers of activity within 200 miles of the site - one near Attica, New York, and one near Anna, Ohio. Moderate size earthquakes have occurred in these centers of activity. The maximum earthquake potential at the site is an earthquake of Modified Mercalli (MM), Intensity VI, occurring near the site, corresponding to a peak horizontal ground acceleration of 0.07g. The safe shutdown earthquake (SSE) has been specified as 0.125g and the operating basis earthquake (OBE) has been specified as 0.06g.

2.5.2.1 Seismicity

Most of the information concerning earthquake activity in the eastern United States is based on historical reports, old diaries, and newspaper accounts. These earthquakes are classified on the basis of intensity corresponding to the Modified Mercalli (MM) scale. This scale, shown in Table 2.5.2-1, is based on observations of effects of earthquakes and damage to structures. The instrumental monitoring of earthquakes in the eastern United States began in the mid 1920's. Since that time, the number of seismograph stations has greatly increased. Historical reports of earthquakes and information obtained from instrumental coverage in recent years form the basis of the examination of the seismicity of the site region.

2.5.2.1.1 Totality and Reliability of Earthquake Catalog

Even though major historical catalogs carry entries dating back almost to the 1800's, the coverage of this long a period is not homogeneous. The completeness and reliability of the data are related to population distribution and to the seismograph network coverage. Therefore, the accuracy of epicentral coordinates and the assigned maximum intensities have to be evaluated carefully.

For the earlier historical events, epicenters near dense settlements are probably located incorrectly due to the absence of felt reports from the true epicentral area. The intensity of an earthquake at a given location depends not only on accurate and complete human observations but also on foundation conditions, structure, design, type, and quality of construction. Construction practices, particularly of chimneys in the earlier centuries, were certainly not those envisaged in the MM scale. Interpretation of historical damage reports, without consideration of construction practices, may result in overestimated intensities. Furthermore, the tendency of early settlers to build structures near rivers, where soil conditions often amplify the ground motion, resulted in a biased sampling of earthquake damage and overestimated intensities. Seismological information for the instrumental period (post-1900) must also be evaluated carefully. Seismic instrumentation began in the early 1900's in the United States and Canada and progressively improved the quality of earthquake data. Epicentral locations based on felt reports were complemented and somewhat controlled by instrumental data. From the 1900's until the 1960's, only a few seismographs operated in the eastern United States. Most of these stations were part of the regional network operated by the Jesuit Seismological Association. In the early decades, numerous factors were potential sources of errors such as the type of instrumental response, lack of accurate time control, awkward configuration, use of graphical methods and limited knowledge of crustal velocities. These produced large uncertainties in the epicentral coordinates which in many cases, amounted to tens of kilometers. Since the 1960's, increased interest in understanding local seismicity has resulted in the installation of dense seismographic networks.

2.5.2.1.2 Earthquake History

A chronological list of all earthquakes known to have occurred within 200 miles of the site is provided in Table 2.5.2-2. The basic information for this seismic data base was taken largely from the earthquake catalog developed by Barstow et al (1981) which lists 4289 events which have occurred in the eastern and central United States and portions of Canada between 1534 and April 1978. Several additional events not noted in Barstow et al (1981) were taken from the data bases prepared by Weston Geophysical (1972), Pomeroy and Faukundiny (1976), and Stover et al (1981).

To account for any additional events which may have occurred more recently then 1978, a search was made of the Regional Seismic Network Bulletins prepared by St. Louis University between January 1978 and March 1983 and the Northeastern United States Seismic Network Bulletins for January 1978 through September 1981 (Chiburis et al). Use was also made of a computerized earthquake catalog developed by the National Oceanic and Atmospheric Administration (NOAA) which lists worldwide events for the period between 1900 and the end of 1979 (SWEC 1980).

Figure 2.5.2-1 shows the location of the earthquakes listed in Table 2.5.2-2; Figures 2.5.2-2 and 2.5.1-5 show the location of the earthquakes in relation to geologic structures and tectonic boundaries, respectively. These figures show that BVPS-2, situated within the Appalachian Plateau Tectonic Province, is located in an almost aseismic area.

The cumulative historical seismicity data (Figure 2.5.2-1) reveal the presence of two areas of concentrated seismic activity. They are Attica, New York and Anna, Ohio. These will be addressed in this section in terms of their location, areal extent, and level of historical seismicity. The tectonic frame work of these sources as inferred from current research will be discussed in Section 2.5.2.3.

Activity in Attica, New York

The Attica area has been the site of a significant amount of historical seismic activity and includes the August 12, 1929 event discussed in Section 2.5.2.1.3. Recent low level seismic activity has been correlated with high-pressure

fluid injection operations in brine fields which are developed in the area (Fletcher and Sykes 1977).

Activity in Anna, Ohio Area

A localized concentration of seismic activity exists in Shelby County, Ohio near the town of Anna. Several moderately damaging earthquakes have occurred in the area. These include the earthquakes of June 18, 1875, Modified Mercalli Intensity (VII), September 19, 1884 (VI), September 30, 1930 (VII), March 2, 1937 (VII), and March 9, 1937 (VII-VIII) (Bradley and Bennett 1965). Understanding of the seismicity and tectonics of the Anna, Ohio region will be improved by the data being gathered by the microearthquake network recently installed in the area by the University of Michigan.

The cumulative historical seismicity data, carefully interpreted, can yield valuable information on the spatial and temporal distribution of larger and more significant earthquakes and the location of zones of concentrated activity. In the northeastern United States, several years of operation of the seismographic network have produced a complete record of accurately located events of magnitude 1.8 through 2.0 and larger in the region. Sbar and Sykes (1977) have noted that the spatial distribution of instrumental seismicity closely tracks the distribution of less accurately located historical events, thus reinforcing confidence that older events are fairly well located and that areas of seismic activity are stationary. Although the midwestern United States is not as densely monitored as the northeastern region, we can assume that a similar analogy exists. The site region can then be assumed to exhibit in reality very low levels of seismicity except in the Attica, New York and Anna, Ohio areas.

The low level of seismicity in the site region is also evident in several other comprehensive studies of earthquake hazard in the eastern United States. A portion of the seismic frequency map prepared by Hadley and Devine (1974) is shown in Figure 2.5.2-10. The contours were drawn to differentiate the areal distribution of earthquake epicenters for earthquakes having epicentral intensities \geq II (MM), on the basis of the total number of earthquakes per 10,000 km² during the time period between 1800 and 1972. Hadley and Devine (1974) point out that the contours are considerably generalized and are drawn only as a guide for estimating regional seismicity. Figure 2.5.2-10 shows that BVPS-2 is situated in an area that has experienced less than four earthquakes per 10,000 km² during the historical period studied.

A study similar to that of Hadley and Devine (1974) was conducted by Barstow et. al. (1981). They developed an earthquake catalogue for the eastern and central United States covering the period between 1800 and 1977. The beginning date, 1800, was chosen since a more uniform demographic coverage of the study area was achieved. An epicenter map was then computer-plotted which showed the location of all earthquakes with a Modified Mercalli Intensity \geq III or with a magnitude \geq 2.0. A uniform, rectilinear coordinate system with grid points 85 km apart was superimposed on the epicenter map and fixed at 96°W longitude and 39°N latitude. A computer program was used to count and plot the number of earthquake epicenters within a radius of 61 km (11,689 km²) from each grid point. A seismic frequency contour map was then hand drawn, a portion of which is shown on Figure 2.5.2-11. It shows that BVPS-2 is located in an area with an earthquake frequency less than four per 11,689 km² during the historic period used for the study.

Although the contours are drawn somewhat differently in Figures 2.5.2-10 and 2.5.2-11, they do illustrate the extremely low level of seismicity in the vicinity of the site and that BVPS-2 is located in one of the least seismic areas in the eastern United States.

2.5.2.1.3 Earthquakes Felt at the Site

In order to determine earthquake hazard to BVPS-2, it is necessary to examine how severely the site has been affected by large earthquakes in the past. This examination is based on available historical records. A discussion of these earthquakes follows:

<u>New Madrid, Missouri Earthquakes, 1811 and 1812</u>

The New Madrid, Missouri earthquakes of December 16, 1811, January 23, 1812, and February 7, 1812 (location - 36.6°N, 89.6°W - Intensity XI-XII), were felt over most of the eastern two-thirds of the United States, an affected area of at least 2,000,000 mi². Topographic changes including uplifts, landslides, and fissures took place over an area of 30,000 to 50,000 mi², principally along the Mississippi and The Beaver Valley Power Station (BVPS) site is located Ohio Rivers. 408 miles from the presently accepted Northern limit of the New Madrid fault zone at Vincennes, Indiana (USNRC 1982). The nearest report of significant damage from these earthquakes came from the Cincinnati, Ohio area about 330 miles from the epicenter and 250 miles from the site. In the Cincinnati area, the tops of chimneys were thrown down and some walls were cracked, indicating a probable Intensity VI (MM), perhaps low VII (MM), when considering the type and quality of construction and the foundation conditions. Fuller (1912) reports that "the earthquake was severe at Pittsburgh, being greater than any previously experienced. Many persons left their houses." Eppley (1965) reports that the earthquake was "strongly felt in Butler County, Pennsylvania." Butler, in the center of Butler County, is about 35 miles east-northeast of the site. Nuttli (1973) has reevaluated ground motion at various locations in the eastern United States and published an isoseismal map of this earthquake which is reproduced on Figure 2.5.2-3. Based on the available data and Nuttli's re-evaluation, the intensity at the site is estimated at low to middle V (MM).

Charleston, S.C. Earthquake August 31, 1886

This earthquake (location - 32.9°N, 80.0°W - Intensity IX-X) was felt over a 2,000,000-mi² area of the eastern United States. In the epicentral area, located a few miles north and west of Charleston, South Carolina, chimneys and fireplaces collapsed, railroad tracks were bent and laterally displaced, and fissures occurred in the ground with ejection of some water, sand, and mud. The area within 100 miles of the epicenter was strongly affected with damage to plaster and chimneys. C.E. Dutton (1889) conducted a thorough investigation of the effects of this earthquake in the epicentral area and throughout the eastern United States. Dutton prepared an isoseismal map which showed a Rossi-Forel Intensity of V (MM) in the vicinity of the site. Reports from Pittsburgh and other towns in the site area indicated a similar intensity except along and near the rivers where somewhat stronger effects were noted. In towns located along rivers, dishes were thrown from shelves and clocks were stopped, indicating an approximate intensity of low V (MM). Bollinger (1977) has reevaluated ground motion at various locations in the eastern United States and published an isoseismal map for this earthquake which is reproduced on Figure 2.5.2-4. The site, located adjacent to the Ohio River, may have experienced Intensity IV-V (MM).

St. Lawrence River Earthquake February 28, 1925

The epicenter was located in the St. Lawrence River Valley (47.6°N, 70.1°W - Intensity IX - Magnitude 7.0) northeast of Quebec City, a distance of 700 miles from the site. The earthquake was felt over an area of approximately 2,000,000 mi², extending south to Virginia and west to the Mississippi River. Important damage was confined to a narrow belt along the St. Lawrence River Valley. Isoseismals prepared by the Dominion Observatory and the United States Coast and Geodetic Survey (Figure 2.5.2-5) show that the estimated intensity at the site was II (MM).

Other earthquakes of Intensity IX and X (MM) have originated in the St. Lawrence River Valley near the epicenter of the February 28, 1925 earthquake. Nearly all of these earthquakes took place during colonial times when reporting of earthquake effects may be accurate in some cases and inaccurate and exaggerated in others. Based on attenuation data and the effects of the February 28, 1925 earthquake, it is estimated that some of these historical earthquakes may have had an intensity of III (MM) in the site area.

Attica, N.Y. Earthquake, August 12, 1929

This earthquake was centered near Attica, New York, (location - 42.9°N, 78.3°W - Intensity VIII - Magnitude 5.8) about 180 miles northeast of the site. It was originally assigned an Intensity VIII (MM) by Coffman and Von Hake (1973), but a re-evaluation by Fox and Spiker (1977) suggested that the epicentral intensity was about VII (MM). The earthquake was felt over a

100,000-mi² area of the northeastern United States and Ontario, Canada, extending from Cleveland, Ohio and Port Huron, Michigan on the west; to Montreal and the Connecticut River Valley on the east. The maximum intensity was confined to the eastern part of the city of Attica and the immediate area to the east, where many chimneys were thrown down and some buildings were structurally damaged. Intensity VI (MM) or greater was noted at Batavia, Dale, East Bethany, Johnsonburg, Warsaw, and Wyoming, New York. All of these localities are within 10 miles of the epicenter.

In the vicinity of the site, intensities ranged from IV (MM) at New Castle (25 miles north) and Butler (35 miles northeast) where windows rattled, to III (MM) at Pittsburgh (25 miles southeast) where the earthquake was only slightly felt. Similar intensities are estimated for the site (U.S. Geological Survey 1974). Figure 2.5.2-6 shows that the site is near the western boundary of the area affected by this earthquake.

Timiskaming, Quebec Earthquake, November 1, 1935

The epicenter was located approximately 425 miles north of the site, near Timiskaming Station, Quebec, (location - 46.8°N, 79.1°W -Intensity VII - Magnitude 6.25) where some damage was reported. The earthquake was felt over a 1,000,000-mi² area of the northeastern United States and eastern Canada. The earthquake was felt as far south as Virginia and Kentucky and as far west as Wisconsin. Damage in the epicentral region was relatively small when compared to the large area affected. Isoseismals prepared by the Dominion Observatory of Canada and the U.S. Coast and Geodetic Survey (1968) (Figure 2.5.2-7) show that the intensity in the vicinity of the site was III (MM).

Anna, Ohio Earthquake, March 8, 1937

This earthquake occurred in western Ohio in the vicinity of Anna (location - 40.6°N, 84.0°W - Intensity VII-VIII) where walls of brick buildings cracked, chimneys were thrown down, and furniture was upset. The earthquake was felt over a 150,000-mi² area including all of Ohio, most of Indiana and adjacent areas of Michigan, Kentucky, West Virginia, and southeastern Ontario, Canada. The site is located at the eastern limit of the perceptible area and may possibly have experienced an intensity of II (MM) (Westland and Heinrich 1940) (Figure 2.5.2-8).

Massena, N.Y. Earthquake, September 4, 1944

The epicenter was located in the vicinity of Massena, New York and Cornwall, Ontario (location - 44.95°N, 74.9°W - Intensity VIII -Magnitude 5.9) about 405 miles northeast of the site. Damage was estimated at two million dollars. The earthquake was felt over an estimated area of 175,000 mi². Isoseismals prepared by the Dominion Observatory of Canada (Figure 2.5.2-9) show that the area of damage (Intensity VI (MM) or greater) was elongated along the St. Lawrence River Valley. The isoseismals show that the intensity in the vicinity of the site was II (MM).

The review shows that the site has experienced vibratory ground motion primarily from large, distant earthquakes, most notably the 1811-1812 earthquakes near New Madrid, Missouri and the 1886 Charleston earthquake. The Attica, New York and Anna, Ohio earthquakes were barely perceptible at the site.

2.5.2.2 Geologic Structures and Tectonic Activity

Portions of four tectonic provinces are located within a 200-mile radius of the BVPS-2 site (Figure 2.5.1-7). The provinces have been defined on the basis of the following criteria:

- 1. Style and degree of deformation,
- 2. Age of the relationships with the basement rock, and
- 3. Age of the orogenic or tectonic activity found within the province.

The four provinces, from northwest to southeast are:

- 1. Central Stable Region,
- 2. Appalachian Plateau Province,
- 3. Valley and Ridge Province, and
- 4. Piedmont-Blue Ridge Province.

They are defined in accordance with 10 CFR 100, Appendix A, which defines a Tectonic Province as "A region of the North American continent characterized by a relative consistency of the geologic structural features contained therein." The conclusions are in general agreement with those of Rodgers (1970), Hadley and Devine (1974), and King (1969). The names for the tectonic provinces are taken from the physiographic provinces with which they generally correspond.

2.5.2.2.1 Appalachian Plateau Province

The BVPS-2 site is located on the Ohio River within the Appalachian Plateau Tectonic Province. Geologically, the province is a broad, gentle synclinal basin whose youngest rocks are the Dunkard Group of probable Early Permian age (Eardley 1962). The basin forms the western part of the former Appalachian geosyncline, with sediments thickening generally southeastward from the Cincinnati-Findlay Arch. Precambrian basement dips beneath the province in the same direction. Deformation in the province occurred primarily during the Permian Allegheny orogeny. The same type of structure exist in both the Appalachian Plateau and Valley and Ridge Provinces, the principal difference being a gradual decrease in intensity of deformation from east to west. "Thin-skinned" tectonics was the dominant mode of deformation in the Appalachian Plateau with movement occurring mainly along sole thrusts in Silurian salt beds and Cambro-Ordovician shales (Rodgers 1964, 1970; Gwinn 1964, 1970). Deep drilling has not as yet delineated the regional extent of thrusting in the Appalachian Plateau. Mild epeirogenic uplift has been the only tectonic event to affect the province since Late Paleozoic time.

