1. INTRODUCTION

This report presents the results of aquatic ecological studies conducted by Ecological Analysts, Inc. (EA) during 1982 in the vicinity of the Nine Mile Point promontory in southeastern Lake Ontario. These aquatic studies were conducted in accordance with Environmental Technical Specifications for the Nine Mile Point Unit 1 and the James A. FitzPatrick nuclear generating stations, as prescribed by the United States Nuclear Regulatory Commission.

The ecological interaction of the Nine Mile Point Unit 1 and James A. FitzPatrick plants with the Lake Ontario environment in the vicinity of the Nine Mile Point promontory has been under study since the 1960s. This 1982 study represents a continuation of those early studies which were initiated during construction of the two nuclear plants (Nine Mile Point began operation in December 1969, James A. FitzPatrick started operation in July 1975).

The two stations are located on the shore of Lake Ontario approximately 11 kilometers (seven miles) northeast of the city of Osweyo, New York. Nine Mile Point Unit 1 is a 620 MWe boiling water reactor with the cooling water intake structure located off shore in approximately 7.6 meters (25 feet) of water and the discharge structure located near shore in approximately 5.2 meters (17 feet) of water. James A. FitzPatrick is an 821 MWe boiling water reactor with the water intake structure located near shore in approximately 7.3 meters (24 feet) of water and the discharge, with a 236-meter (774-ft) diffuser, located off shore in approximately 9.1 meters (30 feet) of water.

This annual report consists of data descriptions and discussions of results from the sampling program conducted by EA from January 1982 through December 1982. The sampling program included impingement studies at both power plants throughout the year and gill net collections from the vicinity of the two nuclear generating stations from April through December. Chapter 2 describes field fisheries, impingement, and laboratory methodologies. Chapter 3 treats the results of in-plant impingement studies and Lake Ontario Studies. Chapter 4 is a comparison of results from gill net and impingement sampling. Chapter 5 provides an environmental impact assessment as required by the Environmental Technical Specifications.

2. METHODS AND MATERIALS

2.1 LAKE ONTARIO STUDIES

The sampling design and methods described in this section represent a continuation of a program that has evolved as a result of changes which occurred during the spring of 1979 in U.S. Nuclear Regulatory Commission Environmental Technical Specifications for the Nine Mile Point Unit 1 and the James A. FitzPatrick nuclear power plants.

2.1.1 Gill Net Sampling

Gill net sampling for the 1982 program was conducted along four transects extending perpendicular from the Lake Untario snoreline (Figure 2-1). The transects NMPP (Nine Mile Point Plant) and FITZ (James A. FitzPatrick Plant) represent a zone in the lake near the two plants submerged intake and discharge structures. This zone can be influenced by the removal of cooling water and by subsequent thermal discharges and has been referred to as the experimental area. The transect to the west of the power stations, NMPW (Nine Mile Point West), is generally upcurrent (approximately 1.1 statute kilometers) of the experimental area with respect to the prevailing currents, and thus represents a zone considered outside the influence of the intakes and thermal discharges; this area has been referred to as a control area. The NMPE (Nine Mile Point East) transect is usually downcurrent (approximately 1.9 statute kilometers) from the discharge structures with respect to the prevailing currents and represents an area that sometimes is influenced by the thermal discharges; this zone has been referred to as the far-field area.

Sampling of finfish with gill nets during 1982 was conducted twice a month from April through August and monthly from September through December (Table 2-1). One experimental gill net was set at each of the four sampling stations. Each gill net measured 2.4 meters (8-ft deep) and 45.7 meters (150-ft long), comprised of six 7.6-meter (25-ft) panels with bar-mesh sizes ranging from 1.3 cm to 6.4 cm in 1.3 cm (0.5 to 2.5 inches in 0.5-in.) increments. All nets were set parallel to shore at the 9.1-meter (30-ft) depth contour. The nets were set at sunset of the night preceding an impingement collection and retrieved approximately 12 hours later.

2.1.2 Laboratory Processing

After collection of the nets, the samples were returned to the laboratory and all organisms were sorted, identified, and enumerated. Identification was made to the lowest possible taxonomic level, which was usually species. For the convenience of the reader common names are used in the text; nowever, a list of common and their associated scientific names are included in Appendix E. For each taxa collected, total number and total weight were determined. In addition, individual lengths and individual weights were recorded for a maximum of 40 specimens per species per gill net collection. Total lengths were measured to the nearest millimeter; weights were measured to the nearest 0.1 gram for specimens less than 10 grams, to the nearest 1.0 gram for specimens between 10 and 2,000 grams, and to the nearest 25 grams for specimens over 2,000 grams based on the precision of the scales used for measurement. Any unusual conditions, abnormalities, or presence of fish tags were noted on the data sheets.

Totals for Year	56	56	56			

⁽a) Bottom water temperatures and dissolved oxygen concentrations were recorded when gill nets were harvested.

2.1.3 Data Analysis

Catch data from gill nets were expressed as a catch-per-unit-effort (c/f) where a unit of effort was defined as a 12-hour set:

$$c/f = \frac{(X)(12)}{f}$$

wnere

X = number of fish caught in the sample
T = duration of set in nours.

2.2 IN-PLANT STUDIES

2.2.1 Impingement Sampling

In accordance with the requirements of the NRC's Environmental Technical Specifications, impingement catches were monitored on a frequency of 4 to 20 samples per month from January through December 1982 at the Nine Mile Point Unit 1 and the James A. FitzPatrick nuclear power stations (Table 2-2).

Samples were collected over a 24-hour period on randomly selected days. Samples were initiated around 1300 hours of the sampling day and were terminated 24 hours later. Organisms impinged on the traveling screens were mechanically washed into a collection basket with a 9.5-mm (3/8-in.) stretch mesh net liner. The collection basket remained in place for the duration of the sample, unless high impingement or debris loads required that it be emptied, in which case it was removed, emptied, and repositioned.

Plant operational data were obtained for each sampling date to document cooling water flow rates, intake and discharge temperatures, and power production. Meteorological data such as wind speed and direction and air temperature were obtained twice during the impingement sample.

Plans existed for continuing impingement monitoring at either power plant if impingement rates exceeded 20,000 fish per 24-hour period. In addition, plant procedures at James A. FitzPatrick required continued impingement sampling when limits of the fish contingency plan were exceeded. The fish contingency plan specified a maximum number of individuals for each species, based on historical impingement patterns, which might be expected to be impinged during one 24-nour sampling period.

2.2.2 Laboratory Processing

Laboratory processing of organisms collected in impingement was conducted as described for organisms collected with gill nets (see Section 2.1.2).

TABLE 2-2 IMPINGEMENT SAMPLING REGIME ASSOCIATED WITH ENVIRONMENTAL TECHNICAL SPECIFICATIONS FOR NINE MILE POINT UNIT 1 AND JAMES A. FITZPATRICK, 1982

	No. of Sampl	ing Days per Month(a)
	Nine Mile Point	James A. FitzPatrick
January	4	4
February	4	4
March	4	4
April	16	16
May	20	20
June	4	6
July	4	4
August	6	4
September	4	4
October	4	4
November	4	4
December	<u>5</u> (b)	<u>6</u> (b)(c)
TOTALS	79	80

(a) Days assigned within each month were selected randomly using random number tables (Rand Corporation 1955).

(b) One additional impingement sample, above the required four samples, was scheduled to coordinate with the December gill net collection.

(c) At James A. FitzPatrick, an additional impingement sample was required because impingement rates exceeded 20,000 fish in one 24-hour period.

