ABSTRACT

This report is a critical review of the published literature on the adsorption of radioactive krypton and xenon on activated charcoal. The report includes a tabulation and evaluation of the adsorption coefficients for these two gases as related to temperature, pressure, moisture, mass transfer effects, and the nature of the carrier gas. Wherever possible, the resulting data have been used to develop simple correlations for quantitatively evaluating the effects of these parameters on noble gas adsorption. Important conclusions of the study include the observations that (a) individual charcoals have a wide range of adsorption coefficients and therefore the performance of a given bed is heavily dependent on the quality of the charcoal it contains; (b) because of the detrimental effects of mass transfer on noble gas adsorption, consideration should be given to including this factor in developing technical specifications for adsorption beds; and (c) additional research is needed on the determination of the inter-relationship of moisture and temperature and their effects on adsorption bed performance.

ϵ	fraction of adsorption bed consisting of interparticle void volume, dimensionless
γ	tortuosity factor for interparticle diffusion, dimensionless
H	height equivalent to one theoretical plate, cm
h	reduced height equivalent to one theoretical plate, dimensionless
k	adsorption coefficient, cc(NTP)/gm
Δk	loss in adsorption coefficient, present
k_a, k_b	adsorption coefficients at temperatures T_a and T_b, respectively, cc(NTP)/gm
k_1	adsorption coefficient of xenon (krypton) at infinitely low xenon and krypton concentrations, cc(NTP)/gm
K_1	adsorption coefficient at 1 atmosphere (abs), cc(NTP)/gm
K_2	adsorption coefficient at pressure, P_2, cc(NTP)/gm

LIST OF SYMBOLS (Continued)

Symbol	Definition
λ_p	coefficient for axial dispersion, dimensionless
m	mass of adsorbent, gms
n	number of data points
N	number of theoretical plates
NTP	normal temperature and pressure [25°C and 1 atmosphere (abs.)]
P	partial pressure of the adsorbed gas, atmospheres
P_o	vapor pressure of the pure liquid at the temperature of the measurement, atmospheres
ppm	concentration, parts per million
q	volume of adsorbed gas per gram of adsorbent, cc(NTP)
ρ	bulk density of the adsorbent, gm/cc
RH	relative humidity
R	ideal gas constant, cal/gm mole-°K
σ	geometric standard deviation, dimensionless
T	absolute temperature, °K
$t_{\frac{1}{2}}$	isotopic half life, sec
$\dot{V}$	flow of carrier gas, cc/sec
v_f	reduced interparticle velocity, dimensionless
V_s	superficial carrier gas velocity, cm/sec
z	$mk/\dot{V}t_{\frac{1}{2}}$, dimensionless

ACKNOWLEDGMENT

The authors gratefully acknowledge the many helpful suggestions and comments offered by their colleagues in the preparation of this report. Particular appreciation is expressed to Clifford A. Burchsted, Engineering Technology Division, Oak Ridge National Laboratory, and to Ronald R. Bellamy, Division of Site Safety & Environmental Analysis, U. S. Nuclear Regulatory Commission, for their detailed reviews of the final manuscript, and to Professor Yves Alarie, Chairman, Department of Industrial and Environmental Health Sciences, Graduate School of Public Health, University of Pittsburgh, for providing time to the senior author to complete this report.

Chapter 1

INTRODUCTION

Of all the components in the safety systems of a nuclear reactor, among the most difficult to quantify in terms of performance are the activated charcoal beds used to remove radioactive noble gases. Knowledge of the basic parameters influencing adsorption behavior has often not been sufficient to permit the calculation of adsorption coefficients under the full range of necessary conditions. Further complicating this situation is that samples of charcoal taken from sequential lots, or even from the same lot, can be significantly different in their adsorption effectiveness.

In spite of this situation, it appears that existing uncertainties in the analyses of the performance of fission gas adsorption systems can be reduced. This can be accomplished through better summarization and interpretation of data relating to the various parameters that affect the performance of such systems. The resulting information should make it possible not only to gain a better understanding of the variabilities associated with the performance of adsorption systems, but also to predict their behavior under conditions that differ substantially from those described in licensing documents for specific nuclear facilities. The purpose of this report is to review the published information on the adsorption of krypton and xenon and to tabulate and present it in a format that accomplishes these goals.

1.1 Correlations With Surface Area

If the adsorption coefficients for krypton and xenon can be correlated successfully with commonly measured physical parameters, such as pore

structure or the surface area of the adsorbent, then these parameters can serve as secondary standards in evaluating charcoals. However, current correlations between surface areas and adsorption coefficients of activated charcoals are not good. This can be shown by specific examples from the literature. As may be noted from the data in Table 1.1, First, et al. (1971b), were unable to observe any apparent correlation between the adsorption coefficients for krypton and the surface areas of several samples of charcoal tested. Table 1.2, from Kitani, et al. (1968), and Table 1.3, from Nakhutin, et al. (1976), also show no apparent relationship between either the pore volume or the surface area and the adsorption coefficient for krypton. In experiments with radon, Strong and Levins (1979) observed a linear relationship between surface area and the adsorption coefficient. Why a similar relationship has not been observed for krypton and xenon is not known.

1.2 Correlations With Density

Nankhutin, et al.(1976), showed that there appears to be a positive correlation between the apparent density of a charcoal sample and its adsorption coefficients for krypton and xenon. This result may be related to the observation of Kovach and Etheridge (1973) that the adsorption coefficient for krypton was a maximum if the charcoal was activated to give a surface area of 900 square meters per gram (Figure 1.1). Schroeter, et al. (1974), obtained a patent for the use of dense charcoals for the adsorption of krypton and xenon. The data developed by these authors (Table 1.4) also show clearly that the

adsorption coefficients for krypton and xenon are not proportional to the surface area of the adsorbent, and that high surface area and/or pore volume are not necessarily indicators of high adsorption capacity for krypton and xenon. This is also shown by the data of Kovach and Etheridge (Figure 1.1). In view of past practice, this is an important point for the U. S. Nuclear Regulatory Commission and other regulatory agencies to recognize.

1.3 Correlations Among Charcoals at Different Temperatures

Correlations between coefficients for the adsorption of different gases on a single sample of charcoal are more easily established. As may be noted from Figure 1.2, charcoals that have good adsorption coefficients for krypton and xenon at one temperature are likely to have correspondingly good adsorption coefficients for these same two gases at another temperature. Similarly, a charcoal that has a high adsorption coefficient for krypton is likely to have a high adsorption coefficient for xenon. Data from the published literature illustrating this latter fact are shown in Figure 1.3.

1.4 Predictions of Adsorbent Performance

Although such a capability would be desirable, it is not possible at this time to predict the adsorption coefficients for krypton and xenon with high accuracy on the basis of the physical properties of a charcoal. Chapters 2 through 6 of this report describe present approaches to the development of other general and, hopefully, more useful correlations. In Chapter 2, the adsorption coefficients for dilute krypton and xenon, at atmospheric pressure and under moisture free conditions, are tabulated and analyzed as a function of temperature.

Chapters 3, 4, and 5 present data and analyses related to the effects on adsorption of moisture, pressure, and concentration, respectively. Chapter 6 then concludes with an analysis of the effects of mass transfer. It is hoped that the provision of all such information in a single document will prove useful both in the design of fission gas adsorption beds and in the evaluation of their performance.

Chapter 2

THE EFFECTS OF TEMPERATURE ON THE ADSORPTION OF KRYPTON AND XENON

Coefficients for the adsorption of dilute krypton or xenon from a dry carrier gas at one atmosphere are summarized in Tables 2.1.1 through 2.1.14. These data are based on a review of reports obtained through searches of Chemical Abstracts, Nuclear Science Abstracts, Atomindex and the computerized data bank of the Nuclear Safety Information Center. In these Tables, the adsorption coefficients are presented separately for each carrier gas, since the carrier gas can strongly influence the numerical value of the coefficient. Information regarding the nature of each adsorbent and the experimental conditions under which the data were obtained are also included in the Tables.

In order to provide the most useful tabulation of the available data, the authors have taken the liberty of omitting from the summary tables the results of tests which they judged to be misleading or in error. To make such a judgment, two tests of consistency were applied. As will be shown in Chapter 6, the adsorption coefficient should remain independent of carrier gas velocity. Whenever this was not the case, reliance on the data was considered unjustifiable and the results of these particular experiments were omitted. A second requirement was that, in a given test, sufficient charcoal should have been used to negate the effects of dead space. In some experiments, patterned after the methodology of gas chromatography, such small amounts of charcoal were used that it appears doubtful that the results could be either accurate or representative. In these cases, the data were again omitted.