Orogenic stresses were persistent and extensive during Permian time and affected all the rocks of the former Appalachian geosyncline. The Valley and Ridge region was the most intensely deformed, with effects diminishing north and west of the Allegheny Front. The Appalachian Plateau region shows only mild deformation and only within the higher stratigraphic units, generally above Silurian evaporites. These effects are recognized in east central Ohio as the Parkersburg-Lorain Syncline and the Cambridge Arch (Figure 2.5.1-7). The syncline can be traced from Parkersburg, West Virginia, north-northwest to Lorain County on Lake Erie. It is a structural trough parallel to the Cambridge Arch to the east and is nearly 5 miles in width with a structural relief of 300 feet (Lamborn 1951). The folds are known to affect the Devonian shale sequence above the Delaware limestone but they have not been investigated at depth (Janssens 1977). These folds are believed to have been formed because of their stratigraphic proximity directly above the low shear resistance zone of Salina salt (Janssens 1977). The thick salt beds are believed to have reduced the resistance to lateral compressive stresses during Permian time, facilitating "thin-skinned" movement of post-Salina rocks (decollement) over a very large area (Gwinn, 1964, 1970; Rodgers 1964, 1970).

Geiser and Engelder (1983) summarize the results of their work on evidence for Allegheny orogenic deformations in New York and eastern Pennsylvania. They believe that the "layer parallel shortening fabrics," which are identified in the rocks of the area "reflect the presence of deeper hidden or blind detachments." The subsurface thrust zones can then be mapped on the basis of the presence of the layer shortening fabrics. Maps showing the limit of the layer parallel shortening fabrics in central and western New York closely coincide with the limit of Silurian evaporite deposits in the Salina Basin.

Unfortunately, similar fabrics were not developed in the Carboniferous rocks on the surface in western Pennsylvania and eastern Ohio. Ver Steeg (1942), however, has identified a form of cleavage in the coal fields of eastern Ohio which controls mining techniques and direction. A set of perpendicular joints, or coal "cleats", is seen to be arranged in a broad arc from north-central Ohio to southern Ohio. The arc is convex to the west and corresponds to the curve of the Appalachian fold belt in eastern Pennsylvania. Ver Steeg (1942) believes that the joints were formed at the same time as the folds.

In order to include all of the rocks which might have been affected by the Allegheny orogenic events, the western boundary of the Appalachian Plateau province is drawn along the mapped limit of Silurian salt (Clifford 1973; SWEC 1978) except where other Allegheny evidence is known to exist further to the west, such as the Parkersburg - Lorain syncline. The present extent of the salt beneath Lake Erie is unknown but most authors indicate continuous salt across the Findlay Arch into the Michigan Basin. Since Allegheny deformation is not known to exist in the Michigan Basin, the boundary of the Appalachian Plateau Province is inferred where it is drawn beneath Lake Erie. South of Ohio, the limit of salt swings eastward, oulining the southeast edge of the Silurian Salina Basin. The Appalachian Plateau Province boundary, however swings westward to include unnamed, low amplitude anticlines and synclines east of Huntington, West Virginia, which parallel similar Allegheny deformational features further east (Rodgers 1970; Cardwell 1977).

The Appalachian Plateau Province is characterized in general by infrequent earthquakes of low intensity. Figures 2.5.2-10 and 2.5.2-11 show that a large part of the Province in the vicinity of the site has experienced less than four earthquakes per 10,000 to 11,680 km². Figure 2.5.2-1 shows that during the entire period of historical reports, only about 18 earthquakes, with epicentral intensities between II and VI (MM), have occurred in the Appalachian Plateau Province, indicating that it is in one of the least seismic areas in the eastern United States.

Barstow, et. al. (1981), using the results of the earthquake frequency study discussed in Section 2.5.2.1.2, developed a contour map of the cumulative strain released by earthquakes that occurred in the eastern United States between 1800 and 1977. A portion of the map is shown on Figure 2.5.2-12. Also shown is a table indicating the amount of strain released by a single event of a given intensity. By comparison with the contours of cumulative strain during the entire historical period, most of the Appalachian Plateau Province has experienced strain release corresponding to an earthquake of Intensity V (MM) or less. Only in the vicinity of Cleveland, Ohio; northwest of the site, is the cumulative strain equivalent to an earthquake of Intensity VII-VIII (MM).

The largest seismic events to occur in the Appalachian Plateau Province, not associated with tectonic structures (Figure 2.5.2-2), are two Intensity VI (MM) events. One is the April 9, 1900 shallow event near Cleveland, Ohio, and the other is the July 13, 1935 event in Blair County, Pennsylvania.

2.5.2.2.2 Central Stable Region

The Central Stable Region bounds the Appalachian Plateau on the north and west and begins about 85 miles from the site. The northern boundary of the Region is the Canadian Shield. Westward, it extends to the east flank of the Rocky Mountains and includes a wide variety of morphology and structure. The Coastal Plain overlaps the region to the south. The Central Stable Region is made up of a foundation of Precambrian crystalline rock with a veneer of sedimentary cover, which varies widely in thickness. It represents the craton or central stable area of the North American crustal plate. Deformation within the region has been restricted to the development of several broad basins, arches, and similar features, mostly during the Paleozoic. Several of the basins have in excess of 10,000 feet of strata in them, while some of the arches expose Precambrian crystallines. Movements since the Paleozoic have been mostly a series of epeirogenic uplifts and downwarps, followed by long episodes of erosion. The largest earthquakes to occur in this province are the March 9, 1937 event near Anna, Ohio, with Intensity VII-VIII (MM) (Coffman and Von Hake 1973), and the Intensity VIII (MM) event of August 12, 1929 near Attica, New York.

2.5.2.2.3 Valley and Ridge Provinces

The Northern and Southern Valley and Ridge Provinces contain the major portions of the sediments which were deposited in the Appalachian geosyncline, of which they comprise the southeastern part. They are bounded on the north and west by the Appalachian Plateau Province, on the south and east by the Piedmont-Blue Ridge Province, and on the northeast end by the New England Province. The Valley and Ridge Provinces are characterized by unmetamorphosed Paleozoic sediments that were tightly folded and thrust faulted during the Allegheny orogeny, approximately 250 million years ago. Intense pressure from the southeast folded the sediments into large synclines and anticlines, some overturned to the northwest. Thrust faults were commonly developed with the horizontal attitude of the sediments barely disturbed. The division of the Valley and Ridge Province into northern and southern sections is based on the difference in structural styles. The northern section is typified by folding, whereas the southern section is characterized by thrust faulting. The southern section has historically experienced a higher level of seismic activity south of an east-west line through central Virginia (Hadley and Devine 1974). This line is somewhat indistinct, but would fall outside the 200-mile site region.

The largest earthquake to occur in the northern province is the February 21, 1954 event near Wilkes Barre, Pennsylvania, approximately 235 miles from the site. This event was estimated to be Intensity VIII (MM) by Sbar and Sykes (1977), and Intensity VIII (MM) by Barstow et. al (1981) and Stover et. al (1981). Damage was restricted to a five-block area, suggesting that the earthquake resulted from the collapse of an abandoned mine and occurred at very shallow depths.

The Northern Valley and Ridge Province lies approximately 105 miles east of the site at its closest approach.

2.5.2.2.4 Piedmont-Blue Ridge Province

The Piedmont-Blue Ridge Province is characterized by metamorphosed Precambrian and early Paleozoic eugeosynclinal rocks which were deformed during the Taconic and Allegheny orogenies and may have been recrystallized during the Acadian orogeny. It includes the Blue Ridge Anticlinorium, a relatively narrow belt of folded and faulted Upper Precambrian crystalline schists and gneisses, which were thrust westward several kilometers over the rocks of the Valley and Ridge. Terrains of intrusive igneous rocks are notable in the Piedmont of Virginia and North Carolina. The eastern part of the province was also effected by the Allegheny orogeny. Long narrow graben structures filled with continental deposits of Late Triassic age are superimposed intermittently on the crystallines from Pennsylvania to South The effects that each orogeny had on the rocks in the Carolina. Piedmont are not yet fully understood, due to the lack of outcrop, lack of fossils, and the strong recrystallization. The

Piedmont-Blue Ridge Province is bounded on the northwest by the Northern and Southern Valley and Ridge Provinces. The southern and eastern boundary of the province is drawn at the present westward limit of Cretaceous Coastal Plain deposits. Piedmont geology certainly continues beneath the Coastal Plain for some distance, but the line where Coastal Plain becomes dominant is presently not well established. The northern boundary of the Piedmont with the New England Province is hidden beneath the Triassic Newark-Gettysburg Basin.

The largest earthquake to occur in this province is the January 1, 1913, event in Union County, South Carolina. Different sources have assigned Intensity VI-VII (MM) (Coffman and Von Hake 1973) or VII-VIII (NM) (Bollinger 1973, 1975). The most recent reference assigns it Intensity VII (MM) (Barstow et. al., 1981).

2.5.2.3 Correlation of Earthquake Activity With Geologic Structure Or Tectonic Provinces

The relationship between earthquake locations and geologic structures is important in assessing earthquake hazard to a particular site. Figure 2.5.2-2 reveals no direct spatial relationship between earthquake epicenters and known geologic or tectonic structures within 200 miles of the site, except in the area of the Clarendon-Linden fault zone in western New York. No evidence of tectonically induced faulting has been reported or inferred to have displaced Cenozoic age deposits in the Appalachian Plateau Province, and no rupture of the ground surface or man-made structures resulting from tectonic faulting has been recorded anywhere in the eastern United States (York and Oliver 1976).

2.5.2.3.1 Correlation with Geologic Structures

Clarendon-Linden Fault Zone

The Clarendon-Linden fault system has been traced from near Lake Ontario in the Central Stable Region to the northern part of Allegheny County in the Appalachian Plateau Province. A significant amount of seismic activity has taken place along the zone (Sbar and Sykes 1977; Pomeroy et al, In Press). Van Tyne (1975, 1976) reports that the Clarendon-Linden fault is not a single fault but a zone consisting of several parallel basement faults which become surface flexures. Most of the movement is believed to be confined to formations below the Silurian deposits. Movement is believed to have been initially downthrown to the east, reversing later to become now downthrown 100 feet on the west. Recent low-level seismic activity has been correlated with high-pressure fluid injection operations in brine fields which are developed in the area (Fletcher and Sykes 1977), and may be relieving stress along the fault system. These events are small but may be felt locally and number up to 80 per day. This activity and the occurrence of several small earthquakes near Attica indicate that the Clarendon-Linden structure is active and therefore is considered as a localized source. The Clarendon-Linden fault zone lies approximately 160 miles northeast of the BVPS-2 site at its closest approach.

Anna Fault System

2.5.2.3.2 Correlation with Tectonic Provinces

In accordance with 10 CFR 100, Appendix A, earthquakes in the site region which are not correlated to the Clarendon-Linden fault system are presumed to be associated with the tectonic provinces in which they occur. The seismicity of all tectonic provinces within the site region is discussed in Section 2.5.2.2.

2.5.2.4 Maximum Earthquake Potential

Maximum earthquake potential for the site is evaluated by utilizing maximum earthquakes associated with all nearby tectonic provinces and geologic structure. This analysis is made for two different sets of conditions. First, actual site intensities resulting from the larger historical earthquakes are determined. Second, the maximum potential site intensities resulting from hypothetical events are specified as arising from the largest known earthquakes in each adjoining tectonic province, postulated to occur at the point where the province or structure most closely approaches the site.

2.5.2.4.1 Maximum Historical Site Intensity

As discussed earlier, in the site region there are sources of earthquake activity at Attica, New York and Anna, Ohio. The largest earthquakes in each of these sources are discussed in Section 2.5.2. These earthquakes were barely perceptible at the site. Other than these two sources, Figure 2.5.2-2 shows that the largest earthquake in the site region took place on November 6, 1926 in southeastern Ohio, approximately 130 miles southwest of the site. The epicentral intensity of this earthquake was VI-VII (MM). Chimneys were toppled at Keno and Pomeroy in Meigs County, Ohio, and a stove was overturned in Pomeroy (Von Hake 1976). As indicated in Table 2.5.2-2, this event had a small felt area of only 300 square miles and was probably not felt at the site. Three earthquakes have been reported within 50 miles of the site (Figure 2.5.2-1). One was reported at Sharon, Pennsylvania, approximately 40 miles north of the site, on August 17, 1873. Limited details have resulted in an estimated Intensity III-IV (MM) for this event. Using the attenuation relationship of Gupta and Nuttli (1976) given in Section 2.5.2.4.2, this event would have attenuated to about an Intensity II at the site; it is not likely that it was felt. On September 26, 1885, an Intensity III (MM) earthquake occurred near Pittsburgh, about 30 miles southeast of the site. It was probably not felt. Another was the Intensity V (MM)

event of October 29, 1927, approximately 45 miles northwest of the site. This event would have attenuated to approximately Intensity III-IV at the site and may have been felt at the site.

This examination of ground motion effects of earthquakes within 200 miles of BVPS-2 indicates that the site has not experienced ground motion exceeding Intensity III-IV (MM). It is likely that in the last 180 years, only the October 29, 1927 earthquake may have been felt at the site. This is clearly a reflection of the low intensity of earthquakes which are reported to have occurred within 200 miles of BVPS-2.

The BVPS-2 site has, however, experienced more severe ground motion from larger, but more distant earthquakes. Examination of isoseismal maps of larger earthquakes felt in the eastern United States shows that the New Madrid events of 1811-1812 probably caused a maximum ground motion at the site corresponding to Intensity low to middle V (MM). Therefore, the maximum historical intensity at the site was probably Intensity low to middle V (MM).

2.5.2.4.2 Maximum Earthquake Potential From Tectonic Province Approach

The BVPS-2 site is located near the center of the Appalachian Plateau Tectonic Province. As discussed in Section 2.5.2.2.1, two earthquakes with epicentral Intensity VI (MM) have occurred in the province. No earthquake with epicentral intensity greater than VI (MM) has been reported to have occurred in the province. None of these earthquakes appear to be associated with a particular known geologic or tectonic structure, so that it is assumed that a similar random event of this intensity could occur anywhere within the province. Consequently, if such an earthquake occurred near the site, it would generate ground motion corresponding to Intensity VI (MM). The magnitude of an earthquake can be estimated on the basis of the Nuttli and Herrmann (1978) relationship:

 $I = 2m_b - 3.5$

where: I = epicentral intensity

 $m_b = body wave magnitude$

Using this relationship, an earthquake of Intensity VI would have a magnitude of 4.75.

The maximum earthquake potential at BVPS-2 from earthquakes in other tectonic provinces is computed by attenuating the largest known earthquake in each province from the point of nearest approach to the site in that province. If the size of the earthquake is specified in terms of epicentral intensity, Io (MM), then the expected intensity at the site can be computed by using the Gupta and Nuttli (1976) attenuation relationship.

Rev. 0

 $I(R) = I_0 + 3.7 - 0.0011R - 2.7 \log_{10}R$

where: I(R) = Intensity at site

 I_{\circ} = Epicentral intensity

R = Epicentral distance (kilometers), for $R \ge 20$ kilometers

If the size of the earthquake is specified in terms of bodywave magnitude, m_b , then ground motion at the site can be computed in terms of peak horizontal acceleration using the Nuttli and Herman (1981) relationship:

 $\log a = 0.57 + 0.50 m_b - 0.83 \log (R^2 + h^2)^{1/2} - 0.0016R$

where: a = peak horizontal acceleration, cm/sec²

 $m_b = body wave magnitude$

R = epicentral distance kilometers

h = focal depth, kilometers.

The largest event to occur in the Central Stable Region was the 1937 Anna, Ohio earthquake which had an epicentral intensity of VII-VIII (MM) and a magnitude, m_b , of 5.3 (Table 2.5.2-2). The minimum distance from the site to the boundary of the Central Stable Region is about 85 miles (136 km). A repeat of the 1937 Anna earthquake at this minimum distance from the site would result in an Intensity V-VI (MM) at the site if the Gupta and Nuttli (1976) attenuation relationship is used. Assuming zero focal depth, an earthquake with a magnitude of 5.3, at a distance of 85 miles, would cause a peak horizontal acceleration of 0.017g at the site according to the Nuttli and Herman (1981) relationship.

The largest earthquake to occur in the Northern Valley and Ridge Province was the February 21, 1954, Wilkes Barre, Pennsylvania event of Intensity VIII (MM) (Coffman and Von Hake 1973). The Northern Valley and Ridge Province lies approximately 105 miles east of the site at its closest approach. This earthquake was felt only within a five block area, suggesting that the earthquake resulted from the collapse of an abandoned mine. Earthquakes with epicentral Intensity VII (MM) occurring in the Northern Valley and Ridge Province at a distance of 105 miles (168 km) will cause ground motions at the site corresponding to Intensity IV-V (MM).

The Piedmont Province is at a minimum distance of 165 miles (264 km) east of the site. The largest earthquake in this province was the January 1, 1913 event with Intensity VII (MM) in Union County, South Carolina. Attenuation of this event to the site results in an Intensity IV (MM) at the site. If it were assumed that the 1929 Attica, New York event, which had an Intensity VII (MM), reoccurred on the Clarendon-Linden fault zone at its closest approach to the site, it would produce ground motions corresponding to Intensity IV (MM) at the site.

Hence, the maximum earthquake for the BVPS-2 site is equivalent to an Intensity VI event occurring in the Appalachian Plateau Province near the site.

2.5.2.5 Seismic Wave Transmission Characteristics of the Site

The amplification characteristics of the soil at the BVPS-2 site were originally discussed by Whitman (1968), and his results led to the development of the BVPS-1 response spectra and, as later modified, to the BVPS-2 response spectra. The BVPS-2 response spectra for the SSE is shown on Figure 3.7B-1.

