2.5D-103 Direct Shear Test Report Boring 906, Sample 1 2.5D-104 Direct Shear Test Summary Boring 906, Sample 1

# 2.5D.1 INTRODUCTION

The purpose of this report is to summarize and present the data obtained from tests performed to evaluate the index and engineering properties of the in situ soils at the Beaver Valley Power Station (BVPS) site.

Attempts to obtain undisturbed samples of the in situ sands and gravels were unsuccessful. Consequently, laboratory testing of undisturbed samples was only performed on the intermediate and lower terrace silts and clays. Grain size analyses on the terrace sands and gravels are discussed in Section 2.5D.2.1, and in situ density tests performed at the foundation elevation of the reactor containment are given in Section 2.5D.2.4.

2.5D.2 Index Tests

## 2.5D.2.1 Grain Size Analyses

Sixty-two grain size analyses were performed on soil samples obtained from exploratory borings for Beaver Valley Power Station - Unit 1 (BVPS-1). Grain size analyses, predominantly of the upper terrace sands and gravels, performed on samples from the 100 series borings can be found in Appendix 2F of BVPS-1 FSAR (Duquesne Light Company (DLC) 1972a). Grain size analyses performed on the 300 series borings can be found in Appendix 2H of BVPS-1 FSAR (DLC 1972b).

Fourteen additional grain size analyses were performed on samples obtained from exploratory borings for Beaver Valley Power Station - Unit 2 (BVPS-2). They are presented on Figures 2.5D-1, 2.5D-2, 2.5D-3, 2.5D-4, 2.5D-5, 2.5D-6, 2.5D-7 and 2.5D-8.

To document the soils at the foundation grade of the BVPS-2 reactor containment, in-place density tests were performed at the locations shown on Figure 2.5D-9. At each of the test locations, a bag sample was obtained and a grain size analysis was performed. The in-place density tests are described in Section 2.5D.2.4. The grain size analyses performed on the bag samples are shown on Figures 2.5D-10, 2.5D-11, 2.5D-12, 2.5D-13, 2.5D-14, 2.5D-15, 2.5D-16, 2.5D-17, 2.5D-18, 2.5D-19 and 2.5D-20.

2.5D.2.2 Specific Gravity

Four specific gravity determinations were made on samples of the in situ soils from the BVPS site in accordance with the procedures given in Appendix IV (Department of the Army 1965). The results are summarized in Table 2.5D-1.

2.5D.2.3 Atterberg Limits and Natural Water Contents

Atterberg limits and natural water contents were performed on samples of the clays and silts of the intermediate and lower terraces as an index of their variability across the site. Natural water contents were performed in accordance with ASTM D2216 (Standard Methods of Laboratory Determination of Moisture Content of Soil). Atterberg limits were determined in accordance with the methods presented in Appendix III (Department of the Army 1965). The grooving tool was as specified in ASTM D423 (Liquid Limit of Soils).

Table 2.5D-2 summarizes the Atterberg limit and water content data. Additional natural water contents can be found by referring to the various test summary tables presented herein. Data from the 300 series borings were prepared by others and are included for completeness (DLC 1972a). The plasticity chart shown on Figure 2.5D-21 indicates that the in situ silts and clays are in general slightly to moderately plastic. The points plot roughly parallel to the A line indicating a similar mineralogy across the site.

2.5D.2.4 Unit Weights

Dry unit weights were determined for each sample tested. These data are presented in the various test summary tables. At the completion of the reactor containment excavation to approximately el 679 feet, a series of the in-place density tests were performed in accordance with ASTM D1556 (Test for Density of Soil in Place by the Sand Cone Method) at the locations shown on Figure 2.5D-9. A summary of the tests is presented in Table 2.5D-3. Bag samples were recovered and grain size analyses were performed. The grain size analyses are shown on Figures 2.5D-10, 2.5D-11, 2.5D-12, 2.5D-13, 2.5D-14, 2.5D-15, 2.5D-16, 2.5D-17, 2.5D-18, 2.5D-19 and 2.5D-20.

As a result of this program, a lens of stiff silty clay was discovered beneath the northern portion of the excavation, which was later removed end replaced with compacted fill. A more detailed discussion is given in Section 2.5.4.5.

2.5D.3 Constant Rate of Strain Consolidation Tests

2.5D.3.1 Procedure

Four constant rate of strain consolidation (CRSC) tests were performed on 2.5-inch diameter specimens of in situ clay soils trimmed from undisturbed samples. Specimen preparation was in accordance with Appendix VIII (Department of the Army 1965). Tests were performed according to the procedures described in Wissa and Heilburg (1969). The maximum past consolidation pressure was calculated by the Schmertmann method (Ladd 1971).

