TABLE 11.2-7 LIQUID RADWASTE SYSTEM – COMPONENT DESIGN PARAMETERS

Component	Number	Liquid Pumped	Flow Rating (gpm)	Total Dynamic Head (ft)	Materials (Casing/ Shaft/ Impeller)	Type	Design Code
PIB Tank Forwarding Pump	1	Condensate	10	170	316 SS	Horizontal 4-Stage Centrifugal	Manufacturer's Standard
Sample Batch Tank Forwarding Pump	1	Water	40	170	316SS	Horizontal 4-Stage Centrifugal	Manufacturer's Standard

Floor Drain Demineralizer

Type - Mixed-bed, anion and cation resin, nuclear grade, nonregenerative, with stainless steel wire mesh underdrain

Capacity - 140 gpm, batch process

Resin bed - 49 ft^3

Vessel size - 4 ft 6 in. O.D. by 4 ft 9 in. vertical shell and ASME heads

Design temperature - 150°F

Design pressure - 150 psig

Pressure drop - 7 psid

Design code - ASME Section VIII, Division I, 2010

Material – Shell, heads, nozzle pipes, flanges and internals – stainless steel

Waste Demineralizer

Type - Mixed-bed, anion and cation resin, with stainless steel wire mesh underdrain

Capacity - 140 gpm, batch process

Resin bed - 49 ft^3, resin depth 3 ft minimum, 5 ft maximum

Vessel size - 4 ft 6 in. O.D. by 9 ft 6 in. shell height

Design temperature - 150°F

Design pressure - 150 psig

Material - Shell, heads, flanges, and nozzle pipes - carbon steel

Internals - 304 stainless steel

Tank lining - 1/4-in. EPDM (ethylene propylene)

Pressure drop - 10 psid

Design code - Demineralizer Vessel - ASME Section III, Class C, 1968

TABLE 11.2-7 LIQUID RADWASTE SYSTEM – COMPONENT DESIGN PARAMETERS

Post Treatment System Mixed Bed Demineralizer

Type – Mixed-bed, anion and cation resin, nuclear grade, nonregenerative, with stainless steel wire mesh underdrain

Number of Demineralizers - 2

Capacity - 20 gpm, batch process

Resin bed - 20 ft^3

Vessel size – 30 in. O.D. by 5 ft 8 in. vertical shell and ASME heads

Design Temperature - 150°F

Design Pressure - 150 psig

Pressure drop - 5 psid

Material - Shell, heads, flanges, and nozzle pipes - 316 SS

Internals - 304 Stainless steel

Design Code - ASME Section VIII, Division I, 2001

Post Treatment System Granulated Activated Charcoal Bed Filter

Type - Granular Activated Carbon Bed Filter

Number of Filters - 2

Capacity - 20 gpm, batch process

GAC bed – 24 ft^3

Vessel size - 30 in. O.D. by 5 ft 8 in. shell height

Design Temperature - 150°F

Design Pressure - 150 psig

Material - Shell, heads, flanges, and nozzle pipes - 316 SS

Internals - 304 Stainless steel

Pressure drop - 10 psid

Design Code - ASME Section VIII, Division I, 2001

Floor Drain and Waste Collector Etched-Disk Filters (two)

Type - Etched disk

Capacity - 190 gpm maximum

Materials - Shell and heads - 304 stainless steel

Internals - 316L stainless steel

Design pressure - 350 psig

Design temperature - 150°F

Design code - ASME Section VIII, Division I

TABLE 11.2-7 LIQUID RADWASTE SYSTEM – COMPONENT DESIGN PARAMETERS

Floor Drain and Waste Collector Oil Coalescers (two)

Type - Oil separator vessel with oil-coalescing cartridges

Capacity - 150 gpm design

Material - 316 stainless steel

Design pressure - 150 psig

Design temperature - 150°F

Design code - ASME Section VIII, Division 1

Process Evaporators (two)

Type - Low-pressure, horizontal batch type with submerged U-tube heating bundle - single shell, with continuous spray demister

Capacity - 30 gpm of distillate

Steam pressure to tube bundle - 10 psig

Cooling water pressure - 100 psig

Overpressure protection - 3 in. rupture disk to discharge

Condensing space vacuum - 20 in. Hg

Distillate temperature - 190°F

Operating temperature - 160°F (evaporator and condenser)

Distillate temperature at cooler discharge - 125°F

Shell size - 8 ft 6 in. diameter by 11 ft 4 in. long over elliptical heads

Material and thickness - 304 stainless steel, 1/2-in.-thick plate

Tubes and tube sheets - Incoloy-825, 3/4 in., 17-gage tubes; 2-1/16-in.-thick tube sheets

Decontamination factor - 3×10^5 bottoms to distillate (gross activity basis)

Max. activity of concentrated waste liquid - 5×10^{-2} μCi/ml

Volume of concentrated waste liquid - 800 gal

Design codes - Evaporator shell - ASME Section III, Class C, 1968

Evaporator tube bundles - ASME Section VIII, Division 1, 1980

Channel sections of tube bundles - ASME Section VIII, Division 1, 1968

Process piping - ANSI B31.7, 1969 Class III for stainless steel

Pumps and valves - ASME Draft Code for Pumps and Valves for Nuclear Power, Class III, 1968, and March 1970 Addenda

Distillate cooler - ASME Section VIII, Division 1, 1968, and TEMA Class C

Piping for steam and cooling water - Carbon steel ANSI B31.1

TABLE 11.2-7 LIQUID RADWASTE SYSTEM – COMPONENT DESIGN PARAMETERS

Precoat Filters (two)

Surface area - Waste collector filter: 115 ft^2

- Floor drain filter: 64 ft^2

Max. differential pressure - Waste collector filter: 30 psid

- Floor drain filter: 30 psid

Amount of precoat - 0.2 lb/ft^2 (each filter)

Filter vessel volume - Waste collector filter: 460 gal

-Floor drain filter: 210 gal

Total backwash air required - Waste collector filter: 61 scf

- Floor drain filter: 28 scf

Materials - Vessel - carbon steel

- Internals - 304 stainless steel

- Lining – Plasite

---

[a] Except SA-240-304/stainless steel bottom.

[b] Design code for tank modifications is ASME III, Class 3.

TABLE 11.2-8 ESTIMATED CONDENSATE STORAGE WATER QUALITY

Parameter	Value
Specific conductivity at 25 °C	≤ 1µmho/cm
pH at 25 °C	6 to 8
Silica (as SiO_2)	≤50 ppb
Chloride (as Cl^-)	≤25 ppb
Boron (as BO_3)	≤0.1 ppm
Total Organic Carbon (TOC)	≤500 ppb

Note: pH and conductivity apply after correction is made for dissolved carbon dioxide.

11.3 GASEOUS RADWASTE SYSTEM

11.3.1 Design Objectives

The design objectives of the gaseous radwaste system are to process and control the release of gaseous radioactive effluents to the site environs so that the releases are a small fraction of the concentration limits as defined in 10 CFR 20, Appendix B, and are as low as reasonably achievable, as required by 10 CFR 50, Appendix I; to keep iodine releases within the total yearly release limit of Regulatory Guide 1.42;* and to operate within the emission rates established in the Offsite Dose Calculation Manual radiological effluent controls.

Subsections 11.3.6 and 11.3.9 establish that the gaseous radwaste system adequately meets the above design objectives.

11.3.2 System Description

The largest single source of gaseous radwaste from the Fermi 2 plant is the offgas removed from the main condenser. For the treatment of this source of gaseous radwaste, the gaseous waste processing system, referred to as the offgas system, has been incorporated in the plant design. This system is discussed in Subsection 11.3.2.7.

Other sources of gaseous radwaste include releases from the turbine gland seal steam condenser and releases to the various plant ventilation systems from potential leakage of main steam and primary coolant. Although attempts are made to limit leakage to a minimum, small leaks at rates which make their detection difficult are expected. These other sources of gaseous waste are discussed in Subsections 11.3.2.1 through 11.3.2.6.

11.3.2.1 Turbine Gland Seal Steam

Steam is provided to the turbine gland seal to prevent air inleakage to the condenser during operation. Steam to the gland seal is provided from the main steam line or from the auxiliary boiler during startup and from the high-pressure turbine inner steam seal leakoffs during operation. The steam from the turbine gland seal and air inleakage is exhausted to the gland steam condenser where the steam is condensed. The condensate is returned to the main condenser. Subsection 10.4.3 provides a detailed description of the turbine gland sealing system.

The noncondensibles from the gland steam condenser contain a source of radioactive gaseous effluents from Fermi 2. Estimated sources from the gland steam condenser were based upon the parameters given in Appendix A of Regulatory Guide 1.42.

In order to reduce the concentration of short-lived radionuclides in offgas from the gland seal condenser, additional piping has been incorporated in the gland seal condenser exhaust system to provide a minimum 2-minute delay. Estimated releases from the turbine gland seal condenser are given in Table 11.3-1.

---

* Regulatory Guide 1.42 was withdrawn March 18, 1976, with the adoption of Appendix I to 10 CFR 50 and the development of a series of implementing guides.

11.3.2.2 Sources to Turbine Building Ventilation System

The source of radionuclides to the turbine building atmosphere is small potential leaks from valves in piping systems carrying main steam. Although attempts are made to limit this potential leakage to a minimum, small leaks are expected to occur. For calculational purposes, the total steam leakage into the turbine building is assumed to be 1700 lb/hr consistent with Regulatory Guide 1.42, Revision 1. Noble gas concentrations in the steam are presented in Table 11.1-2. Assumptions for iodine releases are the same as those provided in Appendix A of Regulatory Guide 1.42, Revision 1. The total main steam line flow is 15,221,000 lbm/hr for the design basis of 102 percent of uprated reactor power.

Due to the extremely high turbine building ventilation exhaust flow rates, treatment of this release path is not practicable. Within the turbine building area, ventilation flow is controlled by maintaining pressure differentials between the various turbine building areas. This ensures proper ventilation flow patterns and also prevents releases of radioactive gases to areas of the turbine building normally accessible during plant operation. In evaluating the ventilation system in the steam piping area (that is, the valve area and east and west reheater bays at Elevation 641 ft 6 in.), it was conservatively determined that a minimum 10-minute holdup is provided by the ventilation system. This allows adequate decay for short-lived isotopes. Monitoring of the turbine building ventilation exhaust is performed, and if the radioactivity concentration exceeds the monitor setting as described in Section 11.4, turbine building ventilation is terminated. The turbine building ventilation system is described in Subsection 9.4.4. The expected releases from the turbine building are listed in Table 11.3-1.

11.3.2.3 Sources to Reactor Building Ventilation System

Since the noble gas concentrations are negligible in the primary coolant liquid present in fluid systems located in the reactor building, only the release of radiohalogens from primary coolant leakage into the reactor building represents a source of radioactivity to the reactor building ventilation. A primary coolant leakage rate of 500 lb/hr was used in estimating a conservative radiohalogen source term. This value is the total of a number of minor leaks assumed to exist. The assumptions used in determining the quantity of radiohalogen releases are those presented in Appendix A of Regulatory Guide l.42, Revision 1. The estimated releases from the reactor building are given in Table 11.3-l.

Normally, ventilation of the reactor building is performed by the reactor/auxiliary building ventilation system, which does not process the ventilation effluent. However, if the radioactivity concentration in the release exceeds the associated exhaust radiation monitor setpoint (Section 11.4), ventilation by the reactor/auxiliary building ventilation system is terminated and the reactor building is ventilated and maintained under negative pressure with respect to outside atmosphere by the standby gas treatment system (SGTS). The reactor/auxiliary building ventilation system is described in Subsection 9.4.2.

11.3.2.4 Sources to Drywell Purge System

Neutron activation of air around the reactor pressure vessel (RPV) and potential small system leaks could provide sources of radioactive gases to the drywell atmosphere. Since the drywell is a closed system and is not normally vented, most isotopes will have decayed out prior to initiation of ventilation of the drywell. The atmosphere can be sampled prior to purging and is also monitored during purging. If high radiation levels are detected, the purge can be terminated or processed by the SGTS. Therefore, any release from the Fermi 2 drywell is expected to be negligible. The drywell purge system is described in Subsection 6.2.3.

11.3.2.5 Sources to Radwaste Building Ventilation System

The source of radioactive gases in the radwaste building could be from evaporation of leakage from equipment, from valves, or from the ventilation of atmospheric storage tanks. The iodine concentration in the liquid radwaste system is significantly lower than that in the primary coolant due to removal by processing and to dilution of the iodine by noncontaminated water entering the system from sumps. Assuming an average reduction of 100 for iodine in the liquid radwaste system, the radiohalogen release to the radwaste building atmosphere has been determined to be negligible.

11.3.2.6 Other Potential Sources of Radioactive Gaseous Waste

It will be necessary to vent certain tanks and discharge gases from specific laboratories and building service areas to a reactor building, turbine building, or radwaste building ventilation exhaust system. These additions are of a low level and add insignificant increments to the total radioactive gas releases.

11.3.2.7 Offgas System

The noncondensibles removed from the main condenser are the largest source of radioactive gaseous waste from the plant. In order to reduce the releases from this source, the offgas system has been incorporated in the plant. The offgas system consists of two effluent streams, one from the mechanical vacuum pump and the second from the steam-jet air ejectors. The offgas system is described in Figure 11.3-1 and shown schematically in Figure 11.3-2.

11.3.2.7.1 Mechanical Vacuum Pump Offgas

The mechanical vacuum pump is used before startup to reduce the condenser pressure to approximately 4 in. Hg abs, at which point the mechanical vacuum pumps stop and the steam-jet air ejectors are started manually.

The mechanical vacuum pump is also used for normal shutdowns, SCRAM related shutdowns, and during periods of low power operations when the Offgas system is not available. The expected quantity of gaseous radwaste released from these operations of the mechanical vacuum pump are also small. Controls for the release path contained in the Offsite Dose Calculation Manual (ODCM) are designed to prevent exceeding ODCM limits. An active mechanical vacuum pump trip on high radiation in the main steam lines will ensure that 10 CFR 50.67 limits are not exceeded on transient or “puff” releases. These controls prevent the release limits from being exceeded.

Since the mechanical vacuum pump is normally used only under the conditions stated above, it is an infrequent source of gaseous releases. The expected quantity of gaseous radwaste released from this source is dependent upon the chronology of events from initiation of shutdown to startup.

An estimate of the expected concentrations of gaseous radwaste from the mechanical vacuum pump during a startup can be made assuming that:

a. The plant operates with an 80 percent plant capacity factor

b. The average duration per shutdown is 18 days, assuming four shutdowns per year and a total of 20 percent downtime per year

c. The volume of the condenser is estimated to be 1.8 x 10^5 ft^3

d. For noble gases, offgas from the reactor is assumed to be carried to the condenser, at the full power rate, for 2 hr following shutdown of the steam-jet air ejectors

e. For iodine, the partition coefficient within the turbine condenser is taken as 10^{-4} $\frac{\mathrm{mCi/cm^3\ noncondensible}}{\mathrm{mCi/cm^3\ water}}$

Other parameters for iodine are as given in Appendix A to Regulatory Guide 1.42.

During startups, the rate of air removal by the mechanical vacuum pump is greater than the offgas flow rate through the steam-jet air ejector during normal operation. As a result, the offgas from the mechanical vacuum pump does not permit processing through the portion of the offgas system designed to process air ejector effluents. Also, since startup using the mechanical vacuum pump follows an outage period that is long enough to allow significant decay of most gaseous isotopes in the condenser, no processing is provided other than a 2-minute delay of the mechanical vacuum pump offgas. Estimated releases from this effluent stream are given in Table 11.3-1.

During mechanical vacuum pump operation for normal shutdowns, SCRAM related shutdowns, and operations during periods of low power operations when the Offgas system is not available, the release rate of the mechanical vacuum pump offgas is expected to be low. The controls applied to this release path will ensure that ODCM limits on instantaneous release, quarterly dose and annual dose due to untreated release are met. These limits are significantly below the levels originally estimated in Table 11.3-1. This allows mechanical vacuum pump operations for normal shutdowns, SCRAM related shutdowns, and during periods of low power operations when the Offgas system is not available.

11.3.2.7.2 Steam-Jet Air Ejector Offgas

In order to reduce backpressure on the turbine and to maintain turbine efficiency, noncondensible gases must be continuously exhausted from the condenser during plant operation. This is accomplished by the main condenser steam-jet air ejectors. The condenser offgas, which is the major source of the gaseous radwaste, contains hydrogen and oxygen generated by the radiolysis of water, air that leaks into the condenser, and radioactive gases consisting of activation and fission gases. About 98.5 percent of the radioactive gases that exit the RPV with the steam are very short-lived activation gases that have less than a 30-sec half-life, such as ^{16}N and ^{19}O. Additional activation gases are present in much smaller amounts, with half-lives of 10 minutes (^{13}N) and 110 minutes (^{18}F). The remaining radioactive gases, krypton and xenon, are noble gases and result from fissioning. The concentration of these noble gases depends on the amount of tramp uranium in the coolant and on the cladding surfaces, which is usually extremely small, and on the number and size of fuel-cladding leaks. Estimated concentrations of radioactive gases exiting the RPV and entering the offgas system are provided in Table 11.1-1.

In addition to the radiogases removed from the condenser, there are also radioiodines and radioactive particulate daughters due to the decay of krypton and xenon isotopes.

11.3.2.7.3 Radionuclide Inventories in the Offgas System

The calculated design-basis radionuclide inventories in components within the offgas system are presented in Table 11.3-2. Components identified in Table 11.3-2 are shown schematically in Figure 11.3-2.

11.3.2.7.3.1 Noble Gas Inventories

Noble gas inventories have been calculated by using equipment volume, condenser offgas release rate as listed in Table 11.1-2, and decay during residence in the equipment. Decay during transit between equipment was not considered. Residence time in equipment other than the charcoal beds was determined by:

$$T = \frac{V}{F} \qquad (11.3\text{-}1)$$

where

T = residence time

V = equipment volume

F = flow rate (see Subsection 11.3.3.1)

The residence times for the various equipment in the offgas system are:

a. Preheater - 0.2 sec

b. Recombiner - 0.5 sec

c. Condenser - 18 sec

d. Aftercooler - 30 sec

e. Precooler - 15 sec

f. Holdup pipe - 130 sec

g. Sand filter - 30 sec

h. Chiller - 18 sec

i. First charcoal bed - 2.66 days (Xe); 4 hr (Kr)

j. All charcoal beds - 16 days(Xe); 24 hr (Kr)

k. Afterfilter - 60 sec

The residence time for the noble gases in the charcoal delay beds was determined by

$$T = \frac{K_D M}{F} \quad (11.3\text{-}2)$$

where

K_D = dynamic adsorption coefficient, cm^3/g

M = mass of adsorbing material (charcoal), g

F = volumetric flow rate, cm^3/sec (see Subsection 11.3.3.1)

The values of K_D were determined experimentally for the installed Fermi system at the following conditions:

a. Percent moisture of charcoal - approximately 1.4 percent

b. Temperature of charcoal - 70°F

c. Gas pressure - 12.5 psia.

These are the nominal operating conditions in the charcoal delay portion of the offgas system. The derived test data obtained per design calculation were:

Gas	K_D Measure as cm^3/g	Residence Time
Kr	37.6	24.8 hours
Xe	629 – 688	17.3 – 18.9 days

These test results showed charcoal residence times longer than the design basis values of 24 hours and 16 days.

11.3.2.7.3.2 Daughter Product Inventory

Unlike noble gases, the daughter products are either washed out of the free volume in equipment such as condensers and directed to the liquid radwaste system, washed out and trapped on frost in equipment such as the chiller where they are later directed to the liquid radwaste system after the chiller is defrosted, or trapped in equipment such as the sand filter and charcoal beds. A daughter product removal of 100 percent was assumed for the following components:

a. Offgas condenser

b. Aftercooler

c. Precooler

d. Holdup pipe

e. Chiller

f. Sand filter

g. Charcoal beds

h. Afterfilter.

Daughter product activities in each piece of equipment were determined by calculating the quantity produced by decay of the parent during residence in the component, and then calculating the amount removed by decay. For equipment that removes these radionuclides by washout or retention, the concentration in the equipment effluent discharge was assumed to be zero. The equation used to calculate the daughter product inventories was the modified Bateman Equation for decay chain activity computation:

$$N_i(t) = P(\lambda_1.\lambda_2 \ldots \lambda_{i-1}).\sum_{j=1}^{i} \frac{\left(1-e^{-\lambda_j T}\right)}{\lambda_j \prod_{k \neq j}(\lambda_k - \lambda_j)} \qquad (11.3\text{-}3)$$

where

$N_i(t)$ = activity of ith isotope after time (t), lCi

T = equipment residence time, sec

P = continuous release rate, lCi/sec

In equipment that retains these daughter products, the concentrations increase until an equilibrium is reached or until the retention material is changed. The operating times assumed for equipment that retains these products are

a. Chiller (assumed to require defrosting after 6 hr of operation) - 6 hr

b. Charcoal beds - 10 years

c. Afterfilter - 10 years.

The inventories in such components were calculated using the following equation:

$$N_i(t) = P(1 - e^{-\lambda_1 T}) \left[(\lambda_1.\lambda_2 \ldots.\lambda_{i-1}) \sum_{j=1}^{i} \frac{\left(1-e^{-\lambda_j t}\right)}{\lambda_j \prod_{k \neq j}(\lambda_k - \lambda_j)} \right] \qquad (11.3\text{-}4)$$

where

$N_i(t)$ = activity of ith daughter isotope after time t in microcuries

t = operation or accumulation time, sec

T = equipment residence time, sec

11.3.2.7.3.3 Radioiodine Inventory

Major components in the offgas system were provided by Kraftwerk Union. Data on similar process streams of offgas systems provided by Kraftwerk Union and operating in West Germany have been obtained. These data show no detectable iodine entering the charcoal adsorbers. The iodine removal is not assumed to occur due to washout in the recombiner condenser, but rather is assumed to result from iodine reacting with the recombiner catalyst. The iodine inventory in the offgas system given in Table 11.3-2 reflects the data available through Kraftwerk Union and assumes that all iodine is removed in the recombiner.

11.3.2.7.4 Design Bases of the Offgas System

The design bases for the offgas system are

a. To process an annual average offgas rate equivalent to 100,000 μCi/sec after a 30-minute delay (See subsection 11.3.6)

b. To maintain the concentration of hydrogen in the gases from the air ejectors below its flammable limit

c. To provide protection against inadvertent release of significant quantities of gaseous and particulate radioactive material to the environs

d. To ensure that in-plant occupational radiation exposures due to operation of the offgas system are as low as practicable.

11.3.2.7.5 Process Description

Basically, the offgas system processes the condenser offgas by delaying the offgas so that significant decay of radionuclides is allowed before it is released from the plant. The delay is provided by charcoal, which impedes the flow of all gases; however, heavy gases such as krypton and xenon are affected more than are lighter gases. The charcoal provides about a 1-day delay for krypton and about a 16-day delay for xenon.

During plant operation, offgas discharged from the steam-jet air ejector is diluted with steam to keep hydrogen concentrations below 4.0 percent. The gas is heated by steam in the preheater, and enters the recombiner, where the hydrogen and oxygen are recombined catalytically into water. Diluting the gas with steam controls the hydrogen concentration and also provides control over temperature rise during the recombination. After recombination, the gases are cooled and dehumidified. The gas then enters a 2.2 minute (nominal) delay pipe which is followed by a sand filter. The gas is further cooled and enters the ambient temperature charcoal adsorbers. Chilling and drying the air improves the charcoal adsorbers' performance. The discharge from the adsorber system is filtered mainly to remove any charcoal fines that may have been carried out of the last charcoal bed. The gas is then pumped into the offgas discharge piping. The system vacuum pump is used to maintain a slightly negative pressure throughout the system, thus ensuring that any leakage would be into the system. The effluent from the offgas system is discharged from the plant after dilution in the reactor building ventilation system exhaust.

The condenser offgas system removes most of the activity from activation gases and reduces the activity due to fission gases by a factor of at least 90 (when compared to the 30-minute mixture). Essentially all of the hydrogen is removed from the offgas.

The ability to continuously process condenser offgas in the case of equipment failure is ensured by providing redundant standby equipment for each component in the offgas system, except for the six charcoal beds. Since the charcoal beds are passive equipment at ambient temperature and are at a slightly negative pressure, failure of a charcoal bed is unlikely.

The hydrogen concentration in the system is controlled by the addition of dilution steam upstream of the recombiner. Oxygen is injected into the 18" offgas manifold to ensure that hydrogen injected into the feedwater system via the Hydrogen Water Chemistry (HWC) System is recombined. Free hydrogen is essentially nonexistent at the outlet of the recombiner. Increased hydrogen concentration, which is measured in the 2.2-minute delay pipe, and the lack of a ΔT across the recombiner would provide indication of a recombiner failure. A switchover to the redundant hydrogen recombiner subsystem would be made.

Protection against inadvertent release of significant quantities of gaseous waste during system operation is accomplished by the following measures:

a. The system is maintained at a negative pressure, which ensures that air leakage is into the system

b. The system is designed to withstand the maximum pressure transient which would result from an instantaneous combination of a stoichiometric hydrogen-oxygen mixture

c. Radiation monitors on the delay line from the mechanical vacuum pumps would alarm should high radioactivity concentrations occur while these pumps are in use. Following an alarm, the plant operator can take proper action to correct/mitigate the situation. The mechanical vacuum pumps are also automatically tripped on main steam line high radiation.

d. The Reactor Building Exhaust Plenum Radiation Monitoring System measures the radioactivity in the Reactor Building exhaust plenum prior to discharge from the Reactor Building vent stack. This monitor will alarm in the main control room should high radioactivity concentrations be present in the Reactor Building or Offgas System exhausts. Following a high-radiation alarm, the plant operator can take proper action to correct the situation.

In-plant occupational radiation exposures due to system operation are maintained as low as practicable as follows:

a. Shielded rooms and a pipe tunnel are provided for the routing of piping, including field-routed piping carrying radioactive fluids

b. Adequate shielding is provided around the offgas system

c. The redundant equipment trains are completely isolated from each other so that if equipment servicing is required, offgas processing can be switched to the standby equipment, and maintenance can be performed on the off-line equipment.

11.3.2.7.6 System Availability

The offgas system operation is required during the operation of the plant. There are two independent 100 percent-capacity trains of equipment consisting of water separators, preheaters, recombiners, condensers, aftercoolers, and precoolers; there is also redundancy in the number of sand filters, chillers, mechanical filters, and water ring pumps. Upon failure of any component in one subsystem, a switchover is made to the redundant subsystem. Although the charcoal adsorbers are not redundant, system availability is protected since charcoal adsorber tanks can be bypassed individually. This arrangement ensures the operation of the offgas system at all times during the operation of the plant.

While there are redundant trains of the Offgas System equipment, the steam jet air ejector line, 2.2 minute delay piping, and the Offgas vent pipe are not redundant and are not required to be redundant. The limiting failure is that of the delay piping and this abnormal operating occurrence is addressed in the analysis in UFSAR Section 15.7.1.

11.3.2.7.7 Decontamination Factors

11.3.2.7.7.1 Particulate Removal

Since, in processing, the offgas is first passed through a sand filter followed by six activated charcoal adsorber beds, none of the particulate activity entering the system is expected to be discharged. Particulate daughter products of noble gas decaying within the charcoal beds are entrapped there. To further prevent particulate releases, charcoal fines in particular, the charcoal beds are followed with a high-efficiency particulate air (HEPA) filter rated at 99.9 percent efficient for all particles 0.3 μm and larger.

11.3.2.7.7.2 Radiogas Removal

Since radiogases are removed by decay, the decontamination factor will vary from isotope to isotope. Table 11.3-3 presents the estimated decontamination factor for each radiogas isotope, assuming a 24-hr holdup for krypton isotopes and a 16-day holdup for xenon isotopes.

11.3.3 System Design

The offgas system shown in Figure 11.3-1 is considered to consist of four subsystems: (1) the recombiner subsystem; (2) the air drying subsystem; (3) the charcoal adsorption subsystem; and (4) the water ring exhaust pump subsystem.

11.3.3.1 Design Parameters

Design parameters of the offgas system are:

a. Hydrogen - 186 cfm nominal at 14.7 psia and 130°F

b. Oxygen - 93 cfm nominal at 14.7 psia and 130°F

c. Air - 40 cfm nominal at 14.7 psia and 70°F

d. Steam - sufficient to reduce hydrogen concentration to ≤4.0 percent by volume at preheater inlet.

Carrier gas is the air inleakage from the main condenser after the radiolytic hydrogen and oxygen are removed by the recombiner. The sixth edition of Heat Exchange Institute Standards for Steam Surface Condensers, Paragraph S-16 c(2), indicates that, with certain conditions of stable operation and suitable construction, noncondensibles (not including radiolytic dissociation and trace gases) should not exceed 6 scfm for large condensers. The air inleakage for Fermi 2 has been considered as 40 scfm (nominal). However the plant can operate at an air inleakage flow higher than 40 scfm as long as the offsite dose rates do not exceed the applicable limits specified in the Technical specifications, and the offgas equipment does not exceed its capacity.

11.3.3.2 Design Pressure Transients

The most severe pressure transient that the system is postulated to experience would proceed as follows. The system is functioning normally; however, condenser air inleakage is so low as to be nondetectable. A recombiner failure occurs, but system switchover to the standby hydrogen removal train is not complete until a considerable quantity of H_2-0_2 gas, in stoichiometric proportions, has entered the vessels downstream of the condenser. Combustion cannot occur upstream of the condenser due to the presence of dilution steam and noncondensed air ejector steam. An ignition source that causes an instantaneous constant-volume combustion of gases is alleged to exist. The calculated pressure is postulated to exist everywhere in the offgas system exhaust pipe. The maximum pressure transient is 3l8 psig. To withstand this pressure transient, the offgas system (except for the water ring exhaust pumps) is designed for an upset pressure of 375 psia.

The recombiner is provided with a rupture disk for overpressure protection of the water separator, the tube side of the preheater, the recombiner, the shell side of the condenser, and the aftercooler. There are no isolating valves between these components and interconnecting piping. This is in accordance with the code requirement for overpressure protection in Article UG 125, ASME Boiler and Pressure Vessel Code Section VIII, Division 1.

In addition, safety valves are provided at the shell side of the preheater and relief valves are provided for the tube side of the condenser, aftercooler, and water ring cooler, for protection of the system piping and components against overpressurization.

11.3.3.3 Component Description

Each major component of the offgas system is described in the following subsections. Design parameters of offgas system components are listed in Table 11.3-4.

11.3.3.3.1 Water Separator

There is one water separator provided per train. The water separator is a vertical tank-shaped vessel. Gas enters near the bottom by way of a tangential nozzle. Water is removed by utilizing the cyclone principle. The gas passes through a stainless steel mesh demister before exiting through the top of the vessel. Detained water is drained to the condensate receiver tank by way of the loop seal.

11.3.3.3.2 Offgas Preheater

There is one offgas preheater provided per train. The purpose of the offgas preheater is to superheat the offgas. This is conducive to more efficient and dependable recombiner performance. The preheaters are flanged-head straight tube-type vessels. The shell side receives main steam which has been throttled to 160 psia. The steam condenses, giving up heat to the offgas that flows through the tubes. The shell-side water level is sensed and controlled, and the shell side is drained directly to the condenser. The tube side drains to the condensate receiver through the loop seal. A shell-side safety valve is provided that discharges into the offgas stream at the preheater inlet.

11.3.3.3.3 Catalytic Recombiner

There is one catalytic recombiner provided per train. The recombiners are vertical tank-shaped vessels. Offgas enters through the side of the vessel near the top. The gas passes down through a bed of homogeneous palladium catalyst that is supported on an aluminum oxide carrier material (pellet). The catalyst causes an exothermic reaction when the free hydrogen and oxygen in the offgas are being recombined into water. Normally, hydrogen concentration in the recombiner outlet will not exceed 20 ppm by volume. Hydrogen concentrations may exceed this value during system transients. The gas is discharged through a nozzle located in the bottom of the vessel. Each recombiner is equipped with thermocouples located at different depths in the catalyst so that a temperature profile for the bed can be continuously observed during operation. This allows the operator to monitor continuously for catalyst attrition.

Each recombiner is equipped with thermostatically controlled electric heaters located in the catalyst bed. These are used to maintain catalyst temperature in the standby recombiner so that system switchover can be accomplished without loss of recombination efficiency. Each recombiner is equipped with a rupture disk rated at 345 psig.

11.3.3.3.4 Offgas Condenser

There is one offgas condenser provided per train. The offgas condensers are horizontal U-tube flanged-head vessels. The tubes are free riding to minimize thermal stresses. Offgas entering the shell side is cooled and some of the moisture is condensed. The condensate drains into the condensate receiver tank through the four-inch loop seal manifold. Condensate from the condensate system is supplied to the tube side. Condensate flow is maintained only in the operating condenser.

11.3.3.3.5 Offgas Aftercooler

There is one offgas aftercooler provided per train. The offgas aftercoolers are straight-tube horizontal flanged-head heat exchangers. Turbine building closed cooling water (TBCCW) flows through the tubes. Offgas from the offgas condenser flows through the shell side, where additional moisture is condensed. The aftercooler drains, by way of the four-inch loop seal manifold, into the condensate receiver tank. Aftercooler discharge is essentially humid air. A demister is provided on the aftercooler outlet.

11.3.3.3.6 Precooler

There is one precooler provided per train. The precooler is a vertical vessel with a removable shell. The tubing design is serpentine with baffle plates. Throttled freon gas from a refrigeration system flows on the tube side. Offgas passes through the shell side and is cooled. The precooler discharges through a demister. Since the precoolers are the last vessels in the recombiner trains (hydrogen removal trains), they are followed by an isolation valve. Offgas passes from the operating precooler through the 2.2 minute delay pipe into the sand filter.

11.3.3.3.7 Sand Filters

There is one sand filter provided per train. Discharge from the delay pipe flows into a sand filter. The sand filters are vertical tanks. The offgas flows up through the sand. The purposes of the sand filters are to remove the nongaseous decay daughters and to attenuate a transient pressure wave, thus providing protection for the vessels downstream.

11.3.3.3.8 Chillers

There are three chillers shared between two trains. The chillers are vertical heat exchangers, flanged with a removable shell. The tubing is serpentine in design. Throttled freon gas from a refrigeration system circulates through the tubes. Offgas circulates through the shell side and is cooled. The tubing will become covered with frost during operation. Switchover to another chiller occurs automatically on a timed cycle, and the first chiller is automatically defrosted by heated freon circulating through the chiller coils. A third chiller is available as a standby unit. Each chiller is equipped with its own refrigeration subsystem. In the event of higher air-inleakage flows, chillers may be operated in manual mode (operating them in parallel) to lower the temperature of the offgas at the chiller outlet.

11.3.3.3.9 Charcoal Adsorbers

There are six charcoal adsorbers provided. The charcoal adsorbers are vertical tanks, each containing approximately 20,000 lb of activated charcoal adsorbent. All molecules, such as those of chemically inert krypton and xenon, and molecules, such as N_2 and O_2 gases, interact mechanically with the charcoal, the net result of which is that the flow of heavy gases is delayed. The delay of the radionuclides of krypton and xenon in the charcoal beds allows a significant portion of these gases to decay, thus reducing the activity of the offgas. Offgas flows up through the charcoal beds. All six adsorbers are piped together in a series arrangement. Because of their size and building space requirements, as well as the passive nature of these vessels, no standby adsorbers are provided. Bypass piping around each adsorber along with isolation valves are provided so that any adsorber can be isolated without inhibiting the use of the other adsorbers. Administrative controls preclude the possibility of bypassing the entire adsorber chain.

Each of the six bypass valves has a keylock switch in the main control room. The keys cannot be removed when bypass has been initiated. The keys are under the administrative control of the Shift Manager or his delegate. Administrative control ensures that no more than one charcoal adsorber can be bypassed at any one time when reactor power is greater than 5 percent.

11.3.3.3.10 Absolute Filter

There is one absolute filter provided per train. Two trains are provided, one of which is standby. The filters are housed in tank-type vessels. The filters are HEPA type, rated at 99.9 percent efficiency for all particles 0.3 μm and larger. The filters are replaceable cartridge-type units, with three cartridges in parallel per absolute filter.

11.3.3.3.11 Water Ring Exhaust Pumps

There is one water ring exhaust pump provided per train. The water ring pumps are used to maintain the system at a slightly negative gage pressure. Thus, should leaks occur, they would leak into the system. One water ring pump operates; the other is a standby unit. Associated with each water ring pump is a ring water buffer tank and a ring water cooler. In operation, a two- phase air/water mixture is discharged by the pumps. This mixture enters the buffer tank where the water is separated and the air is discharged to the reactor building vent. Water drains from the buffer tank through the cooler and returns to the pump.

A water ring pump of proven reliability is used here to hold a slight negative pressure in the offgas system. In the event of higher air inleakage flows, the two water ring exhaust pumps may be operated in parallel to maintain the vacuum in the main condenser.

11.3.3.3.12 Component Drains

The water separators, preheaters (tube side), condensers, and aftercoolers drain into a drain receiver tank by way of a loop seal manifold. Each vessel drain is routed individually to the four-inch loop seal manifold and is equipped with a hand-operated shutoff valve. The receiver tank is vented to the offgas condenser gas outlet. Each vent has a motor-operated shutoff valve. The drain receiver tank is drained, by means of a level controller, into the condensate receiver tank. The condensate tank is vented to the main turbine condenser, and is drained by means of pumps that transport the condensate back to the main turbine condenser.

The steam-jet air ejector intercondensers are drained by means of a manifold and loop seal that are connected directly to the condensate receiver tank. Condensate in the steam-jet air ejector exhaust manifold is drained directly into a collector tank. Condensate in the delay pipes is drained into collector tanks that are drained via level controllers into the condensate receiver tank.

Condensate in the vacuum manifold is drained into a collector tank. When the tank is full, the pipe connecting the tank and manifold is valved shut. The tank is vented to the steam-jet air ejector exhaust manifold and then drained into the condensate receiver tank. After draining, the vent is closed and the valve in the connecting pipe is opened.

Condensate does not form in the sand filter, absolute filter, or adsorbers.

11.3.3.3.13 Component Isolation

Each of the two hydrogen removal trains (i.e., those components from the water separator up to and including the precooler) is located in a separate cell. The trains are completely isolated from each other. One system operates continuously and the other serves as a standby. Because of the high activity of the offgas, it is impossible to perform any service on the operating train. Thus, upon malfunction, operation can be shifted to the standby train without interrupting plant operation. Because either train may be isolated, service can be performed on one train while the other operates.

11.3.3.4 Quality Group Classification

A detailed discussion of equipment Quality Group classification is presented in Subsection 3.2.2. This classification meets the criterion of Regulatory Guide 1.26 since the single failure of any component does not result in an offsite dose in excess of 0.5 rem. This is demonstrated in Subsection 15.11 where the analysis of the offgas system failure is presented.

11.3.3.5 Seismic Classification

Since an assumed seismically induced total failure of the offgas system would not result in an offsite dose in excess of 0.5 rem as specified in Regulatory Guide 1.29, the offgas system does not require Category I design. The analysis of the offgas system failure is provided in Section 15.11.

11.3.3.6 Offgas System Instrumentation and Control

The offgas system is monitored for radiation level at two locations: at the discharge of the 2.2 minute delay pipe and in the reactor building exhaust plenum. The radiation monitor at the discharge of the 2.2 minute delay pipe continuously monitors radioactivity release from the reactor and therefore continuously monitors the degree of fuel leakage. This radiation monitor is used to provide an alarm on high radiation in the offgas. The monitor has no control function.

The radiation monitor for the reactor building exhaust plenum continuously monitors the effluents released from the charcoal beds. If high radiation levels should occur in the discharge of the offgas system, this monitor would alarm in the main control room. Upon receipt of a high radiation alarm, the plant operator can evaluate the situation and initiate the proper action.

The discharge from the mechanical vacuum pump downstream of the 2-minute delay pipe is also monitored as discussed in Subsection 11.4.3.8.2.13.

Offgas system process radiation monitors are discussed further in Subsection 11.4.3.8.2.2.

This system is also monitored by flow, temperature, and pressure instrumentation. In addition, it is monitored by a hydrogen analyzer to ensure correct operation and control and to ensure that hydrogen concentration is maintained below the flammable limit. Oxygen concentration is monitored at the inlet to the delay piping. The Hydrogen Water Chemistry System is tripped on high or low oxygen concentrations. Process monitors are shown in Figure 11.3-1. The offgas system is normally operated automatically; upon operator initiative, however, the equipment can be operated from the main control room. The operator is thus in control of the system at all times, regardless of system operating mode.

System monitors are discussed in Subsection 7.7.2.6. The principal system instrumentation for significant monitored process parameters is listed in Table 11.3-5.

11.3.4 Operating Procedures

11.3.4.1 Startup

As the reactor is pressurized, steam is supplied to the preheater. The recombiner is preheated by means of electric heaters. With the recombiners preheated, charcoal adsorbers are valved in, or initially bypassed to prevent moisture damage below 5 percent power and the main condenser at approximately 4 in. Hg abs, the steam-jet air ejectors are started. As the condenser is pumped down and the reactor power is increased, the recombiner inlet stream is diluted to less than 4.0 percent H_2 (by volume) by a regulated steam supply and the recombiner outlet is maintained at less than 20 ppm hydrogen.

11.3.4.2 Normal Operation

After startup, the noncondensibles pumped by the steam-jet air ejector stabilize. Recombiner performance is closely followed by means of the recorded temperature profile of the recombiner catalyst bed. The hydrogen effluent concentration is measured by a hydrogen analyzer. Below 5 percent power as an option to the above stated method, the mechanical vacuum pumps may be used.

Normal operation is terminated when steam pressure to the steam jet air ejectors is insufficient for operation by closing off steam to the steam-jet air ejectors and preheaters.

11.3.4.3 Charcoal Bypass Mode

There is a charcoal adsorber bypass line that can be used to bypass any single charcoal adsorber. The activity is monitored by a process radiation monitor upstream of the reactor building vent that produces a high radiation alarm. The alarm setting is covered in Subsection 11.4.3.8.2.2.

11.3.5 Performance Tests

This system is in continuous operation during normal plant operation and does not require specific testing to ensure operability. Process equipment is continuously monitored to determine if process parameters are within design limits, as shown in Figure 11.3-1. Monitor equipment is calibrated and maintained according to a specific schedule and upon indication of monitor malfunction.

Process radiation monitors located downstream of the 2.2-minute delay line and downstream of the charcoal beds in the reactor building exhaust plenum provide adequate indication of the system's ability to reduce the radiogas concentration in this effluent.

To ensure that the hydrogen concentration is within design limits, the recombiner performance is continuously monitored by catalyst bed thermocouples monitoring bed temperature profiles and by a hydrogen analyzer measuring the hydrogen concentration of the recombiner effluent.

11.3.6 Estimated Releases

The potential sources of gaseous radwaste releases have been discussed in Subsections 11.3.2.1 through 11.3.2.7. Calculated releases from these potential sources are tabulated in Table 11.3-1. Anticipated operational occurrences would not signifi-cantly vary the total yearly release value because the 100,000 μCi/sec offgas rate after 30 minutes decay is an annual average value. The value of 100,000 μCi/sec is a conservative annual average, and offgas rate is expected to be above this value only for short periods of time.

Table 11.3-6 provides the calculated yearly average radionuclide concentrations at the restricted boundary of the site using the maximum yearly average χ/Q. The information in this table demonstrates that the design objectives of the gaseous radwaste system are met.

11.3.7 Release Points

The two release points for normal gaseous radwaste effluents from Fermi 2 are the reactor building vent and the turbine building vent. These release points are indicated in Appendix 11A Figure III-1.

The reactor building vent is cylindrical in shape, extends 22.5 ft above the top of the reactor building and is 7 ft 2 in. in diameter. The vent centerline is 8 ft 6 in. from the east wall of the reactor building and 9 ft 3 in. from the south wall of the reactor building. The top of the vent is at Elevation 761 ft (New York Mean Tide, l935) and the grade is 583 ft. The exhaust from this vent is approximately 101,940 cfm at a velocity of 2529 fpm.

The turbine building vent is rectangular in shape, extends 4 ft above the upper roof over the turbine building and has a cross-sectional area of approximately 416 ft^2. The top of the vent is at Elevation 714.5 ft (New York Mean Tide, 1935). The exhaust from the vent is approximately 315,900 cfm at a velocity of 759 fpm.

The greatest fraction of the gaseous activity released from the plant will be from the offgas system and the turbine gland seal exhaust. Both of these releases are mixed with the reactor building ventilation exhaust before they leave the plant. Assuming the zero enthalpy for air is fixed at 32°F, the normal heat value of the gland seal exhaust is 248,000 Btu/hr and the normal heat value for the offgas system exhaust is 1650 Btu/hr.

The radwaste building vent is a third ventilation release point (see Figure 9.4-5). The radwaste building ventilation system exhaust is discharged via the radwaste building vent under normal operating conditions through HEPA filters to remove particulate radioactive material.

The radwaste building vent is rectangular in shape, extends 54 ft above the lower roof of the turbine building, and has a cross-sectional area of approximately 16.65 ft^2. The vent centerline is approximately 383 ft from the south wall and 78 ft from the east wall of the turbine building. The top of the vent is at Elevation 729 ft (New York Mean Tide, 1935). The exhaust from the vent is approximately 38,519 cfm at a velocity of 2313 fpm.

11.3.8 Dilution Factors

Estimates of annual average offsite atmospheric dilution factors are presented in Section 2.3. Calculations are provided of the estimated values of χ/Q for 16 radial sectors to a distance of 50 miles from the plant for ground-level releases. The maximum annual average site boundary χ/Q value has been determined to be to the NNW site boundary and is 1.15×10^{-6} sec/m^3.

11.3.9 Estimated Doses

From Table 11.3-1, it can be observed that the calculated radioactive gaseous releases are composed mostly of noble gases with halogens contributing only a small fraction. Since the noble gases do not react chemically with other substances under normal conditions, there is no physical basis for their transport through food chains or reconcentration within the human body. Thus, the most significant exposure pathway for released noble gases is direct external radiation to the skin and whole body.

The opposite is true of the released radioiodines for which inhalation and food chain transport are the critical pathways.

External radiation from iodine is generally insignificant in comparison with the internal dose derived through inhalation and ingestion.

11.3.9.1 External Dose From Gaseous Cloud Immersion

The determination of the external dose from gaseous cloud immer-sion for the "maximum-exposed individual" and the population can be performed using the International Commission on Radiological Protection (ICRP) recommended semi-infinite sphere model (Reference 1). The following relationship was used to determine the dose rate from this source:

$$D(rem/yr) = (0.259)(\chi/Q) \begin{cases} \sum_i \overline{E}_{\gamma,i} Q_i \text{ (for whole body dose)} \\ \text{or} \\ \sum_i \left(\overline{E}_{\gamma,i} + \overline{E}_{\beta,i}\right) Q_i \text{ (for skin dose)} \end{cases} \quad (11.3\text{-}4)$$

where

χ/Q = applicable annual average effluent concentration normalized by source strength, sec/m^3

$E_{\gamma,i}$ = average energy of gamma disintegration of ith radionuclide, MeV

$E_{\beta,i}$ = average energy of beta disintegration of ith radionuclide, MeV

Q_i = annual average activity release for ith radio- nuclide, Ci/yr

0.259 = constant necessary to yield dose rate rems/yr

The normalization constant 0.259 is developed from the following equation:

$$0.259 = (0.5)\left(1.6 \times 10^{-6}\,\frac{\text{ergs}}{\text{MeV}}\right)\left(10^{-2}\,\frac{\text{g-rads}}{\text{erg}}\left(1\,\frac{\text{rem}}{\text{rad}}\right)\right)(1.13)\left(3.7 \times 10^{10}\,\text{dis}/_{\text{sec} - \text{Ci}}\right)\left(\frac{1}{1.29\times10^{3}\text{gair/m}^{3}}\right) \qquad (11.3\text{-}5)$$

where

0.5 = geometry factor accounting for the fact that receptor is irradiated from half the whole available solid angle

1.13 = factor to account for increased stopping power of tissue relative to air for β's and secondary electrons produced by x- and δ- radiation (Section 11.2 and Reference 1)

The basic assumption of this model is that the energy absorption at any point inside an infinite medium of homogeneous material of uniform radioactivity concentration is equal to the energy source from that point. Use of the infinite sphere model provides conservative results because:

a. The surrounding cloud of radioactivity is not infinite in dimension

b. The concentration is not uniform, but is a maximum at the centerline

c. The spatial flux depression caused by the presence of the source-free body in the infinite medium is not accounted for.

Direct exposure to a cloud of radioactivity results in a dose to the skin or to the whole body depending upon the type of radiation emitted. The radiation of interest in this report consists of beta and gamma components. Beta particles and gamma rays are assumed to contribute to the skin dose; however, only gamma rays are assumed to contribute to the total-body dose.

11.3.9.1.1 Maximum Individual External Exposure From Cloud Immersion

For the purpose of estimating the potential annual dose, a hypothetical maximum-exposed individual is assumed to reside at the NNW site boundary continuously over a period of 1 full year, unshielded by housing and clothing. These conservative assumptions resulted in a maximum individual whole-body dose rate of 4.6 mrem/yr and an external skin dose rate of 8.9 mrem/yr.

11.3.9.1.2 Population Exposure From Cloud Immersion

The general relationship presented earlier for the skin dose and external whole-body dose was employed to determine the population dose. The estimated population distributions within 50 miles of the plant, for the years 1980, 2000, and 2020, as defined in Figures 2.1-7, 2.1-9, and 2.1-11, were used for this purpose. The annual segment population exposures, the product of the segment populations and the sector average dose rates, are summed over all 160 segments to evaluate the total population exposure within 50 miles.

The results are summarized as follows:

Year	Population Within 50 Miles of the Site	Annual Man-Rem Within 50 Miles of the Site	
		Whole Body	Skin

1980	6,100,000	1.5×10^2	3.1×10^2
2000	8,200,000	2.2×10^2	4.2×10^2
2020	12,000,000	3.0×10^2	5.8×10^2

11.3.9.2 External Dose From Contaminated Land Surface

An individual downwind from the plant can receive external radiation from material deposited on the ground by a passing radioactive cloud. Airborne radioactive material can be deposited on the ground by dry deposition, rainout and washout, and can consist of any material in the cloud except for the noble gases and tritium (Reference 2).

The whole-body dose from deposited activity was calculated using the equation:

$$D(\mathrm{mrem/yr}) = \sum Q_i(\chi/Q)(V_{gi})(T_i/0.693)(DCF)_i \ldots \left(10^6\,\frac{\mu\mathrm{Ci}}{\mathrm{Ci}}\right)\left(10^{-4}\,\frac{\mathrm{m}^2}{\mathrm{cm}^2}\right)\left(10^3\,\frac{\mathrm{mrem}}{\mathrm{rem}}\right) \tag{11.3-6}$$

where

Q_i	=	release rate of isotope i, Ci/yr
χ/Q	=	annual average effluent concentration normalized by source strength, sec/m^3
V_{gi}	=	deposition velocity of radionuclide is 0.01 m/sec (Reference 3)
T_i	=	radiological half-life of radionuclide i, years
$(DCF)_i$	=	dose conversion factor of radionuclide i, rem/yr per μCi/cm^2

The dose conversion factors for gamma and beta radiation were obtained from Reference 4. The calculated beta exposure rates were reduced by a factor of two to account for the self-shielding of the human body against fission product beta radiation.

The whole-body dose to the maximum-exposed hypothetical individual at the NNW site boundary was calculated using an effective deposition velocity of 0.015 m/sec for the iodines, the only significant contributors. It was calculated that an annual whole-body dose of 0.08 mrem from gamma radiation would result. Including the beta contribution, a body surface dose of 0.23 mrem/yr was calculated.

11.3.9.3 Internal Exposure From Gaseous Effluents

Release radionuclides must be either inhaled or ingested in order to yield internal radiation exposure. Ingestion requires that the physical transport of the radioactivity be through some form of food chain. This is possible for the radioactive halogen isotopes. Inhalation is a significant pathway for the radioactive halogens and tritium.

11.3.9.3.1 Internal Exposure From Released Noble Gases

Since the noble gases do not react chemically with other substances, there is no physical basis for their transport through food chains or reconcentration within the human body.

In terms of continued inhalation and absorption in the body, both krypton and xenon may develop in physical solution, chiefly in the body water and fat (Reference 5). Several human exposure experiments revealed that inhalation of relatively large amounts of radioactive noble gases resulted in very low tissue exposures (References 6 and 7). In general, it may be estimated that the internal dose from radioactive noble gases dissolved in body tissue following inhalation from a cloud is negligible (i.e., less than 1 percent of the associated external whole-body dose) (Reference 8).

11.3.9.3.2 Internal Exposure From Released Radioactive Halogens

In addition to the noble gases, small amounts of radioactive halogens are anticipated to be released as gaseous effluent from Fermi 2. Iodine is an insignificant contributor to the external whole-body dose, but may produce potentially significant internal doses due to the preferential concentration of iodine in the human thyroid gland. Iodine may enter the body either through inhalation or by ingestion. The most critical pathway for environmental transport of the routine release of radioiodine is the pasture-cow-milk-Man pathway.

11.3.9.3.2.1 Iodine Inhalation Thyroid Dose

Exposure rates have been computed for the inhalation of iodine. The dose rate has been estimated using Regulatory Guide 1.42 (Reference 9). For the infant, the inhalation dose is given by the following formula:

$$D(\text{mrem/yr}) = [4.8 \times 10^5\ Q_{131} + 1.2 \times 10^5\ Q_{133}]\ (\chi/Q)R \qquad (11.3\text{-}7)$$

where

Q_{131}, Q_{133} = release rate of ^{131}I and ^{133}I, Ci/yr

χ/Q = applicable annual average effluent concentration normalized by source strength, sec/m^3

R = dimensionless iodine cloud depletion factor, assumed to equal 1

4.8×10^5, 1.2×10^5 = constant terms that take intoaccount breathing rate of infant and dose conversion factor $\frac{\text{mrem} - \text{m}^3}{\text{Ci} - \text{sec}}$

For the adult, the dose due to inhalation is determined from the equation

$$D(\text{mrem/yr}) = [4.0 \times 10^5\ Q_{133} + 9.8 \times 10^4\ Q_{133}]\ (\chi/Q)R \qquad (11.3\text{-}8)$$

The constant terms in this equation take into account the breathing rate of the adult and dose conversion factor for each isotope. The cloud depletion factor is assumed equal to 1. The maximum annual iodine-induced thyroid inhalation exposure to an adult was calculated to be 0.37 mrem/yr. For the child, the corresponding exposure is 0.46 mrem/yr.

11.3.9.3.2.2 Thyroid Milk Ingestion Dose

Although the radioiodines will be released initially in gaseous forms, they may be deposited on grass, ingested by a grazing cow, and subsequently secreted in milk. Various mathematical models have been devised to estimate the dose to the thyroid via this route. In all cases, the exposure is inversely proportional to the mass of the thyroid gland. The most sensitive receptor in the population, in terms of whole thyroid dose per unit intake, is therefore a young child or infant who would have a very small thyroid. Also, the relative radiosensitivity of the thyroid decreases markedly with age. Since the rate of milk ingestion is important in determining the dose, the most critical receptor is not a newborn infant but is more likely to be a child 6 months to 1 year in age.

For the child, the dose was calculated using Regulatory Guide 1.42 (Reference 9). The following formula gives the child dose:

$$D(\text{mrem/yr}) = [1.15 \times 10^8\, Q_{131} + 2.12 \times 10^6\, Q_{133}]\,(\chi/Q)R \qquad (11.3\text{-}9)$$

where

R = dimensionless iodine cloud depletion factor, assumed equal to 1

Q_{131}, Q_{133} = release rate of iodine ^{131}I and ^{133}I, Ci/yr

χ/Q = applicable annual average effluent concentration normalized by source strength at location of nearest cow (sec/m^3)

1.15×10^8, 2.12×10^6 = constant terms that take into account milk ingestion rate of the child, fractional thyroid deposition value from human ingestion, and dose conversion factor $\frac{\text{mrem} - \text{m}^3}{\text{Ci} - \text{sec}}$

The site nearest Fermi 2 at which milk is known to be produced from grazing cows is located about 3 miles to the north-northwest. The applicable χ/Q value for this location has been determined to be 1.27×10^{-7} sec/m^3. It was assumed that the cows graze 5 months per year. The maximum potential thyroid dose to a child from this milk source was calculated to be 2.2mrem/yr.

11.3.9.3.2.3 Adult Thyroid Milk Ingestion Dose

The following model (References 10 and 11) was employed to compute the adult thyroid milk dose from the release of radioiodines:

$$D(\text{rem/yr}) = (\chi/Q)\frac{V_{g_i}K_c I_d}{\lambda_{g_i}} A_i Q_i (2.74 \times 10^3) \qquad (11.3\text{-}10)$$

where

2.74×10^3 = conversion factor changing Ci/yr to µCi/day

V_{gi} = deposition velocity of radionuclide onto pasture 0.015 m/sec; (Reference 3)

K_c = (µCi/l)/(µCi/m^2); milk/grass activity ratio

I_d = adult milk ingestion rate, 1.0 1/day

A_i = dose conversion factor for adult, $\frac{rem}{yr} / \frac{\mu C_i}{day}$

λ_{gi} = mean lifetime for i^{th} isotope on the ground, $days^{-1}$

The maximum potential thyroid dose to an adult was calculated to be 0.44 mrem/year.

11.3.9.3.2.4 Adult Human Thyroid Dose Via Leafy Vegetables

The model for calculation of doses due to ingestion of leafy vegetables having radioiodine deposited on them is taken from Reference 9 with the exception that no cloud depletion is assumed. The model assumes the consumption of 18 kg of fresh leafy vegetables over a period of 3 months. The resulting equation for dose rate due to ingestion of leafy vegetables is:

$$D(mrem/yr) = [2.1 \times 10^6\ Q_{131} + 8.3 \times 10^4\ Q_{133}]\ (\chi/Q)(R) \qquad (11.3\text{-}11)$$

where

R = dimensionless iodine cloud depletion factor, assumed equal to 1

χ/Q = applicable annual average effluent concentration normalized by source strength, sec/m^3

2.1×10^6, 8.3×10^4 = constant term which takes into account amount of leafy vegetables ingested, fractional thyroid deposition dose from human ingestion, and dose concentration factor, $\frac{\mathrm{mrem - m^3}}{\mathrm{Ci - sec}}$

For Fermi 2, it was assumed that the nearest garden was located at the site boundary in the direction with the highest χ/Q value, north-northwest. The total dose via the ingestion of leafy vegetables is 0.95 mrem/yr.

11.3.9.3.3 Internal Exposure From Released Tritium (Released As Vapor)

It is anticipated that approximately 52.5 Ci/yr of tritium will be released from Fermi 2. For tritium, the inhalation dose has been estimated using the following equation:

$$D(\mathrm{rem/yr}) = \sum / Q_i\ (\chi/Q)\ (\mathrm{BR})(\mathrm{DCF})_i \left(10^6 \frac{\mu\mathrm{Ci}}{\mathrm{Ci}}\right)\left(\frac{1\ \mathrm{yr}}{365\ \mathrm{days}}\right) \qquad (11.3\text{-}12)$$

where

Q_i = release rate of tritium, Ci/yr

BR = breathing rate, m^3/sec

$(DCF)_i$ = dose conversion factor for tritium, $\frac{\mathrm{rem}}{\mathrm{yr}} / \frac{\mu\mathrm{Ci}}{\mathrm{day}}$

Since the tritium can rapidly be taken into the body by skin absorption (Reference 12), the total tritium uptake by the body was assumed to be twice the rate due to inhalation alone as recommended by the ICRP (Reference 1). The conversion factor was assumed to be 4.627 x 10^{-2} rem/yr per μCi/day, as derived from Reference 5.

The resultant whole-body dose is 3.6×10^{-3} mrem/yr.

11.3.9.4 Summary of Estimated Doses

Table 11.3-7 presents a summary of the doses to the hypothetical maximum-exposed individual by release pathway.

