EXECUTIVE SUMMARY

The U.S. Army Corps of Engineers Hydrologic Evaluation of Landfill Performance (HELP) model was used to evaluate two design options for the Kerr-McGee Cushing, Oklahoma, Refinery Site disposal cells. Specifically, the HELP model was used to estimate the amount of leachate generated from disposal cells with two different liners. The evaluation was performed to support the final design of two disposal cells with 5-foot *in situ* clay liners with permeabilities of 10^{-8} cm/s. This design is more stringent than the State requirement of a 3-foot recompacted clay liner with a permeability of 10^{-7} cm/s.

Results from modeling a disposal cell having a 5-foot, *in situ* clay liner with 10^{-8} cm/s permeability were compared to results from modeling a disposal cell having a 3-foot, recompacted clay liner with 10^{-7} cm/s permeability. The results show that the disposal cells having 5-foot, 10^{-8} cm/s *in situ* clay liners will produce less leachate than the disposal cell having a 3-foot, 10^{-7} cm/s recompacte clay liner.

The projected leachate volume from a disposal cell modeled by Oklahoma Department of Environmental Quality (ODEQ) was compared to the leachate volume of the cells designed for this project having 5-foot *in situ* clay liners. The model results indicate that the disposal cells with 5-foot *in situ* clay liners will produce significantly less leachate than the disposal cell modeled by the ODEQ.

The 5-foot, *in situ* clay liner protects groundwater as effectively as the 3-foot, compacted clay liner, based on HELP model results for both average annual and peak daily percolation. In addition, the 5-foot, *in situ* clay liner can be considered adequate since the ODEQ concluded that a single, 3-foot, recompacted clay liner was adequate under ODEQ conditions where significantly more leachate was generated.

INTRODUCTION

The remedial design for the Kerr-McGee Cushing site includes two disposal cells, Cell A and Cell B, for the storage of neutralized refinery sludge. As part of the design process, the HELP model was used to evaluate liner and cover alternatives for several disposal cell construction options. This report presents HELP model results for determining the amount of leachate produced by disposal cells having two different liners. These results were also compared to model results generated by the Oklahoma Department of Environmental Quality, who used an altogether different disposal cell configuration.

The first, Cell A, configuration model included a 3-foot thick, recompacted clay liner with a permeability of 10^{-7} cm/s. The second, Cell A, configuration model included a 5-foot thick, in situ clay liner with a permeability of 10^{-8} cm/s. Each of these cell configurations were also modeled for Cell B. The third set of modeling results discussed in this report are associated with a cell configuration modeled by the Oklahoma Department of Environmental Quality (ODEQ).

This evaluation was performed to support the final design of two disposal cells with 5-foot in situ clay liners with a permeability of 10^{-8} cm/s. This design provides more protection for groundwater than the State requirement of a 3-foot recompacted clay liner with a permeability of 10^{-7} cm/s.

MODEL INPUT REQUIREMENTS

- *Climatological Data*
- *Design Data*
- *Soil Data*

The HELP program requires three general types of input data: climatological, design, and soil. A summary of data requirements and corresponding input values is presented below. The input values are also included on the model output sheets provided in Appendices B and C.

CLIMATOLOGICAL DATA

The climatological data required by the model can be classified into three groups; precipitation, temperature, and evapotranspiration. Ten years of precipitation and temperature data were synthetically generated by the model and used for each cell configuration modeled. The model has default precipitation and temperature data for two cities in Oklahoma, Oklahoma City and Tulsa. The default data for Tulsa was chosen for the model calculations because the Cushing site is closer to Tulsa than to Oklahoma City. Statistical characteristics of the synthetically generated, daily precipitation and temperature values were improved by inputting the area's actual normal values. Values for Tulsa were taken from the Water Encyclopedia and are included in Appendix A.

Evapotranspiration data is calculated by using the evaporative zone depth and maximum leaf area index for the site. The evaporative zone depth is the maximum depth from which water can be removed by evapotranspiration. The evaporative zone depth used for all of the cell configurations was 22 inches. This is the depth recommended by the model for the Tulsa area. The maximum leaf area index is the ratio of the leaf area of actively transpiring vegetation to the nominal surface area of the land on which the vegetation grows. The maximum leaf area index used for each model run was 2.0, which is the typical value for vegetation in the Tulsa area.