2.5.2.6 Safe Shutdown Earthquake

The maximum earthquake expected at the site is described in Section 2.5.2.4 and results in ground motion corresponding to Intensity VI (MM). Trifunac and Brady (1975) developed the following correlation between intensity and acceleration:

 $\log a = 0.30I_{mm} + 0.014$

where:

a = Peak horizontal acceleration (cm/sec²)
I_{mm} = Modified Mercalli intensity

Using this correlation, an Intensity VI (MM) earthquake would produce a horizontal acceleration of 0.07g.

Murphy and O'Brien (1977), using a larger data base, determined the following relationship between acceleration and intensity:

 $\log a = 0.25I_{mm} + 0.25$

Using this relationship an Intensity VI (MM) produces an acceleration of 0.06g.

On the basis of these empirical relationships, the peak horizontal ground surface acceleration corresponding to a random Intensity VI (MM) earthquake occurring near the site would be 0.07 g. BVPS-2 has been designed for an SSE corresponding to a peak horizontal ground surface acceleration of 0.125 g, slightly greater than the midpoint acceleration between Intensity VI-VII (MM).

2.5.2.7 Operating Basis Earthquake

An OBE equivalent to one-half the SSE is used. The value of the OBE for BVPS-2 is 0.06.g.

TABLE 2.5.2-1

MODIFIED MERCALLI INTENSITY SCALE OF 1931

- I Not felt except by a very few under especially favorable circumstances.
- II Felt only by a few persons at rest, especially on upper floors of buildings. Delicately suspended objects may swing.
- III Felt quite noticeably indoors, especially on upper floors of buildings, but many people do not recognize it as an earth-quake. Standing motor cars may rock slightly. Vibration like passing of truck. Duration estimated.
- IV During the day felt indoors by many, outdoors by few. At night some awakened. Dishes, windows, doors disturbed; walls make cracking sound. Sensation like heavy truck striking building Standing motor cars rocked noticeably.
- V Felt by nearly everyone, many awakened. Some dishes, windows, etc., broken; a few instances of cracked plaster; unstable objects overturned. Disturbances of trees, poles, and other tall objects sometimes noticed. Pendulum clocks may stop.
- VI Felt by all, many frightened and run outdoors. Some heavy furniture moved; a few instances of fallen plaster or damaged chimneys. Damage slight.
- VII Everyone runs outdoors. Damage negligible in buildings of good design and construction; slight to moderate in well built ordinary structures; considerable in poorly built or badly designed structures; some chimneys broken. Noticed by persons driving motor cars.
- VIII Damage slight in specially designed structures; considerable in ordinary substantial buildings with partial collapse; great in poorly built structures. Panel walls thrown out of frame structures. Fall of chimneys, factory stacks, columns, monuments, walls. Heavy furniture overturned. Sand and mud ejected in small amounts. Changes in well water. Persons driving motor cars disturbed.
 - IX Damage considerable in specially designed structures; well designed frame structures thrown out of plumb; great in substantial buildings, with partial collapse. Buildings shifted off foundations. Ground cracked conspicuously. Underground pipes broken.

- X Some well built wooden structures destroyed; most masonry and frame structures destroyed with foundations; ground badly cracked. Rails bent. Landslides considerable from river banks and steep slopes. Shifted sand and mud. Water splashed (slopped) over banks.
- XI Few, if any, (masonry) structures remain standing. Bridges destroyed. Broad fissures in ground. Underground pipelines completely out of service. Earth slumps and land slips in soft ground. Rails bent greatly.
- XII Damage total. Practically all works of construction are damaged greatly or destroyed. Waves seen on ground surface. Lines of sight and level are distorted. Objects are thrown upward into the air.

2.5.3 Surface Faulting

No surface faulting exists at or near the site. There are no known active or capable faults within 150 miles of the site. There has been no mining, hydrocarbon extraction, or other activity beneath the site which could cause ground rupture at the site.

2.5.3.1 Geologic Conditions of the Site

The geologic conditions in the region and at the site are described in Sections 2.5.1.1 and 2.5.1.2, respectively.

2.5.3.2 Evidence of Fault Offset

There is no evidence of fault offset at the ground surface within 5 miles of the site or in any subsurface boring taken at the site.

2.5.3.3 Earthquakes Associated with Capable Faults

There is no seismic or geologic evidence of capable faulting within 5 miles of the site.

2.5.3.4 Investigation of Capable Faults

There are no known capable faults within 5 miles of the site requiring investigation.

2.5.3.5 Correlation of Epicenters with Capable Faults

There is no seismic evidence to indicate capable faulting within 5 miles of the site to correlate with epicenters.

2.5.3.6 Description of Capable Faults

There are no known capable faults within 5 miles of the site.

2.5.3.7 Zone Requiring Detailed Faulting Investigation

No zone requiring a detailed faulting investigation has been identified within 5 miles of the site.

2.5.3.8 Results of Faulting Investigation

A fault zone requiring a detailed investigation has not been identified in the site area.

2.5.4 Stability of Subsurface Materials and Foundations

This section presents the results of investigations and studies conducted to evaluate the stability of subsurface soils at the site and the foundations which they support. Engineering properties of soils were determined based on detailed field and laboratory investigations described herein. The evaluation of subsurface conditions and soil properties and the results of stability analyses are presented under the following specific headings.

2.5.4.1 Geologic Features

The major structures of Beaver Valley Power Station (BVPS) are located on the highest of three terraces along the south side of the Ohio River. They are composed predominantly of alluvial deposits derived from the cyclic aggradation and degradation of local materials and glacial outwash by the ancestral Ohio River drainage system during the Pleistocene period. Figure 2.5.4-1 is a typical north-south cross section through the site showing the terraces.

The Upper Pleistocene terrace slopes gently toward the Ohio River from about el 760 feet to 735 feet. The soils of this terrace consist predominantly of interbedded sands, gravels, and silty sands and gravels.

A zone of loose granular material from approximately el 640 feet to 660 feet was discovered in the plant area during the excavation for the Beaver Valley Power Station - Unit 2 (BVPS-2) containment foundation. The loose zone was present under approximately the northern portion of the containment and extended east and west beneath most of the Category I structures. The loose zone was successfully densified using the pressure injected footing technique. The extent of the densified area is shown on Figure 2.5.4-15. It has been determined that the densified in situ soil will be stable under all anticipated loading and environmental conditions. The densification program and its evaluation are fully described in the Duquesne Light Company (DLC 1976) Report on Soil Densification Program.

The near surface soils of the intermediate terrace (original ground surface el 685 feet to 700 feet) and the present floodplain (original ground surface el 675 feet) consist of medium stiff to soft clays and silts. These recent river silts and clays extend to approximately el 655 feet where they are underlain by sands and gravels to bedrock. The intermediate terrace is overlain in part by fill placed during the construction of Shippingport Atomic Power Station (SAPS) and Beaver Valley Power Station - Unit 1 (BVPS-1).

The bedrock in the area of the site is Pennsylvanian in age and belongs to the Allegheny group which consists of interbedded sandstones, shales, coal seams, and occasional limestones. The rock underlying the plant site is a dark gray carbonaceous shale which dips gently southeastward about 15 to 20 ft/mi. The rock is slightly weathered for the first few feet with weathering effects decreasing rapidly with depth. A top of rock contour map is provided on Figure 2.5.4-50. The computer program SURFACE II (Sampson 1975) was used as an aid in developing the map. Input to SURFACE II was the top of rock elevations from the irregularly spaced exploratory borings. SURFACE II establishes a regularly spaced, orthogonal grid and interpolates top of rock elevations at these grid points utilizing a data fitting algorithm specified by the user. The computer develops the contour map from the interpolated grid elevations.

A check was made to verify that the computer-drawn map was an accurate representation of the top of rock elevations from the boring data. It was necessary to manually re-contour the computer-generated 800 to 875-feet contours because the computer-drawn contours did not adequately represent the top of rock elevations in an area of known rock surface geometry. Only the exploratory borings were used to evaluate the top of rock elevation; the verification borings performed for several densification programs in the main plant area provided redundant data and were not used.

As discussed in Section 2.5.1.2, there are no areas of actual or potential subsurface subsidence at the plant site.

The ground-water conditions at the site are discussed in detail in Sections 2.4.13 and 2.5.4.6.

Unrelieved residual stresses in rock were not considered to have an influence on the design and operation of the plant due to the thickness of the founding overburden.

2.5.4.2 Properties of Subsurface Materials

The BVPS is founded on the highest of three alluvial terraces. These terraces are described in more detail in Section 2.5.4.1.

Borings drilled within the main plant area indicate a subsurface profile consisting of about 115 feet of medium dense to dense granular soils underlain by shale bedrock with a top surface at about el 620 feet. A zone of loose granular material between about el 640 feet and 660 feet was discovered in the BVPS-2 plant area and was subsequently densified using the pressure injected footing technique (DLC 1976).

A lens of very stiff, silty clay was uncovered along the northern edge of the reactor containment excavation at about el 679 feet, the presence of which was not noted during the original subsurface investigation. The clay lens was removed from within the containment area and replaced with compacted structural fill. It extends eastward and is present beneath the northern portions of the safeguards area and the refueling water storage tank (RWST). Its areal extent is discussed further in Section 2.5.4.7.1.

Subsurface profiles are presented on Figures 2.5.4-2, 2.5.4-3, 2.5.4-4, 2.5.4-5, 2.5.4-6, 2.5.4-7, 2.5.4-8 and 2.5.4-9, Figures 2.5.4-51, 2.5.4-52, 2.5.4-53, 2.5.4-54 and 2.5.4-55, and Figure 2.5.4-60, the locations of which are shown on Figures 2.5.4-10 and 2.5.4-13. The profiles are based upon the data from the boring logs which are referenced in Table 2.5.4-1.

An extensive laboratory testing effort was undertaken to establish the engineering and index properties of the intermediate and lower terrace silts and clays. The results are presented and summarized in Appendix 2.5D. Included are grain size analyses performed on samples of the in situ sands and gravels and the results of in place density

tests conducted during the documentation of the soil conditions at the reactor containment founding elevation (Section 2.5.4.5).

Attempts to obtain undisturbed samples of the in situ sands and gravels were unsuccessful. Consequently, the engineering properties of the sands and gravels developed for design purposes were based upon accepted conservative, empirical correlations of engineering properties to subsurface conditions determined by geophysical surveys, test borings, and field testing.

A plot of relative density versus blow count for the in situ sands and gravels is shown on Figure 2.5.4-11 for borings outside of the area densified by the pressure-injected footing technique. (Borings within the densified area are discussed in DLC'S 1976 Report on Soil Densification Program.) The relative density of most of the samples fall within the range of 50-80 percent, classifying the in situ sands and gravels as medium dense to dense (Terzaghi and Peck 1967). Based on a correlation with relative density (U.S. Department of the Navy 1971), the angle of internal friction of the in situ sands and gravels may range between about 33 and 40 degrees; an angle of 30 degrees was conservatively chosen for design purposes.

The dry unit weight of the in situ sands and gravels was taken as 117 pcf, based on an average of in place density tests performed during excavation for plant structures.

The specific gravity was taken as 2.65 and was based upon laboratory determination (Appendix 2.5D).

The void ratio was computed to be 0.4 from the equation:

$$e = \frac{G_{\gamma_w} - \gamma_d}{\gamma_d} \tag{2.5.4-1}$$

where:

e = void ratio G = specific gravity γ_d = dry unit weight (pcf) γ_w = unit weight of water (62.4 pcf)

The saturated unit weight below the ground-water table was taken as 136 pcf from the equation:

$$\gamma_T = \frac{G + Se}{1+e} \bullet \gamma_w \tag{2.5.4-2}$$

where:

 γ_T = total unit weight S = degree of saturation Above the ground-water table, the total unit weight was taken as 125 pcf assuming an average water content of 7 percent.

The low strain shear moduli of the in situ sand and gravel, used in the estimation of building settlements, were determined using Equation 2.5.4-3.

$$G_{\max} = \frac{1,230 \ (2.97 \ -e)^2 \ (\overline{\sigma}_o) \ 0.5}{(1+e)}$$
(2.5.4-3)

where:

$$G_{max}$$
 = shear modulus (psi)
 σ_{o} = effective octahedral stress (psi)

Shear moduli determined from in situ seismic velocity measurements compared quite well with those computed using this relationship as shown on Figure 2.5.4-12. Section 2.5.4.10.2 provides an in-depth discussion of the determination of elastic properties of the in situ sands and gravels used in the estimation of building settlement.

The following tests, the results of which are presented in Appendix 2.5D, were performed on undisturbed block samples of the stiff silty clay lens which was encountered below the reactor containment excavation:

- 1. Atterberg limits and natural water contents,
- 2. Constant rate of strain (CRSC) and incrementally loaded (IC) consolidation tests,
- 3. Unconsolidated undrained (UU) triaxial compression tests, and
- 4. Consolidated undrained (CIU) triaxial compression tests.

Classification tests show that the silty clay has a liquid limit of 50, a plastic limit of 23, and a natural water content of 23 percent. The natural water content being equal to the plastic limit is an indication that the clay has been precompressed. The presence of small fissures with discoloration along their surfaces suggests that the precompression may have been due to dessication.

Consolidation tests show that the clay has been preloaded to a maximum past pressure ranging between 9.5 and 18 ksf. The estimated overburden pressure prior to the excavation for the containment foundation was approximately 7.5 ksf, indicating an overconsolidation ratio (OCR) of 1.3 to 2.4. The recompression ratio (RR) is approximately 0.02 and the compression ratio (CR) is approximately 0.12. The coefficient of consolidation (c_v) varies from approximately 5X10 to 1.8x10 cm/sec in the overconsolidated region and is approximately 2.5x10 cm/sec in the normally consolidated region. From the incremental consolidation test, the

average coefficient of secondary consolidation (c $_{\alpha}$) ranges between 5X10⁻⁴ and 2X10⁻³ in/in/log cycle of time.

The effective friction angle (ϕ) as determined from the *CIU* triaxial test was 25.7 degrees, assuming that the effective cohesion intercept was zero. The undrained shear strength measured in the UU tests is approximately 4.3 ksf.

In situ shear wave velocity measurements are discussed in Section 2.5.4.4. Field measurements of permeability are discussed in Section 2.5.4.6. Dynamic engineering properties of the soils underlying the site are discussed in Section 2.5.4.7.3.

2.5.4.3 Exploration

Site specific exploration activities at the BVPS site, for the purpose of evaluating subsurface conditions, consisted of drilling exploratory borings, installing piezometers, and performing geophysical surveys.

2.5.4.3.1 Exploratory Borings

A total of 298 exploratory borings were performed under the supervision of Stone & Webster Engineering Corporation (SWEC) at the BVPS site for the construction of SAPS, BVPS-1 and BVPS-2. The locations of the exploratory borings are shown on Figures 2.5.4-10 and 2.5.4-13. A list of borings, along with the dates that they were drilled and the locations of the boring logs for reference purposes, is provided in Table 2.5.4-1. Boring logs which have not been published in previous documents are included in Appendix 2.5B.

The primary functions of the exploratory borings were to establish the nature of the overburden soils and rock, to study the geology of the site area, and to obtain representative samples to develop engineering properties for design purposes.

A series of borings, PL-1 through PL-66, was performed by others in conjunction with the construction of a sludge pipeline system for the Bruce Mansfield Plant. Borings TH-1 through TH-13 were performed by others for the BVPS emergency response facility. The borings are shown on Figure 2.5.4-13 and are referenced in Table 2.5.4-1. Site subsurface profiles within the BVPS-2 area, based on data derived from the borings, are shown on Figures 2.5.4-2, 2.5.4-3, 2.5.4-4, 2.5.4-5, 2.5.4-6, 2.5.4-7, 2.5.4-8 and 2.5.4-9, Figures 2.5.4-51, 2.5.4-52, 2.5.4-53, 2.5.4-54 and 2.5.4-55; and on Figure 2.5.4-60.

Six piezometers were installed, at the locations shown on Figure 2.5.4-14, for the purpose of studying ground-water conditions at the site. Discussion of the data obtained is contained in Section 2.5.4.6.

2.5.4.3.2 Verification Borings

A total of 154 verification borings were performed to evaluate the results of the in situ densification program in the BVPS-2 area described in the Report on Soil Densification Program, (DLC 1976). A boring location plan is given on Figure 2.5.4-15, which also outlines the area densified. Each boring was evaluated on a sample-by-sample basis to verify that the desired degree of densification had been achieved. The logs of the verification borings can be found in Appendix I of the Report on Soil Densification Program, (DLC 1976).

Borings 501 through 562 were performed to verify the effectiveness of a vibroflotation densification program of the soil underlying the river water and service water system pipelines during the construction of BVPS-1. The limits of densification are shown on Figure 2.5.4-16, and Figure 2.5.4-54 presents the subsurface conditions beneath the 30inch service water system lines from the valve pit to the intake structure. The purpose of the program was to remove the potential for liquefaction of the underlying sands and gravels. This work is described in the Response to USNRC Questions 2.26 and 2.27 of the BVPS-2 PSAR, (DLC 1972e).

Borings 537T through 577T (Figure 2.5.4-13) were performed to verify the effectiveness of the Terra Probe densification program around the main intake structure. It was postulated that the nondensified soils, should they liquefy, could block the intake structure. The Terra Probe densification program was undertaken to prevent such an occurrence. This work is described in Section 2.5.4.12. The boring logs are included in Appendix 2.5B.