TABLE 11.3-1 EXPECTED GASEOUS RELEASES FROM FERMI 2 (ACTIVITY RELEASE RATES BASED ON 3499 MWt)

		SOURCE OF RELEASE						SOURCE OF RELEASE				
		Reactor Building Ventilation (R.B. Vent)		Turbine Building* Ventilation (R.B. Vent)		Mechanical Vacuum Pump (R.B. Vent)		Turbine Gland Seal Condenser (R.B. Vent)		Offgas System (R.B. Vent)		
Isotope	Half-Life	µCi/sec	Ci/yr	µCi/sec	Ci/yr	µCi/sec	Ci/yr	µCi/sec	Ci/yr	µCi/sec	Ci/yr	Total Curies/Year
Pr-143	13.58 days			8.46E-06	2.19E-04							2.2E-04
Np-239	2.35 days			5.33E-02	1.35E+00							1.4E+00

NOTES:

1. The drywell purge, radwaste building ventilation, and other potential sources of radioactive gaseous waste are discussed in UFSAR Subsections 11.3.2.4, 11.3.2.5, and 11.3.2.6. These potential sources have been evaluated, and it has been determined that the potential releases are negligible.

2. Isotopes with total released activities in excess of 1.0E-04 curies are listed.

---

* The source of radionuclides released to the turbine building is assumed to be steam leakage, and since this is the only source of steam leakage, only the turbine building releases will contain particulate radionuclides other than halogens.

** This release will occur following a plant shutdown lasting longer than 10 hr. The mCi/sec represent an average concentration over a 4-hour pump down period.

*** A total of 105 Ci of tritium is expected to be released yearly with 52/5 Ci released via liquid effluents and 52.5 released via gaseous effluents. The gaseous tritium releases are not attributed to any particular source.

TABLE 11.3-3 OFFGAS SYSTEM DECONTAMINATION FACTORS[a]

Isotope	Decontamination Factor[c]	Isotope	Decontamination Factor[c]
Kr-83m	7,660	Xe-131m	2.5
Kr-85m	44	Xe-133m	136
Kr-85	1	Xe-133	8.2
Kr-87	50,000	Xe-135m	b
Kr-88	388	Xe-135	b
Kr-89	b	Xe-137	b
Kr-90	b	Xe-138	b
Kr-91	b	Xe-139	b
Kr-92	b	Xe-140	b
Kr-93	b	Xe-141	b
Kr-94	b	Xe-142	b
Kr-95	b	Xe-143	b
Kr-97	b	Xe-144	b

The decontamination factor provided by the offgas system for noble gases only is approximately 1160. If all gases and particulates entering the offgas system were considered in determining the decontamination factor, this would be much higher.

[a] Decontamination Factor equals:

$$\frac{\text{Concentration at inlet to offgas system}}{\text{Concentration at outlet to offgas system}}$$

[b] Extremely large--essentially all of the isotope has been removed.

[c] Values are based on condenser offgas rate equivalent to 100,000 mCi/sec after 30 minutes delay and condenser air inleakage rate of 40 scfm (nominal).

11.4 PROCESS AND EFFLUENT RADIATION MONITOR SYSTEMS

11.4.1 Introduction

The process and effluent radiation monitor systems are contained in the process radiation monitoring system. The process radiation monitoring system furnishes information to operations personnel regarding the levels of radioactivity in effluent and selected process streams. This information is used to maintain radiation levels as low as reasonably achievable and to verify compliance with applicable governmental regulations for the containment, control, and release of radioactive liquids, gases, and particulates generated as a result of normal or emergency operation of the plant.

The process radiation monitoring system is composed of the following process and effluent radiological monitoring systems:

a. Gaseous and airborne monitors

    1. Offgas radiation monitor system
    2. Main steam line radiation monitor system
    3. Reactor building ventilation exhaust radiation monitor system
    4. Offgas vent pipe radiation monitor system (installed spare)
    5. Radwaste building ventilation exhaust radiation monitor system
    6. Turbine building ventilation exhaust radiation monitor system
    7. Deleted
    8. Standby gas treatment system (SGTS) radiation monitor system
    9. Reactor building exhaust plenum radiation monitor system
    10. Fuel pool ventilation exhaust radiation monitor system
    11. Control center makeup air radiation monitor system
    12. Two-minute holdup pipe exhaust radiation monitor system
    13. Control center emergency air inlet radiation monitor system
    14. Onsite storage facility ventilation exhaust radiation monitor system
    15. Standby gas treatment system postaccident radiation monitor system
    16. Primary containment monitor system.

b. Liquid monitors

    1. Radwaste effluent radiation monitor system
    2. General service water effluent radiation monitor system

3. Reactor building closed cooling water (RBCCW) radiation monitor system
4. Emergency equipment cooling water (EECW) radiation monitor system
5. Residual heat removal service water (RHRSW) radiation monitor system
6. Circulating water reservoir decant line radiation monitor system.

c. Containment area high-range monitor.

d. Post Accident Gaseous Effluent Radiation Monitors
   1. Noble gas effluent monitor system
   2. Radioactive iodine and particulate effluent monitor system
   3. Torus hardened vent radiation monitor system

The process radiation monitoring system described in the following sections serves in conjunction with a comprehensive sampling program. The sampling program is the primary method for quantitatively and qualitatively evaluating system and effluent activity levels to comply with Regulatory Guide 1.21, Revision 1.

11.4.2 Design Objectives

The process radiation monitoring system is designed to measure and record radioactivity levels, to alarm on high radioactivity levels, and to control, as required, the release of radioactive liquids, gases, and particulates produced during operation of the plant. It is also designed to comply with the requirements of 10 CFR 50, 10 CFR 20, and Regulatory Guide 1.21, Revision 1. The process radiation monitoring system aids in protection of the general public and plant personnel from exposure to radiation or radioactive materials in excess of those allowed by the applicable regulations of governmental agencies. All the building gaseous effluent monitors have been upgraded to meet the range requirements of NUREG-0737 (refer to Subsection 11.4.3.11).

The design objectives of the process radiation monitoring system for normal operation are:

a. To provide continuous surveillance of radioactivity levels in process and effluent streams from minimum detectable levels to levels commensurate with Offsite Dose Calculation Manual radiological effluent control limits by indicating and recording these levels and by alarming at abnormal activity levels

b. To provide data for estimating total released activity to comply with Regulatory Guide 1.21, Revision 1

c. To give early warning of increasing radioactivity levels indicative of equipment failure, system malfunction, or deteriorating system performance

d. To initiate prompt corrective action, either automatically or through operator response.

For some anticipated operational occurrences resulting from accidents or malfunctions, the process radiation monitoring system activates necessary isolation or diversion valves, thereby terminating releases if radioactivity levels exceed alarm setpoints, as indicated in Tables 11.4-1 and 11.4-2.

11.4.3 Continuous Monitoring

11.4.3.1 Design Criteria

The following design criteria were employed in the design of the process radiation monitoring system:

a. To facilitate compliance with applicable regulations and guides (10 CFR 50 and Regulatory Guide 1.21), monitors and detectors were selected with sensitivities and ranges in accordance with radiation levels anticipated at specific detector locations

b. Independence of redundant monitors that are safety related is maintained by providing adequate separation of detectors, signal cabling, power supplies, and actuation circuits for isolation and diversion valves to meet IEEE-279 criteria

c. Radioactivity levels are continuously indicated in the relay room or at local panel H21P284 (PCRMS only) and recorded in the main control room

d. Main control room alarms annunciate high radioactivity levels and signal, circuit, or power failures

e. For selected detectors, alarms and recorders are provided in the radwaste control room

f. Access to the alarm setpoints is under the administrative control of the Executive Director – Nuclear Production or his authorized delegate

g. Adequate lead shielding is provided for detectors when the ability to sense low activity levels requires that background radiation have a minimum effect on the instruments

h. Monitor components requiring maintenance and inspection are readily accessible or spare equipment is available in the plant

i. Environmental design conditions for the components are listed in Table 11.4-3. In addition, those safety- related components of the system are protected from the effects of extreme winds, floods, tornadoes, or missiles because they are housed in a structure designed to withstand the above environmental conditions as described in Chapter 3

j. None of the monitors are designed to Category I requirements unless specifically stated in the section describing the particular monitor

k. All in-line monitors have detector housings of the same quality level and category as the system being monitored. Off-line monitors are provided with valves to permit manual isolation of monitors from the process.

11.4.3.2 Basis for Detector Location Selection

An aid for the selection of each location to be continuously monitored is found in Regulatory Guide 1.21, which suggests "all normal and potential paths for release of radioactive material during normal reactor operation, including anticipated operational occurrences and accidents should be monitored." Based on the above, monitors are provided for:

a. Process lines that may discharge radioactive fluids to the environment, in order to indicate the radioactivity level and to alarm in the main control room when preestablished limits for the release of radioactive materials are reached or exceeded

b. Process lines that do not discharge directly to the environment, in order to indicate possible process system malfunctions by detecting increases in radioactivity levels.

11.4.3.3 Expected Radiation Levels

Expected radioactivity concentrations in the process and effluent streams will be such that radiation levels at the site boundary are a small fraction of 10 CFR 20 limits and will be as low as reasonably achievable. The expected concentrations each monitor will be measuring are listed in Tables 11.4-1 and 11.4-2.

11.4.3.4 Quantity To Be Measured

The principal radionuclides that are monitored are indicated in Tables 11.4-1 and 11.4-2. All channels measure gross radioactivity.

11.4.3.5 Detector Type, Sensitivity, and Range

The detectors are Geiger-Mueller tubes, ionization chambers, or scintillation crystals that detect beta radiation or gamma radiation over an energy range of at least 0.07 to 2.5 MeV. The sensitivity and range have been selected so that the alarm setpoint is at least an order of magnitude higher than the detector threshold, and so that the instrument reads on scale during normal operation. If it does not read on scale, a small "bug" source, attached to the detector, is used to clear the low (failure/operate) alarm. Detector type, estimated sensitivity, and nominal ranges of each process and effluent monitor are indicated in Tables 11.4-1 and 11.4-2.

11.4.3.6 Setpoints

Setpoints for effluent monitors are established to meet Offsite Dose Calculation Manual radiological effluent control limits that encompass 10 CFR 20 limits and 10 CFR 50, Appendix I, limits. Setpoints for process monitors are established to provide a warning of increased system activity and to take corrective action where appropriate.

Two independently adjustable radiation setpoints are provided for most monitors. The lower, or high setpoint, normally activates only an alarm, while the upper, or high-high setpoint, activates an alarm and initiates corrective action where appropriate. Setpoints are at least twice the background level to reduce the number of spurious trips. High setpoints when used in conjunction with high-high setpoints are between background and the high-high setpoints. The setpoints are under the administrative control of the Executive Director – Nuclear Production or his authorized delegate, and can be changed if needed as long as Offsite Dose Calculation Manual radiological effluent control limits are not exceeded.

11.4.3.7 Annunciators and Alarms

All process and effluent radiation monitors are annunciated in the main control room on panel H11-P603. A specific annunciator window alarms for low (failure/operate), alert, high or high-high (high) radiation alarm or low-sample-flow alarm, as shown in Tables 11.4-1 and 11.4-2.

An operator can acknowledge and silence the audible alarm but cannot clear the annunciator window until the alarm has been cleared. General Atomics alarms must be reset in the relay room to clear the annunciator window and the Eberline alarms must be reset in the main control room.

For the process radiation monitoring system, the channel that alarmed and the type of alarm are determined by the lights associated with the three types of alarms. These alarms are as follows:

a. A high (or alert) alarm light illuminates when the radioactivity exceeds preset limits that have been selected to provide an early warning

b. A high-high (or high) alarm light illuminates when radioactivity levels exceed a preset limit that is set at or slightly below the Offsite Dose Calculation Manual radiological effluent control limits. This initiates prompt corrective action either automatically or through operator response

c. A low (failure/operate) alarm light is activated when the meter reaches a downscale trip point that indicates that there is a detector signal, circuit, flow, or power failure. In certain cases, as discussed in Subsections 11.4.3.8 and 11.4.3.9, this downscale trip also initiates action.

11.4.3.8 Description of Gaseous and Airborne Monitors

Each channel of the system contains a completely integrated modular assembly as described below. Specific details of each monitor are described in Subsections 11.4.3.8.2.1 through 11.4.3.8.2.16.

11.4.3.8.1 General

11.4.3.8.1.1 Sampling Devices

For each off-line monitor, a sample is drawn from the vessel or system through a sample line. For the Eberline Sping 3/Sping 4/AXM-1 and the containment system (which have detectors viewing the filters) and the GE offgas vent pipe monitor (spare detector), the sample air stream then passes through a paper filter to collect particulates and then through an iodine-adsorbent cartridge. The air stream next passes through a shielded, internally polished chamber (or chambers), where the air is monitored for any radioactive gases by a scintillation detector and/or an energy- compensated Geiger-Mueller tube. The air is then drawn through a sample pump and returned to the vessel or system from which it was sampled.

Each sample pump is capable of drawing 2 cfm of air through the monitor (with the exception of the AXM-1s). Each monitor has a flow out of limits alarm. A local flow indicator is also provided for vent stack monitors that have particulate and iodine filters so that the total volume that has passed through the filters can be determined.

The filter papers used to collect particulates have a collection efficiency of at least 90 percent for 0.3-μm particulates. The iodine-adsorbent cartridges used to collect iodine have been tested and shown to have an efficiency of at least 90 percent for elemental and organic iodine. The filters and cartridges are replaced periodically and are counted in the counting room to determine particulate and iodine activity.

Each monitor has manually operated sample valves, and several types also have solenoid-operated valves. This allows room air to be purged through the gas monitor to check the background radiation level and allows for samples to be taken, or calibrated gas to be introduced, to check the monitor calibration.

The location of sample probes and off-line monitors has been chosen to minimize sample plateout. Unavoidable bends are made with gradual radii of approximately five times the tubing diameter. Stainless steel lines and ball valves are used to further minimize plateout.

11.4.3.8.1.2 Detector-Preamplifier Unit

The detectors are Geiger-Mueller tubes, solid-state, ionization chambers, or scintillation detectors. The General Atomic (Gulf) scintillation detectors, either beta (plastic) or gamma (NaI), generally have preamplifiers mounted on top of the detectors. The Eberline detectors use an interface box (IB-X) to provide this function. The detectors are designed to remain fully operational over a wide range of temperatures, as listed in Table 11.4-3.

Solenoid-operated check sources are provided to check detector response on all General Atomic (Gulf) supplied monitors (nine μCi ^{137}Cs for gamma detectors and 0.5 μCi ^{36}Cl for beta detectors), on the Eberline Sping 3/Sping 4 (30 μCi ^{137}Cs for the beta particulate detector, 0.5 μCi ^{133}Ba for the iodine detector, 30 μCi ^{137}Cs for the beta gas detector, 0.5 μCi ^{90}Sr/Y for the gamma gas detectors, and 0.5 μCi ^{90}Sr/Y for the gamma area detector), on the Eberline AXM-1 (30 μCi ^{137}Cs for the intermediate-range detector and 0.5 μCi ^{90}Sr/Y for the high-range detector), and on the GE-supplied offgas vent pipe radiation monitor (installed spare - 5 μCi ^{137}Cs). Each source is operated from the respective radiation analyzer in the relay room for the General Atomic monitors and from a panel in the main control room for the Eberline monitors (with the exception of the offgas vent pipe radiation ratemeter, which was removed and support equipment abandoned in place). One method of performing effluent monitor source checks is by local activation of the check source mechanism. Other approved check sources may be used if needed.

Off-line detectors are mounted as close as practicable to the system being monitored in a low-radiation area so that the detectors have maximum sensitivity and there is minimum sample plateout.

11.4.3.8.1.3 Radiation Monitor

The radiation analyzer for General Atomic, Mirion, and GE units, which is located in the relay room on panel H11-P604, P606, P883, P884, P914, or P915, is typically composed of an amplifier, a single channel analyzer (if used), a count rate meter (if used), a trip unit, and power supplies as described below:

a. The amplifier accepts pulses from the detector or preamplifier, performs a log integration (if required), and amplifies the output

b. The single channel analyzer, if used, has an adjustable pulse height window and a low-level discriminator for high- and low-level energy discrimination of gamma scintillation detector outputs

c. The meter displays the output in counts per minute, counts per second, or milliroentgens per hour on a four to seven-decade log scale

d. The trip unit provides adjustable trips that can be set for alarm control functions over the entire range of the unit. One low (failure/operate), one high, and one high-high trip are provided for most monitors

e. The Mirion power supply provides the necessary AC and DC voltages for the radiation analyzer and the detector-preamplifier unit. A separate power supply unit provides the necessary DC voltage for the associated trip units. Power for these units and other auxiliary equipment is supplied from the reactor protection system (RPS) buses A and B (120 VAC), the instrument power supply (120 VAC), or the plant 48/24 VDC battery.

All of the analyzer, monitor, and trip functions of the Eberline systems are performed remotely in the Sping units.

11.4.3.8.1.4 Recorder

A recorder is provided in the main control room or radwaste control room to record the output of required channels. Alarms are displayed out on the sequence-of-events recorder. The Eberline instrument channels are displayed in digital format on a control room terminal.

11.4.3.8.2 Specific Gaseous and Airborne Monitor Details

11.4.3.8.2.1 Primary Containment Radiation Monitor System

The primary containment radiation monitor system measures the activity in the drywell and suppression chamber and, in doing so, complies with Regulatory Guide 1.45 and General Design Criterion (GDC) 30. It is designed to detect leakage from the reactor coolant pressure boundary during normal operation (Subsection 5.2.7).

The monitor subsystem includes a noble gas detector. Primary containment atmosphere source terms are discussed in Section 11.1.

A continuous representative sample is extracted from either the drywell or the suppression chamber and is passed through the monitor. The sample is then returned to the suppression chamber through 1-in. stainless steel sample lines. The drywell sample system has five inlet lines of approximately equivalent flow rates that carry the sample from various locations in the drywell to a manifold located outside the containment. A single line routes the sample from the manifold to the monitors and then returns it to the suppression chamber. A single line from the suppression chamber branches into the line above before it enters the monitor, and another line on the discharge of the monitors returns to the suppression chamber as shown in Figure 11.4-1. Valves are provided on these lines to prevent flow when a sample of the suppression chamber is not desired. Normally, the five drywell lines are open to provide an averaged, representative sample. Electrically controlled air operated valves are provided on each of the six inlet lines and the one discharge line so that any one of the drywell sample lines or the suppression chamber sample line can be selected. The valve selector station is located in the main control room on panel H11-P808.

The sample selected is first passed through a coalescer, which removes moisture, and a filter paper to collect particulates. Capability to perform a laboratory analysis of the sample media is retained. The sample is then passed through an impregnated charcoal cartridge to a shielded chamber, where the noble gases are viewed by a shielded beta-sensitive scintillation detector mounted in the top of the chamber. The sample stream then passes through a flow-regulating valve, through a sample pump, and finally returns to the suppression chamber. Table 11.4-1 lists the sensitivity and range of the detectors.

The Primary Containment Radiation Monitoring channel consists of the local detector-preamplifier unit, a radiation analyzer at local panel H21P284, and one pen on a recorder in the main control room. The recorder is a three-pen, six-decade strip-chart recorder located on panel H11-P812. The system provides no control function but is a diagnostic tool that enables the main control room operator to take appropriate action. Power is supplied from the 120-V ac inductive bus for the channel components and 120-V dc instrument bus for the recorder.

This monitor subsystem can withstand the changes of the atmosphere expected for normal conditions as listed in Table 11.4-3. This subsystem is a part of the primary containment monitor system described in Subsection 7.6.1.12. Arrangement details are shown in Figure 11.4-1.

This monitoring subsystem is provided with remotely controlled check-source features to allow on-line operability tests to be performed from the local control panel H21P284.

11.4.3.8.2.2 Offgas Radiation Monitor System

This monitor subsystem measures the radioactivity in the condenser offgas at the discharge of the 2.2-minute delay pipe after it has passed through the steam-jet air ejector and the recombiner. The monitor detects the radiation level that is attributable to the fission gases produced in the reactor and transported in the steam through the turbine to the condenser. It complies with GDC 13.

A continuous representative sample is extracted from the offgas pipe via a 1-in. stainless steel sample line. It is then passed through a sample chamber and a flow indicator and returned to the offgas system. The sample chamber is a 3-ft long section of a 4-in. Schedule 40 stainless steel pipe, which is internally polished to minimize plateout. It can be purged with room air to check detector response to the background radiation by using a three-way solenoid-operated valve. The valve can be controlled locally or from a switch located under the recorder on panel H11-P601 in the main control room. Three gamma-sensitive ion chambers are positioned adjacent to the vertical sample chamber. Two of the chambers are connected to channels that have logarithmic readouts, and the third is connected to a channel with a linear readout. These chambers are listed in Table 11.4-1 for sensitivity and range.

The linear channel consists of a local detector (gamma-sensitive ion chamber), current to frequency converter, and digital ratemeter in the relay room, and a recorder in the main control room. A linear readout with a range of 1 to 10^6mR/hr is used in conjunction with a recorder. The recorder is located on panel H11-P601 in the main control room. The channel has no trip functions and no alarms. Power is supplied from the 48/24-V dc battery for the channel and the 120-V ac instrument bus for the recorder. The auxiliary trip unit is powered from a 24/12 VDC power supply. This channel is classified Quality Level NQ and nonseismic.

The radiation level detected by the logarithmic channels can be directly correlated to the concentration of the noble gases. This concentration can be determined by using the semiautomatic sample system incorporated as part of this monitor. To use this system, a septum bottle is inserted into a sample chamber so that a hypodermic needle pierces the rubber cap. A vacuum pump is used to evacuate the bottle and then a solenoid-operated sample valve is opened to allow offgas to enter the bottle. The bottle is then removed and counted in the counting room with a multichannel gamma pulse height analyzer to determine the concentration of the various noble gas radionuclides. The correlation of sample activity and monitor reading can then be used by the operators to determine what activity is being discharged from the steam-jet air ejectors and ultimately from the roof vent.

Each of the two logarithmic channels consists of a local detector (gamma-sensitive ion chamber), current to frequency converter, a digital ratemeter in the relay room, and a recorder in the main control room. The recorder is a six-decade recorder located on panel H11-P601. The system provides no control function but is a diagnostic tool that enables the main control room operator to take appropriate action. Power is supplied from RPS bus A for one channel, from RPS bus B for the second channel, and from the 120-V ac instrument bus for the recorder. The auxiliary trip unit is powered from a 120 VAC/12 VDC power supply. These channels are classified Quality Level 1M and nonseismic. Arrangement details are shown in Figures 11.4-2 and 11.4-3 and in Sheet 3 of Figure 11.3-1.

11.4.3.8.2.3 Main Steam Line Radiation Monitor System

This monitor subsystem measures the radioactive gases coming from the reactor through the main steam lines. These gases are activation gases that come mainly from activation of oxygen, and fission gases that come from small fuel leaks and tramp uranium impurities. If the reactor fuel fails and a gross release of fission products occurs, the monitoring subsystem provides signals to trip the gland seal exhausters (when reactor power is below the low power setpoint associated with RWM), trip the condenser mechanical vacuum pumps and line valves, and isolate the reactor water sample system to contain the released fission products, thus mitigating the potential for release through these pathways as described in Chapter 15. The main steam line radiation monitoring system complies with Regulatory Guide 1.22 and GDC 13, 20, 21, 23, and 24.

The six detectors are located near the main steam lines just downstream of the outboard main steam line isolation valves in the space between the primary containment and secondary containment walls. The detectors are geometrically arranged so that this system is capable of detecting significant increases in radiation level with any number of main steam lines in operation. Their location along the main steam lines allows the earliest practical detection of a gross fuel failure. Two of the detectors are installed spares that can be electrically connected, if needed, outside the main steam tunnel. Table 11.4-1 lists the sensitivity and range of the detectors, as well as the alarm and trip setpoints.

The subsystem consists of four separate, redundant instrument channels. Each channel consists of a local detector (gamma- sensitive ion chamber) and a radiation analyzer in the relay room. A two-pen, six-decade strip-chart recorder on panel H11-P601 in the main control room is used to record two of the four channels. There are two selector switches located under the recorder, one to select channel A or C and the other to select channel B or D for recording.

A "one-out-of-two-taken-twice" logic is used to provide a trip signal to the gland seal exhausters (when reactor power is below the low power setpoint associated with RWM) and condenser mechanical vacuum pumps and line valves. Two “two-out-of-two” logics are used to provide an isolation signal to the reactor water sample system valves, with one logic closing the inboard valve and the other closing the outboard valve. Power is supplied from RPS bus A for two channels, from RPS bus B for two channels and from the 120-V ac instrument bus for the recorder. This subsystem is Quality Level 1 and Category I. Arrangement details are shown in Figure 11.4-3.

The alarms for this monitor subsystem are set to 1.5 times the “full power background” to allow for prompt sampling of the reactor coolant to determine possible sources of contamination and the need for corrective/mitigative actions.

11.4.3.8.2.4 Reactor Building Ventilation Exhaust Radiation Monitor System

This monitor subsystem measures the radioactivity in the reactor building ventilation system exhaust duct prior to its discharge from the building and, in doing so, complies with GDC 13, 23, and 64. The exhaust duct is in the form of a "T" with north and west legs that come together into a common line prior to passing through the building isolation dampers. During normal operation and during refueling operation (including criticality tests), the monitors act to detect a high activity level in the ductwork. Two independent redundant monitors are located on the common line downstream of the isolation dampers.

A continuous representative sample is extracted from the common duct through the gas monitor, a low-flow alarm switch, and then through a sample pump prior to being returned to the ventilation duct.

The shielded gas monitor has a beta-sensitive scintillation detector mounted in the top of a stainless steel chamber. Table 11.4-1 lists the sensitivity and range of the detector. In the event that this chamber becomes highly contaminated, it can be disassembled for cleaning or replacement.

Each channel consists of the local detector and preamplifier and a radiation analyzer in the relay room. No recorder is provided. One high-high trip or two low alarms (one from each detector) start the SGTS, close the primary containment vent valves, trip and isolate the reactor building vent system, isolate the control center, and initiate emergency recirculation mode for the control center ventilation system. A low trip also initiates all the above actions because the trip circuit has been designed to fail safe in the event of loss of power. Power is supplied from the 120-V ac instrument bus for each channel. This system is Quality Level 1M and seismic II/I. Arrangement details are shown in Figures 11.4-2, 11.4-4, 11.4-5, and 9.4-4, Sheets 1 and 2.

11.4.3.8.2.5 Offgas Vent Pipe Radiation Monitor System

This monitor system is not required since the reactor building exhaust plenum monitor measures the activity leaving the reactor building stack and is therefore not in operation. The system measures the activity in the offgas vent pipe before it discharges into the reactor building ventilation exhaust plenum. The activity this monitor detects is the effluent from the offgas system, which is composed of fission gases from the reactor. During startup, the condenser offgas passes through the mechanical vacuum pumps, through a 2-minute delay line, at the discharge end of which is a monitor, as described in Subsection 11.4.3.8.2.13, and into the common vent pipe.

A continuous representative sample is extracted from the vent pipe through an isokinetic probe, passed through a filter paper to collect particulates, and through an impregnated charcoal cartridge to collect iodine. The sample continues past a pressure switch used as a low-flow alarm, through the sample pump, through two gas monitors in series, and then through a rotameter prior to being returned to the vent pipe. Table 11.4-1 lists the location, sensitivity, and range of the monitors.

Each gas monitor has a sample chamber viewed by a shielded gamma-sensitive (NaI) scintillation detector. Each channel consists of a local detector and preamplifier, a radiation analyzer in the relay room (ratemeter removed and supporting components abandoned in place), and a recorder in the main control room. The recorder is a seven-decade recorder located on panel H11-P601. A switch located under the recorder is used to operate solenoid valves to stop the sample flow and admit room air to purge the detectors. Two other switches, also under the recorder, can be used to move solenoid- operated check sources into position to check detector response. Three local control switches are also provided for the same purposes at the rack where all the local equipment is mounted.

This subsystem provides no control function but is a diagnostic tool that enables the main control room operator to take appropriate action. Power is supplied from the 48/24-V dc batteries for the channels and from the 120-V ac instrument bus for the recorder. This subsystem is Quality Level NQ and seismic II/I. Arrangement details are shown in Figures 11.4-2 and 11.4-3 and in Sheet 3 of Figure 11.3-1.

11.4.3.8.2.6 Radwaste Building Ventilation Exhaust Radiation Monitor System

This monitor subsystem measures the radioactivity in the building exhaust prior to its discharge to the environment and, in doing so, complies with Regulatory Guide 1.21, Revision 1, and GDC 23 and 64. The activity this monitor detects is from samples in the laboratory fume hoods, tank vents, and the extruder fill station and ventilation exhaust from contaminated cubicles. The gaseous activity is normally expected to be below detectable levels. The particulate and iodine activity is accumulated on filters. These filters are periodically changed-out for counting. The filters are counted using certified equipment to aid in determining the quantities of specific radionuclides released. The gaseous activity is monitored by a beta scintillator and energy-compensated Geiger-Mueller tube viewing the same gas sample volume. The analysis results, combined with the data files and printouts from the detectors, provide a record of the activity released to the environment.

A continuous representative sample is extracted from the exhaust vent through an isokinetic probe. The sample first passes through a filter paper to collect particulates. Next the sample passes through an iodine-adsorbent cartridge. The sample then passes through the gas monitor, a combined high/low-flow alarm switch and indicator, and then a regulated sample pump before being returned to the exhaust vent.

The shielded gas monitor has a beta scintillator and energy-compensated Geiger-Mueller tube viewing a common sample plenum. A second Geiger-Mueller tube embedded in the shield exterior serves as a spare detector. Background compensation for both detector channels is performed using fixed background subtraction. Table 11.4-1 lists the sensitivity and ranges of these detectors. In the event that the sample chamber or detector housings should become highly contaminated, the units can be disassembled for cleaning or replacement.

This Sping 3 Radwaste Building Ventilation Exhaust Radiation Monitor (D11-N503/D11-P281) is a self-contained microprocessor-based detection system for sampling of particulates and iodines, and for monitoring of noble gases. The microcomputer performs the tasks of data acquisition, history file management, operational status check, and alarm determination. The monitor is powered from 120-V ac instrumentation and control (I&C) panel H21-P515. All data are accessed and printed out from the Eberline SS-1 system server located in the control room complex. A high- or low-flow condition, a high or low failure of a detector channel or a channel reading above setpoint results in an audible and visual alarm in the control room. In addition, a high channel alarm on the noble gas channel will initiate a trip of the radwaste building ventilation fans and automatically close the isolation dampers.

This system is Quality Level 1M and nonseismic. Arrangement details are shown in Figures 11.4-2, 11.4-4, and 9.4-5.

11.4.3.8.2.7 Turbine Building Ventilation Exhaust Radiation Monitor System

This monitor subsystem measures the radioactivity in the turbine building exhaust prior to its discharge to the environment and, in doing so, complies with Regulatory Guide 1.21, Revision 1, and GDC 23 and 64. The activity this monitor detects is from fission products in the steam that may leak from the turbine or other components in the building. The gaseous activity is normally expected to be below detectable levels. The particulate and iodine activity is accumulated on filters. These filters are normally changed out weekly. The filters are counted using certified equipment to aid in determining the quantities of specific radionuclides released. The gaseous activity is monitored by a beta scintillator and energy-compensated Geiger-Mueller tube viewing the same gas sample volume. The analysis results, combined with the data files and printouts from the detectors, provide a record of the activity released to the environment.

A continuous representative sample is extracted from the exhaust vent through an isokinetic probe. The sample first passes through a filter paper to collect particulates. Next the sample passes through an iodine-adsorbent cartridge. The sample then passes through the gas monitor, a combined high/low-flow alarm switch and indicator, and then a regulated sample pump before being returned to the exhaust vent.

The shielded gas monitor has a beta scintillator and energy- compensated Geiger-Mueller tube viewing a common sample plenum. A second Geiger-Mueller tube embedded in the shield exterior serves as a spare detector. Background compensation for both detector channels is performed using fixed background subtraction. Table 11.4-1 lists the sensitivity and ranges of these detectors. In the event that the sample chamber or detector housings should become highly contaminated, the units can be disassembled for cleaning or replacement.

This Sping 3 Turbine Building Ventilation Exhaust Radiation Monitor (D11-N504/D11-P279) is a self-contained microprocessor- based detection system for sampling particulates and iodines and monitoring noble gases. The microcomputer performs the tasks of data acquisition, history file management, operational status check, and alarm determination. The monitor is powered from 120-V ac I&C panel H21-P563. All data are accessed and printed out from the Eberline SS-1 system server located in the control room complex. A high- or low-flow condition, a high or low failure of a detector channel or a channel reading above setpoint results in an audible and visual alarm in the control room. In addition, a high channel alarm on the noble gas channel will initiate a trip of the turbine building ventilation fans. This system is Quality Level 1M and nonseismic. Arrangement details are shown in Figures 11.4-2, 11.4-4, and 9.4-7.

11.4.3.8.2.8 Deleted

11.4.3.8.2.9 Standby Gas Treatment System Radiation Monitor System

This monitor subsystem measures the radioactivity in the exhaust vent lines from the SGTS prior to its discharge to the environment and, in doing so, complies with Regulatory Guide 1.21, Revision 1, and GDC 23 and 64. There is a monitor on both SGTSs. The activity these monitors are designed to detect is composed of fission products from the reactor building that have been treated by the SGTS. The gaseous activity in the exhaust is normally expected to be below detectable levels. Particulate and iodine activity is accumulated on filters. These filters are normally changed-out weekly. The filters are counted using certified equipment to aid in determining the quantities of specific radionuclides released. The gaseous activity is monitored by a beta scintillator and energy-compensated Geiger-Mueller tube viewing the same gas sample volume. The analysis results, combined with the data files and printouts from the detectors, provide a record of the activity released to the environment.

A continuous representative sample is extracted from the exhaust vent through an isokinetic probe. The sample first passes through a filter paper to collect particulates. Next the sample passes through an iodine-adsorbent cartridge. The sample then passes through the gas monitor, a combined high/low-flow alarm switch and indicator, and then a regulated sample pump before being returned to the exhaust vent.

The shielded gas monitor has a beta scintillator and energy- compensated Geiger-Mueller tube viewing a common sample plenum. A second Geiger-Mueller tube embedded in the shield exterior serves as a spare detector. Background compensation for both detector channels is performed using fixed background subtraction. Table 11.4-1 lists the sensitivity and ranges of these detectors. In the event that the sample chamber or detector housings should become highly contaminated, the units can be disassembled for cleaning or replacement.

These Sping 3 SGTS System Exhaust Radiation Monitors (D11-N510A/ D11-P275 and D11-N510B/D11-P276) are both self-contained microprocessor-based radiation detection systems for sampling particulates and iodines and monitoring noble gases. The microcomputer performs the tasks of data acquisition, history file management, operational status check, and alarm determination. The monitors are powered from 120-V ac I&C panels. All data are accessed and printed out from the Eberline SS-1 system server located in the control room complex. A high- or low-flow condition, a high or low fail of a detector channel or a channel reading above setpoint results in an audible and visual alarm in the control room. The system provides no control function but is a diagnostic tool that enables the main control room operator to take appropriate action. This system is Quality Level 1M and seismic II/I. Arrangement details are shown in Figures 11.4-2 and 11.4-4.

See Subsection 11.4.3.8.2.16 for a discussion of the SGTS post-accident radiation monitor system.

11.4.3.8.2.10 <u>Reactor Building Exhaust Plenum Radiation Monitor System</u>

This monitor subsystem measures the activity in the reactor building exhaust plenum prior to its discharge to the environment and in doing so complies with Regulatory Guide 1.21, Revision 1, and GDC 64. The activity this monitor is designed to detect is due to corrosion and fission products from the reactor/auxiliary building ventilation system (Subsection 11.4.3.8.2.4) and from the offgas system (Subsection 11.4.3.8.2.5). The gaseous activity in the exhaust is mainly due to the condenser offgas. The particulate and iodine activity is accumulated on filters. These filters are normally changed-out weekly. The filters are counted using certified equipment to aid in determining the quantities of specific radionuclides released. The gaseous activity is monitored by a beta scintillator and energy-compensated Geiger-Mueller tube viewing the same gas sample volume and a high-range noble gas monitor using another energy-compensated Geiger-Mueller tube. The analysis results, combined with the data files and printouts from the detectors, provide a record of the activity released to the environment.

A continuous representative sample is extracted from the exhaust vent through an isokinetic probe. The sample first passes through a filter paper to collect particulates. Next the sample passes through an iodine-adsorbent cartridge. The sample then passes through the gas monitor, a combined high/low-flow alarm switch and indicator, the high-range noble gas monitor, and then a regulated sample pump before being returned to the exhaust vent.

The shielded gas monitor has a beta scintillator and energy- compensated Geiger-Mueller tube viewing a common sample plenum. A second Geiger-Mueller tube embedded in the shield exterior serves as a spare detector. Background compensation for both detector channels is performed using fixed background subtraction. The high-range noble gas monitor consists of an energy-compensated Geiger-Mueller tube viewing a shielded 1-in. stainless steel tube as its sample volume. Table 11.4-1 lists the sensitivity and ranges of these detectors. In the event that the sample chamber or detector housings should become highly contaminated, the units can be disassembled for cleaning or replacement.

This Sping 4 Reactor Building Exhaust Plenum Radiation Monitor (D11-N507/D11-P280) is a self-contained microprocessor-based radiation detection system for sampling particulates and iodines and monitoring noble gases. The microcomputer performs the tasks of data acquisition, history file management, operational status check, and alarm determination. The monitor is powered from a 120-V ac I&C panel. All data are accessed and printed out from the Eberline SS-1 system server located in the control room complex. A high- or low-flow condition, a high or low failure of a detector channel or a channel reading above setpoint results in an audible and visual alarm in the control room. The system provides no control function but is a diagnostic tool that enables the main control room operator to take appropriate action. This system is Quality Level 1M and seismic II/I. Arrangement details are shown in Figures 11.4-2, 11.4-4, and 9.4-4, Sheets 1 and 2.

11.4.3.8.2.11 Fuel Pool Ventilation Exhaust Radiation Monitor System

This monitor subsystem measures the activity from the fuel pool area ventilation exhaust ducts that discharge into the east and west legs of the reactor building ventilation exhaust system. The fuel pool contains gaseous activity due to mixing with the reactor coolant system during each refueling. Diffusion of this activity from the pool generates airborne activity that is swept into the spent fuel pool area ventilation system. Gaseous activity released during a fuel-handling accident is also swept into this ventilation system. Two detectors are located on each leg of the ventilation system downstream of all the spent fuel exhaust ducts. During refueling operation (including criticality tests), the monitors act to detect a high radiation level in the ductwork that could be due to fission gases from a refueling accident or a control rod drop accident. Two independent redundant monitors are provided on the east and west exhaust duct legs. The detectors are located as far upstream of the building isolation valve as practicable to allow for reaction time to close the valve to prevent the release of activity. Table 11.4-1 lists the range and sensitivity of the detectors. Subsection 15.7.4 contains a discussion of the accident analyses.

Each channel consists of a local sensor-convertor unit (gamma- sensitive detector and associated circuitry as discussed in Subsection 12.1.4), a radiation analyzer mounted in the relay room, and one pen on a recorder in the main control room. There are two, two-pen, four-decade strip-chart recorders provided, one on panel H11-P601 for channels A and B and one on panel H11-P812 for channels C and D. A high-high trip on any channel starts the SGTS, closes the primary containment vent valves, trips and isolates the reactor building vent system, isolates the control center, and initiates emergency recirculation mode for the control center ventilation system. The radiation monitors' maximum allowable value is 6mR/hr.

Two failure alarms (one from each detector on one leg) also initiate all the above actions because the trip circuit has been designed to fail safe in the event of loss of power, downscale/inop condition. Power is supplied from RPS bus A for one channel on each leg, from RPS bus B for the second channel on each leg, and from the 120-V ac instrument bus for the recorders. This system is Quality Level 1 and Category I. Arrangement details are shown in Figures 11.4-2, 11.4-3, and 9.4-4, Sheets 1 and 2.

11.4.3.8.2.12 Control Center Normal Makeup Air Radiation Monitor System

This monitor system measures the activity in the makeup air to the main control room. No measurable activity is expected to be present in the makeup air. However, in the event of a design- basis accident, fission gases could escape from the main coolant system and be drawn into the makeup air intake. There are two independent monitors at each normal makeup air intake. The system complies with GDC 13 AND 19.

A representative sample for each monitor is extracted from the ventilation duct and passes through the gas monitor, a low-flow alarm switch, and finally through a sample pump before being returned to the ventilation duct. Four source taps are located in the normal air intake prior to the normal air-intake isolation valves.

Each shielded gas monitor has a beta-sensitive scintillation detector mounted in the top of a stainless steel chamber.

Table 11.4-1 lists sensitivity and range for this detector. In the event the chamber becomes contaminated, it can be disassembled for cleaning or replacement.

Each channel consists of the local detector and preamplifier and a radiation analyzer in the relay room. No recorder is provided. One high-high or two low alarms (one from each detector) isolate the control center and initiate emergency recirculation mode for the control center ventilation system. Power is supplied from the 120-V ac instrument bus for the channel components. This system is Quality Level 1M and seismic II/I. Arrangement details are shown in Figures 11.4-2, 11.4-3, and 9.4-2.

11.4.3.8.2.13 Two-Minute Holdup Pipe Exhaust Radiation Monitor System

This monitor system measures the activity from the mechanical vacuum pumps after the discharge from the 2-minute delay pipe. In addition, it also monitors the turbine gland sealing system exhaust that enters the offgas system at the discharge of the mechanical vacuum pumps. The mechanical vacuum pumps are used during startup to remove large quantities of air from the system at high flow rates. After the offgas flow rate is reduced to normal levels, the flow is rerouted through the offgas treatment system and the mechanical vacuum pumps are shut off. The mechanical vacuum pump is also used for normal shutdowns, SCRAM related shutdowns, and during periods of low power operations when the Offgas system is not available. The mechanical vacuum pumps are shutdown when Shutdown Cooling is placed in service for normal shutdowns and SCRAM related shutdowns. The operating time for low power operations when the Offgas system is not available is generally shorter than three to five days. The monitors initially detect the activity due to fission gases produced in the reactor and transported in the steam through the turbine to the condenser. Later, the monitors detect the same gases that come through the turbine gland sealing system. Two independent redundant monitors are provided with the detectors mounted adjacent to the discharge line. The system complies with GDC 13, 23, and 64.

Each shielded monitor has a gamma-sensitive scintillation detector mounted adjacent to the offgas pipe. Table 11.4-1 lists the sensitivity and range of this detector.

Each channel consists of the local detector and preamplifier, and a radiation analyzer in the relay room. No recorder is provided. The system provides no control function, but the alarms for this monitor subsystem are set to 1.5 times the “full power background” to allow for prompt sampling of the reactor coolant to determine possible sources of contamination and the need for corrective/mitigative actions. Power is supplied from the 120-V ac instrument bus for the channel components. This system is Quality Level NQ and nonseismic. Arrangement details are shown in Figures 11.4-2, 11.4-3, and in Sheets 1 and 2 of Figure 11.3-1.

11.4.3.8.2.14 Control Center Emergency Air Inlets Radiation Monitor System

This monitor system measures the activity in the emergency air supply ducts to the main control room. No measurable activity is expected in the emergency air supply. A secondary emergency air makeup intake is provided on the north side of the auxiliary building, along with radiation detectors in both the existing air makeup intake and the second air intake. Therefore, either inlet for makeup air to the control center can be selected from either side of the potential release points, depending on the relative activity. The system is in compliance with GDC 13 and 19.

A representative sample for each of the four monitors is extracted from the emergency ventilation duct through a stainless steel sample tube, which passes through the gas monitor, a low- flow alarm switch, and a sample pump before being returned to the duct. The source taps (four each) are located in the north and south emergency air intakes upstream of the emergency intake isolation valves.

The sampling assembly consists of an off-line gas monitor, a beta-sensitive scintillation detector mounted on top of a stainless steel chamber, and a preamplifier and radiation analyzer in the relay room panel. High-radiation and low-flow or inoperative alarms are provided in the main control room. The sensitivity and range of these detectors are listed in Table 11.4-1. Recorders are not provided.

This system makes an initial automatic selection of emergency air inlets during a radiation-release accident. The monitors would sample the air for 5 minutes; after 5 minutes, if there were high radiation at either the north or south inlet, the corresponding damper with the lower radiation would stay open. The operators then would assume manual control of the selection process following the radiation release, using the radiation monitors to determine which inlet has the lowest radiation level.

This system is Quality Level 1 and Category I. For redundancy, two detectors are provided for each intake (north and south). Arrangement details are shown in Figures 11.4-2, 11.4-5, and 9.4-2.

11.4.3.8.2.15 Onsite Storage Facility Ventilation Exhaust Radiation Monitor System

This monitor subsystem measures the radioactivity in the radwaste onsite storage facility exhaust prior to its discharge to the environment and, in doing so, complies with Regulatory Guide 1.21, Revision 1, and GDC 23 and 64. The activity this monitor detects is a result of the storage and handling of radwaste and equipment in the building. Resultant radioactivity is normally expected to be below detectable levels. The particulate and iodine activity is accumulated on filters. These filters are periodically changed out for counting. The filters are counted using certified equipment to aid in determining the quantities of specific radionuclides released. The gaseous activity is monitored by a beta scintillator and energy-compensated Geiger-Mueller tube viewing the same gas sample volume. The analysis results, combined with the data files and printouts from the detectors, provide a record of the activity released to the environment.

A continuous representative sample is extracted from the exhaust vent through an isokinetic probe. The sample first passes through a filter paper to collect particulates. Next the sample passes through an iodine-adsorbent cartridge. The sample then passes through the gas monitor, a combined high/low-flow alarm switch and indicator, and then a regulated sample pump before being returned to the exhaust vent.

The shielded gas monitor has a beta scintillator and energy-compensated Geiger-Mueller tube viewing a common sample plenum.

A second Geiger-Mueller tube embedded in the shield exterior serves as a spare detector. Background compensation for both detector channels is performed using fixed background subtraction. Table 11.4-1 lists the sensitivity and ranges of these detectors. In the event that the sample chamber or detector housings should become highly contaminated, the units can be disassembled for cleaning or replacement.

This Sping 3 Onsite Storage Building Ventilation Exhaust Radiation Monitor (D11-N508/D11-P299) is a self-contained microprocessor-based radiation detection system for sampling particulates and iodines and monitoring noble gases. The microcomputer performs the tasks of data acquisition, history file management, operational status check, and alarm determination. The monitor is powered by a 120-V ac I&C panel. All data are accessed and printed out from the Eberline SS-1 system server located in the control room complex. A high- or low-flow condition, a high or low failure of a detector channel or a channel reading above setpoint results in an audible and visual alarm in the control room. This system provides no trip or control function but is a diagnostic tool that enables operations personnel to take appropriate action. This system is Quality Level 1M and nonseismic. Arrangement details are shown in Figures 11.4-2, 11.4-4, and 9.4-7.

11.4.3.8.2.16 Standby Gas Treatment System Postaccident Radiation Monitor System

This monitor subsystem measures the radioactivity in the exhaust vent lines from the SGTS after an accident has occurred and prior to discharge to the environment. In doing so, the subsystem complies with Regulatory Guide 1.97 and GDC 60 and 64. The activities these monitors are designed to detect are fission products (following an accident) from the reactor building that have been treated by the SGTS. The activity in the exhaust is expected to be high levels of noble gases resulting from a breach of primary system integrity. The gaseous activity of the SGTS unit exhaust is monitored by two shielded energy-compensated Geiger-Mueller tubes. In addition, a grab sample pallet (GSP-1) contains a particulate filter and charcoal cartridge in a removable shielded holder to allow count room analysis of particulates and iodine in the exhaust using certified equipment. The GSP-1 also has hose-barbed sample taps for removal of a gaseous sample for count room analysis. The analysis results, combined with the data files and printouts from the units, provide a record of the activity released to the environment.

A continuous representative sample is extracted from the exhaust vent through an isokinetic probe. The sample passes through a heat-traced line and bulk filter assembly (BFA-1) to remove any particulates. The filtered sample then passes through a regulated sample pump that provides a continuous sample flow rate of 5.43 liter/minute and a local flow indicator on the noble gas pallet (NGP-1). A flow switch tapped into the sample line at this point provides a loss-of-flow alarm trip to the unit. On the NGP-1 the sample passes through two shielded detector assemblies in series, the intermediate-range noble gas detector (SA-14), and the high-range noble gas detector (SA-15). Both the SA-14 and the SA-15 consist of an energy-compensated Geiger- Mueller tube viewing a shielded polished stainless steel sample volume. The SA-15 also has a second Geiger-Mueller tube embedded in its shield exterior which serves as a spare detector. Background compensation is provided using fixed background subtraction. The sample then returns to the SGTS exhaust header.

In addition to the NGP-1, another isokinetic probe in the sample line upstream of the BFA-1 splits off a portion of the sample flow (1/73.2) for the grab sample pallet assembly (GSP-1). The grab sample pallet flow driving head is provided by a manual throttling valve (V-3). The sample flow of ≥ 74.1 cm^3/minute passes through a shielded, removable particulate filter and iodine cartridge holder (SA-16), a visual flow indicator before returning to the sample line upstream of the BFA-1. The SA-16 contains an energy-compensated Geiger-Mueller tube to indicate the relative amount of radiation present in the filter and cartridge.

The detector outputs are translated by interface boxes and the resultant signal is transmitted to the data acquisition module (DAM-4) for each monitor (D11-N520A/D11-P300A and D11-N520B/D11-P300B). The DAM-4s are both self-contained microprocessor-based radiation detection systems for monitoring accident-range noble gases. The microcomputer performs the tasks of data acquisition, history file management, operational status check, and alarm determination. The monitors are powered from 120-V ac I&C panels. All data are accessed and printed out from the Eberline SS-1 system server located in the control room complex. A low-flow condition, a high or low failure of a detector channel or a channel reading above setpoint results in an audible and visual alarm in the control room. This system provides no control functions but is a diagnostic tool that enables the main control room operator to take appropriate action. This system is Quality Level 1M and seismic II/I. Arrangement details are shown in Figures 11.4-2 and 11.4-4.

The SGTS radiation monitor system for normal operation is described in Subsection 11.4.3.8.2.9.

11.4.3.9 Description of Liquid Monitors

Each channel of the system contains a completely integrated modular assembly as described below. Specific details of each monitor are described in Subsections 11.4.3.9.2.1 through 11.4.3.9.2.6.

11.4.3.9.1 General Liquid Monitor Details

11.4.3.9.1.1 Sampling Devices

For each off-line monitor except the circulating water decant line monitor, a sample is drawn from a process line through a sample tap, passed through a shielded sample chamber, through the sample pump, and returned to the system. The circulating water decant line radiation monitor does not have a sample pump (see Subsection 11.4.3.9.2.6).

Each sample pump is capable of drawing 1 gpm of liquid through the monitor. The sample flow rate is controlled with a manual flow-control valve. Each monitor has a low sample-flow alarm.

The monitor inlet and outlet lines are flanged and have isolation valves so that the monitor can be disassembled if decontamination is necessary. Sample valves are provided so that clean water can be purged through the chamber to check the background radiation level, and so that samples can be taken for analysis, or calibrated liquids introduced, to check the monitor calibration.

Each in-line monitor has a polished stainless steel well bolted to a flange on the line being monitored. The pressure and temperature limits and the Category and Quality Level for the well are the same as that for the line in which the well is mounted.

11.4.3.9.1.2 Detector-Preamplifier Unit

Each detector is a NaI gamma-sensitive scintillation detector. A preamplifier is mounted on top of the detector. The detectors are designed to remain fully operational over a wide range of temperatures, as shown in Table 11.4-3. If they are exposed to high radiation transients exceeding the channel range, the channel maintains full-scale deflection and returns to normal functioning when the transient has subsided. Since gamma detectors are used, comparison of monitor readout with the results of grab samples is easily made. The grab samples are counted in the plant multichannel gamma pulse height spectrometer to check monitor calibration. Solenoid-operated check sources are provided to check detector response on the General Atomics-supplied monitors. Each check source is operated from the respective radiation analyzer in the relay room.

Off-line detectors are mounted as close as practicable to the system being monitored, and yet are still in a low-radiation area (γ<0.5 mR/hr in most cases) so that the detectors have maximum sensitivity and so there is minimum sample plateout.

11.4.3.9.1.3 Radiation Analyzer

Subsection 11.4.3.8.1.3 contains a description of the radiation analyzer.

11.4.3.9.1.4 Recorder

Subsection 11.4.3.8.1.4 contains a description of the recorder.

11.4.3.9.2 Specific Liquid Monitor Details

11.4.3.9.2.1 Radwaste Effluent Radiation Monitor System

This monitor subsystem measures the activity in the radwaste effluent discharge line to comply with Regulatory Guide 1.21 and GDC 23 and 64. The radwaste effluent line discharges through the blowdown discharge line into the circulating water decant line, which dilutes the waste prior to its discharge to Lake Erie. This monitor detects the activity in the blowdown discharge line to prevent the concentration in the circulating water decant line from exceeding the 10 CFR 20, Appendix B, Table II, Column 2, activity limits. Waste liquid can be discharged from any of the three waste sample tanks. The liquid radwaste system for Fermi 2 is designed to be a closed-loop system which does not normally discharge effluent to Lake Erie. As discussed above, provision is made for a discharge should it be required, and instrumentation that satisfies the requirements of NUREG-0473, Revision 2, is provided on the decant line.

Prior to discharge, the liquid in the appropriate waste sample tank is sampled and analyzed in the laboratory for radioactivity to comply with Regulatory Guide 1.21. Based upon this analysis, a discharge permit is issued specifying the release rate, the dilution rate, and the tank to be discharged. The release rate and dilution rate are used to determine the alarm setpoints. Prior to the release, the radwaste control room operator or other authorized personnel on approval of radiochemistry may reset the High alarm point for a flow rate that will be lower than the maximum for which the alarm is normally set. The Shift Manager or his authorized delegate verifies that it is set correctly and initials the permit to signify that he has checked the setting.

The shielded detector is located in a well in the common discharge line from the liquid radwaste system through which all liquid radwaste discharges to the blowdown line must pass. Table 1.4-2 lists the sensitivity and range of this detector. The piping arrangement is designed so that the section of pipe in which the well is located can be flushed to remove crud to lower the background radiation levels or to remove a slug of highly radioactive liquid to clear the high alarm. The flanged stainless steel well, which protrudes into the liquid flow path, is bolted to the blowdown pipe. If the well becomes highly contaminated, it can be removed for decontamination after draining the line.

The channel consists of the local detector and preamplifier, a digital ratemeter in the relay room, and a recorder in the radwaste control room. The recorder is a seven-decade recorder located in the radwaste control room on panel G11-P604. A high alarm also sounds in the radwaste control room and light annunciator window 4D30 on panel G11-P604. A high-high trip or downscale failure initiates closure of the radwaste discharge isolation valve. A low trip also initiates an alarm. Power is supplied from the 48/24-V dc battery for the channel components and from the 120-V ac instrument bus for the recorder. The auxiliary trip unit is powered from a 24/12 VDC power supply. This subsystem is Quality Level 1M and nonseismic. Arrangement details are shown in Figures 11.4-2 and 11.4-3.

11.4.3.9.2.2 General Service Water Radiation Monitor System

This monitor subsystem measures the activity in the general service water line to comply with GDC 64. The general service water line discharges into the main condenser circulating water discharge line. Some of this liquid is evaporated, and the remainder is discharged to the circulating water reservoir where a portion is decanted through the circulating water decant line to Lake Erie. No activity attributable to reactor operation is expected to be present in this line. To have activity in this line, a leak would have to develop simultaneously in equipment cooled by the reactor building closed cooling water system (RBCCWS) and in the RBCCW heat exchanger, or simultaneously in equipment cooled by the turbine building closed cooling water system (TBCCWS) and TBCCW heat exchanger. Samples of the closed cooling water systems are checked periodically for activity that would warn if a leak had developed in a component. In addition, there is an in-line radiation monitor on the RBCCWS (Subsection 11.4.3.9.2.3), which would warn of any gross leak from a component cooled by that system between analyses.

The service water monitor provides a backup for the above detection methods and detects gross leaks of radioactive liquid into the service water.

The shielded detector is located in a well in the service water discharge line. Table 11.4-2 lists the sensitivity and range of this detector. The flanged stainless steel well, which protrudes into the liquid flow path, is bolted to the service water pipe. If the well should become contaminated, it can be removed for decontamination.

The channel consists of the local detector and preamplifier, a digital ratemeter in the relay room, and a recorder in the main control room. The seven-decade recorder is located in the main control room on panel H11-P601. The recorder is shared with the RBCCW monitor. The system provides no control function but is a diagnostic tool that enables the main control room operator to take appropriate action. Power is supplied from the 48/24-V dc battery for the channel and from the 120-V ac instrument bus for the recorder. The auxiliary trip unit is powered from a 24/12 VDC power supply. This subsystem is Quality Level NQ and nonseismic. Arrangement details are shown in Figures 11.4-2, 11.4-3, and 9.2-1, Sheet 1.

11.4.3.9.2.3 Reactor Building Closed Cooling Water Radiation Monitor System

This monitor subsystem measures the activity in the RBCCWS and, in doing so, complies with GDC 64. The RBCCWS cools components that contain radioactive liquids, but does not normally have any activity unless one of these components develops a leak. Samples of the RBCCWS are checked periodically for activity to determine if a leak is starting in a component. A laboratory analysis has much greater sensitivity than a radiation monitor, and therefore can detect smaller leaks. Since leaks usually start small and develop gradually, the radiological analyses performed in the laboratory normally detect the leak prior to the monitor. If a leak should increase dramatically between samples, or if a gross failure should occur, the monitor would detect it. Each RBCCW supplemental cooling loop and the associated EECW loop it services form a separate flow circuit that does not circulate fluid past the RBCCW radiation monitor. These circulation loops (one for each EECW division) are provided with sample points. As stated above, laboratory analysis has a better sensitivity for detecting small leaks. For larger leaks into a RBCCW supplemental cooling circuit, the extra fluid added to the circuit upsets the hydraulic balance between the RBCCW circulation inside and outside of RBCCW supplemental cooling. This hydraulic imbalance forces fluid into the flow of RBCCW outside of the RBCCW supplemental cooling which does pass by the RBCCW radiation monitor. The RBCCW radiation monitor will then detect the increase in activity as it does when the RBBCW supplemental cooling loops are not in operation.

This design meets the criteria stated above that small leaks are detected by sampling and large leaks are detected with the radiation monitor.

The shielded detector is located in a well in the 20-in. discharge header of the RBCCW pumps. Table 11.4-2 lists sensitivity and range of this detector. The flanged stainless steel well, which protrudes into the liquid flow path, is bolted to the cooling water pipe. If the well should become contaminated, it can be removed for decontamination.

The channel consists of the local detector and preamplifier, a digital ratemeter in the relay room, and a recorder in the main control room. The recorder is a seven-decade recorder located on panel H11-P601. The recorder is shared with the general service water effluent monitor. The RBCCWS monitor system provides no control function but is a diagnostic tool that enables the main control room operator to take appropriate action. Power is supplied from the 48/24-V dc battery for the channel and from the 120-V ac instrument bus for the recorder. The auxiliary trip unit is powered from a 24/12 VDC power supply. This subsystem is Quality Level NQ and seismic II/I. Arrangement details are shown in Figures 11.4-2 and 11.4-3.

11.4.3.9.2.4 Emergency Equipment Cooling Water Radiation Monitor System

This monitor subsystem measures the activity in the emergency equipment cooling water system (EECWS) and, in doing so, complies with GDC 64. The EECWS cools certain vital components in the reactor building if use of the RBCCWS is lost. When this system is used, the components it cools have water that contains radioactive contaminants. This monitor is used to determine if a leak occurs. One detector is located on each of the two redundant systems.

Each shielded detector (Table 11.4-2 lists the sensitivity and range of this detector) is located in a well in the 8-in. EECW line downstream of the components that have been cooled. The flanged stainless steel well, which protrudes into the liquid flow path, is bolted to the pipe. If the well should become contaminated, it can be removed for decontamination.