DESIGN DATA

Design data required by the model includes the area of the cell, the number of layers in the cell, and the type and thickness of each layer. Two cells were modeled under the disposal cell design, Cell A and Cell B. The configuration of each cell was based on dimensions provided in Table 4-4 of the Report on Disposal Cell Option Evaluation, Cushing Remedial Design. Table 4-4 has also been included in Appendix A. The cell configuration remained constant for each layer, except for the bottom, barrier clay liner. The thickness and soil properties of the fourth layer were varied to compare the effect of the liner on model results.

An area of 572,000 square feet and a total depth of 20 feet was used for Cell A. An area of 400,000 square feet and a total depth of 20.7 feet was used for Cell B. The cells were divided into four layers, numbered one to four, with layer one being the top layer.

Layer 1 for Cells A and B represents a topsoil/vegetation layer, and is considered a lateral drainage layer. A lateral drainage layer allows for vertical and lateral flow of water. A slope of 3 percent and a thickness of 6 inches was used for this layer. A runoff curve number for the site was generated by the model, and it was based on factors such as slope, soil texture, and vegetative cover. This number was constant for the two liner thicknesses modeled. The model also requires a drainage length for a lateral drainage layer. The drainage length for Cell A is 650 feet, while the drainage length for Cell B is 500 feet.

Layer 2 for Cells A and B is a barrier soil layer of 30 inches of clay. The barrier soil layer is intended to restrict water flow into and through the other soil layers. Since the program considers only downward flow, any water moving into a barrier soil layer will eventually percolate through the liner. Percolation rate depends on the depth of water saturated soil (head) located above the base of the layer.

Layer 3 of the disposal cells represents a layer of treated waste, and is considered a vertical percolation layer. The thickness of the waste in Cell A is 168 inches, and the thickness of the waste in Cell B is 176.4 inches.

Layer 4 is the barrier clay liner, and is the variable for evaluation of the disposal cell configuration. The first configuration has a 3-foot, recompacted clay liner for Layer 4 of Cells A and B. The second configuration has a 5-foot, in situ clay liner for Layer 4 of Cells A and B.

SOIL DATA

Required soil data includes soil type and initial soil moisture content. A soil texture can be entered manually, but the model also has 42 default soil textures with characteristic values for each. Each soil texture in the model has values for the following characteristics:

- Porosity (in vol/vol): the soil water content at saturation
- Field capacity (in vol/vol): the soil water content after a prolonged period of gravity drainage
- Wilting point (in vol/vol): the lowest soil water content that can be achieved by plant transpiration
- Saturated hydraulic conductivity (in cm/s): the rate at which water drains vertically through a saturated soil with no vertical pressure gradient.

Initial soil water content, in vol/vol, is also required. Initial soil water content is the ratio of the volume of water in a soil to the volume occupied by the soil. This can be initialized by the computer or input manually.

Soil texture, for Layer 1 of Cells A and B, is a fine, sandy loam with a saturated hydraulic conductivity of 1.5×10^{-3} cm/s and a fair stand of grass. Fine, sandy loam was chosen based on topsoil native to the area. Model default characteristics assigned to fine, sandy loam include a porosity of 0.4730 vol/vol, a field capacity of 0.2217 vol/vol, a wilting point of 0.1043 vol/vol, and an initial soil water content of 0.2217 vol/vol.

Soil texture, for Layer 2 of Cells A and B, is a clay with a permeability of 10^{-8} cm/s. Model default characteristics of a clay with 10^{-8} cm/s permeability include a porosity of 0.4 vol/vol, a field capacity of 0.3560 vol/vol, and a wilting point of 0.2899 vol/vol. An initial soil water content of 0.15 vol/vol was input manually because the clay will be compacted at optimum moisture content.

Layer 3 of Cells A and B represents treated waste. A hydraulic conductivity of 8.1×10^{-3} cm/s was input for the treated waste, based on measured permeabilities for treated waste.

Model default characteristics of a soil with a saturated hydraulic conductivity of 8.1×10^{-3} cm/s include a porosity of 0.4570 vol/vol, a field capacity of 0.1309 vol/vol, a wilting point of 0.0580 vol/vol, and an initial soil water content of 0.1309 vol/vol.