2.5.4.4 Geophysical Surveys

Geophysical surveys were conducted at the site by Weston Geophysical Engineers, Inc., to measure the in situ compression and shear wave velocities of the soil and rock. Appendix 2G of the BVPS-2 PSAR, (DLC 1972f) presents the results of measurements taken in 1968 in the area of the reactor containment for BVPS-1. Subsequent to the soil densification program at BVPS-2, additional crosshole seismic velocity measurements were made in the densified area. The results of this study are presented in the Report on Soil Densification Program, (DLC 1976). A summary of the information obtained from the geophysical surveys is given on Figure 2.5.4-17. A comparison of the measured in situ shear wave velocities on Figure 2.5.4-18 shows little difference before and after densification.

The field work involved with the measurement of the postdensification, in-situ, seismic velocities was performed between June 9 and June 22, 1977. From piezometer data presented in Appendix 2.5A, the ground-water levels within the terrace sands and gravels of the main plant area during this period averaged approximately el 665.7 feet. Consequently, the water level of el 652 presented by Weston Geophysical Engineers appears to be incorrect. The soil layer between approximately el 652 and el 667 with a compressive wave velocity of 3,000 ft per second was mostly below the ground-water table at the time of the seismic survey.

Since water is relatively incompressible, as compared to the soil skeleton, measurements of compressive (P) wave velocities below the ground-water table are more representative of the water than the soil. The compressive wave velocity of water is about 5,000 ft per second; therefore, the reported compressive wave velocity of 3,000 ft per second between el 652 and el 667 is anomolous.

This value of compressive wave velocity from the seismic survey was not used in analyzing the behavior of safety-related plant structures, systems, or components.

2.5.4.5 Excavations and Backfill

A comprehensive onsite quality control program was instituted at BVPS-2 to ensure compliance with excavation, material, and compaction requirements as specified by SWEC. This program was under the control of Duquesne Light Company Site Quality Control (DLC-SQC).

Field inspection and testing, as required, were performed by Dick Corporation Field Quality Control (DC-FQC), which reported directly to DLC-SQC.

2.5.4.5.1 Excavation

Permanent Seismic Category I excavations are not present at the site. All excavations are temporary and are related to the construction of the plant structures. They will be backfilled as required prior to plant operation. The areal extent of excavations in the plant area is shown on Figure 2.5.4-19. Profiles through the plant area are given on Figures 2.5.4-2, 2.5.4-3, 2.5.4-4, 2.5.4-5, 2.5.4-6, 2.5.4-7, 2.5.4-8 and 2.5.4-9.

To ensure the suitability of the excavated foundation levels for Category I structures, buried piping, and duct lines, the DC-FQC inspector verified the following (DLC 1979, SWEC 1978):

- 1. Excavated areas were within the limits shown on the drawings,
- All excavated or bedding areas or fill areas, as applicable, were graded to within 0.2 foot of the grades shown on the drawings,
- Tests were performed on granular excavated material and/or founding elevation, as applicable, as required in Table 2.5.4-2,
- 4. Any soft spots at the bottom of excavations were removed and backfilled at the direction of the Geotechnical Engineer, and
- 5. The founding elevations or prepared surfaces, as applicable, were approved by the Geotechnical Engineer.

The excavation for the reactor containment was made within a steel sheetpile cofferdam driven to el 671 feet. Upon completion of the excavation to el 679 feet, a foundation documentation program was conducted which consisted of the following:

- 1. Establishing a 25-foot square grid over the floor of the containment excavation,
- 2. Photographing the floor of the containment excavation,
- 3. Performing in-place density tests at each grid intersection, and
- 4. Obtaining a bag sample of the founding soil at each grid intersection for classification.

Grain size analyses performed on each bag sample and the results of the in-place density tests are presented in Appendix 2.5D.

The foundation documentation program revealed the presence of a lens of stiff silty clay along the northern perimeter of the containment excavation at el 679 feet; the presence of which was not encountered during the original subsurface investigation. The lens extends eastward beneath roughly the northern half of the safeguards area and the RWST. The areal extent of the clay lens is discussed further in Section 2.5.4.7.1. Soil profiles beneath the safeguards area and the RWST are shown on Figures 2.5.4-8 and 2.5.4-9. Laboratory tests performed on undisturbed block samples recovered from the containment excavation are presented in Appendix 2.5D and are summarized in Section 2.5.4.2.

The clay was removed from within the containment excavation and replaced with compacted structural fill; it was not removed from beneath the safeguards area and the RWST. Estimates of the settlements of the safeguards area and the RWST were found to be within tolerable limits (Figure 2.5.4-20) and the stiff clay was not considered to be a concern to the stability of the structures insofar as a bearing capacity failure was concerned due to the overlying thickness of compacted structural fill. The area beneath the northern portion of the safeguards area and the RWST was excavated to el 690 feet during the soil densification program (Section 2.5.4.12) and then backfilled with compacted structural fill.

Portions of the intermediate terrace and present floodplain (Figure 2.5.4-1) have been overlain by uncontrolled fill and nonstructural fill placed during the construction of SAPS and BVPS-1. The limit of the uncontrolled fill in the plant area was determined from a comparison of the original ground topography that existed prior to the construction of SAPS with the topography after the completion of BVPS-1. The excavation to el 690 feet north and east of the containment shown on Figure 2.5.4-19 was conducted to remove this material. The excavated area was then backfilled with compacted select granular fill.

Measures to control ground-water levels during excavation were not required. The ground-water level reflects the Ohio River water level which has a normal pool elevation of 665 feet. With the exception of a local area within the containment cofferdam, the bottom of all excavations were well above el 665 feet.

2.5.4.5.2 Backfill

<u>Specifications</u>

Structural or select granular fill for use beneath and adjacent to Category I structures consisted of well-graded sand and gravel, which conformed to the following grain size requirements:

<u>Sieve size</u>	Percent passing <u>by dry weight</u>
6 (inches)	100
No. 200	0-15 (nonplastic fines)

Figure 2.5.4-21 shows the upper and lower gradation limits Of 115 grain size analyses on material used for structural fill. Compaction tests performed on these samples according to ASTM 1557, Method D, indicated a mean maximum dry density of 136.9 pcf with a mean optimum water content of 7 percent.

The material was placed in loose lifts of 6 to 12 inches and compacted to a minimum of 95 percent of the maximum dry unit weight obtained from compaction tests performed in accordance with ASTM D1557, Method D, with a minimum required in-place density of 130 pcf.

Material testing requirements were as given in Table 2.5.4-2 (SWEC 1978).

Granular borrow material meeting the gradation requirements for structural/select granular fill was obtained from the suppliers listed in Table 2.5.4-6. Also shown are quantities of backfill provided by each supplier.

In situ soils removed from on-site excavations were not used as structural fill beneath or around Category I structures.

Soil Properties

The dry unit weight of compacted structural fill was taken as 130 pcf, corresponding to 95 percent of the mean maximum dry density from 115 moisture density tests.

The specific gravity was taken as 2.65.

The void ratio was computed to be 0.27.

The saturated unit weight below the ground-water table was taken as 144 pcf from the equation:

$$\gamma_T = \frac{G + Se}{1 + e} \bullet \gamma_W \tag{2.5.4-4}$$

where:

γ_T	= total unit weight (pcf)
G	= specific gravity
S	= degree of saturation, decimal (100%)
е	= void ratio
γ_w	= unit weight of water = 62.4 pcf

Above the ground-water table, the total unit weight was taken as 136 pcf assuming an average water content of 5 percent.

The angle of internal friction of compacted structural fill was conservatively assumed to be 36 degrees.

Low strain shear moduli were estimated using Equation 2.5.4-5 as follows (Hardin and Drenewich 1972):

$$G = \frac{1,230 \ (2.97 - e)^2 \ (\overline{\sigma}_o)^{0.5}}{1 + e}$$
(2.5.4-5)

where:

G = shear modulus (psi) σ_{\circ} = effective octahedral stress (psi) (2.5.4-5)

The vertical coefficient of subgrade reaction for buried pipe was computed according to the following equation (Vesie 1961, 1961a):

$$k_{\nu} = \frac{0.65^{12}}{D_{o}} \sqrt{\frac{E_{s} D_{o}^{4}}{E_{p} I_{p}}} \left(\frac{E_{s}}{1 - \nu^{2}}\right)$$

(2.5.4-5a)

where :

 $k_v = vertical coefficient of subgrade reaction (lb/in³)$ $D_o = outside diameter of pipe (in)$ $E_s = Young's modulus of soil (lb/in²)$ $E_p = Young's modulus of pipe (lb/in²)$ $I_p = moment of inertia of pipe section (in⁴)$ v = Poisson's ratio of soil

An average, low strain value of shear modulus, G, was estimated using equation 2.5.4-5 for two ranges of pipe embedment depth, H_e :

Using these values of shear modulus, Young's modulus, with a reduction to account for strain, was estimated as:

$$E_s = 2 \ (1+\nu) \ \frac{G}{3} \tag{2.5.4-5b}$$

Vertical coefficient of subgrade reaction is shown on Figure 2.5.4-62 as a function of depth of embedment and pipe diameter.

The horizontal coefficient of subgrade reaction for buried pipe was determined according to the empirical procedure described by Audibert and Nyman (1977). An analytical procedure was developed to determine the horizontal load-displacement (p-y) curve for any size pipe embedded at any given depth. Considering the horizontal coefficient of subgrade reaction as the amount of soil pressure reaction generated by a given amount of horizontal displacement (that is, as a secant to the p-y curve), the coefficient of horizontal subgrade reaction can be expressed by:

$$k_h = \frac{p}{y} = \frac{1}{A' + B'y}$$
(2.5.4-5c)

where:

$$\begin{array}{ll} k_{\rm h} & = \mbox{ horizontal coefficient of subgrade reaction (lb/in3)} \\ p & = \mbox{ pressure (lb/in2)} \\ y & = \mbox{ displacement (in)} \\ A' & = \frac{0.145 \ yu}{q_u} & (in^3 / lb) \\ B' & = \frac{0.855}{q_u} & (in^2 / lb) \\ y_{\rm u} & = \mbox{ ultimate displacement (in)} \\ q_{\rm u} & = \mbox{ ultimate soil resistance (lb/in2)} \end{array}$$

Considering the buried pipe as horizontal footing, the ultimate soil resistance, \mathbf{q}_{u} is computed as:

$$q_u = \gamma Z N_q$$

where:

The bearing capacity factor is given on Figure 2.5.4-63. The ultimate displacement, y_u , was evaluated from Figure 2.5.4-63. The iterative procedure used to calculate displacements assumes an initial value of displacement in order to compute an initial value of k_h . Then, using this initial value of k_h , an actual displacement is computed. This procedure continues until the iterative values converge at a final displacement.

2.5.4.6 Ground-water Conditions

Regional and local aquifer characteristics are described in detail in Section 2.4.13.

At the bottom of the excavation for the reactor containment foundation, four temporary observation wells were installed at the locations shown on Figure 2.5.4-22. These observation wells were abandoned when the reactor containment foundation mat was placed. Ground-water level readings as well as the Ohio River elevation were recorded daily from March 19, 1976 until May 21, 1976. The data are shown on Figures 2.5.4-23, 2.5.4-24, 2.5.4-25 and 2.5.4-26 along with | installation details of the observation wells. As can be seen from the data, there is essentially no hydrodynamic time lag between the elevation of the Ohio River and the ground-water level in the observation wells.

Falling head permeability tests were conducted in three of the wells in order to estimate the coefficient of permeability. The results were:

(2.5.4-5d)

Well <u>No.</u>	Coefficient of permeability <u>(x10⁻³ cm/see)</u>
1	1.3-3.9
3	0.9-1.7

In 1977, as part of the settlement monitoring program that is described in Section 2.5.4.13, six piezometers were installed at the locations shown on Figure 2.5.4-14. A typical piezometer detail is shown on Figure 2.5.4-27 and installation data are given in Appendix 2.5A. Tip elevations range between el 646 feet and 651 feet, and all of the piezometers are located within the in situ sand and gravel.

Piezometer data and Ohio River elevation data were recorded during construction on a weekly basis since mid-1977 and are included in Appendix 2.5A. With the exception of one period during February 1979, the ground-water levels recorded in the piezometers show very good correlation with the Ohio River elevations. During February 1979, the river rose to el 681 feet and the piezometer data indicate an apparent time lag. However, the piezometers were only read weekly during this period and in the interim between readings the water level in the piezometers may have risen higher thereby reducing the apparent elevation difference between the ground-water level and the Ohio River elevation indicated by the data.

For the purpose of design, the ground-water level in the plant site area can be expected to reflect the various stages of the Ohio River as discussed in Section 2.4 and repeated as follows:

<u>River stage</u>	Elevation <u>(feet)</u>
Normal water level	665
Ordinary high water	675
Twenty-five year flood	690
Standard project flood	705
Probable maximum flood	730

The design basis for substructure hydrostatic loading is discussed in Section 2.4.13.5.

As stated in Section 2.5.4.1, dewatering for the control of ground water in the plant area during excavation was not required.

The exterior surfaces of the reactor containment shell and foundation mat are protected from water seepage during flood stages caused by the standard project flood and the probable maximum flood by a continuous waterproof membrane. In the event that leakage should occur through the membrane, a supplementary water relief system is provided in the containment to prevent the buildup of water pressure under and behind the steel liner. This system is described in Section 3.8.1.1.1.

2.5.4.7 Response of Soil and Rock to Dynamic Loading

This section describes the dynamic engineering properties of the soils underlying the site and the method used to determine relative displacement between two structures during a seismic event.

Soil structure interaction analyses and the response of buried pipe to dynamic loading is discussed in Sections 3.7B.2 and 3.7B.3, respectively. A discussion of the liquefaction and dynamic settlement potential of the soils at the site is given in Section 2.5.4.8.

2.5.4.7.1 Subsurface Conditions

Subsurface exploration activities conducted at the site are described in Section 2.5.4.3. Soil profiles through the main plant area with the major structures superimposed are shown on Figures 2.5.4-2, 2.5.4-3, 2.5.4-4, 2.5.4-5, 2.5.4-6, 2.5.4-7, 2.5.4-8 and 2.5.4-9. The geology of the site is described in Sections 2.5.1.2 and 2.5.4.1. Soil profiles under Category I pipelines are shown on Figures 2.5.4-51, 2.5.4-52, 2.5.4-53, 2.5.4-54 and 2.5.4-55.

The major structures of BVPS-2 are located on the highest of three alluvial terraces along the south side of the Ohio River. These terraces are described in more detail in Section 2.5.4.1. Foundation information for Category I structures is given in Table 3.7B-2. Category I structures are founded on compacted select granular fill overlying dense in situ granular soil which extends to rock or directly on the in situ granular soil with one exception. The soil in the vicinity of the safeguards area was excavated to el 690 feet BVPS-2 UFSAR

as shown on Figure 2.5.4-8 to remove uncontrolled fill placed during the construction of SAPS and BVPS-1. Beneath the northern portions of the safeguards area and the RWST, underlying the select granular fill which was placed subsequent to the excavation, is a layer of stiff silty clay with a top surface at approximately el 688 feet. The layer is about 20 feet thick at the northern edge of the safeguards area and about 10 feet thick at the northern edge of the RWST. The layer thins to the south and is no longer present at about the east-west centerline of the safeguards area (Figures 2.5.4-8 and 2.5.4-9).

A zone of loose, in situ granular material located from approximately el 640 feet to 660 feet was discovered in the BVPS-2 plant area during the excavation for the reactor containment. This zone was successfully densified using the pressure-injected footing technique.

Site investigations did not detect evidence of features or conditions indicative of disturbance during prior earthquakes.

2.5.4.7.2 In Situ Seismic Velocity Measurements

The results of geophysical surveys conducted at the site are presented in Section 2.5.4.4.

2.5.4.7.3 Dynamic Soil Properties

Measurements were made of the in-situ shear wave velocity of the terrace sands and gravels by Weston Geophysical (DLC 1976). The results are tabulated on Figure 2.5.4-17 and plotted on Figure 2.5.4-18. The 1968 survey was performed in the vicinity of the BVPS-1 reactor containment building and the 1977 survey was performed after the soil densification program in the vicinity of the BVPS-2 fuel building. The terrace soil conditions at the two locations are very similar. The shear wave velocities in the densified zone are similar to those in the vicinity of the BVPS-1 reactor containment. This suggests that the soil densification program increased the density and modulus of the formerly loose sands and gravels such that they are similar to the density and modulus of the soils outside the densified area.

A finite element, soil-structure interaction analysis was performed to evaluate the effect of the densified zone on the response of the reactor containment structure. The densified zone is present beneath about one-half of the containment mat. A benchmark analysis was performed without the densified layer present and was compared with an analysis of an unsymmetric case which included the densified layer. In the latter analysis, conditions were exaggerated because the shear modulus value assigned to the densified zone was very much greater than that computed from the shear wave velocity measurements. The results indicated very little difference in the computed response of the containment structure for the two cases and it was therefore concluded that assuming properties within
the densified zone consistent with those outside the densified zone was justified.

As discussed in Section 2.5.4.2, and shown on Figure 2.5.4-12, the low strain shear moduli of the in-situ sands and gravels determined from the measured shear wave velocities outside the densified area compare quite well with those determined using the empirical relationship of Hardin and Drenevich (1972).

Shear strains generated by earthquake motions cause a reduction in the low strain value of shear modulus. Using test data presented by Seed (et al 1975), the low strain values of shear modulus were reduced for anticipated strain levels during the safe shutdown earthquake (SSE) as shown on Figure 2.5.4-12.