Each channel consists of the local detector and preamplifier and radiation analyzer in the relay room. No recorder is provided. The system provides no control function but is a diagnostic tool that enables the main control room operator to take appropriate action. Power is supplied from the 120-V ac instrument bus for each channel. This subsystem is Quality Level NQ and seismic II/I. Arrangement details are shown in Figures 11.4-2, 11.4-3, 9.2-3, and 9.2-4.

11.4.3.9.2.5 Residual Heat Removal Service Water System Radiation Monitor System

This monitor subsystem measures the activity in the residual heat removal service water system (RHRSWS) and, in doing so, complies with GDC 23 and 64. The RHRSWS cools the RHR system, which is used when the reactor is shut down to remove decay heat from the reactor coolant system. The RHRSWS is discussed in detail in Subsection 9.2.5. This cooling water is discharged to the RHR cooling tower and then into the RHR reservoir. This monitor detects gross leaks to warn of contamination. One detector is located on each of the two redundant systems downstream of the respective RHR heat exchanger.

A representative sample is extracted from each 24-in. line through a sample tap, the liquid monitor, a low-flow alarm switch, and then a sample pump prior to being returned to the RHRSW line downstream.

The shielded detector is mounted in the top of a stainless steel chamber. Table 11.4-2 lists the location, sensitivity, and range of this detector. In the event that this chamber becomes contaminated, it can be disassembled for cleaning or replacement.

Each channel consists of the local detector and preamplifier and radiation analyzer in the relay room. No recorder is provided. Power is supplied from the 120-V ac instrument bus for each channel. This subsystem is Quality Level NQ and seismic II/I and has been upgraded to Quality Level 1 and Seismic I for pressure boundary integrity only. Arrangement details are shown in Figures 11.4-2 and 11.4-3.

11.4.3.9.2.6 Circulating Water Reservoir Decant Line

This monitor subsystem measures the activity in the circulating water decant line and, in doing so, complies with Regulatory Guide 1.21, Revision 1, and GDC 64. The decant line is the blowdown line from the circulating water reservoir to Lake Erie and provides dilution for the liquid radwaste that discharges into this line upstream of the monitor. This is the final point at which a measurement can be made prior to discharge into Lake Erie. This monitor provides a permanent record of this discharge.

A continuous sample flows from the decant line through a tap, the liquid monitor, and a low-flow alarm switch prior to being discharged into the circulating water reservoir downstream.

The shielded detector is mounted in the top of a stainless steel chamber. Table 11.4-2 lists the sensitivity and range of this detector. In the event this chamber becomes contaminated, it can be disassembled for cleaning or replacement.

The channel consists of the local detector and preamplifier, a radiation analyzer in the relay room, and one pen on a recorder in the main control room. The recorder is a two-pen, six-decade strip-chart recorder located on panel H11-P812.

The system provides no control function but is a diagnostic tool that enables the main control room operator to take appropriate action. Power is supplied from the 120-V ac instrument bus. This subsystem is Quality Level 1M and nonseismic. Arrangement details are shown in Figures 11.4-2 and 11.4-3.

11.4.3.10 Containment Area High Range Monitors

Redundant monitors manufactured by General Atomic have been installed to meet the requirements of NUREG-0578, NUREG-0737, and Regulatory Guide 1.97, Revision 2.

These monitors are General Atomic Model RP-2C, and the detectors are Model RD-23 units. This system hardware, including cables, has been designed and qualified to meet the requirements contained in Table II.F.1-3 of NUREG-0737, with the exception of the upper decade criteria for "special environmental qualifications." This exception has been presented to the NRC and approved in Supplement 6 to the Fermi 2 Safety Evaluation Report, NUREG-0798, July 1985.

Radiation levels resulting from gamma photons in the general area of the detectors are indicated in the relay room and displayed on strip-chart recorders in the main control room. The two detectors are located in the primary containment, one at drywell azimuth 302 degrees, Elevation 605 ft 0 in., approximately 6 ft from the shield wall, and the other at drywell azimuth 125 degrees, Elevation 605 ft 0 in., 7 ft from the shield wall. The area chosen is relatively free of massive shielding and is accessible for maintenance.

The monitors and power supplies are located in the plant relay room and are powered from divisional ac power supplies.

11.4.3.11 Postaccident Gaseous Effluent Radiation Monitoring

11.4.3.11.1 Noble Gas Effluent Monitor

Extended range requirements for noble gas effluent monitors have resulted in the installation of an Eberline Company Sping-3/4 series digital monitor on each gaseous effluent discharge point. The effluent channels affected are listed in Table 11.4-4.

All of the normal range channels will trip their respective ventilation system on high-radiation level and/or downscale failure. Following a postulated design-basis accident, the reactor building's ventilation system is tripped, and the SGTS exhaust becomes the single primary discharge vent for the entire secondary containment air space. For this reason, only the SGTS discharge has been provided with Eberline AXM monitors.

Each Sping monitor is a self-contained unit that uses a multisensor approach to meet the broad-range requirements. The Sping employs a local microprocessor to perform the necessary control and digital signal conversion and processing. A history file of the data from each detector is maintained by the processor. This file consists of the last 4 hr of 10-minute averages, the last 24 hr of 1-hr averages, and the last 24 days of 1-day averages.

A control and display are provided in the main control room to allow bidirectional communication with any of the individual radiation channels. This same data base is accessible in the technical support center. Radiation data are reported to operating personnel via both alarms and typewritten data summaries.

The AXM channels are installed in the discharge of the SGTS and use a low-flow isokinetic sample of approximately 5.43 liters/ minute. The accident monitor meets the range requirement of 1 x 10^5 μCi/cm^3 imposed by NUREG-0737 for noble gas accident monitors in this application. The AXM monitors are environmentally qualified by the vendor to meet IEEE 323-1974.

The Sping and AXM monitors have backup local battery power supplies that are part of the instrument system. These batteries are continuously maintained in a state of full charge by self- contained chargers. The battery has a capacity of 8 hr of operation without recharge. The sampling pump power is derived from the power feed supplying the particular ventilation system fan being monitored.

These monitors provide an activity release rate in units of μCi/sec by direct comparison with the results of actual samples of the effluent that have been analyzed on a gamma isotopic analysis system. All monitor calibrations are performed using approved site procedures developed from the vendor instructions.

The flow rate of each stack/vent is initially determined by measurement to a reasonable degree of accuracy. Each of the Sping monitors includes an isokinetic sample provision. In the case of the SGTS, the actual process airflow is automatically controlled to a design value within a tolerance of ±10 percent. Since the AXM channels include an isokinetic sample system and the process flow is maintained at a constant value, no additional provisions are required to maintain system accuracy.

11.4.3.11.2 Radioactive Iodine and Particulate Effluent Monitoring

Each of the Eberline Sping monitors installed on the plant ventilation discharge stacks provides continuous sampling of both radioactive iodine and particulates. Following a design-basis postulated accident, the SGTS becomes the single primary discharge vent; hence the AXM monitors, which are installed on the SGTS, use a special particulate filter and iodine cartridge assembly that is designed for easy retrieval and incorporates integral shielding. Procedures for retrieval of the samples have been developed with Eberline assistance. The accessibility of the sample locations has been considered, and the GDC 19 requirements are satisfied during retrieval of the samples.

All of the sample probes are designed to take isokinetic samples. In the case of the SGTS, the flow is controlled, which obviates any concern with regard to the adequacy of the sampling system.

The AXM system sample lines have been analyzed and correction factors identified to address potential sample line losses attributable to the plate-out of radioiodines.

None of the effluent streams measured have water entrained in the gas, and moisture degradation is not considered a problem.

11.4.3.11.3 Torus Hardened Vent Radiation Monitor System

This monitor subsystem measures the radioactivity in the exhaust vent line from the torus after a severe accident has occurred and prior to discharge to the environment. Torus venting is used only during accidents which are beyond the plant design basis. This release path is not required to be used during normal or design basis accident conditions, and therefore, need not comply with Regulatory Guide 1.97. When used, the torus vent will prevent rupture of the primary containment by permitting direct vent to the environment. If fuel damage occurs concurrent with the loss of all containment cooling, the effluent would consist primarily of noble gases. The majority of the iodines and particulates would be removed by scrubbing action in the wetwell.

The THVRMS consists of a Process Radiation Detector and Ratemeter. The radiation monitor is mounted adjacent to the 24-inch vent pipe on RB4. The radiation monitor covers a range of 1E-4 R/hr to 1E+5 R/hr.

The THVRMS provides no control function but does provide an alarm and indication in the control room that alerts the operator of a radioactive release in progress. The monitor is also interfaced with the emergency response function of the Integrated Plant Computer System (IPCS). The THVRMS is classified as QA Level 1M and Seismic II/I. The system is powered from an Uninterruptable Power System (UPS). During normal plant operation input power will be from a BOP 120 VAC Distribution Panel (from BOP MPU #3). During a BDBEE the UPS provides input power to the HCVS Radiation Monitoring System for the first 24 hours of the Hardened Containment Venting scenario. After 24 hours into a Hardened Containment Venting scenario, power is shifted to a Class 1E Distribution Panel (from Class 1E MPU #2). Arrangement details are shown in Figure 11.4-4.

For further information on primary containment venting see Section 6.2.5.2.5.1.

11.4.3.12 In-Plant Iodine Radiation Monitoring

In-plant iodine radiation monitoring is implemented to accurately determine the airborne iodine concentration in areas within the facility where plant personnel may be present following an accident.

An adequate number of in-plant iodine monitoring instruments are available for the four vital areas necessary for postaccident operation of the plant. These areas are the operational support center, the technical support center, the postaccident sampling facility, and the postaccident sample analysis area.

Three separate laboratory facilities with gamma isotopic analysis capability are available: one in the chemistry laboratory counting room (located in the radwaste building), one in the Radiation Protection Count Room (located in the plant office service building), and one remote laboratory facility (located at the Nuclear Operations Center in the Emergency Operations Facility).

To perform rapid postaccident in-plant determinations of the airborne iodine concentration, a stabilized sodium iodide detector coupled to an analyzer will be used to continuously evaluate an iodine adsorbent cartridge. This cartridge will be coupled to a flow-stabilized air sampler. These entire units are cart-mounted and portable. Procedures for the use and calibration of the unit are available. Personnel are trained in the use and calibration of the unit.

To evaluate air samples, health physics routinely uses gamma isotopic analysis to identify and quantify the results. This analyzer will be backed up by two units in the chemistry laboratory. In addition, if both the chemistry and health physics counting rooms are unavailable (such as might occur during worst-case accident conditions), a remote laboratory facility located at the emergency operations facility will be available for air sample analysis. This remote facility will basically use the same analysis equipment and procedures as those normally used by health physics and chemistry.

In addition, a supply of silver zeolite, or equivalent, adsorbent cartridges is available to allow the determination of the airborne iodine concentrations in the presence of noble gas.

11.4.4 Sampling

The following sections present a detailed description of the radiological sampling procedures, frequencies, and objectives for all plant process and effluent sampling. This sample program provides the means to comply with the Offsite Dose Calculation Manual radiological effluent controls for the process radiation monitoring system and radwaste system.

11.4.4.1 Process Sampling

Subsection 9.3.2 presents a detailed description of the design of sampling facilities provided for general sampling. The sample frequency, type of analyses, analytical sensitivity, and the purpose of the sample are summarized in Table 11.4-5 for each liquid process sample location, and in Table 11.4-6 for each gas process sample location. The analytical procedures used in sample analysis are presented in Subsection 11.4.4.3. These samples monitor activity levels within various plant systems.

11.4.4.2 Effluent Sampling

Effluent sampling of all potentially radioactive liquid and gaseous effluent paths is conducted on a regular basis in order to verify the adequacy of effluent processing to meet the discharge limits to unrestricted areas. This effluent sampling program provides the information for the effluent measuring and reporting programs required by 10 CFR 50.36a in annual reports to the NRC. The frequency of the periodic sampling and analysis described herein is nominal and may be increased if the effluent levels approach the Offsite Dose Calculation Manual (ODCM) Radioactive effluent control limits. Radioactive effluent sampling and analysis requirements are given in the ODCM Radiological Effluent Controls.

11.4.4.3 Analytical Procedures

Samples of process and effluent gases and liquids may be analyzed for alpha, beta, and gamma radiation.

Instrumentation available on-site for the measurement of radioactivity includes:

a. 2-π proportional counter

b. Liquid scintillation counter

c. Gamma isotopic analysis

Gross beta analyses of liquid process samples are performed with a proportional counter. These samples are evaporated to dryness on planchets prior to counting. Sample volume, counting geometry, and counting time are chosen to achieve the required measurement sensitivities. Correction factors are applied for sample-detector geometry, self-absorption, and counter-resolving time, as needed.

Gross beta and gross alpha analyses are performed with the proportional counter. The samples are prepared for counting by evaporation onto planchets. Sample volume and counting times are chosen to achieve the required measurement sensitivity. Correction factors are applied for self-absorption.

Gross beta and alpha analyses of air particulate composite samples will be performed by counting using the proportional counter.

Gamma isotopic analysis will be used exclusively for the radionuclide analysis of gaseous, air particulate, and liquid samples. The detectors are calibrated against gamma energy for a variety of sample detector geometries.

Gaseous tritium samples are collected by the use of bubblers, condensation, or adsorption (silica gel). Liquid samples for tritium analysis are purified prior to analysis by either passing the samples through mixed-bed ion-exchange columns or by distilling the samples, or both. The liquid scintillation counter is used to count the samples.

Radiochemical separations and gas proportional counting are used for the routine analysis of ^{89}Sr and ^{90}Sr.

Depending on initial experience, either activated charcoal, impregnated charcoal, or silver zeolite will be employed as the adsorption media in gaseous radioiodine sampling devices.

11.4.4.4 Postaccident Sampling System

The postaccident sampling system (PASS) provides the capability of obtaining reactor coolant and containment atmosphere samples under accident conditions. To ensure the ability to sample under post-LOCA environments, the design incorporates sufficient safeguards (shielding/ventilation) to keep the radiation exposure to individuals within the limits of 10 CFR 50, Appendix A, General Design Criteria 19. Compliance to these limits was verified by performance of a time and motion study covering sampling, transport and analysis.

This system has the capability for dilution and remote operation in order to safely obtain representative reactor coolant, suppression pool and containment atmosphere samples.

The design and operation of the Fermi 2 PASS was approved by the NRC in Supplement 5 of the Fermi 2 Safety Evaluation Report and NRC Safety Evaluation dated June 12, 2001.

11.4.4.4.1 Sampling System

A schematic of the PASS is shown in Figure 11.4-6. The general arrangement of the postaccident sample station is shown in Figure 11.4-7 and a schematic diagram of the station is shown in Figure 11.4-8.

The PASS isolation valves and sampling panel are supplied with Class 1E power and on-site backup power, respectively. Both can be operated within 30 minutes of an accident in which there is a loss of offsite power.

The system is installed in the auxiliary building adjacent to the secondary containment, and consists of liquid- and air-sampling subsystems. Appropriate procedures have been written to ensure proper operation.

From the sample station, samples are transported to the analytical laboratory or to an exit for offsite analysis. The short transport route within the building ensures that radiation doses received during transport are minimal.

The PASS will be operated periodically to ensure operability and to provide the opportunity for training. Nuclear Chemistry technician proficiency in PASS operation is verified and maintained in accordance with the Chemistry Technician Training and Qualification Program Description, which includes initial classroom and on-the-job (OJT) training. Documentation of this training is maintained as part of training department records.

The PASS has the capability to obtain:

a. Reactor coolant samples via RHR, when in the shutdown cooling mode, or via jet pumps #5 and #15 when the reactor is at pressure.

b. Containment atmosphere samples

c. Suppression pool atmosphere samples

d. Suppression pool liquid samples from the RHR system when in the suppression pool cooling mode

e. Reactor building (secondary containment) atmosphere.

The ability to obtain these samples does not rely on the use of any isolated contaminated auxiliary system.

Sample lines tie in upstream of automatic isolation systems and are provided with isolation valves operated from the control room. Routing is as direct as possible, and gas lines are heat traced. Long sweep bends and continuous pitch minimize plate- out, blockage, and dissociation of dissolved gases. Shielding is provided in areas where personnel exposure may occur.

Restriction devices are not being used because they are potential crud traps. The small size of the sample lines essentially serves as a flow limiter in case of line rupture.

The PASS sample station, as well as the sample return lines, are purged with either demineralized water or nitrogen gas after taking samples. This reduces the chance of system plugging, reduces radiation buildup by minimizing plate-out, and provides assurance of obtaining representative samples.

Return lines provide a closed loop and return any unused liquids to the suppression pool, and any unused gases to the suppression pool or secondary containment. Refer to Figure 11.4-6.

Postaccident containment sampling is accomplished by connecting into the primary containment monitoring system lines. These lines are routed from opposite sides within containment. The elevation and location on opposite sides of containment permit representative sampling of the upper portion of containment where gases could accumulate. The upper elevation also minimizes the probability of blockage should flooding of the containment occur. Sample nozzle blockage is reduced by pointing the nozzles downward, having the nozzles the same size as the pipes, and not installing traps or filters on the inlet. Recirculation is accomplished by a metal-bellows-type pump at the sample station that draws containment samples through the sample station and returns the sample back to containment.

Suppression pool atmosphere is sampled by tying into two 1-in. primary containment monitoring system lines that connect to suppression pool penetrations X-230 and X-231. The elevation, locations, and nozzle designs similar to primary containment sampling aid in ensuring a representative sample and in minimizing blockage. A pump separate from the primary containment sampling pump recirculates the sample from and back to the suppression pool.

The gas sample system is designed to operate at pressures ranging from subatmospheric to the maximum design pressures of the primary and secondary containments. Heat-traced sample lines are used to prevent the precipitation of moisture and to minimize plate-out.

The gaseous sample flow is chilled to remove entrained moisture, and a nominal grab sample can be taken for the determination of gaseous activity and for hydrogen or oxygen analysis by gas chromatography. A standard sample vial has been adopted for all gas samples to be consistent with present offgas sample vial counting factors. Provision has been made in the laboratory to aliquot fractions of the initial vial contents to other vials if the activity is too high to count directly.

A sample line is provided to obtain reactor coolant samples from two points (jet pumps 5 and 15) in the jet pump pressure instrument system when the reactor is at pressure. This sample location is recommended over the normal reactor sample points as the reactor cleanup system is expected to be isolated under accident conditions, and it is possible that the recirculation line containing the normal reactor water sample lines may be secured. The jet pump pressure system has been determined to be an optimum sample point for accident conditions. The pressure taps are well protected from damage and debris. If the recirculation pumps are secured, there is normally excellent circulation of the bulk of the coolant past these taps. The pressure taps are located sufficiently low to permit sampling at a reactor water level even below the lower core support plate.

In order to ensure that these pressure taps provide a representative sample, two conditions should exist:

a. Enough core flow to allow circulation of water from inside the shroud to the jet pump intake

b. No significant dilution by makeup water.

Two assumptions were made for this determination:

a. Reactor water level can be maintained at or near normal water level after the accident

b. Reactor power level is greater than 1 percent rated, up to approximately 10 percent rated, when the water sample is taken.

Regarding condition (a), after a small break or non-break accident, the reactor water level will be maintained at or near normal water level by the operator using emergency procedures. For decay power above 1 percent of rated power, the core flow is estimated to be greater than 10 percent rated recirculation flow due to natural circulation. This amount of core flow ensures the existence of a flow route from the core to the sampling points; it takes about 3 to 4 minutes to circulate the entire reactor water inventory through the jet pumps. Therefore, a representative sample of the core water will be available at the jet pumps.

Regarding condition (b), for small steam line breaks or non-break accidents, makeup water is pumped in to remove decay heat and to make up for steam loss through the break. This makeup water amounts to approximately 2 percent of the core flow present. Even for small liquid line breaks, the makeup water flow rate is estimated to be less than 18 percent of the core flow present. Therefore, it can be concluded that no significant dilution would occur; the bulk of the water going through the jet pump comes from the reactor core.

A single sample line is also connected to both loops in the RHR system. This provides a means of obtaining a reactor coolant sample when the reactor is depressurized and at least one of the RHR loops is operated in the shutdown cooling mode. To ensure that the sample is representative under these conditions, samples will be acquired after the reactor water level has been raised (approximately 18 in.) to the point where water flows from the steam separators. Similarly, a suppression pool liquid sample is obtained from the RHR loop lined up in the suppression pool cooling mode. These lines are installed on the discharge side of the RHR pumps, downstream of the pump check valves. The representativeness of the suppression pool sample is ensured by the following:

a. No safety/relief valves discharge directly into RHR suction

b. The selected RHR loop will be recirculated approximately 30 minutes prior to taking a sample

c. Sample lines are installed on the discharge side of the RHR pumps, downstream of the pump check valves.

Suppression pool atmospheric samples are taken from taps on opposite sides of the pool proper. Each tap location is selected to maximize the distance to either a downcomer or safety/relief valve discharge sparger.

The sample station is provided with a sump to collect spillage, should it occur. The sump drains into the collector, which is then emptied back into the suppression pool. The collector contains provisions for purging. Should contamination take place, the spread of the contamination is precluded by the fact that it is enclosed and shielded and returned via a closed loop to the suppression pool and the collector has the capability to be purged to eliminate any further contamination.

The PASS isolation valves are independent of automatic isolation or safety injection signals. These isolation valves are always maintained in a closed position by administratively controlled, key-locked pushbuttons in the control room and are opened only when required for sampling, training, maintenance, or testing. Valve position is indicated on the control panel and operability is ensured by the use of Class 1E power. The Target Rock isolation valves conform to IEEE 323-1974 and IEEE 382-1972, and are environmentally qualified. It is estimated that conformance to these requirements ensures the operability of the valves for the period when secondary containment is inaccessible.

11.4.4.4.2 Radiological and Chemical Analysis

Onsite radiological and chemical analysis is provided (in accordance with the guidelines of NUREG-0737 and Reg. Guide 1.97) to quantify source-term radionuclides in the nuclide categories as discussed in Regulatory Guide 1.3. In conjunction with gamma isotopic analysis, selected radionuclides are quantified for use in procedure 78.000.15 (determination of extent of core damage). Analysis of hydrogen levels in the containment and suppression pool atmosphere is performed by gas chromatograph. The PASS can provide diluted liquid samples, which will subsequently minimize personnel exposure during analysis. The sensitivity of onsite liquid sample analysis will permit the measurement of nuclide concentration from approximately 1 μCi/g to 10 Ci/g. Background radiation levels in the onsite laboratory are such that an acceptably small error, less than a factor of 2, will result during sample analysis. The instruments will provide the operator with the radiological and chemical status of the reactor coolant. A remote analysis facility is provided and has the same capabilities as outlined above. Confirmatory analysis may also be performed by an offsite facility.

Automatic, on-line, analytical-type monitors are not used in the PASS. The sample station control panel contains indicators for pressure, temperature, flow, radiation, and conductivity.

A Fermi 2 Radiation Chemistry procedure has been developed for estimating core damage based on the concentrations of volatile and nonvolatile radionuclides. By appropriately normalizing actual Fermi plant data with reference plant data under postulated LOCA conditions, an estimation of core damage can be provided.

11.4.4.4.3 Evaluation

The sample lines up through the second isolation valve are designed to the nuclear classification of the process lines to which they connect. Remote manual isolation valves are provided on these lines. The PASS system is not safety related.

11.4.4.4.4 Testing

The PASS is operated periodically to ensure operability. Operability is demonstrated by obtaining a liquid and gas sample consistent with plant operating mode.

11.4.4.4.5 Procedures

Procedures for sample collection, sample transfer or transport, and sample analysis have been prepared and are summarized below.

All liquid samples are taken into septum bottles mounted on sampling needles. The sample panel is basically a bypass loop on the sample purge line. In the diluted sample lineup, the sample flows through a conductivity cell (readable range 0.1 to 1000 µmho/cm) and then through a ball valve. Flow through the sample panel is established, the valve is rotated 90°, and a syringe is used to flush the sample plus a measured volume of diluent through the valve and into the sample bottle. This provides an initial dilution and supplies a sample for further dilution and subsequent counting on a gamma spectrometer. Alternatively, the flow can be diverted through a sample bomb to obtain a large, pressurized volume. This volume can be circulated and depressurized into a gas sampling chamber where the dissolved gases are stripped from the coolant sample. A gas sample can then be obtained for gas chromatography and quantitative analysis of the dissolved gases associated with the liquid volume. Aliquots of this degassed liquid can also be taken for offsite chemical analyses requiring a relatively large sample. A radiation monitor in the liquid sample enclosure monitors liquid flow from the sample station to provide immediate assessment of the sample activity level. This monitor also provides information as to the effectiveness of the demineralized-water flushing of the sample system following sample operation.

For gas samples, appropriate sample-handling tools are used within the sample station. A gas sampler vial positioner and gas vial cask are also used. The gas vial is installed and removed by the use of the vial positioner through the front of the gas sampler. The vial is then manually dropped into the cask with the positioner, which allows the vial to be maintained about 3 ft from the individual performing the operation.

For liquid samples, a small-volume liquid sample is remotely obtained through the bottom of the sample station by the use of the small-volume cask and cask positioner. The cask positioner holds and positions the cask directly under the liquid sampler. The sample vial is manually raised within the cask to engage the hypodermic needles. When the sample vial has been filled, the bottle is manually withdrawn into the cask. The sample vial is always contained within lead shielding during this operation. The cask is then lowered and sealed before transport to the laboratory.

A large-volume cask and cask positioner containing a nominal 25 ml bottle within a lead-shielded cask are also provided. This sample bottle is raised from its location in the cask to the sample station needles for bottle filling. The sample station will deliver approximately 10 ml to this sample bottle. When filled, the bottle is withdrawn into the cask. The sample bottle is always shielded by lead when in position under the sample station and during the fill and withdraw cycles; thus operator exposure is controlled.

The cask is transported to the required position under the sample station by a dolly cask positioner. When in position, this cask is hydraulically elevated by a small handpump for contact with the sample station shielding under the liquid sample enclosure floor. The sample bottle is raised, held, and lowered by a simple push-pull cable. The cask is sealed by a threaded top plug that inserts above the sample bottle. The weight of this large-volume cask is approximately 700 lb.

Sample radionuclide analysis is performed in a counting laboratory that is shielded to limit exposure rates under accident conditions. Prepared samples are introduced into a gamma isotopic analysis system for automatic peak search and identification. It is calibrated for geometries required for PASS samples under accident conditions.

A wet analysis/sample preparation facility is employed to prepare the sample. Equipment is provided to minimize exposure to personnel.

For extended storage of samples, a shielded facility is available in the laboratory.

The analytical laboratory has the capability to perform the following postaccident analyses on samples acquired from primary coolant, suppression pool and containment air. The analysis of post-accident samples utilize established, routinely-performed analytical procedures to ensure chemistry laboratory technician proficiency.

<u>Primary coolant</u>

Total activity

Gamma isotopic analysis

Dissolved hydrogen

pH

Conductivity

Dissolved oxygen (performed if chloride is greater than 0.15 ppm and dissolved hydrogen is less than 10 cm^3/kg)

Boron (performed if boron is injected)

Chlorides

Containment air

Hydrogen

Oxygen

Gamma isotopic analysis

A more specific discussion of each analysis is given below.

11.4.4.4.5.1 Gamma Isotopic and Total Activity Analysis

Gamma isotopic analysis of postaccident samples will follow normal counting room procedures. Gas samples will be counted in standard offgas sample vials, and liquid samples will be counted in standard sample bottles.

Previously established geometries and calibration curves for liquids and gases will be readily available and regularly updated. Gamma isotopic analysis will handle the acquired samples.

A total activity determination based on the gamma isotopic analysis will be used for the gross beta and gamma activity. The determination of total activity from the gamma isotopic analysis will minimize personnel exposure.

11.4.4.4.5.2 Dissolved-Hydrogen Analysis

Dissolved hydrogen will be determined by gas chromatography. Gas chromatography has been demonstrated to be successful in the determination of hydrogen in the presence of gamma radiation through testing and analysis by Babcock & Wilcox on TMI-2 post-accident gas samples.

11.4.4.4.5.3 pH Analysis

The pH will be determined by micro-pH probe. Confirmatory analysis may be performed by an offsite analytical laboratory.

11.4.4.4.5.4 Conductivity Analysis

The PASS is equipped with a 0.1-cm^{-1} conductivity cell. The conductivity meter has a linear scale with a six-position range- selector switch to give a conductivity range from 0.1 to 1000 μs/cm.

11.4.4.4.5.5 Dissolved-Oxygen Analysis

The dissolved oxygen concentration will be assumed to be less than 0.1 ppm if the measured positive hydrogen residual is greater than 10 cc/kg. If necessary or desirable, the oxygen concentrations will be measured directly, when ALARA conditions so permit.

11.4.4.4.5.6 Boron Analysis

Boron analysis will be performed by using the carminic acid colorimetric method, if boron injection is initiated.

11.4.4.4.5.7 Chloride Analysis

Chloride analysis may be performed by an offsite analytical laboratory.

11.4.5 Inservice Inspection, Calibration, and Maintenance

11.4.5.1 Inspections and Tests

During reactor operation, daily checks of monitor operability are made by observing channel behavior. At monthly intervals during reactor operation, the detector response of each monitor to remotely positioned check sources supplied as specified in the Offsite Dose Calculation Manual radiological effluent controls is recorded together with the instrument background count rate to ensure proper functioning of the monitors.

Some channels have electronic testing and calibrating equipment, which permits channel testing without relocating or dismounting channel components. An internal trip test circuit, adjustable over the full range of the readout meter, is normally used for testing. Each channel is tested at an interval specified in the Offsite Dose Calculation Manual radiological effluent controls prior to performing a calibration check. Verification of valve operation, ventilation diversion, or other trip function is done at this time if it can be done without jeopardizing plant safety. The tests are documented.

11.4.5.2 Calibration

Continuous radiation monitor calibrations are traceable to certified National Bureau of Standards or commercial radionuclide standards. The source-detector geometry during primary calibration approximates the sample-detector geometry in actual use. Secondary standards that were counted in reproducible geometry during the primary calibration are supplied with each continuous monitor for calibration after installation. The check sources have also been related to the primary standard. Each continuous monitor is calibrated every once per fuel cycle during plant operation, or during the refueling outage if the detector is not readily accessible, using the secondary radionuclide standard. A calibration can also be performed by using liquid or gaseous radionuclide standards or by analyzing liquid, particulate, iodine, or gaseous grab samples with laboratory instruments.

11.4.5.3 Maintenance

The channel recorders are serviced and maintained on a periodic basis or per manufacturers' recommendations to ensure reliable operation. Such maintenance includes cleaning, lubrication, and assurance of free movement of the recorder in addition to the replacement or adjustment of any components required after performing a test or calibration check. If any work is performed that could affect the calibration, a recalibration is performed at completion of the work.

11.4.5.4 Laboratory Radiation Detectors

Counting efficiencies of all laboratory radiation detectors are determined with certified radionuclide standards having accuracy better than 6 percent. The gamma isotopic analysis detectors are calibrated in terms of photopeak efficiency versus gamma energy and counting efficiencies for individual gamma emitters.

The response of each laboratory detector to alpha, beta, or gamma check sources is recorded during the primary calibration with the certified radionuclide standards. These check sources are fabricated to maintain their integrity during repeated handling. The response of each counter to the appropriate check source and the background count rate of each detector are determined at least weekly. A control chart showing check source response is maintained for each laboratory counter. A control chart showing counter background is maintained for each laboratory counter for which no automatic background correction of results is performed. Instrument responses falling outside statistical limits imposed by counting statistics are investigated and the instruments serviced as required.

TABLE 11.4-1 PROCESS RADIATION MONITORING SYSTEM (GASEOUS AND AIRBORNE MONITORS)

PRM Number	Monitor	Configuration	Type	Detector Sensitivity	Readout Range	Principal Radionuclides Measured	Expected Activity	Alarms & Trips	Control Function
1.	Primary Containment Radiation Monitor (GA)[a]	Offline						Low Flow	
	Gas (T50-N003)		β-Scint.	30 cpm/pCi/cm^3	10^1-10^7 cpm	Xe-133[b] Kr-85		Failure High	None
2.	Off-Gas Radiation Monitor (GE/Mirion)	Offline						Low Flow	
	Gas - Log Scale (N004A, N004B)		γ-Ion Chamber	3.7 x 10^{-10} Amp/R/h	10^0-10^6 mR/h	Xe-133 Xe-135 Xe-138	Off-gas activity defined in Table 11.3-1	Failure High High-High = (c)	None
	Gas - Linear Scale (N005)		γ-Ion Chamber	3.7 x 10^{-10} Amp/R/h	10^0-10^6 mR/h	Kr-85M Kr-87 Kr-88		None	
3.	Main Steam Line Radiation Monitor (GE) Steam (N006A, N006B, N006C, N006D) (N006E, N006F - Spares)	Adjacent to steam lines	γ-Ion Chamber	3.7 x 10^{-10} Amp/R/h	10^0-10^6 mR/h	N-16 O-19 Xe-133 Xe-135 Xe-138	Steam line activity defined in Section 11.1	Failure High = 1.5 x background High - High = 3 x background	1 High-High alarm in each trip system trips the gland seal exhausters and trips the condenser mechanical vacuum pumps and line valves. 2 High-High alarms in one trip system close the associated reactor water sample system valve.
4.	Reactor Building Ventilation Exhaust Radiation Monitor (GA)[a] Air (N408, N410)	Offline	β-Scint.	30 cpm/pCi/cm^3	10^1-10^7 cpm	Xe-133[b] Kr-85	Reactor Building activity defined in Table 11.3-1	Low Flow Failure High High-High = (c)	1 High-High or 2 (one from each detector) Low alarms start the SGTS, close the P/C vent valves, trip & isolate R/B vent system, isolate control center and initiate emergency recirculation mode for the control center ventilation system.
5.	Off-Gas Vent Pipe Radiation Monitor (GE) Gas (N105, N106)[e]	N/A	N/A	N/A	N/A			N/A	N/A
6.	Radwaste Building Ventilation Exhaust Radiation Monitor (Eber)[d] Air (N503A through N503G)	Offline	Part. Filter Iodine Filter α-Solid-State β-Scint. γ-Scint. 11.5 SOLID RADWASTE SYSTEM

The Fermi 2 Solid Radwaste System is intended primarily to process and package radwaste for ultimate burial/disposal. It could be considered as three separate systems. The first is for handling dry waste (DAW), whereas the other two are for handling waste resulting from processing liquids. One of these is a vendor supplied system, located in the radwaste onsite storage facility (OSSF), which normally processes liquid radwaste by dewatering or solidification, etc. The second is the asphalt-extruder process system, located in the radwaste building. Each of these systems would produce end products which can be shipped and disposed of in full compliance with the appropriate state and federal regulations.

Note: Section 11.5 describes the as-designed and as-installed design basis of the Radwaste Solidification System (asphalt extruder system). However, this system has never been operational. Pre-operational testing of this system was suspended in 1987 before testing was completed (see Section 14.1.1). Part of the system remains in place. Equipment was removed by modification (e.g., drum turntable, Drum Capper/Seamer, Transfer car, conveyors and conveyor drive units). The centrifuge feed line from the centrifuge feed tank is also capped by a modification. The original design-basis description, design data, figures, and tables for the solidification system are being retained in Section 11.5 and in other pertinent sections of this UFSAR as historical information. Currently, full-time “solid radwaste” processing takes place in the Onsite Storage Facility with a vendor-supplied system, as described in UFSAR Sections 11.5 and 11.7.

The installed Fermi 2 solid radwaste system is the radwaste volume reduction and solidification system, which was designed by the Werner-Pfleiderer Corporation; the volume reduction and solidification system is described in detail in a topical report (WPC-VRS-1) through Amendment II, approved for use as a reference by the NRC on April 12, 1978. This system, which includes the VRS-T 120 extruder/evaporator, is described in Subsection 11.5.3.2.16.7.

The key difference between the design described in the referenced topical report and the Fermi 2 design is the feed concept. The topical report describes a slurry feed, whereas the Fermi 2 plant was originally designed to use a centrifuge feed concept with a slurry feed as a backup. Subsection 11.5.3.2.16.2 describes the primary method of feed.

Three subsystems described in the topical report are not included in the Fermi 2 scope of supply. First, the distillate skid has been replaced by a process that returns the water to other parts of the radwaste system for cleanup. Second, the lubrication oil skid was eliminated by using an extruder gear box design with integral lube oil circulation capability. Third, the overhead bridge crane listed in the topical report has been replaced with a monorail.

11.5.1 Design Objectives

The objectives of the solid radwaste system are to collect, process (solidify or dewater), and package liquid and wet solid wastes and slurries from the liquid radwaste system, the reactor water cleanup (RWCU) system, the fuel pool cooling and cleanup system, and the condensate demineralizer system. The solid radwaste system collects and processes the increased volumes of wastes and slurries that are produced during anticipated operational occurrences without affecting the operation or availability of the plant. It processes, packages, handles, and temporarily stores radioactive wastes and provides a means to transfer solidified or dewatered wastes to vehicles for transport ultimately to an offsite burial facility.

A subsystem also packages, stores, and prepares for transport compressible dry wastes generated during operation of the plant. These wastes include paper, rags, and other disposables that are normally processed conveniently by compaction.

The process equipment and disposable containers prevent the release of significant quantities of radioactive material, and keep the radiation exposure of plant personnel and the general public as low as reasonably achievable (ALARA).

The system is designed to:

a. Collect and solidify or otherwise process radioactive wastes, which consist primarily of evaporator bottoms, filter backwash, tank sludge letdown, and spent resins

b. Provide for the transfer of decantate, resin sluice water, etc., to the liquid radwaste system for processing and eventual reuse or controlled discharge

c. Package, handle, and temporarily store processed, solidified, and compressed radioactive wastes generated as a result of normal operation of the plant, including those from anticipated operational occurrences

d. Provide a means to transfer the packaged wastes to vehicles for transport ultimately to an offsite burial facility

e. Package radioactive wastes in a manner that will allow shipment and burial in accordance with all applicable federal and state regulations

f. Provide means for processing or the solidification of wet wastes that results in freestanding water in the final product less than that required for disposal

g. Provide means to transfer wet wastes to the vendor-supplied system in the OSSF

h. Compact dry waste in a container that is suitable for transportation and eventual burial

i. Protect plant personnel from radiation exposure and incorporate the basic ALARA principles through the use of automated systems, shielding, and remotely operated instrumentation and controls.

Fermi 2 is operated in accordance with its process control program (PCP). The purpose of this PCP is to provide reasonable assurance of the complete solidification, encapsulation, or dewatering of processed wastes and the absence of free water in excess of required limits in the processed waste. For vendor-supplied processing services, a PCP approved by Edison in accordance with Section 17.2 will be utilized. This is described in greater detail in Subsection 11.5.6.

11.5.2 System Inputs

Table 11.5-1 lists the conservative values for all major inputs to the solid radwaste system. This table shows that the majority of the input to the solid radwaste system is from the condensate filter-demineralizer backwash when the two etched-disk filters are in use. On the other hand, when the precoat filters are used in place of the etched-disk units, their inputs would be the largest contributor to the totals.

11.5.3 System and Equipment Description

11.5.3.1 System Description

11.5.3.1.1 General

The solid radwaste system collects, processes, and packages the liquid wastes, wet solid wastes, and slurries from the liquid radwaste system, the RWCU system, the fuel pool cooling and cleanup system, and the condensate demineralizer system. The solid waste package produced by the process must be suitable for transportation to an offsite burial facility. In the course of processing liquid inputs, the solid radwaste system must be able to separate solids from the incoming slurries, which maximizes the amount of liquid that can be returned to the liquid radwaste system for recycling to the plant.

The solid radwaste system will receive periodic inputs from a variety of plant sources. Since the operator should know in advance of major impending inputs of waste batches to the solid radwaste system, system operation can usually be planned before most inputs are received.

The design and classification of the solid radwaste system is essentially the same as the liquid system, and therefore the general discussion of Subsection 11.2.3.1 applies also to the solid system. The principal design parameters for the major components are listed in Table 11.5-2.

The inputs to the solid radwaste system consist of filter backwashes of several types, evaporator concentrates, and spent bead resin. By volume, most of this input is liquid. A major goal of the solid radwaste system is to allow solids in the liquid inputs to settle, leaving a relatively clear decantate, which is sent to the liquid radwaste system for processing. The remaining solids are pumped to an intermediate set of collection tanks from which the sludge (resin beads, powdered resin, and tank sludge) is pumped for final processing, either to the vendor system in the OSSF or to the asphalt solidification system. With the centrifuge currently in a non-functional configuration, the wet waste can be forwarded directly to the solidification process, where the liquid is driven from the waste, leaving only a dry, solid product. One exception to this process is the evaporator concentrates source, which is pumped directly to the solidification process without an intermediate solids settling step. The drains from the high-chloride laboratory are also fed directly to the extruder/ evaporator via the chloride waste tank and the concentrates feed tank.

For the installed system, asphalt is used as the solidification binder. The asphalt and waste are heated and mixed in an extruder/evaporator that simultaneously removes the remaining moisture from the waste while producing a homogeneous product. When the asphalt/waste mixture cools, it forms a solid, homogeneous product that has no freestanding water. The asphalt storage tank is located at grade, on the north side of the radwaste building, opposite the floor drain filter. The radiation zone in this area is designed to be less than 1 mrem/hr and is therefore in compliance with Branch Technical Position (BTP) ETSB 11-3, which states that solidification agents should be stored in low-radiation areas that are less than 2.5 mrem/hr.

11.5.3.1.2 Solid Radwaste System Process Rates

The solid radwaste system uses a batch-type process. Individual batches of inputs from the sources listed in Table 11.5-1 are delivered to the solid radwaste system collection tanks. The radwaste operator will be aware of an expected input for the etched-disk filter backwash, which occurs automatically, and also for the waste collector and floor drain precoat filter backwashes. Thus, the minimum processing rates required for the solid radwaste system components are based on the system's ability to pump out a tank of its decantate, sludge, or bead and powdered resin in a time frame consistent with the incoming batch frequency.

In several cases, the solid radwaste system processing rate and pump size are determined by the recirculation conditions needed to mix tanks or by the flow rate needed to avoid plugging. Design parameters for components of the solid radwaste system are given in Table 11.5-2.

11.5.3.1.3 Chemistry of Inputs

The chemical characteristics of the solid radwaste system sources are dominated by their high concentrations of suspended and dissolved solids. Most of the suspended solids consist of spent powdered and bead resin particles, which usually are fairly large, at least 45μ. Dissolved-solids concentrations from the evaporator are expected to average less than 8 percent by weight. Table 11.5-1 lists the assumed batch solids content of each stream.

The pH of all streams except the evaporator concentrates is expected to be fairly neutral, between 6 and 8. The pH of the waste in the chloride waste tank is neutral because it will be preneutralized in the laboratory before draining to the tank. The evaporator-concentrates stream pH could fluctuate extensively, and therefore can be adjusted to the range 7 to 9 before processing by the extruder/evaporator. The pH of the feed to the extruder/evaporator process is controlled only to protect the machine's construction materials.

11.5.3.1.4 Dry Wastes

Typical values of the radionuclide content and volumes of dry solid waste for BWRs are provided in the table below:

Radionuclide Content and Volumes of Dry Solid Waste

Radionuclide	Activity (percent)	Total Annual Activity (Ci)
58_{Co}	24.0	0.96
60_{Co}	7.2	0.29
51_{Cr}	62.0	2.48

Radionuclide Content and Volumes of Dry Solid Waste

Radionuclide	Activity (percent)	Total Annual Activity (Ci)
^{95}Nb	6.8	0.27
^{137}Cs	traces	--
Total	100.0	4.00

The data in the table were obtained from AIF/NESP-0800, "A Survey and Evaluation of Handling and Disposing of Solid Low- Level Nuclear Fuel Cycle Wastes," October 1976. An average gross curie content of 1.0 Ci/1000 ft^3 was used in the above estimate. This was obtained from a range of 0.001 to 4.0 Ci/1000 ft^3 (obtained from the above reference). The average volume of compacted trash is given in the above reference as 6000 ft^3/yr. If the data are corrected for skewing, an average of 4000 ft^3/yr is obtained; this average was used. The volume of trash generated per year is primarily a function of housekeeping activities and is not heavily influenced by plant size. It should be noted that the Fermi 2 design includes a high-efficiency compactor. The 6000 ft^3/yr number is suspect, and it probably includes dry trash that has not been compacted. The 4000 ft^3/yr number agrees fairly well with the annual upper limit of 500 drums (3700 ft^3) from "A Study of Nuclear Fuel Cycle Radioactive Solid Waste Management," NESP Low-Level Waste Handling and Disposal Alternatives, March 1976.

Dry wastes (usually of low activity) can normally be handled by direct contact. These wastes are collected in bags or containers located in appropriate zones at certain locations within the plant, as determined by the volume of waste generated during plant operation and maintenance. The filled waste containers are sealed and transported for further processing.

Compressible, dry, low-activity wastes can be compacted into standard 55-gal drums by a hydraulic compactor. First, an empty drum is placed on the support plate at the front of the compactor and is moved into position under the ram by a hydraulic cylinder. Then a hinged work table is swung into position against the drum, clamping it in place and providing a seal for the air space above the drum that holds loose waste in place for compaction. Loose waste is deposited in the drum through an access door above the work table. Finally, the access door is closed and locked, and the loose waste is compacted.

An air evacuation system provided by a built-in fan prevents the escape of airborne contaminants generated during the compaction cycle. The fan directs the air trapped above the drum through a roughing filter and 0.3-μm high-efficiency particulate air (HEPA) filters. Differential pressure gages on the compactor control panel indicate when the filters require replacement. Used filters are normally dropped into a drum and compacted.

Noncompressible wastes are normally packaged in strong, tight containers. Because of its low activity, this waste can be stored until enough is accumulated to permit its economical transport to an offsite burial ground for final disposal. During outages or other heavy trash-generating periods, or for packaging of large pieces of noncompactible materials, boxes may also be used to limit handling and ensure packaging efficiency.

Activated charcoal, HEPA filters, and other dry wastes are treated as radioactively contaminated solids. Those that normally do not require solidification processing are packaged and disposed of in accordance with applicable regulations.

11.5.3.1.5 Wet Wastes

Wet wastes consist of spent bead and powdered resins, filter sludge, and evaporator concentrates (when running). They normally result as by-products from liquid processing systems and contain liquid components that require immobilization or removal. By evaporating the liquid components and combining the residues with the asphalt binding agent when the asphalt-extruder system is used, a homogeneous solid matrix of reduced volume and free of water is developed prior to offsite shipment. When the vendor-supplied system is used, wastes can be dewatered or solidified.

Spent cartridge-filter elements may be packaged in a shielded receptacle containing a suitable absorber. If necessary, they will be stored and shipped in the same manner as other radwaste in accordance with applicable regulations.

11.5.3.1.6 Irradiated Reactor Components

Because of its high activation and contamination levels, used reactor equipment is normally stored in the spent-fuel storage pool to allow sufficient radioactive decay before its removal to in-plant or offsite storage and its final disposal in shielded containers or casks.

11.5.3.2 Equipment Description

11.5.3.2.1 General

The selection of the solid radwaste system process components was based on the primary process requirement to dewater solid-laden waste inputs. The process of removing the moisture from the solid waste streams provides a volume reduction of the incoming feed, thus reducing the ultimate amount of waste to be disposed of. The liquid generated by the dewatering processes is returned to the liquid radwaste system for further processing.

Solid wastes are collected in several different ways. Liquid wastes with a low solid content are received in the condensate phase separators, where they are allowed to settle; then the clarified decantate is pumped to the waste clarifier tank. Over-flow from the clarifier tank is directed into the waste surge tank and finally into the liquid radwaste system (waste collection subsystem). The sludges from all three tanks are normally fed to the centrifuge feed tank. Other wastes with higher solids content are added to this basic line at intermediate points. The sludge from the RWCU phase separator is fed directly to the centrifuge feed tank. The spent-resin tank feeds either the centrifuge feed tank or the spent-resin slurry feed tank, which feeds directly into the extruder/ evaporator. The evaporator bottoms and the chloride wastes are fed to the concen-trate feed tank, where a caustic is added for neutralization, before they are pumped into the extruder/evaporator.

The two condensate phase separators perform a primary clarification of the waste sources that contain high suspended solids (excluding evaporator bottoms and exhausted demineralizer bead resins). After collection, the wastes are allowed to settle, clarified liquid is decanted off the top, and sludge is drawn off the bottom.

The waste clarifier tank performs a secondary clarification of condensate phase separator decantate and other wastes with low concentrations of suspended solids. The influent wastes flow through the waste clarifier tank, where the solids settle to the bottom and the clarified liquid overflows into the waste surge tank. From the waste surge tank, the clarified liquid is forwarded to the waste collector subsystem for processing. Sludge collected in the bottom of the clarifier tank is pumped out periodically to the centrifuge feed tank. Any solids that might collect in the waste surge tank can be blown down to the condensate phase separators. The waste clarifier tank also provides a source of relatively clear water, which is used for diluting the contents of the centrifuge feed tank and transporting resins from the spent-resin tank.

The spent-resin tank receives bead-type ion-exchange resins and demineralizer flushes that are produced by dumping the exhausted floor drain and waste collector demineralizer beds. The spent resins and flush water are forwarded to the centrifuge feed tank.

To summarize, the centrifuge feed tank receives concentrated sludges from the condensate phase separators, waste clarifier tank, cleanup phase separators, and spent-resin tank. The feedtank contents are mixed by recirculation and mechanical agitation to give a consistent concentration; a side stream is taken off the recirculation loop for ultimate processing, either to the vendor equipment in the OSSF or to the asphalt-extruder system. When the extruder system is used, high dissolved-solid waste from the concentrates feed tank is sent to the unit, where the waste is dried and mixed with asphalt. The asphalt/solid mixture is emptied into drums that are capped and sent to storage for eventual offsite disposal. Distillate from the evaporation process is returned to the waste clarifier tank. The sludge, originally routed to the centrifuge for dewatering, can be routed directly to the extruder/evaporator. Similarly, spent resin can be routed to the alternative spent-resin slurry feed tank for forwarding to the extruder/evaporator.

11.5.3.2.2 Normal Waste Generation and Holdup Rates

For normal waste generation rates, the holdup capacity provided in the radwaste system for spent resins and filter-demineralizer sludges is described below.

11.5.3.2.2.1 Sludge Collection

The RWCU system has two phase separators, each designed to hold the sludge from 10 RWCU filter-demineralizer backwashes (a total of about 580 lb of sludge).

In addition to the RWCU phase separators, there are two condensate phase separators in the radwaste building, each estimated to have a sludge holdup capacity of approximately 5400 gal, or 2250 lb of solids at a 5 weight-percent concentration.

Total input to the condensate phase separators will depend upon whether the precoat filters or the etched-disk filters are in use, since the precoat filters generate more waste volume. Based upon the conservative design values for input water quality (TSS, TDS), the estimated design inputs are as follows:

Condensate filter-demineralizer backwashes	214 lb/1.3 days	4940 lb/30 days
Fuel pool filter-demineralizer backwash	65 lb/10 days	195 lb/30 days
Floor drain precoat filter backwashes	17 lb/batch 11 batches/day 187 lb/day	5610 lb/30 days
Waste collector precoat filter backwashes	28 lb/batch 1.5 batches/day 42 lbs/day	1260 lb/30-days
Floor drain etched-disk filter backwashes	2.64 lb/batch 6 batches/day 15.9 lb/day	475 lb/30-days
Waste collector etched-disk filter backwashes	1.0 lb/batch 3.7 batches/day 3.7 lb/day	111 lb/30-days
Total solids generated for 30 days		5,721 or 12,000 lb

Conservatively estimated, overall solids input (over 30 days) to the condensate phase separators averages 12,000 lb when the precoat filters are used, and 5,721 lb if the etched-disk filters are used (in their un-precoated design condition).

With the etched-disk filters in use at the estimated normal solids-generation rates, both condensate phase separators would be full in approximately 23 days (about 12 days each per separator). At this time, the contents of one of the condensate phase separators would be transferred to the centrifuge feed tank in preparation for processing through the volume reduction and solidification system. The centrifuge feed tank has a working capacity of approximately 6000 gal, which is equivalent to about 2500 lb of solids at 5 weight-percent concentration. The phase separator just emptied would then have a solids-accumulation capacity of approximately 12 days at normal sludge-generation rates. Thus, the total solids holdup capacity of the two condensate phase separators and centrifuge feed tank is approximately 35 days.

11.5.3.2.2.2 Spent-Resin Collection

Spent resins are produced in the floor drain and waste collector demineralizers. Each of the two demineralizers is estimated to produce about 2250 lb of spent resin once every 16 days, or a total of about 8500 lb of spent resin every 30 days. The spent-resin tank and the spent-resin slurry feed tank can each accommodate two batches of spent bead resin, or a total of about 9000 lb.

11.5.3.2.3 Waste Clarifier Tank and Condensate Phase Separator Tanks

The waste clarifier tank collects decantates primarily from the condensate and RWCU phase separators and the centrifuge to allow solids carried over to settle. It also provides the source of the dilution water for adjusting the solids concentration in the centrifuge feed tank and the source of carrier waste for sluicing resin from the spent-resin tank.

The condensate phase separators provide for an undisturbed period during which the solid materials that enter the vessels as slurries can settle to the bottom. After the settling period, the clarified water can be decanted off to allow enough volume for the receipt of the next slurry input. The units are designed to enable measurements of the quantities of sludge and water they contain, to adjust (by decanting) the sludge concentration, and to mix the water and sludge to a uniform slurry so it can be transferred to the centrifuge feed tank for further processing. To accomplish these functions, additional auxiliary equipment including: level instrumentation, decant pumps, sludge discharge and mixing pumps, and an internal arrangement of mixing educators is provided.

11.5.3.2.4 Waste Surge Tank

The 65,700-gal-capacity waste surge tank accumulates input surges from the waste collector and floor drain collector subsystems. However, its primary function is to receive the overflow from the waste clarifier tank. Periodically, it receives the wastewater from the reactor well drain, one of the radwaste emergency drain sumps, and off-standard recycle from the waste sample tanks.

The waste surge tank also can receive inputs from the RWCU system during reactor startup.

The waste surge tank can hold the maximum daily input from the floor drain collector subsystem, the waste collector subsystem, or the solid radwaste system via the waste clarifier tank. The largest of these inputs is from the waste clarifier tank, from the condensate filter-demineralizer backwash during reactor startup. Including other design daily inputs, the estimated maximum daily input would then be 52,368 gal.

11.5.3.2.5 Centrifuge Feed Tank (See also Subsection 11.5.3.2.16.2)

This tank collects the sludge and wastewater containing high suspended solids from the condensate phase separators, waste clarifier tank, RWCU phase separators, and spent-resin tank and, if required, adjusts the solids content in the water in the range of 5 percent by weight by diluting it with decant water from the waste clarifier tank.

The contents of this tank are processed to the vendor solidification system located in the OSSF. With the isolation of the centrifuge, the contents of the tank can be processed directly by the solid radwaste system extruder/evaporator after decanting the contents to approximately 15 percent by weight.

The centrifuge feed tank is equipped with a mechanical agitator which, together with the mixing flow provided by the centrifuge feed/recirculation pumps, ensures a uniform slurry concentration in the tank.

The largest batch input to the centrifuge feed tank-5400 gal- is from the condensate phase separator. The contents of the tank are processed in a batch operation. The tank has a capacity of approximately 6000 gal.

11.5.3.2.6 Spent-Resin Tank (See also Subsection 11.5.3.2.16.4)

This tank collects the spent resin from the floor drain and waste collector demineralizers. The collected spent resin is transferred either to the centrifuge feed tank or to the slurry feed tank for further processing.

The spent-resin tank is sized to accommodate two batches of spent resin and sluicing water from either the floor drain or the waste collector demineralizer. One resin bed, including wastewater, occupies approximately 700 gal. The tank has a capacity of 1400 gal, which allows a contingency for accommodating an additional batch.

11.5.3.2.7 Chloride Waste Tank

The chloride waste tank can collect laboratory waste containing chlorides, mainly hydrochloric acid. Chloride waste can be segregated from other chemical wastes and drained directly to this tank. The waste is normally preneutralized in the laboratory before drainage. This waste can be segregated from others in the liquid radwaste system because its high chloride content could have a deleterious effect on equipment and stainless steel materials, particularly the evaporator.

The estimated monthly input to the tank is about 300 gal, reflecting the design daily volume of 10 gal. The tank volume of 250 gal requires pumping out the contents to the concentrates feed tank about once per month.

11.5.3.2.8 Condensate Phase Separator Decant Pumps

The condensate phase separator decant pumps decant the clear liquid from the condensate phase separator tanks and transfer it either to the waste clarifier tank or to the condenser hotwell (during startup only).

The pumps are designed to pump the volume of condensate demineralizer backwash decantate to the waste clarifier tank in about 0.5 hr. Either pump can also be used to pump back to the condenser hotwell, as determined by reactor-startup conditions. This ensures that the decantate can be removed before receipt of the next batch. These two pumps are shared by the two condensate phase separator tanks.

11.5.3.2.9 Condensate Phase Separator Sludge Discharge Mixing Pumps

The condensate phase separator pumps transfer the sludge from the condensate phase separators to the centrifuge feed tank and, at the same time, recirculate part of the sludge through mixing eductors in the condensate phase separator to keep the sludge mixed homogeneously.

The capacity of the pumps is based on the recirculation flow requirements to keep powdered resin in suspension and to transfer sludge to the centrifuge feed tank. The solids content during sludge transfer is in the general range of 5 percent by weight. Two 100 percent-capacity pumps are shared by the two condensate phase separator tanks.

11.5.3.2.10 Chloride Waste Pump

The chloride waste pump transfers the chloride waste collected in the chloride waste tank to the concentrates feed tank. The pump rating of 35 gpm was based on emptying the chloride waste tank in less than 10 minutes.

11.5.3.2.11 Centrifuge Feed and Recirculation Pumps

The centrifuge feed and recirculation pumps perform the following functions:

a. Mix the contents of the centrifuge feed tank by recirculating the slurry back to the tank through the mixing eductors

b. Decant the clear liquid from the centrifuge feed tank to the waste clarifier tank

c. Provide a constant flow and slurry concentration when feeding to the vendor station in the OSSF or the waste-slurry metering pump.

The capacity of the pumps is determined by the flow through eductors that is needed to keep the powdered and bead resin in suspension.

11.5.3.2.12 Slurry Dilution Pump

The slurry dilution pump provides dilution water to either the centrifuge feed tank or the spent-resin tank, taking suction from the waste clarifier tank. It can also be used to spray the waste clarifier tank bottom to assist in sludge removal. The pump capacity is based on the maximum dilution-water requirement for centrifuge feed tank operation. (The spent-resin tank requires approximately 30 gpm of dilution water.)

11.5.3.2.13 Waste Clarifier Sludge Pump

The waste clarifier sludge pump transfers sludge from the waste clarifier tank to the centrifuge feed tank. It is also used as a backup to the spent-resin transfer pump to pump the contents of the spent-resin tank to the centrifuge feed tank.

11.5.3.2.14 Spent-Resin Transfer Pump

The spent-resin transfer pump transfers the spent resin from the spent-resin tank either to the centrifuge feed tank or to the slurry feed tank. It can also be used as a backup for the waste clarifier sludge pump to pump clarified sludge to the centrifuge feed tank.

11.5.3.2.15 Centrifuge

The centrifuge, in its design configuration, dewaters the slurry of either spent bead resin or powdered resin fed by the centrifuge feed/recirculation pump so that dry solid is fed to the extruder/evaporator. Dewatering the slurry by centrifuging will maximize the solids processing rate through the extruder/evaporator.

The centrifuge is designed to dewater slurries consisting of either bead resin or spent precoat-filter cake to 40 percent to 50 percent of dry solids in the cake. The estimated recovery of solids in the cake is about 98.5 percent. The water content in the centrifuge cake has an upper limit to match the evaporative capacity of the extruder-evaporator (rated at 0.53 gpm). The centrifuge feed rate is controlled, on the basis of the percent of solids in the feed, to achieve this maximum moisture input to the extruder/evaporator, thereby ensuring that its nominal evaporative capacity is not exceeded.

