Commission

NOTICE

This report was prepared as an account of work sponsored by an agency of the United States Government. Neither the United States Government nor any agency thereof, or any of their employees, makes any warranty, expressed or implied, or assumes any legal liability or responsibility for any third party's use, or the results of such use, of any information, apparatus, product or process disclosed in this report, or represents that its use by such third party would not infringe privately owned rights.

NOTICE

Availability of Reference Materials Cited in NRC Publications

Most documents cited in NRC publications will be available from one of the following sources:

1. The NRC Public Document Room, 1717 H Street, N.W.
Washington, DC 20585
2. The Superintendent of Documents, U.S. Government Printing Office, Post Office Box 37082,
Washington, DC 20013-7082
3. The National Technical Information Service, Springfield, VA 22161

Although the listing that follows represents the majority of documents cited in NRC publications, it is not intended to be exhaustive.

References: documents available for inspection and copying for a fee from the NRC Public Document Room include NRC correspondence and internal NRC memoranda; NRC Office of Inspection and Enforcement bulletins, circulars, information notices, inspection and investigation notices; Licensee Event Reports; vendor reports and correspondence; Commission papers; and applicant and licensee documents and correspondence.

The following documents in the NUREG series are available for purchase from the GPO Sales Program: formal NRC staff and contractor reports, NRC sponsored conference proceedings, and NRC booklets and brochures. Also available are Regulatory Guides, NRC regulations in the *Code of Federal Regulations*, and *Nuclear Regulatory Commission Issuances*.

Documents available from the National Technical Information Service include NUREG series reports and technical reports prepared by other federal agencies and reports prepared by the Atomic Energy Commission, forerunner agency to the Nuclear Regulatory Commission.

Documents available from public and special technical libraries include all open literature items such as books, journal and periodical articles, and transactions. *Federal Register* notices, federal and state legislation, and congressional reports can usually be obtained from these libraries.

Documents such as theses, dissertations, foreign reports and translations, and non-NRC conference proceedings are available for purchase from the organization sponsoring the publication cited.

Single copies of NRC draft reports are available free, to the extent of supply, upon written request to the Division of Information Support Services, Distribution Section, U.S. Nuclear Regulatory Commission, Washington, DC 20585.

Copies of industry codes and standards used in a substantive manner in the NRC regulatory process are maintained at the NRC Library, 7920 Norfolk Avenue, Bethesda, Maryland, and are available there for reference use by the public. Codes and standards are usually copyrighted and may be purchased from the originating organization or, if they are American National Standards, from the American National Standards Institute, 1430 Broadway, New York, NY 10018.

Submission for the CSNI/GREST Benchmark Exercise on Chemical Thermodynamic Modeling in Core-Concrete Interaction Releases of Radionuclides

Manuscript Completed: August 1988

ABSTRACT

A submission for the CSNI/PWG-4/GREST standard problem on chemical thermodynamic modeling in core-concrete interaction releases of radionuclides is described. Part A of the exercise is a highly defined benchmark calculation in which data and speciation are specified. The problem is, however, ambiguous concerning the definition of an ideal solution. Consequently, two solutions are provided. In one solution, specified species are treated as molecular entities to define the ideal solution. In the second, mixing is assumed to occur ideally on cationic and anionic lattices. The different results obtained in these calculations illustrate the importance of condensed phase modeling in the analyses of high temperature melt interactions with concrete.

Part B of the exercise consists of six problems in which the temperatures, pressures and bulk compositions of the melts are specified. Data and speciation are to be supplied as parts of the solutions to the problems. Results of calculations for these six problems are presented. Additional solutions are provided to illustrate the effects of speciation in the condensed oxide phase, non-ideality in the condensed metal phase and uncertainty in the thermodynamic properties of gas phase species.

It is demonstrated by the calculations that a variety of challenges arise in the accurate modeling of thermochemistry of high temperature melts. A systematic exploration of approximations is clearly needed. Experimental data on the thermochemistry of such high temperature melts will not be useful if there is not an adequate theoretical framework to interpolate and extrapolate the data.