2.2.3 Data Analysis

Data were tabulated to present impingement rates (number and weight) for each species as well as all species combined. Total estimated impingement for each month was calculated using the formula:

$$D = \frac{\Sigma C}{\Sigma V} \quad (X)$$

where

c = the number of fish collected during the sampling period
v = the volume of cooling water used during the sampling period

X = the total monthly volume of cooling water used.

The annual impingement estimate was then calculated by adding the 12 monthly impingement estimates.

2.3 WATER QUALITY DETERMINATIONS

2.3.1 Impingement Sampling

At the onset and completion of each impingement sample, discharge temperature (+0.5 C) was determined with a bucket of water retrieved from the discharge.

2.3.2 Gill Net Sampling

In association with each gill net sample, temperature and dissolved oxygen were measured at each gill net station (NMPE, NMPP, FITZ, and NMPW) (Table 2-1). Water was collected with a Kemmerer bottle at the 7.6-meter (25-ft) depth. Temperatures were determined with a hand-neld thermometer $(\pm\ 0.5\ C)$. Samples for dissolved oxygen analysis were fixed, stored on ice, and taken to the laboratory.

2.3.3 Laboratory Analysis

Dissolved oxygen values were determined (to the nearest 0.1 mg/ℓ) using the U.S. Environmental Protection Agency's modified version of the Winkler method (U.S. EPA 1979).

3. RESULTS

3.1 LAKE ONTARIO STUDIES

The 1982 Lake Ontario monitoring program was designed to describe the composition, relative abundance, and seasonal patterns of fish in the vicinity of the Nine Mile Point promontory. For ease in describing seasonal patterns, the months of the year were divided into winter (January through March), spring (April through June), summer (July through September), and fall (October through December). The aquatic studies also monitored water quality (temperature and dissolved oxygen) in the collection area. The results obtained during the 1982 gill net program using the methods and materials described in Chapter 2 follow.

3.1.1 Species Composition

Of the 14,395 specimens collected with gill nets from the Nine Mile Point study area during 1982, 23 species of fish and one taxa of crustacean were identified (Table 3-1). Alewife accounted for over 80 percent of all fish collected. Spottail shiner comprised almost 12 percent of the total catch, rainbow smelt comprised 3.3 percent, and the remaining 4 percent of the total catch was represented by 21 taxa.

Spottail shiner and white sucker were the only species collected during all months sampled in 1982. Alewife, brown trout, lake chub, and white perch were collected during seven of the nine months sampled. The remaining species were collected in six or less of the months sampled. The number of species collected each month remained between 11 and 13, with the exceptions of August when 16 different species were caught and October and December when only four and eight species, respectively, were collected.

3.1.2 Temporal and Spatial Distribution

The temporal distribution of fish collected by gill nets showed that peak abundance occurred during spring and early summer; July was the month of highest abundance. Collections of fish dropped in September and continued low through the fall (Table 3-1). Alewife was the dominant species during eight of the nine months sampled. In October, lake trout was the most numerous species collected.

Catch rates (catch per 12-hour set) among the transects ranged from one fish per 12-hour set to 820 fish per 12-hour set (Table 3-2). The lowest catch rate occurred in October at transect NMPE and the highest catch rate was in July at transect NMPW. The annual mean catch rates for all the transects, NMPW, NMPP, FITZ, and NMPE were similar in 1982. However, the annual mean catch rate for the FITZ transect was 5.0-7.7 percent lower than the annual mean catch rate for the other transects.

3.1.3 Selected Key (RIS) Species

Niagara Mohawk Power Corporation, the U.S. Nuclear Regulatory Commission, the Power Authority of the State of New York, the Environmental Protection Agency, and the New York State Department of Environmental Conservation nave classified

⁽a) Monthly mean catch rate.

nine species of fish in the Nine Mile Point area as representative important species (RIS). The species so designated are alewife, brown trout, cono, rainbow smelt, smallmouth bass, spottail shiner, threespine stickleback, white perch, and yellow perch. Of these nine species six nave been selected, because of their abundance and trophic level, for detailed studies in the 1982 report. These six include alewife, rainbow smelt, smallmouth bass, spottail sniner, white perch, and yellow perch. The following results relate to the temporal and spatial distribution (catch per 12-nour set) and the length-frequency distribution of the six selected RIS species.

Alewife

Gill net catches of alewives were nigh in the spring and reached a peak (mean catch rate of 573 fish) in July. Catches declined rapidly in August and remained low (mean catch rate less than or equal to 101 fish) through the fall (Appendix Table A-1). These trends are consistent with gill net data from previous years. Annual mean catch rates for alewife were nighest at transects NMPW, NMPP, and NMPE and were lower at transect FITZ (Table A-2).

Alewife collected with gill nets during 1982 ranged from 105 to 240 millimeters (mm) in total length. Most alewife collected were adult fish in the 150-190 mm range with a mean length of 172.7 mm; this size group was most abundant during the spring and summer (Table A-3).

Rainbow smelt

Gill net catches of rainbow smelt were highest in early spring and November (mean catch rate greater than or equal to 8 fish). Catches of smelt declined in late spring and no smelt were collected from August through October (Table A-1). A large catch of rainbow smelt at transect FITZ in April resulted in the highest annual mean catch rate at this transect.

Total lengths of rainbow smelt collected with gill nets ranged from 124 to 254 mm; with 163.3 mm as the mean length. Most rainbow smelt collected in the spring were yearling or older and fell within the length intervals of 130-170 mm, whereas rainbow smelt from the fall collections fell within 150-190 mm. However, the mean lengths for rainbow smelt in all months collected were quite similar.

Spottail shiner

Spottail shiner were collected with gill nets in each month sampled during 1982. Low catch rates in the early spring gave way to larger collections in the summer and declining catches in the fall. Annual mean catch rates were identical at transects FITZ and NMPE (33 fish per 12-hour set), lower for transect NMPW (20 fish per 12-hour set), and half that value for transect NMPP (16 fish per 12-hour set) (Table A-2).

Spottail sniners from the yill net collections ranged in length from 97 to 138 mm. The mean length was 118.0 mm and the most abundant length interval was 110-130 mm, generally adult fish in spawning condition. Approximately 94 percent of the adult spottail sniners caught were collected from June through August (Table A-3).

Small mouth bass

Gill net catches of smallmouth bass were low throughout the year (Table A-1). The higher catch rates in August and September were due to relatively large catches of bass at transect FITZ (5 and 8 fish per 12-hour set) in those months (Table A-2).

Gill net collections yielded adult smallmouth bass ranging from 298 to 456 mm in total length, with a mean length of 363.4 mm. Although most of the smallmouth bass were caught in August and September, the lengths were evenly distributed over five length categories (310-410 mm) (Table A-3).

White perch

Collections of white perch with gill nets were highest in late spring and summer (June through August) (> mean catch rate of 3 fish) and only one white perch was caught in the fall (Table A-1). The most numerous collections of white perch occurred at transect NMPW during the summer months (Table A-2).

White perch collected with gill nets varied from 91 to 311 mm. Almost 75 percent of the white perch caught were adults in the length range of 210-270 mm, and the only white perch caught in the fall was a young of the year at 97 mm (Table A-3).

Yellow perch

Gill net catches of yellow perch were highest (mean catch rates of 2-6 fish) during the late spring, summer, and in November. Catch rates (Table A-1) were near zero during the cold water sampling months in early spring and in October and December.

Yellow perch from gill net collections were yearling to adult and ranged from 142 to 330 mm in total length with a mean length of 239.7 mm. The most abundant catch for yellow perch occurred in July and approximately 45 percent of those individuals were adults between 190 and 230 mm in length (Table A-3).