11.5.3.2.16 Extruder/Evaporator Volume Reduction and Solidification System

11.5.3.2.16.1 General

The extruder/evaporator volume reduction and solidification system (VRS) is designed to perform the following functions:

a. Accepts waste inputs from the liquid radwaste system evaporator and chloride waste tank via the concentrates feed tank as well as waste in slurry form from the centrifuge feed tank

b. Accepts dewatered solid waste inputs from the centrifuge or slurry inputs (approximately 50 percent by weight) from the slurry feed tank

c. Removes moisture from waste feed while homogeneously mixing the waste with asphalt

d. Discharges the asphalt/waste mixture into 55-gal drums where the waste product cools to form a solid mass with no freestanding water

e. Crimps the 55-gal drums to form suitable containers for offsite disposal

f. Returns the cooled distillate resulting from the evaporative process to the waste clarifier tank.

The nominal rated capacity (120 liters per hr) of the VRS-T 120 is for evaporative liquid. A weight percent of solid to liquid is present in each incoming stream so that the amount of incoming water does not exceed the capacity of the extruder/evaporator. The mass flow rate into the centrifuge, by design, is controlled so that the moisture input to the extruder/evaporator, in the form of chemical-bound and surface-bound water, does not exceed its evaporative capacity.

The VRS is designed to process the radioactive wastes from the solid radwaste system collection tanks described above. The principal types and quantities of wastes processed have been estimated in the design as follows:

a. Concentrates Feed Tank

Volume/batch	800 gal
Annual volume	34,679 gal

b. Bead Resin

Volume/batch, dewatered	49 ft^3
Resin type	Rohm & Haas IRN-150 or equivalent
Annual volume	6500 ft^3 (50,000 gal)

c. Powdered Resin

1. Condensate Phase Separators

Batch weight, dewatered	2250 lb
Annual quantity, dewatered	64,800 - 137,000 lb
	(10,300 - 21,800 gal)

2. Reactor Water Cleanup Phase Separators

Batch weight, dewatered	580 lb
Annual quantity, dewatered	3480 lb
	(575 gal)

The volume reduction and solidification system includes the following subsystems:

a. Centrifuge feed system (when functional)
b. Concentrate feed system
c. Spent-resin slurry feed system
d. Asphalt feed system
e. Auxiliary steam system
f. Extruder/evaporator and utility manifold
g. Steam-dome boilout system
h. Cooling water booster pumps
i. Fill station/drum-handling system (Equipment removed by modification)
j. pH adjustment system.

Figures 12.1-3, Sheet 2, and 12.1-4 show the general layout of this equipment.

11.5.3.2.16.2 Centrifuge Feed System

The centrifuge feed system feeds radwaste resin and sludge to the extruder/evaporator, normally in a dewatered form. The slurry feed system acts as a backup.

A homogeneous solution of radwaste resin and sludge slurry, ranging from 2 percent to 15 percent by weight, is recirculated around the centrifuge feed tank. A tap is taken from this recirculation line to feed the extruder, directly in slurry form. The designed primary extruder feed method is to distribute the slurry to the centrifuge, where all free water is removed. The slurry cake is then gravity fed to the extruder/ evaporator. A valve in this gravity line diverts all washdown during flushing operations to the waste clarifier tank. The backup extruder feed method is to feed the recirculated radwaste slurry solution directly to the extruder/evaporator via the waste slurry metering pump. In both feed methods, asphalt is fed simultaneously; flow rates are proportioned.

11.5.3.2.16.3 Concentrates Feed System

The concentrates feed system collects and feeds concentrates from the evaporator and the chloride waste tank when these systems are in use.

The 1500-gal concentrates feed tank receives the radwaste concentrate directly from the evaporator, from the evaporator drain holdup tank, and from the chloride waste tank. This solution is recirculated by the concentrates recirculation pump back to the tank to keep a homogeneous solution. Caustic can be injected into the solution in the recirculation line to adjust the pH.

A tap is taken from this recirculation line to feed the extruder/evaporator through the concentrates metering pump. Asphalt is also fed to the extruder/evaporator simultaneously to provide the correct mix.

The concentrates feed tank has electrical strip heaters on its bottom head, and all lines are electrically heat traced to keep the solution at about 165°F.

11.5.3.2.16.4 Spent-Resin Slurry System

The spent-resin slurry feed tank collects bead resin from the spent-resin tank, prepares the resin slurry to a fixed concentration (normally 50 percent by weight), and feeds the slurry to the extruder/evaporator.

A slurry containing approximately a 25 percent by weight concentration of spent bead resin is transferred from the existing spent-resin storage tank to the spent-resin slurry feed tank. A decanting operation is performed to increase the slurry concentration. This operation reduces the carrier water before the resin slurry is fed to the extruder. Due to the distance between the spent-resin slurry feed tank and the extruder/evaporator, a resin recirculation loop is provided to maintain the bead resin in a homogeneous slurry form. This loop is routed from the spent-resin slurry feed tank to near the extruder and back to the tank; a positive displacement progressive cavity pump is provided for this recirculation.

The spent-resin slurry feed tank is equipped with decant screens. A vertical in-line centrifugal decant pump removes water from the resin to adjust the concentration of resin in the tank to the normal value of about 50 weight percent.

A turbine agitator supplied with the tank keeps the contents thoroughly mixed. The tank also has connections for flushing and for fluffing the resin bed, if required.

A line tap is taken from the recirculation line for feeding the extruder/evaporator through the spent-resin slurry metering pump.

11.5.3.2.16.5 Asphalt Feed System

Asphalt is used as the binder material for the radwaste resins and evaporator concentrates. It is fed to the asphalt storage tank from a tanker through the duplex fill strainer. The 9000-gal bulk-storage asphalt tank is equipped with four externally mounted steam-heating panels. These removable panels maintain the temperature in the tank at approximately 325°F so the asphalt is a pumpable liquid.

The asphalt storage tank is located at grade, outside the radwaste building. Its radiation zone is designed to be less than 1 mrem/hr. The tank is located on the north side of the radwaste building, opposite the floor-drain filter.

A positive displacement pump recirculates the asphalt through a duplex recirculation strainer back to the storage tank to keep a homogeneous, clean flow. A backup positive displacement recirculation pump acts as an operational spare.

Two lines are tapped into the recirculation line to feed the asphalt metering pumps, which are positive displacement pumps that feed directly to the extruder/evaporator. A flow element exists in the feedline. A signal from any of the three radwaste slurry flow elements is sent to a flow ratio controller to establish automatically a proper waste/asphalt mix ratio, via asphalt pump speed control.

All lines in this system are steam traced, and all pumps and strainers are steam jacketed. The steam comes from the solid radwaste system electric auxiliary boiler.

All asphalt valves in this system are the plug type.

11.5.3.2.16.6 Auxiliary Steam System

The auxiliary steam system supplies steam at approximately 400°F and 230 psig to the following:

a. The extruder/evaporator steam domes and barrels

b. The asphalt tank and asphalt supply system (at reduced pressure).

This steam is used to heat the extruder/evaporator to promote the evaporation of water from the radwaste feed. Steam at a reduced pressure is used to heat the asphalt storage tank and to heat trace the asphalt transfer and metering lines so that the asphalt is maintained at approximately 325°F. The auxiliary boiler system is a packaged unit. Demineralized makeup water is provided from plant sources. The blowdown of the boiler is via a flash tank; subsequent discharge is directed to the floor drain sump. Twin boiler feed pumps ensure reliable system operation.

11.5.3.2.16.7 Extruder/Evaporator and Utility Manifold

The heated extruder/evaporator mixes the liquid radioactive wastes with asphalt. It also evaporates free and chemically bound water from the mixture and homogeneously disperses the waste residues in the asphalt matrix. The utility manifold distributes steam to heat each barrel section and distributes cooling water to the feed barrels, discharge barrel, and vapor condensers in the steam domes.

The extruder/evaporator and utility manifold consist of three basic sections, as follows:

a. The drive section provides counter-rotating torque to the screw shafts of the extruder/evaporator

b. The process section evaporates water and transports and mixes the waste/asphalt mixture

c. The extruder/evaporator manifold, a skid-mounted assembly, has cooling water, steam, and condensate supply and return headers, distribution piping, associated temperature control valves, solenoids, and manually operated valves. Flow rates of cooling water and steam required to maintain the operating temperature in the extruder/ evaporator barrels are controlled by temperature elements in the extruder/evaporator. These elements modulate the steam or water control valves, as required. There are two levels of steam pressure on the manifold. The first is for the extruder/evaporator process section heating, which is about 230-psig steam, supplied from the auxiliary boiler; the second, for cleaning the dome devolatizing ports, is about 150-psig steam supplied from a self-contained pressure regulator mounted on the manifold.

   A condensate collection system is provided with associated valves, strainers, and steam traps. The condensate is returned to the condensate return tank on the auxiliary boiler skid, and from there it is returned to the auxiliary boiler.

11.5.3.2.16.8 Steam-Dome Boilout System

The steam-dome boilout system cleans and removes any salt sediment that might accumulate in the steam-dome ports.

This system supplies a predetermined amount of demineralized water through the respective port connection to the steam domes. It consists of a wall-mounted frame supporting a feed tank, a piping manifold, and remotely operated valves. It is operated from the main control panel. The tank is filled with water when the operator opens the tank inlet valve. When the water reaches a preset level, the valve is closed automatically by a signal from the level switch. The operator starts the boilout of one of the three steam domes by opening the valve in the distribution line to the dome to be cleaned. The boilout water flows by gravity to the selected dome. When the operator releases a pushbutton, the boilout cycle terminates automatically by closing the same valve. This sequence is repeated for the domes remaining to be cleaned.

11.5.3.2.16.9 Cooling Water Booster Pump System

This system increases the supply pressure of cooling water to approximately 105 psig (at a temperature of 85°F) to the following equipment via the utility manifold:

a. The extruder/evaporator domes

b. The extruder/evaporator feed and discharge barrels.

Note: This system has been deactivated. The Turbine Building Closed Cooling Water (TBCCW) supply line has been terminated in the turbine building and the wall penetrations have been reused to supply General Service Water (GSW) to the Side Stream Liquid Radwaste System.

11.5.3.2.16.10 Fill Station and Drum-Handling System (Equipment removed by modification)

The fill station and drum-handling system

a. Positions a drum under the extruder for filling
b. Provides ventilation of the drum being filled
c. Provides visual monitoring of the drum-filling process
d. Provides a remote indication of the drum level
e. Provides temporary storage for cooling on the turntable
f. Provides an automatic/manual indexing operation
g. Provides a drum-capping and drum-seaming operation
h. Provides for measuring drum radiation level at the capper/seamer
i. Provides drum handling, which consists of a monorail, a drum grab, conveyors, and a capper/seamer.

The fill station subsystem collects the final product from the extruder/evaporator. The fill station contains a vent hood, filter train, and exhauster, which provide ventilation of the fill area to prevent loose surface contamination of drums and the buildup of vapors. A drip-pan mechanism is provided for product collection during drum-indexing operations. The pan with drippings is put in the next drum available after indexing. The drum-handling system is designed to transport drums to and from the six-drum turntable via the monorail, hoist, and drum grab. The drums are filled on the turntable after being indexed, either manually or automatically. Filled drums are remotely transported via monorail and hoist to the capping station. They are capped, seamed closed, and put on the transfer cart.

The drum-handling system provides a means by which 55-gal drums filled with the solidified radwaste can be remotely moved, transported, and stored. It consists of a transfer cart, an accumulation conveyor, and a 10-ton remotely operated bridge crane equipped with a drum grab for transport of drums to onsite storage. Drums are retrieved from onsite storage by means of the same bridge crane. They are discharged to a truck dock designed to accommodate offsite shipments to a burial repository.

Except for the drum-transfer cart, these actions occur in the onsite storage facility, a separate structure adjacent to the radwaste building. This facility, its systems and equipment, and its operations are described in Section 11.7.

One method of movement of drums is as follows: Filled and seamed drums are moved from the drum capper-seamer area, by means of the transfer cart, to the onsite storage facility. There they are transferred to the accumulation conveyor to await transport offsite or to their storage location. Closed-circuit television (CCTV) cameras throughout the system permit surveillance of the drum's movement.

Drums can also be stored on the solid-radwaste storage conveyors in the radwaste building (first floor). The storage system consists of the transfer cart, 13 reciprocating gravity storage conveyors, 13 drum escapement devices, and a chain-driven live roller drum-exit conveyor.

All components of this system are remotely operated, and visual surveillance of the total system is provided by CCTV cameras, periscopes, and viewing ports. Drums are discharged from the transfer cart onto any one of the 13 reciprocating gravity storage conveyors. The reciprocating gravity storage conveyors can store approximately 380 drums.

11.5.3.2.16.11 pH Adjustment System

The pH adjustment system consists of a caustic holding tank, pumps, and a distribution system. It is used to adjust the pH in the three slurry feed tanks to protect the extruder/evaporator. The caustic is fed from the caustic tank and distributed through the caustic addition pumps to one of the three slurry tanks:

a. The centrifuge feed tank

b. The spent-resin slurry feed tank

c. The concentrates feed tank.

When the pH in the selected tank is within the allowable range, the operator manually shuts down the caustic addition pump.

The system also provides for the injection of caustic for neutralizing the contents of the chemical waste tank.

11.5.4 Estimated Quantities

Estimated design values of the principal radionuclides processed yearly through the radwaste system are presented in Table 11.5-3. This table covers system operation with the evaporator and the etched-disk filter/oil coalescer trains in service. Calculations have also been made for normal system operation with both precoat filters in use and the evaporators not in service. It was found that the total curies processed were nearly identical, which is as expected. The radioactivity inputs to the radwaste system come from various external sources, such as leakage into sumps, laboratory drains, various cleanup resins, and sludges. These input sources are independent of how the internal radwaste equipment/trains are configured. Therefore, since the radwaste systems are designed to essentially capture (and ultimately ship for burial) the majority of radionuclides, rather than releasing them in liquid discharges, it is expected that the final solid-system totals would be essentially independent of system configuration. Source quantities will be redistributed throughout various pieces of radwaste equipment, depending upon specific system configurations. The nuclide distribution for each type of solid waste was calculated by assuming that all waste initially had the same distribution of nuclides as reactor water, and by applying appropriate decay factors for utilization, collection, or processing times involved with each type of solid waste.

The estimated yearly quantity (volume, weight) of wastes to be generated and shipped, however, does depend upon the specific configuration of the overall liquid and solid system. When vendor processing is performed in the OSSF, quantities will depend upon the specific vendor being utilized, fill efficiencies, etc. If the asphalt-extruder system is utilized, results and quantities will depend on such things as drum-fill efficiencies, achievable waste-to-asphalt ratios and extruder throughput, etc. One nominal design example is given in Table 11.5-4 for the situation of waste processed with the evaporators, etched-disk filters/oil coalescers, and asphalt extruder in operation.

11.5.5 Packaging and Shipment

The solid waste system product will be packaged and shipped in accordance with current federal regulations. The majority of normal radwaste will be staged in the onsite storage facility for shipment. Waste quantities, activities, and economics will dictate shipment frequency.

11.5.6 Vendor-Supplied Solidification or Dewatering System

The Fermi 2 solid radwaste system has been set up and hard-piped so that either a full-time (mobile) vendor system can be used or the asphalt system could be used.

The portable solid waste management system is supplied and operated by the vendor. The types and quantities of waste to be processed are the same as for the Fermi solidification system. System operation will be closely monitored by Edison personnel. The vendor will utilize a process control program (PCP), which is reviewed and approved by Edison in accordance with Section 17.2. Conformance to 10 CFR 61 criteria is discussed in the vendor-supplied documentation. Fermi 2 or contractor operating procedures are used for operating this system as interfaced with the Fermi 2 solid radwaste system.

Depending upon the particular system and the expected radiation levels, portable (vendor) radwaste processing in the OSSF can take place in the pallet-loading room, in the storage bays, in the laydown areas immediately adjacent to the truck bay, or in the shielded container-processing room. It is expected that primarily this latter room will be used for such processing. If large bulk cement and chemical containers are used for such processing, however, they may be located outside of the truck bay door. These areas of the onsite storage facility were specifically designed and constructed to contain and handle mobile process systems (see Subsection 11.7.2.2.11). Concrete floors and walls of this region are coated, and drains are routed back to the liquid radwaste system. The remote-operated overhead crane is available to move equipment onto or from trucks located in the truck bay. The basic design of these areas and the methods of system operation have incorporated features to maintain operator exposures ALARA. Permanent piping installed in the shielded onsite storage facility pipe tunnel transports the radioactive process fluid directly to the vendor's equipment.

The interface connections between the portable system and the Fermi 2 system are shown in Figure 11.2-15 and described in Table 11.2-4. In general, liquid from the centrifuge feed tank is transported directly to the vendor equipment, and clarified liquid is returned to the waste clarifier tank. The waste is normally pumped to a disposable liner or high-integrity container (HIC).

If solidification of waste is performed, pretreatment of the waste with chemical additives may be conducted in accordance with values derived from a PCP. Solidification agents are then added and the waste is allowed to cure to complete the solidification process.

If dewatering of the waste is performed, the waste is transferred into a steel liner or HIC containing an internal underdrain assembly. Vacuum is applied to the underdrain system. Liquid from the underdrain system is sent back to the liquid radwaste system by a dewatering pump while the solids are trapped in the container. Some vendors provide additional accelerated dewatering capability. This accelerated capability is achieved by recirculating air at high velocity through a liner or HIC. Procedures ensure no drainable liquid at the time of shipment and <1 percent drainable liquid in HICs or <0.5 percent drainable liquid in steel liners upon receipt at the burial site.

The liners or HICs are suitable for transportation and burial at an approved burial facility. Additionally, the liners and HICs are compatible with numerous approved shipping casks if the liner or HIC requires shipment in a cask.

TABLE 11.5-1 SUMMARY OF ESTIMATED DESIGN INPUTS TO THE SOLID RADWASTE SYSTEM

Stream[a] Number	Description	Design Daily Volume (gpd)	Solids Content per Batch	Maximum Volume per Batch (gal)	Batch Frequency	
					Normal	Maximum
20	Reactor water cleanup phase separator decantate	635	200 ppm	2000	2/6.3 day	2/day
21	Condensate filter – demineralizer backwash	4838	214 lb	6400	1/2 day	8 day
22	Fuel pool filter backwash	216	65 lb	2160	1/10 day	1/10 day
27[b]	Floor drain precoat filter backwash	5170	17 lb	470	11/day	N/A
28[b]	Waste collector precoat filter backwash	1380	28 lb	920	1.5/day	N/A
29, 31, 32	Waste surge tank, FDC tank, waste collector tank sludge letdown	Infrequent (not included in mass balance)				
30	Reactor water cleanup phase separator sludge	23	580 lb	1400	1/60 day	1/60 day
35[b]	Floor drain etched-disk filter backwash	124	2.64 lb	21	6/day	6/day
36[b]	Waste collector etched-disk filter backwash	78	1.0 lb	21	4/day	15.5/day
58	Spent-resin tank	126	45 ft^3	1011	1/8 day	1/1.7 day
59	Evaporator concentrates	103	<8% by weight	800	1/8 day	1/4.5 day

[a] Refer to Figure 11.2-15.

[b] The precoat filters and the etched-disk filters are not in operation at the same time.

TABLE 11.5-2 SOLID RADWASTE SYSTEM – COMPONENT DESIGN PARAMETERS

Component	Number	Capacity (gal)	Material	Pressure (psig)	Temperature (°F)	Design Code
Condensate phase separator tank	2	12,000	Carbon steel Lastiglas 78	Atmospheric	--	(a)

Centrifuge
- Type - Bowl with screw conveyor
- Capacity - 20 gpm, 98 percent recovery
- Material - 316 stainless steel
- Design Pressure - Atmospheric
- Design Temperature - 40 to 140 °F
- Design Code - Manufacturer's standard

Extruder/Evaporator (VRS)
- Type - Twin screw
- Capacity - Variable depending on input

Design Pressures
- Barrel heating jackets - 300 psig
- Barrel cooling jackets - 300 psig
- Steam dome jackets - 43 psig
- Steam dome condensers, tube side - 150 psig

Design Temperatures
- Barrel heating jackets – 410 °F
- Barrel cooling jackets – 410 °F
- Steam dome jackets – 330 °F
- Steam dome condensers, tube side – 150 °F

Materials
- Barrels, screw elements - DIN 1.8519 double nitrided
- Screw shafts - DIN 1.8550
- Steam domes, wetted surfaces - DIN 1.4571
- Steam dome condenser tubing - DIN 1.4571
- Interfacing connection - See nozzle schedule

Design Code - Manufacturer's standard

---

[a] The design code for tank modification is ASME III, Class 3.

[b] SA-240-304 stainless steel bottoms.

[c] Identical pumps.

[d] Total differential pressure.

[e] These vessels function as atmospheric storage tanks and are vented. However, they are designed as pressure vessels under the rules of ASME VIII and so are more conservatively designed than called for in the code.

TABLE 11.5-4 ESTIMATED ANNUAL VOLUME OF SOLIDS TO BE SHIPPED FROM PROCESSING THROUGH THE EXTRUDER SYSTEM

System	Estimated Annual Shipped Solidified Volume[a] (gal)	Annual Number of Drums Shipped[a]
RWCU demineralizer resins Condensate filter-demineralizer resisns Waste collector and floor drain etched-disk backwash solids Fuel pool filter backwash	6,584	133
Radwaste demineralizer resins	11,286	228
Evaporator bottoms	5,148	104
Total	23,018	465

[a] These volumes are the solidified product volumes as shipped in 55-gal drums assumed to be 90 percent full and assumed to have a final waste-to-asphalt weight ratio of 50 percent/50 percent. They assume operation of the evaporators and the etched-disk filter/oil-coalescer trains and a dry (centrifuge) feed to the extruder.

11.6 RADIOLOGICAL ENVIRONMENTAL MONITORING PROGRAM

A program is provided to monitor the radiation and radionuclides in the environs of the plant. The program provides (1) representative measurements of radioactivity in the highest potential exposure pathways, and (2) verification of the accuracy of the effluent monitoring program and modeling of environmental exposure pathways. The program is (1) contained in the ODCM, (2) conforms to the guidance of Appendix I to 10 Part CFR 50, and (3) includes the following:

1. Monitoring, sampling, analysis, and reporting of radiation and radionuclides in the environment in accordance with the methodology and parameters in the ODCM,

2. A Land Use Census to ensure that changes in the use of areas at and beyond the SITE BOUNDARY are identified and that modifications to the monitoring program are made if required by the results of this census, and,

3. Participation in an Interlaboratory Comparison Program to ensure that independent checks on the precision and accuracy of the measurements of radioactive materials in environmental sample matrices are performed as part of the quality assurance program for environmental monitoring.

11.7 ONSITE STORAGE FACILITY

11.7.1 Introduction

The onsite storage facility is essentially an above-grade structure for holding low-level radioactive waste. It provides interim storage capacity for an amount of waste estimated to be generated in 5 years of plant operation. This surge capacity is primarily intended to be used to allow Fermi 2 to continue operating during a period when no offsite disposal facilities are available. Under normal conditions, when offsite disposal is available, a portion of the storage facility will be used as a staging area for waste. The onsite storage facility also includes space for a dry active waste compactor, offices, a control room, and rooms for housing the radwaste solidification system's asphalt storage tank and pumps. Provision is also made to allow processing of radwaste by transportable vendor-supplied equipment inside the facility.

11.7.1.1 Design Objectives

The onsite storage facility provides a protective barrier around the stored waste to

a. Protect the waste containers from the effects of the environment

b. Prevent an uncontrolled release of the waste to the environment

c. Provide shielding from the radiation emitted by the waste.

The waste will be retrievable from the facility. Waste will not be stored permanently in the facility. Handling of the waste within the facility can normally be done remotely with a crane or, when radiation levels allow, with a hand truck or a forklift vehicle.

The waste containers will be stored inside the structure, which protects them from the external environment. The storage facility has full-length trench drains in each storage cell to prevent collection of water on the facility floor.

All potential pathways for the release of radioactivity to the environment are controlled and monitored in accordance with 10 CFR 50, Appendix A, Criteria 60-64. In particular, all potentially contaminated drains within the facility are collected and routed to the liquid radwaste system. All ventilation exhaust from the onsite storage facility is filtered and monitored for radioactivity.

11.7.1.2 Description of Waste Stored

Normally, the radioactive wastes to be stored in this facility are of three general types: dry active wastes, processed wastes, and miscellaneous unprocessed wastes. Storage containers for processed waste could be either liners, high-integrity containers, or drums. High integrity containers will be used for processed waste which is potentially corrosive. Containers for dry active wastes could be drums, low specific activity boxes, or other appropriate containers. Waste with the potential for gas generation is stored in vented containers, or the container shall be vented at least every 5 years.

The dry wastes, which are generally of low radioactivity, can normally be handled by direct contact. These wastes normally are collected in containers or bags located in various zones around the plant. The filled containers are closed and then transferred to the onsite storage facility. These wastes are of two types: compressible and noncompressible. The compressible wastes are normally processed and packaged. The noncompressible wastes are manually packaged into containers meeting transportation criteria and stored until shipment.

This facility is also used for the storage of mixed, hazardous and radioactive waste materials in accordance with applicable regulations and permit requirements.

11.7.1.3 Design Safety Features

To reduce the possible exposure of personnel during maintenance, the following concepts have been incorporated into the design of the onsite storage facility:

a. Lighting will be provided via the bridge crane. No lights have to be replaced over the high level radwaste storage cells

b. The container processing room has been provided with adequate shielding to minimize exposure during these operations

c. Epoxy coating has been provided on all floors and walls where potential contamination could occur

d. Access to the bridge crane and its cables will normally be over the truck bay to reduce exposure to maintenance personnel

e. Normal operations involving the storage containers and bridge crane can be performed remotely.

11.7.2 Onsite Storage Facility

11.7.2.1 Location

The onsite storage facility is located at the northeast corner of the existing radwaste building (see Figure 11.7-1). The facility's control room, compactor area, offices, and asphalt tank rooms are located adjacent to the north wall of the radwaste building and are attached to the onsite storage facility (see Figures 11.7-1 and 11.7-2). The entire complex is located within the site-protected area.

11.7.2.2 Design Features

11.7.2.2.1 Structural and Architectural

All surfaces in the onsite storage facility are sloped to drainage ditches or drains that are connected with the liquid radwaste collection systems. Rainwater is prevented from entering the facility by a rise in the grade at the entrance of the facility and a drainage ditch that connects to the onsite sewer system. Drains from the heating, ventilating, and air conditioning (HVAC) system are connected to the radwaste collection system.

The onsite storage facility is a non-safety-related structure and is designed and constructed in accordance with the following codes and standards:

a. ACI-318-77: American Concrete Institute, Building Code Requirements for Reinforced Concrete

b. AISC-1978: American Institute of Steel Construction, Specification for the Design Fabrication and Erection of Structural Steel for Buildings

c. ANSI-58.1-72: American National Standards Institute, Building Code Requirements for Minimum Design Loads in Buildings and Other Structures. The wind loading will be based on the 50-year mean recurrence interval

d. UBC-79: Uniform Building Code. The main plant requirements for the operating-basis and safe-shutdown earthquakes will not be considered, in accordance with NRC Generic Letter 81-38. The onsite storage facility is designed to comply with UBC-79 requirements for Seismic Zone 1

e. OSHA: Occupational Safety and Health Administration requirements

f. ACI-531-79: American Concrete Institute, Building Code Requirements for Concrete Masonry Structures

g. NRC Regulatory Guide 1.143: Pipes, joints, and fittings of the piping from the main radwaste system to the piping connection for the portable solidification system.

The onsite storage facility is constructed of the following non-combustible materials:

a. Exterior - reinforced-concrete and reinforced-concrete block walls, reinforced-concrete roof, insulated metal siding, and hollow metal doors

b. Interior - reinforced-concrete walls.

The rooms housing the asphalt storage tank and pumps are constructed of concrete block walls and have approved fire-rated doors (see Figure 11.7-2). Both rooms are accessible only from an outside entrance. A high wall with a door sill that can contain the full contents of a tank rupture is located in the asphalt storage tank room. There are no drains in this room, nor are there any in the adjacent pump room.

To ease any potential problems with decontamination, all floors in the facility are finished with two layers of epoxy coating. The walls are coated to a level of 2 ft above the floor, with the exception of the truck-bay area and the container processing room, where the coating extends to the top of the interior wall.

11.7.2.2.2 Shielding

Shielding has been provided for the onsite storage facility to ensure that the radiation doses resulting from its use and operation will be as low as reasonably achievable (ALARA). In general, the criteria to which shielding is designed are as follows: less than 1.0 mrem/hr in working areas within the facility; less than 0.1 mrem/hr in areas outside the facility; and less than 1.0 mrem/yr in areas at or beyond the boundary of the restricted area. The shielding design assumed the entire storage space to be filled with drums of processed waste, each containing a conservative design-basis source. The shielding design takes into full account such considerations as

a. Direct and scattered radiation paths

b. Ducts and other voids or penetrations in shield walls

c. Multiple radiation sources and source transport paths that may contribute to the dose rate in any given area.

The major components of the shielding design include

a. The facility's outer shield walls, which protect the yard area from direct radiation

b. The facility's roof slab, which protects the yard area from air scatter and the HVAC equipment room from direct radiation

c. The north and south truck-bay shield walls, which protect truck-bay workers from direct radiation

d. The low roof of the truck bay which protects truck-bay workers from the scatter off the main roof slab

e. The shielding around the container processing room, which protects truck-bay workers during the associated operations

f. The storage cell walls, which protect workers during any necessary maintenance in adjoining storage cells

g. The shielding around the dry-active-waste compactor area, which protects surrounding areas from potential sources in this area.

11.7.2.2.3 Radiation Monitoring

Area radiation monitors are provided in the truck-bay area and near the dry-active-waste compactor (see Figure 11.7-2). If predetermined radiation setpoints are exceeded, alarms will be sounded both locally and in the control room of the onsite storage facility.

Effluent radiation monitoring is provided by an off-line noble gas, particulate, and iodine monitor. This system takes a representative sample from the exhaust duct of the HVAC system. The HVAC system is designed to hold the building at a minimum of 1/4-in. negative water gage, thus ensuring that no unmonitored releases can occur. Readings of the noble gas channel will be displayed in the main control room. If predetermined setpoints are exceeded, an alarm will sound.

11.7.2.2.4 Fire Protection

The onsite storage facility is structurally a separate building and is, therefore, a separate fire-protection area. Only a portion of the facility is attached to any other building. The walls, floor, and ceiling of the onsite storage facility are of reinforced concrete or concrete block.

Fire-detection equipment is designed to annunciate and alarm locally and in the control room of the onsite storage facility. Fire-suppression equipment consists of a hydraulically designed sprinkler system. Automatic sprinkler system protection is provided in all areas of the onsite storage facility except the control room, office area, corridor, and empty-drum storage area. Combustible loading in these areas does not justify a suppression system. A manual hose station with enough hose to reach all areas in the onsite storage facility, except the asphalt storage and pump rooms, is located in the truck-bay area. An additional hose reel will be used to access the asphalt storage and pump rooms from the truck bay.

Water is supplied from the existing fire protection system by a 6-in.-diameter header pipe. Fire-suppression water will be collected in the liquid drain trenches and routed to the radwaste treatment system. Inadvertent operation of the automatic fire- suppression system will have no adverse effect upon the ability to shut down the plant.

The HVAC system for the onsite storage facility will automatically shut down on sensing smoke in the outside air supply and exhaust air ducts. Ionization detection is provided in the control room, office area, empty-drum storage area, HVAC room, and asphalt storage and pump rooms. Combustible materials in the storage areas are normally kept in storage containers as described in Section 11.7.1.2, and are protected by an automatic sprinkler system. In addition, the sprinkler system alarms upon activation.

Fire-protection equipment is listed by Underwriters Laboratories. Fire-protection and fire-detection drawings were approved by Edison and its insurer.

Significant quantities of potential combustibles which are stored in the facility are normally kept in storage containers as described in Section 11.7.1.2, which are segregated into two distinct areas (see Figures 11.7-2 and 11.7-3, Sheets 1 through 3). This configuration reduces the probability of ignition to insignificant levels. A portion of the dry-active-waste storage area is used for trash sorting before further processing.

Fire protection for the truck bay is provided by the sprinkler system. The truck-bay area is separated from the storage areas by reinforced-concrete walls. The fire protection system for the onsite storage facility was designed using NFPA-13 for guidance.

The rooms housing the asphalt storage tank and pumps contain 3-hr fire-barrier walls and doors, even though no plant safety-related equipment is located therein. They also contain an automatic fire-detector and sprinkler system. The HVAC systems for these rooms are completely separate from the rest of the storage facility, with no interactions possible, and fusible links automatically close the fire dampers in the HVAC systems in the rooms in case of fire.

The onsite storage facility is separated from the radwaste building with a 3-hr fire barrier except for the door opening to the access aisle which is a nonrated metal door. However, the door leads to a corridor that is a low-combustible area.

11.7.2.2.5 Flood Protection

The onsite storage facility is located above the maximum flood elevation of 586.9 ft. The drum storage area is at Elevation 587.0 ft. This is 4 ft above the plant grade elevation of 583.0 ft. Therefore, flooding is not considered a design-basis event.

11.7.2.2.6 Tornado Protection

The minimum thickness of concrete walls below Elevation 624 ft is 54 in.; above Elevation 624 ft, it is 28 in. The minimum thickness of the concrete slab for the roof is 24 in. It is unlikely that a tornado would damage a building with this structural integrity to the extent that the building's contents would be scattered. Therefore, a tornado is not considered a design-basis event.

11.7.2.2.7 Facility HVAC Systems

The HVAC system in the onsite storage facility is composed of (1) the heating and ventilating system for the onsite storage facility; (2) the HVAC system for the onsite storage facility control room and offices; (3) the heating and ventilating system for the asphalt storage pump room; (4) the heating and ventilating system for the asphalt storage tank room; and (5) the heating and ventilating system for the HVAC equipment room. Each system is described below.

11.7.2.2.7.1 Onsite Storage Facility Heating and Ventilating System

The heating and ventilating system for the onsite storage facility is designed to maintain a suitable environment for equipment and for proper air flow from normally accessible areas to potentially contaminated areas. The system is also designed to maintain the facility at a 1/4-in. water gage negative pressure with respect to the ambient air to minimize the release of potentially contaminated air to the outside. The exhaust air is filtered to remove any radioactive particulates and is monitored before its release to the environs.

The system is designed to maintain a minimum temperature of 50°F in all areas and to limit the maximum temperatures to 104°F in the truck-loading area, the empty-drum area, the compactor area, and the aisle, and to 110°F in the remaining areas.

The system provides 100-percent outside air by two 50 percent- capacity supply systems, each consisting of an air-intake louver, a prefilter, a medium-efficiency filter, an electric blast coil, a fan, and associated controls. The air is exhausted through prefilters and high-efficiency particulate air (HEPA) filters and is monitored before its release to the outdoors. Electric unit heaters are provided to offset the heat loss due to the infiltration of air in the truck-loading area. All the major equipment of the system is located in the HVAC equipment room.

11.7.2.2.7.2 Control Room and Offices HVAC System

The HVAC system for the control room and offices is designed to maintain a suitable environment for the comfort of personnel and for proper functioning of the equipment. A minimum of 20 percent outside air is provided to maintain a positive pressure with respect to the outside and to remove odors.

The HVAC system is designed to maintain a temperature of 75°F ± 2°F year round. It consists of (1) a packaged cooling unit comprising an air-cooled condensing unit, a filter, a DX coil, and a supply fan; and (2) zone electric heating coils for winter heating.

The packaged cooling unit is located on the roof of the asphalt storage tank room, and the electric heating coils are located in the supply ductwork.

11.7.2.2.7.3 Asphalt Storage Tank Room, Asphalt Storage Pump Room, and HVAC Equipment Room Heating and Ventilating Systems

These three heating and ventilating systems are designed to maintain a suitable environment for the equipment housed in each room.

The heating and ventilating system for the asphalt storage tank room is designed to limit summer and winter temperatures to a maximum of 110°F and a minimum of 50°F, respectively. The system consists of an air-intake louver, an exhaust fan, control dampers, and unit heaters.

The heating and ventilating systems for the asphalt storage pump room and the HVAC equipment room are designed to limit summer and winter temperatures to a maximum of 104°F and a minimum of 50°F, respectively. Each system consists of an air-intake louver, a supply fan, control dampers, and unit heaters. The heating and ventilating system for the HVAC equipment room provides 1000-cfm outside air to maintain the room at a positive pressure with respect to the ambient air.

The equipment for each of these systems is located in its respective room.

11.7.2.2.8 Provisions for Liquid Drainage

The onsite storage facility is provided with an extensive system of drains and trenches. All surfaces in the facility are sloped so that any spillage is directed toward one or more of the drains. Because of this network, permanent curbs are not provided.

Drains in potentially contaminated areas of the onsite storage facility are routed directly to the floor drain collector subsystem of the liquid radwaste system. These include drains in the drum-storage areas, the truck-bay area, the HVAC equipment room, and the drum-compactor area. These drains are adequately sized for all normally expected influents and will also drain water from the fire-suppression system.

11.7.2.2.9 Container-Handling Systems

Within the storage structure proper, containers are handled by a 10-ton electric overhead traveling bridge crane, by forklift truck or, when radiation levels allow, by hand truck. The bridge crane is remotely operated from the control room located in the annex structure. The crane system is designed for precise placement of the containers. The bridge and trolley is accurately positioned by the use of a closed-circuit television (CCTV) monitoring system and a coordinate target system. Dedicated TV cameras mounted on the trolley are directed at the indices of each of two perpendicular coordinates: One coordinate hangs from a crane rail, and the other is attached to a wall. This system enables the operator to accurately position the bridge and trolley by viewing the TV monitor and lining up cross hairs on the camera system with the appropriate coordinate. Additional dedicated TV cameras are mounted in the drum accumulator-conveyor (see Subsection 11.7.3.1) and in the container processing room.

Downward-viewing TV cameras mounted on the bridge crane and incandescent lights provide a view of the area below the bridge on three control-console monitors. In addition, a solid-state digital grab elevation readout is located on the control console. The readout tells the operator the height of the grab above a fixed reference point.

The drum grab is designed to lift drums weighing up to 6000 lb and has the capability to handle closed-head drums. It is supplied with a motor-operated jaw actuator for positive load-release control. For the jaw to operate, the cable has to be slack (no load). This ensures positive control.

For personnel safety and to assist positioning accuracy, containers must be raised to the full up position before high-speed operation is possible with the bridge or trolley. In this position, the container is between the bridge beams. It will clear all obstacles cleared by the crane and is supported to eliminate swinging.

The bridge crane is capable of placing containers into any storage bay, the pallet room, the container processing room, onto the conveyor, and onto a truck.

Crane bearings inside gear cases and high-speed gearing bearings are splash lubricated. Other bearings are lifetime lubricated. A weight-type hoist limit switch is provided for the upper hoist limit, and a screw-type limit switch is provided for upper and lower limits. A tipped drum uprighting attachment will be used if necessary. Two bridge motors with separate bridge circuitry are provided so that if one motor fails, the other can be used as a backup. Eye-bolts are attached to the bridge to allow towing of the crane by a building-mounted winch if both motors become defective. Magnetic-particle testing has been used by the manufacturer to determine the presence of discontinuities at or near the surface of the crane hook, lifting eyes, and all weldments.

11.7.2.2.10 Compaction

To decrease the volume of solid waste, the onsite storage facility contains a high-efficiency, in-drum, ram-head compactor system with a filtration and ventilation system.

The ventilation system controls any contaminated particles that may be released while the packaging equipment is being operated. The compacting press has an air exhaust system, consisting of a hood, a prefilter and absolute filter, and an exhaust fan.

This system is so arranged that when the ram descends to compress waste material, the air exhaust system is in position to filter the air from the drum as the material is compressed.

When the compactor is used, the compressible trash, which is made up of low-activity material, including glass, paper, rags, mop heads, booties, gloves, and towels, is normally transported to the compactor room in plastic bags. The trash is then placed in the drums and compacted. When a drum is filled, the top is fastened onto the drum, and a forklift truck or, when radiation levels allow, a hand truck is used to transport the drum from the compactor room to drum-staging or drum-storage areas.

11.7.2.2.11 Temporary Processing

Permanent piping is routed from the radwaste system to the onsite storage facility to allow vendor processing and/or solidification of wet waste in the truck-bay area and adjoining rooms.

All pipes run in a shielded pipe tunnel beneath the storage facility and conform to ANSI B31.1. An access hatch to the pipe tunnel beneath the storage facility is located in the truck bay area. The radwaste pipelines terminate in the truck bay (see Figure 11.7-2). A blind flange is at the termination of each line. Each pipeline is capable of being flushed as necessary with condensate. Water decanted from processed waste in the truck bay will be returned through the pipelines to the liquid radwaste system in the radwaste building. When vendor processing is utilized, the wet waste will be pumped through the pipelines to commercial process equipment provided by the vendor. The permanent radwaste piping will be connected at the flange fittings to the equipment provided by the vendor. Details concerning the vendor-supplied mobile processing equipment are given in Subsections 11.2.10 and 11.5.6.

11.7.3 Operations

11.7.3.1 Storage

The asphalt solidification system in the radwaste building dewaters and solidifies the radwaste in 55-gal drums; these drums can be moved from the radwaste building to the onsite storage facility by the method described in Section 11.5.

Drums of compacted waste are normally brought into the facility by a forklift truck or, when radiation levels allow, by a hand truck. The crane can then lift each drum and perform essentially the same functions as with the drums of solidified waste. Alternatively, the forklift or hand truck can be used to place the drums of compacted waste into storage.

The facility is designed for one-on-one stacking of 55-gal drums, up to eight layers in height, with steel grating between each layer. Tests performed for Sargent & Lundy Engineers indicate that the maximum compressive load that an 18-gage 55-gal DOT-17H drum can carry before failure is approximately 6000 lb. During storage, a 17H drum on the bottom layer (with seven layers above) will be subjected to a maximum compressive load of 3395 lb, which is only 57 percent of the failure load. Drum manufacturers' data indicate that the maximum compressive load a 55-gal DOT-17E drum can withstand before failure is 10,000 lb. During storage, a 17E drum on the bottom layer will be subjected to a maximum compressive load of 4970 lb. Thus, the maximum load that a 17E drum on the bottom layer will be subjected to is only 50 percent of the failure load. This provides confidence that eight-high drum stacking is safe and justifiable for 55-gal drums. The dry active waste can be stored in 55-gal drums having the same dimensional, physical, and strength characteristics as Department of Transportation (DOT) type 17H drums. The solidified waste will be stored in drums having the same dimensional, physical, and strength characteristics as DOT type 17E drums. In such cases, eight-drum stacking is possible. When other storage containers (liners, HICs, non-standard drums, etc.) are utilized, eight-high stacking would not be used.

The storage facility is separated into cubicles by inner walls. This allows the potential segregation of waste containers by radioactivity level and/or waste type. Compacted dry active waste can be stored separately from processed waste. Also, sample drums from each batch of solidified radwaste resins can be stored in the test and sample area of the onsite storage facility (see Figure 11.7-2).

A record board is located in the control room of the onsite storage facility, which can be used to record the position of all containers stored in the facility. The board consists of a plan view of the storage areas, with container setdown positions identified by alphanumeric designations that correspond to the bridge crane coordinate grid system. The operator can place a tag on the board for each container. The tag can contain such information as container number, weight, radiation level, and date of storage, etc.

11.7.3.2 Loading

Retrieving containers of processed waste from storage for offsite disposal is also performed with the bridge crane. Retrieval of drums of compacted trash will be done by either a forklift truck, a hand truck, or the bridge crane. Containers of processed waste are picked up from storage and loaded into a truck (for drums, one method is by use of a circular shipping pallet) for ultimate offsite disposal. Drums of compacted trash are placed onto transport vehicles by the bridge crane, forklift truck, or hand truck.

If a drum of asphalted waste were accidentally dropped while being manipulated from the bridge crane, no airborne radioactive material would be released because the waste, being solidified in asphalt, is inherently bound within this matrix. The bridge crane is designed to have the capability of righting a fallen drum.

11.7.4 Radiological Assessment: ALARA Doses

Design features included to ensure that doses due to external radiation sources are ALARA are described in Subsection 11.7.2.2.1.

Control of potential airborne contamination is provided by an HVAC design that ensures that air will flow from areas of lesser potential contamination to areas of greater potential contamination. Specifically, air will tend to flow

a. From outside the facility to inside the facility

b. From the truck-bay to the drum-storage area

c. From the control room and offices to the compactor area for dry active waste.

Measures have been taken to provide airflow barriers in the two openings between the two buildings so as to minimize any differential flow.

The exhaust of the dry-active-waste compactor is filtered and routed directly to the facility's exhaust to minimize airborne contamination.

All drain lines that are potential pathways for airborne cross-contamination are trapped and provided with fill lines.

Control of surface contamination is provided by segregating clean areas (the control room and offices) from potentially contaminated areas (the drum-storage, truck-bay, and dry-active-waste compactor areas).

All lines and equipment in the facility that can carry radioactive sources are capable of being flushed after use.

11.7.4.1 Onsite Doses

The building shielding is sufficient to reduce the dose rates from the drums to persons at the site to acceptably low levels (see Subsection 11.7.2.2.2). The potential for significant airborne or surface contamination is very remote, and the overall design of the facility is in accordance with the ALARA philosophy.

11.7.4.2 Offsite Doses

The design of the facility ensures that the annual dose to the unrestricted area will be below 1.0 mrem/yr (see Subsection 11.7.2.2.2), in compliance with 40 CFR 190.

Although no radioactivity is expected to be released from this facility under normal conditions, the single controlled atmospheric release path is monitored (see Subsection 11.7.2.2.3) in accordance with 10 CFR 50, Appendix A.

11.8 ISFSI STORAGE PAD

The Independent Spent Fuel Storage Installation (ISFSI) storage pad provides a level resting surface for dry fuel storage casks. The pad is a 141' by 141' square reinforced concrete structure that is two feet thick designed to accommodate sixty four dry storage casks. The pad is compliant with ACI 349, "Code Requirements for Nuclear Safety-Related Concrete Structures," 2001, and designed in accordance with NUREG-1567, "Standard Review Plan for Spent Fuel Dry Storage Facilities." The pad is surrounded by a fence with signage identifying the location as a radiologically controlled area. The pad is also surrounded by a subsurface drainage system to minimize the effects of freeze and thaw cycles on the soil under the pad to preclude soil displacement. Additional information regarding the ISFSI storage pad is available in the Holtec Final Safety Analysis Report for their HI-STORM 100 Cask System to which Fermi 2 is a declared general licensee in accordance with 10CFR72.

I. INTRODUCTION

This Appendix was prepared to demonstrate compliance of the Enrico Fermi Atomic Power Plant Unit 2 with Section II of Appendix I of 10 CFR Part 50 (Reference 1). Applicable portions of Section II of Appendix I specifically set forth the following design objectives:

A. The calculated annual total quantity of all radioactive material above background to be released from each light-water-cooled nuclear power reactor to unrestricted areas will not result in an estimated annual dose or dose commitment from liquid effluents for any individual in an unrestricted area from all pathways of exposure in excess of 3 millirems to the total body or 10 millirems to any organ.

B.1. The calculated annual total quantity of all radioactive material above background to be released from each light-water-cooled nuclear power reactor to the atmosphere will not result in an estimated annual air dose from gaseous effluents at any location near ground level which could be occupied by individuals in unrestricted areas in excess of 10 millirads for gamma radiation or 20 millirads for beta radiation.

B.2. Notwithstanding the guidance of paragraph B.1:

(a) The Commission may specify, as guidance on design objectives, a lower quantity of radioactive material above background to be released to the atmosphere if it appears that the use of the design objectives in paragraph B.1 is likely to result in an estimated annual external dose from gaseous effluents to any individual in an unrestricted area in excess of 5 millirems to the total body; and

(b) Design objectives based upon a higher quantity of radioactive material above background to be released to the atmosphere than the quantity specified in paragraph B.1 will be deemed to meet the requirements for keeping levels of radioactive material in gaseous effluents as low as practicable if the applicant provides reasonable assurance that the proposed higher quantity will not result in an estimated annual external dose from gaseous effluents to any individual in unrestricted areas in excess of 5 millirems to the total body or 15 millirems to the skin.

C. The calculated annual total quantity of all radioactive iodine and radioactive material in particulate form above background to be released from each light-water-cooled nuclear power reactor in effluents to the atmosphere will not result in an estimated annual dose or dose commitment from such radioactive iodine and radioactive material in particulate form for any individual in an unrestricted area from all pathways of exposure in excess of 15 millirems to any organ.

This Appendix also supplies the responses requested of Detroit Edison Company by NRC letter, R. C. DeYoung to H. Tauber, dated February 23, 1976. The information requested was in the form of two enclosures. Enclosure 1 provided guidance for use in the evaluation of Appendix I. Enclosure 2 requested additional information which would be used by NRC in their evaluation of Section II of Appendix I. Tables I-1 and I-2 provide cross references to the location of the information requested by Enclosures 1 and 2, respectively. References to the FSAR in Tables I-1 and I-2 refer to the original FSAR.

Detroit Edison chose to comply with 10 CFR 50, Appendix I, Section II.D, for Fermi 2 by choosing the option of showing compliance with the design objectives of RM-50-2 as an optional method of demonstrating compliance with the cost-benefit analysis of Section II.D.

Tables 4.7 and 4.8 of NUREG-0769, "Draft Environmental Statement Related to the Operation of Enrico Fermi Atomic Power Plant, Unit No. 2" demonstrate compliance with the design objectives of Appendix I and RM-50-2, respectively.

TABLE I-1 LOCATION OF ENCLOSURE 1 GUIDANCE[a.]

Item	Guidance	Location
1.	Licensees should provide an evaluation showing their facility capabilities to meet the requirements set forth in Section II of Appendix I to 10 CFR Part 50.	This Appendix is the evaluation.
2.	Radioactive source terms used in the evaluation should be consistent with the parameters and methodology set forth in Draft Regulatory Guide 1.BB and 1.CC (as appropriate). Note: For BWR's, gaseous releases from the containment building and auxiliary building should be combined with the reactor building release for pre-BWR/6 Mark III Containment designs.	Annex A provides the source term information.
3.	Meteorology/hydrology information used in the calculation of doses should be consistent with Draft Regulatory Guides 1.DD and 1.EE.	Annex B provides the meteorology dispersion information. The hydrology dispersion information is provided in Section III of this Appendix.
4.	Dose calculations should be consistent with Draft Regulatory Guide 1.AA.	Sections III and IV provide the description of the models used.

TABLE I-1 LOCATION OF ENCLOSURE 1 GUIDANCE[a.]

Item	Guidance	Location
5.	Effluent release data from previous reactor operation should be provided, if available, for use in evaluating the source term calculations. Such data should include at least one full year of effluent release data tabulated by effluent release point, month, mode of operation (e.g., full power operation, refueling shutdown), excluding the first year of reactor operation.	Effluent release data are not available since Fermi 2 is not yet operational.
6.	The above evaluations should be accomplished by the information requested in Enclosure 2.. Exceptions from the information requested will be considered on a case-by-case basis.	Table I-2 provides a cross reference to the Enclosure 2 information.
7.	The staff is preparing standard Technical Specifications and will issue further guidance to licensees regarding changes to Technical Specifications to implement Appendix I objectives. Proposed revisions to Technical Specifications by licensees based on the limiting conditions for operation set forth in Section IV of Appendix I should be withheld pending further guidance from the staff.	Fermi 2 Technical Specifications are based on the BWR 4 STS effective in 1982.

[a.] Draft Regulatory Guide 1.AA is now Regulatory Guide 1.109.
Draft Regulatory Guides 1.BB and 1.CC are now Regulatory Guide 1.112.
Draft Regulatory Guide 1.DD is now Regulatory Guide 1.111.
Draft Regulatory Guide 1.EE is now Regulatory Guide 1.113.

TABLE I-2 LOCATION OF ENCLOSURE 2 REQUESTED INFORMATION[a.]

Item	Request	Location
1.	Provide the information requested in Appendix D of Draft Regulatory Guide 1.BB or 1.CC, as appropriate.	Annex A.
2.	Provide, in tabular form, the distances from the centerline of the first nuclear unit to the following for each of the 22-1/2 degree radial sectors centered on the 16 cardinal compass directions: a) nearest milk cow (to a distance of 5 miles) b) nearest meat animal (to a distance of 5 miles) c) nearest milk goat (to a distance of 5 miles) d) nearest residence (to a distance of 5 miles) e) nearest vegetable garden greater than 500 ft^2 (to a distance of 5 miles) f) nearest site boundary. For radioactivity releases from stacks which qualify as elevated releases as defined in Draft Regulatory Guide 1.DD, identify the locations of all milk cows, milk goats, meat animals, residences, and vegetable gardens, in a similar manner, out to a distance of 3 miles for each radial sector.	Table 3.1 of Annex B.
3.	Based on considerations in Draft Regulatory Guide 1.DD, provide estimates of relative concentration (χ/Q) and deposition (D/Q) at locations specified in response to Item 2 above for each release point specified in response to Item 1 above.	Tables 3.3 through 3.8 of Annex B.
4.	Provide a detailed description of the meteorological data, models and parameters used to determine the χ/Q and D/Q values. Include information concerning the validity and accuracy of the models and assumptions for your site and the representativeness of the meteorological data used.	Sections 1 through 3 of Annex B.

TABLE I-2 LOCATION OF ENCLOSURE 2 REQUESTED INFORMATION[a.]

Item	Request	Location
5.	If an onsite program commensurate with the recommendations and intent of Regulatory Guide 1.23 exists. a) Provide representative annual and monthly, if available, joint frequency distributions of wind speed and direction by atmospheric stability class covering at least the most recent one-year period of record, preferably two or more years of record. Wind speed and direction should be measured at levels applicable to release point elevations, and stability should be determined from vertical temperature gradient between measurement levels that represent conditions into which the effluent is released. b) Describe the representativeness of the available data with respect to expected long-term conditions at the site.	a) Annex B and Reference 3 of Annex B b) Reference 2 of Annex B
6.	If recent onsite meteorological data are not available, or if the meteorological measurements program does not meet the recommendations and intent of Regulatory Guide 1.23: a) Provide …	Onsite meteorological data are available that meet Regulatory Guide 1.23 (Reference 2)
7.	Describe airflow trajectory regimes of importance in transporting effluents to the locations for which dose calculations are made.	References 2 and 3 of Annex B, ER Section 2.6.2.4.2, and FSAR. Sections 2.3.2.3 and 2.3.2.4.2 (References 3 and 4).

TABLE I-2 LOCATION OF ENCLOSURE 2 REQUESTED INFORMATION[a.]

Item	Request	Location
8.	Provide a map showing the detailed topographical features (as modified by the plant), on a large scale, within a 10-mile radius of the plant, and a plat of the maximum topographic elevation versus diatance from the center of the plant in each of the sixteen 22-1/2 degree cardinal compass point sectors (centered on the true north), radiating from the center of the plant, to a distance of 10 miles.	According to NRC Procedure RPOP-514 Revisions 2 and 3, copies of topographical maps submitted to NRC under separate cover. Figure 2.6-37 through Figure 2.6-38 (sheet 3) of ER. Figure 2.3-37 through Figure 2.3-38 (sheet 3) of FSAR.
9.	Provide the dates and times of radioactivity releases from intermittent sources by source location bases on actual plant operation and, if available, appropriate hourly meteorological data (i.e., wind direction and speed, and atmospheric stability) during each period of release.	Fermi is not yet operational.

[1.] Draft Regulatory Guide 1.AA is now Regulatory Guide 1.109.
Draft Regulatory Guides 1.BB and 1.CC are now Regulatory Guide 1.112.
Draft Regulatory Guide 1.DD is now Regulatory Guide 1.111.
Draft Regulatory Guide 1.EE is now Regulatory Guide 1.113.

II. SUMMARY AND CONCLUSIONS

This evaluation shows that the doses associated with the proposed operation of Fermi 2 at uprated power conditions (3486 MWt) meet the Appendix I objectives. Maximum individual doses have been estimated under normal operating conditions using site dispersion characteristics, 3499 MWt (102 percent of 3430 MWt), and a power uprate scale-up factor of 1.04 (Table 11.1-1).

For liquid effluents, the doses are:

A. 0.0048 mrem to the total body

B. 0.077 mrem to the bone (maximum dose to an organ).

For airborne releases, the doses are:

A. 4.93 mrad/year gamma air dose at the site boundary

B. 2.79 mrad/year beta air dose at the site boundary

C. 0.75 mrem/year total body dose to the maximum individual

D. 3.80 mrem/year skin dose to the maximum individual

E. 11.64 mrem/year thyroid dose to the maximum individual from radioactive iodine and radioactive material in particulate form.

The detailed breakdowns of doses are given in Tables III-2 and IV-3 for the liquid and gaseous effluents, respectively.

III. RADIATION EXPOSURE FROM LIQUID EFFLUENTS

Small amounts of liquid radwaste from Fermi 2 will be released to Lake Erie via discharge into the circulating water reservoir blowdown line which provides a minimum dilution flow of 10,000 gpm. The discharge point is shown in Figure III-1.

Dilution of the blowdown is provided by the material mixing characteristics of Lake Erie in the vicinity of the discharge. The estimated annual activity liquid releases (Table 5 of Annex A) were calculated in accordance with Regulatory Guide 1.112 (Reference 5).

A. Estimated Liquid Dilution Factors

For the evaluation of the maximum individual exposures from liquid effluents, two locations for dilution factor calculations were selected. These two locations were the nearest shoreline resident northeast and south of the site boundary. In addition, the dilution factor for the Monroe water intake approximately 2 miles south of the Fermi 2 discharge was also calculated, since it was assumed that the nearest shoreline resident to the south would drink water from this source.

The dilution calculations were based on the analysis presented previously in Section 5.1 of the ER and on Equation 17 of Regulatory Guide 1.113 (Reference 6). Although 3 decant pumps are available for use (Section 10.4.5.2), only 2 pumps are operated during liquid radwaste releases. The relative frequency of discharge flow (either 10,000 or 20,000 gpm) was taken from Table 3.4-1 of the ER, yielding a flow rate of 20,000 gpm 9 percent of the time on an annual basis. Lake Erie current direction frequencies were taken as 40 percent toward the south and 60 percent toward the north. For the dilution factor to the north, no additional dilution by Swan Creek was assumed.

In addition it was assumed that locations south of the discharge would be affected by all southerly flowing currents, and those to the north by all northerly flowing currents. The recirculation factor was calculated to be 0.020 with a travel time for the recirculated water (discharge to intake) of 0.672 hour. The dilution factors were calculated to be:

1. 45 at 1770 meters northeast of Fermi 2
2. 67 at 1530 meters south of Fermi 2
3. 77 at 3200 meters south of Fermi 2
4. 100 at distances greater than 3200 meters.

B. Estimated Radiation Exposure

The maximum individual for liquid exposure was assumed to be located, as discussed in Section III.A above, at 1770 meters northeast of Fermi 2 and 1530 meters south of Fermi 2. The resident south was assumed to drink potable water obtained from the Monroe water intake located 3200 meters south of Fermi 2. The resident north was assumed to obtain his potable water from the Detroit municipal water system, which will be unaffected by Fermi 2 operation. Table III-1 presents conservative usage factors for liquid exposures. The activities usage factors represent 2 hours per day for boating, swimming, and shoreline use, each for a period of 90 days per year for the teenager and child, while the adult will participate one hour per day in each activity. The ingestion rates are those recommended by Regulatory Guide 1.109 (Reference 7).

The liquid effluents given in Table 5 of Annex A were used as input into the NRC computer code LADTAP II (Reference 9), which uses Regulatory Guide 1.109 models. The usage factors of Table III-1, the minimum dilution flow of 10,000 gpm, and the appropriate dilution factors in Lake Erie were used. The doses to the individual are presented in Table III-2.