1. INTRODUCTION

The release of radionuclides during core debris interactions with concrete in a severe nuclear reactor accident has been recognized since the early 1970's [1]. The relative importance of the melt/concrete release process has increased in reactor accident analyses as new methods of source term analysis have been introduced [2,3] and more mechanistic models of the melt/concrete interaction process have been devised [4]. The newer models and experiments [5,6,7,8] have shown that during melt interactions with concrete, tremendous quantities of aerosol material are produced which can drastically affect the longevity of radioactive material suspended in the reactor containment. Radionuclide releases predicted with the modern models are highly dependent on the peculiarities of the accidents and power plants in question [9]. In some situations the releases are less than those predicted in the older models such as that developed for the Reactor Safety Study [1]. In other cases, however, significantly higher releases of particularly the more refractory alkaline earths and the rare earths are predicted.

The chemical system created by the interaction of core debris with concrete is, obviously, quite complex. Any model of the release of radionuclides and generation of aerosols during core debris interactions with concrete will, necessarily, be approximate. Data for evaluating the accuracy of modern models of radionuclide release and aerosol generation are scarce. Where comparisons have been possible, the predictions of the VANESA model [4] of aerosol generation during core debris interactions with concrete have agreed with experiment results to within about a factor of 2 to 3. Available data do not, however, extend into regimes where the highest releases of radionuclides are predicted to occur. Until more data are available, it is useful to examine the assumptions and approximations made in the model that lead to predictions of high (and low) generation rates of radioactive and non-radioactive aerosols.

A key element of models of aerosol generation during core debris interactions with concrete is the treatment of thermochemistry. It is, in fact, the analyses of melt thermochemistry that distinguishes modern models from those used in the past and even release models developed for other accident phenomena. The thermochemistry defines the driving force for vaporization of volatile constituents while core debris interacts with concrete. It also defines the maximum extent of vapor formation and consequently aerosol production. Approximations made in the description of the thermochemistry of the complex melts have a direct influence on the quality of predictions of vaporization during melt interactions with concrete.

The Group of Experts on the Source Term (GREST) of the Committee for the Safety of Nuclear Installations (CSNI) has recently turned its attentions to the issues of core debris interactions with concrete and the attendant release of radionuclides. Dr. P. Clough, chairman of GREST, has defined a set of "benchmark problems" to assess the current capabilities for predicting the thermochemistry of melts interacting with concrete. That is, the benchmark problems do not test the adequacy of models used to predict radionuclide release during core debris interactions with concrete. They are, instead, tests of one part, albeit an important part, of the analyses necessary to predict these releases. The exercise is then of value for the modeling of other chemical processes in reactor accidents as well as for the modeling of core debris interactions with concrete.

The benchmark exercise is divided into two types of standard problems to be confronted by the analysts. Part A of the exercise consists of a highly specified standard problem in which the temperature, pressure, bulk composition, and speciation of the melt are defined along with thermochemical data for the melt and gas phase species. The standard problem in part A is "...intended to test the numerical solution techniques involved in defining chemical equilibrium....". Part B of the benchmark exercise consists of a set of six standard problems in which only the bulk compositions, temperatures and pressures of the melts are defined. Speciation of the gas phase and the melt phases is deliberately left to the discretion of the analyst as are the thermochemical data for the species. The purpose of the part B standard problems is to illustrate the variability of results obtained when various treatments are employed to determine the equilibrium chemistry.

The balance of this document consists of a submission for the GREST benchmark exercise for chemical thermodynamic modeling. The submission was prepared at the request of J. Mitchell of the U. S. Nuclear Regulatory Commission as part of the work on modeling core debris-concrete interactions sponsored at Sandia National Laboratories. Solutions to both the part A and part B problems are discussed below. The document concludes with some additional calculations to illustrate the sensitivities of the equilibrium analyses to factors not considered in the benchmark exercise.

2. MODEL USED IN THE EXERCISE

The benchmark exercise does not test computer codes used in accident analyses for predicting the release of radionuclides during core debris interactions with concrete. It tests only the treatment of chemical equilibrium that is a part of such computer models. Computer codes that model the

the dynamic release process are optimized to treat release as it is hypothesized to occur in reactor accidents. Such codes are ill-suited to treat the generalized, static problems defined in the benchmark exercise. No attempt was made then to use one of these accident analysis models for the benchmark exercise. Instead, the equilibrium solver in the VANESA model [4] was extracted and modified to serve as a "stand-alone" chemical equilibrium computer code.