Coefficients for the adsorption of krypton and xenon from oxygen, nitrogen, and air are listed in Tables 2.1.3 to 2.1.5 and 2.1.11 and 2.1.12. The data in all of these Tables, however, may not be equivalent. Kitani, et al. (1968), observed that at $0^{o}C$ differences existed in the adsorption of krypton from oxygen, from nitrogen, and from equal mixtures of these two gases. As may be noted in Figure 2.1, Schumann (1973) found that the coefficients for the adsorption of krypton at $-20^{o}C$ from oxygen-nitrogen mixtures depended on the percent of oxygen present. Examination of these findings indicates that adsorption coefficients obtained with a nitrogen carrier gas are low (conservative) in relation to those obtained with air or oxygen.

2.1 Analysis of Adsorption Data

To calculate the coefficients for the adsorption of krypton and xenon on charcoal, use was made of the Antoine equation (Antoine, 1888) where k, the adsorption coefficient [in units of cc (NTP)/gm], is expressed as follows:

$$k = e^{\left(A + \frac{B}{C + T(^{o}C)}\right)} \qquad (2.1)$$

The geometric standard deviation, σ, is given by:

$$\ln(\sigma) = \sqrt{\frac{\Sigma_n \left[\ln(k_i) - \ln(k_i')\right]^2}{n - 3}} \qquad (2.2)$$

where k_i' is the estimate of the i^{th} data point, k_i. The adsorption coefficient, k_j, corresponding to the j^{th} percentile was calculated from the equation:

$$\frac{100}{\sqrt{2\pi}} \int_{-\infty}^{\frac{\ln k_j - \ln k_{50}}{\ln \sigma}} e^{-x^2/2}\, dx = j \qquad (2.3)$$

To correct for the change in temperature,

$$\frac{k_a}{k_b} = e^{B\left(\frac{1}{C+T_b} - \frac{1}{C+T_a}\right)} \qquad (2.4)$$

where k_a and k_b are the adsorption coefficients at temperatures T_a and T_b(^oC), respectively.

The constants obtained by fitting the adsorption coefficients in Tables 2.1.1 through 2.1.14 to this equation are presented in Table 2.2. Included in these calculations were the standard deviations from the values predicted by the Antoine Equation. From this analysis, it was possible to construct Tables 2.3 through 2.10 and Figures 2.2 through 2.5, which provide the expected values for the adsorption coefficients for krypton and xenon from several common carrier gases over a range of temperatures.

The wide range in the distribution of values for the adsorption coefficients at any one temperature is illustrated in Figures 2.4 and 2.5, which give the distribution of adsorption coefficients for krypton and xenon in air. To be specific, at 25^oC the adsorption coefficient (Table 2.6) for krypton from

air was estimated to be < 22 cc (NTP)/gm for five percent of the charcoals; for 95% of the charcoals tested the corresponding value was 72 cc (NTP)/gm. If two adsorption beds were being operated, one of which contained charcoal represented by the lower of these two extremes, and the second of which contained charcoal represented by the higher of these two extremes, the difference in their adsorptive capacities for krypton would be greater than a factor of three. In this regard, it is worthy to note that a value of 70 cc(NTP)/gm, suggested by Cardile and Bellamy (1979), has been used by the NRC as an estimate for the adsorption coefficient under these same conditions. Although this value could probably be surpassed by a number of commercial charcoals, it is significantly higher than the 40 cc(NTP)/gm mean value found here.

The above example illustrates what should be well known; that is, that there are numerous commercial charcoals that are not suited for the adsorption of krypton and xenon and that it is unwise to assume adsorption coefficients for krypton and xenon without conducting tests to confirm them. In order to obtain adequate information for design purposes, representative samples of the adsorbent must be tested for the holdup of krypton and xenon at the temperature and in the carrier gas to be used in the actual system. If it becomes necessary to estimate the adsorption coefficients at other temperatures, Equation 2.4 can be used.

It is generally accepted that there is no scaleup factor for applying laboratory data to full scale plant design (Kabele and Bohringer, 1975; Foerster, 1971). Care must also be taken in applying laboratory data directly to operational adsorption systems. Littlefield, et al. (1975), for example, showed significant variations in data collected under different conditions. Although the data in Table 2.11 show that intralaboratory reproducibility of adsorption coefficients is quite good, the reproducibility of interlaboratory data (Table 2.12) leaves much to be desired. Further complicating the situation is that other factors create day-to-day variability in the effectiveness of adsorption beds (Table 2.13).

In order to calculate the release of fission gases in the event of the rupture of a pressurized adsorption bed, it is necessary to know the adsorption coefficient of the carrier gas (Underhill, 1972). Data on the adsorption coefficients of argon, nitrogen, and helium have been published by Hotchkiss (1976) and Trofimov and Pankov (1965). Similar information on the adsorption of air on several grades of charcoal have been published by Nakhutin, et al. (1976). Adsorption coefficients for argon at NTP are summarized in Table 1.1. These data can also be used to calculate the holdup of ^{41}Ar in an argon carrier gas.

On the basis of the above information, it is apparent not only that temperature has a strong effect on the adsorption coefficients for krypton and xenon, but also that there is a significant range in the possible values of the adsorption coefficients for these two gases at any one temperature.

CHAPTER 3

THE EFFECTS OF MOISTURE ON THE ADSORPTION OF KRYPTON AND XENON

A number of published papers contain data on the effects of moisture on the adsorption of krypton and xenon on charcoal. Experimental data are usually reported either in terms of the relative humidity of the carrier gas or in terms of the water content of the charcoal. Both factors are significant. It is important to know the effect of a given relative humidity since this determines the input of water into an adsorption bed.

Most charcoals saturate very slowly with water -- 16 hours exposure being required for equilibrium in some adsorption experiments. In addition, because of hysteresis effects, what appears to represent a steady state saturation of the charcoal may actually correspond to one of several water contents. For these reasons, measurements of the reduction in adsorption capacity as a function of water content of the charcoal may be more reproducible than similar measurements made as a function of the relative humidity of the incoming carrier gas.

3.1 Krypton Adsorption on Charcoal

3.1.1 Effect of Relative Humidity (RH) of the Carrier Gas

Figure 3.1 from Castellani, et al. (1975), shows the effect of the RH of the carrier gas on the adsorption coefficient for krypton on charcoal. The adsorbent was Barnebey-Cheney Type 592, 8/14 mesh, activated coconut base shell charcoal. The RH was calculated from the temperatures of the

bed and of a water condenser through which the input air was passed. The data have considerable scatter, but by a least square analysis Castellani, et al.(1975), found that the percent loss in the adsorption coefficient, from the value at zero percent RH, could be expressed by the following equation:

$$\Delta k = (0.0037 \pm 0.0007)\ RH \qquad (3.1)$$

The effect of the RH of the carrier gas and the water content of an activated charcoal native to India has been examined by Khan, et al. (1976). Figure 3.2 shows that at 100% RH the charcoal had lost 50% of its capacity for krypton. At intermediate RH levels, the dew point rather than the RH is given, so that correlation of these results with RH is not possible. Examination of Figure 3.2, however, makes it clear that the water content of the charcoal is more important than the momentary RH of the input air. A major difficulty in using Khan's adsorption coefficients is that they are strongly influenced by the carrier gas velocity. According to the theory developed in Chapter 6, the adsorption coefficient should be independent of the carrier gas velocity.

Roemberg (1964) developed values for the adsorption coefficient as a function of both the RH and the weight of adsorbed water. For this reason his data (Table 3.1) are especially valuable. At a low RH, the loss in the adsorption coefficient--about a 1.2% loss for each percent increase in the relative humidity--is far less than that given by Cardile and Bellamy (1979). These latter authors observed that at 25°C the reduction in the adsorption coefficient for krypton was 64% at a RH of 4% and 74% at a RH of 32%.

The percent decrease in the adsorption coefficient for each percent increase in RH (at low RH values), as reported by the above authors, is given in Table 3.2. As may be noted, these values show considerable variation. If a decision were to be made at this time, the data of Roemberg (1964) could probably best be defended, as his are the only data which include both the relative humidity of the incoming gas stream and the water content of the charcoals. In obtaining such a correlation, Roemberg clearly indicated his awareness of potential sources of error, such as incomplete saturation and hysteresis.