3.2 IN-PLANT STUDIES

Nine Mile Point Unit 1 and James A. FitzPatrick power plants have once-through cooling systems with intake and discharge structures located nearby in Lake Ontario. Aquatic organisms, detritus, and other detris enter with the water pumped from the vicinity of the submerged intake pipes. These organisms, detritus, and debris are impinged on trash racks, which are used for screening out large items, and the traveling screens are used for screening out smaller materials. The traveling screens are backwashed to remove any accumulation of organisms, detritus, and debris into a sluiceway which empties into the impingement collection baskets. Studies of fish impingement began in the Spring of 1972 at Nine Mile Point Unit 1 and in 1975 at James A. FitzPatrick. The fish impinged at both plants have been monitored yearly in order to estimate abundance and biomass losses for each species.

The objectives of the 1982 impingement sampling program were to estimate annual fish losses, to determine species composition of impinged fish, and to describe

seasonal patterns of fish impingement. In addition, plant operating conditions (Table 3-3 and Appendix Tables B-1 and B-2) were logged during 1982. The results obtained during the 1982 impingement sampling program follow.

3.2.1 Nine Mile Point Unit 1 Nuclear Station

3.2.1.1 Species Composition and Estimated Impingement

Impingement sampling at Nine Mile Point Unit 1 during 1982 resulted in the collection of 27 taxa. Twenty-six fish species or genera and one invertebrate species, crayfish, were identified. Rainbow smelt was the most numerous species collected comprising 66.8 percent of the total catch. Rainbow smelt together with alewife and the sculpin family accounted for 90 percent of all the taxa collected (Table 3-4). No single species was caught in all 12 months. Sculpins, which were the most frequently caught taxa, were caught during nine months of the year. Alewife were caught in six months of the year and rainbow smelt in only five months during 1982 (Table 6-3).

Ninety-two percent of the total biomass collected at Nine Mile Point Unit 1 during 1982 was comprised of gizzard shad, alewife, and rainbow shelt (Table 3-5). Gizzard shad dominated biomass collections during the winter months. During the spring, summer, and fall months of 1982, Nine Mile Point Unit 1 was shut down for repairs and impinged few fish. Therefore, no one species dominated biomass collections. Rather, the dominant species, by weight, in each of the other months was determined by the largest fish caught in that month (Table 8-4).

The total number of aquatic organisms impinged at Nine Mile Point Unit 1 during 1982 was estimated to be approximately 89,526 individuals (Table 8-5). Rainbow smelt were estimated at 59,921 which is 67 percent of the total. Total weight was estimated to be 1,860 kilograms with gizzard shad estimated at 1,409 kilograms and 76 percent of the total biomass.

3.2.1.2 Temporal and Length Distributions

January was the month of peak impingement at Nine Mile Point Unit 1 in 1982. However, overall impingement collections were very low in 1982. The fact that Nine Mile Point Unit 1 main circulating water pumps were shut down for repairs from March through December accounts for the low impingement collections.

Rainbow smelt dominated the winter impingement collections, comprising over 60 percent of the total catch during those months. Alewife ranked second in abundance in January, accounting for 14.5 percent of the total catch. Sculpins ranked second in abundance in February and March comprising 22.4 and 15.1 percent, respectively, of the total monthly catch.

Length-frequency distributions are given for six representative important species (RIS): alewife, rainbow smelt, spottail sniner, smallmouth bass, white perch, and yellow perch (Table B-6). Alewife collected in the spring and summer at Nine Mile Point Unit 1 were subadult to adult fish; a few young-of-the-year alewife were collected in the late summer. Young-of-the-year as opposed to adult rainbow smelt dominated impingement collections in the winter.

Unidentified fish	0	0.0
Total	182,256	100.0

Adult spottail sniner and adult yellow perch were also collected during this period; whereas the white perch collected in the winter of 1982 were less than one year in age. Few smallmouth bass were impinged.

3.2.2 James A. FitzPatrick Nuclear Power Plant

3.2.2.1 Species Composition and Estimated Impingement

Impingement sampling at James A. FitzPatrick during 1982 resulted in the collection of 48 taxa; 45 fish species or genera were identified. Three of the 48 taxa collected were non-fish species: a mollusk, a crustacean, and an amphibian. Alewife and rainbow smelt comprised approximately 97 percent of the total impingement catch (Table 3-6) and were caught in each month sampled. Also caught in each of the 12 months were rock bass and yellow perch. White perch and spottail shiner were collected during 11 months of the year and sculpin and smallmouth bass were found in 10 months (Table B-7).

Alewife comprised 78 percent of the total fish biomass collected in 1982 (Table 3-7). Gizzard shad and rainbow smelt comprised 13.9 percent of the total biomass. Alewife dominated biomass collections in the spring, summer, and fall. In January, gizzard shad presented the largest percentage of the total biomass collected. Brown trout comprised roughly half of February catches, by weight; rock bass and gizzard shad codominated in March (Table 8-8).

The total number of aquatic organisms impinged at James A. FitzPatrick during 1982 was estimated to be approximately 603,242 individuals (Table B-9). Alewife were estimated at 346,503 which is 57 percent of the total. The rainbow smelt population impinged in 1982 was estimated at 235,289 (39 percent of the total). Total weight was estimated to be 11,235 kilograms and alewife were estimated at 8,670 kilograms or 77 percent of the total biomass.

3.2.2.2 Temporal and Length Distributions

Periods of peak estimated impingement at James A. FitzPatrick in 1982 occurred during the spring and in July and December. In April and May, adult alewife and subadult to adult rainbow smelt contributed to the large impingement. July's peak impingement was composed primarily of adult alewife and, in December, a large collection of young-of-the-year rainbow smelt increased the estimated impingement numbers. Overall, rainbow smelt dominated the winter and early spring (>55 percent of total monthly catches) collections. Alewife prevailed during the rest of the spring and summer (>80 percent of total monthly catches) impingement catches. In the winter months, alewife and rainbow smelt codominated the collections, with the exception of December when one large rainbow smelt collection caused a sharp increase in the impingement estimates. White perch, which was the third most prevalent species impinged in 1982, were caught in large numbers in April (616 fish) and December (126 fish). Sculpins were also collected in large numbers in April (545 fish). Gizzard shad catches were low (<270) in 1982.

Length-frequency distributions are given for the six representative important species (RIS): alewife, rainbow smelt, spottail shiner, smallmouth bass, white perch, and yellow perch (Table B-10). Adults were the principal age group of alewife collected in 11 of the 12 sampling months. In the late summer (September), young-of-the-year alewife predominated the collections.

Young-of-the-year alewife were also caught in April and August. In contrast to the alewife, the young-of-the-year age group dominated collections of impinged rainbow smelt throughout most of the year. Only in May did adult rainbow smelt outnumber the young-of-the-year smelt. The majority of white perch collected in the spring were adults; however, about one-third of the white perch measured in April were yearlings.

A few young-of-the-year white perch (<55) were collected in the winter and late fall (December). Adult yellow perch were collected at James A. FitzPatrick during most of the year with increased occurrence in the spring and summer. Few young yellow perch (<20) were collected during 1982. The size of the spottail shiners collected increased during the first half of the year and then declined in the latter half of the year: yearling fish in the winter gave way to adult fish during the spring and early summer and then young-of-the-year fish in late summer and fall. Adult smallmouth bass were caught throughout the spring and summer. In the fall, only young-of-the-year smallmouth bass were collected. Generally, at James A. FitzPatrick as at Nine Mile Point Unit 1, adult and subadult fish were impinged during the winter and spring months. Young-of-the-year fish appeared in impingement samples in the summer and dominated the fall collections.