Modern chemical equilibrium solvers fall typically in one of two classes--those that attempt to find the minimum free-energy and those using the so-called Brinkley equilibrium constant method [10]. Free-energy minimization has achieved a broad popularity for the solution of equilibrium problems. Free-energy minimization suffers, however, from the difficulties of mathematical scaling, finite convergence neighborhoods, and truncation caused by convergence criteria. The technique is then poorly suited for the repetitive solution of essentially similar problems. The equilibrium constant method, while it is entirely equivalent in a mathematical sense to free-energy minimization, is more difficult to implement as a generalized solver capable of treating a wide range of problems.

The equilibrium solver in the VANESA model uses a slightly modified equilibrium constant method. The equilibrium constant method converts the problem into a set of non-linear equations. The equations are solved in the code used here by a cyclic Newton technique. Convergence is declared when the mass balance constraints are achieved to 1 part in 10^{10} . This convergence criterion was dictated by the internal precision of the computing machine. More demanding convergence criteria could be imposed in other systems.

The adequacy of the "stand-alone" solver was tested by comparison of calculated results to published results for the so-called "blast furnace problem" [11]. This comparison is shown in Table 1.

3. BENCHMARK PROBLEM A

3.1 Definition of the Problem

The specifications of the problem in part A of the benchmark exercise are shown in Table 2. The problem is highly constrained except where it specifies that the condensed phases are to be treated as ideal solutions. There is no difficulty with the treatment of the metal phase. (It is readily apparent, however, that in reality the prescribed

TABLE 2. Specifications for Benchmark Problem A

Input

- (1) Specification of the system. The system consists of a gas phase, a liquid oxide solution phase, and a liquid metal solution phase, all in equilibrium. The components in each phase are as follows:

Gas phase: O₂, UO₂, UO₃, UOH, H₂, H₂O, Zr, Cr, La, LaO, K, KOH

Oxide solution: UO₂, U₂O_{4.5}, ZrO₂, Cr₂O₃, La₂O₃, K₂O

Metal solution: U, Zr, Cr, La, K

- (2) Thermodynamic data. Expressions for the Gibbs energy of formation are in the form:

$$\Delta G_f^\circ = A + B \cdot T \quad \text{J-mol}^{-1}$$

where T is in Kelvin. The Gibbs energies of formation of all elements in their normal physical form at 298.15 K are taken to be zero. Author's note: This reference state applies to all elements except potassium. Liquid potassium is the reference state for the calculation.)

The values for the coefficients A and B for the species are:

Species	A	B
O ₂ (g)	0.0	0.0
UO ₂ (g)	-5.083560E+5	2.280E+1
UO ₃ (g)	-8.368000E+5	8.117E+1

Zr (m)	1.0E+5
Cr (m)	5.0E+5

(4) Conditions and representation of the melt. The temperature of the system is constant at 2500 K and the gas pressure is 1 atmosphere. The oxide and metal solutions are treated as ideal solutions. The final equilibrium composition that is calculated is such that the gas phase is in equilibrium with the oxide and metal solutions.

Output

The output required is the number of moles of each input vapor species in equilibrium with the melt.

metal solution would not be ideal in its behavior.) It is clear that the architect of the problem intends, as is common in the literature, that the specified metal phase species mix randomly so that the free-energy of mixing consists of only configurational entropy. Ambiguity arises in connection with the treatment of the oxide phase. It may be that the problem architect intends that the specified oxide species be treated as molecular entities and that they mix randomly. But, the specified species are not molecular entities. In the solid-state, they are all extended lattice oxides. An alternate definition of an ideal solution for these oxides, one that is commonly used in the literature, is to hypothesize the existence of two lattices in the liquid phase--a lattice for cations and a lattice for anions. Since the only anion is O^{2-} there is no entropy of mixing on the anionic lattice. An ideal solution is created when the cations mix randomly on the cationic lattice.