The first clay liner configuration modeled for Cells A and B was a recompacted, 3-foot clay liner with a permeability of 10^{-7} cm/s. Model default characteristics for a 10^{-7} cm/s clay include a porosity of 0.43 vol/vol, a field capacity of 0.366 vol/vol, and a wilting point of 0.28 vol/vol. An initial soil water content of 0.15 vol/vol was input manually because the recompacted clay will be installed at optimum moisture content.

The second clay liner configuration modeled for Cells A and B was an in situ, 5-foot clay liner with a permeability of 10^{-8} cm/s. Model default characteristics of a 10^{-8} clay include a porosity of 0.4 vol/vol, a field capacity of 0.356 vol/vol, a wilting point of 0.2899 vol/vol, and an initial soil water content of 0.356 vol/vol.

MODEL RESULTS

MODEL RESULTS

A summary of average annual totals for the 3-foot, recompacted clay liner; the 5-foot, in situ clay liner; and the ODEQ model are shown in Table 1. HELP model output data is included as Appendix B, and the ODEQ HELP modeling memo is included as Appendix C.

Percolation from Cell A, with three feet of recompacted clay, averaged 0.08 inches, or 3,912 cubic feet per year, which is 0.24 percent of the total precipitation. The peak, daily percolation from Layer 4 was 0.0004 inches, or 19.5 cubic feet. Percolation from Cell B, with three feet of recompacted clay, averaged 0.08 inches, or 2,734 cubic feet per year, which is 0.24 percent of the total precipitation. The peak, daily percolation from Layer 4 was 0.0004 inches, or 13.6 cubic feet.

Percolation from Cell A, with five feet of in situ clay, averaged 0.08 inches, or 3,846 cubic feet per year, which is 0.24 percent of the total precipitation. The peak, daily percolation from Layer 4 was 0.0003 inches, or 16.2 cubic feet. Percolation from Cell B, with five feet of in situ clay, averaged 0.08 inches, or 2,687 cubic feet per year, which is 0.24 percent of the total precipitation. The peak, daily percolation value from Layer 4 was 0.0003 inches, or 11.3 cubic feet.

DISPOSAL CELL LINER COMPARISON

Based on HELP modeling results for the average annual and peak daily percolation values, the 5-foot, in situ clay liner is as protective as the 3-foot, recompacted liner. The 5-foot liner is considered as protective because less leachate percolates through the bottom of the cell with the 5-foot, in situ liner than in the cell with the 3-foot, compacted liner.

The average, annual total percolation through Cell A (5-foot, in situ liner) is approximately 0.08 inches, or 3,846 cubic feet. This is slightly less than the 3,912 cubic feet, annual average percolation through Cell A having the 3-foot, recompacted clay liner. The daily peak percolation through Cell A (5-foot, in situ liner) is approximately 0.0003 inches, or 16.2 cubic feet. This is slightly less than the 19.5 cubic feet, daily peak percolation through Cell A having the 3-foot, recompacted clay liner.

The average, annual total percolation through Cell B (5-foot, in situ liner) is approximately 0.08 inches of water, or 2,687 cubic feet. This is slightly less than the 2,734 cubic feet, annual average percolation through Cell B having the 3-foot, recompacted clay liner. The daily peak percolation through Cell B (5-foot, in situ liner) is 0.0003 inches, or 11.3 cubic feet. This is slightly less than the 13.6 cubic feet daily peak percolation through Cell B having the 3-foot, recompacted clay liner.

Approximately 0.24 percent of the total annual precipitation percolated through Cells A and B having the 5-foot, in situ liner.

Average annual and daily peak percolation model results for the 5-foot, in situ liner were approximately two orders of magnitude lower than the ODEQ's model results. Average annual percolation for the cell the ODEQ modeled is approximately 7.5 inches, or 281,000 cubic feet, compared to 0.08 inches, or 3846 cubic feet, for Cell A having the 5-foot, in situ liner. The daily peak percolation through the ODEQ cell is 0.02 inches, or 337 cubic feet, compared to 0.0003 inches, or 16.2 cubic feet, through Cell A having the 5-foot, in situ liner.