3.3 WATER QUALITY

3.3.1 Gill Net Sampling

Water temperature and dissolved oxygen were measured during sampling efforts to indicate the water quality in the vicinity of the Nine Mile Point gill net transects. Collections were made near the bottom of the 30-ft contour using the methods and materials described in Chapter 2 of this report.

Water temperatures taken at the four yill net transects ranged from 2.1 C to 21.4 C during the 1982 sampling program (Table 3-8) and are typical of a northern temperate lake. Temperatures were lowest in April, increased gradually through June, increased rapidly through July and August, to a maximum in mid-August. Water temperatures declined slightly in September, dropped rapidly in October (possibly as a result of an internal seiche), increased in November and declined again in December. Variations of 1 C or more between transects were rare in 1982. In April at transect NMPW, the water temperature was about 4 C higher than the other transects. Influence from nearby streams and tributaries may have contributed to the higher temperature.

Dissolved oxygen (DO) concentrations were greatest (>9.5 ppm) in the spring and fall months when water temperatures were low (Table 3-8). Lower DO values occurred during the late summer months when water temperatures were at the highest values for the year, reflecting the fact that oxygen solubility decreases with increasing water temperature. The lowest DO value recorded was 8.8 ppm on 24 August 1982 at transect FITZ. DO concentrations were not low enough to cause stress in aquatic organisms and were not likely to have influenced distribution.

3.3.2 Impingement Sampling

Intake and discharge temperatures were measured at the beginning and end of each impingement sample. Intake temperatures were taken from plant operational logs. Discharge temperatures were measured in the discharge canal by EA personnel.

Intake temperatures measured by EA on sampling days at Nine Mile Point Unit 1 ranged from a minimum of -0.3 C on 19 and 29 January to a maximum of 22.6 C on 20 August. Discharge temperatures (when the plant was operating near generating capacity during January through March) on sampling days varied from a low of 20.2 C on 20 January to a high of 24.9 C on 6 and 28 January (Table B-1).

At James A. FitzPatrick, intake temperatures measured by EA on sampling days reached a minimum of -1.1 C on 10 March and a maximum of 22.2 C on 20 July. Discharge temperatures during plant operation (at least 75 percent of generating capacity) were lowest on 25 March and highest on 17 August. The lowest discharge temperature was 17.7 and the highest was 38.5 C (Table B-2). Minimum and maximum temperatures corresponded with normal seasonal cycles in lake temperatures.

4. COMPARISON OF SPECIES COMPOSITION AND TEMPORAL DISTRIBUTION FOR FISH COLLECTED IN GILL NETS AND IMPINGEMENT SAMPLES, 1982

Trends in the species composition and temporal distribution for fish collected with gill nets were generally comparable to trends observed in the impingement collections at Nine Mile Point Unit 1 and James A. FitzPatrick during 1982. Differences in these trends were largely due to several factors: the selectivity of the gill net year to certain age or size class fish, scheduled or unscheduled outages at the power plants, and the different lengths of the sampling seasons.

Size selectivity of the gill nets may account for some differences in species composition between impingement and gill net collections. Although all of the 24 taxa (23 fish and one crustacean) with the exception of walleye collected with gill nets were present in the impingement collections, more than an additional 20 species were caught in impingement at James A. FitzPatrick. James A. FitzPatrick impinged 46 species of fish and Nine Mile Point Unit 1 impinged 27 species of fish. Many species such as sculpins, darters, and sticklebacks were too small to be caught in the gill nets used.

Size selectivity of the gill nets and absence of winter gill net sampling also explained a difference in temporal abundance of fish between gill nets and impingement collections. Gill net collections (catch per 12-hour set) of fish were highest in spring and early summer with peak catches coinciding with the spawning runs of several fish species. The highest impingement collections (number per 1,000 m³ of water pumped) for Nine Mile Point Unit 1 were in January (Figure 4-1) and for James A. FitzPatrick during early winter and late fall (January and December), spring (April and May), and midsummer (July) months (Figure 4-2). The impingement abundance peaks in January reflected large collections of rainbow smelt. Because gill nets were not collected in January, coincidental peaks were not observed. A large collection of young-of-the-year rainbow smelt in December contributed to the impingement peak at James A. Fitzpatrick. Gill nets do not effectively catch young-of-the-year fish, therefore, no similar abundance peak was observed in the December gill net catch.

A power plant outage can obscure the usual trends in the temporal distribution of impingement catches. For example, few fish were impinged at Nine Mile Point Unit 1 from March through December during the outage. In past years, high numbers of alewife were impinged in the spring. Data from the Spring 1982 gill net collections reflected this trend as large numbers of alewife in spawning condition were caught. Spring collections of alewife in 1982 at James A. FitzPatrick and in gill nets compared similarly. In both types of collections, adult alewife dominated the spring catches.

Another factor that made comparison of yill net data and impingement data difficult was the different lengths of the sampling seasons. Gill net collections were made in nine months, April through December, whereas impingement sampling was conducted year-round. In terms of species composition some fish species, for example whitefish and gizzard shad, were present and/or abundant during winter impingement samples but were absent or poorly represented in the Nine Mile Point area during the gill net sampling season (spring through fall).

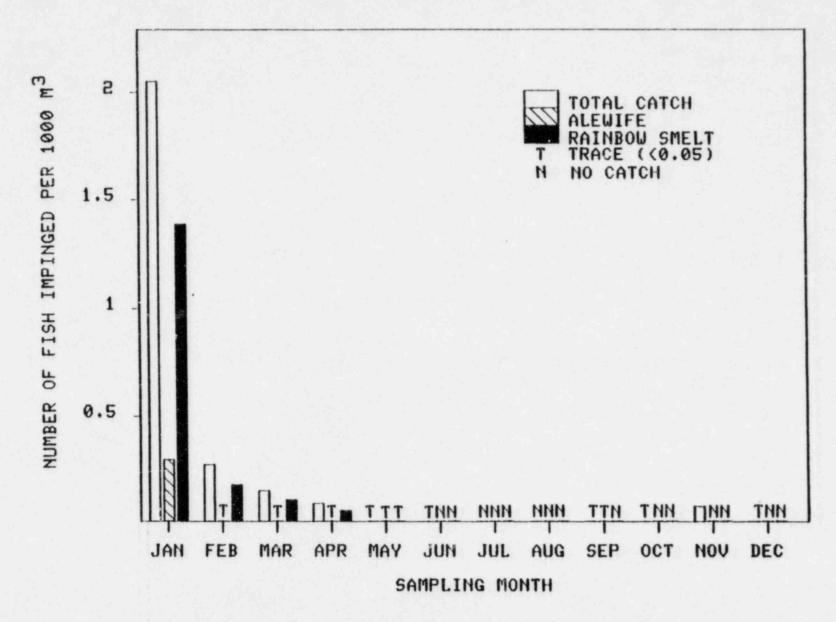

Figure 4-1. Seasonal variations in impingement rates at Nine Mile Point Unit 1, 1982.