3.1.2 Effect of Water Content of the Charcoal

Foerster (1971) examined the effect of the water content of charcoal on the adsorption of krypton from argon. His results (Figure 3.3) show that over the range of 0% to 35% adsorbed water by weight, the adsorption coefficient is reduced by a factor of nearly 10. For the first several percent of adsorbed water, the loss in the adsorption coefficient is 6% for each 1% increase in water content. Above 5% water by weight, the average reduction is about 1.5% for each 1% of additional water. A confounding factor in these data is that results obtained from wood, coal and peat base charcoals are plotted on the same graph without any identification as to the type of charcoal.

Data reported by Ackley, et al. (1960), shown in Figure 3.4, also indicated that above loadings of 3% water by weight, the effect of additional water becomes less important. However, the magnitude of the

effect as determined by Ackley, et al., is much greater than that determined by other investigators. This can be seen by comparing Figure 3.4 with Figures 3.1 through 3.3. The reason for this difference is unknown.

Littlefield, et al. (1975), determined the effect of water over the range of 0.0 to 2.5 weight percent. The large number of experimental points in their data (Figure 3.5) show considerable scatter, but are consistent with a linear reduction in the adsorption coefficient of 6% for each 1% of added water at loadings below 3% to 5% by weight.

Roemberg (1964) observed an initial loss of adsorption capacity of about 10% for each added percent of water up to a 2% water content, and a leveling off in the effect of added water at higher water contents (Table 3.1). His correlations between RH and water loading, given in Table 3.3, are useful in assessing the effects of both factors on the adsorption behavior of charcoal.

The effect of low water loadings on the adsorption of krypton is summarized in Table 3.4. Except for the data from Ackley, et al. (1960), these results are consistent. At high water contents, only the data of Foerster (1971) are available, so no further comparisons can be made.

3.2 Xenon Adsorption on Charcoal

3.2.1 Effect of the Relative Humidity (RH) of the Carrier Gas

Considerably less information exists on the effect of the relative

humidity of the carrier gas on the adsorption of xenon. Based on studies conducted at 25°C, Cardile and Bellamy (1979) reported adsorption coefficient reductions of 62% and 72%, at relative humidities of 4% and 32%, respectively.

Collard, et al. (1977), using a European charcoal designated as Type RBL-3, found a factor of three reduction in the adsorption coefficient when the relative humidity was increased from 0% to about 62%.

Underhill (1974)*found a ninefold reduction in the adsorption coefficient at -29°C in passing from 0% to 100% relative humidity.

Although not apparent from the results cited here, under the same conditions the adsorption of xenon appears to be more affected by coadsorbates than is the adsorption of krypton. Whether adsorbed water differentially affects the adsorption coefficients of krypton and xenon can be determined only after more data have been accumulated.

3.2.2 Effect of the Water Content of the Charcoal

Few data on this subject could be located in the published literature. Those that were are given in Table 2.11. Because no test results were reported for dry charcoals, however, the overall effect of water content on the adsorption coefficient for xenon on charcoal cannot be calculated.

3.3 Experimental Difficulties

Results obtained from charcoals from India, the United States, the Federal Republic of Germany and the United Kingdom have been presented here. Because different base materials and manufacturing technologies

*Underhill, D. W. (1974): Unpublished Results.

are employed in these countries, differences are to be expected in the surface areas and the pore structures of the charcoals produced. Because smaller pores become filled with adsorbed water at much lower RH values, a charcoal with relatively small micropores will probably lose its effectiveness at a lower RH. Unfortunately, the effects of relative humidity on the adsorption coefficient are generally presented without concurrent data on the pore structure of the charcoal. As a result, available data on the effects of the RH of the carrier gas and the water content of the charcoal are deficient in this respect. In addition, it should be noted that a number of carrier gases, i.e., helium, air, oxygen and argon, were used in these studies. Whatever effect, if any, that this had is probably more important at low than at high RH values.

It is unfortunate that the published papers in this field often do not contain sufficient information to permit a subsequent investigator to fully reproduce the experimental conditions. A related factor is that frequently each investigator uses his own technique to determine the effects of relative humidity. The resulting differences make intercomparisons difficult.

Given the wide variation in experimental techniques and results, it would appear that the most pressing need is not to obtain more experimental data, but to caution researchers to be more careful in specifying the properties of the charcoals used in their tests, and to better define the experimental conditions under which their tests are conducted.

Only when these conditions are met, can reproducible data be generated. Specific features of a protocol that we believe should be considered for future tests include:

3.3.1 The pore size distribution and surface area of the charcoal should be reported. Also it is important that the base material and the manufacturer's designation be given. Generally, most of this information is available from the manufacturer or vendor of the charcoal. Unless this information is published with the experimental data, there will be no means for future investigators to correlate the observed effects of moisture with the physical properties of the charcoal.

3.3.2 The charcoal should be dried overnight in a stream of nitrogen gas at a temperature greater than 100°C. Drying is necessary to remove water and organic contaminants that may have been picked up by the charcoal. The reason that nitrogen rather than air should be used as the drying agent is that the use of the former eliminates the possibility of modifying the surface of the charcoal by oxidation during the drying procedure.

3.3.3 The charcoal should be allowed to come into equilibrium with a stream of air at a known relative humidity. It is necessary that humidification be continued until equilibrium is established; otherwise, the bed being tested will contain charcoal of varying degrees of saturation and the experimental results will be impossible to interpret.

3.3.4 The adsorption test should be made, after the above equilibrium has been established, by the injection of a tracer of either ^{85}Kr or ^{133}Xe into

the humidified air entering the bed. The adsorption coefficient can then be determined from the breakthrough curve.

3.3.5 After the dynamic measurement has been made, the charcoal should be removed from the system and the amount of adsorbed water determined by weighing before and after a second drying.

This permits the adsorption coefficient to be determined as a function of the weight of adsorbed water and, as discussed above, this may prove to be a more reliable correlation. These steps also permit the construction of water vapor isotherms, and their comparison with water vapor isotherms obtained by other procedures can be useful in identifying experimental error.

3.4 Recommendations and Conclusions

3.4.1. Only a very limited amount of data could be found regarding the effect of relative humidity of the carrier gas on the adsorption of xenon. Because xenon adsorption may be more strongly affected by moisture than krypton adsorption, obtaining additional xenon data should be given priority.

3.4.2 The effects of moisture on the adsorption of radioactive fission gases are better correlated with the water content of the charcoal than with the transient RH of the carrier air. Future experiments should include provisions to obtain measurements of both the RH of the air

in equilibrium with the charcoal as well as the water content of the charcoal under these conditions.

3.2.3 A protocol for reproducible experimental procedures needs to be established.

3.4.4 Excluding the results of one investigator, the effects of adsorbed water on the adsorption of krypton was found to be a 6% to 10% loss in the adsorption coefficient for each percent of adsorbed water (by weight) in the range of 1% to 2%.

3.4.5. As the water content increased beyond 2%, the data indicate a reduction in the effects of additional water.

CHAPTER 4

THE EFFECTS OF CONCENTRATION ON THE ADSORPTION OF KRYPTON AND XENON

When krypton and xenon are present at high concentrations, their adsorption coefficients are reduced. If this reduction becomes significant, adsorption beds could become ineffective under the very circumstances where they are most needed. Summarized in this Chapter are a number of published reports relating to the effects of concentration on the adsorption coefficients for these two gases.

4.1 Concentration Effects in the Presence of a Helium Carrier Gas

Because helium does not compete with krypton and xenon for adsorption sites, the krypton and xenon isotherms obtained in the presence of helium should be the same as those obtained in the absence of a carrier gas. Figure 4.1 (Eshaya and Kalinowski, 1961) demonstrates this point. The lines in this figure represent isotherms determined statically by Amphlett and Greenfield (1958) in the absence of a carrier gas. The data points are from dynamic adsorption experiments conducted by Eshaya and Kalinowski (1961) using the same types of charcoal, but this time in the presence of a helium carrier gas. Within the limits of experimental error there is no difference between the results obtained by these procedures.

Adsorption isotherms often follow the Freundlich isotherm,

$$q = aP^b \qquad (4.1)$$

where

q = volume (cc at NTP) of adsorbed gas per gram of adsorbent;

P = partial pressure of the adsorbed gas;

a,b = coefficients for the Freundlich isotherm.

This definition omits the contribution of the interparticle gases, which for bulk charcoal at NTP amounts to about 0.8 cc/gm.

As may be noted from Figure 4.1, a plot of isotherm data on log-log coordinates results in a straight line. This demonstrates that the Freundlich isotherm is applicable to the data of Eshaya and Kalinowski (1961).

A relationship between the adsorption coefficient and the Freundlich isotherm is:

$$k = aP^{b-1} \qquad (4.2)$$

where k = adsorption coefficient, cc(NTP)/gm.