2.5D.3.2 Results

Table 2.5D-4 summarizes the results of all CRSC tests performed. Individual test results are presented on Figures 2.5D-22, 2.5D-23, 2.5D-24, 2.5D-25, 2.5D-26, 2.5D-27, 2.5D-28 and 2.5D-29. Three tests were performed on undisturbed block and bag samples recovered from a stiff silty clay layer that was discovered beneath the northern portion of the reactor containment excavation. The clay was removed from beneath the containment foundation. The clay layer extends beneath the northern portion of the safeguards area and refueling water storage tank.

Classification tests indicate that the clay has a liquid limit of 50, a plastic limit of 23, and a natural water content of about 23 percent. A natural water content equal to the plastic limit indicates that the clay has been overconsolidated. The presence of small fissures and discoloration along the fissure surfaces suggests that the precompression may be due to desiccation. The maximum past pressure ranged between about 13 and 18 ksf. The estimated overburden pressure prior to excavation for the containment foundation was about 7.5 ksf, resulting in an overconsolidation ratio (OCR) of between 1.7 and 2.4.

Incremental consolidation tests, unconsolidated undrained (UU) triaxial compression tests, and consolidated isotropically undrained (CIU) triaxial compression tests performed on this material are described in subsequent sections.

2.5D.4 Incremental Consolidation Tests

2.5D.4.1 Procedure

Four incremental consolidation tests were performed: three on clay samples from the lower terrace and one on the stiff silty clay recovered from the reactor containment excavation. Tests were performed on 2.5-inch diameter specimens in accordance with the method given in Appendix VIII (Department of the Army 1965). The maximum past consolidation pressure was determined by the Schmertmann method (Ladd 1971).

2.5D.4.2 Results

Table 2.5D-5 summarizes the results of the tests performed. Individual test results are presented on Figures 2.5D-30, 2.5D-31, 2.5D-32, 2.5D-33, 2.5D-34, 2.5D-35, 2.5D-36, 2.5D-37, 2.5D-38, 2.5D-39, 2.5D-40, 2.5D-41, 2.5D-42, 2.5D-43, 2.5D-44, 2.5D-45, 2.5D-46, 2.5D-47, 2.5D-48, 2.5D-49, 2.5D-50, 2.5D-51, 2.5D-52, 2.5D-53, 2.5D-54, 2.5D-55, 2.5D-56, 2.5D-57, 2.5D-58, 2.5D-59, 2.5D-60, 2.5D-61, 2.5D-62, 2.5D-63, 2.5D-64, 2.5D-65, 2.5D-66, 2.5D-67 and 2.5D-68.

2.5D.5 Unconfined Compression Tests

Forty-one unconfined compression tests were performed on undisturbed and remolded specimens for the site investigations of BVPS-1 (DLC 1972a, 1972b, 1979). A summary of the test results is presented in Table 2.5D-6. Individual test plots are presented for the AB series borings on Figures 2.5D-69, 2.5D-70, 2.5D-71, 2.5D-72, 2.5D-73, 2.5D-74 and 2.5D-75. The remaining test figures can be found in the references indicated. 2.5D.6 Unconsolidated Undrained Triaxial Compression Tests

2.5D.6.1 Procedure

Six unconsolidated undrained triaxial compression tests were performed on undisturbed tube and block samples in accordance with the procedures given in Appendix X (Department of the Army 1965). No membrane correction was considered necessary.

# 2.5D.6.2 Results

Curves of deviator stress versus axial strain are presented for each test on Figures 2.5D-76, 2.5D-77, 2.5D-78, 2.5D-79, 2.5D-80 and 2.5D-81. A summary of the test data is presented in Table 2.5D-7.

The block samples were recovered from a stiff silty clay layer beneath the reactor containment excavation as described in DLC's Report on Soil Densification (DLC 1976). The undrained shear strength of this material is about 4.3 ksf. Constant rate of strain and incremental consolidation tests were performed on this material and are described in Sections 2.5D.3 and 2.5D.4, respectively. Consolidated undrained isotropically triaxial compression tests on this material are presented in Section 2.5D.7.

2.5D.7 Consolidated Isotropically Undrained Triaxial Compression Tests

## 2.5D.7.1 Procedure

Two consolidated isotropically undrained (CIU) triaxial compression tests were performed during the site investigation for BVPS-2; one from boring OF6 and one from a block sample recovered from the stiff silty clay layer beneath the reactor containment excavation. Four additional tests were performed on undisturbed samples from the AB series borings for BVPS-1 (DLC 1979). These tests were performed in accordance with Department of the Army (1965) Appendix X.

Fifteen additional CIU tests were performed by Goldberg-Zoino and Associates, Inc. (DLC 1972a) on samples from the 300 series borings.

# 2.5D.7.2 Results

Table 2.5D-8 summarizes the CIU test results for all of the CIU tests performed by Stone & Webster Engineering Corporation (SWEC). Table 2.5D-9 summarizes the test results for the 300 series borings. Individual test results for the tests given in Table 2.5D-8 are shown on Figures 2.5D-82, 2.5D-83, 2.5D-84, 2.5D-85, 2.5D-86, 2.5D-87, 2.5D-88, 2.5D-89, 2.5D-90, 2.5D-91, 2.5D-92, 2.5D-93, 2.5D-94, 2.5D-95, 2.5D-96, 2.5D-97, 2.5D-98, 2.5D-99, 2.5D-100, 2.5D-101 and 2.5D-102. Individual test results from the 300 series borings are given in the BVPS-1 FSAR (DLC 1972a).