TABLE III-1 MAXIMUM INDIVIDUAL USAGE FACTORS FOR LIQUID EXPOSURES

	Activities							
	Adult		Teenager		Child		Infant	
Pathway	hr/day	hr/yr	hr/day	hr/yr	hr/day	hr/yr	hr/day	hr/yr
Boating	1	90	2	180	2	180	0	0
Swimming	1	90	2	180	2	180	0	0

IV. RADIATION EXPOSURES FROM GASEOUS EFFLUENTS

Gaseous source terms are based on the NRC GALE computer code and input data as presented in Annex A. The radioisotopic source terms are given in Table IV-1. The dose calculations are based on the NRC GASPAR computer code, using the models of Regulatory Guide 1.109.

For power uprate (3486 MWt), a scale-up factor of 1.04 was used to update the data in Table IV-1.

Dose contributions from the following pathways, where appropriate, were calculated:

1. Immersion in the plume
2. Ground contamination
3. Inhalation
4. Consumption of vegetables, meat, and milk.

The following data presented in Appendix A.IV was originally generated prior to plant operation and was scaled for power uprate. It is considered historical, and a more accurate presentation of the radioactive elements annually released from Fermi 2 can be found in the Annual Radioactive Effluent Release Report.

A. Gaseous Dispersion Factors

Annex B details the meteorological methodology and calculations. In summary, the data was based on a full year of site measurements (June 1, 1974, to May 31, 1975) taken and reduced in accordance with Regulatory Guide 1.23. Straightline air flow χ/Q's were calculated, with appropriate depletion and terrain correction factors in accordance with Regulatory Guide 1.111 (Reference 8). Table 3.2 of Annex B lists and describes the release points. Due to the characteristics of the release points, all three vent release points were considered as mixed-mode sources.

The containment building vent emits radioactivity from the containment, the auxiliary buildings, the gland seal, the condenser offgas system, and the mechanical vacuum pumps. The turbine building and radwaste building each releases radioactivity through its own vent. In addition, the following are assumed to be released from the containment building vent: 26.0 Ci/yr of argon-41, 9.9 Ci/yr of carbon-14, and 75 Ci/yr of tritium.

Figure III-1 shows the location of the three release points for gaseous effluents. Tables 3.3 through 3.8 of Annex B present the χ/Q and D/Q values for all of the locations listed in Table 3.1 of Annex B.

B. Gaseous Radiation Exposures

From examination of the χ/Q values, the landward site boundary direction that would result in the maximum beta and gamma air doses was determined to be the northwest direction at 915 meters. From the land use and meteorological information presented in Table 3.1 and Tables 3.3 through 3.8 of Annex B, the location of the worst plume dose was determined to be the residence at 1130 meters west-northwest of Fermi 2. The location of the worst consumptive pathway was determined by analyzing doses at two locations in detail, the garden at 1120 meters west-northwest, and the milk goat at 3180 meters northwest.

Table IV-2 summarizes the χ/Q and D/Q data used in GASPAR. Standard usage factors as specified in Regulatory Guide 1.109 were assumed. For the goat milk pathway, the χ/Q and D/Q values obtained for the grazing season were used. It has been determined that the goat is fed almost entirely on supplemental feed and is not grazing on open pasture. For conservatism, it was assumed that only 50 percent of the goat's diet was supplemental feed.

Additionally the goat milk-infant pathway need not be evaluated, since the youngest family member of the goat's owner is approximately 2 years old.

GASPAR does not calculate the effects of radiation exposure from a finite cloud emanating from an elevated release. The gamma air dose and total body and skin doses must incorporate the combined effects of both elevated and ground-level releases occurring during mixed-mode release. GASPAR accounts for the gamma ground level and total beta exposures (both elevated and ground). The elevated gamma doses are accounted for by the use of the NUS computer code FIDOS (FInite DOSe).

FIDOS calculates the gamma air dose from a finite cloud. The basis for the calculation is Equation B-1 of Regulatory Guide 1.109. As can be noted in Equation B-1, the gamma air dose is a direct function of both the energies emitted by each nuclide and the air absorption factor. In order to avoid handling each specific gamma energy emitted by each nuclide, the gamma energies were combined into groups. Decay was calculated during travel from the release point to the receptor location for each nuclide as a function of the wind speed within each stability class. The cloud inventory, the release height, and the receptor location are used as input combined with the joint frequency distributions described in Section 2.3 of Annex B.

The gamma air dose as calculated by FIDOS was corrected by the ratio of the energy absorption coefficient for tissue to that of air and by the application of a shielding factor of 0.7 to derive the total body dose. The skin dose was computed by combining the ground level-gamma and total beta contributions obtained from GASPAR with the elevated gamma contribution from FIDOS as corrected for tissue absorption and shielding.

Table IV-3 presents the results of the dose evaluation. As can be seen in the table, the doses are within the limits specified by Section II of Appendix I.

TABLE IV-1 ANNUAL GASEOUS EFFLUENTS FROM EACH RELEASE POINT (3499 MWt)

		Release Point

CHAPTER 11 APPENDIX A

ANNEX A

DATA NEEDED FOR RADIOACTIVE

SOURCE TERM CALCULATIONS

FOR FERMI 2

TABLE OF CONTENTS

ANNEX A DATA NEEDED FOR RADIOACTIVE SOURCE TERM CALCULATIONS FOR FERMI 2

Following are the data requested in Appendix A to Regulatory Guide (RG) 1.112. This RG states that the information presented should be taken from the contents of the Safety Analysis Report (SAR) and the Environmental Report (ER). However, RG 1.112 (Reference 1) was issued subsequent to the submittal of the Enrico Fermi Atomic Power Plant Unit 2 (Fermi 2) FSAR (Reference 2) and ER (Reference 3). Regulatory Guide 1.112 provided new guideline values (through reference to NUREG-0016) (Reference 4) to be used when projecting the effectiveness of a given BWR radwaste system to reduce the quantity of radionuclides in plant effluents. These new guidelines are based on surveys of operating plants and represent average or expected conditions. Although the RG 1.112 values may vary from the expected values reported in the Fermi 2 FSAR, that does not mean that the Fermi 2 radwaste system will not perform as projected. This is based on the fact that the RG 1.112 value for each parameter is a single value which should best be represented by a range of values and therefore the possibility of a radwaste system parameter actually being greater or less than that predicted by RG 1.112 is to be expected.

On September 9, 1992, the NRC issued Amendment 87 to the Fermi 2 Operating License authorizing a change in the thermal power limit for 3293 MWt to 3430 MWt. Subsequently, on February 10, 2014, the NRC issued Amendment 196 to the Fermi 2 operating license authorizing a change in the thermal power limit from 3430 MWt to 3486 MWt. This Annex has been revised to reflect the changes that resulted from the power uprates.

The item in parentheses following the requested information is the section, page, table, or figure number of the original FSAR and/or ER or UFSAR wherein the information is presented. Also, when parameters reported in the FSAR, ER, and/or UFSAR differ from guideline values given in RG 1.112, the RG values will also be listed and followed by "(RG)". Values given in RG 1.112 were used in the generation of source terms.

1. GENERAL

   a. The maximum core thermal power evaluated for safety consideration in the UFSAR

      Response

      3430 MWt x 1.02 = 3499 MWt (UFSAR Section 1.1)

   b. The quantity of tritium released in liquid and gaseous effluents

      Response

Tritium Released (Ci/yr)

	FSAR		RG
Liquid	52.5	(UFSAR Subsection 11.2.6)	11
Gaseous	52.5	(UFSAR Table 11.3-1)	75

2. NUCLEAR STEAM SUPPLY SYSTEM

a. Total steam flow rate

Response

1.52×10^7 lb/hr at 3499 MWt (UFSAR Subsection 11.3.2.2)

b. Mass of reactor coolant in the reactor vessel at full power (3486 MWt)

Response

5.52×10^5 lb (ER page 3A-3)

3. REACTOR COOLANT CLEANUP SYSTEM

a. Average flow rate

Response

1.33×10^5 lb/hr (ER page 3A-4)

b. Demineralizer type and size

Response

Type - powdered resin and filter aid material (ER page 3A-4)

Size - approximately 135 ft^2 of flow area, 20 lb of dry resin and filter aid material

There are two 50 percent units (UFSAR Table 5.5-2).

c. Replacement frequency

Response

The resin in each demineralizer is replaced about once per week (ER page 3A-4).

d. Backwash volume and activity

Response

Approximately 1100 gallons per backwash (based on data in UFSAR Figure 11.2-15)

Specific activity is 20 percent of reactor coolant (UFSAR Figure 11.2-15).

4. CONDENSATE DEMINERALIZERS

a. Average flow rate

Response

10.8×10^6 lb/hr at 3499 MWt (UFSAR Subsection 10.4.6.1.1)

b. Demineralizer type

Response

Powdered resin (UFSAR Subsection 10.4.6)

c. Number and size of demineralizers

Response

Number - 8 parallel operating demineralizers (UFSAR Subsection 10.4.6.2)

Size - approximately 890 ft^2 of filter surface flow area for non-pleated filters; approximately 17000 ft^2 of filter surface flow area for pleated filters

d. Replacement frequency

Response

10 days per vessel (ER page 3A-4)

e. Indicate whether ultrasonic resin cleaning is used and the waste liquid volume associated with its use

Response

Ultrasonic resin cleaning will not be used.

f. Backwash volume and activity

Response

5300 gallons per backwash (based on data in UFSAR Figure 11.2-15)

Specific activity is 5 x 10^{-6} μCi/ml (UFSAR Figure 11.2-15)

5. LIQUID WASTE PROCESSING SYSTEMS

a. For each liquid waste processing system, provide, in tabular form, the following information:

(1) Sources, flow rates, and expected activities [fraction of primary coolant activity (PCA) for all inputs to each system]

Response

This information as given in the UFSAR is presented in Table 1 of this Annex. Presented in Table 2 of this Annex are the RG 1.112 guideline values for sources to the liquid radwaste system. A power uprate scale-up factor of 1.02 was applied to obtain the sources at uprated conditions.

(2) Holdup times associated with the collection, processing, and discharge of all liquid streams

Response

In calculating the releases of radionuclides reported in the Fermi 2 UFSAR, no credit was taken for decay resulting from holdup within the process system. Holdup times based on the data presented in Table 1 have been calculated per RG 1.112 and are shown in Table 3 of this Annex. Holdup times based on RG 1.112 expected source volumes (Table 2) have also been calculated and are also presented in Table 3.

(3) Capacities of all tanks and processing equipment considered in calculating holdup times

Response

This information is presented in Table 4 of this Annex.

(4) Decontamination factors for each processing step

Response

Decontamination factors (DF) as projected in the FSAR are given in Table 4. Also given in Table 4 are the RG 1.112 guideline values for process equipment DF's.

(5) The fraction of each processing stream expected to be discharged over the life of the plant

Response

This data is presented in Table 4.

(6) For waste demineralizer regeneration, show the time between regenerations, regenerant volumes and activities, treatment of regenerants, and fractions of regenerant discharged. Include parameters used in making these determinations.

Response

There will be no demineralizer regeneration waste. All demineralizers will utilize either disposal deep beds or Powdex beds.

(7) Liquid source term by radionuclide (in Ci/yr) for normal operation, including anticipated operational occurrences

Response

Liquid source terms based on RG 1.112 guideline values are presented in Table 5 of this Annex.

b. Provide piping and instrumentation diagrams and process flow diagrams for the liquid radwaste systems along with all other systems influencing the source term calculations

Response

The requested figures are presented in both the FSAR and the ER. The source term calculations for the floor drain and chemical systems included only the use of filters and demineralizers.

Sump Pump	Figure 11.2-2 Sheets 4 and 5	Sheets 1 and 2

6. MAIN CONDENSER AND TURBINE GLAND SEAL AIR REMOVAL SYSTEMS

a. The holdup time for offgases from the main condenser air ejector prior to processing by the offgas treatment system

Response

From the air ejector to the discharge from the chiller unit just upstream of the first charcoal bed, the holdup time is 0.066 hour (UFSAR Subsection 11.3.2.7.3.1).

b. A description and the expected performance of the gaseous waste treatment systems for the offgases from the condenser air ejector and mechanical vacuum pump.

Include the expected air inleakage per condenser shell, the number of condenser shells, and the iodine source term from the condenser.

Response

Radiogases in the condenser offgas are reduced in concentration by the natural decay process. Most of the decay occurs in the six charcoal adsorbers; however, the short-lived radionuclides, such as N-16, decay off almost entirely prior to the offgas stream entering the charcoal units.

Noncondensable gases, including air inleakage and fission gases, are removed from the main condenser by air ejector (not part of the condenser offgas system). These gases then enter the offgas system where additional steam is injected into the air ejector discharge stream to dilute the hydrogen below 4 percent by volume. The mixture passes through a moisture separator before it is superheated in a preheater to remove water droplets and to decrease humidity. It enters the catalytic recombiner where free hydrogen and oxygen are converted into water vapor. The offgas effluent from the recombiner is passed through a condenser cooled by reactor condensate to remove the bulk moisture, and then through an aftercooler and a precooler for drying.

The gas then enters a 2.2-minute delay pipe which is followed by a sand filter. The gas is then cooled to +14°F and enters the ambient temperature charcoal adsorbers. Chilling and drying the air improve charcoal adsorber performance. Adsorber system discharge is filtered, mainly to remove any charcoal fines that may have been carried out of the last charcoal bed. The gas is then pumped into the offgas discharge piping. The system vacuum pump is used to maintain a slightly negative pressure throughout the system, ensuring that any leakage would be into the system. The effluent from the offgas system is discharged from the plant after dilution in the reactor building ventilation system exhaust. A more detailed discussion of the condenser offgas system is presented in Section 11.3 of the UFSAR.

For the one-shell condenser, the expected inleakage is approximately 6 SCFM; however, the system was designed assuming a 40-SCFM inleakage. The RG 1.112 guideline value for condenser inleakage is 10 ft^3/min per shell; therefore, for Fermi 2 an inleakage of 10 ft^3/ min is used when evaluating this system for Appendix I compliance.

Based on the design value of 40 SCFM inleakage; however, the condenser offgas system is expected to perform as follows:

(1) Holdup time for kryptons, 24 hours

(2) Holdup time for xenons, 16 days

(3) A DF of about 1160 for radiogases of kryptons and xenons (inlet concentration/outlet concentration)

(4) A DF of about 90 over that provided by 30-minute delay.

The above values are not used in the Appendix I calculations, but are utilized as the design basis (see Section 11.3).

The iodine source term from the condenser was not supplied in the FSAR or ER. The RG 1.112 guideline value for the iodine source term from the main condenser to the offgas system for expected conditions is 5 Ci/yr of I-131.

The mechanical vacuum pumps discharge via a 2-minute delay pipe. These pumps are expected to be used only during operation below 5 percent reactor power, and the source term from the condenser to the vacuum pumps is expected to be negligible. However, presented below are the expected quantities of radionuclides released from the condenser via the mechanical vacuum pumps as projected by the Fermi 2 FSAR and RG 1.112.

	Fermi 2 FSAR Estimate (FSAR Table 11.3-1)	RG 1.112 Guideline Values
Xe-133	24 Ci/yr	2393 Ci/yr
XE-135	negligible	364 Ci/yr
I-131	negligible	0.03 Ci/yr

c. The mass of charcoal in the charcoal delay system used to treat the offgases from the main condenser air ejector, the operating and dew point temperatures of the delay system, and the dynamic adsorption coefficients for Xe and Kr

<u>Response</u>

(1) 60 tons of charcoal

(2) 70°F operating temperature

(3) -4°F dew point

(4) The dynamic adsorption coefficients for krypton and xenon are as follows:

Dynamic Adsorption Coefficients

	Fermi 2 FSAR	RG 1.112
Kr	36	25
Xe	610	440

This data is presented in Section 11.3 of the FSAR.

d. A description of the cryogenic distillation system, the fraction of gases partitioned during distillation, the holdup in the system, storage following distillation, and the expected system leakage rate

Response

Not applicable

e. The steam flow to the turbine gland seal and the source of the steam (primary or auxiliary)

Response

1.51×10^4 lb/hr of primary steam; the steam flow rate is consistent with RG 1.112 assumptions

f. The design holdup time for gas vented from the gland seal condenser, the iodine partition factor for the condenser, and the fraction of radioiodine released through the system vent. A description of the treatment system used to reduce radioiodine and particulate releases from the gland seal system.

Response

(1) 0.032 hour holdup

(2) 100 is the iodine partition factor expressed as DF; this is consistent with RG 1.112.

(3) 100 percent of the iodine exiting the 2-minute delay pipe is discharged via the reactor building vent.

(4) No treatment system is necessary downstream of the gland seal condenser and 2-minute delay pipe to further reduce the quantity of radioiodine or particulates released from this system.

g. Piping and instrumentation diagrams and process flow diagrams for the gaseous waste treatment system along with all other systems influencing the source term calculations

Response

The requested figures are presented in both the FSAR and the ER:

Diagram	FSAR Figure	ER Figure
Offgas System P&ID (2 sheets)	11.3-1	3.5-3
Flow Diagram of the Condenser Offgas System	11.3-2	3.5-4

7. VENTILATION AND EXHAUST SYSTEM

For each plant building that houses a main condenser evacuation system, a mechanical vacuum pump, a turbine gland seal system exhaust, or a system that contains radioactive materials, provide the following:

a. Provisions incorporated to reduce radioactivity releases through the ventilation or exhaust systems

Response

(1) Reactor/Auxiliary Building Ventilation System (UFSAR Subsection 9.4.2)

Fermi 2 utilizes a Mark 1 containment design. One ventilation system is provided for both the reactor and auxiliary building portion of the complex. Under normal operating conditions the radionuclide concentration in the ventilation exhaust from these areas is expected to be negligible.

(2) Radwaste Building Ventilation System (UFSAR Subsection 9.4.3)

Under normal operating conditions the radwaste building exhaust is discharged through HEPA filters to remove particulate radioactive material.

(3) Turbine Building Ventilation System (UFSAR Subsection 9.4.4)

Filtration of the turbine building ventilation effluent is not necessary.

b. Decontamination factors assumed and the bases (include charcoal adsorbers, HEPA filters, and mechanical devices)

Response

Although HEPA filters are being installed in the exhaust stream of the radwaste building ventilation system to remove particulate radioactive material, no credit was assumed for this equipment in the Fermi 2 UFSAR. Regulatory Guide 1.112 does allow a DF of 100 on particulates for this equipment. Charcoal filters in the ventilation exhaust are not necessary.

c. Release rates for radioiodines, noble gases, and radioactive particulates and their bases

Response

This information is presented in Table 6 of this Annex for both the expected conditions as given in Table 11.3-1 of the FSAR and the guideline values given in RG 1.112.

d. Release point descriptions, including height above grade, height above and location relative to adjacent structures, expected average temperature difference between gaseous effluents and ambient air, flow rate, exit velocity, and size and shape of flow orifice.

Response

There are three ventilation release points: reactor building vent, turbine building vent, and the radwaste building vent. The reactor building vent is the release point for the following:

(1) Offgas system

(2) Turbine gland seal exhaust

(3) Mechanical vacuum pump

(4) Reactor/auxiliary building ventilation system.

The turbine building ventilation system exhaust is discharged via the turbine building vent, and radwaste building ventilation system exhaust is discharged via the radwaste building vent.

The reactor building vent is cylindrical in shape, extends 22.5 feet above the top of the reactor building and is 7 feet 2 inches in diameter. The vent centerline is approximately 8 feet 3 inches from the south wall of the reactor building. The top of the vent is at elevation 751 feet (mean tide, N. Y., 1935) and the grade is 583 feet. The exhaust from this vent is 112,000 ft^3/min at a velocity of 2750 ft/min (FSAR Subsection 11.3.7, Table 3.2, Annex B).

The turbine building vent is rectangular in shape, extends 8 feet above the upper roof of the turbine building and has a cross-sectional area of approximately 420 ft^2. The vent centerline is approximately 67 feet from the south wall and 73 feet from the east wall of the turbine building. The top of the vent is at elevation 719.5 feet (mean tide, N.Y., 1935). The exhaust from the vent is approximately 390,000 ft^3/min at a velocity of 830 ft/min (FSAR Subsection 11.3.7, Table 3.2, Annex B).

The radwaste building vent is rectangular in shape, extends 54 feet above the lower roof of the turbine building, and has a cross-sectional area of approximately 20 ft^2. The vent centerline is approximately 383 feet from the south wall and 78 feet from the east wall of the turbine building. The top of the vent is at elevation 729 feet (mean tide, N.Y., 1935). The exhaust from the vent is approximately 35,100 ft^3/min at a velocity of 1755 feet/min (UFSAR Figure 9.4-5, Table 3.2, Annex B).

e. For the containment building, the expected purge and venting frequencies and duration and the continuous purge rate (if used)

Response

Fermi 2 is of the Mark I containment design. Following reactor startup, excess air from the reactor drywell will be exhausted along the wall above the refueling floor and discharged by the reactor/auxiliary building ventilation exhaust system (UFSAR Subsection 9.4.2).

Also the drywell atmosphere is controlled by the drywell cooling system (UFSAR Subsection 9.4.5) and will not normally require purging. No significant releases of radionuclides are expected from the Fermi 2 drywell.

[a] RG 1.112 sources are identified assuming the plant in question utilizes a Mark III containment. RG 1.112 data are based on data from facilities of Fermi 2 design. In order to be representative of Mark III containment, RG 1.112 divided the expected releases equally between the containment and the auxiliary building. For Fermi 2, whose reactor building and auxiliary building share the same exhaust line, the RG 1.112 values for each building were added back together.

[b] Negligible quantities of the radionuclide are expected to be released.

[c.] $1.2(-3) = 1.2 \times 10^{-3}$

CHAPTER 11 APPENDIX A

ANNEX B

ATMOSPHERIC TRANSPORT AND DISPERISON

MODELING FOR THE 10 CFR PART 5O APPENDIX I

CALCULATIONS

TABLE OF CONTENTS

1.0 INTRODUCTION

This annex presents the atmospheric transport and dispersion modeling methodology; the meteorological joint frequency distributions; and the normalized effluent concentrations, χ/Q, and relative deposition rates, D/Q, required for the 10 CFR Part 50 Appendix I evaluations. All calculations and methods used are in complete compliance with Regulatory Guide 1.111 (Reference 1). The results presented are used for dose calculations from airborne effluents.

The modeling technique chosen was the Straight-line Airflow Model which is presented and specifically approved in Reference 1. Because of flat terrain and the use of only one data station, it was felt that long term modeling using the mixed mode adaptation of the straight-line airflow technique and the open terrain correction factor developed by the NRC would provide as conservative and valid an estimate of the dispersion as the other more sophisticated techniques.

The mixed mode analyses were performed for three sources at the Fermi 2 site: the containment building vent, the turbine building vent, and the radwaste building vent. In addition, a fourth set of calculations were performed for strictly ground level releases.

The data used were taken at the 60-meter tower at the Fermi 2 site for the period June 1, 1974 through May 31, 1975. As part of the 10 CFR Part 50 Appendix I evaluations, the long term temporal representativeness of this on-site data, based upon 10 years of NWS data, is presented in Reference 2. The degree to which this single year of data base at the 60-meter tower is representative of actual site conditions is further discussed in Reference 3. The discussion of the primary air flow regimes which govern dispersion at the Fermi 2 site can be found in References 2 and 3 and in Section 2.3.2.3 and Section 2.3.2.4.2 of the FSAR (Reference 4).

Section 2 presents a description of the methodology used to calculate χ/Q, D/Q and mixed mode joint frequency distributions. Section 3 presents the results of the calculations for the specific source specifications of the Fermi 2 plant. Joint frequency distributions of a strictly ground level source for the annual average and grazing period average are tabulated in Appendix A. The mixed mode joint frequency distributions used for calculation of the elevated plume dose for the containment building emitting in the mixed mode for these same periods are tabulated in Appendix B. This same information for the turbine building emitting in the mixed mode is tabulated in Appendix C and for the radwaste building vent emitting in the mixed mode in Appendix D.

2.0 DESCRIPTION OF MODELING TECHNIQIES

This section describes the assumptions and calculational methodology used to compute the annual average and grazing period average values of the source-normalized effluent concentration χ/Q and the source-normalized relative deposition rate per unit area D/Q, as well as the joint frequency distributions of wind speeds, directions, and stabilities for these two intervals.

The calculational techniques for χ/Q and D/Q using the Straight-line Airflow Model described in Regulatory Guide 1.111 (Reference 1) require specification of the frequency of time, over a specified period, that each particular meteorological condition existed. In addition, estimates of the wind speeds at the height of release are needed. The models used and justification for the wind speed values used in these analyses are discussed in the following sections.

2.1 Description of χ/Q Calculational Methodology

This section describes the modeling methodology used to calculate the source-normalized concentrations used in the radiological dose calculations for sources considered appropriate to a mixed mode analysis and a ground level analysis following recommendations in Regulatory Guide 1.111 (Reference 1). The applicability of a mixed mode analysis for a particular source depends upon the source's relationship to nearby structures. For effluents released from points above adjacent solid structures, but lower than twice the height of these structures, the effluent plume is treated in a manner consistent with a mixed mode analysis. For effluents released from points below the height of adjacent solid structures, a strictly ground level release is assumed.

The mixed mode analysis is essentially a Straight-line Airflow Model with modifications to permit weighting calculated downwind concentrations by the amount of time the plume is considered to be entrained (or not entrained) in the volumetric wake of the building.

The equation for this model, as presented by Sagendorf (Reference 5), is:

$$\left(\overline{\chi/Q'}\right)_D = 2.032 \sum_{ij} n_{ij} \left[N X \bar{u}_i \Sigma_{zj}(X)\right]^{-1} \exp\left[-h_e^2/2\sigma_{zj}^2(X)\right] \quad (1)$$

where

h_e	is the effective release height;
n_{ij}	is the length of time (hours of valid data) weather conditions are observed to be at a given wind direction, windspeed class, i, and atmospheric stability class, j;
N	is the total hours of valid data;
$\bar{u}_i$	is the midpoint of windspeed class, i, at a height, h_e (effective release height)
$\sigma_{zj}(X)$	is the vertical plume spread without volumetric correction at distance, X, for stability class, j;
$\Sigma_{zj}(X)$	is the vertical plume spread with a volumetric correction for a release within the building wake cavity, at a distance, X, for stability class, j; otherwise $\Sigma_{zj}(X) = \sigma_{zj}(X)$;
$\left(\overline{\chi/Q'}\right)_D$	is the average effluent concentration, χ, normalized by source strength, Q', at distance, X, in a given downwind direction, D; and
2.032	is $(2/\pi)^{1/2}$ divided by the width in radians of a 22.5° sector.

For effluents released from points less than or equal to the height of adjacent solid structures, a ground-level release is assumed ($h_e = 0$).

For effluents released from vents or other points above adjacent solid structures, but lower than elevated release points, the effluent plume is considered as an elevated release whenever the vertical exit velocity of the plume, W°, is at least five times the mean horizontal windspeed, u_r, at the height of release; i.e., as modified from Johnson et al. (Reference 6):

$$W_o/\bar{u}_r \geq 5.0$$

In this case, the effective release height is determined from (Reference 5):

$$h_e = h_s + h_{pr} - h_t - c \tag{2}$$

where

- c is the correction for low relative exit velocity (see equation 9)
- h_e is the effective release height
- h_{pr} is the rise of the plume above the release point, according to Sagendorf (Reference 5), whose treatment is based on Briggs (Reference 7); (see below)
- h_s is the physical height of the release point (the elevation of the stack base should be assumed to be zero); and
- h_t is the maximum terrain height (above the stack base) between the release point and the point for which the calculation is made (for this calculation h_t identically equals zero).

Because of flat terrain around the Fermi 2 site, the terrain height h_t was set equal to zero in all calculations reported herein. Plume rise was calculated using formulae from Briggs (Reference 7). For neutral or unstable conditions,

$$h_{pr} = 1.44 \left(\frac{W_o}{\bar{u}_r}\right)^{2/3} \left(\frac{X}{d}\right)^{1/3} d \tag{3}$$

where

- h_{pr} plume rise
- W_o exit velocity
- X distance
- $\bar{u}_r$ wind speed
- d internal stack diameter

The result from this calculation is compared with that from

$$h_{pr} = 3\left(\frac{W_o}{\bar{u}_r}\right) d \tag{4}$$

and the lesser value is used.

For stable conditions the results from equation (3) or (4) are compared with the results from the following two equations:

$$h_{pr} = 4\left(\frac{F_m}{S}\right)^{1/4} \tag{5}$$

$$h_{pr} = 1.5\left(\frac{F_m}{\bar{u}_r}\right)^{1/3} S^{-1/6} \quad (6)$$

where

F_m = momentum flux parameter

S = stability parameter.

and the smallest value of h_{pr} is used. F_m and S are defined as follows:

$$F_m = W_o^2\left(\frac{d}{2}\right)^2 \quad (7)$$

$$S = \frac{g}{T}\frac{\delta\theta}{\delta z} \quad (8)$$

where

g = acceleration of gravity

T = ambient air temperature

$\frac{\delta\theta}{\delta z}$ = vertical potential temperature gradient.

For the purposes of the calculations for the Fermi 2 site, S was defined as 8.75×10^{-4} for E stability; 1.75×10^{-3} for F stability; and 2.45×10^{-3} for G stability.

When the vertical exit velocity is less than 1.5 times the horizontal windspeed, a correction for downwash is subtracted from Equation (2) according to Gifford (Reference 8):

$$c = 3\left(1.5 - {W_o}/{\bar{u}_r}\right)d \quad \text{for} \quad 1 \leq {W_o}/{\bar{u}_r} \leq 1.5 \quad (9)$$

and $\quad c = 0$ otherwise

where

c is the downwash correction;

$\bar{u}_r$ is the mean windspeed at the height of release; and

W_o is the vertical exit velocity of the plume.

If ${W_o}/{\bar{u}_r}$ is less than 1.0 or unknown, a ground-level release is assumed ($h_e = 0$).

For cases where the ratio of plume exit velocity to horizontal windspeed is between one and five, a mixed release mode is assumed, in which the plume is considered as an elevated release during a part of the time and as a ground-level release ($h_e = 0$) during the remainder of the time. An entrainment coefficient, E_t, modified from Reference 7, is determined for those cases in which W_o/u_r is between one and five:

$$E_t = 2.58 - 1.58(W_o/\bar{u}_r) \text{ for } 1 \leq W_o/\bar{u}_r \leq 1.5 \quad (10)$$

and

$$E_t = 0.3 - 0.06(W_o/\bar{u}_r) \text{ for } 1.5 \leq W_o/\bar{u}_r \leq 5.0 \quad (11)$$

The release is considered to occur as an elevated release $100(1\text{-}E_t)$ percent of the time and as a ground release $100E_t$ percent of the time. Each of these cases is then evaluated separately and the concentration calculated according to the fraction of time each type of release occurs. Windspeeds representative of conditions at the plume heights are used for the times when the release is considered to be elevated. Wind speeds measured at the 10-meter level are used for those times when the effluent plume is considered to be a ground level release.

For the ground-level portion of the releases only ($h_e = 0$), an adjustment is made in Equation (2) that takes into consideration initial mixing of the effluent plume within the building wake. This adjustment, according to Yanskey et al. (Reference 9), is in the form of:

$$\Sigma_{zj}(X) = \left(\sigma_{zj}^2(X) + 0.5\, D_z^2/\pi\right)^{1/2} \leq \sqrt{3}\sigma_{zj}(X) \tag{12}$$

where

D_z is the maximum adjacent building height either up- or downwind from the release point;

$\sigma_{zj}(X)$ is the vertical standard deviation of the materials in the plume at distance, X, for atmospheric stability class, j; and

$\Sigma_{zj}(X)$ is the vertical standard deviation of plume material as above, with the correction for additional dispersion within the building wake cavity, restricted by the condition that

$$\Sigma_{zj}(X) = \sqrt{3}\sigma_{zj}(X)$$

when

$$\left(\sigma_{zj}^2(X) + 0.5D_z^2/\pi\right)^{1/2} > \sqrt{3}\sigma_{zj}(X)$$

For the elevated portion of the releases, no credit is taken for any additional dispersion within the building wake cavity and $\Sigma_{zj}(X)$ is set equal to $\sigma_{zj}(X)$.

Adjustments were made to the normalized effluent concentrations because the Straight-line Airflow Model does not consider the effects of spatial and temporal variations in airflow in the region of the site. The terrain near the site is flat and open so adjustment factors for "sites in open terrain" were applied. The final calculations of χ/Q and D/Q for both strictly ground level release and mixed mode release were multipled by the open terrain correction factor as a function of distance as shown in Figure 2, in Reference 1.

A conceptual flow diagram summarizing the calculational methodology used to calculate χ/Q from the joint frequency distribution is presented in Figure 2.1.

2.2 Deposition Methodology for Calculating D/Q

This section describes the modeling methodology used to calculate the source-normalized relative deposition rate per unit area (D/Q) used in the radiological dose calculations for sources considered as strictly ground level and those considered acceptable to a mixed mode analysis.

The deposition rate per unit downwind distance divided by the source strength was determined from Figures 7 through 10 of Reference 1.

The criteria by which a meteorological condition caused the source to emit in the elevated mode were taken as the same as in the χ/Q calculational methodology. If an elevated release was appropriate, the plume rise was calculated in the same manner as for the χ/Q estimates. Generally this effective plume height was greater than 60 meters but less than 100 meters.

To interpolate relative deposition rate for release heights other than those presented in Figures 7 through 10 of Reference 1, a logarithmic relationship was used,

$$\log D_r(h) = a \log h + b \tag{13}$$

where

$D_r(h)$ relative deposition rate for release height h

$$a = \frac{\log D_{r_1}(h_1) - \log D_{r_2}(h_2)}{\log h_1 - \log h_2} \tag{14}$$

$$b = \frac{\log D_{r_2}(h_2) \log h_1 - \log D_{r_1}(h_1) \log h_2}{\log h_1 - \log h_2} \tag{15}$$

For example, to find the relative deposition rate for a release height of 80 meters under unstable conditions at a downwind distance of one kilometer, first $D_r(100) = 5 \times 10^{-5}$ is found from Figure 10, Reference 1, and $D_r(60) = 6 \times 10^{-5}$ is found from Figure 9, Reference 1. Then, a and b are calculated as follows:

$$a = \frac{\log(5\times10^{-5}) - \log(6\times10^{-5})}{\log 100 - \log 60} = -0.35691$$

$$b = \frac{\log(6\times10^{-5}) \log 100 - \log(5\times10^{-5}) \log 60}{\log 100 - \log 60} = -3.58721$$

Finally, $D_r(80)$ is calculated:

$$\begin{aligned} \log D_r(80) &= -0.35691 \log 80 - 3.58721 \\ &= 0.73356 - 5 \\ D_r(80) &= 5.41452 \times 10^{-5} \end{aligned}$$

In order to calculate values for D_r for distances which are not shown on Figures 7 through 10 of Reference 1, (e.g., values for distances close to the release site under stable conditions for elevated releases) the portions of the curve which are presented were logarithmically extrapolated to a minimum value of 10^{-10}. Any values less than this were set equal to 10^{-10} and used in the calculations.

For the ground level portion of the mixed mode release, no interpolation for height was performed and the values from the curve in Figure 7 of Reference 1 were used. In accordance with recommendations in Reference 1, the final calculations of χ/Q and D/Q for strictly ground level release and mixed mode release were multiplied by the open terrain correction factor as a function of distance as shown in Figure 2, Reference 1.

A conceptual flow diagram summarizing the calculational methodology used to calculate D/Q from the joint frequency distribution is presented in Figure 2.2. Note the similarity between techniques for χ/Q and D/Q.

2.3 Description of Mixed Mode Joint Frequency Distribution for Gamma Doses

This section describes the methodology used to calculate the sets of joint frequency distributions used as input for the calculation of the gamma doses. Each set of joint frequency distributions consists of two combinations: a ground level release and an elevated release. For a ground level release, the frequency of occurrence of each wind speed-wind direction-stability class combination was calculated and was weighted by the percent of time that meteorological combination was considered to be entrained in the building wake cavity. For the elevated release a separate similar distribution was calculated but weighted by the percent of time that each meteorological condition caused the vent to emit in the elevated mode. The entrainment coefficient was calculated in the same manner as for the □/Q estimates. These two joint frequency distributions, taken separately, do not sum to unity. The first sums to the total frequency that the release was considered to be a ground level source, and the second to the total frequency that the release was considered elevated. Together, however, these distributions sum to unity.

Because the criteria for the determination of the entrainment coefficient are dependent upon wind speed only, the relative frequencies of occurrence for stability and wind direction are identical for the mixed mode ground level and mixed mode elevated distributions. However, the relative wind speed frequencies of occurrence are different. Because lower wind speeds tend to be categorized as elevated releases, the average speeds for the mixed mode ground level distribution tend to be higher than those for a strictly ground level release. Similarly, since higher winds tend to be categorized as ground level releases, the average speeds for the mixed mode elevated distribution tend to be lower than those expected from the power law extrapolation of the strictly ground level release.

Presentation of the final plume height attained for each meteorological combination for the elevated portion of the mixed mode source is difficult to include with the joint frequency distribution. For this reason, the most conservative approach possible was taken. That is, since the wind speeds categorized in the elevated joint frequency distribution were calculated at the height of release (e.g., 51.2 meters for the containment building), the radiological dose calculations were performed under the assumption that when an elevated release was considered to exist, the plume rise was zero.

The mixed mode joint frequency distribution tables for the annual average and grazing period average are presented in Appendices B, C, and D for each of the three different sources considered. Note that the grazing period frequencies of occurrence are normalized to the number of hours during that period, i.e., the sum of all frequencies adds to unity.

2.4 Meteorological Data

Meteorological data were taken on-site at 10 meters and at 60 meters from 1 June 1974 through 31 May 1975. A complete description of the on-site meteorological monitoring program, along with instrument accuracy and adequacy, can be found in Reference 4.

The degree to which this year of data base at the 60-meter tower is representative of actual site conditions is discussed in Reference 3. The discussion of the primary airflow regimes which govern dispersion at the Fermi 2 site can be found in References 2 and 4.

The mixed mode release analysis specified in Reference 1 requires that the wind speed be determined at the point of release. Because the measured wind velocities are at heights other than the point of release, a power law wind profile was used for interpolation (section 2.4.2).

2.4.1 Joint Frequency Distributions

The calculational methodology used to develop the joint frequency distributions (other than those used in gamma dose calculations) of meteorological variables used in the analyses is described below.

Joint frequency distributions give the frequency of time, over a specified period, that specified classes of wind speed, wind direction, and atmospheric stability co-existed.

Wind direction, as measured at the 10-meter level, was classified into sixteen 22.5-degree sectors centered on the cardinal compass points. Wind speed, as measured at the 10-meter level, was categorized into 12 classes as shown below:

Class Number	Wind Speed Range (mph)	Interval Medial Used in Calculations (mph)
1 (Calms)	$0.0 \leq u \leq 0.5$	0.5*
2	$0.5 \leq u \leq 2.5$	1.5
3	$2.5 \leq u \leq 4.5$	3.5
4	$4.5 \leq u \leq 6.5$	5.5
5	$6.5 \leq u \leq 8.5$	7.5
6	$8.5 \leq u \leq 11.5$	10.0
7	$11.5 \leq u \leq 14.5$	13.0
8	$14.5 \leq u \leq 18.5$	16.5
9	$18.5 \leq u \leq 23.5$	21.0
10	$23.5 \leq u \leq 30.5$	27.0
11	$30.5 \leq u \leq 39.5$	35.0
12	$39.5 < u$	42.0

* 0.5 was used for calms because the median is less than 1/2 the starting threshold of the instruments.

The joint frequency data used in the radiological dose calculations were derived from the data collected on the 60-meter tower. The meteorological data used in the joint frequency distribution derivation were collected over the period from 1 June 1974 through 31 May 1975. Tables of frequency of occurrence of wind speed by direction for each stability category are presented in Appendix A. For radiological dose evaluations during the grazing period, the data collected over the period 15 April 1975 through 31 May 1975 were sequenced around to the beginning of the 1 June 1974 through 15 October 1974 period and the resultant 6 month period categorized. The grazing period frequencies of occurrence are normalized to the number of hours during that period, i.e., the sum of all frequencies adds to unity.

2.4.2 Power Law Wind Profile

Mixing-Length Theory (Reference 10) predicts that the wind speed profile should follow a simple logarithmic pattern in the presence of purely mechanically generated turbulence over homogeneous terrain and in the absence of thermal stratification. This logarithmic profile fits observations well only when the temperature lapse rate is neutrally stable. Under these conditions, mechanical turbulence dominates and is neither augmented by thermally induced turbulence (unstable case) nor suppressed by thermal stratification (stable case). When the lapse rate is not neutral, the logarithmic law is not a good description of the wind profile. In order to describe the wind speed profile when the lapse rate is not neutral, various empirical methods have been suggested which incorporate corrections for stability. The most successful of these is the power law profile. This is stated as:

$$\frac{u_1}{u_2} = \left(\frac{z_1}{z_2}\right)^m \text{ where } 0 \leq m \leq 1 \qquad (16)$$

where

z_1 = height at elevation 1

z_2 = height at elevation 2

u_1 = wind speed at height z_1

u_2 = wind speed at height z_2

m = a non-dimensional variable which depends on thermal stability

This technique was used to interpolate wind velocities at the point of release at the Fermi 2 site from the on-site data.

To determine the behavior of m with lapse rate at the Fermi 2 site, equation (16) was solved for m in terms of the hourly-averaged wind speeds at the 10- and 60-meter levels:

$$m = \frac{\log u_{60} - \log u_{10}}{\log(60) - \log(10)} \qquad (17)$$

The calculated hourly values of m were then plotted on a scatter diagram as a function of the corresponding hourly average temperature difference between the 10- and 60-meter levels. The diagram shown in Figure 2.3 presents these data for the period 1 June 1974 through 31 May 1975. The number of occurrences of any particular set of values is given by the alphabetic rank of the letter plotted at the location of those values. The average value of m decreases with increasing temperature difference. The Pasquill stability categories are also shown in Figure 2.3 to allow easy comparison with the average value of m in each class. For the annual period considered, the average value of the power law exponent by stability class is given in Table 2.1.

To determine whether there was a seasonal dependence on the power law wind profile exponent for the Fermi 2 site data, the same type of analysis as that done in Figure 2.3 was done for the data for each of the four seasons. The seasonal behavior of the power law exponent is shown in Figure 2.4. From this analysis it can be seen that there is little variation in the average curve for the different seasons.

Because of the possibility of a parametric dependence of the power law exponent upon other meteorological variables, the scatter diagram technique was applied to the 10-meter level wind speed averages as well. These data are shown in Figure 2.5. The dependence of m upon wind speed for values greater than about seven mph is negligible. For wind speeds less than this, the average value of m increases relatively slowly down to a speed of about five mph and then rapidly for lower values. This is probably due to the parametric relationship between low wind speeds and high atmospheric thermal stability where the surface winds essentially decouple from the faster moving upper level flows. This does not invalidate the power law profile extrapolation technique.

In all elevated wind speed calculations, the 10-meter level wind speed was extrapolated to the elevated height using the power law profile with the exponent values shown in Table 2.1 by stability class.

TABLE 2.1. AVERAGE VALUES OF POWER LAW WIND PROFILE EXPONENT BY STABILITY CLASS.

Pasquill Stability Class	Average Value of Exponent	Standard Deviation of Average	Average Wind Speed (mph)	Percentage of Occurrence
A	0.141	0.157	8.95	9.17

F	0.414	0.186	6.82	10.31
G	0.435	0.274	5.41	5.30

3.0 FERMI 2 SITE SPECIFIC χ/Q AND D/Q VALUES

The methodology described in section 2 of this annex was applied to the 60-meter tower data base from June 1, 1974 through May 31, 1975 for the receptor locations shown in Table 3.1. This table describes the distance to the nearest receptor type in each 22 1/2 degree sector out to a distance of 5 miles (8.047 Km). The analyses were performed for the three separate sources whose release specifications are shown in Table 3.2.

The annual average values for the ground level and mixed mode χ/Q and D/Q for the containment building vent, the turbine building vent, and the radwaste building vent are presented in Tables 3.3, 3.5, and 3.7, respectively. The grazing period (April 15 through October 15) values for the ground level and mixed mode χ/Q and D/Q for the three sources are presented in Tables 3.4, 3.6, and 3.8.

APPENDIX B

Mixed Mode Joint Frequency Distribution Between Wind Speed, Wind Direction, and Stability for the Fermi 2 Containment Building Source.

APPENDIX B

Part B-1: Analysis for Ground Level Portion of Mixed Mode Source

a) Wind speed at 10 meters

b) Wind direction at 10 meters

c) Delta temperature between 10 and 60 meters

d) Containment building source

Note: In the tables of computer printout the term, "Split-H", should be replaced by the term, "mixed mode".

ANALYSES FOR GROUND LEVEL PORTION OF SPLIT-H SOURCE

APPENDIX B

Part B-2: Analysis for Elevated Portion of Mixed Mode Source

a) Wind speed at 51.2 meters

b) Wind direction at 10 meters

c) Delta temperature between 10 and 60 meters

d) Containment building source

Note: In the tables of computer printout the term, "Split-H", should be replaced by the term, "mixed mode".

ANALYSES FOR GROUND LEVEL PORTION OF SPLIT-H SOURCE

APPENDIX B

Part B-4: Analysis for Elevated Portion of Mixed Mode Source

a) Wind speed at 51.2 meters

b) Wind direction at 10 meters

c) Delta temperature between 10 and 60 meters

d) Containment building source

Note: In the tables of computer printout, the term, "Split-H", should be replaced by the term, "mixed mode".

ANALYSES FOR ELEVATED PORTION OF SPLIT-H SOURCE

APPENDIX C

Mixed Mode Joint Frequency Distribution Between Wind Speed. Wind Direction, and Stability for the Fermi 2 Turbine Building Source.

APPENDIX C

Part 1: Mixed Mode Joint Frequency Distribution of Annual Data Base for the Turbine Building Source

6/1/74 - 5/31/75

APPENDIX C

Part C-1: Analysis for Ground Level Portion of Mixed Mode Source

a) Wind speed at 10 meters

b) Wind direction at 10 meters

c) Delta temperature between 10 and 60 meters

d) Turbine building source

Note: In the tables of computer printout the term,"Split-H", should be replaced by the term, "mixed mode".

ANALYSES FOR GROUND LEVEL PORTION OF SPLIT-H SOURCE

APPENDIX C

Part C-2: Analysis for Elevated Portion of Mixed Mode Source

a) Wind speed at 51.2 meters

b) Wind direction at 10 meters

c) Delta temperature between 10 and 60 meters

d) Turbine building source

Note: In the tables of computer printout the term, "Split-H", should be replaced by the term, "Mixed mode".

ANALYSES FOR GROUND LEVEL PORTION OF SPLIT-H SOURCE

APPENDIX C

Part C-4: Analysis for Elevated Portion of Mixed Mode Source

a) Wind speed at 51.2 meters

b) Wind direction at 10 meters

c) Delta temperature between 10 and 60 meters

d) Turbine building source

Note: In the tables of computer printout the term, "Split-H", should be replaced by the term, "mixed mode".

ANALYSES FOR ELEVATED PORTION OF SPLIT-H SOURCE

APPENDIX D

Mixed Mode Joint Frequency Distribution Between Wind Speed, Wind Direction and Stability for the Fermi 2 Radwaste Building Source

APPENDIX D

Part 1: Mixed Mode Joint Frequency Distribution of Annual Data Base for the Radwaste Building Source.

6/1/74 - 5/31/75

APPENDIX D

Part D-1: Analysis for Ground Level Portion of Mixed Mode Source

a) Wind speed at 10 meters

b) Wind direction at 10 meters

c) Delta temperature between 10 and 60 meters

d) Radwaste building source

Note: In the tables of computer printout the term, "Split-H", should be replaced by the term, "mixed mode".

ANALYSES FOR GROUND LEVEL PORTION OF SPLIT-H SOURCE

APPENDIX D

Part D-2: Analysis for Elevated Portion of Mixed Mode Source

a) Wind speed at 44.50 meters

b) Wind direction at 10 meters

c) Delta temperature between 10 and 60 meters

d) Radwaste building source

Note: In the tables of computer printout the term, "Split-H", should be replaced by the term, "mixed mode".

ANALYSIS FOR GROUND LEVEL PORTION OF SPLIT-H SOURCE

APPENDIX D

Part D-4: Analysis for Elevated Portion of Mixed Mode Source

a) Wind speed at 44.50 meters

b) Wind direction at 10 meters

c) Delta temperature between 10 and 60 meters

d) Radwaste building source

Note: In the tables of computer printout the term, "Split-H", should be replaced by the term, "mixed mode."

ANALYSES FOR ELEVATED PORTION OF SPLIT-H SOURCE

CHAPTER 12: RADIATION PROTECTION

This chapter describes the radiation protection measures incorporated in plant design and in operating procedures to ensure that internal and external occupational radiation exposures and exposure of the population due to plant conditions, including anticipated operational occurrences, will be as low as reasonably achievable (ALARA) and within all applicable limits. Radiation protection measures include shielding designed to adequately attenuate radiation emanating from sources of significant ionizing radiation, ventilation systems designed to minimize inhalation exposures, operational and administrative controls and procedures including controlled access to hazardous and potentially hazardous areas, and permanently installed radiation-monitoring systems.

In September 1992, the NRC issued Amendment 87 to the Fermi 2 Operating License authorizing a change in the thermal power limit from 3293 MWt to 3430 MWt. The data provided in Chapter 11 for the original power level (3293 MWt) was calculated at 3430 MWt for source terms, activity releases, and doses to the public. As a result of the power uprate, source terms, activity releases, concentrations, and doses have been adjusted linearly to correspond to 102 percent of uprated power, or 3499 MWt. Flow rates, masses, and volumes are also scaled linearly for the uprated conditions. Table 11.1-1 provides the scale-up factors used in Sections 12.1 and 12.2. The source terms shown in Chapter 11 (Table 11.1-2) have not been adjusted for power level because they are derived from the standard annual average design basis release rate of 0.1 Ci/sec at t = 30 minutes.

On February 10, 2014, the NRC issued Amendment 196 to the Fermi 2 operating license authorizing a change in the thermal power limit from 3430 MWt to 3486 MWt, a 1.64 percent increase in thermal power. This Measurement Uncertainty Recapture (MUR) power uprate was performed in accordance with 10 CFR 50, Appendix K and the analyses performed at 102% of the pre-MUR licensed thermal power (3430 MWt) remain applicable at the MUR uprated thermal power (3486 MWt) because the 2% uncertainty is effectively reduced by the improvement in feedwater flow measurement. As such, the source terms, activity releases, concentrations, and doses were not adjusted as a result of the MUR power uprate.

The radiological/ALARA consequences of the addition of a Hydrogen Water Chemistry (HWC) system at Fermi 2 were thoroughly evaluated by Detroit Edison, with the assistance of General Electric personnel. The potential impacts will result from the increased N-16 concentrations in the steam. Detailed high-power radiation levels were measured by survey instruments around the Fermi site prior to the introduction of HWC. These measurements (both inside of major buildings and also outside, in yard areas) were then repeated under the full range of potential HWC conditions, up through high power and maximum hydrogn-injection rates. It was found that the N-16 concentration in the main steam lines increased by a maximum factor of six over the original design basis. Consequentially, radiation levels in many areas throughout the plant also increased. The measurements inside of the major buildings in the RCA showed that (with only two minor exceptions) the HWC radiation levels in normally-accessible areas remained below the original design-basis criteria described in this chapter. This information, along with data from area dosimeter of legal record (DLR) measurements, was then evaluated to assess the impact of HWC injection on:

a. Dose to members of the public, (40 CFR 190)

b. Dose to plant personnel outside of the Radiologically Controlled Area (RCA), (10 CFR 20)

c. Maintenance of ALARA levels during plant operation and maintenance.

The evaluation concluded that due to the large size of the Fermi 2 site, radiological concerns are limited to onsite personnel. Increases in steam-line radiation dose rates will impact activities within the RCA, and it was determined that an additional annual dose of about 5 person-rem would most likely result from the introduction of full-time HWC. Personnel exposures will be maintained ALARA, however, through appropriate compensatory measures. These measures include:

a. Re-posting and locking areas, as needed, in accordance with 10 CFR 20 requirements and Fermi 2 policy

b. Using additional permanent and/or temporary shielding where needed and feasible

c. Temporarily reducing the HWC injection flow during certain maintenance activities

d. Using remote sensing equipment such as closed circuit television, to reduce the need for entry into high radiation areas for inspections and surveillances, when practical

e. Monitoring of personnel as radiation workers, in accordance with 10 CFR 20.

12.1 SHIELDING

12.1.1 Design Objectives

12.1.1.1 Compliance With Federal Regulations

The primary design objective of the plant radiation shielding is to minimize the exposure of plant operating personnel and the general public to radiation due to the reactor, power conversion, auxiliary, and waste processing systems during normal operation, anticipated operational occurrences, postulated accident conditions, and maintenance.

This objective has been accomplished by designing the shielding to

a. Limit exposure to radiation of plant personnel, contractors, and authorized site visitors to as far below the limits set forth in 10 CFR 20 as reasonably achievable for plant operation, including anticipated operational occurrences and maintenance, as recommended in Regulatory Guide 8.8

b. Limit radiation exposure of main control room personnel to as far below the limits in 10 CFR 20 as reasonably achievable, and, in the unlikely event of an accident, to allow habitability of the main control room, as specified in General Design Criterion (GDC) 19 of 10 CFR 50, Appendix A

c. Limit exposures to the offsite general public from direct and air-scattered radiation to within a small fraction of the limits set forth in 10 CFR 20 during normal operation and anticipated operational occurrences, and to within the limits specified in 10 CFR 50.67 for postulated accident conditions

d. Provide barriers for restricting personnel access to high radiation areas and to assist in controlling the spread of radioactive contamination

e. Protect certain plant components from excessive radiation damage or activation. For example, radiation heating of bulk structural concrete is limited and neutron activation of equipment, piping, and other materials is reduced by the reactor sacrificial shield.

Examples of specific steps in design for representative activities that have been taken or are being taken to incorporate the guidance given in Regulatory Guides 8.8, 8.10, and 1.8, where applicable, are given below or are referenced in other chapters of the UFSAR.

The handling, processing, storage, and disposal of various wastes is described in Sections 11.5 and 11.7. In addition to pool storage for irradiated reactor components, the containers of processed waste that may contribute to a radiation level above normal background can be placed in the onsite storage building. Mobile air-handling and -filtering units are available for area airborne contamination control (tenting, bag/gloves, room isolation, etc.).

In the activities of routine operational surveillance and instrument calibration, which will be performed by properly trained personnel, a number of design features have been included to ensure ALARA radiation levels. Remote area alarms and process monitor alarms have been installed to provide advance warning of trouble spots, so that protective clothing and expendable equipment are available to perform surveys. As far as is reasonably achievable, offline monitors are used to allow low background use, maintenance, and calibration of the equipment. Consoles have been located in nonradiation zones wherever possible. Area radiation monitors are mounted to allow safe performance of inplace calibration checks with shielded units, and a calibration facility will be provided for the use of shielded calibration sources.

As an example of response to and cleanup following postulated accidents, the potential for accidents was factored into the design of the basement section of the radwaste building. Each basement room containing radioactive liquid tanks is isolated by a curb and watertight doors, designed to completely contain the liquid contents from a simultaneous rupture of all tanks in the room. Each such room also contains an emergency pump that automatically pumps the liquid released in an accident into an appropriate holdup tank. All of the floors and walls (to an appropriate height) are painted or coated to facilitate cleanup and decontamination. In most cases, provisions exist to flush and drain tanks and associated piping, and both floor and equipment drains are built into each room where applicable. Each room can be isolated from the main corridor and from other rooms, from both physical and ventilation standpoints.

Each demineralizer located in the radwaste building is contained within an individual cubicle; the pumps, piping, and valves are contained in an adjacent shielded area, and any manual valve actuators are located in a third adjacent shielded corridor. This permits remote nonroutine operation and cleanup of a demineralizer. Each cubicle is shielded from adjacent cubicles. The filter-demineralizer retaining screens can be removed from a point above the cubicle with concrete plugs that open to the mezzanine (Figure 12.1-1).

The primary methods used for maintaining ALARA exposures in the maintenance of the radwaste system are the placement of process equipment such as filters, demineralizers, and evaporators in individual cubicles and the separation of components by shield walls. Instruments, controls, and valves, to the extent practicable, are located outside tank and process equipment cubicles. In this way, maintenance can be performed on a component without personnel receiving significant exposure from nearby sources of radiation. In most instances, equipment can be removed from cells either through stepped plugs in ceilings or through (normally blocked) knockouts in walls. Clearance provisions are normally adequate for both in-place maintenance activities and the removal or replacement of components. Most valves, pumps, piping, tanks, and other equipment can be flushed and drained prior to maintenance. Permanent piping is available to drain the contents of any large tank into another appropriate tank located in a different room.

The handling of processed radwaste is covered in Section 11.5. Movement of the radwaste drums from the empty-drum loading point to the discharge point in the OSSF was originally designed to be performed remotely. Viewing was originally designed to be done by television, by means of periscopes, and through special shielded viewing windows. Remote drum-transfer facilities are available after discharge from the onsite storage facility either to temporary storage or to transport trucks.

The gaseous radwaste system (offgas system) was specifically designed to maintain ALARA radiation levels, during both maintenance and operation. Each of the four air ejectors is located in a separate shielded cell, isolated from all other components and other radiation sources. The recombiner system is composed of two completely redundant trains, each housed in a shielded cubicle and separated from each other and all other sources. The chillers, final filters, and sand filters have complete redundance, each unit being contained in a separate, shielded cell. All cells contain knockout walls or overhead plugs for the removal of equipment, and adequate laydown space is provided for the equipment immediately outside most cells.

Instrumentation, controls, and nonradioactive auxiliary systems (e.g., offgas precooler refrigeration units and chiller compressor units) are located exterior to the radioactive cells whenever possible. Separate shielded pipe chases feed the radioactive lines to the separate cells. Hence, when the equipment in a particular cell is shut down for maintenance, little radiation will enter that cell from adjacent radioactive piping. Radioactive lines to the offgas cells have normally been routed so they do not run through any radioactive cells other than the cell they are servicing. The sand filters have provisions for remote drainage into a room below, and their shielded cells can be entered by removing large concrete plugs in the ceiling.

Since the charcoal adsorber beds are passive equipment at ambient temperature and are at a slightly negative pressure, failure and/or maintenance of a charcoal unit has been considered very unlikely. Nonetheless, system availability is protected, since any of the individual units can be bypassed by remote valving operations. Sufficient room has been left between individual charcoal units for portable shielding to be used. A large knockout block, with roll-up door, is located in the shield wall of the adsorber room for equipment removal. This knockout (and the adjoining portion of the adsorber room) is an area of quite low radiation level. Also, space has been provided for an additional six to eight adsorber tanks for future need.

A special portable reactor vessel head unit is available for purging the head of gaseous fission products prior to its removal (see Subsection 9.1.4.2.5). During refueling and its associated outage, all air on the refueling floor is exhausted (and monitored) through special exhaust ports at the top of the fuel pool, equipment storage pool, and vessel cavity. A special watertight gate can be installed between the equipment storage pool and the reactor cavity, thus enabling the storage pool to remain flooded when the cavity is drained. The water in the equipment pool, combined with the concrete shielding blocks between the two regions, protects the personnel working in the cavity and at the refueling floor from radiation originating in equipment (e.g., steam separator and dryer) stored in the equipment pool. Reactor vessel laydown space is available on the refueling floor, and the floor has been painted for ease of cleanup and decontamination.

During refueling, special ventilation provisions are available, and air is exhausted through ports at the top of the pools and reactor cavity. Hence, gaseous activity emanating from refueling should be swept out of these ports and will not contaminate the overall refueling floor. Sufficient water thickness has been designed into the pools to reduce to low levels the radiation from the storage of spent fuel in the storage pool. A description of the special fuel-handling equipment is given in Subsection 9.1.4.2. A special lead "chute" is also available to protect personnel in the drywell during maintenance.