Tables 4.1, 4.2, and 4.3 and Figs. 4.2 and 4.3 present adsorption coefficients determined by Kenney and Eshaya (1960) and Eshaya and Kalinowski (1961). The xenon adsorption coefficient shows a definite increase with decreasing xenon concentration, whereas the krypton adsorption coefficient appears to decrease only slightly under the same conditions. This latter result is probably an artifact since the factor, "b", is expected to have a value less than 1.

Ackley and Browning (1961) also observed that the adsorption of krypton and xenon in the absence of a carrier gas followed the

Freundlich isotherm. Table 4.4 gives their values for "a" and "b" for the Freundlich isotherm over the pressure range, 0.1 to 2.0 mm Hg. The adsorption coefficients are calculated for a pressure of 0.1 mm Hg. Ackley and Browning have pointed out that these isotherms would also be representative of the adsorption coefficients obtained in the presence of helium.

Zeldowitsch (1934) determined that the Freundlich isotherm was consistent with the assumption that the adsorbent surface consists of sites having an exponential distribution of energies of adsorption. In general, "b" will be less than unity, but will approach unity as the temperature increases. For two gases at the same temperature, "b" will be less for the more strongly adsorbed gas. These predictions are in good agreement with the data cited above.

According to the Freundlich isotherm, the adsorption coefficient increases indefinitely as the concentration of adsorbate (adsorbed gas) decreases. In actuality this cannot occur. When the concentration is decreased below the point where there is appreciable coverage of the most active sites, the number of adsorbed atoms at all sites should become proportional to the partial pressure of the adsorbate. At this point the adsorption coefficient becomes independent of the partial pressure and "b" is equal to unity. It is not known how low the concentration of fission gas must be for the isotherm to become linear, but for some gases nonlinear effects may be found well below 10^{-6} Atm.

Cooper, et al. (1975), found evidence that at -140°C the adsorption coefficient for 400 ppm krypton in helium is nonlinear. This is based on their observation that measurements of the krypton adsorption coefficient by frontal and by pulse chromatography gave different results. Their explanation for this phenomenon is that in pulse chromatography the injected pulse, as it passes through the bed, spreads, and the krypton concentration in the pulse becomes far less than the injected value. If the adsorption coefficient is affected by concentration, then by definition the adsorption isotherm is nonlinear.

Below their critical temperatures, adsorption of krypton and xenon from helium can be represented by a Polanyi isostere, which gives the combined effects of temperature and pressure on a single curve. Figure 4.4 shows the Dubinin modification of this method applied by de Bruijn, et al. (1964), to the adsorption of both krypton and xenon. Here the volume of condensed adsorbate, per gram of charcoal, is plotted as a function of the free energy required for adsorption.

This change in free energy per mole of adsorbate is approximately equal to:

$$\Delta F = RT \ln (P_o/P) \qquad (4.3)$$

where:

R = the ideal gas constant

T = the absolute temperature

P = the partial pressure of vapor in contact with the charcoal

P_o = the vapor pressure of the pure liquid at the temperature of the measurement.

Using this method, de Bruijn, et al., combined data from different temperatures, pressures and adsorbates into a single curve. Above the critical temperature, this procedure begins to break down as it becomes necessary to calculate artificial vapor pressures and liquid densities (Hotchkiss, 1976).

4.2 Concentration Effects in the Adsorption of Krypton from Carrier Gases other than Helium.

Carrier gases other than helium compete with the fission gases for adsorption sites. At low concentrations of fission gases, this competition linearizes their adsorption isotherms by converting their heat of adsorption on very active sites into the lesser value of a heat of displacement. The net result is that at moderate and low concentrations of fission gases, the adsorption isotherm is either linear or very nearly linear. At high concentrations the isotherm is nonlinear.

This prediction of the effects of high fission gas concentrations is supported by experimental studies. Ackley, et al. (1960), measured the effect of a high concentration of krypton on its adsorption from oxygen at room temperature. From their results (Figure 4.5) it can be seen that raising the krypton concentration from trace levels to 100% reduced the adsorption coefficient from an initial value of 50 cc(NTP)/gm to a final value of 32 cc(NTP)/gm. Khan, et al.(1976), observed a 10% loss in the adsorption coefficient for krypton at ambient temperature when the krypton concentration was raised from trace levels to 0.2% in an air carrier. Foerster (1971) found a 4% reduction in the krypton adsorption coefficient when the

concentration of krypton in argon was raised from trace levels to 2%. The possible effects of an argon carrier gas should be considered if Foerster's results (Figure 4.6) are used to predict similar effects in other carrier gases.

At low concentrations of fission gases, the independence or near independence of the adsorption coefficient on concentration has been substantiated by several studies. Schumann's (1973) results (Figure 4.7) are consistent with a linear isotherm for trace levels of krypton at -20°C. The adsorption isotherm for trace levels of krypton should remain linear at higher temperatures, and the values of Kitani, et al. (1968), plotted by Schumann (1973) in Figure 4.7 are consistent with this conclusion. The data in Table 4.5, from Kitani, et al. (1968), show that the krypton adsorption coefficient is independent of the krypton concentration at krypton concentrations of 63, 100, and 630 ppm, temperatures of 25, 0, and -30°C, and pressures of 1 and 10 atmospheres.

Wirsing, et al. (1970), observed that, at -170°C in air and at -128°C and -66°C in nitrogen, the krypton adsorption coefficient remained independent of concentration up to 4000 ppm. It will be noted later that these adsorption coefficients were strongly dependent on the carrier gas velocity and that this casts doubt on their reliability.

Kovach (1972) found a nonlinear isotherm for the adsorption of krypton at extremely low concentrations from air. It should be noted from Table 4.7 that two of his three krypton concentrations were below the level

usually present in the atmosphere and cannot be taken as typical of ambient air.

Collins, et al. (1967), reported a large number of measurements of the effect of concentration on the adsorption of krypton and xenon from argon. Their data permit correlations to be made between temperature, krypton concentration, and the adsorption coefficient. From the Langmuir coefficients derived from data published by Collins, et al.(Table 4.8), the effect of krypton concentration on its adsorption coefficient can be calculated for a wide range of krypton concentrations at temperatures from -70 to 60°C. It is found, for example, that at -70°C the loss of adsorption capacity will be less than 1% at krypton concentrations of 100 ppm or less. At 20°C the loss of adsorption capacity will be less than 1% for krypton concentrations up to 10,000 ppm.

It is interesting to apply this analysis to the measurements of Ackley, et al. (1960), for the adsorption of krypton from oxygen. At krypton concentrations of 21% and 100%, the reductions were 21% and 46%, respectively (Figure 4.5), whereas the values calculated from the coefficients in Table 4.8 were 15% and 46%, respectively. This agreement suggests that the coefficients in Table 4.8 may be applicable to results obtained from other carrier gases. It is probable that the coefficients in Table 4.8 are the best available parameters for determining the effects of high krypton concentrations on the adsorption of krypton from air, but it should be

kept in mind that these coefficients were determined using an argon carrier gas.

4.3 Effects of Concentration on the Adsorption of Xenon from Carrier Gases other than Helium

Collard, et al. (1977), found the adsorption coefficient for xenon at room temperatures to be independent of concentration at concentrations in the range of 50 to 600 ppm. Nakhutin, et al. (1976), (Figure 4.2) similarly found the adsorption coefficient for xenon at 21°C to be independent of its concentration at xenon partial pressures approaching 1 mm Hg. However, at -82°C, as the xenon partial pressure approached 0.1 mm Hg, a small but definite nonlinearity was observed.

Table 4.9 from Kovach (1972) shows a concentration effect on xenon adsorption in the ultra-low range of 0.013 ppm to 1.3 ppm xenon in air. Again, it should be noted that the lowest concentration cited by Kovach is below the ambient level of xenon in air.

Again, the most extensive study was by Collins, et al. (1967), in which the effect of xenon concentration on the adsorption of xenon from argon was examined. At low and intermediate xenon concentrations, the Langmuir isotherm (Equation 4.4) closely represents the experimental data (Table 4.8). At the very highest concentrations (i.e., those experiments where the initial xenon concentration was 10% or more), the Langmuir isotherm did not fit the data well, probably because of multilayer adsorption.

An appreciable reduction in the adsorption coefficient occurs at much lower concentrations for xenon than for krypton under comparable circumstances. At 20°C the reductions in their adsorption coefficients are comparable when the xenon concentration is one twentieth of the krypton concentration. Since the fission yield for xenon is greater than that for krypton, it appears that if reductions in the adsorption coefficients due to high concentrations occur, the effect is likely to be greater for the xenon isotopes.

