PREFACE

The purpose of this report is to present the analysis and evaluation of the physics tests which were performed to verify that the North Anna 1, Cycle 3 core could be operated safely, and to make an initial evaluation of the performance of the core. It is not the intent of this report to discuss the particular methods of testing or to present the detailed data taken. Standard test techiques and methods of data analysis were used. The test data, results and evaluations, together with the detailed startup procedures, are on file at the North Anna Power Station; therefore, only a cursory discussion of these items is included in this report. The analyses presented include a brief summary of each test, a comparision of the test results with design predictions, and an evaluation of the results.

The North Anna 1, Cycle 3 Startup Physics Tests Results and Evaluation Sheets have been included as an appendix to provide additional information on the startup test results. Each data sheet provides the following information: 1) test identification, 2) test conditions (design), 3) test conditions (actual), 4) test results, 5) acceptance criteria, and 6) comments concerning the test. These sheets provide a compact summary of the startup test results in a consistent format. The design test conditions and design values of the measured parameters were completed prior to startup physics testing. The entries for the design values were based on the calculations performed by Vepco's Nuclear Fuel Engineering Group[1]. During the tests, the data sheets were used as guidelines both to verify that the proper test

conditions were met and to facilitate the preliminary comparison between measured and predicted test results, thus enabling a quick identification of possible problems occuring during the tests. The Appendix to this report contains the final completed and approved version of the Startup Physics Tests Results and Evaluation Sheets.

Section 1

INTRODUCTION AND SUMMARY

On December 28, 1980, Unit No. 1 of the North Anna Power Station was shut down for its second refueling. During this shutdown, 64 of the 157 fuel assemblies in the core were replaced with fresh fuel assemblies. The cycle three core consists of four batches of fuel: two once burned batches (1A3 and 3A2), one twice burned batch (4), and one fresh batch (5). The core loading pattern and the design parameters for each batch are shown in Figure 1.1. Fuel assembly burnups are given in Figure 1.2. The incore instrumentation locations are identified in Figure 1.3. Figure 1.4 identifies the location and number of burnable poison rods and source assemblies for Cycle 3; and Figure 1.5 identifies the location and number of control rods in the Cycle 3 core.

On April 6, 1981, at 0140, the third cycle core achieved initial criticality. Following criticality, startup physics tests were performed as outlined in Table 1.1. A summary of the results of these tests follows:

1. The drop time of each control and shutdown rod was confirmed to be within the 2.2 second limit of the North Anna Technical Specifications[2].
2. The reactor coolant system flow rate was confirmed to be greater than the minimum limit specified in the Technical Specifications[2].
3. Individual reactivity worths for all control and shutdown rod banks were measured using the rod swap technique[3] and were

found to be within 12.31% of the design predictions with the exception of Shutdown Bank A which showed a percent difference of 19.54% from design predictions. Except for Shutdown Bank A, these results are within the design tolerance of ±15% for individual bank worths (±10% for the rod swap reference bank worth). This deviation is discussed further in Section 4. The sum of the individual control and shutdown rod bank worths was measured to be within 4.78% of the design prediction which is within the design tolerance of ±10%.

4. Critical boron concentrations for two control bank configurations were measured to be within 26 ppm of the design predictions. These results were within the design tolerances and also met the accident analysis acceptance criterion.
5. The boron worth coefficient was measured to be within 4.7% of the design predication, which is within the design tolerance of ±10% and meets the accident analysis criterion.
6. Isothermal temperature coefficients for two control bank configurations were measured to be within 0.74 pcm/°F of design predictions. These results are within the design tolerance of ±3 pcm/°F and also met the accident analysis acceptance criterion.
7. Core power distributions for various HZP and at power conditions indicated measured assemblywise power values to be somewhat larger than the established design tolerance.

These higher-than-expected power values were accompanied by a quadrant power tilt ratio (QPTR), which at hot-zero-power, was measured to be approximately 4%. The QPTR decreased to 1.3% at full power. These deviations of power distribution had no adverse consequences since, for all flux maps, the hot channel factors were measured to be within the limits of the Technical Specifications. All measurement parameters met their respective accident analysis acceptance criteria.

In summary, all startup physics test results were acceptable. Detailed results, together with specific design tolerances and acceptance criteria for each measurement, are presented in the appropriate sections of this report.