Because it is unclear which definition of ideal solution is intended--an *ad hoc* solution treating the species as molecular entities or a two lattice solution model--part A of the benchmark exercise was solved using both models. For the molecular solution model, the free energy of mixing in the oxide phase was taken to be:

$$G_{\text{mix}} = -RT \sum_i Y_i \ln(Y_i)$$

where G_{mix} = free-energy of mixing

R = gas constant

T = absolute temperature

Y_i = mole fraction of the i th specified species

For the two-lattice model, the free-energy of mixing was taken to be

$$G_{\text{mix}} = -RT \sum_i z_i \ln(z_i)$$

where $z_i = n_i m_i / \sum_j n_j m_j$

n_i = number of cations in the i th species

m_i = number of moles of the i th species in the melt.

This definition of the free-energy of mixing in the two-lattice model amounts to considering the species $U_2O_4.5$, La_2O_3 , Cr_2O_3 and K_2O to actually be $UO_2.25$, $LaO_1.5$, $CrO_1.5$, and $KO_0.5$.

3.2 Results of the Calculations for Part A

Results of the calculations for part A using the molecular solution model and the two-lattice model are shown in Tables 3 and 4, respectively. The two calculations yield rather similar oxygen partial pressures--about 7×10^{-14} atmospheres or an oxygen potential of about -150 kcal. Contributions of other vapor species to the equilibrium atmosphere above the melt are also quite similar except in the case of lanthanum-bearing species. The partial pressure of La(g) is 7.16×10^{-7} atmospheres in the case of the molecular model and 2.97×10^{-8} atmospheres in the case of the two-lattice model. The partial pressure of LaO(g) is 8.9×10^{-5} atmospheres for the molecular solution model and 3.7×10^{-6} atmospheres in the case of the two lattice model. This order-of-magnitude difference is directly the result of the solution models since the oxygen potentials are nearly the same in the two calculations. The result illustrates that the vapor pressure of lanthanum-bearing species is not dependent on just temperature and oxygen potential. Further discussions of this issue with respect to lanthanum vaporization have been reported recently [17].

The most substantive differences in the results for the condensed phase have to do with species specified to have two cations in the problem definition. More potassium, chromium and higher valent uranium are predicted to be present in the oxide phase with the two-lattice model than with the molecular solution model.

These results point out the importance of solution phase modeling for the prediction of radionuclide release, which has been noted elsewhere [12]. To date, this aspect of the thermochemistry of core debris has received less attention than has speciation of the gas phase. A much smaller data base is available to guide modeling of the liquid phase.

4. BENCHMARK PROBLEM B

4.1 Definitions of the Problems

Part B of the benchmark exercise presents a set of problems whose specifications are defined in Table 5. Six problems are defined involving three composition cases each analyzed at two temperatures. These problems are substantially more complicated and less constrained than that defined in part A. To address these problems, three distinct tasks are required:

1. Select vapor species.
2. Formulate a model of the oxide phase
3. Decide whether non-idealities in the condensed phases are to be recognized.

TABLE 3. Results Benchmark Problem A - Molecular Solution Model

TABLE 5. Specifications of Benchmark Problem B

This is based on three test cases A, B and C of more realistic composition. Participants should use their own chemical thermodynamic data and choice of species in all phases.

Input

- (1) In each Case, the system consists of a gas phase, a liquid oxide solution phase, and a liquid metal solution phase, all in equilibrium. The initial components in each phase are as follows:

Gas phase: H₂O, CO₂

Oxide solution: UO₂, SiO₂, SrO, CaO, La₂O₃, CeO₂

Metal solution: Zr, Fe, Mo

The methods adopted to define the final equilibrium in terms of permissible species in each phase, activity coefficients, etc. are entirely at the choice of the participant.

- (2) Input amounts. The initial compositions in the three Cases are defined in the following table.