4.4 Cross Interferences in the Adsorption of Krypton and Xenon

The effects of the presence of krypton on the adsorption of xenon (or the effects of xenon on the adsorption of krypton) are important because, in an operational nuclear facility, these two gases are generally found in combination. Measurements (Figure 4.6) by Foerster (1971) show that, at 20°C, the addition of 1% xenon to a trace concentration of krypton in argon reduced the krypton adsorption coefficient by 16%. At -50°C, the same concentration of xenon reduced the krypton adsorption coefficient by 36%.

In apparent contradiction to the above results, Eshaya and Kalinowski (1961) found that in helium at room temperature, raising the xenon concentration from 0.25% to 1% had no effect on the adsorption coefficient of krypton.

A more extensive study of the interference of krypton on the adsorption of xenon is reported by Collins, et al. (1967). Their krypton concentrations were either below 0.1% or above 20%, and this gap in their data certainly complicated our effort to analyze them.

Nonetheless, the Langmuir isotherm (Equation 4.4, Table 4.8) permits calculation of the simultaneous adsorption of krypton and xenon. From the Langmuir coefficients given in Table 4.8, it may be seen that the effect of krypton in reducing the adsorption coefficient of xenon is less than the reduction in the krypton adsorption coefficient brought about by the presence of an equivalent concentration of xenon.

The reverse effect--the reduction in the adsorption coefficient of krypton brought about by the presence of xenon--is expected to be greater because xenon is the more strongly adsorbed gas and therefore would more easily displace the krypton. Unfortunately, there are insufficient data to determine the Langmuir coefficients for this phenomenon.

4.5 Conclusions

A number of reports describing measurements of th effect of noble gas concentrations on their adsorption coefficients have been reviewed in this Chapter. The important findings and recommendations are:

4.5.1 In helium, at temperatures below the critical temperatures of the fission gases, the Polanyi isostere is useful in correlating the combined effects of temperature and concentration. At higher temperatures, the Freundlich isotherm more closely fits the experimental data.

4.5.2 In gases other than helium, the adsorption coefficients of krypton and xenon at low concentrations are independent of, or only very slightly influenced by their concentrations.

4.5.3 For the adsorption of krypton and xenon from argon, the Langmuir isotherm provides a simple procedure for estimating the effects of concentration on the adsorption coefficient. The validity of these coefficients for the adsorption of krypton and xenon from air needs to be confirmed.

4.5.4 The Langmuir coefficient for the effect of xenon on the adsorption of krypton needs to be determined.

60	1,910,000	210,000	

Through application of the Langmuir isotherm, the coefficients given above can be used to calculate the adsorption of noble gases at low and intermediate concentrations. The equation for the Langmuir isotherm is as follows:

$$k = k_1/(1 + C_1/\overline{C}_1 + C_2/\overline{C}_2) \qquad (4.4)$$

where

- k = adsorption coefficient of xenon (krypton)
- k_1 = adsorption coefficient of xenon (krypton) at infinitely low xenon and krypton concentrations
- C_1 = concentration of xenon (krypton), ppm
- $\overline{C}_1$ = Langmuir coefficient for the effect of the xenon (krypton) concentration on the adsorption of xenon (krypton)
- C_2 = concentration of krypton (xenon), ppm
- $\overline{C}_2$ = Langmuir coefficient for the effect of the krypton (xenon) concentration on the adsorption of xenon (krypton)

The geometric standard deviation, σ, between the measured and the predicted adsorption coefficients was 1.11 and 1.19, respectively, for the adsorption of krypton in the absence of xenon and for the adsorption of xenon in the absence of krypton. For the adsorption of xenon from argon containing appreciable concentrations of krypton, the geometric standard deviation between the measured and the predicted values was 1.16.

CHAPTER 5

THE EFFECTS OF PRESSURE ON THE ADSORPTION OF KRYPTON AND XENON

Although operation of pressurized systems has been considered in the design of fission gas holdup beds, most current systems are operated near atmospheric pressure. Under abnormal conditions it may be possible to increase the holdup in such beds by operation at higher pressures. The data in this chapter should permit designers of such systems to estimate, in advance, the effectiveness of pressurization.

5.1 Effect of Pressure on the Adsorption of Krypton and Xenon from Nitrogen and Air

Goldin and Trindade (1973) measured the adsorption of krypton and xenon from both air and nitrogen as a function of pressure at temperatures ranging from ambient to -100°C. Table 5.1 and Figure 5.1 give their original presentation of these data. If, as in Figure 5.1, the logarithm of the adsorption coefficient is plotted versus the pressure, the resultant isotherms are highly curved. In evaluating these data, it was found that very nearly linear results could be obtained by reversing the plot, that is, by plotting the log of the pressure vs. the adsorption coefficient. This approach is shown in Figures 5.2 through 5.4, which present different segments of the pressure and temperature ranges studied.

Kabele and Bohringer (1975) studied the adsorption of krypton from gas mixtures, primarily nitrogen, at temperatures of -80°C and -120°C. Their data (Table 5.2, Figure 5.2) are consistent with the earlier results of Goldin and Trindade.

The data of Kawazoe and Kawai (1972) are unique in describing the effects of very high pressures on the adsorption of krypton. Even at pressures up to 123 Atm, their data show a nearly linear relationship between the adsorption coefficient for krypton and the logarithm of pressure (Figure 5.5).

A dimensionless factor, the pressure coefficient, α, has been derived here to characterize the slope of these adsorption isotherms. This factor may be expressed as:

$$\alpha = \frac{K_2 - K_1}{K_1 (\ln P_2)} \qquad (5.1)$$

where α = pressure coefficient, dimensionless

K_1 = adsorption coefficient at 1 Atm (abs)

K_2 = adsorption coefficient at pressure, P_2

Figure 5.6 shows a plot of the pressure coefficient vs temperature, as calculated using the data discussed above. From this Figure, it is relatively simple to estimate the effects of pressure on the adsorption coefficient for either krypton or xenon. It is apparent from Figure 5.6 that, for a given temperature, an increase in pressure is more effective in increasing the adsorption coefficient for krypton than for xenon. From the standpoint of safety analyses, this shows that pressurization will affect unequally the retention of krypton and xenon isotopes. Another important observation is that the effectiveness of pressurization decreases as the temperature is reduced.

In 1968, Kitani, et al., published a number of measurements of the adsorption of krypton from nitrogen at 1 and 10 Atm. They determined adsorption coefficients for eight charcoals at a krypton concentration of 64 ppm at 0°C (Table 5.4), and for one of these charcoals at temperatures of 25°C and -30°C (Table 5.5 and Figure 5.7). On the basis of a review of these data, Kovach (1972) concluded that the effect of pressure on the adsorption coefficient is less than would have been expected. For example, at 0°C the increase in the adsorption coefficient is less than a factor of three for a tenfold increase in pressure. Although Wirsing, et al. (1970), have also made measurements of the adsorption of krypton from nitrogen and air, their data appear to be too inconsistent to be useful here.

The fact that the data reported by Kitani, et al., were obtained using a wide variety of charcoals (including some manufactured in the United States) points to experimental technique as being the main source of differences between their results and those published by other authors.

5.2 Effect of Pressure on the Adsorption of Krypton and Xenon from Argon

Kabele, et al.(1973), measured the adsorption of xenon from argon at 30°C and -30°C. The pressure coefficients calculated from their data (Table 5.6) are very close to values reported earlier for the adsorption of xenon from a nitrogen carrier gas.

Figure 5.8, from Foerster (1971), shows conclusively that the overall pressure has a nonlinear effect on krypton adsorption from an argon carrier gas. The pressure coefficient calculated from Foerster's data is 1.4 at 20°C.

At low temperatures, adsorbed argon interferes severely with the adsorption of krypton and xenon. Ratney and Underhill (1972) found a regime at -140°C where an increase in pressure actually decreased the adsorption of krypton from argon. This behavior can be explained by the formation of liquid argon in the micropores of the charcoal as the pressure was increased.

5.3 Effect of Pressure on the Adsorption of Krypton and Xenon from Helium

Figure 5.9 (Ratney and Underhill, 1972) shows three isotherms for the adsorption of krypton from helium at temperatures below 0°C. These isotherms are linear or very nearly linear, indicating little interference with adsorption by the helium carrier gas. Because helium is not expected to interfere with the adsorption of krypton or xenon, the adsorption of these latter two gases should be a function only of the temperature and their partial pressures..

If these data were obtained at temperatures below the critical temperature of krypton (-63.8C), the Polanyi isostere would be preferable, as it presents the data most concisely. At significantly higher temperatures, however, the assumptions underlying the Polanyi isostere lose their validity and, as is the case here, the isotherm graph is the better method of data presentation.