Approximately 25 percent of the total annual precipitation percolated through the ODEQ cell, compared to only 0.24 percent of the total annual precipitation which percolated through Cell A with a 5-foot, in situ liner.

It is important to note that the ODEQ assumed very conservative model input data to maximize the amount of leachate generated. The ODEQ assumed equally conservative input data to assess the impact of leachate on the aquifer below the disposal cell, using a fate and transport model. Under this scenario, which resulted in a maximum amount of leachate and worst case fate and transport to the aquifer, the ODEQ concluded that a single, 3-foot thick layer of 1×10^{-7} clay would be adequate as the bottom liner of the proposed disposal cell (see Appendix C).

CONCLUSION

The 5-foot, in situ liner is as protective of the groundwater as the 3-foot, compacted liner, based on HELP model results for average annual and peak daily percolation. In addition, the 5-foot, in situ liner can be considered adequate, since the ODEQ concluded that a single, 3-foot thick, clay liner was adequate under conditions where significantly more leachate was generated.

SUBJECT Cushing Pit 5 Formation
Clay Permeabilities

Pursuant to your request, core samples retrieved from boreholes drilled around Cushing Pit 5 in September 1992 were submitted to Standard Testing in Oklahoma City for determination of permeabilities. In addition, compacted cylinder samples of treated and solidified Pit 5 sludge mixes 2 and 4 provided by you were also submitted for permeability tests.

Formation Clay Permeabilities

One core sample was selected from each of the four boreholes drilled around Pit 5 in September 1992. Locations of these boreholes are shown on the attached map.

Criteria used in the selection of samples was the absence of sand, silt, and visible parting. Thus, only those sections of the cores that appeared to be predominantly clay were selected. When possible, sections of cores that were obviously sandy, silty, or shaly were rejected.

The depth intervals selected for permeability testing are as follows. Depths are given in feet below ground level and elevation in feet above Mean Sea Level:

Borehole	Depth Interval	Elevation
P5-1A	50 - 53.5 feet	789.4 - 785.9
P5-2	53 - 53.5 feet	790.8 - 790.3
P5-3	40 - 44.5 feet	818.6 - 814.1
P5-4	33.5 - 34 feet	818.6 - 818.1

Descriptions of the lithology at these intervals, and the permeabilities as determined by Standard Testing, are presented below. The laboratory report sheet is attached:

Borehole	Description	Permeability (cm/sec)
P5-1A	Reddish-brown silty clay	1.0×10^{-7}
P5-2	Gray silty clay w/gravel	9.9×10^{-7}
P5-3	Reddish-brown silty clay	1.8×10^{-4}
P5-4	Dark red sandy, shaly clay	9.9×10^{-4}

Page 2

Treated/Solidified Pit 5 Sludge

As mentioned above, compacted cylinder samples of the treated and solidified Pit 5 sludge mixes 2 and 4 you provided were also submitted for permeability tests. The permeabilities as determined by Standard Testing for these samples are presented below. The laboratory report sheet is attached:

Solidified Sample	Permeability <u>(CM/sec)</u>
Mix 2	8.1×10^{-3}
Mix 4	3.1×10^{-3}

* * *

Should you have any questions or comments regarding these permeability tests, please call at extension 2696. The Mix 2 and Mix 4 samples will be returned to you as soon I can retrieve them up from the laboratory.

SUBJECT: KERR-MCGEE CUSHING SITE

SUMMARY OF COMMUNICATION:

I spoke with Mike Holmes and asked him if the total depth in the quantities summary table included the bottom liner. He said that it did not. He said it only contained the top two layer and the waste layer. Mike called back and said that in table 4.4 of the Disposal Option Evaluation the total depth included a 3 ft. liner.

Mr. Norm Blaker
Fluor Daniel Williams Brothers
119 East 6th Street
Tulsa, OK 74121-1310

Dear Mr. Blaker:

After reviewing the additional cost estimate data we received today, Roy Smith, Jeff Ostmeyer, and I agreed to go forward with Option 3 in the disposal cell design. We will plan to dispose of all material from Pit 4 in the disposal cell in the northwest corner.