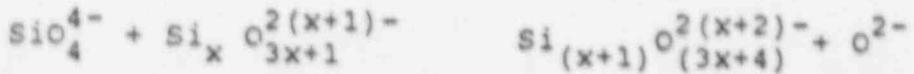

Component	Amount (moles)		
	Case A 'reducing'	Case B 'not as reducing'	Case C 'CaO/SiO ₂ =10'
UO ₂	10 ⁵	10 ⁵	10 ⁵
Zr	10 ⁵	10 ⁴	10 ⁴
SiO ₂	10 ⁴	10 ⁵	10 ⁴
Fe	10 ⁵	10 ⁵	10 ⁵
SrO	10 ²	10 ²	10 ²
CaO	10 ⁴	10 ⁵	10 ⁵
La ₂ O ₃	10 ²	10 ²	10 ²
CeO ₂	10 ³	10 ³	10 ³
Mo	10 ²	10 ²	10 ²
H ₂ O	10 ²	10 ²	10 ²
CO ₂	10 ²	10 ²	10 ²

The objective of part B of the benchmark exercise is to illustrate how results vary with the choice of treatment of the equilibrium analyses. It would be of interest, then, to explore how approximations made in each of these three tasks affect the results. Time constraints prevent any such extensive or systematic analysis. Instead, a fairly conventional analysis is done as described below. A few perturbations of this analysis are presented later in this section of the submission to provide some indications of how various treatments could affect the results.

Vapor species considered for the analysis were in the main well-known species listed in the data base for the VANESA model [4]. A few additional species recently suggested to be important [13] were added. The condensable vapor species considered are constituents of the M-O-H systems where M is an element in the bulk composition of the melt. That is, intermetallic vapor species and mixed oxide vapor species such as CaMoO₄(g) were not represented in the species list though there is evidence they could contribute to vaporization. Few vapor phase hydrides are included.

Omissions of some vapor species as cited above is not the only vapor speciation concern arising in the analysis of core debris interactions with concrete. Concretes, when intensely heated by melts, also evolve HCl, HF and sulfur or sulfur oxides. Reactions of these vapors could create volatile species. Certainly it is observed that aerosols collected during tests of core debris interactions with concrete contain halides and sulphides [4].

The oxide melt phase presented in part B is far more complex than that in part A of the benchmark exercise. In part A, no mixing could occur on the anion lattice. In part B, anions other than O²⁻ such as SiO₄⁴⁻ and MoO₄²⁻ can be hypothesized. Mixing models which involve random substitution on both the cationic and anionic lattices could be formulated. Some anions are sufficiently large that the concept of a lattice model becomes difficult to implement. Instead, polymerization models such as

have been used to describe mixing in such systems [14,15]. Some work is underway to develop mixing models of this type for the VANESA model of release during core debris interactions with concrete. These models could not, however, be made available for the benchmark exercise.

A molecular model of the oxide phase was selected. The model was chosen deliberately to be more complex than that currently being used in released versions of the VANESA code. Notable features of the oxide phase model include:

- alkaline earths in the oxide phase are allowed to form oxides, orthosilicates, metasilicates, zirconates and molybdates.
- cerium can be present in both the tri-valent and the tetra-valent states.
- molybdenum can be present in both the tetra-valent and the hexa-valent states.

The many condensed species of the oxide phase are treated as molecular entities, that is distinct anion and cationic lattices are not invoked, and are assumed to form an ideal solution.

The metallic phase was assumed to be an ideal solution. The substantial data base for ferrous melts shows that metal phases such as those arising in the part B problems are not ideal. Consequently, one of the perturbed analyses discussed below examines the effects of non-ideality in the metal phase.

4.2 Results Obtained for the Problems in Part B

Results obtained for the six problems in part B of the exercise are presented in Tables 6-11. Each problem produces a forbiddingly large quantity of numbers. Each element varies in its behavior. Only a limited discussion of the behaviors is presented below.

1. Oxygen Potentials: Oxygen partial pressures calculated for the six problems are

	Oxygen Partial Pressures (atms)	
	2000 K	2500K
Case A	2.3×10^{-18}	2.3×10^{-13}
Case B	4.7×10^{-15}	8.1×10^{-10}
Case C	1.7×10^{-17}	1.9×10^{-12}

Case A is clearly the situation with the lowest oxygen potential. Interestingly, though cases B and C differ only in the amount of silicon dioxide assumed initially to be present, Case C is substantially more reducing than Case B.

2. Uranium Behavior: Substantial reduction of UO_2 to uranium metal occurs in Case A. Much less reduction occurs in Case C and in Case B there is little reduction. In all cases $\text{UO}_2(\text{g})$ is an important uranium-bearing vapor species. In the most reducing cases, $\text{UO}(\text{g})$ contributes to the vapor pressure and at 2500 K in Case B, $\text{UO}_3(\text{g})$ is an important uranium-bearing species.