2.5D.8 Consolidated Drained Direct Shear Tests

# 2.5D.8.1 Procedure

Five drained direct shear tests were performed on specimens of sandy clay from sample 1 of boring 906 in accordance with the procedures given in Appendix IX (Department of the Army 1965). Two different rates of displacement were used: 1.5 mm/hr and 40 mm/hr.

# 2.5D.8.2 Results

The test results are shown on Figure 2.5D-103 and are summarized on Figure 2.5D-104. The drained friction angle is approximately 29.5 degrees with a cohesion intercept of about 0.15 tsf. The rate of strain has little effect on the test results for the materials tested.

## INTRODUCTION

This report presents the results of an evaluation of the stability of slopes in the vicinity of the Beaver Valley Power Station - Unit 2 (BVPS-2) emergency outfall structure (EOS). The work performed to prepare this report comprised subsurface investigation, laboratory testing and slope stability analyses.

The EOS is a Quality Assurance Category I structure which is to be constructed at the far western end of the site (Figure 1-1). Its intended purpose is to provide missile protection for the emergency discharge point of the service water system and to raise the discharge point above the elevation of the probable maximum flood (el 730 feet). Service water normally flows through the circulating water system to the cooling tower. In the event that this route is blocked, the service water will be rerouted through the EOS to the Ohio River. Piping leading from the EOS to the Ohio River is not classified as Category I.

#### SUBSURFACE INVESTIGATION

Eleven borings (EOS series) were drilled in the study area during the months of May and June 1982 by Eger Drilling, Inc. of Bridgeville, Pa. under the supervision of the Stone & Webster Engineering Corporation (SWEC). The locations of these borings and a number of others performed for previous investigations are shown in Figure 1-1. The PL series of borings were performed by others in conjunction with the construction of a sludge transport pipeline for the Bruce Manfield Power Plant (GAI 1976). Logs of borings performed under the supervision of SWEC are contained in Appendix A.

Four piezometers were installed, one each in borings EOS-1, -6, -7 and -7A. Piezometer EOS-6, apparently damaged during installation, is considered inoperable. Installation records for each piezometer can be found in Appendix A.

Along the plant access road, at the base of the valley wall, eight test pits were excavated at the locations shown in Figure 1-1. The test pit logs are given in Appendix A.

## SUBSURFACE CONDITIONS

The Beaver Valley Power Station is founded on a glacial outwash terrace deposited by higher stages of the Ohio River during the Pleistocene age. The study area is at the extreme western end of the terrace where it begins to pinch out against the steep bedrock valley wall. Soil profiles developed from the subsurface investigation data are presented in Figures 3-1 through 3-5. The locations of the sections are shown in Figure 1-1. Due to the complex character of the soil deposits, it was generally not possible to develop a soil profile showing specific continuous soil types between adjacent borings. Instead, at least with the soil data obtained from the EOS borings, soils were categorized according to mode of deposition and roughly by gradation, e.g., coarse and fine colluvium.

Generally, the borings indicate that, on the steep valley walls, the bedrock surface is overlain by what is termed coarse colluvium, derived from the weathering of the parent sandstone bedrock at higher elevations. From the split spoon samples, it can be described as a sandy gravel, largely composed of weathered and decomposed, angular sandstone fragments contained within a matrix of more severely weathered sandstone. The coarse colluvium is, in turn, overlain by fine colluvium derived from the weathering of shales, claystones, and limestones. It is a heterogeneous sandy clay containing fragments of the parent rock. The colluvial soils diminished in thickness with increasing elevation on the valley wall and were found to be absent above el 850 feet (GAI 1976). At the base of the valley and extending northward to the river, there exists an interfingering of the colluvial soils with the outwash and alluvial soils deposited by the Ohio River. Figure 3-2 illustrates in greater detail the complexity of the soil conditions in the vicinity of borings EOS-1 and EOS-6. To the north of boring EOS-10 (Figure 3-1), the terrace has been eroded and portions of the original granular outwash deposits have been replaced with more recent river deposits of silt and clay. This layer is discussed in greater detail in Section 5.3.