A nominal 13 in. has been allowed for the installation of remote operating inservice inspection devices between the reactor vessel and the vessel insulation. Removable metallic reflective insulation is installed on the piping, valves, reactor nozzles, etc. This insulation is designed for quick removal and reinstallation. Concrete surfaces in the drywell are coated or painted for ease of cleanup and decontamination. During refueling, a special lead shielding bridge or chute will be installed in the reactor cavity between the vessel flange and the fuel pool gate. Its purpose is to protect the personnel who may be simultaneously working in the drywell from high radiation levels during fuel transfer (see Subsection 9.1.4.2.7). The sacrificial shield was especially designed to (1) reduce the neutron activation of drywell components and (2) reduce the gamma ray levels from reactor pressure vessel (RPV) shutdown, so that overall radiation levels in the drywell would be ALARA during maintenance and during inservice inspections (Subsection 12.1.2.2.1).

Special shield doors are installed around the important RPV nozzles (Subsection 12.1.2.2.1). These also (1) reduce neutron activation of drywell components for maintenance purposes, (2) provide nozzle access for inservice inspections on an ALARA basis (quick opening and closing of doors), and (3) provide shutdown gamma ray shielding from the RPV sources during shutdown conditions. An area is available near the personnel air lock to the drywell for clothes changing, personal monitoring, etc., both prior and subsequent to drywell entry and maintenance work. A very detailed 16:1 scale model of the drywell and all internals was constructed and was used to design the layout and assembly of the drywell internals for the most advantageous use of space.

In-place work on the control rod drive (CRD) equipment is discussed in Section 4.5. The hot drives are first lowered into a lead-shielded ultrasonic preflush tank, where the majority of the radioactive contaminants are flushed off. This tank has a closed-loop system and filters. The filters are to be periodically removed and stored in special containers filled with lead shot. The cleaned CRDs will be stored in racks in a special shielded storage room. Concrete shield walls have been located in various areas of the CRD repair facility to minimize direct radiation streaming. The use of these processes and devices will reduce radiation exposures and help to control contamination during overhaul and replacement of parts.

An example of the deliberate and detailed attention to principles of ALARA exposure levels incorporated into the Fermi 2 design is the condensate polishing demineralizers, which are located on the first floor of the turbine building. Each of the eight units is located in a separate, completely shielded cell. Auxiliary equipment, instrumentation, and controls are, when practical, located outside the cells in accessible areas. Each cell has its own air supply and exhaust to prevent cross-contamination between cells.

Radioactive valves (and associated piping) are also located outside the cells in special shielded "valve galleries" adjacent to the demineralizers.

A permanent piping system has been installed for chemically cleaning and flushing the original A-G demineralizer filter elements. No chemical cleaning piping was installed on the newer H-demineralizer because this practice is not utilized. Access to the units is through a stepped shielded manhole in the ceiling, with the shield plugs being removed by an overhead monorail system. When filter elements need cleaning or replacement, provisions have been made for their removal from the demineralizer vessels.

12.1.1.2 Direct Dose Rate at the Site Boundary

The average annual external dose at the nearest point on the site boundary due to normal operation (at the design limit) of the plant, including anticipated operational occurrences and excluding normal vent releases, has been calculated to be less than 8.0 mrem. The largest contributor to this dose is the turbine-generator reheaters located in the turbine building.

For the Independent Spent Fuel Storage Installation (ISFSI), the annual external dose at the nearest point on the site boundary resulting from a fully loaded storage pad has been calculated to be 18.1 mRem.

The dose rate at the site boundary from ^{16}N radiation is less than 8.0 mrem/year (see Section 12.1.3.9). The dose rate from the two condensate storage tanks is 3.6 x 10^{-3} mrem/year, or approximately 7.8 x 10^{-4} mrem/year/Ci. Since the radwaste drums are stored inside the onsite storage building, the dose at the site boundary from these drums of stored waste will be negligible (see Subsection 11.7.2.2.2).

12.1.1.3 Dose Rates Within the Site Boundary

Ten main radiation zones have been defined as a means of classifying the occupancy restrictions on various areas within the plant site boundary. These zones are defined in Table 12.1-1. The basis for the values defined in Table 12.1-1 for Zones I through X is that any one individual is limited to a maximum whole-body dose of 100 mrem/week (1.25 rem/quarter) averaged over his occupational work period. This is equivalent to an average of 2.5 mrem/hr for a 40-hr work week. This criterion does not necessarily exclude entry into areas of higher radiation dose rates, since access is determined by an integrated dose to personnel acquired by a combination of exposure time and dose rate. However, the zone criteria establish the need for and extent of the shielding. A description of each radiation zone defined in Table 12.1-1 is given in Subsections 12.1.1.3.1 through 12.1.1.3.10.

A detailed plot plan defining total plant layout is shown in Figure 12.1-2. The radiation area access zones used in the Fermi 2 shielding design are shown in Figures 12.1-1 and 12.1-3 through 12.1-8 for all areas in the facility for normal operation, and for certain conditions of shutdown and anticipated exposures during a LOCA.

NOTE: The radiation zoning was defined and utilized primarily for the analyses of the overall plant shielding (and HVAC) design and for the locating of all components which could potentially contain radioactivity, and therefore the zoning represents maximum design-basis radiation exposure levels (as noted in the aforementioned figures). As such, these design-basis radiation levels do not necessarily always correspond to the actual operational dose rates in any particular area. The radiation zones and their corresponding dose rates, occupancy times, posting requirements, and 10CFR20 references were set-up or delineated based upon an early/preceding design-basis purpose. Since this zoning was used only for the described original plant design-basis, there is no need or purpose to continuously upgrade this original design-basis section of the UFSAR. Therefore, this Section is kept in its original format.

12.1.1.3.1 Zone I

Zone I is the radiation zone classification for the main control room. This zone is designated as an area in which there are no radiological restrictions. The design dose rate for Zone I during normal plant operation, including anticipated operational occurrences, is 0.3 mrem/hr. Following an accident, the dose rate is such that the integrated whole-body dose does not exceed 5 rem over the duration of the accident.

12.1.1.3.2 Zone II

This zone, with a maximum design dose rate of 0.5 mrem/hr, is a restricted area that can be occupied by plant personnel and authorized visitors on a 40-hr per week, 50 week per year basis, without exceeding a fraction of the 1.25 rem per calendar quarter limit specified in 10 CFR 20.101. Most corridors and other areas requiring frequent access in the turbine, radwaste, reactor, and auxiliary buildings are designed to Zone II classification.

12.1.1.3.3 Zone III

This zone, with a maximum design dose rate of 1.0 mrem/hr, is a restricted area that can be occupied by plant personnel and authorized visitors on a 40-hr per week, 50 week per year basis, without exceeding the 1.25 rem per calendar quarter limit specified in 10 CFR 20.101. An example of this zone is the reactor building corridor area below the new-fuel storage vault.

12.1.1.3.4 Zone IV

This zone, with a maximum design dose rate of 2.0 mrem/hr, is a restricted area that can be occupied by plant personnel and authorized visitors on a 40-hr per week, 50 week per year basis, without exceeding the 1.25 rem per calendar quarter limit specified in 10 CFR 20.101. For example, an area classified as Zone IV is the reactor building core spray pump cubicles during normal operation of the plant.

12.1.1.3.5 Zone V

This zone, with a maximum design dose rate of 4.0 mrem/hr, is a restricted area, as defined in 10 CFR 20.202, that plant personnel can occupy on a periodic basis. Posting will normally not be required. However, temporary posting will be required if anticipated occupancy in these areas would result in exposures in excess of 100 mrem for any 5 consecutive days. Any areas within this zone remain accessible to plant personnel.

12.1.1.3.6 Zone VI

This zone, with a maximum design dose rate of 8.0 mrem/hr, is a restricted radiation area as defined in 10 CFR 20.202, and is posted with "Caution - Radiation Area" signs. Occupancy is limited, and Health Physics will evaluate on a case-by-case basis whether entry to such areas will require a radiation work permit. Length of stay in these areas is determined by the actual radiation level in the area, the past radiation history of the person entering, and the nature of the radiation.

12.1.1.3.7 Zone VII

This zone, with a maximum design dose rate of 15 mrem/hr, is also a radiation area as defined in 10 CFR 20.202. Posting and access control requirements are identical to those defined for Zone VI.

12.1.1.3.8 Zone VIII

This zone, with a maximum design dose rate of 30 mrem/hr, is also a radiation area as defined in 10 CFR 20.202. Posting and access control requirements are identical to those defined for Zone VI.

12.1.1.3.9 Zone IX

This zone, with a maximum design dose rate of 60 mrem/hr, is also a radiation area as defined in 10 CFR 20.202. Posting and access control requirements are identical to those defined for Zone VI.

12.1.1.3.10 Zone X

This is a radiation area zone with a design dose rate that exceeds 60 mrem/hr. All areas that exceed 100 mrem/hr are posted with "Caution - High Radiation Area" signs, as prescribed in 10 CFR 20.203. Areas that exceed 1000 mrem/hr are either kept locked or are guarded. Occupancy of such areas is limited in both frequency and duration and must be authorized in advance with a radiation work permit. Length of stay in these areas is determined by the actual radiation level in the area, the past radiation history of the person entering, and the nature of the radiation.

12.1.2 Design Description

12.1.2.1 General Shielding Design Criteria

The following design criteria were used to maintain ALARA personnel exposures:

a. Design of shielding and radiation zones was based on either the operating or shutdown condition of a system, whichever is the most restrictive

b. To the extent reasonably achievable, major sources of radioactivity are located in individually shielded cubicles to facilitate safe inspection and maintenance. Labyrinths are normally used to eliminate radiation streaming through access doorways into the cubicles. Thus, maintenance and repair may be accomplished in one cubicle without shutdown and decontamination of equipment in adjacent cubicles. Shielding of cubicles is designed so that work can be performed with ease, minimizing maintenance time and hence radiation exposure

c. To the extent reasonably achievable, instrumentation is located outside shielding walls (where access is unlimited) within limits dictated by the specifications for each particular instrument and associated equipment, component, or process line

d. Shielded valve stations are used when feasible to allow valve maintenance without drainage of associated equipment. To further minimize personnel exposure, remotely operated valves are used wherever practical, and, if manual valves are required, extension stems through a shield wall to a "clean" area are provided for many locations

e. Attempts have been made to run radioactive piping in such a way as to minimize radiation exposure to plant personnel. This involves

    1. Minimization of radioactive pipe routing through areas that must be kept accessible at all times

    2. Avoidance of high-activity pipe routing through low-radiation zones

    3. Use of shielded pipe chases when Items 1. and 2. cannot be avoided

    4. When feasible, the use of sharp elbows, T's and Y's, pockets, and dead legs is kept to a minimum. Lines can be drained, and drain connections are attached to selected pockets and dead legs.

f. When feasible, pipeline and duct penetrations in shielding walls are located in such a way that they are not in a direct line with a major radioactive source, particularly between zones of significantly different radiation levels. Whenever necessary, shielding of the penetration is provided where this cannot be accomplished to reduce radiation streaming into areas occupied by personnel

g. The plant ventilation and drainage systems are designed so that contamination can be either controlled or confined to its place of origin. Health Physics procedures implementing good contamination-control practices further ensure that contamination is not spread to other areas of the plant. Most areas where contamination may occur are provided with protective coatings to ensure ease of decontamination

h. Health Physics procedures provide for the use of protective clothing to minimize contamination of personnel. Material or equipment being removed from a contaminated area is handled in such a manner as to prevent the spread of contamination. Contamination monitoring of exiting personnel is performed at the access control point or the nearest frisker station

i. Shielding has been provided to permit access to and occupancy of the main control room for normal operation and to ensure that occupancy of the main control room for the duration of the postulated design-basis accident (DBA) will not result in exposures to personnel exceeding 5 rem to the whole body or its equivalent to any part of the body. This design criterion complies with GDC 19 of 10 CFR 50, Appendix A

j. Shielding discontinuities caused by shield plugs, concrete hatch covers, and shield doors to high radiation areas are provided with offsets when necessary to reduce radiation streaming

k. When feasible, equipment deterioration due to cumulative radiation exposure is limited by the selection and use of proper materials as well as by judicious use of permanently installed shielding. Wherever possible, special attention is given to reducing the use of organic and other radiosensitive materials such as electric cable insulation and connectors; solid-state electronics; gaskets and sealants; seats, packings, and diaphragms for valves; and lubricants

l. A number of design features were built into the standby gas treatment system (SGTS) related to minimizing occupational exposures during the removal and replacement of filters. There are three sets of filters in addition to the high-efficiency carbon adsorber section. In the event that any or all filters are contaminated, exposure of maintenance personnel to radioactive material would be limited because of the following design features:

1. The charcoal in the adsorber section can be drained and disposed of remotely by placing it into containers (55-gal capacity) by means of a pneumatic conveying system. This design feature will minimize radiation exposure during charcoal removal. In addition, with the contaminated charcoal removed, exposure to personnel during the removal of filter sections would be minimized

2. The prefilter section and final high-efficiency particulate air (HEPA) filter section are at opposite ends of the SGTS filter housing, thereby minimizing exposures by providing the maximum distance between these filters. All filter sections are separated by at least one piece of intervening equipment or the structural framing of the filter housing

3. Each filter compartment is provided with its own access door. This allows maintenance personnel to go directly to a specific filter section without the need to pass near other filter sections

4. Each filter section is provided with a permanent light fixture to provide adequate internal light to expedite maintenance work. In addition, an

individual electrical plug-in receptacle is provided outside each access door.

m. Steps have been taken to minimize and control the buildup, transport, and deposition of activated corrosion products in the reactor coolant and auxiliary systems and in particular to minimize the production of ^{58}Co and ^{60}Co. These include

   1. Using material in the primary coolant system with very low nickel and cobalt content except for the use of austenitic stainless steel in the recirculation loops. A discussion and listing of the primary coolant system materials are included in Subsection 5.2.3 and Table 5.2-6

   2. Using low-to-moderate flow rates and low temperatures in the filter-demineralizer for the reactor water cleanup (RWCU) system. Both increase the efficiency of capturing radioactive fission products and corrosion products

   3. Selecting valves and packing materials that minimize crud buildup and maintenance

   4. Using butt-welded connections in lieu of flanged connections on lines 2.5 in. and larger in order to eliminate crud traps

   5. Providing drain/flush connections on the valve body of valves 12 in. and larger and on most of the primary system pumps

   6. Making it possible that, if necessary, any or all of the primary system can be drained and flushed by making the proper connections. Chemical cleaning and decontamination connections are provided to enable separate decontamination of the emergency core cooling system and reactor coolant system hardware. The recirculation system is equipped with special blank decontamination flanges, as shown in Figure 5.5-2, for decontamination of the recirculation pump and associated hardware. A blank flange on the RWCU return line also enables the feedwater line to be drained and flushed back to the reactor vessel. The piping has been routed to minimize crud traps and dead legs.

n. Steps and design features taken to achieve and maintain ALARA exposures during normal operation will ensure that radiation exposures during decommissioning will also be ALARA. Examples are as follows:

   1. The steps taken to minimize the collection and buildup of radioactive crud in piping, valves, tanks, and other equipment include special flush and drain connections and lines and minimal crud pockets. These steps are also used to clean, flush, and drain contaminated systems. In addition, they can be used for decontamination immediately before decommissioning as well as during normal plant operation. A majority of these operations can be performed remotely.

   2. Major sources of radioactivity are located in individual shielded rooms or cubicles. Labyrinths prevent radiation from streaming out into the

aisleways. Therefore, personnel performing decommissioning work on any major equipment would not be exposed to radiation from other sources. Items like pumps, valves, nonradioactive lines, and instrumentation are normally located outside such cubicles so they can be dismantled without exposure.

Separate shielded pipe chases are provided for the radioactive lines to the various isolated equipment cubicles. Hence, the residual radioactive sources in pipe galleries would not contribute to the exposure of decommissioning personnel working on adjacent equipment.

3. With a few exceptions, all cells or rooms containing major radioactive sources have built-in provisions for removing such equipment with minimal problems. The cells either have large stepped concrete plugs in their ceilings or else have large stepped block-outs in their walls (normally filled with concrete planks), opening out into major aisleways where sufficient laydown space has been provided

4. Provisions for the remote removal of radioactive contents of equipment internals (such as offgas sand filters, SGTS charcoal, and filter-demineralizers) will reduce decommissioning exposures

5. All concrete surfaces in the drywell are painted for ease of cleanup and decontamination. Special platforms and walkways will be installed in the drywell for speed and ease of movement and consequently to reduce exposures. The sacrificial shield was specially designed to limit neutron levels in the drywell so that long-term neutron activation of drywell equipment and piping would not result in significant radiation exposures when the reactor is shut down

6. Provisions exist to bring power equipment into the main buildings to lift or move major (radioactive) components. These pieces of mobile equipment, combined with the building cranes and monorails, would enable nearly all radioactive items to be removed from the buildings with a minimum of radiation exposure.

Additional descriptive material and diagrams of the design aspects to minimize the exposure to radioactive material are provided in the literature (Reference 1).

To ensure that occupational exposures are kept ALARA, the shielding design was reviewed, updated, and modified as necessary during plant design and construction. Sargent and Lundy and Edison reviewed the shielding design to ensure compatibility with mechanical, ventilation, and monitoring system design.

Building and equipment shielding and layout designs and drawings initiated by the Edison Engineering Design Groups were reviewed by one or both of two shielding evaluation specialists to ensure that occupational exposures will be ALARA.

12.1.2.2 Description of Plant Shielding

12.1.2.2.1 General

Nuclear radiation shielding in the plant is designed and constructed of materials having suitable composition, thickness, and density to satisfy the design dose rate criteria established for the plant and its offsite environs. Radiation shielding is provided so that, in conjunction with appropriate access control patterns, a properly trained operating staff can maintain radiation doses to personnel within the limits specified by applicable regulations during the following modes of plant operation:

a. Normal operation of the reactor, including anticipated operational occurrences

b. Normal shutdown of the reactor

c. Accident conditions.

Provisions have been made for the protection of personnel during access to equipment for the purpose of inspection, preventive maintenance, or repair.

Shielding is provided when necessary to limit nuclear heating of bulk structural concrete, to reduce neutron activation of equipment and materials, and to limit the irradiation of equipment and materials to acceptable levels.

Concrete, steel, and water are the primary shielding materials used in meeting the plant's shielding design criteria. For certain applications, it was necessary to use borated materials (for neutron absorption), special composition concretes, or other special shielding materials. Removable shields, such as floor plugs and block walls, are used where access must be provided for periodic inspection and maintenance.

Whenever feasible, equipment that is used in radioactive service is selected, designed, located, and oriented in such a manner as to minimize the amount of shielding required. A detailed plot plan defining total plant layout is shown in Figure 12.1-2. Radiation zones are defined in Figure 12.1-1 and Figures 12.1-3 through 12.1-8. A general description of the plant shielding in the various buildings containing radioactive process equipment and fluids is outlined below.

12.1.2.2.2 Reactor and Auxiliary Buildings

The reactor building contains four major shielding structures: the reactor sacrificial shield, the drywell biological shield, the main steam line chase, and the spent fuel pool. Portions of the outer (secondary containment) walls also serve as shield walls. The drywell and its contents are shielded so that most areas outside it are accessible during full-power operation.

Within the drywell, sacrificial shielding is provided between the RPV and drywell walls. It serves to protect important portions of the outer drywell space from excessive radiation exposures and heating during operation. After shutdown, it provides protection from the RPV radiation for plant personnel performing inservice inspection, maintenance, and repair of drywell equipment and components. The sacrificial shield minimizes activation of drywell materials near the reactor core and, together with the drywell biological shield, it protects the general reactor building work areas during normal operation.

The following three criteria have been used in designing the sacrificial shield:

a. The energy flux (neutron plus gamma) incident upon the inner face of the sacrificial shield wall is less than 5 x 10^{10} MeV/cm^2/sec

b. The thermal neutron flux emerging from the sacrificial shield is less than 2 x 10^5 neutrons/cm^2/sec so that excessive activation of steel components in the drywell is prevented

c. The total full-power dose rate in the drywell (outside of wall) should not exceed 100 rad/hr in order to reduce the integrated dose to certain sensitive-material components in the drywell.

Table 12.1-2 provides a summary of the sacrificial shield design bases.

During reactor shutdown, the radiation criterion is that the drywell dose rate from radiation through the sacrificial shield 1 day after shutdown should be less than about 30 mrem/hr. Two sources contribute to the drywell radiation field during shutdown: those sources internal to the sacrificial shield, and piping and equipment in the drywell. The internal sources arise from the delayed gamma rays emitted by the fuel and from the activation of structural components such as the RPV or sacrificial shield. The boration of the concrete reduces the activation of the sacrificial shield significantly, enabling the 30-mrem/hr level to be met. Contact radiation levels on much of the piping and equipment are likely to be in the 20 to 1000 mrem/hr range, most of which comes from radioactive depositions in the drywell piping. The thermal neutron flux limit imposed during operation is low enough to minimize the activation of steel in the drywell.

Recirculation piping penetrations of the sacrificial shield wall are shielded from the reactor core so that access to the drywell is provided during shutdown. All major penetrations in the region bounded by 9 ft above the core centerline to 16 ft below the core centerline contain special shielding doors. In the region of the drywell adjacent to those doors, the dose rate during operation is from components of the recirculation system as well as from the core. For local hot spots such as these openings, an increase of a factor of 10 in the neutron flux (that is, a flux of 2 x 10^6 neutrons/cm^2/sec) is assumed to occur in that vicinity in the drywell. The adopted shield door design consists of a combination of steel and a neutron-attenuating material to reduce the streaming of gamma radiation, as well as to limit the streaming of thermal neutrons to within the hot-spot limits.

The drywell biological shield is designed to limit the radiation level from the reactor core and from equipment in the drywell to the predetermined zone levels established for accessible areas during full-power operation. Table 12.1-2 summarizes the biological shield design criteria. In addition to serving as the basic biological shielding for the reactor system, this concrete structure also provides a major mechanical barrier for the protection of the RPV against potential missiles generated external to the primary containment. Whenever feasible, the penetrations through the biological shield are positioned so that they are not in a direct line with the core or major sources of radioactive equipment in the drywell. The penetrations are either terminated in shielded cubicles, located at very high elevations, or furnished with shielding collars or disks where necessary to further reduce radiation levels in the accessible areas.

The shield design criteria for the rest of the reactor and auxiliary buildings are defined in Table 12.1-3. This table lists the design conditions for each pertinent source area; that is, full- power operation (maximum activity for normal operation), shutdown, testing, and LOCA.

It should be noted that the Maximum Design Level in Protected Area column given in Table 12.1-3 represents the maximum- radiation-level shield design in the shielded area, and is a composite of dose rates resulting from radiation levels generated by several shielded sources. Therefore, the actual design criteria on a specific wall from a particular source cell will usually be less than the maximum values given in Table 12.1-3. This also applies to all other tables with a similar column. The Identification Number column given in Tables 12.1-3 through 12.1-5 is defined in Table 12.1-6.

The shielding has been designed and arranged to ensure that, for the area above the RPV flange, sufficient water shielding is provided above the core and the fuel pool to permit access for refueling operations. The shielding requirements have been based on maintaining a sufficient depth of water above the fuel at all times to limit the dose rate to the operators. A special lead-lined fuel-transfer bridge or chute is used to protect personnel working in the drywell when spent-fuel assemblies are being transferred between the core and the spent-fuel storage pool.

A special drywell radiation monitor is provided as a part of the area radiation monitor system to provide radiation protection for personnel working in the drywell during fuel-transfer operations. The monitor and alarm are hand carried into the drywell and plugged into the fixed connector whenever the drywell is opened for maintenance.

Since some areas adjacent to the refueling and fuel storage pool structures are accessible, the pool-wall concrete has been designed to provide the required attenuation. The concrete pool shielding has been adequately designed for both fuel storage and fuel transfer operations.

During normal fuel transfer, the fuel element is covered at all times by a pool of water that serves as a radiation shield. When fuel is transferred from the reactor cavity to the fuel pool, it crosses the narrow transfer canal. It takes about 24 sec to reach the fuel pool, where it is lowered further down into water. During the short time it is in the transfer canal, there is still sufficient water (approximately 7ft) above the actual fuel portion of the fuel assembly to furnish adequate shielding and to maintain low radiation levels at the operating bridge. Although these dose rates will be somewhat higher than when the fuel is lowered further into the storage pool, they will not be of significance. Likewise, there is sufficient water (approximately 5 ft 3 inches) above the actual fuel portion of the fuel assembly to furnish adequate shielding and to maintain low radiation level at the Reactor Cavity Work Platform used for In-service Inspection of the vessel and other outage related activities. Radiation levels from fuel handling to other personnel located elsewhere on the operating floor will be much lower than levels on the bridge.

Since the RWCU system filter-demineralizers are a radiation source during operation and shutdown, they have been located in separately shielded rooms so that each can be maintained while the others are in operation. Valves and instruments have been located outside the demineralizer cubicle. During operation, access to the remaining cleanup equipment (except for the pumps) is normally not required, but shielding requirements were based on location and the need for access to adjacent areas.

The main steam line pipe tunnel shielding has been designed to adequately reduce ^{16}N gamma radiation, emanating from the steam lines during normal full-power reactor operation, to the proper design levels.

A contaminated-equipment storage room, located in the turbine building, is used for the storage of low-activity miscellaneous pieces of small equipment. The walls serve more as a physical barrier than as a radiation shield.

12.1.2.2.3 Turbine Building

The radiation levels existing during plant operation, as well as those experienced during shutdown, were considered in determining shielding requirements for the turbine building. With the main exception of the offgas charcoal units and filters, the major radiation source considered has been the ^{16}N isotope. Figures 12.1-1 and 12.1-3 through 12.1-8 define the access zones used in the turbine building shielding design. The areas are zoned according to their expected occupancy by plant personnel and their design-basis radiation exposure levels under normal plant conditions. Shielding is provided around the following areas, and access to these areas is generally not permitted during full power operation:

a. Main condenser-hotwell area
b. Reactor feedwater system heaters, drain coolers, and associated piping
c. All main steam, extraction steam, and drain piping
d. Condensate demineralizer system equipment and piping
e. Steam-jet air ejectors and piping
f. Gland seal condenser and vacuum pump systems and piping
g. Heater drain pumps
h. Regions around the turbine, reheater separators, and associated steam and condensate piping
i. Reactor feed pump turbine systems and piping
j. Offgas delay lines
k. The offgas combiners, charcoal delay beds, filters, and associated piping and equipment.

As can be seen in Figures 12.1-1 and 12.1-3 through 12.1-8, limited access is allowed to a few areas during full-power operation. Access to the crane and to the turbine floor inside the turbine reheater shielding walls is administratively controlled during reactor operation, by use of locked access doors.

Since the air ejectors are a high radiation source, each is provided with separate shielding to permit maintenance access to the cubicles not in operation. Offgas holdup piping is also shielded. The two recombiner cells are separately shielded to permit limited access to the cell that is shut down while the other is operating. Since access for filter replacement is possible, shielding is provided for the offgas filters, with consideration given to draining the radioactive sand from these filters and separately shielding each filter for maintenance or removal.

The condensate filter-demineralizers are also shielded to accommodate access to adjacent areas. Access to the filter- demineralizers is restricted unless adequate decontamination procedures are taken. Access to valves, pumps, and instrumentation is generally made available by locating this equipment in outer shield cubicles.

The condensate is held up in the hotwell long enough to reduce the dose rate from ^{16}N and ^{19}O to below 1 mrem/hr (normal water chemistry) at points adjacent to the piping. Even though a 2-minute holdup time is sufficient for this purpose, the hotwell is designed for a nominal holdup time of 4 minutes (see Subsection 10.4.1.1.5). However, even though these lines are not normally shielded, the condensate storage tanks are provided with a barrier to prevent close access.

The design criteria for the turbine building shielding design are provided in Table 12.1-4. Though this table does not indicate the design limits for turbine shield design as applicable to skyshine (^{16}N), Subsection 12.1.3.9 describes the pertinent results of skyshine analysis. These data show that the turbine building shielding adequately reduces all direct and skyshine radiation to ensure that both onsite and offsite doses are maintained ALARA.

12.1.2.2.4 Radwaste Building

The radwaste building contains a complex arrangement of settling tanks, filters, demineralizers, evaporators, solidification equipment, and holding and storage tanks of various types and kinds. These serve to remove the impurities (soluble, nonsoluble, radioactive, and nonradioactive) from water collected in floor and equipment drains throughout the plant and from the backwash of reactor water and condensate filter-demineralizer purification systems, prior to reactor recycle usage or ultimate disposal through the liquid- or solid-waste disposal systems. Almost all of the entire radwaste system uses batch processing of liquid volumes. Because of the system complexity, a wide variance in radioactivity levels is encountered throughout the radwaste system. In fact, the activity level at a particular location can vary considerably, depending on the conditions and mode of systems operation. For conservative shielding design calculations, therefore, the condition giving maximum activity levels of each component was first identified. The activity concentrations used in each major shield design effort for the radwaste building are covered in more detail in Subsection 12.1.3.

Table 12.1-5 defines the specific shield design criteria for the radwaste building. Figures 12.1-3 through 12.1-5 define the access zones and the major components. The shielding is designed to maintain the radiation level below 0.5 mrem/hr in the radwaste control room and in the operating aisles of the solid-waste preparation areas. The areas surrounding the radwaste equipment are protected according to the necessary access requirements. The liquid radwaste system is operated remotely from a control panel in the radwaste control room.

As previously indicated, the shield design is based on radiation resulting from the processing of corrosion products and/or fission products resulting from substantial fuel leakage (Subsection 12.1.3). The design is such that when certain low-frequency types of fluid transfer operations are to be performed, slightly higher radiation levels and limited-access restrictions will apply to certain areas that are normally Zone II access areas.

The primary function of the waste surge tank is to receive overflow from the waste clarifier. The waste clarifier is full during normal operation and displaces a volume equivalent to the influent directly to the waste surge tank. The principal inputs to the waste clarifier are the decants from the RWCU and condensate phase separators as well as the centrifuge decant. As these streams enter the waste clarifier, undissolved solids settle out and liquid within the clarifier is displaced to the waste surge tank. The waste surge tank can also be used for storing the waste collected in the radwaste emergency sump in the unlikely event of rupture of either the floor drain collector or waste collector tanks. The principal activity within the waste surge tank is therefore from the phase separator and centrifuge decant water.

Components such as waste collector and floor drain collector tanks are grouped in one common area. These areas contain only tanks and piping and require infrequent access. Resin storage and concentrated-waste storage tanks are located in another area. Access to these areas is not normally required.

Demineralizers and filters have been separately shielded so access to one will not require draining of the others. There is little need for access to the demineralizers, but the filters may require periodic maintenance.

12.1.2.2.5 Main Control Room

The main control room is located in the auxiliary building so that accessibility is normally unrestricted. The shielding provides for normal radiation levels below 0.3 mrem/hr. Advantage has been taken of the shadow shielding from other structures.

Further, the main control room shielding has been designed for the maximum design accident condition so as to allow continuous main control room occupancy during the course of an accident. The regulation followed for the shield design was GDC 19 of 10 CFR 50, Appendix A. As a result, wall, floor, and ceiling concrete thicknesses are provided (as shown in Figures 12.1-9 and 12.1-10) to adequately attenuate sources of direct radiation. The design of the main control room shielding was such that the predominant sources originate during an accident condition rather than during normal plant operation. The shielding design features were reevaluated using Alternative Source Terms and with some additional detail. As a result, calculated doses are substantially lower than originally determined. See Appendix 15A for details.

12.1.2.2.6 Other Plant Areas

Those portions of the service building and all other yard buildings which are fully accessible will be maintained so that no person can receive a radiation dose rate of greater than 0.5 mrem/hr. Access to other portions of these buildings will be controlled, in order to assure all personnel radiation exposures will be ALARA.

12.1.2.2.7 Component Cubicles

Component and equipment cubicles containing radioactive material are designed not only to limit radiation levels in corridors and other adjacent areas requiring frequent access (Figures 12.1-1 and 12.1-3 through 12.1-8), but also to ensure that the maximum radiation level in the cubicles from adjacent cubicles containing radioactive material does not exceed 8 mrem/hr (normal water chemistry). There are some areas or cells in which the maintenance dose criteria were set significantly lower than 8 mrem/hr. The actual design dose rates are shown in Tables 12.1-3 through 12.1-5. This concept means that when the lines and equipment in a particular normally radioactive cubicle are shut down and drained for maintenance purposes, the maximum radiation level from outside sources will produce radiation levels that will not exceed 8 mrem/hr in the cubicle containing the drained equipment. For this particular phase of the shield design, it was assumed that the rest of the plant remained at full-power operation.

12.1.2.2.8 Penetrations, Ducts, and Voids

Normally, a large number of various sizes and types of penetrations exist through the bulk shielding walls surrounding radioactive components. There are mechanical, doorway, instrument and lighting, electrical, ventilation and heating, process piping, and drain line penetrations. As is true in the shield design of all plants, these penetrations represent violations of the bulk shield and consequently represent potential sources of high-level localized radiation streaming.

When necessary, these penetrations, ducts, and other voids in shields are designed so that the radiation streaming through such discontinuities is minimized. The design also ensures that the general dose rate in each plant area, including contributions from radiation streaming, satisfies the design dose rate for that area's radiation zone designation. The shield designers worked closely with other design groups to meet the above criteria. All important proposed penetrations of a shield wall were approved by the shield designer before they were finalized, and appropriate calculations were performed by the shield designers when necessary.

When feasible, penetrations of shield walls, such as pipe and duct penetrations, are located in such a manner that a direct shine from major sources of radiation is minimized. Large empty pipes or ducts penetrating the shield into accessible areas are provided with additional concrete, steel, or other shielding where required. When necessary, penetrations are located sufficiently high above the floor (generally greater than 10 ft) to minimize shielding requirements and personnel exposure in adjacent accessible areas.

Shield discontinuities include such items as concrete hatch covers, plank walls, block walls, shielding doors, and access labyrinths into areas of high radiation. Access labyrinths into rooms containing highly radioactive equipment are designed in such a manner that direct shine through the offset passage to outside accessible areas is eliminated. Where necessary, the equipment is shielded in all directions, including the access passage, with the same equivalent thickness of shield as in the solid shield walls. During normal operations, the access labyrinths are provided with barriers for personnel access control. The labyrinth designs are such that the dose rate at the outer surface of the barrier locations would not be greater than that outside the adjacent bulk shield walls.

Shielding discontinuities are normally designed with offsets in the gap between the movable section and the fixed shield so that radiation streaming is reduced. Wherever possible, gaps are positioned to eliminate a direct line with the radiation source. The tolerance or clearance between the movable section and the fixed shield wall is designed to be as small as practicable.

A general description of the method used for handling such penetrations in the shield design of the Fermi 2 plant is given in the following paragraphs. The design intent was to limit the total radiation passage through shields (that is, the sum of the bulk shield dose rate and penetration dose rate) to the levels given previously in Subsection 12.1.1.

It is desired that personnel working in an operating area for a 40-hr week receive an average dose rate no larger than that specified (usually 0.5 mrem/hr). The Fermi 2 shield design (normal water chemistry) used is as follows:

a. The general area dose rate through the bulk shield was kept somewhat less than 0.5 mrem/hr (approximately 0.2 - 0.4 mrem/hr)

b. Where possible, the combined dose rate (bulk radiation plus streaming) at all floor locations below an elevation of approximately 7 ft (assumed man's head height), taking into consideration the penetrations important to that location, was kept less than 0.5 mrem/hr.

12.1.2.2.9 Valve Operating Stations

Manual valve operating stations for pipelines containing highly radioactive material are designed with the valve body and all piping enclosed in a shielded cell, with only the valve's operating rod extended through the shield wall. When possible, these penetrations are located overhead so that radiation streaming does not shine directly on personnel in the operating aisle. The operating rod, which is a solid steel shaft in most cases, helps attenuate radiation streaming through the penetration. In cases where the quantity of valves requires a large number of penetrations, the valve operating station is isolated from the personnel access corridor by a shield wall, and is declared a limited-access area.

12.1.2.2.10 Shield Materials

Advantage was taken of the shielding properties of structural walls and of distance, whenever possible. The material used for biological shielding throughout the plant is reinforced concrete with a density of approximately 150 lb/ft^3. Other materials, such as steel and lead for gamma shielding and boron or hydrogenous materials for neutron shielding, are used in special instances. Wherever possible, walls that were installed primarily for structural purposes are also used to provide shielding. Whenever cast-in-place concrete was replaced by concrete blocks or special offset shield planks, the design ensured protection on an equivalent shielding basis.

No federal regulations similar to those established for the protection of individuals exist for materials and components. Whenever possible, materials are selected on the premise that their predicted radiation exposure during the design life of the plant would not cause significant changes in their physical properties that might adversely affect their operation.

12.1.2.3 Shield Design Calculations

12.1.2.3.1 General

Presented below is a summary discussion of the analyses performed to define the required shield thickness for the various components containing radioactive material. Included is a general description of the analytical tools used in the analyses, the sources and models used in the analyses, and the required shielding thicknesses. All shielding is designed to ensure that the specific design criteria defined in Tables 12.1-2 through 12.1-6 are met.

For a given process system, consideration of each of its various modes of operation is used to determine the highest expected dose rate to personnel and/or equipment. The shield or series of shields were then designed to attenuate radiation resulting from this design-basis operational mode. The source of radiation (Subsection 12.1.3), the technical description of the nuclear steam supply system, and the descriptions of the operation of the components of each radioactive process system are all used in determining the final shield design.

Shielding that protects areas during normal operation, anticipated operational occurrences, and following DBAs is designed such that adequate protection is provided for the most severe case. Each radioactive source and its shield is modeled mathematically to represent the actual configuration as nearly as possible or as closely as necessary.

To design the sacrificial shield, the one-dimensional transport code ANISN (Reference 2) was used to account for the migration and production of neutrons and gamma rays from the reactor core.

The DLC-9 coupled neutron and gamma ray cross-sectional data (Reference 3) were originally used with the ANISN code to enable all production and loss mechanisms for both neutrons and gamma rays to be handled in a single calculation, and subsequently the DLC-23/CASK coupled cross-sectional set (Reference 4) was used to verify the original calculations.

All other shields are designed for gamma ray attenuation by the standard point attenuation kernel (buildup factor, exponential attenuation, and geometry factor) numerically integrated over the volume of the source. The buildup factors and gamma ray attenuation coefficients were obtained from published nuclear data (for example, References 5 through 10). These data were used in the ISOSHLD-III computer code (Reference 11) and also in various hand calculations that were made. Direct transmission of gamma radiation through bulk shielding was also calculated by CAI-KAP, a modification of the QAD (Reference 12) point kernel attenuation program, written for the IBM 1130 computer. Some of the modifications were made in order to fit the large program into the small machine. For instance, CAI-KAP has no capability to calculate neutron attenuation. The program will accommodate geometries of 50 zones defined by 50 boundaries, up to 15 materials, and 30 gamma energy groups. The program also has the capability of automatically preparing the detailed source description on the basis of an input gross source description.

Scattered radiation from labyrinths and penetrations was analyzed by the albedo or Monte Carlo method (References 13 and 14). As mentioned in Subsection 12.1.2.2.8, penetrations are normally located so that no direct path of escape exists for direct radiation. Thus, the only method of radiation escape from the labyrinth without shield attenuation is through scatter. Wall penetrations are located as much as possible above head height, and the use of wall or floor penetrations that run between radioactive regions and unlimited-access areas is minimized.

The radwaste system modification resulted in the building of new shield walls for new equipment, supplementing existing walls with additional shielding for new equipment, and reanalyzing existing walls where new equipment was installed or where the operating function of existing equipment had changed. In addition to the walls, the floors, ceilings, shield doors, and labyrinths were evaluated. These analyses were done using four shielding codes: KAP VI, CYLDOSE, SCAP, and NUSALB.

KAP VI (Reference 15) is a point kernel code used for complex geometries describable by quadratic surfaces. This was used for all of the larger pieces of equipment. CYLDOSE (Reference 16) is a code for calculating linear attenuation, scatter buildup, and resulting tissue dose rate from cylindrical gamma ray sources. CYLDOSE was used primarily for piping shielding analyses with some usage for smaller components. SCAP (Reference 15) is a point kernel code using energy-dependent single or albedo scatter methods to calculate radiation levels at detector points located within complex geometries describable by a combination of quadratic surfaces. SCAP was used where complex gamma ray scatter-radiation geometries were encountered. The NUSALB code (Reference 17) determines ground backscatter according to the albedo technique through the summation of differential back-scatter doses by means of the appropriate differential albedos. This code was used for the simpler scatter analyses.

Some of the basic assumptions used in the shielding design are as follows:

a. The shielding in the turbine building is based on ^{16}N gamma radiation

MeV/Photon	Photons/Disintegration
2.75	0.01
6.143	0.69
7.112	0.05

b. The original shielding design of the radwaste building walls was based on an average gamma ray energy of 1.5 MeV/photon. The walls that have been added or supplemented as a result of the newer system installation are based on the calculated gamma ray energy spectrum estimated to exist in the components being shielded. Previously designed walls that are being used to shield new equipment or equipment for which the function has been changed or modified were reevaluated on a case-by- case basis using the calculated gamma ray energy spectrum within the component being shielded

c. The magnitudes of all sources of radiation are based on failed fuel operation with the following source terms calculated at 102 percent of 3430 MWt (3499 MWt) (see Chapter 11):

    1. A noble gas release equivalent to 100,000 μCi/sec after a 30-minute holdup

    2. Corrosion and fission product concentration in the reactor water consistent with the values presented in Tables 11.1-2 through 11.1-6.

d. Credit is normally taken for self-absorption within a given source geometry

e. Credit is normally taken for holdup of ^{16}N in various system components

f. Design-basis dose rates in aisles or outside cubicles containing multiple sources are based on the sum of the direct radiation emanating through all adjacent cubicle shield walls (including both floors and ceilings). The shielding for cells is designed so that the maximum radiation dose rate in operating areas outside the cells would be no more than 0.5 mrem/hr (Zone II) from all sources under normal operating modes (normal water chemistry). This is the total combined dose rate from all nearby cells, any piping running through the operating area, and from any miscellaneous sources.

Additional information concerning the shield designs in each building containing equipment for processing radioactive material is given in Subsections 12.1.2.3.2 through 12.1.2.3.5.

12.1.2.3.2 Reactor and Auxiliary Building Shield Design

To ensure that the specific design criteria are met in the reactor building, the RPV is surrounded by a 7-ft-thick biological shield and a 21.25-in.-thick sacrificial shield. Computerized discrete ordinates techniques (that is, the ANISN code) were used to calculate the dose rates outside the biological shield. Table 12.1-7 defines the multigroup coupled neutron and gamma flux as calculated outside the RPV. These data served as the basis spectrum for the sacrificial and biological shield design.

During the course of the shield design, it was found necessary to use borated concrete for the central portion of the sacrificial shield. This borated section extends from 17 ft below the core centerline up to 12 ft above the core centerline. The boration is accomplished by the addition of 6 weight-percent boron frits to the concrete mixture. The frits contain approximately 16 weight-percent natural boron. As previously mentioned, the boration of the concrete reduces the activation of the sacrificial shield significantly, enabling the 30 mrem/hr requirement to be met 1 day after shutdown.

Table 12.1-8 summarizes the shielding design for the important areas in the reactor and auxiliary buildings. This table summarizes

a. The area being shielded

b. The equipment in the shielded cell

c. The operating condition for the source determination that was subsequently used for the shield design

d. The source strength, expressed in curies, in the component/room being shielded

e. The basis calculational source geometry used for the shield design analysis

f. The particular wall or shield location on the cell

g. The shield wall thickness as constructed

h. The radiation level, expressed in mrem/hr, used as a shield design basis for the wall both at the outer wall surface and in the general area around the wall.

12.1.2.3.3 Turbine Building Shield Design

Table 12.1-9 summarizes the turbine building shield design. This table summarizes the data in the same manner as does Table 12.1-8. However, dose-rate estimates due to skyshine have not been included in either of these tables. Further discussions concerning skyshine dose-rate calculations are presented in Subsection 12.1.3.9.

12.1.2.3.4 Radwaste Building Shield Design

Table 12.1-10 summarizes the shield design for the radwaste building. The pertinent items of design as described for Tables 12.1-8 and 12.1-9 are included in this table.

Concrete shielding is used exclusively throughout the radwaste building for bulk shielding, except for several instances where steel wall inserts are used and several instances where tanks are shielded with steel and/or lead shot because of space considerations. There are also several steel shield doors. The general procedure for determining the bulk (wall thickness) shielding requirements for component cells was to use the maximum total activity buildup together with data on component process fluid volume and geometry, and then to reduce the actual component to an appropriate idealized point, line, cylindrical, or disk radiation source for the shielding calculations. Also taken into consideration was the self-shielding effect of the process fluid, where applicable, and radiation buildup due to scattering in the shield walls. In addition, the following nuclear data, ground rules, and assumptions were used:

a. The actual radionuclide inventories in each of the radwaste system components have been calculated. Based on the radionuclides present and the specific activities of those nuclides, a specific energy spectrum has been determined and used for the shielding calculations. This spectrum could be different for each component in the radwaste system

b. The piping inside the cells that contain large sources (such as tanks) or sources where radionuclide inventories can become concentrated (such as filters and demineralizers) has not been considered for the bulk- shielding calculations. This differs from the practice followed in many of the turbine and reactor building cell calculations. However, it is a valid assumption for the radwaste building because of the following:

    1. The volume (size) of the process lines to and from radwaste components is extremely small compared to the component fluid volumes

    2. The radwaste system uses batch processing (compared to continuous processing in the turbine building), and the lines are therefore normally either empty or filled with clean flush water

    3. As opposed to the situation often encountered in the turbine and reactor buildings, there are no significant density differences (due to temperature changes) or specific activity ($\mu Ci/cm^3$) differences (due to either dilution or radioactive decay) between the process fluid in the lines and that in the tanks where cells contain only pumps; however, the piping in those cells is used for bulk-shielding calculations. It is a conservative assumption to consider a pump to be a section of the piping through which it pumps fluid. Compared to the piping within a cell, the volume of the source within a pump is usually very small. The piping must, therefore, be considered.

c. In certain instances of offnormal operation, the Zone II dose rate could be exceeded in some areas. Examples of offnormal operations are the following:

   1. Use of operating modes following tank ruptures
   2. Abnormal operating modes used when components are shut down for maintenance and must be bypassed
   3. Operating modes used during filter or demineralizer malfunction
   4. Abnormal tank-drainage operations.

   It should be emphasized, however, that there are only a limited number of anticipated offnormal operating modes that will result in Zone II radiation dose rates being exceeded in operating areas

d. The shielding for common walls between adjacent shielded cells is designed so that the radiation dose rate inside a cell shut down for maintenance is less than 8 mrem/hr (Zone VI) due to radiation from sources in adjacent cells under normal operating modes. As implied by Item c., the offnormal maintenance dose rate inside such a cell could exceed the Zone VI criteria in certain rare instances.

12.1.2.3.5 Main Control Room Shield Design

As previously described in Subsection 12.1.2.2.5, the main control room is designed so that accessibility is normally unrestricted and, following a postulated accident occurrence, personnel exposure will not exceed 5 rem TEDE as specified in 10 CFR 50.67.

In particular, the shielding in the main control room is designed to protect its inhabitants following a LOCA, as described in Regulatory Guide 1.183. For the LOCA, the fission products that are released from the fuel are assumed to be transported through the primary and secondary containments and entrained on the SGTS filter. LOCA sources are determined using RADTRAD (Reference 24) models with design basis core source terms, credited removal mechanisms, and transport parameters. Uniform mixing in secondary containment is assumed when evaluating secondary containment gamma shine, and 100 percent filter efficiency is assumed when evaluating SGTS filter source terms. RADTRAD calculated time dependent compartment activities are time integrated and then evaluated using MicroShield 5.05 (Reference 25). Sources considered are the primary containment, the reactor building, a standby gas treatment system filter, and an environmental plume outside of the control room shielding. Shielding is provided that is equivalent to the following:

a. The total floor thickness between the main control room and torus area is effectively 8 ft 4 in., as shown in Figure 12.1-9

b. The roof of the main control room is 1 ft thick below the air conditioning equipment room (effectively 6 ft 6 in. thick, including the auxiliary building roof), and 5 ft thick below the SGTS (effectively 10 ft 6 in. thick including the auxiliary building roof)

c. The outside (north) wall of the main control room is 2 ft thick in order to provide shielding of personnel from the overhead plume

d. The wall between the main control room and secondary containment is 4 ft 4 in. thick. Therefore, the dose to personnel from radioactivity in the secondary containment is reduced.

Shielding walls are used to accommodate other design criteria; for example, to provide missile protection. In some instances, therefore, the slab thickness may be governed by criteria other than shielding requirements. Further details on the estimated personnel exposure during a LOCA are provided in Appendix 15A.

12.1.2.4 Inspection and Testing

Inspection and testing of the plant shielding is conducted using ANSI Standard N18.9-1972 as a guide to verify that the shielding performs its function of reducing radiation to design levels. During the initial power operation, radiation surveys are made to identify and correct any defects or inadequacies in the shielding that might affect personnel exposures during normal operation and maintenance of the plant. Surveys consisting of gamma and neutron monitoring, as appropriate, will be performed at various power levels (typically 0, 25, 50, and 100 percent power) as the reactor is initially increased in power.

12.1.3 Source Terms

12.1.3.1 General

The shielding design source terms are based on the three general plant conditions of normal full-power operation, shutdown, or design-basis events. The shield design for normal operation and anticipated operational occurrences is based on design radiation sources. These sources provide a rational basis for design. The source data assume plant operation is at maximum design power, with a noble gas release rate from the core equivalent to 0.1 Ci/sec after 30 minutes decay. Concentrations in the reactor water are based on a fission product equilibrium halogen concentration as defined in Section 11.1. Concentration of other fission and activation products is based on information defined in Section 11.1. The activities of these sources are considered to be maximum values, although it is not anticipated that the plant will normally operate at these high levels. Later, Hydrogen Water Chemistry conditions were also examined and factored in.

Three types of radiation sources occur in the plant: primary radiation from the reactor core, secondary radiation resulting from nuclear reactions between the primary radiation and the reactor environment, and release of radioactive materials from the reactor core to the coolant. During normal plant operation, secondary sources and released radioactive materials are transported in either the reactor coolant or main steam to process equipment in the plant.

The source intensity in equipment and pipelines handling radioactive fluids is determined from that in the reactor water or reactor steam by considering the processes that the reactor water or steam has undergone (dilution, filtering, demineralization, delay, or change of phase) prior to entering the equipment or pipe.

Tables 12.1-8 through 12.1-10 summarize the estimated source terms in the reactor and auxiliary building, turbine building, and radwaste building used for the Fermi 2 shield design for cubicles and components containing radioactive material. These sources are based on the originating source terms provided in Chapter 11, and cover the worst-expected design condition: that is, full-power operation (normal), shutdown, refueling, anticipated operational occurrences (including tests), and the design-basis accident (DBA). For plant operation with Hydrogen Water Chemistry, in-plant tests have shown that the calculated N-16 activity estimates will increase a maximum factor of six from the estimates shown in these tables. LOCA sources are determined using RADTRAD (Reference 24) models with design basis core source terms, credited removal mechanisms, and transport parameters. Uniform mixing in secondary containment is assumed when evaluating secondary containment gamma shine, and 100 percent filter efficiency is assumed when evaluating SGTS filter source terms. RADTRAD calculated time dependent compartment activities are time integrated and then evaluated using MicroShield 5.05 (Reference 25). Sources considered are the primary containment, the reactor building, a standby gas treatment system filter, and an environmental plume outside of the control room shielding.

12.1.3.2 Radiation From Reactor Core

During full-power operation, radiation from the reactor core proper consists of neutrons and gamma radiation resulting from the fission process itself, gamma radiation resulting from capture or inelastic scattering of neutrons within the core, and gamma radiation resulting from fission product decay. In addition, neutron interactions with the core shroud and RPV result in capture or inelastic scattering of gamma rays.

Table 12.1-7 presents multigroup neutron and gamma ray fluxes outside the RPV. The gamma ray fluxes include core fission gamma sources as well as secondary gamma sources that result from neutron capture in the core, water shroud, and vessel.

12.1.3.3 Activity in Steam and Condensate

Piping and equipment that contain reactor water, steam, or condensate are principal sources of radiation. The predominant activity requiring shielding in these systems is the ^{16}N carried in the steam and water from the reactor. Usually, all other activity sources in the steam other than ^{16}N can be neglected, since their magnitude is so much smaller. The radiation source strength at any of the various pieces of equipment containing steam or reactor water is then the RPV appropriate outlet nozzle activity of ^{16}N decayed by the transit time from the reactor outlet to the equipment. Tables 12.1-8 and 12.1-9 define the ^{16}N sources used in the Fermi 2 shield design. With Hydrogen Water Chemistry in operation, these N-16 estimates will increase up to a factor of six.

12.1.3.4 Offgas System Activity

The major radiation source of the offgas system is the ^{16}N in the noncondensables traveling from the condenser to the recombiners. The total transit time of the offgas between the RPV and the steam-jet air ejector is conservatively calculated as about 7 sec. Decay and delay through the offgas system are taken into account. The ^{16}N is the major source of radiation up to the 2-minute delay line. After the delay line, the fission products predominate as the shielding source. The sources used in this system design are defined in Table 12.1-9.

12.1.3.5 Activity for Radwaste, Reactor Water Cleanup, and Condensate Demineralizer Systems

The radiation source in these systems is due to the radioisotopes originating in the reactor water and steam. In the RWCU system, radioisotopes (including corrosion products) present in the water are the source of activity. In the condensate demineralizer system, the sources are the activities carried over in the primary steam and daughters resulting from radioactive gas decay in the condensate demineralizer system itself. In the RWCU system, ^{16}N and similar short-lived activity isotopes were taken into account, with ^{16}N included only for that portion of the RWCU system in the reactor building.

In the reactor water, the corrosion product activity is present in both soluble and insoluble forms. The latter is primarily removed by filtration and the former by ion exchange. When considering fission product accumulation, the predominant fission products were assumed to be essentially soluble. Activity accumulates in equipment such as filters and demineralizers. Activity levels in such equipment build up during plant operation until equilibrium is achieved or until the activity is removed (or diminished) by backwashing, or by discarding resins.

The solid and liquid radwaste systems contain varying degrees of activity, depending on the system and the point of processing.

Table 12.1-10 defines the sources used in the radwaste building shield design.

12.1.3.6 Shutdown Sources

The largest radiation source after reactor shutdown is decaying fission products in the fuel. For shield design purposes, the strength of the fission product source has been based either on data from other operating plants (Section 11.1) or on a reactor operating sufficiently long to establish equilibrium conditions for the buildup of all major fission products (see Table 12.1-15).

A secondary source is the structural material activation of the RPV, its internals, and the piping and equipment located between the RPV and the biological shield.

The third type of source is the activated corrosion products accumulated or deposited on the internals of the RPV, the primary loop piping, the secondary loop piping, and components associated with primary coolant processing. Table 12.1-8 contains further information on the shutdown sources used in the Fermi 2 shield design.

12.1.3.7 Design-Basis Accident Sources

To determine the original shielding requirements for the main control room, the radiation sources used for the DBA assumed that 100 percent of the noble gases, 50 percent of the halogens, and 1 percent of the remaining fission product inventory is released from the fuel at the time of the accident. These accident sources were also considered in conjunction with normal operation sources in determining the required thicknesses.

A complete reevaluation of the shielding design for post-LOCA source conditions was performed in conjunction with the response to NUREG-0737 Item II.B.2. A discussion of the reevaluation is contained in Subsection 12.1.6.

The present shielding design has been reevaluated using Alternative Source Terms per 10 CFR 50.67 and Regulatory Guide 1.183 guidance. This analysis was performed to confirm the 10 CFR 50.67 limits to operator doses will be met, and to credit certain of the available margins provided by the original design.

12.1.3.8 Stored Waste

With the exception of the Independent Spent Fuel Storage Installation there are no plans to store high-level radioactive wastes outside the building structures at the Fermi 2 site. Radioactive waste products are normally stored at designated areas within the plant buildings. These areas are shielded as necessary. Table 12.1-16 defines the site boundary dose rate for a curie of stored waste along with the assumptions used in the calculations.

The condensate storage tanks contain trace amounts of radio-isotopes, the concentrations of which do not normally exceed 1.0×10^{-3} $\mu Ci/cm^3$. The maximum dose rate at the site boundary caused by this activity in two tanks is 3.6×10^{-3} mrem/year, as shown in Table 12.1-17.

12.1.3.9 Turbine Building Skyshine Exposures

The SKYSHINE code (Reference 19), designed to evaluate the effect of the turbine building geometry on site boundary radiation levels, was used to calculate gamma ray dose rates at eight specific locations distributed on and within the site boundary. The SKYSHINE code uses a Monte Carlo method and air transport data, along with concrete and steel transmission and reflection data, to evaluate the structure design. The program designates which portion of the calculated dose rates results from gamma rays penetrating the roof and each wall of the building, as well as that which results from gamma rays emitted through openings in the building roof and walls. The results of these calculations (Reference 19) are shown in Table 12.1-18, and the locations of the receiver points are shown in Figure 12.1-2.

The turbine building is a source of radiation due to the inherent activity of the steam. In the dose-rate calculations, only the ^{16}N activity from the steam was considered since it is the only isotope of any significance. For example, the ^{16}N activity leaving the reactor is at least a factor of 100 greater than any other isotopic activity. Also, the high energy (6 MeV) gamma rays from the ^{16}N will be attenuated in air much less than the lower energy gamma rays from the other isotopes, thereby giving higher dose rates. The turbine, reheaters, and steam lines are enclosed on all sides by shield walls. Hence, all radiation must first travel upward (through the roof and upper walls) and scatter in the air before reaching the ground. The site boundary dose rate, therefore, will be less than that from a corresponding unit with an exposed or unshielded turbine area. The internal or self-attenuation of each source component (that is, reheaters, turbines, high-pressure piping, and low-pressure crossover piping) was included in the calculations.

Receiver points C and D (Figure 12.1-2) are located north of the plant in line with the turbine. Receiver point H is located in the area of the Fermi 2 interpretive building in the environmental center. Point B is located at the main office building complex, whereas point A is located at the far eastern aisleway on the third floor of the turbine building (60 ft above grade). All other points were taken to be 3 ft above ground elevation. All receiver points were positioned in air with no shielding effect of structures, except for points A and B. For point A, the attenuating effect of an 8-in. concrete ceiling was included. This is conservative, since the major portion of the roof of the turbine building is significantly thicker than 8 in. Point B took into account the shadowing effect of the other (eastern) wall of the turbine building. Points E, F, and G were located to the west of the turbine building, in a lateral direction from the major radiation sources.

The computed dose rate at the site boundary in this due west direction (point G) is 3.8×10^{-4} mrem/hr or 3.32 mrem/year. The nearest actual site boundary is in the northwest direction (3200 ft from the turbine). Extrapolation of the SKYSHINE code data to this point results in a dose rate of 7.8 mrem/year at the nearest site boundary. This is a conservative estimate, since the value does not take into account the geometrical "shadowing" effect of the tall reactor building on the sources in this particular direction. For plant operation with Hydrogen Water Chemistry, in-plant tests have shown that these conservative calculated N-16 estimates could increase by a maximum factor of six from the estimates calculated in Reference 19 and shown in Table 12.1-18.

The computed dose rates shown in Table 12.1-18 indicate that the gamma ray emission from the reheaters is the major contributor to the dose rate at all points except for the point at point H near the Quarry Lakes. The next largest contribution to the dose rate results from the gamma rays emitted from the low-pressure crossover pipes. The maximum contribution by the gamma rays emitted from the high-pressure inlet pipes is about 6 percent at points C and D. The dose rate due to gamma rays produced in the high- and low-pressure turbines is insignificant when compared to that from the other sources.

A second source of turbine building radiation comes through the outer walls of the building itself from radiation in hot equipment cells adjacent to the outer building walls. These levels are then further attenuated through air to the site boundary. The maximum radiation level so calculated occurs at the southern boundary of the site, opposite the southern end of the turbine building, and is less than 0.5 mrem/year. Corresponding levels from other walls of the turbine building are at least a factor of 10 lower.