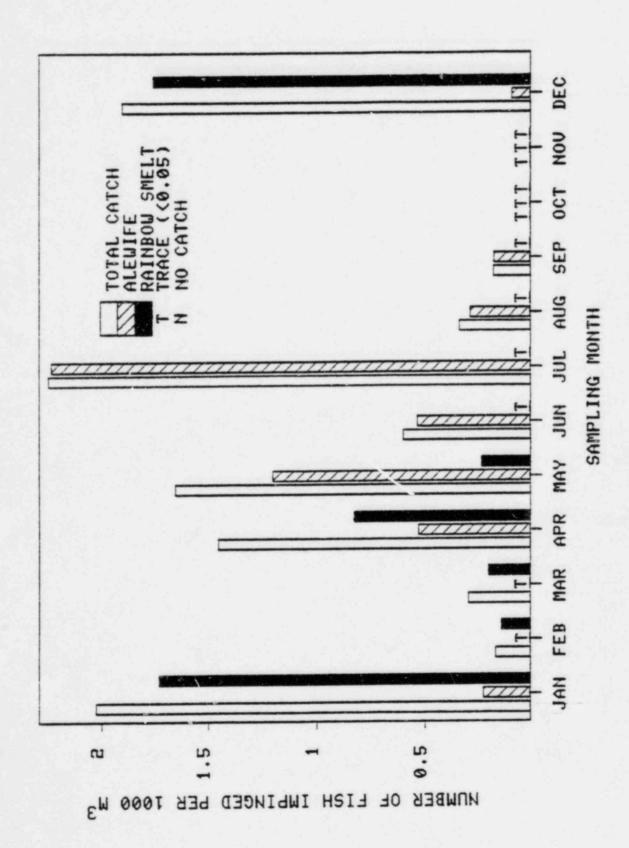

Figure 4-2. Seasonal variations in impingement rates at James A. Fitzpatrick, 1982.

The yill net sampling did not catch as many different species nor did it have identical temporal distribution patterns as did impingement collections. Rainbow smelt, which were dominant in the winter impingement collections, were not dominant in any month in the gill net catches.

Despite the differences mentioned above, the trends in species composition and temporal distribution were similar for gill nets and impingement collections. Almost all of the same species collected with will nets were also found in impingement samples. In terms of numerical abundance, alewife dominated both gill net and James A. FitzPatrick impingement catches. Rainbow smelt, which dominated Nine Mile Point Unit 1 impingement catches, were second in abundance at James A. FitzPatrick and third in abundance in gill net catches. Taking into account the size selectivity of gill nets, temporal distribution patterns between impingement and yill nets were similar. Spring and summer impingement abundance peaks at James A. Fitz-atrick (composed mainly of alewife) coincided with yill net peak catches (also mainly alewife). Spottail shiner were collected at James A. FitzPatrick and in gill nets for most of the sampling season. Rainbow smelt were present in higher numbers in the early spring and in the fall than during the summer. Generally, these trends were evidence that species occurrence and abundance is largely due to temperature preference and migrations of spawning fish populations, and that subadult and adult fish are collected in the winter and spring while young-of-the-year fish are mainly caught in the summer and fall.

5. ENVIRONMENTAL IMPACT ASSESSMENT

5.1 INTRODUCTION

Aquatic ecology studies were initiated for Nine Mile Point Unit 1 in the late 1960s and for James A. FitzPatrick in mid-1975. These studies were designed to evaluate potential effects to the aquatic environment from power plant operation in the vicinity of the Nine Mile Point promontory. A third nuclear station, Nine Mile Point Unit 2, is now under construction at this site.

The 1982 report is submitted to fulfill requirements of Niagara Mohawk Power Corporation and the Power Authority of the State of New York as amended by the U.S. Nuclear Regulatory Commission in the Spring of 1979 to assess any environmental impact. If total monthly impingement catches deviate from the daily ranges as specified in Section 3.1.2 of the Nine Mile Point Unit 1 Environmental Technical Specifications (Table 5-1) or exceed the monthly maximum limit by greater than 50 percent as specified in Section 4.1.1-B of the James A. FitzPatrick Environmental Technical Specifications (Table 5-2), a discussion of events is to be included in the annual report. The results of impingement and gill net studies are detailed in Chapter 3 and discussed with respect to the effects of plant operation on the fish community.

5.2 IMPINGEMENT COLLECTIONS AT NINE MILE POINT UNIT 1 NUCLEAR STATION AND JAMES A. FITZPATRICK NUCLEAR PLANT, 1982

Periodic collections of impinged fish nave been conducted at Nine Mile Point Unit 1 since 1972 and at James A. FitzPatrick since 1975. The species composition of impingement collections in 1982 was similar to that observed during the past years' impingement catches. Between 37 and 48 fish species have been caught at Nine Mile Point Unit 1 in the past years. This year's collection of 26 fish taxa was lower than previous years and may be attributed to the fact that main circulating water pumps were shut down during repairs for most of the year. At James A. FitzPatrick, impingement studies have yielded between 43 and 54 fish species per year. The 1982 study resulted in the collection of 44 fish taxa.

Impingement catches have consistently been dominated by alewife. However, there are two exceptions: in 1978 threespine stickleback was the dominant species and in 1979 rainbow smelt was the dominant species. Rainbow smelt has been second in abundance during most years except in 1976 when threespine stickleback was second in abundance and in 1979 when rainbow smelt was dominant. During 1982, alewife dominated impingement collections at James A. FitzPatrick power plant constituting over 60 percent of the total catch. During the three months of operation, January through 16 March, at Nine Mile Point Unit 1, rainbow smelt was the dominant species constituting 66.8 percent of the total catch. Rainbow smelt was second in abundance during 1982 at James A. FitzPatrick accounting for 36.6 percent of the total catch, and alewife was second in abundance at Nine Mile Point Unit 1. White perch was the third most abundant species at James A. FitzPatrick with 0.5 percent of the total catch. and sculpins were third in abundance at Nine Mile Point Unit 1 with 10.6 percent of the total catch. Threespine stickleback was low in abundance at both power plants during 1982.

TABLE 5-1 COMPARISON OF EXPECTED MONTHLY IMPINGEMENT RANGES AND ACTUAL SAMPLING RESULTS AT NINE MILE POINT UNIT 1, 1982

Month		Average of Fish* High	Actual Daily Average Impingement (No. of Fish/Day)
January	231	631	1,871

TABLE 5-2 COMPARISON OF SPECIFIED MONTHLY MAXIMUM IMPINGEMENT ALLOWANCES AND ESTIMATED MONTHLY IMPINGEMENT FOR 1982 AT JAMES A. FITZPATRCK

Month	Monthly Maximum Impingement*	Plus 50 Percent	Total Estimated Monthly Impingement
January	41,596	62,394	47,283
February	16,646	24,969	3,533
March	22,595	36,152	14,095
April	413,854	620,781	91,148
May	1,750,162	2,625,243	110,301
June	131,769	197,653	38,986
July	67,249	100,873	142,100
August	33,708	50,562	22,753
September	31,570	47,355	11,453
October	32,428	48,642	877
November	87,928	131,892	2,205
December	30,837	46,255	118,508

^{*} From Table 4.1.1-2, Section 4.1.1-B of the James A. FitzPatrick Nuclear Power Plant's Environmental Technical Specifications. The reportable monthly maximum estimated impingement is limit specified plus 50 percent.

In terms of biomass, alewife has been the dominant species during most years of impingement study. Gizzard shad dominated biomass collection in 1978 because of an abundance of large individuals. Rainbow smelt has been either second or third in dominance with other species such as smallmouth bass, white perch, or rock bass dominating in other years. During 1982, alewife was the dominant species, in terms of biomass, at James A. FitzPatrick and second in weight at Nine Mile Point Unit 1. Gizzard shad was the dominant species by weight at Nine Mile Point Unit 1 and third in dominance at James A. FitzPatrick. Rainbow smelt was the second dominant species, by weight, at James A. FitzPatrick and third in dominance at Nine Mile Point Unit 1.