TABLE 6. Results Obtained in the Case A Problem
with T = 2000 K

3. Behavior of Zirconium: Zirconium is oxidized in all cases. Metallic products of reduction do insure relatively low oxygen partial pressures are maintained.

4. Behavior of Silicon: There is a tendency, especially under strongly reducing conditions for silica to be reduced to silicon metal. Otherwise, silica tends to react with available alkaline earths to form usually orthosilicates.

5. Behavior of Carbon: In all cases, the system is reducing-enough that much of the CO₂ is reduced to carbon which is incorporated into the metallic melt.

6. Behavior of Strontium: The most significant feature of strontium behavior is its vaporization from the melt. To track this vaporization, a "figure-of-merit", F(Sr), is defined as:

$$F(\text{Sr}) = \sum_v n_{\text{v}} m(v)$$

where n_v = number of strontium atoms in the v^{th} vapor species

$m(v)$ = moles of the v^{th} vapor species.

Values of these figures-of-merit are summarized below:

F(Sr) at

2000K 2500K

Case A	2.0×10^{-4}	2.1×10^{-2}
Case B	1.4×10^{-6}	5.0×10^{-3}
Case C	2.3×10^{-3}	4.7×10^{-2}

In all cases there is at least an order of magnitude increase in the figure-of-merit in going from 2000 to 2500 K. The increase in strontium release with temperature is due to both the increases in the partial pressures of strontium-bearing gases and to the increase in vapor phase volume by condensable species such as SiO(g). The increases in condensable species contributions to the vapor phase at the highest temperatures also affect release of other radionuclides.

Sr(g) is the dominant vapor species for these calculations. Of course, in other circumstances other vapor species may be important.

7. Behavior of Cerium: Cerium in the oxide melt is predicted to be predominantly in the tri-valent form. To track vaporization of cerium, a figure-of-merit, F(Ce),

which is similar in definition to that used to track strontium vaporization was defined. Summary values of this figure of merit are listed below:

	F(Ce) at	
	2000 K	2500 K
Case A	5.1×10^{-5}	1.1×10^{-2}
Case B	4.3×10^{-6}	1.2×10^{-1}
Case C	1.8×10^{-5}	5.3×10^{-3}

Ce(g), CeO(g) and CeO₂(g) are the important vapor species.

8. Behavior of Lanthanum: Again, a figure-of-merit is used to track lanthanum vaporization among the various problems:

	F(La) at	
	2000 K	2500 K
Case A	4.2×10^{-6}	8.1×10^{-4}
Case B	3.2×10^{-7}	5.6×10^{-3}
Case C	1.5×10^{-6}	4.0×10^{-4}

Little lanthanum release would be expected below 2500 K and what release does occur in predominantly the result of the vapor pressure of LaO(g).

4.3 Comparison to Results of a Simpler Model of the Oxide Phase

A fairly complex model of the condensed phase was employed in the analysis of the problems in part B of the benchmark exercise. Not all models have such complex descriptions of the condensed phase. It is of interest then to compare the results obtained above to results obtained with a simpler model. The simpler model considered here does not allow formation of silicates, zirconates or molybdates. Further, it does not allow reduction of silica to silicon, calcium oxide to calcium metal, strontium oxide to strontium metal, or uranium to uranium metal. Vapor phase speciation, however, is the same in the simpler model as in the analyses for the part B problems.

Results obtained with the simpler model for Case B at 2000 K are collected in Table 12. The most notable feature of these results is the very high partial pressure of silicon monoxide. Whereas with the more complex model, the partial pressure of SiO(g) was calculated to be only 3×10^{-2} atmospheres, with the simpler model, SiO(g) is calculated to be the dominant gas phase species.

Figures-of-merit for strontium, lanthanum and cerium vaporization for calculations with the complex and the simple models of the condensed phase are:

	Simple Model	Complex Model
F(Sr)	1.4	1.4×10^{-6}
F(Ce)	2.0×10^{-3}	4.3×10^{-6}
F(La)	1.6×10^{-4}	3.2×10^{-7}

Vastly higher vaporization of radionuclides is predicted with the simple model largely because of the huge volume of SiO(g) created. Whether this SiO(g) forms or not depends on the activity of SiO₂ in the melt. In the complex model, this activity is kept low by reduction of SiO₂ to Si and by the formation of silicates. There is some experimental evidence that enhanced vaporization does occur when zirconium is added to siliceous melts (8) as is suggested especially by the simpler model.