### GROUNDWATER

Several piezometers were installed within the granular terrace soils of the main plant area and groundwater levels have been recorded on a regular basis since 1977. Groundwater levels in the terrace have been found to follow quite closely the levels of the Ohio River with little observed time lag (SWEC, 1980). Based on the soil profiles in the study area, there should be good groundwater communication between the granular soils of the terrace and the Ohio River. Consequently, groundwater levels within the terrace can be expected to closely follow the various flood stages of the Ohio River which are as follows:

Normal water level: el 665 feet Twenty-five year flood: el 690 feet Probable maximum flood: el 730 feet

Four piezometers were installed within the soils of the colluvial slope, one each in borings EOS-1, -6, -7, and -7A. The piezometer installed in boring EOS-6 was damaged and is considered inoperable. Installation details can be found in Appendix A. The piezometer in boring EOS-7, installed near the top of rock, did not indicate the presence of groundwater, nor did any of other piezometers, even after a heavy rain. The relatively impermeable surface soils and the steepness of the valley walls limit the percolation of runoff into the underlying coarse colluvium and groundwater flow through the bedrock is small; observed groundwater flow from bedrock wells averaged 2 to 4 gpm and surface bedrock seeps along joints were generally less than 1 to 2 gpm (DLC 1983).

Field descriptions indicated that the layered silt/silty sand found in borings EOS1 and EOS6 (Figure 3-2) was somewhat wetter than the surrounding, more coarse grained soil and Hendron (1975) noted what appeared to be a spring at what is approximately the location of boring EOS-1. As mentioned previously, a piezometer was installed in boring EOS-1, but it did not indicate the presence of groundwater. Eight test pits were excavated along the plant access road as shown in Figure 1-1. They should have penetrated this apparent wet zone if it existed beneath the access road; groundwater was not encountered in any of the test pits. It is felt that the condition found in borings EOS-1 and EOS-6 is localized and not extensive.

#### PROPERTIES OF SUBSURFACE MATERIALS

A laboratory testing program was conducted to evaluate the properties of the fine grained soils in the study area. Details of the testing program and the results contained in Appendix B are discussed in this section. Properties of the coarse grained soils, for which undisturbed sampling was not possible, were evaluated from correlations with standard penetration test (SPT) blow counts and sample descriptions, such as Terzaghi and Peck (1967) and Department of the Navy (1971).

#### 5.1 COARSE COLLUVIUM

The effective friction angle of the coarse colluvium will be high due to the nature of the material and, for this analysis, a value of 40 degrees was selected. The total unit weight was assumed to be 135 pcf.

#### 5.2 FINE COLLUVIUM

Shales, claystones and limestones have weathered to form the fine colluvium consisting of a heterogeneous sandy clay containing numerous rock fragments. As the material creeps downslope during the weathering process, slickensides (presheared, polished surfaces) may develop which represent inherent planes of weakness along which residual strength properties are considered to apply.

Two direct shear tests were performed on remolded split spoon samples of fine colluvium to evaluate its residual friction angle, details of which are presented in Appendix B. One test was performed on a sandy clay (Appendix B, Figure B-28) from which the coarse material was removed by washing on a No. 40 sieve and the other test was performed on a sample of silty clay (Appendix B, Figure B-25). The measured residual friction angles were 22 and 28 degrees, respectively.

Testing specimens of the fine colluvium which included the coarse grained materials would have resulted in measured residual friction angles which were too high, since there would have been a high probability of including a rock fragment across the relatively small shear plane of the direct shear device. In situ, the residual friction angle will be larger due to the presence of the rock fragments, gravel, and sand within the fine colluvium. Therefore, sufficient conservatism is included in the chosen residual friction angle of 28 degrees for the stability analysis. Also, the heavy vegetation on the slope will act to reinforce the slope and in effect increase the friction angle of the soil cover. The total unit weight of the fine colluvium was assumed to be 125 pcf.

Two additional direct shear tests on remolded split spoon samples of fine colluvium recovered from the PL series of borings were reported by Hendron (1975). They were performed on what was described in the boring logs as sandy clayey silt (liquid limit = 29 percent; plasticity index = 7.4 percent). The residual friction angles measured were 32 degrees and 33 degrees.

5.3 ALLUVIAL SOILS

Sand, Silty Sand, Sandy Gravel, Gravelly Sand

The derivation of the engineering soil properties of the terrace sands and gravels at the Beaver Valley site, fully described in Section 2.5.4.2 of the BVPS-2 Final Safety Analysis Report (DLC 1983), are summarized below:

| Total ur | nit | weight:   |        |         |  |
|----------|-----|-----------|--------|---------|--|
| above    | gr  | oundwater | table: | 125 pcf |  |
| below    | gr  | oundwater | table: | 136 pcf |  |

Effective friction angle: 30 degrees

For the purpose of simplifying the computer model, a value of 125 pcf was used for this material, since potential failure surfaces critical to the integrity of the EOS did not pass through the terrace sands and gravels below the groundwater table.

#### Silty Clay

The properties of the silty clay layer of the riverward slope were evaluated from the results of the laboratory testing program described in Appendix B.

The top surface of the clay (Figure 3-1) is at about el 690 feet. From borings EOS-4 and EOS-4A, the upper 25 feet is described as moderately plastic and medium stiff to stiff, with standard penetration test N values in the range of 8 to 10 blows per foot. As an index test, unconfined compressive strengths measured in the field with a pocket penetrometer were 1 to 2 tons per square foot (tsf). A consolidation test (Appendix B, Figure B-7) performed on an undisturbed specimen of the upper clay indicates it to be slightly overconsolidated to normally unconsolidated under the weight of the recently added uncontrolled fill.