5.4 Adsorption of ^{41}Ar from an Argon Carrier Gas

The effects of pressure on the adsorption coefficient for ^{41}Ar from an argon carrier gas have been determined in conjunction with the use of argon as a cover gas for liquid metal cooled reactors. Tables 5.7 and 5.8, and Figures 5.10 and 5.11, present results obtained in parallel studies at the Harvard Air Cleaning Laboratory (Underhill, et al. 1973),

and at the Hanford Engineering Development Laboratory (Kabele, et al. 1973). Constants for the Freundlich isotherm for the adsorption of argon are given in Figure 5.12, but the range of pressures over which these constants are valid is not known.

5.5 Conclusions

By examining the available information concerning the effects of pressure on the adsorption of noble gases, a number of factors of importance in the design and evaluation of krypton and xenon holdup beds have been identified. These include:

5.5.1 The percent increase in the adsorption coefficient will be less than the percent increase in absolute pressure. An exception to this rule may occur if helium (and possibly hydrogen) is the carrier gas.

5.5.2 A plot of the adsorption coefficient vs. pressure is approximately linear if the absolute pressure is plotted on the log axis of semi log paper. Coefficients of the normalized slope of these plots, taken as a function of temperature, show promise as a means of correlating data from a wide number of experiments.

5.5.3 At the same temperature, an increase in pressure increases the adsorption coefficient of xenon by a lesser fraction than it increases the adsorption coefficient of krypton.

5.5.4 At reduced temperatures, pressurization is less effective in increasing the adsorption coefficients of noble gases.

5.5.5 There is sufficient information on the effects of temperature and pressure on the adsorption of ^{41}Ar from an argon carrier gas to permit estimates to be made of the adsorption coefficients under a range of conditions.

CHAPTER 6

THE EFFECTS OF MASS TRANSFER ON THE ADSORPTION OF KRYPTON AND XENON

In a series of papers which examined the theoretical bases for mass transfer in fission gas adsorption beds, Underhill (1967, 1969, 1970) demonstrated that the method of moment analysis is the best procedure for determining mass transfer effects. Additional findings of practical importance to this subject are covered in this Chapter.

6.1 Fitting of Breakthrough Data to Theoretical Curves

All of the current knowledge regarding adsorption coefficients and mass transfer in a fission gas adsorption bed has been obtained from the study of breakthrough curves. Such curves are graphic presentations of the concentration of fission gas in the effluent from a bed following the introduction of a pulse or frontal input of fission gas into the carrier gas entering the bed.

J. M. Smith (1975)* developed a computer program that can be used to calculate breakthrough curves for any expected combination of mass transfer parameters, making it possible to determine if a given combination of mass transfer parameters can account for an observed breakthrough curve. This program is written in Fortran IV and uses a fast inverse Laplace transform. Copies of the program are available from the author.*

---

* Smith, J. M. (1975): Personal Communication.

Dr. J. M. Smith

Davis, CA 95616

In practice, equations less general than the inverse Laplace transform are frequently used to describe the data resulting from breakthrough experiments (Table 6.1). How well these theoretical equations fit actual data is not precisely known, but several instructive examples can be given. Figure 6.1, from Kenney and Eshaya (1960), shows data fitted to the theoretical breakthrough equations of Glueckauf (1955) and Jury and Licht (1952). In developing his equation, Glueckauf assumed that mass transfer was controlled by interparticle diffusion, whereas Jury and Licht assumed that mass transfer was controlled by a thin air film surrounding the adsorbent particles. It is interesting to note that both equations produced curves that fit the experimental data quite well, even though a third mechanism, intraparticle diffusion, probably controlled mass transfer in the experiments of Kenney and Eshaya. Perhaps the shape of breakthrough curves is not strongly dependent on the mechanisms of mass transfer.

The theoretical chamber model, which produces a simple breakthrough curve, was developed by Browning and Bolta (1959) at the Oak Ridge National Laboratory. In this model the adsorption bed is artificially divided into a series of chambers and rapid mixing of the fission gases is assumed to take place within each chamber. Although the equation developed from this model does not closely fit data obtained by Ackley, et al. (1960) (Figure 6.2), it does provide good agreement with data developed by Strong and Levins (1979) (Figure 6.3) for the adsorption of radon. There is no ready explanation why this equation worked well in one case and not in another.

Figure 6.4 shows the excellent fit of data of Collard, et al. (1977), to a Gaussian equation. This approach works best when the breakthrough curve can be characterized by a large number of theoretical plates; otherwise the curve will be too skewed to fit the symmetrical Gaussian equation. Three useful techniques for determining the number of theoretical plates from a Gaussian breakthrough curve are described in Figure 6.5.

For skewed breakthrough curves, it may be possible to obtain a straight line relationship between the fraction of the noble gas retained in the bed and the volume of effluent carrier gas by using log-probability coordinates (for example, compare Figures 6.6 and 6.7). In the Japanese literature, use of probability coordinates appears to be a common procedure (e.g., Kitani, et al., 1968).

6.2 Applicability of the van Deemter Equation

The applicability of the van Deemter equation to the analysis of noble gas holdup beds has been confirmed by a number of investigators, including Underhill (1967), Collard, et al. (1977), Castellani, et al. (1975), and Curzio and Gentili (1972). The basic equation may be expressed as:

$$H = \frac{2\varepsilon\gamma D_m}{V_s} + 2\lambda_p d_p + \frac{d_p^2 V_s (k - \varepsilon/\rho)}{30\rho k^2 D_p} \qquad (6.1)$$

where

H = height equivalent to one theoretical plate, cm

d_p = mean adsorbent particle diameter, cm

D_m = molecular diffusion coefficient for fission gas in carrier gas, cm^2/sec

k = adsorption coefficient, cc(at temperature and pressure of bed)/gm

V_s = superficial carrier gas velocity, cm/sec

γ = tortuosity factor for interparticle diffusion, dimensionless

ε = fraction of adsorption bed consisting of interparticle void volume, dimensionless

λ_p = coefficient for axial dispersion, dimensionless

ρ = bulk density of the adsorbent, gm/cc

This equation can be written in a nondimensional form by use of the following nondimensional parameters:

$$h = \frac{H}{d_p} \qquad (6.2)$$

$$v_i = \frac{V_s d_p}{\varepsilon D_m} \qquad (6.3)$$

where

h = reduced height equivalent to one theoretical plate

v_i = reduced interparticle velocity

Then

$$h = \frac{2\gamma}{v_i} + 2\lambda_p + cv_i \qquad (6.4)$$

where

$$c = \frac{\varepsilon D_m (k - \varepsilon/\rho)}{30\rho k^2 D_p} \qquad (6.5)$$

Shown in Figure 6.8 is a plot of H (the height equivalent to one theoretical plate) vs. V_s (the superficial velocity). This relation can be used to determine the coefficients for the van Deemter equation. As discussed below, Figures 6.9 through 6.13 show this equation to be applicable even under conditions of changing relative humidity and temperature.

6.2.1 Effects of Humidity

Castellani, et al. (1975), have observed that the mass transfer of krypton is unaffected by relative humidity (Figure 6.9). This is understandable at intermediate and low carrier gas velocities, because under these conditions, mass transfer is controlled by diffusion and flow patterns external to the granules of adsorbent, and these factors are only slightly altered by the relative humidity. Relative humidity also appears to have little effect on mass transfer at high carrier gas velocities, where mass transfer is controlled by diffusion within the adsorbent granules (intraparticle diffusion). This is an interesting finding, which may be explained by the fact that water first condenses in the micropores of the adsorbent, leaving the macropores (which many research workers believe control intraparticle diffusion) unaffected.

Similarly, Collard, et al. (1977), observed only a slight alteration in the mass transfer of xenon at room temperature when the relative humidity was increased from 0% to 65%.

6.2.2 Effects of Temperature

A straightforward way to determine the effects of temperature on mass

transfer is to plot data in the form of the reduced van Deemter equation (Equation 6.4). In this equation, the values for γ and λ_p should be independent of, or only very slightly affected by, temperature. The coefficient, "c" (Equation 6.5), contains three temperature dependent factors: D_m, D_p, and k. If intraparticle diffusion is controlled by diffusion in the macropores, then D_m and D_p should have the same temperature dependency and the net result would be that the coefficient "c" varies with temperature as the reciprocal of k. It follows from this reasoning that at high carrier gas velocities (where mass transfer is controlled by intra-particle diffusion), the value of h (Equation 6.4) should increase rapidly with increasing temperature, whereas at low and intermediate carrier gas velocities, the temperature effect should be small.