The third source of turbine building radiation is also insignificant. It is due to skyshine, which occurs from radiation leaving the concrete ceilings of the various radioactive cells on the third floor. The total air scattered dose rate of the site boundary from all of these sources was calculated to be less than 0.03 mrem/year.

The reactor building is not a significant source of radiation dosage at the site boundary. This building is shielded such that the radiation levels at its outer walls are below 0.5 mrem/hr.

The maximum dose rate at the site boundary, which is due to the attenuation of core gamma radiation through the concrete walls and then through the air, was calculated to be less than 0.003 mrem/year. Skyshine doses from the fifth (operating) floor of the reactor building are insignificant.

12.1.3.10 Field Run Piping

Steps were taken to ensure that the routing of field run process piping, which carries radioactive fluid, would result in minimal radiation exposure to plant personnel. Only that piping which is 2 in. or smaller (nominal diameter) is field run, fabricated, and erected.

All process piping including field run piping is shown on the appropriate system piping diagrams. These drawings provide enough information for an adequate shielding review. When necessary, field drawings prepared before the installation of the piping were also reviewed for shielding requirements. Similarly, the completed as-built drawings are reviewed and approved.

Onsite inspections were conducted as necessary to review the shielding design. If any of these review steps indicated a necessity for modifying the field routing of a given piping run, such modifications were evaluated and made as necessary.

System piping diagrams that include field run piping are also reviewed for considerations of ALARA exposures. Any piping that may adversely affect occupational exposures is given an additional review.

12.1.4 Area Radiation Monitoring

12.1.4.1 Criteria for Necessity

The objective of the area radiation monitoring system (ARMS) is to provide plant personnel with a continuous record and indication in the main control room of gamma radiation levels at selected locations. These locations are within various plant buildings where radioactive materials may be present or inadvertently introduced. The system is designed to obtain accurate and reliable information concerning radiation levels in selected plant areas to ensure personnel safety.

The design objectives of the ARMS are to provide

a. Supervisory information to plant operators so that decisions on deployment of personnel in the event of an accident resulting in a release of radioactive material can be properly made

b. Supervisory information to plant operators to warn of unauthorized or inadvertent movement of radioactive material in the plant. This system also supplements other systems, including the process and effluent radiation monitor system and reactor coolant leak detection system, in detecting abnormal migrations of any radioactive material from plant process streams

c. Indication and recording in the main control room of the gamma radiation level in selected areas as a function of time, and the alarming of abnormal radiation conditions

d. Local alarms and/or indicators at all points where a substantial increase in radiation levels might be of immediate importance to personnel frequenting or working in the area

e. Indication to operating personnel that a channel is inoperable.

12.1.4.2 Criteria for Location

A total of 47 monitors are provided at various locations inside the reactor, auxiliary, radwaste, service, onsite storage, and turbine buildings. The detectors are located in areas where:

a. Personnel perform regular duties in areas where radiation is present. These duties are performed once per day or more frequently

b. Personnel perform infrequent duties, but where there is a high probability that significant changes in radiation levels could occur

c. Personnel perform infrequent duties, or where there is a low probability that significant changes in radiation levels could occur, but where surveillance is desired.

The functional description, general locations, ranges, and alarm setpoints of the area monitors are given in Figures 12.1-11 through 12.1-13. The locations, which may be changed based on operating experience, were chosen so that a clear indication of radiation levels and radiation trends in occupied areas is given. Figures 12.1-1 and 12.1-3 through 12.1-8 show these general locations.

12.1.4.3 Design Criteria

The following design criteria are used in the design of the ARMS:

a. To facilitate compliance with applicable regulations and guides, monitors and detectors have sensitivities and ranges in accordance with radiation levels anticipated at specific detector locations

b. All monitors register full-scale if exposed to radiation levels that exceed full-scale indication

c. Radiation dose rates are continuously recorded in the main control room and are indicated on meters in the relay room

d. Main control room alarms annunciate high radiation dose rates and signal failures

e. A "mimic panel" in the main control room indicates which monitor has alarmed

f. Local alarms and indications are provided near selected detector locations

g. Access to the alarm setpoints is under the administrative control of Health Physics

h. Monitor equipment is readily accessible for maintenance and calibration, with the exception of a few sensor- converter units and auxiliary units located in high- radiation areas during power operation

i. Environmental design conditions for the components are consistent with the conditions stated for the reactor building and control center

j. Each power supply unit, which has sufficient capacity to power 10 monitor channels, is provided with a power feed that is manually restorable to diesels

k. The detector is responsive to gamma radiation over an energy range of 80 keV to 7 MeV, with an average energy dependence of ±20 percent from 100 keV to 3 MeV (per GEK-32374).

12.1.4.4 Equipment Description

The ARMS functional diagram is shown in Figure 12.1-11. The system has no control functions. All locally mounted instruments are located where accidental damage from movement of material or equipment is highly improbable.

The monitors are well scattered throughout the plant. One monitor does not serve as a backup for another monitor. Requirements for a small number of monitors to be in service during plant operation are contained in the Technical Specifications. Any malfunctioning monitors are repaired as soon as possible. During work in the fuel storage pool when irradiated fuel is handled, the low-range monitor on the refueling platform provides an alarm if an assembly is accidentally raised too high in the water.

Each channel has plug-in modules that make the system easy to test, maintain, or troubleshoot. Each channel contains items described in Subsections 12.1.4.4.1 through 12.1.4.4.8.

12.1.4.4.1 Sensor-Converter

The sensor-converter unit is encased in a small cylindrical aluminum container that is sealed against its environment. It is not affected by water spray and is designed to be fully operational over a wide range of temperatures. The unit is normally mounted on a wall or other vertical surface.

The sensor (detector) is one of a series (depending on the monitor range) of halogen-quenched Geiger-Mueller (GM) tubes that detect gamma radiation over the energy range of 80 keV to 7 MeV. The converter amplifies the detector signal and supplies an integrated logarithmic output. At low dose rates, radiation levels are measured by the usual pulse counting technique. At higher dose rates, a current generated by the detector is added to the pulse counting circuit output current, thus compensating for loss of counts resulting from resolving time losses.

The sensor-converter has good sensitivity at low levels and fast response at high levels because of the count rate circuit, which combines a long integrating time constant at low radiation levels with a fast overall response at high radiation levels. Another circuit is included that keeps the instrument reading full scale for a radiation level greater than full scale. The overall accuracy within the design conditions stated in Subsection 12.1.4.3, including energy dependence (100 keV to 3 MeV), is within 10 percent of equivalent linear full-scale recorder output for any decade.

The sensitivity and range of the detectors have been selected to have the meters and recorders read on scale during normal operation. For the range and setpoints for each detector, see CECO.

If any of the monitor locations chosen prove to be ineffective after a period of plant operation, the sensor-converter unit may be moved to more effective locations.

12.1.4.4.2 Indicator and Trip Unit

The indicator and trip units are mounted in racks in the relay room. Each unit provides channel indication and control. In each unit, there are two solid-state trip circuits that use an extremely reliable low drift differential input bistable amplifier. A four-decade logarithmic meter, which corresponds to the range of the detector, is supplied together with low (failure) and high (radiation) trip indicator lights. Controls include a TRIP RESET pushbutton and a mode switch (TRIP TEST/ZERO/OPERATE). The unit provides an output to the recorder and mimic panel. The power input is provided by the power supply unit.

12.1.4.4.3 Auxiliary Unit

The auxiliary unit is mounted locally near the sensor whenever a local audible alarm or light beacon is used. It is also used when only a local indication of radiation level is desired. The unit has a four-decade logarithmic meter that corresponds to the range of the detector. On a high (radiation) trip, an indicator on the unit lights, and a 120-V ac relay closes. A local lighting circuit is used to supply 120 V ac to this relay to operate any audible and visual signals used.

12.1.4.4.4 Power Supply Unit

Six power supply units are mounted in racks in the relay room. Each unit is capable of supplying power to 10 channels consisting of a sensor-converter unit, an indicator and trip unit, and an auxiliary unit. The voltages supplied to the channel components are +575 V dc, ±24 V dc regulated, +33 V dc unregulated and a trip test voltage. The unit has a high voltage meter (0-1000 V dc), a POWER ON light and a TRIP CHECK ADJUST potentiometer. When the mode switch on the indicator and trip unit is placed in TRIP TEST, this potentiometer can be used to adjust the output of the indicator and trip unit over its entire range to determine the trip setpoints.

12.1.4.4.5 Recorder

There are two multipoint chart recorders located on the combination operating panel H11-P816 in the main control room. These recorders make a continuous permanent record of the radiation levels detected by all the area radiation monitors. A list of the range and trip point of each detector by point number is posted on the recorder. This same information is listed in Figures 12.1-12 and 12.1-13. The signal to be recorded is supplied from the indicator and trip unit located in the relay room. Power to the recorder is supplied from an instrument circuit.

12.1.4.4.6 Mimic Panel

The mimic panel is located on the combination operating panel H11-P816 in the main control room. The panel consists of a layout of the plant buildings with labeled alarm lights for items such as high temperature, high pressure, smoke, and radiation. There are labeled lights that correspond to the location of the detectors (sensor-convertor units). When a high alarm is indicated in the relay room on the indicator and trip unit, a mimic light marked "Channel XX" also illuminates, showing which channel has alarmed and the general location of the detector.

12.1.4.4.7 Audible and Visual Alarms

The alarms of the ARMS consist of

a. A low (failure) alarm, which will be activated whenever the indicator and trip unit reaches a downscale setpoint due to detector failure or circuit failure. This setpoint is adjustable over the entire scale

b. A high (radiation) alarm, which will be activated whenever radiation levels exceed a predetermined alarm setpoint. This setpoint is adjustable over the entire scale.

When the radiation level exceeds the high alarm setpoint, a main control room annunciator sounds. In addition, the light for the specific channel detector lights on the mimic panel in the main control room, the high trip indicator lights on the specific indicator and trip unit in the relay room, an indicator lights on the local auxiliary unit, and a local audible or visual alarm activates, when provided.

If the low alarm setpoint is reached, an annunciator sounds and the low trip indicator lights on the specific indicator and trip unit in the relay room.

The annunciators may be silenced in the main control room, but the alarms have to be reset at the indicator and trip unit when the alarm conditions are corrected. The local audible alarm or light beacon, when provided, remains on until the alarm is reset in the relay room.

Low (failure) alarm setpoints are normally set below the background radiation level to indicate when the system has failed. High alarm setpoints are set at least double the background level to prevent spurious alarms. The alarm setpoints can be changed as required to compensate for changes in the background radiation levels. This is done under the direction of Health Physics.

12.1.4.4.8 Area Radiation Monitor Portable Calibrator

The area radiation monitor portable calibrator is a test and calibration unit designed to facilitate "in-the-field" operational testing of the sensor and convertor. It contains a radioactive test source. To use this unit, the sensor-convertor is removed from the wall and calibrated while still connected to the ARMS circuit. Different gamma radiation levels can be obtained by adjusting the source and shield controls.

Additional sources with higher radiation levels, which are not specifically designed for use with this system, can also be used to check the higher ranges. If the proper radiation level is not indicated by the channel, adjustments to the channel are made.

12.1.4.5 Testing Requirements

Each area monitor is capable of being tested as a channel. The system has testing and calibrating equipment that permits local channel testing without disassembling any components. An internal trip test circuit, located in the indicator and trip unit, is adjustable over the full range of the readout scale using the TRIP CHECK ADJUST potentiometer located on the power supply unit. The test signal is introduced internally into the indicator and trip unit input so that a meter reading is obtained in addition to a trip (alarm). Thus, the alarm point can be easily checked. All of the trip relays are of the latching type and must be manually reset at the front panel of the indicator and trip unit.

12.1.4.6 Calibration

An initial calibration of each monitor/detector is performed before installation. During normal operation, checks of system operability are made by observing channel behavior. Functional checks and/or full-channel detector calibrations are performed at specified intervals and are in accordance with the Technical Specifications, as required. (Only channels 6, 15, 16 and 17).

12.1.4.7 Maintenance

The channel detector, electronics, and recorder are serviced and maintained on a scheduled basis to ensure reliable operation. Such maintenance includes cleaning, lubrication, and assurance of free movement of the recorder in addition to the replacement or adjustment of any components required after performing a test or calibration. The local alarms and readouts associated with the detector, which may require periodic adjustment, are located in radiation fields less than 1 mrem/hr in most cases.

12.1.5 Estimates of Exposures

12.1.5.1 Anticipated Doses

The maximum design dose rates in any designated area of the plant are given in Subsection 12.1.1 and in Figures 12.1-1 and 12.1-3 through 12.1-8. The area zones were determined by either the anticipated radiation level of the equipment in the area or the maximum radiation levels at the walls, achieved through shielding. The maximum design shield dose rates are not expected to occur during normal operation, because of the conservative nature of the design-basis calculations. Inside equipment compartments or adjacent to equipment carrying radioactive material, the anticipated dose will result from the actual operation of the equipment itself. The highest dose rates in the plant will occur in Zone X areas, such as inside the drywell, in the turbine condenser area, and in rooms in which equipment and piping contain highly radioactive material. However, personnel access to these areas is nonroutine, infrequent, and rigidly controlled.

Because of the large number of variables involved, an estimate based on operating histories of similar plants, rather than theoretical calculations, was used to estimate the radionuclide concentration in the fuel pool and the possible resulting exposures or radiation levels that may exist in the area above and around the pool. Only those reactors with more than 2 years of operating experience and recent history of troublesome fuel elements were surveyed.

In the presentation of their paper at the Eighth Midyear Health Physics Society Symposium (Reference 20), Golden and Pavlick state that adequate fuel pool treatment should be provided to limit isotope concentration to 1 x 10^5 pCi/ml (equivalent to less than 1 mrem/hr above the pool) during refueling operations. These numbers show good agreement with the survey. The average isotope concentration in the fuel pool during normal operation was about 1 x 10^{-4} μCi/ml, with no measurable activity that could be attributed to the fuel pool.

A range of peak isotopic concentrations was obtained for refueling operations, from 0.015 to 0.75 μCi/ml. During refueling operations, those plants with filters and demineralizers reported radiation levels from 1 to 15 mrem/hr at the surface of the fuel pool. The maximum reported radiation level at the bridge attributable in part to the radioactive contamination in the fuel pool was about 2 mrem/hr. None reported any measurable radiation level on the main refueling floor attributable to the water.

The Fermi 2 fuel pool cleanup system design is influenced by the lessons learned from the reactors surveyed. Based on their history, less than 2 mrem/hr can be expected on the bridge, and less than 0.5 mrem/hr on the general refueling floor during normal work periods.

Experience in the design and operation of power plants shows that the actual (measured) radiation levels are usually less than those used as shielding design objectives for controlling the radiation doses. The annual doses received by the plant personnel can be kept well below the limits of 10 CFR 20 on the basis of the plant shielding and access control design. Shielding design takes into consideration radiation levels from maximum coolant activities, fission product leakage, and combinations of anticipated occurrences.

The main control room will be a Zone I area and hence will have a maximum allowable dose rate of 0.3 mrem/hr. Service areas will be Zone II areas, with a maximum dose rate of 0.5 mrem/hr. Therefore, annual doses in these areas, considering occupancy factors, will be well within the limits of 10 CFR 20. Boiling water reactor operating experience confirms the above contentions. For instance, dose rates in the main control room, visitor center (interpretive building), and office areas have been measured at operating BWR units and have been found to be between 0.01 and 0.06 mrem/hr during full-power operation. This is considerably below the 0.3 and 0.5 mrem/hr design limit for these areas in the Fermi 2 plant. Dose rates in controlled- access corridors shielded from process equipment containing radioactive material, such as the RWCU system and fuel pool cooling and cleanup system, vary typically between 0.5 and 3 mrem/hr, whereas dose rates outside the shielded steam tunnels are generally less than 0.1 mrem/hr. Dose rates inside the reactor building and in assigned Zone X areas are generally expected to be consistent with data available from operating BWR facilities. For example, typical contact readings on the high-pressure turbine have been found to exceed 400 mrem/hr at full power.

Since measured radiation levels from operating facilities indicate that actual dose rates to be expected in normally accessible areas should be significantly less than the peak external shield design dose rates used for the Fermi 2 design, an exposure analysis (described in Subsection 12.1.5.2) has been performed using average expected dose rates. These average dose rates for all access zones described in Figures 12.1-1 and 12.1-3 through 12.1-8 are defined in Table 12.1-1, Footnote a.

12.1.5.2 Estimate of Exposure of Plant Personnel

12.1.5.2.1 General

The annual exposure that could be received by plant personnel during patrolling, control operations, manual work, and expected maintenance has been estimated. This estimate was made during the intermediate stages of plant design as part of a process to review, examine, and/or evaluate various ALARA considerations and design features (see discussion in Regulatory Guide 8.19). As the Regulatory Guide indicates, these exposure estimates are by their very nature fairly imprecise. Their relationship to the actual man-rem doses received during subsequent plant operation will depend primarily on operating experience and the maintenance and repair problems encountered.

It is estimated that, with the plant operating continuously under expected radiological conditions, personnel exposures would not exceed the 1.25 rem per calendar quarter limit, and average personnel exposures will be less than 5 rem/year. Unexpected major repairing of equipment is excluded from the annual exposure since the 1.25 rem per calendar quarter can be exceeded under such exceptional conditions. For the purposes of the estimate, normal work, control operations, and expected maintenance include

a. Routine patrol

b. Periodic tests, operations, and maintenance jobs (including planned repairs taking place more than once a year)

c. Main control room operations

d. Refueling.

The assumptions for the estimate are as follows:

a. Fermi 2 is operated by three shifts and six crews, each crew consisting of a minimum of six operating personnel as described in Subsection 13.1.2. These personnel are trained in various areas of radiation protection. Shift personnel do not perform technical functions in chemistry, radiochemistry, or instrument and/or control adjustments. Technicians qualified to meet the requirements of ANSI N18.1 perform these functions and are called in during off hours, when needed, by the Shift Manager. Routine patrols, tests, and periodic jobs throughout the facility are alternated between operating personnel to ensure an even distribution of radiation exposure

b. All electrical and mechanical maintenance is performed by the maintenance section. A maintenance crew of 12 is assumed for all expected mechanical and electrical maintenance. Exposures for the maintenance crew are assumed to be uniformly distributed over the personnel available

c. Calibration, testing, and maintenance of most plant instruments and control systems are accomplished by the instrumentation and control group. An instrumentation and control crew of at least eight persons is assumed for all plant instrumentation and control work. Exposures for the instrumentation and control group are assumed to be equally distributed over the normal personnel available, and are included in the maintenance staff exposure data

d. Maximum design-level dose rates in various plant areas are shown in Figures 12.1-1 and 12.1-3 through 12.1-8, and anticipated average design dose rates for these areas are defined in Table 12.1-1.

The estimate of average exposure and total yearly man-rem for each of the Fermi 2 working groups has been based on the plant operating continuously with the expected design-basis radiological conditions, and with personnel performing all their operations and patrolling in areas where in the dose rates have been assumed to be constant and equal to the average expected dose rate in the area (Table 12.1-1).

NOTE: These whole-body dose estimates of Section 12.1.5 have been performed as part of the original overall design-basis determination that the plant was well-designed from an ALARA standpoint. These calculations are/were intended to only represent conservative pre-operational estimates. They were not intended to be updated or revised in order to correspond to operational data or to any revised criteria, assumptions, methodology, etc. Detailed whole-body dose information is continuously taken and analyzed as an integral part of plant operations, and summary dose information is periodically provided to pertinent regulatory agencies.

12.1.5.2.2 Results

The estimates for the various buildings and jobs are as follows:

a. Tables 12.1-19 through 12.1-21 define the exposures operating personnel receive on routine rounds while checking equipment. These tables make the conservative assumption that the rounds are performed once per shift (once every 8 hr) 52 weeks per year

b. Tables 12.1-22 through 12.1-24 define the exposures that operating personnel receive during maintenance, such as filter changing and lubrication

   It should be noted that the radwaste handling (i.e., drumming, capping) and maintenance, as defined in Tables 12.1-19 through 12.1-24 and in Tables 12.1-26 through 12.1-28, include the estimates of exposures that radwaste handlers would experience

c. For the remaining time in the shift, it is assumed that the operations personnel spend their time in the shop, main control room, or other buildings where the average dose rate of 0.10 mrem/hr is expected. Table 12.1-25 defines the bases for which the man-rem exposure estimate has been established

d. Tables 12.1-26 through 12.1-28 define the exposures maintenance personnel receive during normal expected maintenance functions. These tables include man-hours expected for the maintenance groups, including mechanical, electrical, and instrumentation and control maintenance, and are defined for a whole year of operation

e. For the remaining time in the year, it is assumed that the maintenance personnel spend their time in a Zone II area, i.e., a maximum design dose rate of 0.5 mrem/hr, and an expected average dose rate of 0.1 mrem/hr. (See Table 12.1-

25 for this estimate). Table 12.1-25 also gives an exposure estimate for the remaining personnel associated with operation of the Fermi 2 facility and also the basis by which the estimate has been established

f. It is difficult to accurately estimate the amount of personnel exposure associated with the actual refueling process. The same is true for inservice inspection. However, data from the Millstone facility obtained in an AIF study indicate that 61 men had received a total of 74.23 manrem over a period of a year (1972) during routine plant surveillance, inspection, and routine refueling operation, for an average of 1.22 rem/man- year. Refueling exposures as reported by operating facilities normally include maintenance exposures associated with the refueling operation, not those associated with the refueling alone. Thus, it can be concluded that Tables 12.1-19 through 12.1-25 include the estimate of man-rem exposure for the maintenance portion of the refueling operation

g. Radiation exposure received by the chemists or designated technicians is difficult to assess since they perform technical functions in chemistry, radiochemistry, instrument, and/or control adjustments. However, experience indicates that these personnel receive 2 rem/ year/man. The same is true for the health physicists and the Health Physics technicians

h. Table 12.1-29 summarizes the exposure data presented in Items a. through g.

Comparison of the estimated results with data available from the operation of Nine Mile Point, Quad Cities 1 and 2, and Oyster Creek is given in Table 12.1-30. Data from the operating plants were obtained by averaging information presented in WASH-1311 (Reference 21).

12.1.6 Postaccident Shielding Assessment

12.1.6.1 Introduction

A postaccident radiation shielding review has been performed to ensure adequate access to vital areas and protection of safety equipment. The assumptions, approach, and results of the review are outlined below. These analyses were prepared in response to post-TMI guidance with Regulatory Guide 1.3 based source terms, and are typically conservative relative to analyses that would be performed in accordance with 10 CFR 50.67 and Regulatory Guide 1.183 guidance. Evaluations are made of control room doses and impacts on vital area accessibility with AST based parameters.

12.1.6.2 Source Terms

The initial reactor core inventory of radioactive nuclides was determined using assumptions in accordance with Regulatory Guides 1.3 and 1.7 and NRC post-TMI guidance. At time-equals- zero after the reactor shutdown, an instantaneous release of radioactivity from the core was assumed to occur. Liquid- containing systems were assumed to receive 100 percent of the noble gas inventory, 50 percent of the core halogen inventory, and 1 percent of all other radionuclides. Gas-containing systems were assumed to receive 100 percent of the core noble gas inventory and 25 percent of the core halogen inventory. Radioactivity in liquid systems was assumed to be uniformly mixed in a volume of water equal to the total volume of the reactor vessel, the recirculation system volume, and the suppression pool water volume. Radioactivity in the primary containment air was assumed to be uniformly mixed in the total of the drywell and torus free air volumes. (Vapor-containing lines connected to the primary system have this activity confined to the primary system vapor space.) At time-equals-zero, the primary containment air volume was assumed to begin leaking into the reactor building atmosphere at the rate of 0.5 percent per day.

At the same time, the SGTS was assumed to begin drawing activity from the reactor building at a rate of one reactor building volume per day. The above considerations define the airborne radionuclide activity in the reactor building atmosphere. This airborne activity (plus the airborne activity released from an assumed 1500-gal primary liquid leak into the reactor building [with 100 percent noble gas and 10 percent halogen evolution assumed]) was used to determine the radionuclide inventory accumulated on the SGTS filters, the control room emergency makeup and recirculation filters, the process radiation monitor sample filters, and the technical support center emergency makeup recirculation filters.

The initial core inventory and the transport and decay of radionuclides were handled by the RACER computer code (Reference 22). The RACER code is made up of two major subroutines, RIBD and BAFFLE. RIBD is a standard industry code for calculating reactor core inventories. BAFFLE is a code that analyzes the transport of radionuclides between communicating compartments. Leak rates, filtration, and plate-out can all be modeled with this code, taking full account of radionuclide decay and daughter-product buildup.

Section 6.4 of NUREG-75/087 (Reference 23) provided the guideline for modeling the SGTS effluent plume.

For AST based analyses for the main control room, LOCA sources are determined using RADTRAD models with design basis core source terms, credited removal mechanisms, and transport parameters. Uniform mixing in secondary containment is assumed when evaluating secondary containment gamma shine, and 100 percent filter efficiency is assumed when evaluating SGTS filter source terms.

Chapter 15 analyses of accident radiological consequences are performed per Regulatory Guide 1.183 Alternative Source Term (AST) (Reference 27) using core source terms reflective of anticipated fuel cycle conditions obtained with appropriate isotope generation and depletion computer codes. Whereas the original AST analysis of onsite and offsite consequences used ORIGEN-S – based source terms (Reference 29), re-analysis and consideration of the Chapter 15 accidents to support implementation of a 24-month, GNF3 fuel cycle are performed using ORIGEN 2.1-based source terms (References 26 and 30) appropriate for anticipated fuel cycle conditions.

RADTRAD (Reference 24) calculated time dependent compartment activities are time integrated and then evaluated using Microshield (Reference 25). Sources considered are the primary containment, the reactor building, a standby gas treatment system filter and an environmental plume outside of the control room shielding.

12.1.6.3 Radioactive Systems

The systems assumed to contain radioactive liquids include the high-pressure injection system, the core spray system, the reactor core isolation coolant (RCIC) system, and the residual heat removal (RHR) system, as well as portions of the control rod hydraulic system, sample lines, and all piping and equipment in communication with the primary coolant system out to the second isolation valve. A design review was performed to ensure that no systems other than those mentioned above would become contaminated with postaccident primary coolant. In particular, design corrections have been made to ensure that the reactor building sumps (which could contain postaccident primary coolant) would not be pumped out of the reactor building. The radwaste system, therefore, would not be contaminated by postaccident sources.

Systems assumed to contain postaccident primary containment atmosphere are the drywell, the torus free air volume, all piping and equipment connected to the drywell, and torus free air volume out to the second isolation valve. The reactor building atmosphere is assumed to be contaminated as a result of primary containment leakage. Steam lines are assumed to contain the core release fractions for airborne sources outlined in Subsection 12.1.6.2. It is assumed that these sources are restricted to the vapor-containing areas of the primary coolant system. A design review showed that the gaseous radwaste system is not exposed to postaccident source terms.

12.1.6.4 Radiation Environment

The determination of the total radiation environment at any location includes the consideration of all of the many potentially contributing sources. The sources considered include the following:

a. Direct radiation shine from the airborne and liquid radiation sources in the drywell and torus

b. Direct radiation shine from enigneered safety features equipment and piping circulating postaccident contaminated liquids or gases in the reactor building (e.g., RHR, high-pressure coolant injection, RCIC, and core spray system)

c. Immersion in and inhalation of the airborne sources within the reactor building heating, ventilation, and air conditioning (HVAC) boundary, resulting in gamma whole-body doses, beta skin doses, and thyroid doses due to iodine inhalation

d. Direct radiation shine of the reactor building and refueling floor atmospheres to surrounding areas

e. Direct shine from (or immersion in and inhalation of) the SGTS exhaust plume

f. Direct radiation shine from airborne filters that accumulate radionuclides (e.g., SGTS filters, control room and technical support center emergency makeup filters, and continuous air monitor sample filters).

g. Direct shine from the dry cask storage system HI-STORM units emplaced on the ISFSI storage pad.

The total radiation dose at any particular location was determined by summing all of the above-mentioned contributors. The final dose rates were then assembled and presented in the form of radiation zone maps. Zone map sets were prepared for times of 1 hr, 1 day, 1 week, and 1 month after the onset of the accident. These zone maps were prepared from the following zone designations:

I	-	greater than 500 rem/hr
II	-	500 to 100 rem/hr
III	-	100 to 10 rem/hr
IV	-	10 to 1.0 rem/hr
V	-	1.0 to 0.10 rem/hr
VI	-	0.10 to 0.015 rem/hr
VII	-	less than 0.015 rem/hr

12.1.6.5 Method of Analysis

External dose rates due to direct radiation from the drywell, the torus, the various contained sources, and the effluent plume were determined by using Microshield on time integrated concentrations determined using RADTRAD.

Airborne immersion and inhalation doses were calculated using the RADTRAD computer code.

12.1.6.6 Radiological Equipment Qualification

Appropriate radiation calculations were generated, and the ability of safety-related equipment to withstand postaccident radiation levels was determined.

12.1.6.7 Vital Areas

A review was performed to determine the radiological accessibility and habitability of the station's vital areas. Areas considered in this review included the control room, the technical support center, the postaccident sample panel, the postaccident sample analysis areas, the radwaste panel, the motor control centers, instrumentation locations, emergency power supplies, the security center, the hydrogen recombiners, the hydrogen purge control areas, the containment isolation reset areas, and the manual emergency core cooling system (ECCS) alignment areas.

It was determined whether each of these potential vital areas is necessary for postaccident operation of the plant. Besides the control room, four vital areas were identified as listed in Section 11.4.3.12. For those areas necessary for postaccident operation of the plant, the extent of occupancy for these areas to fulfill their functions was established. This information, in conjunction with the postaccident radiation zone maps, made it possible to verify if the postaccident occupancy of vital areas would result in radiation doses to personnel that would exceed the limits set forth in GDC 19 and 10 CFR 50.67.

The postaccident accessibility review of the vital areas concluded that only one major modification was necessary; it was determined that excessive radiation skyshine from the refueling floor could enter the ground floor of the turbine building through a large equipment blockout in the north wall thus limiting the accessibility of this area. A removable concrete shield wall (14 ft 2 in. x 11 ft 8 in. x 18 in.) was constructed in front of the two former door openings in this area. This modification corrected the problem so that postaccident occupancy of vital areas will not be unduly limited by radiation.

The four vital areas identified in UFSAR Section 11.4.3.12 as being necessary for post-accident operations of the plant will continue to be habitable (within 10 CFR 50.67 limits)following a DBA-LOCA, after the application of AST to Fermi 2 as described below.

a. The calculated doses in the Technical Support Center (TSC) with existing TSC HVAC design parameters remains within allowable limits

b. The Operational Support Center (OSC) in the Turbine Building (TB) as well as the alternate OSC in the Service Building machine shop will continue to be habitable with some increase in dose in the primary OSC due to additional postulated activity in the TB due to MSIV leakage

c. The post-accident sampling facility will remain accessible, based on 1-hour occupancy and optional use of self-contained breathing apparatus (SCBA) when taking samples.

d. The post-accident sample analysis areas will continue to be accessible, and based on TSC results, most of these facilities would be expected to have lower exposures based on AST assumptions

An assessment was performed of access paths to the control room to confirm that increased airborne activity in the TB will not interfere with personnel change-over.

TABLE 12.1-1 PLANT RADIATION SHIELDING ZONES FOR NORMAL OPERATION AND ANTICIPATED OPERATIONAL OCCURRENCES[h,i]

Zone Number	Maximum Dose Rate[a] (mrem/hr)	Posting Required[b]	Anticipated Access[c]
I	≤0.3[d]	No	Unrestricted
II	≤0.5	No	Restricted with unlimited access
III	≤1.0	No	Restricted with occupational access
IV	≤2.0	No	Restricted with occupational access
V	≤4.0	No	Restricted with periodic access
VI	≤8.0	Yes[e,f,g]	Restricted with limited access[f]
VII	≤15.0	Yes[f,g]	Restricted with limited access[f]
VIII	≤30.0	Yes[f,g]	Restricted with limited access[f]
IX	≤60.0	Yes[f,g]	Restricted with limited access[f]
X	≤60.0	Yes[f,g]	Restricted with limited access[f]

[a] Except for Zone X, the anticipated average dose rate is approximately 0.25-0.33 times that of the maximum design dose rate.

[b] Refers exclusively to whether posting with the signs "Caution - Radiation or High Radiation Area" is required; not the posting of actual radiation levels.

Actual radiation levels will be routinely posted at selected portions of Zones V through X.

[c] All access within the site boundary is controlled.

[d] This zone applies to the main control room only.

[e] Posting will be required in those areas in which there exists radiation such that a major portion of the body could receive a dose in excess of 100 mrem in any 5 consecutive days.

[f] Access only with Health Physics permission, with duration based on (1) radiation intensity level, (2) nature of the radiation, (3) past radiation exposure history of entering personnel.

[g] Posting with these signs will be required in those areas in which there exists radiation such that a major portion of the body could receive a dose in excess of 100 mrem in any 1 hr.

[h] These are design-basis radiation shielding zones; they do not necessarily represent the maximum actual operational dose in any particular area of the plant.

[i] These zones are original design-bases values, without the operation of Hydrogen Water Chemistry.

TABLE 12.1-2 SUMMARY OF DRYWELL SHIELD DESIGN

Item	Protected Region	Design Condition	Design Value
A	Inner face of sacrificial shield wall	Full power	≤5 x 10^{10} MeV/cm^2/sec
B	Outer face of sacrificial shield, and at mating flange for top head of RPV	Full power	≤2 x 10^5 neut/cm^2/sec (thermal)
C	Outer face of drywell biological shield	Full power	0.3 mrem/hr (laterally) 2 mrem/hr (above plug)
D	Outer face of sacrificial shield	1-day shutdown, with core in place	30 mrem/hr (from sources inside shield)

			B) Adjacent boiler cell	Always	0.5
			C) Extruder/evaporator on floor above	Extruder/evaporator not in use	8.0
3.2.14	Spent-resin slurry feed tank	Maximum activity	A) Adjacent spent-resin slurry recirculation pump cell	Pumps down	8.0
			B) Adjacent concentrates recirculation pump and emergency drain sump pumps cell	Pumps down	8.0
			C) Reciprocating drive units area on operating floor above	Always	0.5
			D) Concentrates feed tank cell	Tank drained	8.0
			E) Access aisle	Always	0.5
3.2.15	Concentrates recirculation pump	Maximum activity	A) Adjacent concentrates feed tank	Tank drained	8.0
			B) Adjacent spent-resin slurry feed tank	Tank drained	8.0
			C) Adjacent aisle outside cell	Always	0.5
			D) Reciprocating drive units on operating floor above	Always	0.5
3.2.16	Spent-resin slurry decant pump and spent-resin slurry recirculation pump	Maximum activity	A) Adjacent spent-resin slurry feed tank cell	Tank drained	8.0
			B) Adjacent emergency drains sump pumps and concentrates recirculation pump cell	Pumps down	8.0
			C) On ceiling above	Pipes drained	0.5
			D) Adjacent boiler and centrifuge feed and recirculation pump cell	Pumps down	8.0
3.2.17	Concentrates feed tank	Maximum activity	A) Adjacent spent-resin slurry feed tank cell	Tank drained	8.0
			B) Adjacent main aisle outside	Always	0.5
			C) Reciprocating drive units area on operating floor above	Always	0.5
			D) Concentrates recirculation pump cell	Pump and pipes drained	8.0
3.2.18	Pipe tunnel	Maximum activity in all pipes	A) Adjacent condensate phase separator cell	Tanks drained	8.0
			B) Adjacent chemical waste tank cell	Tank drained	8.0
			C) Adjacent waste clarifier tank and spent-resin tank cell	Tanks drained	8.0
			D) Adjacent waste surge tank and waste sample tanks cell	Tanks drained	8.0
			E) Above pipe tunnel outside	Always	0.1
3.3.1	Deleted				
3.3.2	Etched-disk filters	Maximum activity	A) Adjacent main aisle	Always	0.5
			B) Adjacent access aisle to coalescer	Pipes drained and coalescer filter removed	15.0

3.4.1	South distillate surge tank and evaporator	Maximum activity	A) Adjacent north distillate surge tank and evaporator cell	Tank and evaporator	8.0
			B) Outside building	Always	0.1
			C) Reciprocating drive units below (583 ft 6 in.)	Always	0.5
			D) Adjacent caustic feed tank and chemical feed tanks area	Always	0.5
			E) Adjacent aisle to stairway	Always	0.5
			F) Drum storage below	Conveyors empty	8.0
3.4.2	North distillate surge tank and evaporator	Maximum activity	A) Adjacent south distillate surge tank and evaporator cell	Tank and evaporator drained	8.0
			B) Adjacent stairway	Always	0.5
			C) Adjacent steam station	Always	0.5
			D) Outside building	Always	0.1
			E) Drum conveyor area below (583 ft 6 in.)	Conveyor area empty	8.0
3.4.3	Evaporator drains holdup tank	Maximum activity	A) Adjacent north distillate surge tank and evaporator cell	Tank and evaporator drained	8.0
			B) Adjacent south distillate surge tank and evaporator cell	Tank and evaporator drained	8.0
			C) Adjacent aisleway	Always	0.5
3.4.4	Centrifuge	Maximum activity	A) Adjacent washdown area and access aisle	Always	0.5
			B) Adjacent vent hood filter train	Filter element removed	8.0
			C) Adjacent turbine building	Always	0.5
			D) Reciprocating drive units area below (583 ft 6 in.)	Always	0.5
			E) Drum conveyor aisle below (583 ft 6 in.)	Conveyor not in use	8.0
			F) Rooms above	Always	0.5
3.4.5	Vent hood filter train	Normal operation	A) Adjacent centrifuge cell	Centrifuge empty	8.0
			B) Adjacent access aisle and stairway from washdown area	Always	0.5
			C) Adjacent turbine building	Always	0.5
			D) Part of reciprocating drive units area below (583 ft 6 in.)	Always	0.5
			E) Part of drum conveyor aisle below (583 ft 6 in.)	Conveyor not in use	8.0
			F) Rooms above	Always	0.5

[a] See Table 12.1-6 for explanation of identification numbers.

TABLE 12.1-6 SPECIFIC SHIELD DESIGN CRITERIA

Explanatory Note for Identification

Number in First Column of Tables 12.1-3, 12.1-4, and 12.1-5

The number in the first column of Tables 12.1-3, 12.1-4 and 12.1-5 is a three-part identifier, A.B.C., which is coded in the following manner:

The first digit, A, represents the general area location of the equipment which is to be shielded.

A	Location
1	Reactor building
2	Auxiliary building
3	Radwaste building
4	Turbine building

The second digit, B, represents the floor elevation of the equipment.

Corresponding Building Elevations

B	Floor	Reactor	Auxiliary	Radwaste	Turbine
1	Subbasement	540 ft	540 ft	-	-
2	Basement	562 ft	551 ft	557 ft 6 in.	564 ft
3	Grade	583 ft 6 in.	583 ft 6 in.	583 ft 6 in.	583 ft 6 in.
4	Mezzanine	600 ft 6 in.	603 ft 6 in.	601 ft 6 in.	-
5	Second	613 ft 6 in.	613 ft 6 in.	613 ft 6 in.	613 ft 6 in.
6	Mezzanine	626 ft	630 ft 6 in.	628 ft 6 in.	-
7	Third	641 ft 6 in.	643 ft 6 in.	-	643 ft 6 in.
8	Fourth	659 ft 6 in.	-	-	-
9	Fifth	684 ft 6 in.	-	-	-

The third digit, C, is simply a sequence number.

Example:

4.3.4. represents the turbine building (A = 4) at Elevation 586 ft 6 in. (B = 3) and is the fourth item (C = 4) in the series of items listed.

[a] FP = Fission Products.
CP = Corrosion Products.
[b] The following notes apply as indicated:

TABLE 12.1-8 SUMMARY OF SHIELD DESIGN IN REACTOR AND AUXILIARY BUILDINGS (3499 MWt)

A. Main source, which is radiation streaming from the main recirculating lines in drywell, determines shield thicknesses. Secondary RCIC source is present for about 0.5 hr per month

B. Source is maximum value of irradiated steel activation products, with no decay

C. Source values given for portion of tunnel in reactor and auxiliary buildings

D. Source strength is maximum value, when unit starts (4 hr decay). Hence, design doses are also maximum values

E. Source values for one tank or unit

F. Source strength (in "effective Ci") is based on measurements of crud deposition at Dresden operating units

G. Source is one-half of a core, with 7-day decay

H. Source value (per cell) is given at a 2-hr decay time post-LOCA

I. Criteria is maximum dose rate of 50 mrem/hr, which occurs when SGTS source is maximum

J. Criterion is less that 5 rem to personnel in main control room, over 30 days.

K. With Hydrogen Water Chemistry in operation, the calculated N-16 steam sources will increase by a maximum factor of six; the design levels are original design-bases values, without Hydrogen Water Chemistry

CP = Corrosion Products.

[b] Notes apply as indicated:

A. Values are given for "worst" (north) cell: other cells have less activity

B. Values are given for one cell, but all cells are typically the same

C. Values are given for startup condition, i.e., maximum sources

D. Values are given for "worst" (low-power) condition: sources are less at full power

E. Various pieces of equipment, such as recombiner, preheater, condenser, aftercooler, and other associated equipment

F. Values are given only for that portion of tunnel inside turbine building.

G. With Hydrogen Water Chemistry in operation, the calculated N-16 steam sources will increase by a maximum factor of six; the design levels are original design-bases values, without Hydrogen Water Chemistry.

H. Charcoal Adsorber Room Knockout (TB3 South End) has a roll-up door installed rather than a block wall.

TABLE 12.1-10 SUMMARY OF SHIELD DESIGN IN RADWASTE BUILDING (3499 MWt)

Floor	Name of Cell	Main Equipment in Cell	Source Strength (Ci)	Source Geometry	Location of Wall	As-Built Wall Thickness	Design Level in Overall Area (mrem/hr)	Design Level at Surface (mrem/hr)	Recommended Wall Thickness	Notes[a]

TABLE 12.1-10 SUMMARY OF SHIELD DESIGN IN RADWASTE BUILDING (3499 MWt)

Floor	Name of Cell	Main Equipment in Cell	Source Strength (Ci)	Source Geometry	Location of Wall	As-Built Wall Thickness	Design Level in Overall Area (mrem/hr)	Design Level at Surface (mrem/hr)	Recommended Wall Thickness	Notes[a]

[a] Notes apply as indicated:

A. Source strength based on condensate sludge. Value for RWCU sludge-filled drum is 772.6 Ci (only six times per year); value for waste demineralizer sludge-filled drum is 29.3 Ci; value for evaporator concentrates-filled drum is 0.7 Ci

B. Values given for westernmost storage aisle (30 drums per conveyor)

C. Design level at wall is well below overall design level to allow for streaming radiation through various wall penetrations

D. Sources are small enough that no shielding (other than distance effect) is required

E. In addition to walls of room, appropriate shadow shielding will be used around sources

F. Recommended thickness is for a composite wall of 21 in. of concrete with a density of 145 lb/ft^3 and 5 in. of steel

G. Source strength based on condensate phase separator dump to centrifuge feed tank. Value for dump from spent-resin tank is 7.89 μCi/cm^3; value for dump from RWCU phase separator is 148 μCi/cm^3 (only six times per year)

H. Source strength based on condensate phase separator processing. Value for waste demineralizer resin processing is 0.79 Ci; value for RWCU phase separator processing is 21.78 Ci (only six times per year); value for evaporator concentrates processing is 0.02 Ci

I. Source strength based on RWCU sludge. Value for processing of waste demineralizer sludge is 6.5 Ci; value for processing of condensate sludge is 11.8 Ci

J. Source strength based on lead waste collector coalescer. Value for second coalescer is 9.0 Ci; value for third coalescer is 2.7 Ci

K. Source strength based on condensate sludge processing. Value for RWCU sludge is 784 Ci (only six times per year)

L. Wall is lead-shot-filled steel-framed wall

M. Value based on spent-resin transfer pump

N. Additional shielding added to original wall to give equivalent of 3 ft 6 in. of concrete

O. Wall made of lead brick

P. Motor-operated shield doors made of 7 in. of steel.

[b] Values are per tank, per drum, per source, or per line.

[c] Values are in μCi/cm^3.

TABLE 12.1-11 THROUGH TABLE 12.1-13
HAVE BEEN INTENTIONALLY DELETED

TABLE 12.1-14 DIRECT MAIN CONTROL ROOM DOSES FOLLOWING A LOSS-OF-COOLANT ACCIDENT (3499 MWt)

		Integrated Dose From Following Sources				
Time After LOCA (days)	Occupancy Factor	SGTS (rem)	Primary Containment (rem)	Secondary Containment (rem)	Plume (rem)	Total[a] (rem)
		<<0.0001	<<0.0001	<0.0001	0.040	0.040

[a] Refers to Total Effective Dose Equivalent (TEDE) contribution, using R.G. 1.183 based analysis. Direct doses are doses as seen by main control room personnel, through various concrete walls and ceilings.

TABLE 12.1-15 PHOTON PRODUCTION RATE OF FISSION PRODUCTS IN THE REACTOR CORE, FOLLOWING FIVE YEARS OF OPERATIONS, AT VARIOUS TIMES AFTER SHUTDOWN (3430 MWt)

		Total Photon Production Rate (photons/sec) After Shutdown				
Group	Average Group Energy (MeV)	0 Time	1 Hr	1 Day	3 Days	7 Days

Total		9.776(20)	3.129(20)	1.341(20)	9.424(19)	6.959(19)

[a] 1.500(-2) = 1.500 x 10^{-2}.

TABLE 12.1-16 DOSE AT SITE BOUNDARY FROM STORED WASTE

$D = 2 \times 10^{-12}$ mrem/hr/Ci of waste, or

$D^1 = 1.8 \times 10^{-8}$ mrem/year/Ci of waste, with a 100 percent occupancy factor

Assumptions:

A. Minimum site boundary distance is 4000 ft

B. Minimum concrete thickness surrounding the drums is 4 ft (north wall of radwaste building)

C. Average gamma ray energy of 1.5 MeV used

D. Photon attenuation and appropriate buildup factors for both air and concrete walls were used

E. Waste drums stored inside building. No drums are to be stored outside

F. Gamma ray self-absorption in the drum is taken into account. Each drum consists of a mixture of water, cement aggregate, and radioactive sludge, resulting in a concrete mixture.

TABLE 12.1-17 DOSE AT SITE BOUNDARY FROM CONDENSATE STORAGE TANKS

Dose rate per tank = 2×10^{-7} mrem/hr, or

Dose rate per tank = 1.8×10^{-3} mrem/year

Assuming 100 percent occupancy factor

Assumptions:

A. Tanks contain their maximum concentrations of 0.001 $\mu Ci/cm^3$

B. Each tank contains its full volume of liquid (600,000 gal), thereby giving a maximum content of 2.3 Ci per tank

C. Distance between tanks and site boundary is 4400 ft. This is the minimum distance which is not interrupted by any of the concrete buildings. In other words, it is the nearest point at which the tanks could be "seen" by a person at the site boundary.

TABLE 12.1-18 DOSE RATES AT VARIOUS POSITIONS NEAR FERMI 2 (3499 MWt)

		Dose Rates, mrem/hr								
	Source	Point No[a].	A[b]	B[c]	C	D	E	F	G	H
Source Description	Strength (photon/sec)	Distance (ft)	120	300	500	900	1200	2600	3600	4560
Low-pressure turbines (3)	1.65E+12		9.9E-05	5.2E-04	1.7E-03	5.7E-04	1.0E-04	1.7E-06	1.4E-07	4.4E-08
High-pressure turbines	2.35E+12		1.0E-04	6.2E-04	1.6E-03	4.7E-04	1.2E-04	2.2E-06	1.6E-07	3.8E-07
Crossover pipes	1.84E+12		4.0E-03	4.2E-02	6.2E-02	2.8E-02	8.6E-03	4.8E-04	1.0E-04	6.3E-05
High-pressure turbine inlet lines	3.06E+12		8.2E-04	5.2E-03	1.6E-02	5.4E-03	1.3E-03	4.2E-05	3.3E-06	1.5E-06
Reheaters (2)	1.53E+14		1.9E-02	1.1E-01	1.5E-01	4.5E-02	3.4E-02	2.0E-03	2.8E-04	4.9E-05
Total	1.62E+14		2.4E-02	1.5E-01	2.3E-01	7.9E-02	4.4E-02	2.6E-03	3.8E-04	1.1E-04

[a] For point designations, see Figure 12.1-2. Distances are measured to the center of the turbine reheater complex.

[b] Point at third floor aisleway of turbine building: photon attenuation through 8-in. concrete roof included in calculation.

[c] Point at center of main office building. Calculations account for the shadowing effect of the outer (eastern) wall of the turbine building.

[d] With Hydrogen Water Chemistry in operation, these N-16 estimates will increase up to factor of six.

TABLE 12.1-19 CALCULATED OPERATOR EXPOSURE DURING ROUTINE ROUNDS IN REACTOR BUILDING

Equipment	Expected Dose Rate (mrem/hr)	Time[a] (minutes/year)	Exposure (man-rem/year)
HPCI turbine and pump	0.15	4368	0.011
CRD pumps	0.15	2184	0.005

TABLE 12.1-19 CALCULATED OPERATOR EXPOSURE DURING ROUTINE ROUNDS IN REACTOR BUILDING

Equipment	Expected Dose Rate (mrem/hr)	Time[a] (minutes/year)	Exposure (man-rem/year)
CRD storage and repair	2.0	2184	0.073
RWCU demin. tank	22[b]	546	0.200
RWCU heat exchangers	22[b]	546	0.200
RHR heat exchangers	22[b]	1092	0.400
Primary containment	22[b]	546	0.200
RWCU phase separator	22[b]	3276	1.201
		Total[c]	2.58

[a] Assumes the rounds are performed once per shift every day of the year.

[b] Values do not include major maintenance. They do consider access to an area or piece of equipment, averaged over a year, both during shutdown and during the time the equipment is still in operation but the reactor is at partial load. It is estimated that, over a year, 10 percent of personnel time (in a given cell) will be in a field of 125 mrem/hr, 10 percent in a field of 55 mrem/hr and 80 percent in a field of 5 mrem/hr.

[c] Total is based on 1346.8 man-hours available. Total man-hour availability for operators is 52,416 man-hours.

TABLE 12.1-20 CALCULATED OPERATOR EXPOSURE DURING ROUTINE ROUNDS IN RADWASTE BUILDING

Equipment	Expected Dose Rate (mrem/hr)	Time[a] (minutes/year)	Exposure (man-rem/year)

Evaporators	3.0	546	0.027
Centrifuge	47.0[b]	1092	0.855
		Total[c]	8.443

[a] Assumes the rounds are performed once per shift every day of the year.

[b] It is estimated that, over a year's time, about 50 percent of personnel time is spent in a field of 80 mrem/hr, 30 percent in a field of 20 mrem/hr, and 20 percent in a field of 5 mrem/hr. For areas with design levels below 20 mrem/hr, the average level was estimated to be one-third of the maximum design level.

[c] Total is based on 1055.8 man-hours available (Column 2). Total man-hour availability for operators is 52,416 man-hours.

TABLE 12.1-21 CALCULATED OPERATOR EXPOSURE DURING ROUTINE ROUNDS IN TURBINE BUILDING

Equipment	Expected Dose Rate (mrem/hr)	Time[a] (minutes/year)	Exposure (man-rem/year)

Reheater/separators	38[a]	240	0.152
		Total[b]	1.67

[a] It is estimated that, over a year, 10 percent of personnel time (in a given cell) will be in a field of 110 mrem/hr, 50 percent in a field of 50 mrem/hr, and 40 percent in a field of 5 mrem/hr.

[b] Total is based on 293.6 man-hours available. Total of man-hours available for operators is 52,416 man-hours.

TABLE 12.1-25 FERMI 2 PERSONNEL EXPOSURES CALCULATED FOR REMAINING MAN-HOURS

Personnel Category	Number of Personnel	Exposure (man-rem/year)
Administration	13	2.60[a]
Operations	32	5.23[b]
Radiation Protection supervision	3	3.00[c]
Equipment division	3	0.60[a]
	8	2.86[d]
	3 (QA personnel)	1.78[e]
Maintenance (electrical, mechanical, instrumentation and control)	20	1.83[f]
	Total[g]	18.37

[a] Assumes each person available 2000 man-hours per year while in a radiation field of 0.1 mrem/hr.

[b] Assumes 30 personnel receive 0.1 mrem/hr for remainder of man-hours not accounted for in Tables 12.1-19 through 12.1-24(48,289 man-hours), and that two supervisory personnel receive a total of 0.4 man-rem for 1 year (i.e., each person available 2000 hr per year while in a radiation field of 0.1 mrem/hr).

[c] Assumes each person accumulates 1 rem per year.

[d] Assumes these personnel receive 30 percent of total operations personnel exposure per man, i.e., sum of total exposures listed Tables 12.1-19 through 12.1-24, divided by 30 personnel, yielding an average of 1.19 rem/man per year. Thus, each of eight personnel in this category will receive an average of 0.357 rem/year.

[e] Assumes QA engineer, assistant QA engineer, and QA technician receive 25, 50, and 75 percent of total operational personnel exposure per man, respectively. That is, sum of 25 percent, 50 percent, and 75 percent of 1.19 rem/year per man (see d.) is 1.78 man-rem/year.

[f] Assumes maintenance personnel receive 0.1 mrem/hr for remaining man-hours available not accounted for in Tables 12.1-26 through 12.1-28 (i.e., 18,340 man-hours).

[g] Total based on available man-hours left over from required operational and maintenance functions. Radwaste personnel and Radiation Protection personnel (i.e., supervisor and technicians) included in other tables and Subsection 12.1.5.2.2.

AREA RADIATION MONITOR SYSTEM

12.2 VENTILATION

12.2.1 Design Objectives

The design of the plant ventilation system for radioactive airborne radiation control is based on the following objectives:

a. The system is designed to maintain the airborne radioactivity levels for normal operation, including anticipated operational occurrences, as far below 10 CFR 20 limits as reasonably achievable

b. The system is designed to maintain the airborne radioactivity levels for normal operations, including anticipated operational occurrences, as far below 10 CFR 20 limits as reasonably achievable for areas within the plant structure and on the plant site where construction workers and visitors are permitted

c. The system is designed to ensure that offsite releases during normal operation comply with limits specified in Appendix I of 10 CFR 50 for release to unrestricted areas beyond the site boundary

d. The system is designed to provide a suitable environment for equipment and personnel in the main control room under postaccident conditions, in accordance with General Design Criterion (GDC) 19 of 10 CFR 50, Appendix A.

The plant ventilation systems are designed to provide a suitable environment for personnel and equipment during normal plant operation, including anticipated operational occurrences. In addition to their primary function of preventing extreme thermal environmental conditions for operating personnel and equipment, the plant ventilation systems also provide effective protection against possible uncontrolled release or spread of radioactive airborne contamination. The systems are described in detail in Section 9.4.

The rooms in the plant buildings that are expected to be maintained below minimum contamination guidelines are separated from the potentially contaminated rooms and cubicles by gravity back- draft dampers at ventilation penetrations to ensure that there will be no backflow of the air from potentially contaminated areas to these generally accessible areas. The rooms are arranged so that, where possible, potentially contaminated rooms are not located at contiguous walls between buildings.

Pressure gradients are maintained in plant buildings by the ventilation systems to prevent the release of unmonitored radioactive gases or particulates to the environment and to prevent airborne radioactivity from entering areas normally occupied by plant personnel. In plant buildings where there is a potential for airborne radioactivity, the ventilation system will maintain the building at a slightly negative pressure with respect to the outside atmosphere. The reactor and radwaste buildings will be maintained at a negative pressure of approximately 0.25 in. of water with respect to the outside atmosphere. The turbine building pressure will be maintained at a pressure below outside atmospheric pressure. The control center, radwaste control room, and chemistry laboratory are located in buildings where the potential for airborne radioactivity exists, and these areas are normally maintained at a slightly positive pressure to prevent the flow of air into these areas resulting from pressure gradients.

Access doors and hatches, which have the capability to be sealed, are provided for most potentially contaminated rooms and cubicles. Most walls, ceilings, and floor penetrations in potentially contaminated rooms and cubicles also are sealed to prevent the uncontrolled flow of air from one area to another. Where the walls, ceilings, and floor penetrations were not sealed, they were evaluated and determined to pose no contamination problem. Flow of air between buildings at common walls is prevented because penetrations at the walls are sealed, and doors are provided at personnel access openings.

The calculated maximum airborne radioactivity levels presented in Subsection 12.2.5 correspond to those that could result from the design-basis reactor coolant inventory loss. The actual expected levels should be considerably smaller, since average coolant inventories and actual equipment leakages will be smaller than those used in the calculations. The estimated maximum airborne radioactivity levels are presented in Tables 12.2-1 through 12.2-13. The methods and assumptions used to calculate these airborne radioactivity levels are presented in Subsection 12.2.3, and a discussion of the resulting inhalation doses is presented in Subsection 12.2.5.

12.2.2 Design Description

The following general guidelines were used in the system design to accomplish the design objectives stated in Subsection 12.2.1:

a. Airflow patterns are maintained for airflow from clean areas to potentially contaminated areas, thus preventing the spread of airborne contamination

b. A negative pressure differential, with respect to surrounding areas, is maintained inside potentially contaminated cubicles by means of control dampers or airflow patterns

c. A slightly positive pressure (1/4 ± 1/8 in. of water in relation to the outside ambient air) is maintained in the main control room under all operating conditions to prevent infiltration of potential contaminants

d. Exhaust from potentially contaminated areas in the radwaste building is routed through high-efficiency particulate air (HEPA) filters to remove airborne radioactivity and reduce onsite and offsite inhalation doses

e. Exhaust from the drywell and suppression chamber or the reactor building in general can be routed through HEPA and charcoal filters in the standby gas treatment system (SGTS) to remove high airborne particulate and iodine radioactivity so that onsite and offsite doses from these sources will be prevented or reduced in the event of high airborne radioactivity that reaches the ventilation system

f. The fresh air supply to the main control room is designed to be operable during all modes of plant operation, including loss of offsite power. The normal air supply is filtered through roll filters, and the emergency air supply is filtered through HEPA and charcoal filters

g. Filters such as the chemistry laboratory fume hood exhaust filters are contained within individual filter housings maintained at a negative pressure by the fume hood exhaust fan. Filter replacement is accomplished by removing a plate on the side of the filter housing. The plate is held in place by wing nuts that are quickly and easily removed. The filter housing is positioned so that the removable panel is accessible. After the panel has been removed, the used filter can be easily removed by pulling the filter into a plastic bag so there will be a minimum spread of radioactivity

h. Portable filter units consisting of a fan and motor assembly, high-efficiency filter, charcoal filter, flexible ducting, and a control panel are provided for use in areas of maintenance and repair activities that may result in the release of airborne radioactivity. The portable filter serves the function of localizing the source and eliminating the spread of contamination by purging the gases from the enclosed maintenance and repair area and then venting them to the normal building ventilation exhaust system after filtering

i. Differential pressure control in the plant buildings is maintained by the building ventilation system to minimize the spread of potential airborne contamination within the plant. The direction of airflow including leakage is controlled by maintaining clean areas at a higher pressure than potentially contaminated areas. A positive pressure is maintained in those areas of the plant normally occupied by operating, maintenance, and administrative personnel under normal or abnormal operating conditions. All other radiologically controlled areas of the plant are maintained at a negative pressure with respect to the outside atmospheric pressure.

The guidelines above are incorporated into the design basis for each individual system. The detailed design of the heating, ventilation, and air conditioning (HVAC) systems is described in Section 9.4. A brief summary of those systems that are expected to handle airborne radioactive material is given in the following subsections.