At about el 665 feet there is a color change from brown to gray. The consistency of the lower clay is described as soft to medium stiff with standard penetration test N values of 6 to 9 blows per foot. Field unconfined compressive strengths were 0.75 to 1.0 tsf. Atterberg limits of the upper and lower clays are similar indicating consistent minerology.

The primary differences between the upper and the lower clay appear mainly to be color and consistency, probably as a direct result of a lowering of the groundwater table. This hypothesis is supported by the change in color and consistency at about el 665 feet, corresponding to the present normal water level of the Ohio River.

Two series of consolidated isotropically undrained (CIUC) triaxial compression tests were performed on undisturbed samples from boring

EOS-4A: sample UO-4 from the upper clay and sample UO-7 from the lower clay. The effective friction angle measured for the upper clay was 33.7 degrees (Appendix B, Figure B-14). The effective friction angles measured for the samples of the lower clay were 31 and 33.9 degrees (Appendix B, Figure B-18). Due to some sample disturbance upon extrusion from the sampling tube, it was necessary to trim the test specimens of the lower clay to a smaller diameter. Consequently, the measured effective friction angle may be low as a result of some sample disturbance. Closer to the river, as indicated by samples recovered from boring EOS-5, the soils are softer in consistency and more silty. The upper 12 feet (el 683 feet to el 671 feet) of boring EOS-5 is described as brown sandy silt/silt with standard penetration test N values of 2 to 3 blows per foot. Between el 671 feet and 655 feet, the soil is described as sandy clay/sandy silt with standard penetration test N values of 4 to 5 blows per foot. A series of three CIUC triaxial compression tests was performed on an undisturbed sample of the sandy clay from boring EOS-5 (Appendix B, Figure B-21). An effective friction angle of approximately 35 degrees was measured.

Based on the triaxial test results, for the analysis of the riverward slope for static or long-term conditions, the recent river deposits were considered to be a single layer with an effective friction angle of 32 degrees and a total unit weight of 125 pcf. Failure surfaces critical to the emergency outfall structure were considered to be through the deeper soils and, for this reason, the generalized soil profiles (Figures 6-5 and 6-6) do not include the upper silts found in boring EOS-5.

Undrained strength parameters of the clay were used for the dynamic analysis of the slope. The entire clay layer was assumed to be normally consolidated and was divided into several sublayers. The undrained strength of each sublayer was determined from the ratio of undrained shear strength to effective confining pressure,  $s_u/\overline{\sigma}_c$ ; an average value of 0.4 was determined from the triaxial test results. The friction angle was set equal to zero for the undrained case.

### Silt, Sandy Silt, Layered Silt/Silty Sand

As shown in the soil profile detail in Figure 3-2, in the vicinity of borings EOS-1 and EOS-6, there is an upper layer of dense or stiff, somewhat clayey, silt which is underlain by a layered silt/silty fine sand.

A series of three CIUC triaxial compression tests was performed on an undisturbed specimen of the upper material from boring EOS-1A. It was described as a slightly plastic, silty clay/clayey silt and the measured effective friction angle was 34.2 degrees (Appendix B, Figure B-8). Pore pressure response measured during the tests indicate that the soil is dilative during shear; i.e., the pore pressures increased during the early stages of the test and then decreased.

A single CIUC triaxial compression test was performed on the layered silt/silty fine sand (Figure B-12). The effective friction angle was 35.5 degrees, and this test specimen was also dilative during shear.

Soil conditions are complex at the base of the valley where it intersects the terrace. To account for the types of soils shown in Figure 3-2 in the stability analysis, the generalized soil profile discussed in Section 6 includes a trapezoidal zone of soil at the bottom of the valley with an effective friction angle of 30 degrees and a total unit weight of 120 pcf.

#### 5.4 UNCONTROLLED FILL

Uncontrolled fill placed in this area was material removed from onsite excavations. Boring EOS-4 shows the fill material to be sandy gravel and gravelly sand with standard penetration test N values of 14 to 29 blows per foot. The material from boring EOS-10 is similar but blow counts are lower, ranging between 2 and 10 blows per foot. Since the fill was placed without control and with a minimum of compactive effort, in-place densities can be expected to vary widely. Based on the granular materials encountered in the borings, the uncontrolled fill was assumed to have an effective friction angle of 30 degrees and a total unit weight of 120 pcf. In terms of the overall stability analysis of the riverward slope, the soil properties assumed for the uncontrolled fill are not critical since its effect is mostly to add weight to a given slice.