However, I would like to address a change in our concept of 400,000 and 600,000 cubic yard designs. We have a much higher degree of uncertainty concerning the volume of pit 5 (compared to the other four pits), and we also know of a significant number of other waste pits in the southern portion of the property. Roy, Jeff, and I therefore decided it would be best to design the 400,000 c.y. cells so the disposal cells contain waste in proportion to their estimated quantities. However, the additional 200,000 c.y. that go into the 600,000 c.y. design should be divided so that 50,000 c.y. goes into the northwestern cell, and 150,000 c.y. goes into the southeastern disposal cell.

Hopfully, this letter is understandable and gives you the information you need to proceed with the disposal cell design. I will be in Washington, D.C. Thursday and Friday, so I will be difficult to reach. If you have questions or comments, you may leave a voice mail message or call me at home over the weekend at (405) 354-8105. I will be in Cushing on Monday, and can be reached at (918) 225-7753. Thanks for your help.

Sincerely,

A handwritten signature in black ink, appearing to read "Jeff Lux".

To: Scott Thompson, Environmental Specialist Supervisor
 From: Terry Andrews, Senior Hydrologist TH
 Subject: Kerr-McGee Cushing site

On March 12, you asked me to evaluate sample analysis from Kerr-McGee Cushing site pit 5 wastes that had been neutralized and solidified. You instructed me to determine, on the basis of fate and transport principles, the type of liner that would be needed if an on-site landfill was constructed and this treated waste was placed within it.

The most likely least cost alternative for landfilling of pit 5 treated wastes is by constructing a landfill with 3 feet of compacted clay as a liner. I decided to use whether or not this situation could lead to ground water contamination by using two predictive models, the Hydrologic Evaluation of Landfill Performance (HELP) model and the ununited version of SUTRA model. The HELP model is used to predict the amount of leachate that could infiltrate and then move through the liner and exit the landfill. The HELP model is currently used by the OSDE and EPA to help determine landfill design. The ununited version of the SUTRA model is used to predict the fate and transport of organic chemicals found in the treated waste as it desorbs from the waste and is mixed into an aquifer. I chose this model because it is very useful for predicting fate and transport of organic chemicals when site characterization is limited and many fate and transport variables are unknown. The ununited version of the SUTRA model has been used on several Superfund site remediations and is considered to be a conservative model. More information about this model can be found in EPA/540/2-89/057.

I gathered information and data needed for the modeling exercise using the Phase I Remedial Investigation Report prepared by Burns & McDonnell Waste Consultants, Inc. for Kerr-McGee Corporation. For input into the HELP model, I used a landfill construction scenario consisting of the following:

- A liner consisting of three (3) feet of clay with resulting saturated hydraulic conductivity of 1×10^{-7} cm/sec.
- A twenty five (25) foot thick fill consisting of treated waste with a saturated hydraulic conductivity of 5.8×10^{-6} cm/sec.
- A cap consisting of two (2) feet of uncompacted clay with a saturated hydraulic conductivity of 4.2×10^{-6} cm/sec.

was used for the Vinita-Ada Aquifer.

- A "mixing zone" of fifty (50) feet was used for the thickness of the dilution zone in the aquifer that the leachate is likely to be diluted into.
- An annual precipitation of thirty (30) inches per year was used.

12/08/93

10:23

25465 271 1342

2003

- The fraction of organic carbon in the liner clay was estimated to be 0.01.

The results of the untrained version of the Summers model are shown in Table 1. The Summer concentration is the chemical specific concentration at which the waste fill would not cause health-based levels and regulatory levels of contaminants in a drinking water supply to be exceeded. These levels are compared with the highest contaminant concentrations indicated in the analysis of the pit 5 treated waste in Table 2. All of the treated waste concentrations are well below the Summer concentrations. Based on these results and knowing that a conservative modeling approach was used, I feel that a single 3 foot thick layer of clay would be appropriate as the bottom liner for the proposed landfill.

Clean-up levels are determined using the uncarmed variation of the Surmaers Model. These critical soil concentrations are derived for both saturated (Sead) and unsaturated (Sursead) soils to prevent ground water in the Vannous-Adz Aquifer from exceeding regulatory or health-based levels (HSU). Sead concentrations represent contaminant concentrations that must not be exceeded in the treated waste fill; further information about this model can be found in EPA/540-R-89/057.