CONTROL ROD DROP TIME MEASUREMENTS

The drop time of each control rod was measured at hot RCS conditions in order to confirm satisfactory operation and to verify that the rod drop times were less than the maximum allowed by the Technical Specifications. The control rod drop time measurements were run with the RCS at hot, full flow conditions (547 °F, 2235 psig) and are described below.

The rod drop time measurements were performed by first withdrawing a rod bank to its fully withdrawn position, and then removing the movable gripper coil fuse and stationary gripper coil fuse for the test rod. This allows the rod to drop into the core as it would in a normal plant trip. The data recorded during this test are the stationary gripper coil voltage, the LVDT (Linear Variable Differential Transformer) primary coil voltage and a 60Hz timing trace which are recorded via a visicorder. The rod drop time to the dashpot entry and to the bottom of the dashpot are determined from this data. Figure 2.1 provides an example of the data that is recorded during a rod drop time measurement.

As shown in Figure 2.1, the initiation of the rod drop is indicated by the decay of the stationary gripper coil voltage when the stationary coil fuse is removed. A voltage is then induced in the LVDT primary coil as the rod drops. The magnitude of this voltage is a function of the rod velocity. When the rod enters the dashpot section of its guide

tube, the velocity slows, causing a voltage decrease in the LVDT coil. The LVDT voltage then reaches a minimum as the rod reaches the bottom of the dashpot. Subsequent variations in the trace are caused by the rod bouncing. This procedure was repeated for each control rod.

The measured drop times for each control rod are recorded on Figure 2.2. The slowest, fastest, and average drop times are summarized in Table 2.1. Technical Specification 3.1.3.4 specifies a maximum rod drop time from loss of stationary gripper coil voltage to dashpot entry of 2.2 seconds with the RCS at hot, full flow conditions. All test results met this limit.

Section 3

REACTOR COOLANT SYSTEM FLOW MEASUREMENT

The reactor coolant flow rate is measured in order to verify that the minimum flow rate requirement is satisfied. The RCS flow rate is determined using the calorimetric measurement technique. Precision calorimetric data (i.e., feedwater temperature, feedwater flow, steam flow, and steam pressure) are obtained in order to accurately determine the secondary-side heat rate. The primary-side enthalpy rise is determined from the RCS pressure and the temperature increase associated with each RCS loop. The flow for each RCS loop is determined by establishing a primary-side to secondary-side heat balance. Steam generator blowdown heat loss, system heat losses, and the power produced by the reactor coolant pumps are taken into account in the heat balance. A reactor coolant flow measurement was performed at 100% power. This data was analyzed using the RXFLOW[4] computer code, and manually adjusted to incorporate steam flow data. A summary of the results for this test is given in Table 3.1. As shown by this table, the results demonstrated that the RCS flow limit was met.

Section 4

CONTROL ROD BANK WORTH MEASUREMENTS

Control rod bank worth measurements were obtained for all control and shutdown banks using the rod swap technique. The first step in the rod swap procedure was to dilute the most reactive control rod bank (hereafter referred to as the reference bank) into the core and measure its reactivity worth using conventional test techniques. The reactivity changes resulting from the reference bank movements were recorded continuously by the reactivity computer[5] and were used to determine the differential and integral worth of the reference bank (Control Bank B). At the completion of the reference bank reactivity worth measurement, the reactor coolant system temperature and boron concentration were stabilized such that the reactor was critical with the reference bank near full insertion. Initial statepoint data for the rod swap maneuver were obtained by moving the reference bank to its fully inserted position and recording the core reactivity and moderator temperature. At this point, a rod swap maneuver was performed by withdrawing the reference bank while one of the other control rod banks (i.e., a test bank) was inserted. The core was kept nominally critical throughout this rod swap and the maneuver was continued until the test bank was fully inserted and the reference bank was at the position at which the core was just critical. This measured critical position (MCP) of the reference bank with the test bank fully inserted is the major parameter of interest and was used to determine the integral reactivity worth of the test bank. Statepoint data (core reactivity, moderator temperature,

and the differential worth of the reference bank) were recorded with the reference bank at the MCP. The rod swap maneuver was then performed in reverse order such that the reference bank once again was near full insertion and the test bank was once again fully withdrawn from the core. The rod swap process was then repeated for all of the other control and shutdown rod banks.