Experimental measurements, although fragmentary, are in agreement with these predictions. Lepold (1965), using a fine mesh charcoal in a gas chromatography column for the rapid separation of short-lived isotopes of krypton and xenon, observed a dependency of H on temperature that agrees very well with the theoretical predictions given here. As he decreased the flow rate of the carrier gas, the separation between the isotherms for both krypton and xenon decreased (Figures 6.10 and 6.11). Curzio and Gentili (1972) (Figure 6.12) found no temperature dependence for h at low values of v_i, but at the same time they found the temperature dependence of the inter-particle diffusion coefficient to be $T^{1/2}$. This latter result is puzzling because the kinetic theory of gases predicts that the

diffusion coefficient would vary as $T^{3/2}$. It is logical to seek some discrepancy in the procedure used by Curzio and Gentili in the analysis of their data. A factor that could account for their results is the temperature dependency of the carrier gas velocity. In this context, it is interesting to note that in plotting their data (Figure 6.13) these authors assumed that interparticle velocity was independent of temperature.*

Browning and Bolta (1959) injected pulses of ^{85}Kr into nitrogen passing through a bed of Columbia ACA activated charcoal and calculated a constant value of 4.3 cm for H at temperatures of 15°C, 5°C, -50°C, and 110°C. At their flow velocity of 5.6 cc (NTP)/cm^2-sec, the effects of temperature on H should have been important. It is not known why this was not the case.

6.2.3 Effects of Adsorbent Particle Size and Carrier Gas Composition

Trofimov and Pankov (1972ab) observed that at low carrier gas velocities, the particle size had little influence on mass transfer. At higher carrier gas velocities, however, particle size strongly influenced mass transfer. This result is consistent with the predictions of the van Deemter equation (Equation 6.1). These authors also found that intraparticle diffusion was more rapid in the presence of air than in the presence of carbon dioxide and still more

---

*Curzio and Gentili actually used a linear equation for the temperature dependence of the diffusion coefficient, but it can be shown that for small changes in the temperature this linear equation is equivalent to the square root relationship given above.

rapid in the presence of helium. This observation is strong evidence that intraparticle diffusion is rate-limited by diffusion in the macropores, where collisions between the molecules of the noble gas and the carrier gas are commonplace.

Figure 6.14 (Ayers, et al. 1975), shows a tenfold reduction in H when the adsorbent particle size is reduced by a factor of about 5. These data were obtained in a flow regime where mass transfer is controlled by intraparticle diffusion. As a result, they are compatible with theoretical predictions.

6.2.4 Effect of Pressure

Pressure affects three parameters that influence intraparticle diffusion. These are the adsorption coefficient, the intraparticle diffusion coefficient, and the carrier gas velocity. The net result is that, if the input to a bed remains constant (measured at NTP), an increase in pressure will increase the number of theoretical plates (Figures 6.14 and 6.15).

Data published by Kawazoe and Kawai (1972) (Table 6.2) show that both the film mass transfer coefficient and the rate of intraparticle diffusion vary inversely with absolute pressure. Again, this is compatible with theory.

6.3 Parameters Affecting Mass Transfer in Charcoal Beds

6.3.1 Effects of Interparticle and Intraparticle Diffusion

Experiments by Madey (1961), using ^{85m}Kr tracer in a helium carrier

gas, showed that interparticle diffusion can reduce the decontamination factor of a charcoal adsorption bed at low carrier gas velocities. These results are in agreement with his theoretical model (Madey, et al., 1962).

Using a rigorous experimental approach, Nakhutin, et al. (1969), studied the effect of intraparticle diffusion on the decontamination factor of a charcoal bed. In these studies, nitrogen containing short-lived krypton and xenon radioisotopes was passed through a bed monitored at various points by a collimated gamma spectrometer. Using this approach, it was possible to determine the concentration of individual radionuclides as a function of their distance from the bed entrance. These experiments showed that the adsorption coefficients for the radionuclides employed were independent of half life. This is in agreement with the hypothesis that under most conditions the effect of intraparticle diffusion is negligible. If this were not the case, the longer lived nuclides would have had a greater time to penetrate the adsorbent granules and to establish equilibrium, and their adsorption coefficient would have appeared to be greater (Thiele, 1939).

Nakhutin, et al. (1969), have also suggested that, at low temperatures (i.e., less than -100°C for krypton and less than 3°C for xenon), conditions may be found under which intraparticle diffusion does become important. However, this suggestion has not yet been tested experimentally.

6.3.2 Overall Effects of Mass Transfer on the Decontamination Factor

The effects of mass transfer on the decontamination factor of a charcoal bed can be determined from Figures 6.16 and 6.17, which were developed for interparticle and intraparticle diffusion, respectively. Many holdup beds operate with the parameter, z, less than 0.1. When this is the case, both Figures 6.16 and 6.17 give essentially the same result. Then the following simple approximate equation can also be used.

$$DF = 2^{\left(\frac{z}{1 + 2\ \ln(2)z/N}\right)} \qquad (6.6)$$

where

DF = Decontamination Factor, $\left(\frac{\text{Input Concentration}}{\text{Output Concentration}}\right)$

m = mass of adsorbent, gms

k = adsorption coefficient, cc/gm

$\dot{V}$ = flow of carrier gas, cc/sec

$t_{1/2}$ = isotopic half life, sec

N = number of theoretical plates, dimensionless

z = $mk/\dot{V}t_{1/2}$, dimensionless

Table 6.3 summarizes calculations obtained by applying Equation 6.6 to the mass transfer data of Collard, et al. (1977). It can be seen from these data that as long as the carrier gas velocity is 0.1 cm/sec or greater, the effects of mass transfer can be neglected. In summary, then, it appears that the effects of mass transfer on the efficiency of

a fission gas adsorption bed are usually quite small, except at very low carrier gas velocities.

6.4 Effects of Carrier Gas Velocity on the Adsorption Coefficient

Theory would predict that the adsorption coefficient for a charcoal bed should be independent of the carrier gas velocity. Any other result would have great impact on the design of noble gas holdup beds. There are, however, a number of studies in which some effect of carrier gas velocity on adsorption coefficient has been reported. For example, Wirsing, et al. (1977), at the Brookhaven National Laboratory conducted extensive measurements of the adsorption of krypton and xenon from air and nitrogen at low temperature. Parish (1979) showed that the adsorption coefficients obtained in these experiments were strongly dependent on the carrier gas velocity (Figure 6.18). Although data taken from the lowest flow regime used by Wirsing, et al., agreed with proprietary data of Parish, at higher carrier gas velocities, the adsorption coefficients obtained by Wirsing, et al., sharply decreased as the carrier gas velocity increased. Not only do the data of Wirsing, et al., show a velocity effect but they also have a high degree of scatter. Parish believes that at higher velocities Wirsing, et al., encountered fluidization and that this influenced their breakthrough curves. If fluidization is the explanation for their erratic results, then it should be noted that this difficulty could have been avoided if the carrier gas had passed down, rather than up, through the adsorbent bed.

Other data from the Brookhaven National Laboratory are in sharp contrast to the results reported by Wirsing, et al., Kenney and Eshaya (1960) and Eshaya and Kalinowski (1961) observed that increasing the carrier gas velocity increased the adsorption coefficient (Tables 6.4 and 6.5, Figures 6.19 and 6.20). Data in Table 6.6 (Koch and Grandy, 1957) also show a strong increase in the adsorption coefficient as the carrier gas velocity is increased. The same effect is apparent in Figure 3.2 taken from Khan, et al. (1976).

There are, on the other hand, a number of studies in which the carrier gas velocity was observed to have no effect on the adsorption coefficient. In a series of carefully controlled experiments, Lovell and Underhill (1979) examined the effect of a 30 fold change in carrier gas velocity on the adsorption coefficient of krypton. These measurements, which had an estimated error of about 3%, appeared to show that the adsorption coefficient, determined from moment analysis, was independent of the carrier gas velocity.

Rozhdestvenskaya, et al. (1975), also observed no effect of the carrier gas velocity on the adsorption coefficient in tests with superficial velocities ranging from 0.8 to 4 cm/sec. In addition, Siegwarth, et al. (1973), found the adsorption coefficient to be independent of the carrier gas velocity. Finally, the results of Kawazoe (1967) (Table 6.7) indicate that, if the adsorption coefficient is affected by the carrier gas velocity, the effect is not great.