The low strain shear modulus of compacted structural fill was determined using the empirical relationship of Hardin and Drenevich (1972) as given in Section 2.5.4.5.

Cyclic triaxial tests to investigate the susceptibility of compacted structural fill to liquefaction were not performed. As stated in Section 2.5.4.5.2, structural fill was placed and compacted to 95 percent of the maximum dry density indicated by ASTM 1557 Method D, with a minimum required in-place dry density of 130 pcf, and this, coupled with the gradation of the material, was considered sufficient to preclude liquefaction. Liquefaction analyses are performed assuming, as a minimum, a groundwater level coincident with the 25year flood, which for BVPS is at el 690 feet. With the exception of an area beneath the northern portion of the reactor containment foundation, as shown on Figure 2.5.4-19, all structural fill within the main plant area was placed above el 690 feet.

Attempts to obtain undisturbed samples of the in situ sands and gravels suitable for dynamic triaxial testing were unsuccessful. The

resistance to liquefaction of the in situ sands and gravels at the site was investigated by two methods:

- 1. Based on dynamic triaxial tests on sands susceptible to liquefaction and
- 2. Based on the observed behavior of sand deposits in previous earthquakes (DLC 1976).

The results of dynamic triaxial tests upon Sacramento River sand, considered to be extremely susceptible to liquefaction, are presented on Figure 2.5.4-28, based on the response to USNRC Question 2.26 and 2.27 of the BVPS-2 FSAR. The figure shows the relationship between shearing stresses, expressed as a ratio of shear stress to effective stress, to the number of cycles necessary to cause initial liquefaction for this sand at several relative densities. It was used to evaluate the liquefaction potential of the soils within the main plant area as described in Section 2.6.5.2 of the BVPS-2 PSAR. This approach was conservative since the Sacramento River sand was considered especially susceptible to liquefaction in comparison to the sands and gravels at the site.

After the discovery of the loose zone in the main plant area and its subsequent densification, a liquefaction analysis was performed for soils within the densified zone (DLC 1976). The shear stress required to cause liquefaction of the in situ sands and gravels was evaluated using Figure 2.5.4-29. This figure presents a lower bound envelope for sites where liquefaction has occurred during earthquakes of Richter Magnitude 5.5 or less, correlated with corrected standard penetration resistance, N_1 , of the sand deposit. This figure was used to evaluate the resistance to liquefaction of the soils in the vicinity of the intake structure as well. Further discussion is presented in Section 2.5.4.8.

The maximum Rayleigh wave velocity used in the analysis of buried pipe was determined to be 3,000 ft/sec, using the procedure described below.

Ewing et.al. (1957) presented data, reproduced on Figure 2.5.4-31, which showed that Rayleigh wave velocity in a layered system was a complicated function of the depth of soil, the shear wave velocity of soil and rock, and the frequency wave length of the Rayleigh wave.

Using Figure 2.5.4-31, for $C_2/C_1=4.5$, the variation of Rayleigh wave velocity with frequency for the in situ soil conditions in the main plant area was determined and is shown on Figure 2.5.4-64. Rayleigh wave velocity is seen to vary widely depending on frequency. Because an earthquake is likely to produce Rayleigh waves of many frequencies, the selection of a control value of Rayleigh wave velocity was based upon a consideration of the predominant frequency likely to be produced by an earthquake occurring near the site. BVPS-2 UFSAR

The peaks of Fourier spectra for earthquake time histories represent frequencies at which large amounts of energy are released by the earthquake. Housner (1970) compared Fourier spectra with velocity response spectra and found that the peaks occurred at about the same frequencies. Accordingly, a predominant frequency of 2-3 Hz was determined from response spectra presented in SWEC (1984). These response spectra were computed for real earthquake time histories, with magnitudes corresponding to the BVPS-2 SSE, that were amplified through the BVPS-2 soil profile. From Figure 2.5.4-64, a frequency of 2-3 Hz corresponds to a Rayleigh wave velocity of about 3000 ft/sec.

2.5.4.7.4 Relative Displacements

Methods used to evaluate the relative displacement of the closely spaced main plant structures during a seismic event for input to pipe stress analyses are discussed in this section. One method considers the theoretical behavior of surface waves and the effect of site layering on the wave velocities. It uses a simple and conservative model which assumes that the wave motion is propagated horizontally without any change in wave form and with no effect of structure ridigity or other interference. The maximum displacement between two points is enveloped by the first term of a Taylor series expansion of the displacement. The second method, used in only two cases, uses an earthquake acceleration time history to determine a relative displacement time history from which the maximum value is determined. The mass and rigidity of the structures involved and of adjacent structures are not considered in either method. The motion of the ground surface, upon which is founded a massless structure, is estimated. The two methods estimate the magnitude of the relative displacement, but not the direction of movement of the individual structures involved. The earthquake time history method results in smaller estimates of relative displacement, but it represents a more realistic approach, since it is based upon actual recorded ground motions.

SIMPLE MODEL

It is assumed that relative displacement results from the horizontal propagation of seismic waves with little or no change in wave form. It is further assumed that the maximum particle motions produced by each wave occur simultaneously, and that the foundations behave as rigid bodies.

For soil sites such as BVPS, relative displacements are caused by Rayleigh waves and Love waves. The particle motion for the Rayleigh wave occurs in the vertical plane and is elliptical and retrograde with respect to the direction of propagation. By their nature, Rayleigh waves cause horizontal push-pull (R_x) and vertical (R_y) displacements. The particle motion of Love waves is transverse to the direction of propagation and as a result, they are the cause of translational (R_y) displacements.

For wave propagation parallel to the axis between structures under consideration, the horizontal push-pull and translational displacements between two points A, and B, as shown on Figure 2.5.4-30 are given as follows (Christian 1976):

$$R_x = V_m \frac{b}{C_r}$$
$$R_y = V_m \frac{b}{C_L}$$

where :

$R_{\rm X}$	= push-pull displacement along axis between
	two points
Vm	= peak velocity of design earthquake
b	= centroidal distance between structures
Cr	= Rayleigh wave velocity
Ry	= horizontal displacement perpendicular to the axis between two points
Ст	= Love wave velocity

The peak velocity of the design earthquake was determined from the empirical formulation that a V_m of 48 in/sec corresponds to a peak acceleration, a_m of lg; defined by Christian (1976) as:

 $V_m = 48a_m$

Generally, the vertical ground acceleration is taken as $2/3\ \text{of}\ a_h$ and therefore:

$$R_z = 2/3 R_x$$

where:

For oblique waves, the maximum relative displacement occurs when the direction of propagation is at an angle of 45 degrees to the line between two points. The relative displacement between points A and B (Figure 2.5.4-30) is determined by resolving the relative displacement of points A' and B' into components parallel and perpendicular to line AB. Both the Rayleigh wave and the Love wave contribute to the relative displacement between A and B.

For the Rayleigh wave:

$$R_{xr} = R_{yr} = \left(48a_m \frac{b}{C_r}\right) \sin^2 45^\circ$$

(2.5.4-6)

 R_z = vertical displacement

For the Love wave:

$$R_{xL} = R_{yL} = \left(48a_m \frac{b}{C_L}\right) \sin^2 45^\circ$$
(2.5.4-7)

Symbols are as defined previously.

The vertical displacement ${\tt R}_{\rm z}$ is a result of the Rayleigh wave only; therefore:

$$R_z = 2/3 \left(48a_m \frac{b}{C_r} \right) \sin^2 45^{\circ}$$
(2.5.4-8)

Soil sites underlain by stiffer materials such as denser soil or rock will have Rayleigh wave and Love wave velocities that are affected by the wave length, soil and rock characteristics, and depth of overburden to the stiffer layer. The relationship between the parameters already mentioned used to evaluate the Rayleigh wave velocity is given on Figure 2.5.4-31 (Ewing et al 1957). The wavelength was taken as twice the distance between points under consideration. The Love wave velocity was determined from the following expression (Bullen 1963):

$$G_{2}\left(1-\frac{C_{L}}{C_{2}^{2}}\right)^{1/2} - G_{1}\left(\frac{C_{L}^{2}}{C_{1}^{2}}-1\right) \tan\left[\frac{2\pi H}{\lambda}\left(\frac{C_{L}^{2}}{C_{1}^{2}}-1\right)^{1/2}\right] = 0$$
(2.5.4-9)

where:

G_2	=	shear modulus of lower denser layer (rock)
C ₂	=	shear wave velocity of lower denser layer
G_1	=	shear modulus of upper layer (in situ sand and gravel)
C ₁ H	=	shear wave velocity of upper layer depth of upper layer
λ	=	<pre>wavelength = 2b for parallel waves;</pre>
	=	2bsin 45° for oblique waves

There is a unique solution for the Rayleigh and Love wave velocities for each value of b.

The shear moduli, G_1 , and G_2 , of the in situ sand and underlying rock were computed from the measured in situ shear wave velocities (DLC 1976). Average values of 1,250 fps and 5,000 fps were chosen for the soil and rock, respectively.

The relative displacements for parallel waves and for oblique waves determined by this approach for the SSE are shown on Figure 2.5.4-30. For the operating basis earthquake (OBE), the values are one-half those shown for the SSE.

Earthquake Time History Method

The relative displacement of the centroids of two building foundations are computed using the computer program CORD2B, a shortened acronym for "Calculation of Relative Displacements between Two Buildings during an Earthquake" (SWEC 1982). The program does not consider the mass and rigidity of the structures; but rather, computes the displacements of points under massless, rigid buildings caused by the passing of an earthquake wave. It is assumed that each foundation is subjected to the same time history; i.e., that the wave shape is not changed while passing between the centroids. CORD2B filters the acceleration time history, averaging the effect of the accelerations to account for the time required for the earthquake to pass beneath an individual building. This averaging accounts for the fact that different parts of the foundation are subjected to different accelerations as the wave passes, and, in effect, the acceleration time history for each structure is integrated twice to determine a displacement time history. The two displacement time histories are then shifted by the time required for the wave to pass between the centroids, namely:

t = b/c

where:

```
t = time lag
```

- b = centroid to centroid distance
- c = Rayleigh wave velocity (Figure 2.5.4-31)

Subtracting the time shifted displacement time histories results in a relative displacement time history and identification of the peak relative displacement.

The push-pull and transverse relative displacement is computed as the mean peak horizontal displacement determined from the eighteen horizontal ground surface acceleration time histories listed in Table

BVPS-2 UFSAR

2.5.4-9. These time histories were recorded at soil sites for which soil properties and profiles are matched as closely as possible by BVPS-2 (SWEC 1985). They are scaled to the SSE ground surface acceleration of 0.125 g by CORD2B before computing displacements. The vertical relative displacement is assumed to be two-thirds of the horizontal.

The procedure is used to compute the relative motion between the auxiliary building and the main steam and cable vault and between the safeguards area and the main steam and cable vault. The results are summarized in Table 2.5.4-10.

2.5.4.8 Liquefaction Potential and Dynamic Settlement

2.5.4.8.1 Liquefaction Potential

Main Plant Area

A zone of loose, potentially liquefiable, granular soil was identified in the BVPS-2 main plant area during the excavation for the reactor containment foundation. The loose zone was successfully densified and a liquefaction analysis of soils within the densified zone indicated adequate factors of safety (DLC 1976). For further discussion of the densification program, refer to Section 2.5.4.12.

The extent of the loose zone was determined from the exploratory borings as a zone within a given boring containing a significant number of samples with N_1 values less than 10 determined using the data of Gibbs and Holtz (1957). N_1 is the measured standard penetration test resistance, N, corrected to an overburden pressure of 1 ton/ft 2 . This criterion was determined from an analysis of liquefaction potential. The analysis was performed with the groundwater table assumed at el 705 feet. A constant value of N_1 was assumed within the free field soil profile of the main plant area and at a number of depths. Δn allowable shear stress was determined from Figure 2.5.4-29 for this (Further discussion of Figure 2.5.4-29 is assumed value of N_1 . provided in the following section concerning the main intake structure.) At the same depths, the applied shear stress was determined from Figure 2.5.4-39 and the factor of safety was determined as the ratio of the allowable shear stress to the applied It was determined that an N_1 value of 5 would result in shear stress. a safety factor against liquefaction of 1.0. As an N_1 of 10 resulted in a factor of safety of about 2, it was conservative to define the loose zone in terms of N_1 values less than 10.

The applied shear stresses given on Figure 2.5.4-39 are based on BVPS-2 PSAR Figure 2.6-6, which shows free field shear stresses for the N69W component of the 1952 Taft accelerogram scaled to an estimate of the SSE bedrock acceleration, and then amplified through a BVPS-2 soil profile by a mass-spring-dashpot computer model (DLC, 1972i). The average stress for the 10 largest peaks has been increased slightly to account for differences between current

building loads and soil unit weights and those used in the original analysis described in DLC (1972i). The peak ground surface acceleration associated with PSAR Figure 2.6-6, and, therefore, Figure 2.5.4-39 is 0.098g. This is lower than the SSE ground surface acceleration of 0.125g, but the shear stresses given by Figure 2.5.4-39 are shown on Figure 2.5.4-39a to represent a very conservative estimate of shear stresses at the site during the SSE.

Figure 2.5.4-39a presents a comparison of the stresses shown on Figure 2.5.4-39 with those computed as an average of those from 28 rock outcrop time histories amplified through a BVPS-2 free field soil model using the computer program SHAKE (Schnabel, et al., 1972). The analysis technique is similar to the soil response analysis described by SWEC (1985), which used the same 28 earthquake records to estimate a BVPS-2 site dependent response spectrum.

The rock outcrop time history is input at the bedrock level of a BVPS-2 free field soil model and scaled to the SSE magnitude, using a procedure described by SWEC (1985). The peak acceleration contained in the record is not considered; magnitude is the design parameter. The scaled time history is then amplified through the soil model by SHAKE to compute peak shear stresses as a function of elevation. An average stress is taken as 65 percent of the peak value as recommended by Seed and Idriss (1971). An average of the responses of the 28 time histories is computed and is shown on Figure 2.5.4-39a. The groundwater table is taken at el 690 ft, the level of the 25 year flood. Shear stress from this analysis technique is seen to be very much lower than the original, but similar analysis based on only one earthquake record. Therefore, use of Figure 2.5.4-39 to evaluate shear stresses in the soil generated by the SSE is very conservative.

Using the criterion of a minimum N_1 of 10, the borings in the main plant area were examined and a thickness contour map of the zone requiring densification was prepared. This map is presented in Appendix Figure B-10 of the Report on the Soil Densification Program (DLC 1976). The extent of the area densified by the pressure-injected footing technique is shown on Figure 2.5.4-15. To the north, east, and west of the main plant area, the densified zone was extended beyond the foundation limits of the plant structures in order to provide continued support to the foundations in the event of the liquefaction of the adjacent, nondensified soil.

 N_1 values from borings under the main plant structures outside of the densified zone are presented on Figure 2.5.4-59. From a total of 541 samples, 15 show N values less than 10 and none are less than 5. Figure 2.5.4-11 shows relative density versus standard penetration test N values for the same boring as those on Figure 2.5.4-59. The mean relative density for the sand and gravel is 77.3 percent and the means relative density less one standard deviation is 62.9 percent.

Main Intake Structure

The main intake structure is located as shown on Figure 2.5.4-32 and is common to both BVPS-1 and BVPS-2. The structure is directly adjacent to the Ohio River with founding elevation varying between el 634 feet 6 inches and 640 feet 6 inches. A sheetpile cofferdam driven to rock was used to facilitate the construction of the 85-foot by 88foot structure. Extending along the river to the east and west of the intake structure are two rows of sheetpile walls that are tied together (Figure 2.5.4-32). The area directly north of the structure was dredged to el 645 feet, with an average side slope of approximately 3.5:1. A simplified north-south section through the intake structure is shown on Figure 2.5.4-66.

The onshore and offshore areas east and west of the intake structure, and the area to the south beneath the BVPS-1 river water lines and the BVPS-2 service water lines were densified. The limits of densification are shown on Figure 2.5.4-16. The purpose of densifying the sands around the intake structure was to prevent the soils from liquefying during the SSE and blocking the intake channel. A detailed discussion of the densification program is presented in Section 2.5.4.12. The areas north of and below the intake structure were not densified. No adverse effects to the structure, slopes, or wingwalls are anticipated. Stability of soils at the intake structure is considered in three parts: a. liquefaction analysis of soils around the intake structure, b. liquefaction analysis of soils below the intake structure and, c. stability of intake channel slopes.

a. Soils Around Intake Structure

Liquefaction analysis of the soils around the intake structure considers three separate areas: 1. the offshore densified area, 2. the onshore densified area, and 3. the intake channel. The factor of safety against liquefaction is taken as the ratio of the shear stress required to cause liquefaction of the soil and the shear stress induced by the design earthquake. The minimum factor of safety is 1.1. Ohio River elevations are assumed coincident with normal river conditions at el 665 ft, and with the 25-year flood at el 690 ft.

The shear stress required to cause liquefaction is evaluated using the relation developed by Seed et al (1975a) that is shown on Figure 2.5.4-29. This curve is described as a lower bound envelope for sites where liquefaction has occurred during earthquakes with Richter magnitudes between 5 and 6, correlated with the corrected penetration resistance, N_1 , of the sand deposit involved. N_1 is the measured standard penetration test (SPT) resistance, N, corrected to an overburden pressure of 1 ton/ft².

The values of N_1 are computed using the computer program RELDEN (SWEC 1979). The measured SPT resistance, N, is corrected to a maximum N_1 value of 42 by RELDEN, although the actual value could be higher. Since the resistance to liquefaction is related to N_1 , the computed factor of safety against liquefaction will be conservative for those samples with an N_1 value greater than 42.