A summary of the results for these tests is given in Table 4.1. As shown by this table and the Startup Physics Tests Results and Evaluation Sheets given in the Appendix, the individual measured bank worths for all of the control and shutdown banks were within the design tolerance (±10% for the reference bank and ±15% for the test banks), except for Shutdown Bank A. This deviation was reviewed with respect to the licensing bases. As a result of this review it was concluded[6-7] that the deviation did not exceed the bounds of the licensing bases nor did it represent an unreviewed safety issue. The sum of the individual rod bank worths was measured to be within 4.78% of the design prediction. This is well within the design tolerance of ±10% for the sum of the individual control rod bank worths.

The integral and differential reactivity worths of the reference bank (Control Bank B) are shown in Figures 4.1 and 4.2, respectively. The design predictions and the measured data are plotted together in order to illustrate their agreement. In summary, all measured rod worth values were acceptable.

Section 5

BORON ENDPOINT AND WORTH MEASUREMENTS

Boron Endpoint

With the reactor critical at hot zero power, reactor coolant system boron concentrations were measured at selected rod bank configurations to enable a direct comparison of measured boron endpoints with design predictions. For each measurement, the RCS conditions were stabilized with the control banks at or very near a selected endpoint position. The critical boron concentration was then measured. If necessary, an adjustment to the measured critical boron concentration was made to account for off-nominal core conditions, i.e., for rod position and moderator temperature.

The results of these measurements are given in Table 5.1. As shown in this table and in the Startup Physics Test Results and Evaluation Sheets given in the Appendix, all measured critical boron endpoint values were within their respective design tolerances. All measured values met the accident analysis acceptance criterion. In summary, all results were satisfactory.

Boron Worth Coefficient

The measured boron endpoint values provide stable statepoint data from which the boron worth coefficient was determined. A plot of the boron concentration as a function of integrated reactivity can be constructed by relating each endpoint concentration to the integrated

rod worth present in the core at the time of the endpoint measurement. The value of the boron coefficient, over the range of boron endpoint concentrations, is obtained directly from this plot.

The boron worth plot is shown in Figure 5.1. As indicated in this figure and in the Appendix, the boron worth coefficient of reactivity was measured to be -8.54 pcm/ppm. The measured boron worth coefficient is within 4.7% of the predicted value of -8.16 pcm/ppm and is well within the design tolerance of ±10%. The measurement result also met the accident analysis acceptance criterion. In summary, this result was satisfactory.

Section 6

TEMPERATURE COEFFICIENT MEASUREMENTS

The isothermal temperature coefficient measurements were accomplished by controlling the RCS heat gains/losses with the steam dump valves to the condenser and/or steam generator blowdown, establishing a constant and uniform heatup/cooldown rate, and then monitoring the resulting reactivity changes on the reactivity computer. These measurements were performed at very low power levels in order to minimize the effects of non-uniform nuclear heating, thus, the moderator and fuel were approximately at the same temperature (between 543 - 549 °F) during these measurements. To eliminate the boron reactivity effect of outflow from the pressurizer, the pressurizer level was maintained constant or slightly increasing during these measurements.

Isothermal temperature coefficient measurements were performed at various control rod configurations. For each rod configuration, reactivity measurements were taken during both RCS heatup and cooldown ramps during which the RCS temperature varied approximately 6°F. Reactivity was determined using the reactivity computer and was plotted against the RCS temperature on an x-y recorder. The isothermal temperature coefficient was then determined from the slope of the plotted lines. The x-y recorder plots of reactivity changes versus RCS temperature for each measurement are shown in Figures 6.1 and 6.2.

The predicted and measured isothermal temperature coefficient values are compared in Table 6.1. As can be seen from this summary and from the Startup Physics Test Results and Evaluation Sheets given in the

Appendix, all measured isothermal temperature coefficient values were within the design tolerance of ±3 pcm/°F and met the accident analysis acceptance criterion. In summary, all measured results were satisfactory.

Section 7

POWER DISTRIBUTION MEASUREMENTS

The core power distributions were measured using the incore movable detector flux mapping system. This system consists of five fission detectors which traverse fuel assembly instrumentation thimbles in 50 core locations (see Figure 1.3). For each traverse, the detector output is continuously monitored on a strip chart recorder. The output is also scanned for 61 discrete axial points by the PRODAC P-250 process computer. Full core, three-dimensional power distributions are then determined by analyzing this data using the Westinghouse computer program, INCORE[8]. INCORE couples the measured flux map data with predetermined analytic power-to-flux ratios in order to determine the power distribution for the whole core.