It is recognized that the vast majority of adsorption sites are located internally, apart from the flow paths of the carrier gas, and therefore it would appear that the carrier gas velocity should have no effect on the adsorption coefficient. As Lovell and Underhill (1979) point out, this is almost but not quite true. A pulse injection in the case of a highly nonlinear adsorption isotherm would lead to a situation where the carrier gas velocity affects the measured adsorption coefficient, but then the results are essentially meaningless because there is no way to determine the concentration to which this adsorption coefficient corresponds.

In the experiments of Kenney and Eshaya (1960), Eshaya and Kalinowski (1961), and Wirsing, et al. (1970), step function inputs were used. Under this condition there seems to be no possible explanation for a carrier gas velocity effect on the adsorption coefficient. In other cases where pulse inputs were used, the noble gas isotherms are so nearly linear that the possibility that nonlinearity had any influence on these results can be discounted. Most of the reported effects that the carrier gas velocity has had on the adsorption coefficients appear to be experimental artifacts. Other researchers (as noted above) have not observed a velocity effect.

6.5 Conclusions

From the large amount of data presented in this chapter, four basic guidelines have emerged. These may be summarized as follows:

6.5.1 Use of Theoretical Breakthrough Curves

It is important to determine whether the theoretical equation adequately fits the experimental data. Table 6.1 lists conditions of mass transfer for which specific breakthrough curves are most appropriate.

6.5.2 Use of the van Deemter Equation

The van Deemter equation permits correlation of mass transfer data from a wide range of experimental conditions, including allowances for the effects of velocity, particle diameter, temperature, relative humidity, and pressure.

6.5.3 Calculation of the Decontamination Factor

The effect of mass transfer on the decontamination factor (DF) can be determined from Figures 6.16 and 6.17.

6.5.4 Effect of Carrier Gas Velocity on the Adsorption Coefficient

There are experimental data showing that the adsorption coefficient increases, decreases or remains constant as the carrier gas velocity is increased. From theoretical considerations, it appears that the adsorption coefficient should not be affected by velocity and that the contrary findings cited here are in error.

Chapter 7

SIGNIFICANCE AND APPLICABILITY OF DATA

One of the major objectives of this review has been to summarize clearly and concisely the published data on the adsorption of krypton and xenon on activated carbon. A secondary objective has been to determine our current ability to specify mean values and the ranges of probable errors for adsorption coefficients under specified conditions. Such information is essential for making accurate estimates of the performance of noble gas adsorption beds. These data can also provide guidance for upgrading the performance of existing beds and for assessing the adequacy of current design criteria as well as for specifying additional criteria that would result in improved performance. Only with the availability of such data is it possible to determine what efficiency of performance is reasonable to accept and what is possible through applications of the As Low As Reasonably Achievable (ALARA) criterion.

7.1 Variability of Adsorption Coefficients

The large body of data compiled in this report has permitted a statistical analysis to be made to determine the most likely values for the adsorption coefficients for krypton and xenon as well as the variability associated with the selection of a specific value. As may be noted, there was a wide range of possible values for these adsorption coefficients at any particular temperature. For example, at 25°C the adsorption coefficient for krypton in an air carrier was estimated to be $\leq$ 22 cc/gm for 5% of the charcoals tested; for 95% of the charcoals, the corresponding value was $\leq$ 72 cc/gm. Unfortunately, this could result in a possible error of a factor of more than

three if the charcoals represented by these two extremes were accidentally interchanged in an adsorption bed.

The estimated value of the adsorption coefficient for krypton from air at 25°C, as quoted by the U. S. Nuclear Regulatory Commission (Cardile and Bellamy, 1979), is 70 cc/gm. This value is significantly higher than the mean value of 40 cc/gm found here for beds operated under similar conditions. Although the NRC estimate is within the range of adsorption coefficients determined from this analysis to be realistic, the difference in the value observed here and that suggested by the NRC could mean that licensees who have adsorption beds designed on the basis of the NRC value may have facilities that are undersized. These data also show that significant upgrading of many fission gas adsorption beds could be accomplished by replacing lower quality charcoals with those having better characteristics. The quality of commercially available charcoals covers a wide range; licensees should be encouraged to specify, through their purchase orders, charcoals that are in the higher ranges with respect to their adsorption coefficients for krypton and xenon.

7.2 Significance of Mass Transfer

This review has shown that interparticle mass transfer can have significant effects on the performance of a charcoal adsorption bed, particularly in those cases where the velocity of the carrier gas is extremely low. At such velocities, molecular diffusion of krypton and xenon becomes competitive with transport of the carrier gas by convection. These two mechanisms, operating in concert, reduce the efficiency of the adsorption bed.

This problem can be eliminated by keeping the diameter of a bed sufficiently small to raise the convection velocity of the carrier gas above the regime where interparticale particle diffusion can be important. The actual velocity at which such effects become important is a function of temperature, carrier gas, the adsorption coefficient of the bed, and the decay constant of the radionuclide, under consideration. In general, a flow rate greater than 0.1 cm/sec is recommended. This is a matter that the NRC should consider including in its design specifications for adsorption systems for krypton and xenon in commercial nuclear power plants.

7.3 Significance of Pressure and Moisture

This review of the data shows that knowledge of the effects of pressure is sufficiently complete to permit reasonably good estimates to be made of the change in the adsorption coefficient brought about by variations in this parameter. One of the major results of this analyses has been to show that the commonly held assumption, that the adsorption coefficients for krypton and xenon increase directly with the absolute pressure, is not valid. This review has similarly disproved the assumption that the adsorption coefficient increases directly with the surface area of the adsorbent. On the other hand, this review did confirm that for most adsorption systems the assumption of linear adsorption isotherms is justified.

Unfortunately, data on the effects of moisture on adsorption coefficients are less complete than those for pressure. As this review has shown, there is only a limited amount of data on the effects of moisture at temperatures other than ambient. In addition, there are essentially

no data on the combined effects of moisture and pressure. Both of these are areas in need of additional research.

7.4 Commentary

Using the data in this report, there are a number of additional correlations that could be made. For example, a comparison could be made between the data developed by research personnel in the U. S. and the U.S.S.R. to determine if there are appreciable differences in their observations. This would be particularly interesting since adsorption phenomena have been a focal point of U.S.S.R. technology for several decades. Another evaluation that could be made would be to examine the data published over the past three decades (the time span for which data are available) to determine if there have been any improvements in the performance of activated charcoals. If improvements have been observed, the next step would be to try to determine what has been responsible for the changes noted and what steps can be taken to further improve the performance of charcoals selected for the adsorption of radioactive noble gases.

Such analyses, and the continuing publication of additional data on the various parameters affecting the performance of fission gas adsorption beds, should assist in updating and improving the data presented in this report. Regardless of such additions, however, one conclusion is clear. There are wide variations in the adsorption coefficients of different charcoals. Although nominal values can be used for purposes of system design, it is imperative that those responsible for evaluating such systems recognize that the only positive method of predicting bed

behavior is through direct measurements of the adsorptive capacity of the adsorbent as installed. This is particularly true in light of the fact that there is no scaleup factor for applying laboratory data to full scale plant design.

In the design of noble gas retention systems, the goal should be to maintain an acceptable holdup time for the specific radionuclides being released. This review has shown that non-critical acceptance of adsorption coefficients obtained from the published literature can lead to considerable error both in the design and the expected performance of such systems. Through the data provided here, people responsible for such systems have been provided with a range of acceptable values for adsorption coefficients under a variety of operating conditions. This should enable them to estimate in advance what type of performance should be possible as well as reasonable to expect. This, in turn, should lead to the design of adsorption systems that will provide not only better, but also more reliable, performance. Knowledge of the degree of variability of charcoal adsorbents for the retention of krypton and xenon can also assist regulatory agencies, such as the NRC, in establishing more meaningful and realistic testing requirements to assure the adequate performance of such systems.

16. ABSTRACT *(200 words or less)*

This report is a critical review of the published literature on the adsorption of radioactive krypton and xenon on activated charcoal. The report includes a tabulation and evaluation of the adsorption coefficients for these two gases as related to temperature, pressure, moisture, mass transfer effects, and the nature of the carrier gas. Wherever possible, the resulting data have been used to develop simple correlations for quantitatively evaluating the effects of these parameters on noble gas adsorption. Important conclusions of the study include the observations that (a) individual charcoals have a wide range of adsorption coefficients and therefore the performance of a given bed is heavily dependent on the quality of the charcoal it contains; (b) because of the detrimental effects of mass transfer on noble gas adsorption, consideration should be given to including this factor in developing technical specifications for adsorption beds; and (c) additional research is needed on the determination of the interrelationship of moisture and temperature and their effects on adsorption bed performance.