The applied shear stress is calculated from the equation presented by Seed (1976):

$$\tau_{app} = 0.65 \ x \ \frac{\sigma_{vo}}{g} \ x \ a_{\max} \ x \ r_d \tag{2.5.4-10}$$

where :

- τ_{app} = applied shear stress
- σ_{vo} = total overburden pressure on sand layer under consideration
 - g = acceleration of gravity
- a_{max} = maximum acceleration at the ground surface, 0.125g for SSE
- rd = a stress reduction factor varying from a value of 1 at the ground surface to a value of 0.9 at depth of about 30 feet (Seed and Idriss 1971)

Although this equation was developed to predict applied shear stress for a horizontal ground surface, it is used for both horizontal and sloping ground conditions in this analysis. Since the intake channel side slopes are graded to a shallow slope of about 3.5:1, the use of this equation gives a reasonable approximation of the applied shear stresses.

Liquefaction analyses are performed on a sample-by-sample basis, using soil data obtained from the borings shown on Figures 2.5.4-13 and 2.5.4-32. Borings performed after the densification program was completed are used in the analysis of the onshore and offshore densified zones east and west of the intake structure. Borings were not drilled in the channel area immediately north of the structure and since this area was not densified, borings drilled offshore prior to densification are taken as representative of soil conditions in the intake channel.

In the analysis of the onshore areas, the entire soil profile is assumed to be saturated for cases with river level at or above el 665 feet. Therefore, changes in water level from normal to flood conditions do not change the results. Offshore, the total stress at a given sample is computed as the product of saturated weight of the soil and the depth below the river bottom to the soil sample. The total stress is computed neglecting the weight of the overlying water, since the water cannot transmit shear stress. As a result, the computed total stress and therefore the applied shear stress are unaffected by fluctuating river levels. Since the effective stress used to evaluate the allowable shear stress (Figure 2.5.4-29) is likewise not affected, the factor of safety against liquefaction offshore does not change with changes in the Ohio River elevation.

Safety factors for the onshore densified areas and the offshore densified areas are shown on Figures 2.5.4-33 and 2.5.4-35, respectively. The onshore densified areas south of the riverward sheetpile walls have satisfactory factors of safety against liquefaction with all alues at or above 1.6. The offshore densified

soils are not susceptible to liquefaction as shown by the preponderance of samples having factors of safety greater than 1.1. Two samples at a depth of less than 5 feet in two different borings have factors of safety less than 1.1, but this is neither significant nor unusual due to low confining stress at shallow depths.

Safety factors for the undensified intake channel area north of the intake structure are shown on Figure 2.5.4-34. Ten samples between el 645 ft and el 634 ft had factors of safety less than 1.1. Most of these samples occur within the top 5 to 10 feet of the soil profile. One sample at approximately el 623 ft was unsatisfactory. A similar analysis performed for samples above el 645 ft along the intake channel slopes outside the densified area shows that the upper 10 feet of soil is loose and may liquefy. Therefore, in the dynamic slope stability analysis of the intake channel described in Section c., the upper 10 feet along the slopes outside of the densified zone and below the dredge line in front of the intake structure were assumed to be liquefied at the end of the seismic event.

b. Analysis of Soils Beneath Intake Structure

Examination of the soil conditions below the intake structure indicates the possible presence of some low blow count granular soil with an average N_1 of about 7 blows/ft. The liquefaction potential of this granular soil and the underlying more dense soil are evaluated using a different approach than that used for the soils adjacent to the structure. The results indicate that the factor of safety against liquefaction within any low blow count material beneath the intake structure is between 1.2 and 1.6, which is acceptable.

A cross section through the intake structure showing soil conditions that existed prior to the Terra Probe densification program is given on Figure 2.5.4-67. It was developed using data from borings performed in 1954 and 1974 prior to the densification program.

Examination of the corrected blow counts indicates that low blow count materials could have existed below and on either side of the intake structure location between about el 635 ft and 640 ft prior to construction and the subsequent insitu densification by Terra Probe and vibroflotation adjacent to the structure. N₁ values between 4 and 10, with an average N₁ of about 8 are indicated on Figure 2.5.4-67. In contrast, most of the soil has N₁ values between 11 and 50, and averaging about 21. The majority of samples are described as gravelly sand, and the presence of gravel could cause N₁ values to be high. The Report on the Soil Densification Program, BVPS-2 (DLC 1976) indicates that a 13 percent reduction on average to N₁ is appropriate to account for gravel. Applying this correction reduces the average N₁ value for the low blow count material to 7, and to 18 for the deeper material. Using the Marcusson and Bieganouski (1976)

data, N_1 values of 7 and 18 correspond to relative densities of about 40 percent and 60 percent, respectively.

The low blow counts were eliminated on either side of the intake structure within the limits of the Terra Probe densification. Excavation for the intake structure mat was accomplished using a clamshell within the confines of a heavily braced steel sheetpile cofferdam. There were three vertical layers of cross bracing placed in two orthogonal directions. Horizontal spacing of the bracing was at about 17 feet on center. Considering the difficulty involved with using a clamshell in this confined space, it is unlikely that the bottom of the excavation would have conformed to the shape of the mat indicated on Figure 2.5.4-66. It is more likely that the bottom was overexcavated to about el 634.5 feet, corresponding to the bottom of the gravel layer at the south end of the mat, and then backfilled to the required elevation. This would have effectively eliminated the presence of the low blow count material below the structure.

A liquefaction analysis for materials beneath the intake structure is described below for the SSE occurring coincident with the 25-year flood at el 690 ft. Applied shear stresses determined by the computer program SHAKE (Schnabel et al 1972) are compared to shear stresses required to cause liquefaction determined using the two relationships shown on Figure 2.5.4-29a and from cyclic triaxial tests performed on reconstituted samples.

The procedure used to determine the applied shear stresses below the intake structure is shown schematically on Figure 2.5.4-68. It represents an extension of the method used by SWEC (1985) to compute site dependent ground surface response spectra.

A rock outcrop time history is input at the base of a BVPS-2 free field soil profile model. It is amplified through the profile by SHAKE to compute a ground surface time history which is scaled to the SSE magnitude. The scaling procedure, described by SWEC (1985), does not consider the acceleration level of the earthquake; magnitude is the design parameter. The scaled time history is then deconvoluted by SHAKE through the free field profile to compute a site and magnitude consistent bedrock motion, which is input below the intake structure to compute applied shear stresses.

The three rock outcrop records listed in Table 2.5.4-7 are used in this analysis. They were selected from the 28 rock outcrop records used by SWEC (1985). The basis for their selection is that applied shear stresses generated in the free field by these three records approximate the average of the shear stresses from all 28 records. Note, that for the purpose of earthquake record selection, the free field shear stresses are computed by scaling the rock outcrop time histories to the SSE magnitude prior to amplifying them through the free field profile. The free field soil model is shown on Figure 2.5.4-69. Shear wave velocities are those suggested by Whitman (1968), and are based upon insitu measurements. Soil unit weights are taken from Section 2.5.4.2. The soil model below the intake structure is shown on Figure 2.5.4-70. The structure is represented as a pseudo-soil with a unit weight and shear wave velocity compatible with characteristics of the structure. The shear wave velocity of the pseudo-soil layer is computed from the equation for the first harmonic natural period of the structure as:

$$V_s = \frac{4H_e}{T}$$

where :

 V_s = equivalent shear wave velocity

H_e = height or thickness of equivalent soil layer

T = natural period of structure

The equivalent height of the pseudo-soil is taken as the ground surface elevation around the structure minus the founding elevation. The liquefaction analysis is performed for the 25-year flood at el 690 ft, which is higher than the ground surface at el 675ft. Since SHAKE cannot handle a free water surface, the ground water table in the model is input at the ground surface. The equivalent unit weight of the pseudo-soil layer is selected so that the effective stress at the bottom of the layer is the same as the effective contact pressure of the structure for a water level at el 690 ft. Shear wave velocities of the soil layers below the structure were calculated from low strain shear moduli determined using equation 2.5.4-3. The void ratio of the low blow count layer estimated to be 0.68, based on data from the loose zone in the main plant area (DLC 1976). The void ratio of the denser layer is taken as 0.4 from Section 2.5.4.2.

SHAKE iterates to compute modulus and damping values compatible with strain levels induced by earthquake ground motions. Strain dependent variations of shear modulus and damping used in the analysis are based on data presented by Seed and Idriss (1970), and are shown on Figure 2.5.4-71.

Using the procedure shown on Figure 2.5.4-68, applied shear stresses are determined for each of the three selected rock outcrop motions and then averaged. Since SHAKE computes peak values of applied shear stress, an equivalent uniform shear stress is taken as 65 percent of the peak value (Seed and Idriss 1971). The results are shown in Table 2.5.4-8.

The resistance to liquefaction of the soils below the intake structure is evaluated using the two relationships shown on Figure 2.5.4-29A. One shows a correlation with N_1 , developed by Seed et al (1975a). It is described as a lower bound envelope for sites where liquefaction has occurred during earthquake having magnitudes between 5 and 6. The BVPS-2 SSE is approximately equivalent to a

BVPS-2 UFSAR

magnitude 5.0 earthquake, and, therefore, the cyclic stress ratio required to cause liquefaction shown by the Seed (1975a) curve is somewhat low for BVPS. Seed et al (1983), considering more recent earthquake data, discuss a procedure which accounts for the effect of varying magnitude on the cyclic stress ratio. Using this procedure, a curve for a magnitude 5 earthquake was determined and is shown on Figure 2.5.4-29A. It shows a higher cyclic stress ratio required to cause liquefaction for the same value of N_1 . The allowable shear stress at the center of the soil layers in the intake structure model, determined using the two relationships shown on Figure 2.5.4-29A.

The factor of safety against liquefaction, defined as the ratio of the allowable shear stress to the applied shear stress, is between 1.2 and 1.6 for the low blow count material, and between 3.3 and 4.6 for the higher blow count material. The minimum acceptable factor of safety is 1.1.

The resistance to liquefaction of the low blow count layer is also found to be satisfactory, based on the results of cyclic triaxial testing. The evaluation is described below.

During a study of the liquefaction potential of the soils at BVPS-1, and at the request of the U.S. NRC, a laboratory testing program was conducted to estimate the cyclic shear strength of the soil samples recovered from the freeze hole excavated in the low blow count zone beneath the BVPS-2 containment (SWEC 1977).

Cyclic triaxial testing was performed on eight reconstituted samples that were prepared from material finer than the No. 10 sieve and compacted to dry densities approximating the insitu dry density. The grain size curve of the minus No. 10 fraction is parallel to the grain size curve of the complete sample, indicating that the materials should have essentially the same mechanical properties when compacted to the same dry densities.

Samples were anistropically consolidated and tested isotropically at two confining pressures, one corresponding to the average depth of the loose zone and the other to the deepest level of the loose zone below BVPS-2. From the test results, a cyclic stress ratio was selected to define liquefaction as 2.5 percent double amplitude strain in 8 cycles as:

$$\frac{(\sigma_1 - \sigma_3) \text{ cy}}{2\overline{\sigma}_c} = 0.155$$

where:

 $(\sigma_1 - \sigma_3)$ cy = cyclic deviator stress

 σ_c = effective confining pressure

Seed (1979) contends that the cyclic simple shear test is more representative of actual field stress conditions than the cyclic triaxial test. The results of the two tests are related by a factor, CR, as shown below:

$$\left(\frac{\tau_h}{\overline{\sigma}_v}\right)$$
 simples hear = $CR \bullet \frac{(\sigma_1 - \sigma_3)_{cy}}{2\overline{\sigma}_c}$

where: τ_h = shear stress on horizontal plane

 σ_v = vertical effective stress

From the data presented by Seed (1979) and assuming a $K_{\rm o}$ of 0.5 for the low blow count soil, CR is 0.74.

Seed (1979) also recommends reducing laboratory simple shear test results an additional 10 percent to account for multidirectional shaking in the field. Therefore, an allowable field shear stress ratio, based on the results of the cyclic triaxial tests is:

$$\left(\frac{\tau_h}{\sigma_v}\right)_{field} = (0.74)(0.9)(0.155) = 0.104$$

Based on this relation, the factor of safety of any low blow count material below the intake structure is 1.4.

In summary, low blow count soils may have been present below the intake structure location, but were probably removed during excavation and foundation preparation. Should they still be present, liquefaction analyses based on blow count data and cyclic triaxial test data give satisfactory factors of safety for the soil below the intake structure.

c. Main Intake Structure: Sliding and Slope Stability

Figure 2.5.4-65 presents the loading diagram used to calculate the factor of safety against sliding of the main intake structure. The water level within the intake structure is the same as the river level. During plant operation, a maximum of one bay can be dewatered which would reduce the frictional resisting force along the base of the structure. During a seismic event, undrained shear behavior will govern sliding stability of the intake structure. Changes in vertical stresses at the soil structure interface will cause a

corresponding change in pore pressure. Therefore, the effective contact pressure will remain constant and equal to the effective building weight (total building weight minus static buoyant force). Consequently, only the horizontal component of inertial force is considered in the sliding stability analysis. Under the conservative conditions of the SSE plus standard project flood and one intake bay empty, the factor of safety against sliding is 1.3, which is satisfactory. The dynamic sliding stability analysis of the intake structure was conservatively performed without taking into account the passive resistance of the soil.

Two cross-sections of the intake channel slope at the locations shown on Figure 2.5.4-32 were analyzed for dynamic slope stability using the computer program LEASE II (SWEC 1980). One section was taken adjacent to the intake structure through the densified zone while the other section was taken approximately 100 feet from the intake structure beyond the densified zone.

The upper 10 feet of loose soil along the undensified slope and below the dredge line is susceptible to liquefaction. The pore pressure buildup in the loose zone during the seismic event is accounted for by reducing the friction angle from 25° for the drained case to 17° for the undrained case. This is conservative and assumes the pore pressure parameter equals 1, which is appropriate for loose soils (Lambe & Whitman 1969). A static, post-earthquake slope stability analysis was performed assuming that the liquefied soil would have completely liquefied at the end of a seismic event of short duration and therefore would have weight but not strength (where: $\phi = 0, c = 0$). The minimum acceptable factor of safety for the dynamic and postearthquake cases is 1.1. This is considered adequate since the liquefied soil will regain strength with time due to the dissipation of excess pore pressures generated by earthquake shaking.

The results of the dynamic slope stability analysis of the section through the densified portion of the intake channel slope presented on Figure 2.5.4-57 show satisfactory factors of safety of 1.4 for a failure circle passing behind the tied-back sheetpile wall under normal water conditions, and 1.1 for a shallow failure surface along the slope. The static, post-earthquake case with the water at the 25-year flood level and the upper 10 feet of the river bottom assumed to have liquefied ($\phi = 0$, c = 0) resulted in satisfactory factors of safety. Changing the water level from normal water at el 665 feet to the 25-year flood at el 690 feet has no significant effect on the results of the slope stability analysis since the slope is almost totally submerged under normal conditions.

Figure 2.5.4-37 presents the cross-section and soil properties assumed for the stability analysis of the intake channel slope in natural soil outside of the densified area. No borings were performed along the slope outside of the densified area. Therefore, the borings performed before densification, as shown on Figure 2.5.4-32, were used to develop the soil profile used in the analysis. The static analysis of the slope resulted in a satisfactory minimum factor of safety of 2.

As discussed previously, the upper 10 feet of the river bottom to the north of the intake structure between el 645 feet and el 635 feet, as well as the upper 10 feet along the undensified channel slopes, may The dynamic analysis, including earthquake forces, used a liquefy. reduced friction angle for the loose silty sand of 17° to account for pore pressure buildup prior to liquefaction. The results of the dynamic analysis indicated a family of failure surfaces extending below the loose silty sand layer with factors of safety less than the minimum acceptable value of 1.1. It was hypothesized that the 10-foot layer of loose silty sand along the surface of the intake channel would liquefy and flow downslope until it stabilized at about a 10:1 to 15:1 slope. The denser soils underlying the liquefied soils will remain stable as will the densified zone immediately adjacent to the intake structure, with perhaps some localized sloughing in areas directly adjacent to liquefied soils. These densified areas on either side of the intake structure will serve to prevent liquefied soil from moving directly towards the intake bays.

The intake structure draws water from 646 feet to el 659.5 feet; the pit floor at the pump intakes is at el 640 feet. The New Cumberland Lock and Dam maintains the Ohio River at a normal water elevation of 664.5 feet. A single failure of the dam during minimum river flow | conditions would result in an extreme low water level at the intake bays of el 648.6 feet. Even at this water level, there is a water depth of about 9 feet at the pump intakes. The minimum flow requirements for safe plant shutdown following the design basis accident were evaluated and found adequate for this extreme low water condition, (Sections 2.4.11 and 9.2). A proposed Technical | Specification discussed in Section 2.4.14 limits the operation of BVPS-2 to a minimum Ohio River level of el 654 feet.

Considering the geometry of the intake structure and adjacent densified areas, and the flow requirements which are adequate for safe shutdown even under extreme low water conditions, it is unlikely that the volume of soil on the intake channel slopes which may flow until stabilized at a very shallow angle would be sufficient to block the intake channel such that the safe shutdown of the plant would be jeopardized.