Estimated annual impingement at both power plants has been nightly variable over the years. Estimated annual impingement at Nine Mile Point Unit 1 from 1974 to 1981 ranged from a low of 135,000 fish in 1977 to a nigh of 3.4 million fish in 1976. James A. FitzPatrick annual estimated impingement ranged from 244,000 fish in 1979 to a high of 4.3 million fish in 1976. Impingement estimates for 1982 were low compared to estimates for previous years. Nine Mile Point Unit 1 impinged 89,526 organisms; James A. FitzPatrick impinged 603,242 organisms. In comparison to the standing stock estimates (O'Gorman and Berystedt 1983, personal communication) for the two most abundant impinged species, alewife (4 to 4.5 billion) and rainbow smelt (0.5 billion), the numbers impinged at either power plant represented a negligible portion of the fish community of Lake Ontario.

5.3 OCCASIONS WHEN SPECIFIED LIMITS WERE EXCEEDED

During 1982, the average daily catch at Nine Mile Point Unit 1 was lower than the established daily ranges in March through July and October through December (Table 5-1). Nine Hile Point Unit 1 main circulating water pumps were shut down from March through December and therefore few organisms were impinged. However, in January, the established daily impingement range was exceeded. The January impingement catch was approximately three and one-half times greater than the specified range. Of the total fish collected in January, over 68 percent were rainbow smelt, and of the total rainbow smelt collected, over 95 percent were young-of-the-year fish. According to the Uswego Fish and Wildlife Station (FWS) (O'Gorman and Berystedt 1982, 1983 personal communication), the rainbow smelt population has oscillated during recent years resulting in higher recruitment of smelt during the odd years. Impingement data on young-of-theyear rainbow smelt collected during the 1981 and 1982 winter seasons at the Nine Mile Point power plants was comparable with the FWS data. Collections of rainbow smelt at both Nine Mile Point Unit 1 and James A. FitzPatrick during the 1981 winter (EA 1982) were low (1,202 and 2,639, respectively). Young-ofthe-year smelt, which were spawned in spring 1980, comprised a low percentage (less than 20 percent) of the total smelt catch. However, during the winter of 1982, the catches of rainbow smelt at both power plants were night and young-ofthe-year smelt, spawned in spring 1981, comprised a nigh percentage (around 95 percent) of the total smelt catch.

Established monthly limits at James A. FitzPatrick were exceeded by 50 percent in July and December 1982 (Table 5-2). In July, large collections of alewives caused the monthly limits to be exceeded. At this time of the year, alewife move inshore in large numbers to spawn. Gill net data collected in spring and early summer 1982 pointed to a large spawning population of alewife in the vicinity of the Nine Mile Point promontory. In addition, one impingement

collection on 22 July contained almost 42 percent of the total fish collected for the month. In December, one large collection of young-of-the-year rainbow smelt caused the monthly limits to be exceeded. The impingement collection of 30 December contained over 86 percent of the total fish collected for the month. Of the fish collected, over 93 percent were rainbow smelt and over 90 percent of the smelt caught were young-of-the-year fish. One very large collection can introduce a considerable bias to monthly impingement estimates if it is included in calculation of the mean monthly impingement collection. Since large impingement collections typically have been associated with short-lived meteorological phenomenon, an alternate method can be used to estimate the December total: the total number collected on 30 December was added to the estimate for the other 30 days of December which was based on the other five 24-hour samples collected that month. By this method the estimated impingement for December 1982 was approximately 40,000 as compared to 118,508 using the mean of all six 24-hour samples.

The high impingement on 30 December 1982 may be attributed to unusually high west winds of about 40 knots during the sampling period. Previous studies at the Nine Mile Point power plants have indicated that higher rates of impingement may occur during specific weather conditions, such as high winds from the west or northwest. Studies by Ecological Analysts, Inc. in the vicinity of Nine Mile Point have supported these observations. For example, on 25 and 26 August, the wind blew from the west to northwest at 15-40 knots. The impingement collection at James A. FitzPatrick on 26 August constituted over 56 percent of the total collection for that month. On four other dates Lin 1981 (29 September and 29 December) and 1982 (5 April and 26 August)] west or northwest winds exceeded 25 knots and impingement collections were greater than on adjacent sampling dates with lower wind velocity.

Environmental factors other than strong winds may also lead to higher impingement at the power plants. Biological factors such as population size, migration patterns, schooling, and spawning behavior in conjunction with environmental factors such as water temperature, currents, heavy waves, and plant operating parameters could affect impingement. Migrations of large populations of adult alewife and rainbow smelt during the spring and early summer seasons are triggered by responses to certain environmental and biological conditions. As the water temperature of the lake increased, these two species move inshore to spawn. The high impingement of adult alewife and rainbow smelt during spring and early summer has been well documented at the Nine Mile Point power plants and elsewhere. Spigarelle et al. (1982) noted similar results at three power plants on Lake Michigan. After spawning, the adult fish moved offshore to deeper, cooler waters and were impinged in fewer numbers at the power plants. In summer and early fall, the young-of-the-year alewife and rainbow smelt tended to remain inshore and appeared in the impingement collections, sometimes in large numbers. During late fall and early winter, alewife and rainbow smelt congregated at deep and midwater depths, respectively, in Lake Untario (O'Gorman and Bergstedt 1983, personal communication). In addition, from observations by Ecological Analysts, other fish species, such as white perch, although not as numerous as alewife and rainbow smelt, exhibited similar seasonal patterns of occurrence in the impingement collections.

Although seasonal lake temperatures, spawning behavior, and population size were major factors contributing to high impingement, other factors could also cause increases in impingement. Brandt et al. (1980) discussed the possibility

that the most abundant fish species in Lake Michigan were positioned at different temperature strata to reduce competition for food resources. Shifts in the thermocline could cause fish to adjust their position in the water column. In addition, schools and aggregates of certain fish species could induce localized increases in population densities of fish in the lake. O'Gorman and Bergstedt (1983 personal communication) noted that inshore schools and aggregates of fish can disintegrate at night and scatter throughout the water column. Because of the forementioned influences on fish behavior, it is possible that individual fish or whole schools of fish could become more susceptible to impingement. Incidences of high impingement may not, therefore, be the direct result of power plant operation, but may have been caused by biological behavior of fish in combination with external environmental influences.

5.4 EFFECTS OF POWER PLANT OPERATION AT NINE MILE POINT ON THE FISH COMMUNITY

One of the five Great Lakes in North America, Lake Ontario is roughly oval in shape, 190 miles long, and 53 miles wide. The lake was formed by extensive glaciation some 10,000 years ago. It has a surface area of 7,340 square miles with an average depth of 250-300 (TI 1978). Historically, Lake Ontario was listed as an oligotrophic lake with the principal offshore fish stocks consisting of coregonines, lake trout, and burbot (Christie 1974). Lake Ontario as well as the other Great Lakes have undergone some extensive biological changes. Lamprey invasion, overfishing, and changing water quality have played an important role in the fish species and fish population shifts and changes through the years. Introduction of the alewife in the 1870s and the rainbow smelt in 1912 added additional pressure to the changing natural fish community.