#### 5.5 COMPACTED GRANULAR FILL

Some regrading and filling of the area around the EOS will be required. The evaluation of engineering soil properties for the compacted granular fill used at the site was discussed in Section 2.5.4.5 of the BVPS-2 Final Safety Analysis Report (DLC 1983). The following properties were used in this analysis:

| Effective friction and | gle: 36 degrees |
|------------------------|-----------------|
| Total unit weight:     | 136 pcf         |

## SLOPE STABILITY

Both static and dynamic stability of the slopes in the vicinity of the EOS were examined. The steep valley wall to the south of the EOS is termed the colluvial slope; the terrace to the north of the EOS is termed the riverward slope. The stability analysis of each slope will be discussed under a separate heading.

Two methods of analysis were employed: the simplified Bishop method and the Morgenstern-Price method. The simplified Bishop method assumes a circular arc failure surface and the Morgenstern-Price method allows for an arbitrary shaped failure mass, which, in this analysis, was assumed to be a sliding wedge with straight line boundaries. The stability analyses were performed using the computer program Lease II (SWEC 1980).

The dynamic stability analyses included the effect of earthquake accelerations and the resulting inertial forces applied to the potential sliding mass in the event of the safe shutdown earthquake (SSE). Lease II uses a pseudo-static approach in which a constant force is computed as the weight of a given slice multiplied by a seismic coefficient.

This type of analysis is considered conservative since the applied inertial forces are constant and are related to the peak acceleration of the SSE. No consideration is given to the time variation of acceleration during an actual earthquake event nor is consideration given to the cyclic nature of the direction of acceleration and the resulting seismic forces.

The horizontal ground surface acceleration for the SSE at the site has been determined to be 0.125g and the vertical acceleration is taken as two thirds of the horizontal or 0.08g (DLC 1983). Therefore, the following seismic coefficients were used for both the riverward slope and colluvial slope stability analyses:

horizontal:  $\alpha_h$  = 0.125 vertical:  $\alpha_v$  = 0.08

The pseudo-static forces were applied horizontally away from the slope, i.e., downslope, and vertically down.

## 6.1 COLLUVIAL SLOPE

Profiles representative of soil conditions within the colluvial slope in the immediate vicinity of the EOS are presented in Figures 3-1 and 3-3. As discussed in Section 3, the soil conditions within the slope consist of fine colluvium overlying coarse colluvium which, in turn, overlies bedrock. At the base of the slope, there has been a complex and somewhat unpredictable interfingering of the colluvial soils with alluvial sands and silts deposited by the Ohio River.

#### BVPS-2 UFSAR

On a large scale, the soil and conditions depicted in Figures 3-1 and 3-3 are similar. Since the data obtained from the EOS series of borings are the most recent (1982) and since the engineering soil properties used were developed from soil samples obtained from these borings, more emphasis was placed on the EOS borings when developing the computer model to use in the stability analysis. Section 1-1A (Figure 6-1) depicts the generalized soil profile used in the analysis of the colluvial slope. It was developed from Figure 3-1, but simplified somewhat to facilitate the analysis.

The EOS is shown on the generalized soil profiles at its approximate distance from the toe of the slope so that conclusions can be drawn regarding the impact of any potential sliding of the slope on the structure.

Groundwater levels within the lower portion of the slope were assumed to coincide with the normal level of the Ohio River at el 665 feet for the static case and at the level of the 25-year flood, el 690 feet, for the dynamic case.

#### 6.1.1 Colluvial Slope - Static Case

Results of the analysis indicate that the overall stability of the colluvial slope under static or long-term loading conditions is acceptable. Several typical circular arc failure surfaces examined using the simplified Bishop method of analysis are shown in Figure 6-1. Failure surfaces analyzed using the Morgenstern-Price method are shown in Figure 6-2.

The analysis shows that the fine colluvium is generally stable and that movement of the entire mass of soil downslope is not likely to occur. Safety factors of potential failure surfaces which include the majority of the fine colluvium are greater than 1.5. However, since the residual friction angle of the fine colluvium chosen for the analysis is approximately equal to the angle of the slope above el 780 feet, the analysis did indicate that minor surface sloughing of the upper slope (above el 780 feet) was possible; i.e., shallow circular arcs exhibited safety factors of 1.0. Deeper circular arcs through the upper slope, such as the typical one shown in Figure 6-1, had safety factors of about 1.3 and were considered marginally stable. The distance from the EOS to the toe of this circular arc is about 160 feet and is sufficient to preclude structural damage should movement along the surface actually occur.

#### 6.1.2 Colluvial Slope - Dynamic Case

Results of the analysis, including the effect of pseudo-static forces determined for the peak accelerations of the SSE, indicate that the overall stability of the colluvial slope is acceptable. Failure surfaces examined using the Morgenstern-Price method are shown in Figure 6-2. Several typical circular arcs analyzed using the simplified Bishop method are shown in Figure 6-3.

The analysis shows that movement of the entire mass of fine colluvium downslope is not likely. Safety factors of potential failure

#### BVPS-2 UFSAR

surfaces which include the majority of the fine colluvium are 1.1 or greater. However, the minimum factor of safety for circular arcs within the fine colluvium above the mid-slope region was 0.8. A typical circle is shown in Figure 6-3. A factor of safety less than 1.0 indicates that the fine colluvium in this region may not possess sufficient residual shear strength to resist the additional forces developed by the horizontal and vertical accelerations applied to the soil by the SSE.