2.5.4.8.2 Dynamic Settlement

Ground vibrations during an earthquake tend to densify cohesionless soil and thereby cause settlement of structures founded upon them. The dynamic subsidence or settlement potential of the granular soil at the site was evaluated using concepts and data presented by Lee and Albaisa (1974). The dynamic settlement of saturated sand results from volumetric strain following the dissipation of excess pore pressures developed during cyclic loading. The magnitude of the volumetric strain is a function of several variables, including the peak pore pressure ratio developed during cyclic loading, the grain size distribution, and the relative density of the soil. The peak pore pressure ratio is the ratio of the peak excess pore pressure, Δ_u , to the effective confining pressure, $\overline{\sigma_c}$. From the results of cyclic triaxial tests, it has been found that $\Delta_u/\overline{\sigma_c}$ is primarily a function of the cycle ratio, N_c/N_L , which is the ratio of the number of significant applied cycles of loading, N_c , to the number of cycles required to cause liquefaction of the soil, N_L .

The steps used to compute dynamic settlement are outlined as follows:

- 1. The soil profile beneath the structures under consideration was divided into layers according to N_1 values, the standard penetration resistance corrected to an overburden pressure of 1 ton/ft².
- 2. An applied shear stress at the center of a given layer was determined from Figure 2.5.4-39 assuming a free field condition and the ratio of applied shear stress to total vertical stress was computed.
- 3. The applied shear stress at the center of the layer beneath the structure was computed as the applied shear stress ratio determined above for the free field case multiplied by the total vertical stress beneath the structure. Applied shear stresses below the intake structure were taken from Table 2.5.4-8.

- 4. The number of cycles to cause initial liquefaction, N , was estimated from Figure 2.5.4-38.
- 5. The volumetric strain for each layer was determined from Figure 2.5.4-40 which is based on test data reported by Lee and Albaisa (1974). A value of eight cycles was used for N for the site SSE as mentioned in Section 2.5.4.9 (DLC 1976).
- 6. Vertical strain was assumed equal to volumetric strain, implying that dynamic settlement is one-dimensional. The volumetric strain was multiplied by the layer thickness to determine the settlement of an individual layer, and the sum of these settlements for all layers beneath the structure was taken as the total settlement due to earthquake vibration.

This method was applied to soils above and below the ground-water table. It was found that the ground-water table had little effect on the calculated settlements and for the purpose of calculating dynamic settlement, it was taken at el 665 feet, or normal water level.

Considering the free field case, the average applied cyclic stress ratio is approximately 0.07. If an N_1 value within compacted structural fill beneath a given structure was as low as 10, N_1 determined from Figure 2.5.4-38 would be greater than 1,000, resulting in a volumetric strain determined from Figure 2.5.4-40 that is negligibly small. Consequently, the compacted structural fill was not considered as contributing to the dynamic settlement.

A summary of predicted dynamic settlements is given in Table 2.5.4-3.

2.5.4.9 Earthquake Design Basis

The seismicity of the Appalachian Plateau Province, of which the site is a part, is discussed in Section 2.5.2. The maximum earthquake expected at the site is an Intensity VI (MM), with a horizontal ground acceleration of 0.07g. The body-wave magnitude, m_b , of the SSE is 4.75 (SWEC 1985). The plant is designed for an SSE with a horizontal ground acceleration of 0.125g, which is slightly greater than the midpoint acceleration between Intensity VI-VII (MM). The horizontal acceleration for the OBE is 0.06g. Vertical accelerations are twothirds of the corresponding horizontal accelerations.

The BVPS-2 response spectra for the SSE are shown on Figure 3.7B-1. Analyses described by SWEC (1984) and SWEC (1985) clearly demonstrate that the BVPS-2 design response spectra are appropriate when compared to site dependent response spectra determined by current state-of-the-art methods.

To facilitate the analysis of liquefaction potential and dynamic settlement at the site, eight equivalent uniform stress cycles are used to represent the irregular acceleration-time history of the SSE.

Seed et al (1975) describe a statistical analysis of western United States earthquake time histories that is used to develop a relationship between earthquake magnitude and number of cycles of uniform motion. The BVPS-2 SSE is shown by SWEC (1985) to be equivalent to a western United States earthquake with a local (Richter) magnitude of 4.95. Seed et al (1975) shows that three to four cycles on average are representative of a magnitude 5 earthquake.

2.5.4.10 Static Stability

Foundation analyses related to the static stability of Category I structures included evaluation of bearing capacity, estimate of settlement, and the development of design lateral earth pressure parameters.

2.5.4.10.1 Bearing Capacity

All Category I structures are founded on mat foundations.

The design of mat foundations, particularly those on dense sands and gravels, is generally limited by a consideration of maximum tolerable settlements rather than by ultimate bearing capacity, since the factor of safety against a bearing capacity type failure is typically quite high. Estimated static settlements of plant structures are presented in Section 2.5.4.10.2. However, for completeness, the bearing capacity of the foundations of Category I structures and the factors of safety against a bearing capacity type failure have been computed for both static and dynamic loading conditions and are presented in Table 2.5.4-4.

The ultimate bearing capacity of the supporting soil is a function of the soil properties, the size and shape of the foundation, the depth of embedment and the depth to the ground-water table. The equation used for computing ultimate static bearing capacity is:

Square or rectangular footings:

$$q_{ult} = cN_c \left(1 + 0.3\frac{B}{L}\right) + \gamma DN_q + 0.4\gamma BN_{\gamma}$$

Circular footings: radius = R

$$q_{ult} = 1.3 \ cN_c + \gamma DN_q + 0.6 \ \gamma RN_{\gamma}$$
 (2.5.4-11)

where:

 $\begin{array}{rll} q_{ult} &= ultimate \mbox{ bearing capacity} \\ C &= \mbox{ cohesion} \\ D &= \mbox{ depth to base of mat foundation} \\ \gamma &= \mbox{ unit weight of soil} \\ B &= \mbox{ width of foundation} \\ L &= \mbox{ length of foundation} \\ N_c, N_q, N\gamma &= \mbox{ bearing capacity factors} \end{array}$

The following assumptions were made in computing the ultimate static bearing capacity:

- 1. Each structure was considered individually, ignoring increases in confinement due to adjacent structures.
- 2. Each structure was assumed to be founded on the in situ sand and gravel with the following properties:

friction angle	=	30°
cohesion	=	0
unit weight	=	125 pcf above ground-water table
	=	136 pcf below ground water table

3. The ground-water table was taken as that corresponding to probable maximum flood conditions at el 730 feet.

As discussed in Section 2.5.4.7, a portion of the safeguards area and the RWST is underlain by a layer of stiff silty clay with a top surface at approximately el 688 feet. Soil profiles depicting the conditions underlying these structures are shown on Figures 2.5.4-8 and 2.5.4-9. This stiff clay was not considered to be a concern to the stability of the structure insofar as a bearing capacity failure is concerned due to the thickness of the overlying compacted structural fill. The bearing capacities given in Table 2.5.4-4 for the safeguards area and the RWST were computed for their respective foundations on compacted fill with the preceding assumptions.

The ultimate static bearing capacity was also used as the ultimate dynamic bearing capacity when computing the factor of safety against a bearing capacity failure for dynamic loading conditions. The ultimate dynamic bearing capacity is conservatively represented by the computed ultimate static bearing capacity. Tests reported by Vesic et al (1965) for both dry and saturated dense sands, performed at various loading rates, showed a slight drop in bearing capacity with increased loading rate, followed by a steady slow increase. The observed minimum dynamic bearing capacities were about 30 percent lower than the static bearing capacities, which corresponds to a 2 degree decrease in the angle of internal friction. The in situ sands and gravels at the BVPS-2 site have an internal friction angle which ranges between 33 and 40 degrees (Section 2.5.4.2), while a 30 degree value was conservatively chosen for design purposes. Since a 2-degree reduction in the actual minimum internal friction angle of the in situ soils would result in a friction angle still higher than that used for design, the actual dynamic bearing capacity is higher than the computed static bearing capacity shown in Table 2.5.4-4. Therefore, the ultimate dynamic bearing capacity is conservatively represented by the computed ultimate static bearing capacity.

2.5.4.10.2 Settlement

This section describes the calculation procedure used to estimate the static settlement of selected points on plant structures. The same procedure is used to estimate a profile of settlement along buried, safety-related piping that extends from the structures out into the yard. The settlement profile is used to evaluate stresses imposed on the piping system using procedures described in Section 3.7B.3.12.3. This section also describes the calculation procedure used to estimate the differential settlements between the closely spaced main plant area structures that are used for pipe stress analysis. Dynamic settlements during a seismic event are discussed in Section 2.5.4.8.2.

A summary of the estimated total static settlements of the plant structures is provided on Figure 2.5.4-20. Observed settlements as of January 1, 1984 are shown on Figure 2.5.4-46.

Foundation soils in the main plant area consist of compacted select granular fill and medium dense to dense in situ granular soils. The northern portions of the safeguards area and RWST are underlain by a layer of stiff silty clay as discussed in Section 2.5.4.7. Site subsurface profiles within the plant area are shown on Figures 2.5.4-2, 2.5.4-3, 2.5.4-4, 2.5.4-5, 2.5.4-6, 2.5.4-7, 2.5.4-8 and 2.5.4-9.

The ground-water level was assumed to coincide with normal river level at el 665 feet.

Total static settlement of the plant structures founded on granular soils was assumed to consist of two components: an elastic component and a time-dependent component which was assumed to be equal in magnitude to the elastic component (Swiger 1974).

The elastic settlement of the structures in the main plant area was calculated using the computer program SETTLE II (Jubenville 1976). This program computes the elastically distributed stress with depth and computes the compression of each layer in the soil profile beneath a selected point on a given structure due to the load imposed on the soil by that structure along with any adjacent structures. The stresses induced by the loaded areas can be calculated using either Boussinesq or Westergaard solutions; the Boussinesq solution was used in this analysis. The foundation configurations, structural loads, and founding elevations of the plant structures are shown on Figure 2.5.4-41.

Certain assumptions accompany the use of SETTLE II in determining settlement. These are: 1) the load imposed by a structure was placed instantaneously, 2) the loads on all structures were placed simultaneously, and 3) settlements occurred simultaneously with load application.

In calculating settlement, the program sums the vertical strains between the founding elevation and the top of the rock according to Equation 2.5.4-12:

$$\rho = \int_{0}^{z} \varepsilon_{v} dz = \sum_{i=1}^{n} \frac{\Delta q_{i} \Delta z_{i}}{D_{i}}$$
(2.5.4-12)

where:

The constrained modulus was calculated according to the equation:

$$D_i = \frac{E_i (1-\mu)}{(1+\mu) (1-2\mu)}$$

(2.5.4 - 13)

where:

$$E_i$$
 = Young's modulus of layer $_i$
 μ = Poisson's ratio = 0.3

To account for the change in constrained modulus that occurs with changes in effective stress as construction continues and additional load is applied, an average value of constrained modulus was used to estimate the elastic settlement. Typically, an initial value of constrained modulus was computed based on the in situ stress conditions after excavation but before the structural loads were applied. SETTLE II was then used to determine the change in stresses at the center of each layer due to structural loads (including loads imposed by adjacent structures). Using these stress changes, values of the final constrained modulus were determined for each layer. Average values of the initial and final constrained moduli were then used in SETTLE II to calculate the settlement of the structures.

Young's modulus was determined by Equation 2.5.4-14:

$$E = 2G(1 + \mu)$$
 (2.5.4-14)

where:

E = Young's modulus G = Shear modulus μ = Poisson's ratio

Low strain shear moduli were estimated using the following Hardin and Black equation (Hardin and Drenevich 1972):

$$G = \frac{1,230 \ (2.97 - e)^2 \ (\overline{\sigma}_o)^{0.5}}{(1 + e)}$$
(2.5.4-15)

where:

Shear moduli determined from in situ seismic velocity measurements compared quite favorably with those computed using the Hardin and Black equation as shown on Figure 2.5.4-12. Standard penetration test N values in the densified zone showed a marked increase after densification as compared to before (DLC 1976). However, in situ seismic velocity measurements that were made after densification do not show the same marked increase (Figure 2.5.4-18), suggesting that the elastic properties of the densified zone are similar to those of the naturally dense in situ soil. Consequently, for the purpose of computing elastic properties for use in the analysis of settlement, no differentiation was made between soils within and outside the densified zone.

The value of low strain shear modulus was reduced by a factor of three to account for the reduction of shear modulus with strain (Swiger 1974).

The settlement of isolated structures outside of the BVPS-2 main plant area were calculated manually using published elastic solutions generally of the form (Poulos and Davis 1974):

$$\rho = \frac{IpB}{E}$$

(2.5.4 - 16)

where:

ρ	=	elastic settlement
I	=	influence factor which accounts for the
		shape of the loaded area and the position
		of the point for which settlement is calculated
р	=	foundation loading
B	=	characteristic dimension of structure
Е	=	Young's modulus

As with the analysis of settlement using the computer program SETTLE II, the value of moduli used was the average of the moduli determined for the initial and final stress conditions.

The settlement of the clay layer underlying the northern portion of the safeguards and the RWST was analyzed using one-dimensional consolidation theory. The estimated total settlement included both the clay layer consolidation and the elastic settlement of the in situ sand and compacted fill computed using SETTLE II. The properties of the stiff silty clay layer for use in the settlement analysis were developed from consolidation tests presented in Appendix 2.5D.

The active and passive earth pressure coefficients were computed for the case of a vertical wall, horizontal backfill, and no soil/wall friction according to the Rankine equations (Bowles 1977):

$$K = \tan^2 (45 - /2)$$

$$K = \tan^2 (45 + /2)$$

where:

К	=	coefficient of active earth pressure
K	=	coefficient of passive earth pressure
	=	effective friction angle of soil

The lateral earth pressure on a rigid wall, which experiences no appreciable deflections, is governed by the at-rest earth pressure coefficient, K_0 , computed as (Bowles 1977):

 $K = 1 - \sin \overline{\phi}$

(2.5.4 - 17)

For in situ sands and gravels with $\phi = 30^{\circ}$, K_{\circ} is 0.5. For compacted select granular fill with $\phi = 36^{\circ}$, the computed value of K_{\circ} is 0.41. From empirical correlations of strength characteristics such as that presented in U.S. Dept. of the Navy (1971), for a well-graded sand and gravel compacted to the density specified in Section 2.5.4.5.2, ϕ may be in excess of 40°, which corresponds to a K_{\circ} of 0.36 or less. A conservative K_{\circ} of 0.6 was generally used; however, lateral pressures on the walls of the lower pump cubicles on the east side of reactor containment were evaluated for a K_{\circ} of 0.36 ($\phi = 40^{\circ}$), and for the southwest wall of the control room extension and for the north and south walls of the adjoining electric cable tunnel, a K_{\circ} of 0.45 ($\phi = 33^{\circ}$) was used. These values are consistent with the estimate of ϕ for the compacted select granular fill.

The active, passive, and at-rest earth pressure coefficients for the in situ sands and the compacted select granular fill are given in Table 2.5.4-5. No safety factors have been applied to the coefficients presented.

Equations for determining the static and dynamic lateral earth and groundwater pressure distributions against unyielding walls are shown on Figure 2.5.4-42. Walls are designed for the combination of static and dynamic lateral earth and groundwater pressures and, in some cases, for compaction-induced lateral earth pressures.

Dynamic lateral earth pressures are those developed by Mononobe-Okabe and described by Seed and Whitman (1970). Hydrodynamic groundwater pressures are taken as 70 percent of the free water pressures determined by Westergaard (1933). Lateral loads on the reactor containment for seismic conditions are determined as described in Section 2.5.5.4 of the BVPS-2 PSAR (DLC 1972g). Compaction-induced lateral earth pressures are considered for the control room extension and the electrical cable tunnel. The earth pressure diagram shown on Figure 2.5.4-42 is computed using the procedure presented by Broms (1971) for the compaction equipment used at BVPS-2. The compaction-induced lateral earth pressure is added to the static lateral earth pressures computed for $K_o = 0.45$.

Design basis for structure hydrostatic loading is discussed in Section 2.4.13.5.

The differential settlements for safety-related piping that spans the shake spaces between adjacent main plant area structures are estimated by using the settlement data obtained from the settlement monitoring program described in Section 2.5.4.13. The observed settlement data is used to make a prediction of the total settlement of the two adjacent structures that are penetrated by the pipe. An average line is drawn through the log-time plots of observed settlement and extrapolated over an assumed 40-year plant life. The total settlement at the end of 40 years is reduced by the settlement that occurred prior to the date of the final weld connecting the pipe to the structures. Since settlement markers are typically not located at piping penetrations, it is necessary to interpolate between adjacent markers to estimate the total settlement at the penetration. The differential settlement of the pipe is the difference between the total settlements of the two adjacent structures at the piping penetration points subsequent to the final weld. An analysis is made of the stresses imposed on the piping system by this differential movement. For the purpose of pipe stress analysis, a minimum differential settlement of 0.5 inch has been used for initial analysis. If this assumption proves to be too conservative, the predicted differential settlement is used instead.

2.5.4.11 Design Criteria

State-of-the-art methods were used in the analysis of foundation stability of Category I structures. Methods used to evaluate bearing capacity, settlement, and lateral earth pressure are discussed in Section 2.5.4.10. The liquefaction potential and an estimate of the dynamic settlement of the granular soils at the site are discussed in Section 2.5.4.8. Soil properties used in the analyses are provided in Sections 2.5.4.2 and 2.5.4.5.