Aquatic collections in the vicinity of Nine Mile Point have been in progress since the 1960s through 1982. During the 1960s and early 1970s, studies on the current flow patterns and aquatic populations were conducted by Dr. J.F. Storr under contract to Niagara Mohawk Power Corporation. From 1973 through early 1977, Lawler, Matusky, and Skelly Engineers (LMS) employed gill nets, trawls, seines, and fish traps in their survey of the Nine Mile Point nearfield. Texas Instruments (TI) continued sampling with various gears until early 1979 when the current sampling program utilizing gill nets at four selected transects was initiated. Ecological Analysts has conducted this sampling program since 1981. In addition, trawls were conducted by the New York State Department of Environmental Conservation (NYSDEC) in the spring of 1977 (Elrod et al. 1978) and by the U.S. Fish and Wildlife Service (FWS) and NYSDEC in 1978, 1979 (Elrod et al. 1979, 1980), and 1980 and 1981 (O'Gorman and Bergstedt 1982, 1983 personal communication).

Previous data collected by gill net suggest that the fish community structure in the Nine Mile Point vicinity during any given year varies seasonally from one of low species diversity during the winter and early spring to one of high species diversity from spring to fall. However species composition in the vicinity of Nine Mile Point has changed little during the nine years of power plant operation. A total of 23 taxa of fish were collected during the 1982 gill net program. Collections during 1979, 1980 and 1981 yielded 18 to 20 taxa. The similarity indices (Pinkham and Pearson, 1976) between years were consistently greater than 0.75 (where 1.0 indicates identical collections) indicating a relatively high level of similarity in the species composition of the fish community sampled by gill nets between 1979 and 1982 (Table 5-3). The

TABLE 5-3 SIMILARITY INDEX (PINKHAM AND PEARSON, 1976) BETWEEN YEARS CALCULATED FOR RANKS OF ALL TAXA COLLECTED BY GILL NETS IN THE VICINITY OF NINE MILE POINT 1979 TO 1982

	1982	1981	1980	1979
1982	1.0	0.904	0.782	0.773
1981	-	1.0	0.773	0.751
1980	-		1.0	0.860
1979				1.0

occurrence of certain dominant species in yill net collections coincided with either spawning benavior (e.g., rainbow smelt and trout perch during spring and brown bullheads in summer) or temperature preference (e.g., lake trout during spring and fall and rainbow smelt in fall). In contrast alewife, spottail sniner, and white sucker are ubiquitous, appearing throughout the sampling season.

Although species composition remained fairly constant, variations in the size of fish populations have been observed throughout Lake Ontario, as well as localized fluctuations. Alewife and rainbow smelt, two species which dominate the fish community in the vicinity of Nine Hile Point in terms of abundance, have exhibited distinct oscillations in population size. Christie (1974) using experimental yill nets showed annual oscillations, which could vary ten-fold, in the size of the spawning run of the alewife from 1958 to 1970. Christie (1974) also correlated certain peaks in the gill net data with significant mortalities along the lakeshore. In the vicinity of the Oswego Steam Station in Oswego, New York, Lawler, Matusky and Skelly Engineers (LMS 1975) reported fluctuations in natural concentrations of the alewife population by as much as 800 percent from year to year. LMS (1977) also reported that populations of alewife in the vicinity of Nine Mile Point vary by as much as half an order of magniude. An important factor in the fluctuations in alewife abundance appears to be periodic large die-offs of the alewife stocks during the spring, possibly due to low temperature shock (Graham 1956, in Colpy 1971) reported since their introduction in the Great Lakes. In recent years the greatest numbers were recorded in 1974 and 1976 (LMS 1975, 1977). According to the FWS and NYSDEC (Elrod et al. 1979, 1980), the population of alewife declined because of a die-off during the severe cold winter of 1976-1977. Losses were estimated as high as 60-75 percent of the population in the vicinity of the Nine Mile Point promontory. This population decline was reflected by decreasing catches of alewife in impingement collections from 1975 through 1978 which were not only recorded at Nine Mile Point power plants, but also at Ontario Hydro power stations in Canadian waters (TI 1981). According to the FWS (O'Gorman and Bergstedt 1983, personal communication), lakewide populations of alewife increased through 1981 and then decreased slightly during 1982 as a result of a probable die-off during the winter of 1982.

Increases in the adult alewife population in the 1982 gill net catches and impingement collections at James A. FitzPatrick were local and did not correspond to the lakewide population reduction as noted by the Oswego FWS. Large impingement collections of young-of-the-year alewife during August through October 1981 at the Nine Mile Point power plants were not experienced at the Ginna or Russell power plants near Rochester, New York (Dakin 1982, personal communication). Local fluctuations in the size of spawning alewife populations collected by gill nets are not unique to the Nine Mile Point vicinity but have also been recorded in the Bay of Quinte in Lake Ontario from 1958 to 1972 (Christie 1974). The size and condition of future alewife stocks would most likely be influenced by climatic conditions and possibly by the numbers of salmonids stocked (O'Gorman and Berystedt 1982, 1983 personal communication).

Rainbow smelt populations have also displayed some oscillations in the Great Lakes from year to year. Introduced in 1912 in Lake Michigan, populations of rainbow smelt became abundant in Lake Ontario in the late 1940s (Christie 1974). This species has also been noted to suffer large population losses possibly as a result of disease (Van Oosten 1947, in Scott and Crossman 1973),

as noted in Lake Huron and Lake Michigan in 1942-1946 and in Lake Erie as recently as 1969 (Scott and Crossman 1973). Rupp (1968, in Kircheis and Stanley 1981) showed ten-fold variations in rainbow smelt abundance during the spawning runs in Branch Lake, Maine over an 8-year period. Commercial yield of rainbow smelt (christie 1974) was noted to decline in Lake Ontario from 1960 through 1970 and then increase after 1970. Studies by NYSDEC and FWS indicated an eleven-fold increase in rainbow smelt populations from 1972-1978 (TI 1981).

Yearly oscillations in the lakewide rainbow smelt population were noted by the biologists at the Oswego Fish and Wildlife Station (O'Gorman and Berystedt 1982, 1983 personal communication). As gill net collections of rainbow smelt over the past four years were low when compared to population estimates and, because no age measurement determinations of the adults were made, a population trend in the vicinity of Nine Mile Point cannot be identified clearly. However, the number of smelt caught by gill nets in the vicinity of Nine Mile Point has shown an increase from 1979 (TI 1980) when only 103 rainbow smelt were caught compared with 466 rainbow smelt in 1981 (EA 1982) and 473 rainbow smelt collected in 1982. In conclusion, gill net surveys in the Nine Mile Point vicinity during 1982 did not reveal any significant changes in the area's smelt populations. Nevertheless, increases in the local population of alewife were observed. Rainbow smelt also are not evenly distributed in Lake Ontario. The FWS estimated that nearly half the rainbow smelt in all U.S. waters of Lake Ontario were concentrated around Cape Vincent (TI 1981).

Thus it appears that changes in relative abundance of fish populations in the vicinity of Nine Mile Point are the result of fluctuations in natural mortality and variation in both localized and lakewide spawning success of various species which compose the local fish community. Such oscillations in population size of various species should not be confused with community instability in an ecological sense. Stability has numerous definitions and connotations with respect to ecosystems but very generally refers to the ability of a system to remain relatively similar to itself in the presence of perturbation (Levin 1975). That is stability is some measure of the response of a system and its ability to oscillate about and return to some "equilibrium state." Therefore a certain level of fluctuation in population size among various species in a community is inherent in the concept of stability as an ecosystem responds to changes or extremes in natural and anthropogenic factors in the biotic and abiotic environment.