A list of all the flux maps taken during the test program together with a list of the measured values of the important power distribution parameters is given in Table 7.1. The measured power distribution parameter values are compared with their Technical Specifications limits in Table 7.2. Flux Maps 2 and 3 were taken at zero power (Map 1 was aborted due to low incore detector signals). These flux maps serve as base case design checks. Figures 7.1 and 7.2 show the resulting radial power distributions associated with these flux maps. These maps indicated the presence of a significant quadrant power tilt (~4%) and some assemblywise relative power values in excess of the design tolerances, but all measured hot channel factor values were within the Technical Specifications limits.

Flux maps 4 through 14 were taken over a wide range of power levels and control rod configurations. These flux maps were taken to check the at-power design predictions and to measure core power distributions at various operating conditions. These maps also provide incore/excore calibration data for the nuclear instrumentation system as well as base data for axial power distribution surveillance. The radial power distributions for these maps are given in Figures 7.3 through 7.11. These figures show that the measured relative assembly power values are generally within 8% of the predicted values. Some relative assembly power values were in excess of design tolerances, but all measured hot channel factor values were acceptable. These figures also show that the value of the quadrant power tilt ratio decreased significantly during power ascension.

In conclusion, all power distribution measurement results were considered to be acceptable with respect to the accident analysis acceptance criteria and the Technical Specifications limits. It is therefore anticipated that the core will continue to operate safely throughout Cycle 3.

NOTES: HOT SPOT LOCATIONS ARE SPECIFIED BY GIVING ASSEMBLY LOCATIONS (E.G. H-8 IS THE CENTER-OF-CORE ASSEMBLY LOCATION) FOLLOWED BY THE "Y" COORDINATE WITH THE SEVENTEEN ROWS OF FUEL RODS LETTERED A THROUGH Q AND THE "X" COORDINATE DESIGNATED IN A SIMILAR MANNER).
IN THE "Z" DIRECTION THE CORE IS DIVIDED INTO 61 AXIAL POINTS STARTING FROM THE TOP OF THE CORE.

1. F-Q(T) INCLUDES A TOTAL UNCERTAINTY OF 1.05 X 1.03

2. F-DH(N) INCLUDES A MEASUREMENT UNCERTAINTY OF 1.04

3. F(XY) MAX. INCLUDES A TOTAL UNCERTAINTY OF 1.05 X 1.03.

4. QPTR - QUADRANT POWER TILT RATIO.

5. MAP 1 WAS ABORTED DUE TO LOW DETECTOR SIGNAL.

6. MAPS 6 AND 7 WERE QUARTER CORE M/D FLUX MAPS.

1 The Technical Specifications limit for the heat flux hot channel factor, F-Q(T) is a function of core height. The value for F-Q(T) listed above is the maximum of F-Q(T) in the core. The Technical Specifications limit listed above is evaluated at the plane of maximum F-Q(T). The minimum margin values listed above are the minimum percent differences between the measured values of F-Q(T) and the Technical Specifications limit for each map. All measured F-Q(T) hot channel factors include 5% measurement uncertainty and 3% engineering uncertainty.