4.4 Effects of Non-Ideality in the Metal Phase

Solutions to the problems posed in part B of the benchmark exercise were all calculated assuming the mixture of U, Fe, Zr, Mo, Si, Ca, Sr, and C was an ideal solution. There is substantial evidence such an alloy would not be ideal. Calcium and carbon are well-known to be non-ideal when alloyed with iron. To ascertain the effects of non-ideality in the metal phase a very approximate model drawn from the ferrous-metallurgy literature [16] was formulated and the Case B problem at 2000K was recalculated. The activity coefficients in the non-ideal metal phase model are:

$$\begin{aligned} \ln\gamma(Zr) &= \ln(0.037) \\ \ln\gamma(U) &= \ln(0.027) + 9.4X(U) \\ \ln\gamma(Mo) &= -4X(C) \\ \ln\gamma(Ca) &= \ln(2240) - 15.8X(C) - 10.7X(Si) \\ \ln\gamma(Si) &= \ln(0.0013) + 9.7X(Si) - 10.7X(Ca) - 10.7X(Sr) \\ \ln\gamma(C) &= \ln(0.70) + 6.9X(C) - 15.8X(Ca) - 4X(Mo) \\ &\quad + 9.7X(Si) + 11.6X(C)^2 + 8.8X(Si)^2 - 15.8X(Sr) \end{aligned}$$

where $\gamma(i)$ = activity coefficient of the constituent i of the metal phase

$X(i)$ = mole fraction of the constituent i of the metal phase.

The activity coefficient of iron was assumed to be approximately 1. No data for the activity of Sr in iron were found so the activity coefficient was taken to be the same as that for Ca.

Results of the recalculation are shown in Table 13. Introduction of non-idealities into the model of the metal

Ca ₂ O	1.098e-22	1.034e-24	-153188	
La ₂ O	1.442e-23	1.358e-25	-128800	
Sr ₂ O	6.614e-21	6.229e-23	-174459	
(SiO) ₂	2.575e-11	2.424e-13	-218392	

phase enhanced reduction of silica to silicon and inhibited reduction of uranium and calcium. It also inhibited graphite formation in the melt. Figures-of-merit for the vaporization of strontium, cerium and lanthanum are:

	Non-ideal Metal Phase	Ideal-Metal Phase
F(Sr)	1×10^{-7}	1.4×10^{-6}
F(Ce)	3.0×10^{-6}	4.3×10^{-6}
F(La)	8.5×10^{-8}	3.2×10^{-7}

Clearly, introduction of metal phase activity coefficients different than one affected the vaporization of strontium. The depressed vaporization of Sr is the result of changes in the concentrations of SrO and Sr in the condensed phases and the increased oxygen potential - $P_{O_2} = 1.3 \times 10^{-12}$

atmospheres as opposed to $P_{O_2} = 4.7 \times 10^{-15}$ atmospheres

when activity coefficients were equal to 1. The effects of the non-ideal metal phase model on the vaporization of lanthanum and cerium are less pronounced since neither of these species contribute to the metal phase.

4.5 Effects of Uncertainty in the Properties of Gas Phase Species

The thermodynamic properties of many of the gas phase species of interest here are not well-known. To illustrate the effects of uncertainties in the thermodynamic properties on the calculations, case B at 2000 K was recalculated with properties of selected radionuclide vapor species varied toward more stable values within their recognized uncertainty ranges. To do this, the uncertainties in the free-energies of the vapor species were ascribed to the enthalpies of formation. The uncertainties in these enthalpies of formation were taken from the literature [17,18,19,20] to be:

$\Delta H_f(Sr(g))$	=	39200 ± 400
$\Delta H_f(SrO(g))$	=	-3200 ± 4000
$\Delta H_f(SrOH(g))$	=	-49120 ± 5000
$\Delta H_f(Sr(OH)_2(g))$	=	-142400 ± 10000
$\Delta H_f(SrH(g))$	=	52103 ± 5000
$\Delta H_f(Sr_2O(g))$	=	-50470 ± 5960
$\Delta H_f(Ce(g))$	=	99150 ± 600
$\Delta H_f(CeO(g))$	=	-29600 ± 4000
$\Delta H_f(CeO_2(g))$	=	-125180 ± 6000
$\Delta H_f(Ce_2O(g))$	=	-5960 ± 17900
$\Delta H_f((CeO)_2(g))$	=	-153000 ± 15900

$\Delta H_f(La(g))$	=	103125 ± 994
$\Delta H_f(LaO(g))$	=	-27818 ± 2000
$\Delta H_f(La_2O(g))$	=	0 ± 13900
$\Delta H_f(LaO_2(g))$	=	-125200 ± 21900
$\Delta H_f((LaO)_2(g))$	=	-133130 ± 17900

Results of the recalculation are shown in Table 14. Figures-of-merit for the vaporization of strontium, cerium and lanthanum are:

	Lower Bound Free-Energies	Best-Estimate Free-Energies
F(Sr)	1.6×10^{-6}	1.4×10^{-6}
F(Ce)	1.3×10^{-5}	4.3×10^{-6}
F(La)	5.2×10^{-7}	3.2×10^{-7}

The small uncertainties in the properties of strontium-bearing vapor species little affect the predicted vaporization of strontium. The larger uncertainties in the properties of cerium-bearing and lanthanum-bearing vapor species have more distinct effects on vaporization. The predicted vaporization of cerium may be uncertain by a factor of 3 because of uncertainties in the vapor properties.

It is unlikely that uncertainties in the thermodynamic properties of vapor species will soon be resolved. Consequently, the uncertainty in vaporization created by uncertainties in the vapor properties constitute a limit on the accuracy that can be obtained in thermodynamic calculations of core debris interacting with concrete. They also define a limit on the extent to which condensed phase models need to be refined.

5. CONCLUDING DISCUSSION

The analyses presented above have illustrated a few of the important topics that need to be considered in the thermochemical modeling of core debris interactions with concrete. An emphasis has been placed on modeling the condensed oxide phase. To obtain accurate estimates of radionuclide release and aerosol generation during core debris interactions with concrete, a far more systematic examination of this type of modeling needs to be conducted.

The need to develop models on the condensed phase of core debris cannot be abridged by experimentation alone. It is apparent from the calculations presented here that the properties of the condensed phases vary with both temperature and melt composition. Because of this, it is unlikely that so complete a data base on the thermochemical

properties of the condensed phases can be developed that analytic models will not be needed to interpolate and extrapolate the data base.

It should, however, be remembered that uncertainties in the thermodynamic properties of vapor species define a limit on the refinement of condensed phase models. It should also be remembered that modeling of the condensed oxide phase is not the only technical issue of thermochemical analyses of core debris interactions with concrete. Other topics that can be just as important include:

1. Completeness of the gas phase speciation including the importance of vapor phase hydrides, mixed oxides and intermetallics.
2. Non-ideality of the metal phase
3. Importance of halide and sulphide-bearing gases evolving from the concrete.

13. ABSTRACT (200 words or less)

A submission for the CSNI/PWG-4/GREST standard problem on chemical thermodynamic modeling in core-concrete interaction releases of radionuclides is described. Part A of the exercise is a highly defined benchmark calculation in which data and speciation are specified. The problem is, however, ambiguous concerning the definition of an ideal solution. Consequently, two solutions are provided. In one solution, specified species are treated as molecular entities to define the ideal solution. In the second, mixing is assumed to occur ideally on cationic and anionic lattices. The different results obtained in these calculations illustrate the importance of condensed phase modeling in the analyses of high temperature melt interactions with concrete.

Part B of the exercise consists of six problems in which the temperatures, pressures and bulk compositions of the melts are specified. Data and speciation are to be supplied as parts of the solutions to the problems. Results of calculations for these six problems are presented. Additional solutions are provided to illustrate the effects of speciation in the condensed oxide phase, non-ideality in the condensed metal phase and uncertainty in the thermodynamic properties of gas phase species.