Minimum design factors of safety are as follows:

Bearing capacity	3.0 for all loading conditions.
Slope stability	<pre>1.5 for all permanent loading conditions; 1.1 for SSE loading conditions and for construction slopes.</pre>

Hydrostatic uplift 1.1 for maximum water levels.

Sliding

1.5 for all permanent loading conditions; 1.1 for SSE loading conditions.

A discussion of loads and load combinations used in the design of Category I structures is provided in Sections 3.8.1.3 and 3.8.4.3.

2.5.4.12 Techniques to Improve Subsurface Conditions

A zone of loose granular material from approximately el 640 to 660 feet was discovered in the BVPS-2 area during the excavation for the containment foundation. The extent of the loose zone was conservatively defined from exploratory borings as a zone containing a significant number of samples having N_1 values less than 10, as determined by the Gibbs and Holtz (1957) relationship. A discussion of the criteria used to establish the limits of the densified zone is provided in Section 2.5.4.8. Subsequent investigation revealed that the loose zone was present under roughly the northern half of the containment and extended east and west beneath most of the Category I structures. The loose zone was successfully densified using the pressure injected footing technique. The densification program and its evaluation are fully described in the Report on Soil Densification (DLC 1976). Plots of N_1 values obtained during Program the verification program are presented on Figures 3-29, 3-30, and 3-31 of These plots show that all samples of the loose sand and the report. gravel zone have been densified to obtain N_1 values greater than 10. Figure 3-30 shows five data points with N_1 values that are less than 10; however, these samples are not sand.

The removal of uncontrolled fill that was placed during the construction of SAPS and BVPS-1 is discussed in Section 2.5.4.5. The removal of a lens of stiff silty clay found during the containment excavation is also discussed in Section 2.5.4.5.

The approximate limits of densification of the lower terrace sands and gravels beneath the BVPS-1 circulating water lines and river water lines (WR) and the BVPS-2 service water lines (SWS) are shown on Figure 2.5.4-16. This densification program is described in responses to USAEC questions 2.26 and 2.27 in the BVPS-2 PSAR (DLC 1972e).

Initially, BVPS-1 had been designed with a once-through cooling system with an intake structure located near the present location of the BVPS-1 cooling tower. The Category I river water lines for BVPS-1 had been located directly adjacent to the 108-inch circulating water lines leading to this intake structure. Concern had been expressed that in the event of the liquefaction of soils along the circulating water lines leading to this intake structure. Concern had been expressed that in the event of the liquefaction of soils along the circulating water lines, erosion resulting from their possible rupture could disturb the adjacent river water lines and it was decided to densify the sands and gravels beneath the circulating water lines using vibroflotation to preclude this problem. After completion of the densification program, but before the installation of the circulating water lines, the decision was made to change from a once-through cooling system to closed-cycle cooling towers. Due to space limitations on the site, it was necessary that the intake structure be relocated to its present location as shown on Figure 2.5.4-16.

The soil conditions underlying the service water and river water lines from the point where they cross the circulating water lines to the present location of the intake structure are similar to the previous location and are typical of the low level terrace. The subsurface profile extending from the valve pit to the intake structure is provided on Figure 2.5.4-54. Although the results of a liquefaction analysis of the soils north of the circulating water lines to the intake indicated an adequate factor of safety against liquefaction (Appendix 2H, BVPS-1 PSAR), it was decided to densify the sands and gravels beneath the river water and service water system lines also. A typical section through the densified zone is shown on Figure 2.5.4-58.

The granular soil to the south of the densified zone on the intermediate terrace will not be subject to liquefaction (DLC 1976). If zones of granular material underlying the lower terrace outside of the densified zone were liquefied, flow slides are improbable since the rock surface does not slope toward the river appreciably but remains relatively flat at el 620 feet.

Although some surface subsidence of the soils outside of the densified zone could occur, major movements affecting the support of the service water and river water lines are not likely. The densified area would be constrained against movement towards the river by the densified area adjacent to the intake structure itself.

The limits of densification of the lower terrace sands and gravels beneath the Category II circulating water lines and the Category I service water lines to the intake structure are shown on Figure 2.5.4-As shown, the soil was densified to the top of rock using 16. vibroflotation under two of the circulating water lines from just west of the service water lines eastward to near the cooling tower. The soil underlying the service water lines to the intake structure was also densified. The subsurface profile extending from the valve pit to the intake structure is presented on Figure 2.5.4-54. The locations of verification borings 537 through 562 are shown on Figure 2.5.4-13. The results of the verification borings are presented on Figure 2.5.4-56. The minimum allowable relative density for this area was 75 percent. Only two of 178 sand and gravel samples show relative densities less than 75 percent; therefore, the program was successful. The mean relative density indicated by the verification boring data was 97.7 percent and the mean-less-one-standard-deviation relative density was 91.4 percent. The densification under the circulating water lines was done because the intake structure was originally planned for a different location,

near the present BVPS-1 cooling tower, and the service water lines were to run parallel to the circulating water lines. This work is described in the BVPS-2 PSAR response to USNRC Questions 2.26 and 2.27 addressed in Appendix 2A of the BVPS-2 FSAR.

There was a concern that the nondensified granular soils adjacent to the main intake structure, should they liquefy during an SSE, could block the intake channel and/or clog the pumps. To prevent this from occurring, two areas approximately 75 feet by 90 feet on the east and the west side of the main intake structure were densified in 1974 by the L. B. Foster Company of Union, New Jersey using the Terra Probe method. The approximate limits of the densification program are shown on Figure 2.5.4-16. The Terra Probe consists of a vibratory pile driving hammer to which a 30-inch diameter open-ended tubular probe is attached. The unit is suspended from a crane and vibrated into the soil. Densification occurs as the vibrating probe is withdrawn from the soil.

Forty-six verification borings were performed to evaluate the effectiveness of the densification program, the locations of which are shown on Figure 2.5.4-32. The median relative density at each boring location was required to be not less than 75 percent in the sands and gravels as determined using the Gibbs and Holtz relationship. In any one boring, not more than one sample point within the sands and gravels was allowed a relative density less than 70 percent and none were allowed to be less than 65 percent. If these criteria were not met, the area around the failing boring was redensified.

A test program was conducted to determine the optimum grid spacing for the Terra Probe. Three borings, TH-1 through TH-3, were performed before the test densification and three borings, TH-4 through TH-6, were performed afterwards. It was decided that a 5-foot grid spacing would be adequate to achieve the densification requirements.

Prior to beginning the production densification program, 12 borings were performed to allow a comparison of relative densities before and after densification. (Figure 2.5.4-32). A summary plot of relative densities before and after densification is given on Figure 2.5.4-43. Relative density plots of each individual verification boring are provided in Appendix 2.5C. Boring logs are provided in Appendix 2.5B.

Upon the completion of the initial series of borings, both of the areas were densified using the 5-foot grid spacing. Prior to densification, the material between the sheetpile walls was excavated to expose the tie rods at approximately el 663 feet to facilitate the insertion of the Terra Probe. After densification, backfill material was placed before performing the verification borings. Verification borings performed subsequent to the initial densification revealed that the desired densities were not being achieved in all cases. A second test panel was conducted in which a single Terra Probe was inserted and withdrawn from the soil. Three verification borings were performed, one in the center of the probe location and two at increasing distances from the probe (Borings 559T, 560T, 561T). It was found that in this particular area, densification was occurring within the probe itself and for a distance of about 8 inches outside the probe.

Selected areas offshore were redensified using a 5-foot grid spacing which overlapped the original densification pattern. The onshore areas were redensified using a 2.5-foot grid spacing. Figure 2.5.4-32 shows the approximate areas in which each of the densification patterns were performed.

BVPS-2 UFSAR

Eleven borings performed after the final densification program indicated that the densification requirements had been achieved. The boring locations are given on Figure 2.5.4-32 and summary plots of relative density before and after densification are given on Figure 2.5.4-43. The densification program required that the mean relative density at each boring location be not less than 75 percent for the sands and gravels as determined by the Gibbs and Holtz (1957) relationships. In any one boring, not more than one sample within the sands and gravels was allowed a relative density less than 70 percent and none were allowed to be less than 65 percent.

The results of the after-densification borings are summarized on Figure 2.5.4-43. Only three of 93 sand and gravel samples have relative densities less than 65 percent, and of these, two are very close to the soil surface. Thus, it is concluded that adequate densification of the sands and gravels was achieved with a mean relative density of 92.3 percent and a mean-less-one-standard-deviation relative density of 79.8 percent.

2.5.4.13 Surface and Subsurface Instrumentation

In 1977, a comprehensive settlement monitoring program was established for BVPS-2. The settlement of each BVPS-2 Category I structure was monitored during construction, and is monitored through the plant's life until the settlement of a particular structure has been determined to be stable as defined by the settlement monitoring program. For such structures, settlement monitoring is then discontinued.

Differential settlements along buried, safety-related piping that extends from the structures out into the yard and differential settlements of piping that spans the shake spaces between the closely spaced main plant area structures are not monitored as part of the settlement monitoring program. Section 2.5.4.10.2 describes the calculation procedures used to estimate the differential settlements that are used for pipe stress analysis.

During construction, settlement markers are monitored monthly, but, after construction when the structures are fully loaded and their settlement profiles begin to level out, the period between readings will be increased. Permanent bench marks are installed at various locations around the site to provide reliable survey reference points. Several piezometers monitor changes in ground-water elevation to evaluate possible correlations between settlement data and changes in ground-water elevation. In each structure several settlement markers are installed during construction, and are located so that they can be monitored during and after construction. The locations of the bench marks and piezometers are shown on Figure 2.5.4-14 and the locations of the settlement markers installed at present are shown on Figures 2.5.4-44 and 2.5.4-45.

The observed settlements to date (Figure 2.5.4-46) can be compared with the predicted total static settlements shown on Figure 2.5.4-20.

2.5.4.13.1 Bench Marks

Six permanent bench marks were installed at the locations shown on Figure 2.5.4-14. A typical bench mark installation detail is shown on Figure 2.5.4-47. It consists of a 2-inch diameter extra strong steel pipe anchored into bedrock inside of a 3 1/2-inch diameter casing extending to the top of rock. The bench marks are identified by a brass monument inscribed with the bench mark number, elevation, coordinates, and date of initial survey.

The elevations of the bench marks were checked at three-month intervals for the first year after installation and once per year thereafter. In addition, the elevations of bench marks in the

immediate vicinity of construction activities are monitored monthly and any bench mark that is disturbed or is suspected of being disturbed is resurveyed.

Bench marks are checked by running one or a series of leveling loops within the established bench marks. If, by comparison with the elevation measured during the original survey, it has been determined that a bench mark has been disturbed, a new brass monument is installed and the bench mark resurveyed.

All survey work performed in conjunction with checking and reestablishing bench marks is done using first order vertical control.

2.5.4.13.2 Piezometers

Six stand pipe piezometers were installed at the locations shown on Figure 2.5.4-14. Typical piezometer installation details are shown on Figure 2.5.4-27 and specific installation data are given in Appendix 2.5A. Tip elevations range between el 646 and el 651 feet and all of the piezometers are located within the in situ sand and gravel.

Piezometer data and Ohio River elevation data are recorded weekly and are included in Appendix 2.5A. With the exception of one period during February 1979, the ground-water levels recorded in the piezometers show very good correlation with the Ohio River elevations. During February 1979, the river rose to el 681 feet and the piezometer data indicate an apparent time lag. However, the piezometers were only read weekly during the period of high water and in the interim between readings the water level in the piezometers may have continued to rise, thereby reducing the apparent elevation difference between the ground-water levels and the Ohio River elevation.

2.5.4.13.3 Settlement Markers

The locations of the currently installed settlement markers are shown on Figures 2.5.4-44 and 2.5.4-45. Details of the several types of markers are shown on Figure 2.5.4-48. Construction activity in certain structures requires that settlement markers be relocated periodically in order to provide continuing access to the markers. In such structures, temporary markers have been installed instead of permanent markers. Temporary settlement markers have been installed on the reactor containment building, the safeguards area, the fuel and decontamination building, and the cooling tower. When construction activity diminishes to the point that markers are no longer subject to periodic relocation, the temporary settlement markers are replaced with permanent ones.
2.5.4.13.4 Data Processing

Data processing is accomplished using a SWEC computerized data storage system entitled Settlement Monitoring System (IS-233). The settlement marker elevations are input into the computer storage files and a computer printout providing the complete settlement record of each marker is produced. A specimen page of output is given on Figure 2.5.4-49.

For each settlement marker, settlement versus log-time plots have been prepared. These plots are not included herein but are provided in the report on Settlement Monitoring Program (DLC 1980). A summary of the observed settlements to date is shown on Figure 2.5.4-46.

The Ohio River elevation and piezometer data are included in Appendix 2.5A.

2.5.4.14 Construction Notes

The removal of uncontrolled fill placed during the construction of SAPS and BVPS-1 is discussed in Section 2.5.4.5. The removal of a lens of stiff silty clay found during the reactor containment excavation is also discussed in Section 2.5.4.5.

A zone of loose granular material was discovered in the BVPS-2 area during the excavation for the reactor containment excavation. It was densified using the pressure injected footing technique. The densification program and its evaluation are fully described in the Report on Soil Densification Program, (DLC 1976).

TABLE 2.5.4-2

MATERIALS TESTING REQUIREMENTS AND FREQUENCY

Materials	Type Of Test	Test Designation	Minimum Frequency Of Testing	Remarks	
Excavated material	In-place density	Washington densometer ASTM D2167 and/or Nuclear densometer ASTM D2922	One per 5 ft of depth	Testing to be on exca- vated material which is to be stockpiled for later use.	
	Moisture density	ASTM D1557 Method D	Whenever visual inspection indicates a significant change in material gradation.		
	Sieve analysis	ASTM D422 and ASTM D1140	One per moisture density test.		
Founding elevation material	In-place density	Washington densometer ASTM D2167 and/or Nuclear densometer ASTM D2922	As directed by the Geotechnical Engineer.		
Select granular/ structural fill	In-place density	Washington densometer ASTM D2167 and/or Nuclear densometer ASTM D2922	 Areas greater than 1,000 ft², one per 1,000 yd³ placed or one per alternate lift, whichever results in a greater frequency. Areas less than 1,000 ft², one for every 2.5 ft of compacted fill. For each 200 linear ft of trench, one per alternate lift of compacted fill, or as directed by the Geotechnical Engineer. 		
	Moisture density	ASTM D1557 Method D	 One per new source. One per 5,000 yd³ placed Whenever visual inspection indicates a significant change in material gradation. 	Material for moisture density test shall be taken adjacent to an in-place density test.	
	Sieve analysis	ASTM D422 and ASTM D1140	One for each moisture density test	Material for sieve analysis shall be taken from material sampled for the moisture den- sity test

- I. OBSERVED DATA SHOWN REPRESENTS THE SETTLEMENT (HEAVE) OF A GIVEN SETTLEMENT MARKER ESTIMATED BY AN AVERAGE LINE THROUGH THE SURVEY DATA AS OF JAN. 1, 1984. IF NO DATA IS GIVEN, INSUFFICIENT SURVEY DATA WAS AVAILABLE WITH WHICH TO ESTIMATE SETTLEMENT (HEAVE) OF THE MARKER.
- 2. LETTERED DESIGNATION OF SETTLEMENT MARKERS GIVEN IN FIGURE 2.5.4-44 AND 2.5.4-45.
- 4. APPROXIMATE PERCENTAGE OF TOTAL STRUCTURAL LOAD, INCLUDING MAJOR PIECES OF EQUIPMENT, AS OF JAN. 1, 1984. DOES NOT INCLUDE WEIGHT OF WATER FOR STRUCTURES 17, 18 AND 21.

3. 0.024 = SETTLEMENT, INCHES; -0.024 = HEAVE, INCHES.

FIGURE 2.5.4-70 SOIL MODEL - INTAKE STRUCTURE BEAVER VALLEY POWER STATION-UNIT 2 FINAL SAFETY ANALYSIS REPORT

BEAVER VALLEY POWER STATION - UNIT 2 FINAL SAFETY ANALYSIS REPORT

#### 2.5.5 Slope Stability

Both static and dynamic stability analyses of the riverward slope involving the service water pipelines leading to the intake structure were performed and are described in DLC (1976). The factors of safety were found to be acceptable.

The dynamic stability analysis of this slope was supplemented using more conservative seismic coefficients as indicated below. Additional failure surfaces through the silty clay layer in the soil profile were also considered. The results are presented in Figure 2.5.4-57 and were acceptable. (Refer to Figure 2.5.4-16 for location of section.)

Two methods of analysis were employed: the Simplified Bishop method and the Morgenstern-Price method. The Simplied Bishop method assumes a circular arc failure surface while the Morgenstern-Price method allows for an arbitrary shaped failure mass, which, in this case, was assumed to be a sliding wedge with straight line failure surfaces. The stability analyses were performed using the computer program LEASE II (SWEC 1980). LEASE II uses a pseudo-static approach to dynamic stability analysis in which a constant force is applied to each slice and is computed as the weight of the slice multiplied by a seismic coefficient. The horizontal seismic coefficient was taken as 0.125, corresponding to the ground surface acceleration for the SSE; the vertical seismic coefficient was taken as 0.083. This analysis was considered conservative since the applied pseudostatic force was constant and no consideration was given to the variation of acceleration with time, direction, or with depth in the soil profile.

The analysis of the intake channel slopes is discussed in Section 2.5.4.8.

The analysis of the stability of the slopes in the vicinity of the emergency outfall structure is fully described in Appendix 2.5E.