Neglecting the fact that the LEASE II pseudo-static analysis is conservative and assuming that some movement of the slope will actually occur in the event of the SSE, the amount of movement that may occur along this typical failure surface was estimated by an approach first suggested by Newmark (Newmark 1965) using the computer program SIDES (SWEC 1980). This analysis is based upon the following:

- 1. An earthquake acceleration-time history record may be input, normalized to any peak acceleration.
- 2. No motion will occur within the slope until the strength of the soil is exceeded, i.e., the acceleration is greater than the limiting acceleration producing a safety factor of 1.0. For the typical circle shown in Figure 6-3, the limiting horizontal and vertical accelerations were 0.045g and 0.030g, respectively.
- 3. When the soil moves, it slides as a rigid mass downslope; movement upslope is conservatively disallowed.
- 4. Displacements occurring each time the soil strength is exceeded are cumulative throughout the duration of the earthquake.

The time histories from the El Centro 1940 earthquake northsouth component and the 1952 Kern County earthquake (S69E component of the Taft record) were used. The El Centro record was chosen because it is representative of the strongest motions available from deep soil sites, whereas Taft was chosen because of its wide frequency range and strong motion characteristics. For these acceleration-time histories, the cumulative displacement of the slope was less than 1 in. This magnitude of movement is considered to be small and, given the distance of the EOS from the potential sliding mass, no damage to the EOS will occur.

Safety factors increase as the circles become larger. A typical circular arc with a safety factor of 1.0 is shown in Figure 6-3 and is considered to be marginally stable. At the limit is the large radius circular arc which includes almost all of the fine colluvium within the sliding mass, its safety factor is 1.1. Sliding wedge stability analyses were performed using the Morgenstern-Price method for failure surfaces which included most of the fine colluvium. The results shown in Figure 6-2 indicate factors of safety of 1.1 to 1.2 which are similar to those obtained using the Bishop method (Figure 6-3) for the large radius circle.

#### BVPS-2 UFSAR

In summary, the overall stability of the colluvial slope for dynamic conditions is acceptable. Failure surfaces which could affect the structure should movement actually occur along them exhibited safety factors which were adequate. Safety factors for extensive failure surfaces encompassing most of the fine colluvial material were about 1.1 for both the simplified Bishop and the Morgenstern-Price methods of analysis. The fine colluvium above about the mid-slope region appears to be unstable. However, failure surfaces within this area will involve limited amounts of material and are of a sufficient distance away from the EOS that any potential movement along the failure surfaces will not affect the structure itself.

### 6.2 RIVERWARD SLOPE

Generalized soil profiles showing the soil properties used in the stability analysis of the riverward slope are given in Figures 6-4 and 6-5. The soil profiles, based on Section 3-3 (Figure 3-5), are simplified somewhat to facilitate analysis. An amount of compacted granular fill was added to the soil profile in the immediate vicinity of the structure to account for raising the existing grade to el 730 feet. No differentiation was made between granular colluvial and alluvial soils for the purpose of assigning soil properties to the computer model. The soil model used in the dynamic analysis (Figure 6-6) is the same as that for the static case except that undrained soil properties were substituted for the clay layer.

6.2.1 Riverward Slope - Static Case

Results of the analysis (Figure 6-4) indicate that the riverward slope is stable under static loading conditions. The minimum factor of safety was found to be 1.6 for a very shallow circular arc. Potential failure surfaces through the silty clay layer were considered to be the most critical to the structure; two typical circular arcs are shown which exhibit adequate safety factors.

## 6.2.2 Riverward Slope - Dynamic Case

Results of the analysis indicate that the riverward slope is stable under dynamic loading conditions. The analysis was performed using both the simplified Bishop method and the Morgenstern-Price method. A number of typical failure surfaces is shown in Figure 6-5.

Since the most critical failure surfaces were considered to be through the clay layer, the groundwater level was taken at el 665 feet, the normal Ohio River level. Generally, the dynamic analyses, including the effect of SSE loading, is performed for groundwater levels appropriate to the 25-year flood. As stated in Section 4, the groundwater level within the granular soils of the riverward slope will closely follow the level of the Ohio River. However, given its lower permeability, it is unlikely that groundwater levels in the clay would change substantially during the relatively short duration of the 25year flood. It was therefore considered acceptable to evaluate failure surfaces through the clay layer with the groundwater level taken at el 665 feet. A deep circular arc, the majority of which passed through granular soils, was analyzed for both normal water and the 25-year flood as shown in Figure 6-5. The computed safety factors were acceptable.

## CONCLUSIONS

The results of the stability analyses indicate that there is a potential for movement of the upper portions of the colluvial slope; however, these movements will not affect the EOS, should they actually occur. The lower portion of the colluvial slope is stable for both static and dynamic loading conditions.

The riverward slope is stable for both static and dynamic loading conditions.