2 The measured values for the enthalpy rise hot channel factor, F-dH(N), includes 4% measurement uncertainty.

3 All measured F(XY) MAX values include 5% measurement uncertainty and 3% engineering uncertainty.

STARTUP PHYSICS TEST RESULTS AND EVALUATION SHEETS

A.1

North Anna Power Station Unit 1 Cycle 3

Startup Physics Tests Results and Evaluation Sheet

I Reference	Test Description: Reactivity Computer Checkout Procedure Number/Section: 1-PT-94/App. B Sequence Step Number: 6	
II Test Conditions (Design)	Bank Positions (steps) SDA: 228 SDB: 228 CA: 228 CB: 228 CC: 228 CD: * RCCA: NA	RCS Temperature (°F): 547 +0 -5 Power Level (%F.P.): 0 Other (specify): Below Nuclear Heating *At the just critical position
III Test Conditions (Actual)	Bank Positions (steps) SDA: 228 SDB: 228 CA: 228 CB: 97 CC: 228 CD: 228 RCCA: NA	RCS Temperature (°F): 544.2°F Power Level (%F.P.): 0% Other (specify): Below Nuclear Heating
IV Test Results	Date/Time Test Performed: 4/7/81 0518	
	Measured Parameter (description)	$\Delta\rho_c$ = Measured reactivity using the reactivity computer $\Delta\rho_r$ = Inferred reactivity from reactor period
	Measured Value	$\left\lvert \frac{\Delta\rho_c - \Delta\rho_r}{\Delta\rho_r} \right\rvert = 0.0251$
	Design Value (Actual Conditions)	$\left\lvert \frac{\Delta\rho_c - \Delta\rho_r}{\Delta\rho_r} \right\rvert \leq 0.04$
	Design Value (Design Conditions)	$\left\lvert \frac{\Delta\rho_c - \Delta\rho_r}{\Delta\rho_r} \right\rvert \leq 0.04$
	Reference	WCAP-7905, Rev. 1, Table 3.6
V Acceptance Criteria	FSAR/Tech Spec	NA
	Reference	NA
VI Comments	The reliability of the reactivity computer has been tested to be within ± 40 pcm. Acceptance criteria was met.	

Completed By J P Smith
Test Engineer

Evaluated By Jay H. Lebenstein

Recommended For Approval By C. J. Snow
NFO Engineer

Startup Physics Tests Results and Evaluation Sheet

I Reference	Test Description: Critical Boron Concentration - ARO Procedure Number/Section: 1-PT-94/App. C Sequence Step Number: 7	
II Test Conditions (Design)	Bank Positions (steps) SDA: 228 SDB: 228 CA: 228 CB: 228 CC: 228 CD: 228 RCCA: NA	RCS Temperature (°F): 547 +0 -5 Power Level (%F.P.): 0 Other (specify): Below Nuclear Heating
III Test Conditions (Actual)	Bank Positions (steps) SDA: 228 SDB: 228 CA: 228 CB: 228 CC: 228 CD: 228 RCCA: NA	RCS Temperature (°F): 544.2°F Power Level (%F.P.): 0% Other (specify): Below Nuclear Heating
IV Test Results	Date/Time Test Performed: 4/7/81 1040	
	Measured Parameter (description)	$(C_B)^M_{ARO}$; Critical Boron Concentration - ARO
	Measured Value	C_B = 1466.7 ppm
	Design Value (Actual Conditions)	C_B = 1492 ± 50 ppm
	Design Value (Design Conditions)	C_B = 1492 ± 50 ppm
	Reference	Vepco NFE Technical Report No. 161, December 1980; Memorandum from T.S. Rotella to C.T. Snow, dated January 20, 1981.
V Acceptance Criteria	FSAR/Tech Spec	$\left(\frac{\partial \rho}{\partial C_B}\right) \times C_B \leq 24{,}000$ pcm
	Reference	FSAR Section 15.2.4
VI Comments	Use $\frac{\partial \rho}{\partial C_B}$ = -8.16 pcm/ppm for preliminary analysis $\frac{\partial \rho}{\partial C_B}$ = -8.54 pcm/ppm used for final analysis. Acceptance criteria met; Design tolerance met.

The measured value for F_{xy} exceeds the Technical Specifications limits for F^{RTP}_{xy}. In accordance with Technical Specification 4.2.2.2.d, an additional full-core flux map was obtained within 24 hours after reaching a power level which is 20% higher than the level at which the F^{RTP}_{xy} limit was exceeded.

V Acceptance Criteria	FSAR/Tech Spec	NA	$F^N_{\Delta H} < 1.55 \times [1 + .2(1-P)] \times [1 - RBP(BU)]$	$F^T_Q \leq 2.10 \times K(Z)/P$	NA
	Reference	NA	TS 3.2.3	TS 3.2.2	TS 3.2.4
VI Comments	* Design tolerance not met, but test result is acceptable per Reference: 1. North Anna Power Station Deviation Report No. 81-257.				

Completed By J. P. Sweet
Test Engineer

Evaluated By J. S. Reille

Recommended For Approval By TK Ross
(Name and Title)

The measured value for F_{xy} exceeds the Technical Specifications limit for F^{RTP}_{xy}. In accordance with Technical Specification 4.2.2.2.d, an additional full-core flux map was obtained at a power level within 20% of the power level at which the F^{RTP}_{xy} limit was exceeded.
Acceptance criteria met.