No long-term trends toward reductions in the major fish population in the vicinity of Nine Mile Point have been apparent. The observed fluctuations in population size appear to have occurred over a range within the ability of those populations to maintain themselves. The success of these populations will most likely be determined by natural environmental factors (e.g., temperature, disease) and man-induced changes in the trophic structure (e.g., salmonid stocking programs).

5.5 SUMMARY

Impingement of fish by Nine Mile Point Unit 1 and James A. FitzPatrick power plants appears to have little affect on the fish community structure or fish population size in the vicinity of Nine Mile Point or on the entire Lake

Ontario aquatic ecosystem. Impingement of fish at the power plants tends to affect the populations in the manner of a stationary predator, as discussed by Voigtlander (1980); the fish populations can generally adapt to the predator.

Species composition in the vicinity of Nine Mile Point has shown little variation from year to year. Natural biological factors such as nabitat and temperature preference, schooling, and migration behavior play an important role in seasonal variations in species occurrence or absence. Oscillations in fish abundance reflect the biology of species coupled with interactions among species and variable environmental factors. While certain fish species around Nine Mile Point, such as alewife and rainbow smelt, exhibit wide fluctuations in population size, other species, such as white sucker, remain fairly static.

In conclusion, no alterations to the existing fish community or population levels occurred as a result of power plant operation in the Nine Mile Point area during 1982 based on the impingement study. No incidents of cold snock to fish due to shutdowns at either plant were reported or observed during 1982.

No rare, endangered, or threatened fish species were collected in the Nine Mile Point area during 1982. No <u>Corbicula</u> sp. mollusks were found in the 1982 impingement collections at Nine Mile Point Unit 1 or James A. FitzPatrick power plants. High impingement estimates at Nine Mile Point Unit 1 in January 1982 reflected a large recruitment of young-of-the-year rainbow smelt. High impingement estimates at James A. FitzPatrick in July 1982 reflected a large local spawning population of alewife and in December 1982 reflected one large, wind-induced catch of young-of-the-year rainbow smelt. Finally, no unusual or high occurrence of diseases, parasites, or other abnormalities were noted on the fish collected in the Nine Mile Point vicinity during 1982.

NOTE: Volume of water pumped each day was derived from gross circulating water flow data reported in James A. FitzPatrick '401' monthly reports. Water volumes were corrected for temperins when applicable. Power production is daily average (gross MWe) from James A. FitzPatrick '401' monthly reports. All temperatures were derived from James A. FitzPatrick '401' monthly reports. Average intake temperatures were from the main condenser inlet water boxes which do reflect any temperature effects. Average discharge temperatures were taken in the discharge tunnel.

N = Number of lengths; MIN = Shortest length
X = Mean length; MED = Hedian length
SD = Standard deviation; MAX = Greatest length

APPENDIX C

EXCEPTIONS TO STANDARD OPERATING PROCEDURES

C-1 EXCEPTION TO STANDARD OPERATING PROCEDURES FOR IMPINGEMENT AT NINE MILE POINT UNIT 1 NUCLEAR STATION

Rescheduled Impingement Sample - During the impingement sample, traveling screen No. 11 became inoperable. It could not be determined when the screen shut down, thus an accurate impingement rate could not be calculated. The sample was rescheduled and completed on 15 January 1982.

NOTE: No impingement samples were missed during the 1982 sampling season. The sample was rescheduled using a randomly selected day as required by the Environmental Technical Specifications.

C-2 EXCEPTIONS TO STANDARD OPERATING PROCEDURES FOR IMPINGEMENT AT JAMES A. FITZPATRICK NUCLEAR POWER PLANT

- 29 JAN 1982 Time Delay in Starting Impingement Sample Maintenance work on the traveling screens prevented wasning the screens at the scheduled onset of the impingement sample. Wasning of the traveling screens and sample initiation were accomplished at 1700 nours and the impingement sample was terminated 24 hours later.
- 9 JUL 1982 Rescheduled Impingement Sample Cleaning of the water boxes inadvertently introduced fish that were not part of the impingement sample into the collection basket. The sample was rescheduled and completed on 20 July 1982.
- 10 AUG 1982 Rescheduled Impingement Sample A full scale test of the radiological emergency response system limited access to the power plant on the scheduled impingement collection day of 11 August. The sample was rescheduled and completed on 10 August 1982.

NOTE: No impingement samples were missed during the 1982 sampling season. All samples were rescheduled using randomly selected days as required by the Environmental Technical Specifications.

JUN 1982

The second gill net collection required by Nine Mile Point Unit 1 Technical Specifications could not be accomplished on the last two scheduled impingement days in June due to bad weather. A gill net set made on 30 June 1982 was voided because a tangled net reduced the fish catch. A successful gill net set and collection was made on 6-7 July 1982; weather conditions prevented gill net sampling between 30 June and 6 July.

19 JUN 1982

Weather conditions: West to northwest winds at 15-25 knots, waves building to 3-5 feet, showers or thunderstorms, small craft advisory issued.

29 JUN 1982

Weather conditions: Northwest winds at 10-20 knots, waves to 1-3 feet, hazy, humid, thunderstorms, dense fog settled over lake.

DEC 1982

The gill net collection for December could not be accomplished on the first two scheduled impingement dates because of bad weather. Since weather conditions are generally adverse and unpredictable during December on Lake Untario, the final gill net collection was scheduled and completed on the next day with favorable weather conditions, 14-15 December 1982.

7 DEC 1982

Weather conditions: West winds at 20-30 knots, waves to 5-8 feet, cloudy with snow possible.

13 DEC 1982

Weather conditions: South to southwest winds at 15-25 knots, waves to 3-6 feet, fair weather.

APPENDIX D

CONDITION OF FISH: ABNORMALITIES, DISEASES, AND EXTERNAL PARASITES

Fish collected in the impingement and yill net samples were checked for any outstanding abnormalities, diseases, or external parasites and for general physical condition. Nineteen species from impingement and six species from gill nets were found to have some kind of abnormality or affliction.

Rainbow smelt and sculpins from impingement collections were most commonly found to have afflictions. Sculpins exhibited an internal abdominal tumor characterized by one or more small white sacs. Fungus (Saprolegnia) affected rainbow smelt caught in February, March, April, May, June, and October. Other abnormalities observed on rainbow smelt were: two occurrences of a tumor-like infection of the intestine, one occurrence of "popeye" (projection of eye), four occurrences of "pugnose" (deformity of snout), six occurrences of scoliosus (curvature of spine), and vertical lacerations on sides of body during April and May.

The three most common afflictions affecting other fish species were fungus, lamprey, and other scars, and black spot infection (characterized by small black spots scattered on body and fins). Black spot infection was noticed on white sucker, yolden shiner, yellow perch, central mudminnow, emerald shiner, and pumpkinseed. In most cases, only one specimen of each species was found with the infection. Fungus affected a few individuals of each of the following species: gizzard shad, white perch, yellow perch, brown trout, trout perch, rock bass, smallmouth bass, and alewife. An occasional lamprey scar was observed on white sucker, brown trout, and rainbow trout in the impingement collections and on brown trout, lake trout, and a rainbow smelt from gill net collections. Other incidents of disease affected a variety of species. Two white perch exhibited "popeye." A spottail shiner and white sucker had a tumor-like growth on their bodies. A rock bass from gill net collections had "pugnose."

Overall, the physical condition of the fish collected in impingement and gill nets was healthy. However, alewife in the August impingement collections appeared emaciated. Some gizzard shad exhibited hemmorhaging around the head, and nine lake trout from gill net collections had scars or lacerations on their bodies. All of the aforementioned diseases, abnormalities, and presence of scars are naturally occurring and do not generally result from power plant operation.