FORM G-G-O PIEZOMETER INSTALLATION REPORT PIEZOMETER NO. P-EOS-1 STONE & WEBSTER ENGINEERING CORP. J.Q. NO. SITE 12241 Beaver Valley Power Station-Unit 2 INSPECTOR \_\_ J. W. McCoy DATE \_\_\_\_\_6-7-82 ORILLER Eger/Jarvis COORDINATES N3843 E6223 741.0 ft \_ GROUND ELEV. INSTALLED IN BORING EOS-1 743.9. ft ELEY. TOP OF LEADS. RIG & CREW TIME \_\_\_\_\_ 3 hours DETAILED INSTALLATION DESCRIPTION : Hole cleaned to 52.0 ft. Filled with sand to 27 ft. Bentonite seal from 27 to 25 ft. 35" Sand placed from 25 to 22 ft 9 in. Porous stone - SOILTEST piezometer mmm 7771 with centering spider 10 ft from piezometer tip installed. 1 ft 9 in sand placed above piezometer. 3.5 ft Bentonite seal placed. Sand placed 2 ft from ground surface. Guard pipe grouted into place. Sand DESCRIPTION OF PIEZOMETER TIP AND STAND PIPE ASSEMBLY 15'6" 2 ft section of SOILTEST porous 521 Bentohite stone piezometer. Approximately 24 ft 3/4 in I.D. PVC 19' riser pipe. 20'9" 2 DESCRIPTION OF SOIL AT TIP ELEVATION : 22'9" Silt - wet with sandy silt lenses. Sand 251 251 Bentonite 27' Sand 52' NOTE : SKETCH IN ALL COMPONENTS PERTINENT TO THE INSTALLATION WITH APPLICABLE, DIMENSIONS EG : FILTER SAND, SEALS, GROUT, CASING, ETC.

#### B1 INTRODUCTION

The purpose of the laboratory testing program described herein was to evaluate the index and engineering properties of the soil samples recovered from EOS series of borings that are pertinent to the study of the stability of slopes in the vicinity of the emergency outfall structure. The scope of the testing program consisted of the following:

Atterberg Limits and Grain Size Analyses Consolidation Test Triaxial Compression Tests Direct Shear Tests

B2 INDEX TESTS

B2.1 Grain Size Analyses

Eight grain size analyses were performed on split spoon samples, the results of which are shown in Figures B-1, B-2, B-3, B-4, and B-5. Tests were performed in accordance with Appendix V of WES (1970).

B2.2 Atterberg Limits and Natural Water Contents

Atterberg limits and natural water contents were performed on selected split spoon and undisturbed samples as summarized in Table B-1 and Figure B-6. Natural water content determinations were made in accordance with ASTM D2216. Atterberg limits were determined in accordance with the methods presented in Appendix III of WES (1970); however, the grooving tool used was as specified in ASTM D423.

B3 CONSTANT RATE OF STRAIN CONSOLIDATION TESTS

A single constant rate of strain consolidation (CRSC) test was performed on a 2.5-inch diameter by 1.0-inch high specimen of sandy clay trimmed from an undisturbed sample from boring EOS-4 on the riverward slope. Specimen preparation was in accordance with Appendix VIII of WES (1970). Testing was performed according to the procedures described by Wissa and Heilberg (1969).

The results of the test (Figure B-7) indicate that the clay is only slightly overconsolidated with a maximum past pressure of about 5.6 ksf, compared to an in situ vertical effective stress of about 4.6 ksf.

#### B4 TRIAXIAL COMPRESSION TESTS

Twelve consolidated isotropically undrained triaxial compression tests were performed on undisturbed samples of the alluvial soils in accordance with the methods described in Appendix X of WES (1970). Table B-2 summarizes the results shown in Figures B-8, B-9, B-10, B-11, B-12, B-13, B-14, B-15, B-16, B-17, B-18, B-19, B-20, B-21, B-22, B-23, and B-24.

B-1

#### B5 DIRECT SHEAR TESTS

Two direct shear tests were performed on 2.5-inch diameter, remolded specimens of the fine colluvial material, the results of which are presented in Figures B-25, B-26, B-27, B-28, B-29, and B-30 and summarized in Table B-3. The tests were performed in accordance with Appendix IX of WES (1970); sample preparation is described in this section.

Since the residual friction angle was desired, tests were performed on remolded split spoon samples, using only the finer fraction of the fine colluvium. Test 3 was performed on a sample of silty clay which did not contain the coarser fractions, and Test 4 was performed on the minus No. 40 sieve fraction of the sample. The remolded samples were tamped into the direct shear box to obtain an initial specimen height of one inch. The specimens were initially consolidated to approximately twice the in situ vertical effective stress. The normal load on the test specimens was then reduced and the specimens reconsolidated to approximately the in situ vertical effective stress. Tests were terminated after about one inch of cumulative horizontal displacement since material was slaking from between the halves of the direct shear box.

The measured residual friction angles were 22 and 28.4 degrees.