Maximum Contaminant Levels or Proposed Maximum Contaminant Levels are shaded. Other health-based levels were calculated using Risk Assessment Guidance for Superfund.

Contaminants indicated in analysis of Pt 5 treated wastes are bolded.

Memorandum

Date: March 25, 1993

To: Scott Thompson, Environmental Specialist Supervisor

From: Terry Andrews, Senior Hydrologist *T.A.*

Subject: Kerr-McGee Cushing site

On March 18, you asked me to evaluate sample analysis from Kerr-McGee Cushing site pit 5 waste that had been neutralized and solidified. You instructed me to determine, on the basis of fate and transport principles, the type of liner that would be needed if an onsite landfill was constructed and this treated waste was placed within it.

The most likely least cost alternative for landfilling of pit 5 treated waste is by constructing a landfill with 3 feet of compacted clay as a liner. I decided to test whether or not this situation could lead to ground water contamination by using two predictive models, the Hydrologic Evaluation of Landfill Performance (HELP) model and the unnamed version of Summers model. The HELP model is used to predict the amount of leachate that could infiltrate and then move through the liner and exit the landfill. The HELP model is currently used by the OSDH and EPA to help determine landfill design. The unnamed version of the Summers Model is used to predict the fate and transport of organic chemicals found in the treated waste as it desorbs from the waste and is mixed into an aquifer. I chose this model because it is very useful for predicting fate and transport of organic chemicals when site characterization is limited and many fate and transport variables are unknown. The unnamed version of the Summers Model has been used on several Superfund site remediations and is considered to be a conservative model. More information about this model can be found in EPA/540/2-89/057.

I gathered information and data needed for the modeling exercise using the Phase I Remedial Investigation Report prepared by Burns & McDonnell Waste Consultants, Inc. for Kerr-McGee Corporation. For input into the HELP model, I used a landfill construction scenario consisting of the following:

- A liner consisting of three (3) feet of clay with resulting saturated hydraulic conductivity of 1×10^{-7} cm/sec.
- A twenty five (25) foot thick fill consisting of treated waste with a saturated hydraulic conductivity of 5.8×10^{-5} cm/sec.
- A cap consisting of two (2) feet of uncompacted clay with a saturated hydraulic conductivity of 4.2×10^{-6} cm/sec.

- A topsoil layer placed on top of the cap consisting of one (1) foot of topsoil with a saturated hydraulic conductivity of 3×10^{-3} cm/sec with fair grass.
- I estimated a total landfill area of 450,000 square feet.
- I used climatological data from Tulsa and adjusted this for the Cushing location by correcting the latitude.
- I used default values of typical soils for the soil and moisture variables.

The HELP model results are attached with this memorandum. The solution indicated that 24.6 percent of the annual rainfall will move through the landfill and through the bottom liner. I feel that this value is relatively high when compared to other landfill leachate designs. However, for the purpose of this exercise it will help insure that a conservative approach has been used. The actual percent of precipitation that moves through the landfill and liner will probably be much less. The treated waste will likely have a much lower saturated hydraulic conductivity than the municipal waste which was used in this modeling run. I used the results of the HELP model as inputs into the fate and transport model.

For additional input into the unnamed version of the Summers model, I used chemical characteristics data from EPA Guidance material (EPA/600/R-90/003) and information from the Phase I Remedial Investigation Report. The Maximum Contaminant Levels (MCLs) were obtained in the Code of Federal Regulations (441 subpart B) and the health based levels were calculated by OSDH using the Risk Assessment Guidance for Superfund and modifying the resultant levels by multiplying a safety factor of 0.25. The following assumptions were made while using the fate and transport model:

- The movement of leachate was modeled as if the Vannessa-Ada aquifer was directly beneath the landfill. Although this is definitely not the case because the landfill would be separated from the Vannessa-Ada aquifer by approximately 180 feet of marlstones in the Vannessa Group, travel of leachate could potentially occur through the Vannessa Group through fractures. Also, even if fracture systems through the Vannessa do not exist, movement of ground water likely occurs through the Vannessa albeit very slowly. The lagges in time of leachate transport into the aquifer is not likely to significantly affect the resultant contaminant concentration of the aquifer. By modeling the aquifer as if it is directly beneath the landfill liner, a conservative answer to the leachate effect on the aquifer can be calculated.