Ventilation flow diagrams for the reactor/auxiliary building, radwaste building, and turbine house are presented in Figures 9.4-4, Sheets 1 and 2, 9.4-5, and 9.4-7, respectively. Points of air transfer, flow rates on a cubicle-by-cubicle basis, and the location of those process radiation monitors specific to the ventilation system are shown in these flow diagrams. In addition to the process radiation monitors, area radiation monitors that will detect airborne radiation are located in a network throughout the plant. Area radiation monitors are listed in UFSAR Figures 12.1-12 and 12.1-13, including grid location references. The location of the instruments can be determined using these grid references and referring to the radiation zone drawings in Figures 12.1-1 and 12.1-3 through 12.1-8. Details of the process radiation monitors are given in Table 11.4-2 and Figures 11.4-2 through 11.4-4. The gaseous cleanup systems are covered in Section 11.3.

12.2.2.1 Control Center Ventilation System

The control center ventilation system is described in detail in Subsections 9.4.1 and 6.4.2.3.

Basically, two 100 percent-capacity, redundant air conditioning systems having a common ductwork maintain habitability inside the main control room and other areas served by this system. The other areas include the relay room, cable spreading room, computer room, conference room, main control room office, air-conditioning equipment room, and SGTS rooms. The total volume for these areas is 275,960 ft^3.

Outside air is supplied through a missile-protected inlet located approximately halfway up the south wall of the auxiliary building. The incoming air passes through redundant dampers and joins the recirculated air prior to passing through one of the two redundant air conditioning systems. Each system contains an electronic air cleaner, a roll filter, a 37,000-cfm supply fan, an electrical heater-chiller section, and control dampers. The air is then supplied to the various rooms previously described, and is exhausted from these areas using one of the two 35,550-cfm redundant return fans. A damper on the exhaust is modulated to restrict the airflow to maintain a positive pressure ($1/4 \pm 1/8$ in. of water) in the control center relative to the outside ambient air pressure. The air from the return fans is either completely exhausted or a fraction is exhausted and the remainder returned and mixed with incoming outside air.

The emergency air makeup system can take air from either of two inlet sources, depending on the relative radiation at these inlets (see Subsection 11.4.3.8.2.14). One emergency inlet is located at approximately the same location on the south wall of the auxiliary building as the normal control room air inlet. The second inlet is also missile protected and is located about halfway down the north wall of the auxiliary building.

A maximum flow of 1800 cfm, which is used as makeup air for pressurization, passes through a mist eliminator, an electric heater, a HEPA filter, a charcoal filter, and a second HEPA filter. This flow joins with the 1200-cfm recirculation flow. The total flow of 3000 cfm passes through the recirculation filters consisting of a prefilter, a HEPA filter, a charcoal filter, and a second HEPA filter. The air is discharged by one of the two 3000-cfm redundant emergency recirculation fans into the recirculating airflow prior to entering one of the normal air conditioning systems.

The normal air conditioning system has a motor-driven roll filter with automatically renewable media, whereas the emergency recirculation filter has a fixed prefilter. The HEPA filters used in both emergency filters are fire-retardant fiberglass with a design efficiency of 99.97 percent for 0.3-μm particles at rated capacity using the dioctyl phthalate (DOP) test method. They are installed and tested for bypass leakage such that a decontamination efficiency of 95 percent can be assumed for removal of particulate iodine. The emergency makeup air charcoal adsorber uses 2-in. deep trays of impregnated charcoal assumed to adsorb 95 percent of the elemental and organic iodine from the outside air. The effluent from this filter, which is mixed with recirculated air, is passed through the recirculation charcoal adsorber. This filter is a 4-in.-deep gasketless charcoal adsorber that also is assumed to adsorb 95 percent of the elemental and organic iodine.

Four process radiation monitors (Section 11.4) are located before the makeup filters to determine the airborne activity entering the main control room.

In addition to the protection provided by the systems discussed above, respiratory protection devices, as discussed in Section 12.3, are also available when needed. The ventilation system is designed to limit the whole-body dose to less than 5 rem and the thyroid dose to less than 30 rem for the duration of an accident, in accordance with GDC 19. Evaluation of the system to meet GDC 19 with regard to inhalation dose is presented in Appendix 15A. All portions of the system required to operate during emergency conditions are designed to Category I requirements.

12.2.2.2 Reactor/Auxiliary Building Ventilation System

The reactor/auxiliary building ventilation system is described in Subsection 9.4.2. The volume of both buildings is 3,500,000 ft^3. Outside air is supplied to the buildings through an inlet located midway down the south side of the auxiliary building. The inlet flow rate is normally 96,060 cfm. The inlet air passes through a filter, a heater, and two of three 50 percent-capacity inlet fans before being supplied to accessible areas of the building. The air is exhausted from areas of higher potential contamination by two of the three 50 percent-capacity exhaust fans. A lower pressure is maintained in potentially contaminated areas than in general access areas, and the entire building is maintained at a lower pressure than the outside ambient air, thus preventing the spread of contamination and exfiltration of unmonitored contaminated air.

The refueling floor area ventilation is sized for a minimum of 7 air changes per hour in the lower 15 ft of the floor area. The airflow is directed across the refueling floor toward the pools and is exhausted through ducts in the dryer-separator pool, fuel storage pool, and the reactor well. This system limits the spread of activity to other parts of the building.

The ventilation system also serves to purge the primary containment to permit personnel access. Sufficient airflow is provided to purge the drywell and suppression chamber at the rate of three air changes per hour. The purge air can be discharged through the normal building exhaust system or, if there is activity, through the SGTS, which is discussed in Subsection 6.2.3.

Radiation monitors are supplied on both major fuel pool area exhaust ducts (Section 11.4) to warn if radioactive gases rise from the fuel pool by sounding an alarm in the main control room. The two pairs of radiation monitors, which are located on the east and west branches of the reactor building exhaust duct, will trip the ventilation fans, isolate the building, close the primary containment isolation valves, and start the SGTS on a high (radiation) alarm. In addition, a radiation monitor is provided in the reactor building exhaust plenum to provide a record of the amount of activity discharged to the environment.

The supply and exhaust isolation valves, which are required to operate during or after a design-basis accident (DBA), are designed to Category I requirements.

12.2.2.3 Radwaste Building Ventilation System

The radwaste building ventilation system is described in Subsection 9.4.3. The volume of the building is 861,000 ft^3. Outside air is supplied to the building through louvers located above the turbine building low roof. The flow rate is approximately 22,567 cfm. The inlet air passes through a prefilter, high efficiency filter, and one of the two 100 percent-capacity (32,800 cfm) supply fans before being supplied to accessible areas of the building. These fans also supply 1650 cfm to the pipe tunnel between the radwaste and turbine buildings. During periods of high ambient outdoor conditions, the supply air is maintained at a temperature of approximately 80°F to ensure safe operating temperatures for the equipment. The air is cooled with a water-cooled refrigerated chilled-water system. The air is supplied to general access areas and is exhausted from potentially contaminated areas. A lower pressure is maintained in the potentially contaminated areas than in the general access areas, and the entire building is maintained at a lower pressure than the outside ambient air, thus preventing the spread of contamination and the exfiltration of contaminated air.

The exhaust fans take suction from all principal areas and from the vents of radwaste tanks (as listed in Subsection 9.4.3). The air flows through a prefilter, a HEPA filter, and one of the two 100 percent-capacity (approximately 31,818 cfm) exhaust fans, which discharge the air through an exhaust vent above the turbine building high roof.

The HEPA filters, located on the fume hood exhausts and on the main exhaust, have an efficiency of 99.97 percent for 0.3 μm particles at rated capacity according to the DOP test method.

The hood exhaust from the drum-loading station on the turntable is filtered through a HEPA filter, charcoal adsorber, and a HEPA filter before discharge into the radwaste building ventilation exhaust duct. An area radiation monitor measures activity in the vicinity of the charcoal filter to ensure safe access for servicing the filter.

An airborne radioactivity monitor is located on the exhaust to provide a record of the amount of activity discharged to the environment (Section 11.4). On a high alarm, the monitor will trip the building ventilation fans and close the isolation dampers in the radwaste building.

The radwaste building ventilation system is required to operate only during normal plant operation and is therefore not designed to Category I requirements.

The HVAC design provides clean, fresh air in the corridors and normally accessible areas and exhausts the air from potentially contaminated areas such as the extruder/evaporator room, centrifuge room, filter room, evaporator room, and valve rooms. In all instances, airflow is directed to keep the corridors and maintenance areas clean of airborne radioactivity. All HVAC exhaust from potentially contaminated spaces is filtered through a high-efficiency (99.97 percent) filter before discharge to the radwaste building exhaust vent stack.

12.2.2.4 Turbine Building Ventilation System

The turbine building ventilation system is described in Subsection 9.4.4. Outside air enters the building through an intake located on top of the building. The design flow rate was approximately 315,900 cfm (actual flow rates have been measured and were found to be 15% to 20% lower). The inlet air passes through a prefilter, a high-efficiency filter, and two of the three 50 percent-capacity (195,000 cfm) supply fans before being distributed to general access areas.

Air is circulated into potentially contaminated areas by propeller fans. If the air is initially supplied to a potentially contaminated area, it is discharged from that area to the exhaust duct.

A lower pressure is maintained in potentially contaminated areas than in general access areas, and the entire building is maintained at a lower pressure than the outside ambient air, thus preventing the spread of contamination and exfiltration of unmonitored contaminated air.

The air is exhausted by two of the three 50 percent-capacity exhaust fans through an exhaust vent located on the roof.

An airborne radioactivity monitor is located on the exhaust to provide a record of the amount of activity discharged to the environment (Section 11.4). On a high (radiation) alarm, the monitor will trip the ventilation fans.

The turbine building ventilation system is required to operate only during normal plant operation, and is therefore not designed to Category I requirements.

12.2.2.5 Service Building Machine Shop Ventilation System

The volume of the machine shop in the service building is 257,400 ft^3. Outside air enters through two intakes, one for each supply fan, located on top of the warehouse roof. One supply fan has a capacity of 23,000 cfm and the other has a capacity of 6000 cfm. The inlet air passes through low efficiency filters and is discharged into the machine shop by one or both fans, depending upon whether or not the machines are operating. If the machines are in use, air is exhausted from the machines through a roughing filter and through a HEPA filter by a 15,000-cfm exhaust fan before being discharged to the stack located on the machine shop roof. The air from the ultrasonic cleaner fume hood is exhausted through a HEPA filter by a 10,000-cfm exhaust fan before being discharged to the stack.

The general shop area air is exhausted through a HEPA filter by a 7000-cfm exhaust fan before being discharged to the stack. The HEPA filters used on the exhaust have an efficiency of 99.97 percent for 0.3 μm particles at rated capacity.

12.2.3 Source Terms

Potential leakage from the reactor coolant and main steam systems can result in the release of radionuclides to the atmosphere of plant buildings.

The plant ventilation systems are designed such that areas that contain possible sources of leakage are kept at a slightly negative pressure. Clean and tempered air is supplied to general access areas from which it passes to potentially contaminated areas.

To estimate the doses to personnel in the plant structures from reactor coolant and main steam system leakage, the sources as defined in Sections 11.1 and 11.3 are used. These sources, in conjunction with estimates of personnel occupancy time and possible leakage rates, are used to calculate the inhalation doses presented in Subsection 12.2.5.

12.2.4 Airborne Radioactivity Monitoring

12.2.4.1 Design Objectives

The process radiation monitoring system (PRMS), which performs airborne radioactivity monitoring, is designed to measure and record airborne radioactivity levels, to alarm on high airborne radioactivity levels and, when required, to control the release of radioactive gases and particulates produced in the operation of the plant. It also ensures compliance with the requirements of 10 CFR 50; 10 CFR 20; Regulatory Guides 1.21, 8.8, and 8.10; and GDC 64. The system aids in the protection of the general public and plant personnel from exposure to airborne radioactivity in excess of that allowed by applicable regulations. This system controls or terminates releases exceeding discharge limits and warns plant personnel so that they can take appropriate measures to protect themselves and the general public.

The design objectives of the fixed system for normal operation are

a. To provide continuous surveillance of airborne radioactivity levels in effluent streams that discharge to the environment from minimum detectable levels to levels commensurate with Offsite Dose Calculation Manual radiological effluent control limits. The system indicates and records these levels in the main control room or the radwaste control room and alarms at abnormal levels

b. To provide data for estimating total released activity to comply with Regulatory Guide 1.21

c. To give early warning of increasing radioactivity levels indicative of equipment failure, malfunction, or deteriorating system performance

d. To initiate prompt corrective action, either automatically or through operator response, on high airborne radioactivity level

e. To provide continuous surveillance in the main control room of airborne radioactivity levels by indicating and recording exhaust duct radiation levels and by alarming at abnormal activity levels. This aids in preventing a person from inadvertently entering an area where he can inhale airborne activity in excess of limits defined in 10 CFR 20, Appendix B, Table I, Column 1.

For some anticipated operational occurrences resulting from accidents or operator error, the PRMS will activate necessary isolation or diversion valves to terminate or reduce releases, if the airborne radioactivity levels exceed alarm setpoints (as indicated in Table 11.4-1). Independence of redundant monitors is maintained by providing adequate separation of detectors, signal cabling, power supplies, and actuation circuits for isolation and diversion valves.

The fixed continuous monitors, which are described in Section 11.4, serve in conjunction with a comprehensive air sampling program using portable continuous airborne monitors (CAMs) and air samplers, both short and long term. It is necessary to use a local CAM or air sampler to determine the airborne activity of an enclosure because in many instances a fixed monitor sampling a ventilation duct indicates the activity coming from a group of areas.

12.2.4.2 Continuous Airborne Monitors

The following criteria were used in the design and selection of the equipment.

a. General

1. The filter media used in all monitors and air samplers to collect particulates have an efficiency of at least 98 percent for 0.3 μm particles

2. The iodine adsorbent cartridge, used in monitors and air samplers to sample radioactive iodine, has a collection efficiency of approximately 95 percent for elemental and organic iodine.

b. Fixed continuous airborne monitors - Details are given in Subsection 11.4.3.8

c. Portable continuous airborne monitors

1. The sample flow rate is automatically controlled to within ±1 liter/minute of the set value
2. A flow indicator is provided
3. Power requirements are 115 V ac ±15 percent, 60 Hz ±5 percent from a normal distribution panel
4. Environmental design conditions for the components are 40° to 120°F, 0 to 95 percent relative humidity, and atmospheric pressure
5. Adequate lead shielding approximately 3 in. thick is provided for detectors so that background radiation has a minimum effect on the ability of the monitors to sense low levels
6. The CAM is mounted on a cart on wheels so that it can be moved from one location to another
7. A meter with digital readout or an appropriate strip-chart recorder is provided
8. A low (failure) trip, a high (radiation) trip, and an audible alarm may be provided. The trips are adjustable over the full range of the meter. All alarms are local, but relays are provided if remote alarms or initiation are needed.

12.2.4.3 Air Samplers

The following criteria were used in the selection of portable air samplers.

a. Long-term air samplers

1. The sampler flow rate is controlled between 1 and 4 cfm
2. The filter holder holds a 47-mm or 2-in. filter media to collect particulates and iodine-adsorbent cartridge
3. An elapsed-time meter is installed to determine air sample time; however, this feature is not utilized, the time is recorded manually
4. The samplers are designed to operate at 40° to 140°F, 0 to 95 percent relative humidity, and atmospheric pressure
5. Power requirements are 115 V ac ±10 percent, 60 Hz ±5 percent.

b. Short-term air samplers

1. The sampler flow rate is between 1 and 28 cfm depending on the sampler
2. The air sampler uses a 47-mm or 2-in.-diameter filter media to collect particulates at 2 to 28 cfm. In conjunction with this, an iodine-adsorbent cartridge can be used to collect iodine. A 4-in. sample head and filter may be used to collect particulate samples above 8 cfm
3. Power requirements are 115 V ac ±10 percent, 60 Hz ±5 percent

4. The sampler is small enough to be carried by one man.

12.2.4.4 Air Sample Location Selection

a. Fixed continuous airborne monitors

   1. A separate effluent monitor samples the ventilation exhaust from each building that may contain radioactive material (reactor and auxiliary building, radwaste building, and turbine building) before it is discharged to the environment, to determine the level of airborne activity and to terminate the discharge if a preselected setpoint is exceeded

   2. Two monitors sample the control center ventilation system to determine the radioactivity level of intake air

   3. Four monitors (two pairs) monitor the air exhausted from the fuel pool area to determine the radioactivity level of the air in this area. The pool area is a potential source of high activity because of fuel handling. These monitors provide in-depth protection.

b. Portable continuous airborne monitors

   1. A portable CAM may be used to monitor work areas where it is likely there will be high levels of airborne radioactivity because of conditions in the area, equipment being worked on, or the type of work being performed

   2. A portable CAM can be used as a replacement for a fixed monitor in the event of a failure.

c. Portable air samplers

   1. Long-term air samplers are used to sample at low flow rates (1 to 4 cfm) over extended periods of time (often 24 hr or more). They are usually moved from one location to another in the plant to evaluate the long-term airborne exposures throughout the plant. They can also be used to obtain an average airborne activity level at a job of long duration if a portable CAM is not used

   2. Short-term air samplers are used to sample at high flow rates (2 to 40 cfm) over short periods of time to evaluate the air activity in local areas during maintenance jobs or other special operations. Short term air samplers can also be used to evaluate the air activity in enclosed spaces prior to entry for maintenance or other special operations as deemed necessary by Health Physics.

12.2.4.5 Expected Airborne Radioactivity Levels

The expected airborne radioactivity levels in the effluent streams are such that radiation levels at the site boundary are a small fraction of 10 CFR 20 limits and will be as low as reasonably achievable (ALARA).

The expected airborne radioactivity levels in the plant vary depending upon conditions in a given area and the maintenance work or special operations being performed. In clean areas, the expected airborne radioactivity after allowing for decay of radon-thoron daughters is on the order of 10^{-12} to 10^{-13} μCi/cm^3 for gross beta-gamma activity, and 10^{-14} to 10^{-15} μCi/cm^3 for gross alpha activity.

12.2.4.6 Quantity To Be Measured

a. Fixed continuous airborne monitors

The principal nuclides monitored by the fixed monitors are listed in Table 11.4-1. Each channel measures gross radioactivity

b. Portable continuous airborne monitors

Two CAMs measure gross particulate activity, iodine activity, and noble gas activity

c. Portable air samplers

The air samplers collect particulate samples that are normally counted for beta activity. When the gross beta activity is high, alpha activity may be counted to help evaluate radon-thoron activity and an attempt may be made to identify the gamma isotopes present on the filter by using a multichannel pulse height analyzer. During handling and inspection of new fuel, air samples taken in the work area are counted for alpha activity.

Impregnated charcoal or iodine-adsorbent cartridges are used to collect iodine when it is suspected that airborne iodine activity is likely to be present in a work area. These cartridges may be analyzed for radioiodine activity using a multichannel pulse height analyzer or iodine-specific analyzer.

12.2.4.7 Detector Types, Sensitivity, and Range

a. Fixed continuous airborne monitors

The detector types, sensitivity, and nominal range of each fixed monitor are listed in Table 11.4-1. The location of the sample probe and detector for offline monitors was chosen to minimize sample line length and number of direction changes to avoid sample plate-out. Unavoidable bends are made with radii not less than five times the tubing diameter. Probes are isokinetic

b. Portable continuous airborne monitors

The detectors in the portable CAMs are similar to those on the gaseous effluent monitor discussed in Table 11.4-1

c. Air sample counting

Long- and short-term particulate air sampler filter papers are counted using calibrated counting equipment, including Geiger-Mueller detector and rate meter combinations, proportional counters, and a high- resolution gamma spectrometry system. Gamma radionuclide identification can be performed on an air sample if there is sufficient activity on the sample so that a spectrum can be obtained in a reasonable amount of time. The efficiency of the gamma analyzer varies with the energy of the radionuclide measured. In addition to the efficiency and the background of the counter, the sensitivity of the measurement of air sample activities depends on the length of the sample collection and the counting time.

12.2.4.8 Inservice Inspection, Calibration, and Maintenance

a. Inspections and tests

The following inspections and tests are performed:

1. Fixed continuous airborne monitors - See Subsection 11.4.5.1
2. Portable continuous airborne monitors - During normal operation, daily checks of system operability are made by observing channel behavior. Each portable CAM is calibrated at least annually using an approved procedure
3. Air samplers - During normal operation, air samplers will be checked and calibrated at least annually using an approved procedure.

b. Calibration

1. Fixed continuous airborne monitors - See Subsection 11.4.5.2
2. Portable continuous airborne monitors - An initial certification of each CAM is performed at the factory. The certification of the sources is traceable to the National Institute of Standards and Tests or commercial standards

   After delivery to the plant, the calibration is rechecked by using calibration sources. Calibration is performed at least annually
3. Portable air samplers - The flow of each air sampler is checked initially with a flowmeter. The flow rate is checked at least annually and after maintenance work that could change the flow rate.

c. Maintenance

The detectors, electronics, recorders, and air samplers are serviced and maintained during the calibration process and as required to ensure reliable operation. Such maintenance includes cleaning, lubrication, and assurance of free movement of the recorder in addition to the replacement or adjustment of any components required during testing or calibration

d. Audits and verifications

Independent audits and verifications of test, calibration, and maintenance records and procedures shall be conducted at least annually.

12.2.5 Estimates of Inhalation Doses

12.2.5.1 Introduction

Low-level concentrations of airborne radionuclides are to be expected in the atmosphere of some plant structures. The inhalation dose received by individuals depends on many factors, a few of which are the following:

a. Period of time spent in the various compartments

b. Fluid leak rates to the compartments

c. Type of fluid leakage (water or steam)

d. Concentration of radionuclides in the leaking fluid

e. Volume of and airflow rate through each compartment

f. Use of respiratory equipment or supplemental air.

The plant ventilation systems, as described in Section 9.4, are designed to minimize operating personnel inhalation doses by supplying clean and tempered air to all areas normally accessible during plant operation. Equipment with radioactive leakage potential is located in compartments that are kept at a slightly negative pressure, so air flows into those compartments where leaking equipment might be a source of airborne activity. These compartments are not normally occupied during plant operation and are subject to Health Physics control, with respiratory protective devices or supplemental air used if necessary to allow entry. Also provided is a drywell purge system with sufficient capacity to reduce the airborne radioactivity levels in the drywell and suppression chamber so that short-term access is provided for minor inspection during reactor hot standby, and long-term access is provided for maintenance and inspection during the refueling shutdown.

The ventilation systems are designed such that clean and tempered air is supplied initially to normally occupied areas. The air flows through these areas into the individual equipment compartments, which are kept at a slightly negative pressure, and thence out of the building. This arrangement prevents any airborne activity present in the compartments from reaching normally occupied areas. Because of the ventilation system design and Health Physics controls, the inhalation dose to operations personnel in areas normally occupied during operation (such as the main control room, corridors, and areas not containing potential sources of airborne activity) will be ALARA as required by Regulatory Guide 8.8. The ventilation systems are designed, in conjunction with the shielding, to keep the whole-body dose ALARA.

Inhalation doses for areas with potential airborne activity have been estimated based on the radionuclide concentrations of Section 11.1, anticipated occupancy times, leakage rates, and appropriate ventilation flow rates. These estimates of the personnel inhalation doses received are presented in Tables 12.2-3 through 12.2-12. The inhalation doses as presented by these tables are well below the guidelines applicable to radiation workers as set forth in Table I of Appendix B to 10 CFR 20.

A survey of available information pertaining to operating BWR plants has shown that in cases where the permissible concentration was reached or exceeded, the condition usually existed for a very limited time and was confined to a limited area. When access for extended periods is necessary to an area where the airborne concentration is greater than MPC, the leaking equipment will be isolated and the area purged, occupancy time will be limited, or respiratory equipment will be used (Section 12.3) to ensure that personnel exposures to airborne radioactive material are both ALARA and within applicable regulatory limits.

Estimates of both maximum airborne concentrations and annual inhalation doses to plant personnel within the reactor building and turbine building are summarized in Tables 12.2-3 through 12.2-12. These are the buildings where the potential for significant inhalation doses would be expected to occur. The liquid in the radwaste building is essentially degassed liquid at atmospheric pressure. Equipment used in the radwaste building is designed to reduce the possibility of equipment leakage by the use of welded piping. The auxiliary building contains no normal sources for inhalation doses.

The most significant potential for inhalation doses in the reactor building is from liquid leakage from the reactor water cleanup (RWCU) system and from entry to the drywell. The drywell may be entered for short periods of time during reactor hot standby and will be opened for extensive maintenance and inspection activities during refueling outages. The reactor/auxiliary building ventilation system is sized to reduce the airborne activity levels in the normally occupied areas to a safe level that affords normal, continuous occupancy. The RWCU system components are enclosed in compartments that are kept at a slightly negative pressure to preclude the leakage of airborne radioactivity to the accessible areas of the building.

The most significant potential for inhalation doses in the turbine building is from liquid leakage from equipment containing condensate and reactor feedwater and from entry to the third floor turbine enclosure area. Leakage to the equipment compartments is primarily liquid, and leakage into the turbine enclosure is primarily steam. The heater feed pumps area is representative of low airborne concentrations where plant personnel may be expected to spend greater lengths of time than in the area of high airborne concentrations.

The turbine building ventilation system is sized to reduce the airborne levels in the normally occupied areas to a safe level that affords normal, continuous occupancy. Pieces of equipment that have the potential to become significant sources of airborne radionuclide concentrations are located in compartments, which are kept at a slightly negative pressure to preclude leakage to the accessible areas of the building. Periodic entrances to the turbine enclosure during normal operation could result in an inhalation dose to the person in the enclosure from steam leakage.

The calculated maximum airborne concentrations and annual inhalation doses presented by Tables 12.2-4 through 12.2-12 are based on the following assumptions:

a. An individual is exposed (without respiratory protection) for the maximum time estimated for each area, per year. In actual practice, several different people would make entries at different times during the year. Also, the use of respiratory protection would reduce the inhalation exposure to specific individuals to much less than those shown

b. The estimated airborne concentrations are based on the concentration of radionuclides in the reactor water and steam presented in Section 11.1 calculated at 102 percent of 3430 MWt (3499 MWt) and the proposed calculational leakage and partition factors as presented in Section 11.3.

Only the radionuclides that were considered to contribute significantly to personnel inhalation doses from the leakage have been included. Since hot and cold liquid leakage is essentially degassed, only halogens are considered.

Other radionuclides are present in such low concentrations that they should not significantly affect the estimated personnel dose. Steam leakage to the turbine enclosure includes noble gases, ^{16}N, and halogens. Radionuclide concentrations in the steam are those presented by Tables 11.1-2 through 11.1-5.

The estimated air concentrations and inhalation doses have been calculated utilizing conservative assumptions for leakage rates, partition factors, and radionuclide concentrations. These estimated annual inhalation doses are higher than would be anticipated during actual reactor operations because of the conservatism used in the calculations. The summary doses presented in Table 12.2-13 are the maximum doses that one person would receive if he remained in each of the areas for the estimated times. Since no individual would ever be exposed to all the areas, Table 12.2-13 does not represent the actual expected dose to a single specific individual, but would represent the "worst-case" total dose from each of the areas considered.

A plant load factor of 80 percent and appropriate building volumes and ventilation rates have been used in the calculations. For each case it has been assumed that the initial concentration is zero and that the leakage has occurred long enough to reach equilibrium condition in the area; that is, 90 hr. For assumptions of leakage rate, type of leakage, compartment volume ventilation flow rate, and the partition factors from the leakage to the atmosphere, see Tables 12.2-1 and 12.2-2. Operating plant data may be found in References 1 through 4.

NOTE: These inhalation-dose estimates of Section 12.2.5 have been performed as part of the original overall design-basis determination that the plant was well-designed from an ALARA standpoint. These calculations were/are intended to only represent conservative preoperational estimates. It was not intended to update or revise these values in order to correspond to operating plant data or to any revised criteria, assumptions, etc. Operational inhalation doses data is routinely measured in plant airborne areas, and summary dose information is periodically provided to pertinent regulatory agencies.

12.2.5.2 Air Concentration Calculation Methodology

Equation 12.2-1 was used to calculate the air concentration of the radionuclides given in Tables 12.2-3 through 12.2-12.

$$c = \frac{Lc_pPF}{V_{\lambda_s}} M\left(1 - e^{-2\lambda_s t}\right) \qquad (12.2\text{-}1)$$

$$\lambda_s = \lambda_d + \lambda_p \qquad (12.2\text{-}2)$$

$$\lambda_d = \frac{0.693}{T_{1/2}} \qquad (12.2\text{-}3)$$

$$\lambda_p = k\frac{F}{V} \qquad (12.2\text{-}4)$$

where

c	=	concentration of each radionuclide in compartment atmosphere, $\mu Ci/cm^3$
c_p	=	concentration of each radionuclide in system leakage, $\mu Ci/cm^3$
L	=	leak rate from system to compartment, g/sec
PF	=	partition factor for each radionuclide
k	=	building mixing factor (0.8)
λ_s	=	total removal constant for each radionuclide, hr^{-1}
λ_d	=	decay constant for each radionuclide, hr^{-1}
λ_p	=	purge constant for each radionuclide, hr^{-1}
$T_{1/2}$	=	half-life of radionuclide, hr
V	=	compartment volume, ft^3
F	=	volumetric airflow rate of compartment, ft^3/hr
t	=	time, hr
M	=	constant, sec $ft^3/hr\ cm^3$

The following relationships are used to estimate the doses:

$$c/MPC \times 5 = \text{Whole-body dose, rem/year} \qquad (12.2\text{-}5)$$

$$c/MPC \times 30 = \text{Thyroid dose, rem/year} \qquad (12.2\text{-}6)$$

where

c	=	airborne concentration of each radionuclide, $\mu Ci/cm^3$
MPC	=	maximum permissible concentration for each radionuclide as given in Table I, Appendix B of 10 CFR 20, $\mu Ci/cm^3$

[a] During purging.

[b] Halogen concentration based on GE values from Table 11.1-2 adjusted to agree with Regulatory Guide 1.42. Regulatory Guide 1.42 gives ^{131}I as 0.5 x 10^{-2} µCi/g. Thus, Table 11.1-2 values are multiplied by 0.385 to obtain concentrations in the reactor coolant.

[c] Obtained from the degassed reactor coolant multiplied by an internal reactor PF of 0.01 and a polishing PF of 0.1.

TABLE 12.2-2 TURBINE BUILDING INHALATION DOSE PARAMETERS (3499 MWt)

Compartment and Location	Volume V (ft^3)	Ventilation Rate F (cfm)	Leak Rate L (g/sec)	Thermal Condition of Leakage	Partition Factor PF	Purge Constant $^{\lambda}p_1$ (hr)	Occupancy Time	Description of Leakage
Third floor turbine enclosure (Elev. 643 ft 6 in., K-N, 5-10)	703,550	81,870	128.5	N/A	1.0	5.59	0.5 hr/week	Steam at 7 sec[a]
Condenser pump (Elev. 564 ft 0 in., M-N, 4-9)	8062	350	19.4	Cold	0.001	2.08	1 hr/week	Degassed condensate[b]
Offgas system condensate return pump (Elev. 564 ft 0 in., P-R, 2-3)	6118	120	4.85	Cold	0.001	0.94	1 hr/week	Degassed condensate[b]
Gland steam condensate pump (Elev. 564 ft 0 in., N-P, 8-9)	33,120	10,490	4.85	Cold	0.001	15.2	1 hr/week	Degassed condensate[b]
Equipment drains (Elev. 564 ft 0 in., R-S, 8-10)	25,829	2,610	3.22	Cold	0.001	4.83	3 hr/week	Degassed condensate[b]
Heater feed pump (Elev. 583 ft 6 in., N-R, 12-14)	114,912	38,865	8.06	Hot	0.1	16.2	20 hr/week	Degassed condensate[b]

[a] Noble gas concentrations based on Table 11.1-2 (t = 7 sec) values adjusted to a 1000 lb/hr release rate. Halogens are based on Regulatory Guide 1.42 values for ^{131}I at 1700 lb/hr and ratioed for the 1000 lb/hr leak rate.

[b] Degassed reactor coolant concentrations based on GE values from Table 11.1-3 adjusted to agree with Regulatory Guide 1.42. Regulatory Guide 1.42 gives ^{131}I as 0.5×10^{-2} µCi/g. Thus, Table 11.1-3 values are multiplied by 0.385 to obtain concentration in the reactor coolant. The degassed reactor coolant concentrations are then reduced by a reactor internal PF of 0.01 and a condensate polishing PF of 0.1 to obtain the degassed condensate concentrations

[a] As defined in Appendix B of 10 CFR 20.

12.3 RADIATION PROTECTION PROGRAM

12.3.1 Program Organization and Objective

12.3.1.1 Program Organization

The Fermi 2 organization, including the Radiation Protection Section, is described in Section 13.1. The Manager - Radiation Protection has the responsibility for the Radiation Protection Program and for ensuring that plant operation meets the radiation protection requirements set forth in 10 CFR 19, 10 CFR 20, 10 CFR 50, applicable Regulatory Guides, and the Technical Specifications and licenses.

12.3.1.2 Program Objective

The objective of the Radiation Protection Program is to provide administrative control of persons on the site to ensure that personnel dose is within the requirements of 10 CFR 20 and that such exposure is kept as low as reasonably achievable (ALARA).

This program consists of rules, practices, and procedures that are used to accomplish the objectives previously stated in a practical and safe manner. The program meets the intent of Regulatory Guides 8.2, 8.8, and 8.10. The Radiation Protection Program is designed to ensure that

a. Operations, maintenance, technical, etc., personnel are provided radiation protection training appropriate for their assigned responsibilities. Contractors and other supporting personnel are provided orientation training to the extent required by the work that they are to perform. This training meets the requirements of 10 CFR 19, 10 CFR 20, and Regulatory Guide 1.8

b. Detailed procedures are prepared and approved to implement the Radiation Protection Program requirements. Major aspects and those that affect general plant personnel are documented in Administrative Procedures in the Plant Conduct Manual

c. Access-control procedures are followed so that access to Radiologically Controlled Areas (RCA) are controlled. Radiation and high radiation areas are segregated and identified in accordance with 10 CFR 20. Control is exercised over each individual entry into high radiation areas

d. All tools and equipment used in the RCAs are surveyed by Radiation Protection personnel before they are removed from the RCA. Normally, tools or equipment moved from one contaminated area to another are wrapped or packaged to prevent the spread of contamination to intermediate areas

e. Appropriate protective clothing is used as required to help prevent personnel contamination and the spreading of contamination from one area to another

f. Airborne radioactivity is measured in accordance with 10 CFR 20 and appropriate engineered controls, and respiratory protective equipment is used as required to keep inhalation of radioactive material ALARA

g. Radiation levels in the plant are measured and posted, so that when personnel enter an area, they can keep their dose ALARA by staying in areas with lower radiation levels

h. Personnel are provided with radiation monitoring equipment to measure their radiation dose (Subsection 12.3.4)

i. A Bioassay Program has been developed using guidance from Regulatory Guides 8.9 and 8.34. This program includes whole body counting and/or a urinalysis sampling program to measure uptakes of radioactive material

j. Records of occupational exposure to radiation are maintained using guidance from Regulatory Guide 8.7. Reports are made to the NRC as required by 10 CFR 20 and to the individual as required by 10 CFR 19

k. Entrance to high radiation areas and maintenance work in radiation or high radiation areas is controlled by using a radiation work permit. This permit typically states dose rates, protective clothing requirements, monitoring requirements, and any special notes or cautions pertinent to the specific job. These permits are prepared by and require approval of Radiation Protection. Jobs involving significant dose to personnel are preplanned and, where conditions require, practice runs on a mockup are made to reduce exposure time on the actual job. Use of special tools and temporary shielding to reduce dose is evaluated on a case basis. On complex or new jobs that involve significant dose, a debriefing session is held after the completion of the job in an attempt to improve methods and keep dose ALARA

    l. Periodic radiation, contamination, and airborne activity surveys are performed to determine and document radiological conditions throughout the plant. Radiological status in the plant is posted so that personnel can review the radiological conditions prior to entering an area.

m. Incoming and outgoing shipments that may be radioactive are surveyed to ensure compliance with applicable provisions of 10 CFR and 49 CFR

n. A record of radiological surveys is maintained in accordance with 10 CFR 20

o. Routine work involving radiation exposures is subject to a periodic review by Radiation Protection to identify situations in which dose can be reduced. Selection of items for review will be based upon area radiation and contamination surveys, personnel contamination surveys, personnel observations, and incidents

p. Process radiation, area radiation, portable radiation, and airborne radioactivity monitors are routinely calibrated and maintained in accordance with approved procedures

q. Radiological incidents are investigated and documented in an attempt to prevent their recurrence. Reports of radiological incidents are made to the NRC in accordance with 10 CFR 20.

r. Plant administrative procedures assure adequate control of radioactive material stored outside of the plant Radiologically Controlled Area (RCA). These controls include: (1) a total limit of 200 Curies for all radioactive material stored outside of the plant RCA, (2) an outdoor activity limit of 10 Curies per package or unpackaged component, (3) containment to prevent runoff of wet material stored longer than 30 days, (4) the use of skids or other means to raise outdoor packages and unpackaged components off of the ground, and (5) packaging in noncombustible containers suitable for shipment. Unpackaged radioactive material may be stored outdoors if it is nondispersable and noncombustible, and if any removable contamination is within transportation limits. In lieu of packaging in a noncombustible container suitable for shipment, packages stored indoors may be in a noncombustible cabinet or device appropriate for the type, form, and quantity of radioactive material stored. In lieu of a non-combustible package cabinet, or device, radioactive material may be stored in an area with approved fire detection and suppression systems. An inventory, survey and tracking system will be used to assure that quantity limits are not exceeded, radiological postings are appropriate, and packaging is in good condition. These controls do not apply to radioactive material in transit, radioactive material exempted from licensing requirements under 10 CFR parts 30, 40, and 70, and radioactive material maintained under the provisions of an outside license.

s. An In-Plant Radiation Monitoring program ensures the capability to accurately determine the airborne iodine concentrations in vital areas under accident conditions. This program includes the following:

   1. Training of personnel,
   2. Procedures for monitoring, and
   3. Provisions for maintenance of sampling and analysis equipment.

12.3.2 Facilities and Equipment

12.3.2.1 Facilities

The Radiation Protection facilities include an access-control checkpoint, low background counting facilities room, instrument calibration room, offices, personnel decontamination area, change areas, and areas for the storage of protective clothing, respiratory equipment, air-sampling equipment, portable radiation instruments, personnel dosimeters, and special shielding.

The main access-control point is located at the entrance to the RCA. The control point consists of personnel monitors and friskers located at the doorway to the service building.

Personnel change areas, disposal/laundry bags, and stepoff pads are available for major work in contaminated areas. Stepoff pads and other supplies are available for other jobs as needed.

A clothing supply is available, and protective equipment and clothing requirements are contained in radiation work permits as applicable.

If contamination is found on the body or work clothing of an individual, clean protective clothing is available for transit to the personnel decontamination area. Personnel-monitoring friskers are also located at the main access-control point and at various locations throughout the plant.

The personnel decontamination area is equipped with a sink and shower for decontamination. The personnel decontamination area is equipped with a cabinet supplied with common decontamination supplies and chemicals. Decontamination is done under the supervision of Radiation Protection. Areas are also provided for minor medical treatment and first aid of contaminated personnel.

Protective clothing is worn in contaminated areas. These areas are well marked, and stepoff pads are installed at the entrances to prevent inadvertent entry into the areas. The objective of this is to keep exposure to radioactive material as limited as possible. In the event of an incident that contaminates large portions of the plant, personnel can don clothing at an access-control point.

The low background counting facilities contain various radiation-detecting instruments including the following:

a. Low background proportional detector with an automatic sample changer and associated electronics for gross alpha and/or beta measurements

b. Liquid scintillation counter for counting tritium and other beta emitters

c. High resolution gamma spectrometry system to identify and quantify gamma-emitting radionuclides.

The low radiation level chemistry laboratory is divided into four working peninsulas. Each peninsula is equipped with a fume hood; sink; counter with storage drawers; and electrical, air, vacuum, gas, and water service. An exhaust is also supplied for an emission spectrophotometer. Sufficient space is provided so that the laboratory equipment that is used on a routine basis can be left set up. Sample evaporation, and other processes which will release activity, or noxious fumes, are performed inside one of the fume hoods.

Samples may be prepared by evaporation, filtration, ion-exchange chromatography, or chemical separation. A standard source geometry is obtained that can be counted in the counting room or the spectrometer room.

The counting room, which can be entered from the low-level laboratory, contains a sink, fume hood, storage cabinets, and counter space on which to set the various radiation detecting instruments.

A Radiation Protection instrument calibration room is provided. Portable radiation survey instruments and air sampling equipment are normally calibrated in this area. Solid and liquid sources, which may be stored here, are also used to calibrate counting room instruments and plant radiation monitoring systems.

The calibration sources include high- and low-level sources. The high-range calibrator contains a mechanism to expose or shield the source. The room is equipped with an area radiation monitor with the radiation detector located near the high-range calibrator.

Visible warning lights are activated when the high-range calibrator is in use. The sources include high- and low-level gamma sources. The box calibrator contains a mechanism to raise or lower, or move the detector closer or farther to obtain the desired source-to-detector distance and thus the desired radiation level. Various jigs, designed to hold the portable instruments and dosimeters used at Fermi 2, are used to properly position the detector chamber in the calibrator.

A copy of the instrument calibration and repair record for each portable radiation detecting instrument is kept on file in accordance with Radiation Protection procedures.

The main Radiation Protection offices are located in the office service building. In-use survey records are normally stored in this office area. Permanent record storage is provided by Information & Procedures.

12.3.2.2 Equipment

12.3.2.2.1 Anticontamination Protective Clothing

Anticontamination clothing is worn in contaminated areas to prevent the contamination of personnel. It is removed at the exit from contaminated areas and placed in containers at the local job site to prevent the spread of contamination to other plant areas.

At the end of the job, or when the container is full, the container is monitored and transported to a storage area for laundry service.

Personnel are trained in the proper donning and removal of anti-contamination clothing as part of their radiation worker training. The selection of clothing for a specific job or area is determined by Radiation Protection on the basis of survey results and type of work. Clothing requirements are specified on the radiation work permit for the area or job.

Appropriate protective clothing is stocked at the plant.

12.3.2.2.2 Respiratory Equipment

Airborne contamination is minimized by keeping floor contamination level low, reducing leaks as much as possible, using local ventilation, and by using enclosures such as glove boxes. However, where airborne contamination levels exceed, or there is a potential for exceeding, values listed in Appendix B of 10 CFR 20, respiratory equipment may be worn to minimize personnel exposure.

The airborne contamination levels will be determined by the use of air samplers. The concentrations measured or expected will be used to select proper respiratory equipment.

A respiratory protection program has been developed which meets the requirements of 10 CFR 20. Personnel who will wear respiratory equipment are trained in the use of the equipment. Typical respiratory equipment used at Fermi 2 includes the following.

a. Air-purifying respirators

b. Supplied-air respirators

c. Self-contained breathing apparatus.

Emergency respiratory equipment for the operators is stored in the main control room.

12.3.2.2.3 Air Sampling Equipment

Air sampling may be performed using continuous air monitors (CAMs) and air samplers, which are described in Sections 11.4 and 12.2.4. The CAMs can be used to measure particulate, iodine, and gaseous activity. The air samplers are used to collect particulate and/or iodine samples for analyses in the counting facilities

12.3.2.2.4 Portable Radiation Instruments

A complement of portable instruments is available for use by Radiation Protection. Certain instruments are also available to other personnel who have been trained in self-monitoring techniques and have passed a written and/or oral examination. A variety of instruments have been selected to cover the entire spectrum of radiation measurements expected to be made at Fermi 2. Sufficient quantities of each type have been obtained to permit use, calibration, maintenance, and repair. These instruments are calibrated at least annually when in use. The calibration is normally performed in the Radiation Protection instrument calibration room.

12.3.2.2.5 Other Radiation Instruments

Portal monitors are used to check personnel for contamination. A monitor is located in the security area at the main exits from the plant.

Frisker stations are located near contaminated areas in the plant so that personnel leaving the area can monitor themselves for radioactive contamination, thus minimizing the spread of the contamination.

The gamma radiation levels in certain key areas are monitored by area radiation monitors (ARMs) which are discussed in Section 12.1. The ARMs locations, ranges, and alarm setpoints are described in Section 12.1.

12.3.2.2.6 Shielding

Temporary shielding in the form of concrete blocks, lead bricks, lead sheets, lead wool, water, or other material is provided where necessary to reduce personnel dose during operational and maintenance activities in radiation and high radiation areas. Each activity in these areas requires a specific evaluation of dose rates, job complexity (number of people and overall time required), available space, and time required to place and remove temporary shielding. For these reasons, the use of temporary shielding is determined on a case basis rather than at a specific dose-rate action level.

12.3.3 Operating Procedures

Administrative and technical procedures, in conjunction with facility design, are used to ensure that the exposures to personnel are kept ALARA.

Edison personnel will be trained in radiation protection as necessary, as stated in Section 13.2. To ensure compliance with Edison's policy of keeping exposures ALARA, Radiation Protection personnel have the authority to prevent unsafe practices and to halt any activity deemed radiologically unsafe. The Radiation Protection Manager has a direct line of communication with the Assistant Plant Manager regarding any activity or condition that is causing, or threatens to cause, a radiological incident or occurrence.

New procedures and procedure revisions that impact the Radiation Protection program are reviewed by Radiation Protection as a normal part of the plant procedure review/approval cycle. The Radiation Protection Section also participates in ALARA planning and review to identify administrative and operational methods by which dose can be reduced. Approved changes are promptly implemented. In addition, procedures for receiving and evaluating suggestions from employees relating to radiation protection and ALARA dose control have been established.

The following practices, which are described in written procedures, or training are followed:

a. Permanent shielding is used, when feasible. Dose may be reduced by having workers stay behind walls or in areas of lower radiation level when not actively involved in work in radiation areas. On some jobs temporary shielding, such as lead sheets draped over a pipe on either side of a valve, or concrete blocks stacked around a piece of equipment, is used to reduce dose. The use of temporary shielding will be considered if the total dose, which includes the dose to install and remove the shielding, is reduced.

b. Systems and major pieces of equipment that are subject to crud buildup, such as the radwaste system, the cleanup pumps, and the reactor water recirculation pumps, have been equipped with connections that are used for flushing. Prior to performing maintenance work, consideration will be given to flushing and/or chemically decontaminating the system or piece of equipment to reduce the crud levels, and thus reduce the dose received to complete the work

c. Work in high radiation or airborne radioactivity areas is planned and controlled by the use of a radiation work permit. The purpose of the planning is to carefully prepare for the job so that it can be expeditiously performed in a proper and safe manner with minimum exposure to personnel

d. On complex jobs or jobs with exceptionally high radiation levels, "dry runs" are made, and in some cases mockups are used, to familiarize the workers with the exact operations they must perform at the job site. These techniques assist in making the work go more smoothly and thus minimize the amount of time spent in the radiation field

e. As many work activities as reasonably achievable are performed outside radiation areas. Reading instruction manuals or maintenance procedures, adjusting tools or jigs, repairing valve internals, and prefabricating components are examples of activities that are performed outside radiation areas whenever feasible

f. For long-term repair jobs involving radiation exposure, consideration is given to setting up communications systems, such as sound-powered telephones or closed-circuit television, so that key personnel can check on the progress of work from a lower radiation area. In addition, both local and radio communication devices suitable for use with respirators are available

g. On some jobs, special tools or jigs are used when their use would permit the job to be performed more efficiently or would prevent errors, thus reducing the time in the radiation field. Special tools may also be used if their use would increase the distance from the source to the worker, thus reducing the exposure rate. These tools or jigs are used only if the total exposure, which includes that received during installation and removal, is reduced

h. Local access control for prolonged work in high radiation areas is set up in low radiation areas so that personnel do not receive unnecessary dose when not actually performing radiation work and because personnel may spend significant amounts of time changing protective clothing and respiratory equipment in these entry and exit areas. These entry and exit locations are set up to control the spread of contamination from the job site and, when feasible, to confine local contamination to a small area

i. Protective clothing and respiratory equipment specification takes the worker's comfort into consideration. This can increase efficiency and reduce the time spent in radiation areas

j. Local containments such as glove bags may be taped around valves or other fixed components during maintenance so that personnel will be less likely to be exposed to the contamination produced during the work

k. Radiation levels are posted for personnel to review, and when a wide range of radiation and contamination levels exists, high-radiation areas are identified. Individuals are instructed to avoid high radiation areas as much as possible, consistent with performing their assigned jobs, and to minimize time spent in areas where significant radiation and contamination levels exist

l. Personnel wear direct-reading or electronic dosimeters so that they can monitor their accumulated dose during the job. In addition, on certain jobs where the radiation fields may vary or cannot be clearly delineated to personnel, personnel may be provided with a personal electronic doserate device or dose-rate instrument. Personal electronic devices provide display and/or an audible alarm function. Thus, personnel will receive warning if they enter areas of high radiation, which would aid in minimizing time spent in these areas

m. On jobs with exceptionally high radiation levels, stay-time limitations are used to ensure that personnel are removed from an area before exceeding their allowable dose for the job being performed

n. On maintenance jobs involving high radiation levels, the job preplanning includes estimates of the man-rem needed to complete the job. At the completion of the job, a debriefing session is held involving people who actually performed the work to investigate lessons learned as to how the work could have been completed more efficiently, thus resulting in lower exposure. This information, together with the procedures used and actual man-rem expended, is maintained for future reference. The information recorded includes the radiation, contamination, and airborne activity levels determined during the work. Records of any external body contamination or internal contamination resulting from the job are maintained to provide guidance at the planning stage of future similar operations

o. High levels of contamination that may become airborne normally occur in areas controlled by Radiation Protection. Access control procedures, as described in plant procedures, help prevent inadvertent entry into contaminated areas. In addition, any areas that are airborne radioactivity areas will be posted. The sign will have instructions for personnel who must enter the area. A radiation work permit is also required for entry to posted airborne radioactivity areas

p. The airborne radioactivity level is determined in enclosed spaces prior to entry for maintenance or other special operations if there is potential airborne contamination. If airborne radioactivity levels are above control limits, reasonable measures will be taken to remove or control the source of this airborne radioactivity prior to commencing the job. If personnel entry is required into areas of known airborne radionuclide concentration where the source of airborne radioactivity cannot be removed or controlled below a threshold value, either occupancy will be limited and monitored or respiratory protection equipment use will be evaluated to maintain total effective dose equivalent ALARA. If entry into an area of unknown but potentially significant airborne radionuclide concentration is required, respiratory protection equipment may be required.

12.3.4 Personnel Dosimetry

12.3.4.1 External Dosimetry

All personnel who enter a radiologically controlled area are monitored with both primary and secondary dosimeters, except those members of the public who are designated as visitors by Plant Management. These visitors are escorted and are normally monitored only by a secondary dosimeter.

12.3.4.1.1 Dosimeters of Legal Record

Dosimeters of Legal Record (DLRs) are used as primary dosimeters to determine beta-gamma and neutron dose.

Area-monitoring DLRs are placed in or around normally occupied areas, including office areas, warehouses, and the visitor center to determine total exposure in these areas. These badges are normally exchanged quarterly.

12.3.4.1.2 Direct-Reading Dosimeters

The pocket dosimeter provides an immediately available indication of radiation dose and may be used as a secondary dosimeter. Direct-reading dosimeters are tested and calibrated at least annually, whenever new dosimeters are put into use, whenever the dosimeter has been damaged, and whenever a significant discrepancy exists between primary and secondary dosimetry. The testing of direct-reading dosimeters is performed in accordance with the provisions of Regulatory Guide 8.4.

The choice of range of direct-reading dosimeters to be used is specified by Radiation Protection. Direct-reading dosimeters of appropriate ranges are provided.

Dosimeter chargers are available for rezeroing the dosimeters.

12.3.4.1.3 Electronic Dosimeters

Electronic dosimeters, which provide an immediate indication of gamma radiation dose, may be used as secondary dosimeters. These dosimeters will give indication of failure conditions, e.g., low battery or detector failure.

12.3.4.1.4 Neutron Dosimetry

Neutron dose exposure is determined by the use of the normal primary dosimeter or by an estimation of dose based on survey results and time spent in the area.

12.3.4.1.5 Extremity and Special Dosimetry

Personnel assigned to work involving dose to the extremities significantly higher than dose to the whole body are issued finger rings, wrist badges, or other special dosimeters to determine the extremity dose.

Special dosimetry devices or additional DLRs may be issued when unusual conditions or nonuniform radiation fields exist. Personnel involved in high radiation work may also be assigned alarming dosimeters or audible rate-dependent dosimeters (chirpers) to help them minimize their time in local high radiation fields and thus minimize their exposure.

12.3.4.1.6 Abnormal Exposures

Abnormal personnel-monitoring results are immediately reported to Radiation Protection supervision who initiates an investigation to determine if the abnormal dose is valid and the related circumstances. The investigation is documented. Abnormal monitoring results include those that result from lost or damaged dosimeters as well as anomalies.

12.3.4.2 Internal Dosimetry

Internal dosimetry bioassay analysis is provided using both body counting (direct bioassay) and biological sample analysis (indirect bioassay) techniques.

Bioassay analysis will be used to assess the amount of radioactive material (if any) that has been taken up by plant personnel. Bioassay analysis will be performed whenever significant internal contamination is suspected. Additional bioassay analysis may be performed during periods of extensive maintenance activity, such as refueling, and as directed by Radiation Protection.

Radiochemical analysis of urine and/or feces may also be used to evaluate possible intakes of non-gamma-emitting radionuclides. Both urine and fecal sample kits will be available and will be issued to an individual as deemed necessary. These samples will be processed by a contracted service agency.

12.3.4.3 Processing and Recording

The official and permanent record of accumulated external radiation dose received by individuals will be obtained from the interpretation of DLRs and associated information.

Readout of DLRs will be performed quarterly or as deemed necessary. Daily dosimetry updating will be based upon direct reading or electronic dosimeter readouts. A record of each person's official dose as determined by the DLR will be maintained.

The personnel dose records will document the following:

a. Period and amount of occupational dose to sources of radiation external to the body from Fermi 2 licensed material

b. Documentation of external dose received during a period when monitoring devices were damaged or lost

c. Evaluation of exposure due to internal radiation dose, including bioassay analysis from Fermi 2 licensed material.

Each monitored radiation worker will be advised at least annually of the worker’s dose if it exceeds 100 mrem TEDE or 100 mrem to any organ, or if requested by the worker.

Additionally, radiation monitoring records, environmental monitoring records, instrument repair records, and calibration records provide supportive information regarding occupational dose data. Radiation Protection records are transferred periodically for permanent retention and filming or imaging.

12.3.5 Sealed Source Leak Testing

Licensed sealed sources with the potential for significant radiological impact, except sources that have been installed in the reactor or are inaccessible, are leak tested at least semiannually.

CHAPTER 13: CONDUCT OF OPERATIONS

This chapter describes the framework within which Fermi 2 will be operated. It summarizes the organizational structure, the training program, review and audit procedures, plant procedures, plant records, and industrial security.

13.1 ORGANIZATIONAL STRUCTURE

The DTE Electric Company (DTE) is providing the operational organization for operating Fermi 2. This chapter describes the DTE organization as it pertains to testing and operation of the plant.

DTE Energy is an investor-owned public utility, incorporated and engaged in the generation, transmission, and sale of electrical energy in the State of Michigan.

DTE has had considerable experience in designing, constructing, and operating fossil-fueled facilities for generating electricity. Normally, the design engineering effort and the construction management for such facilities have been performed by DTE personnel with the assistance of design and construction contractors. Such contractors are guided and directed in their work by the responsible divisions that report through the DTE Corporate Organization. The corporate functions, responsibilities, and authorities related to Fermi 2 are described in this section. Figures 13.1-1 through 13.1-4 show the Corporate Organization; the Nuclear Generation Organization; and the Executive Director – Nuclear Production's Organization, including the Operations organization.

NOTE: The titles of Plant Manager and Executive Director – Nuclear Production have the same functional responsibility.

NOTE: When a position is not filled, reporting order will be to the next higher position.

13.1.1 Corporate Organization

See Figure 13.1-1 for reporting relationship.

13.1.1.1 Not Used

13.1.1.2 President and Chief Executive Officer – DTE Energy

The President and Chief Executive Officer, DTE Energy is subject to the control of the Board of Directors. This individual has responsibility for the company's DTE Electric subsidiary and other DTE Energy subsidiaries.

13.1.1.3 Senior Vice President and Chief Nuclear Officer (CNO)

The Senior Vice President and Chief Nuclear Officer reports to the President and Chief Executive Officer, DTE Energy. This individual has responsibility for the overall administration of DTE nuclear power. The CNO is the ultimate management authority for establishing QA policy and responsibility for the Quality Assurance function. Reporting to the CNO are the Director – Nuclear Oversight, the Site Vice President – Nuclear Generation, Vice President – Engineering and Technical Support, Director – Strategic Business Operations, and the Nuclear Safety Review Group (NSRG) Chairman. The Senior Vice President and Chief Nuclear Officer is also responsible for the Employee Concerns Program.

13.1.1.3.1 Director – Nuclear Oversight

The Director – Nuclear Oversight is responsible for establishing a sustainable oversight model for Fermi. This includes responsibility for Quality Assurance. Reporting to the Director – Nuclear Oversight is the Manager – Nuclear Quality Assurance.

13.1.1.3.1.1 Manager – Nuclear Quality Assurance

The responsibilities of the Manager – Nuclear Quality Assurance are discussed in Section 17.2.

13.1.1.3.2 Corporate Support

Corporate Support groups provide several functions to DTE nuclear organizations such as Information Technology Services, Supply Chain, Human Resources, Business Performance, Facilities, Communications and Controller Services.

When corporate support groups perform quality-related activities for Fermi 2, such activities are performed under the Fermi 2 Quality Assurance Program.

13.1.1.3.3 Director – Strategic Business Operations

The Director – Strategic Business Operations is responsible for strategic planning and business support, including information and procedure management. The Director – Strategic Business Operations is also responsible for managing budgets for site projects and contracts providing services. In the absence of a Director, the role and responsibilities may be filled by a Manager – Strategic Business Operations.

13.1.1.4 Site Vice President - Nuclear Generation

The Site Vice President – Nuclear Generation reports to the Senior Vice President and Chief Nuclear Officer and also has access to the President and Chief Executive Officer, DTE

Energy for the reporting of nuclear safety problems. This individual has responsibility for the administration of the Fermi 2 plant, overall plant safety including operation, maintenance, modification, training, security, outage management, and the fire protection program, with the exception of engineering aspects of the program (see Section 13.1.1.5). Refer to section 13.1.2 for the detailed description of the Nuclear Generation Organization including those organizations reporting to the Site Vice President – Nuclear Generation.

13.1.1.5 Vice President – Engineering and Technical Support

The Vice President – Engineering and Technical Support reports to the Senior Vice President and Chief Nuclear Officer and also has access to the President and Chief Executive Officer, DTE Energy for the reporting of nuclear safety problems. This individual has responsibility for the administration of engineering, including engineering aspects of the fire protection program, and technical support organizations. Supply Chain has a functional relationship to the Vice President – Engineering and Technical Support. Refer to section 13.1.2 for the detailed description of the Nuclear Generation Organization, including those organizations reporting to the Vice President – Engineering and Technical Support.

13.1.2 Nuclear Generation

Nuclear Generation refers collectively to all organizations reporting to the Site Vice President - Nuclear Generation and the Vice President – Engineering and Technical Support. See Figure 13.1-2.

Reporting to the Site Vice President - Nuclear Generation are the Executive Director – Nuclear Production, Manager – Nuclear Security, Manager – Nuclear Performance Improvement, and Director – Nuclear Training.

Reporting to the Vice President – Engineering and Technical Support are the Director – Nuclear Engineering, the Director – Nuclear Technical Support – Project Management, and the Manager – Nuclear Licensing.

13.1.2.1 Director - Nuclear Training

The Director - Nuclear Training is responsible for developing and implementing training programs in support of safe and efficient operation of the plant. The training program is described in Section 13.2. The Director - Nuclear Training also provides the support for licensed operator medical issues.

13.1.2.2 Executive Director - Nuclear Production

NOTE: The positions of Executive Director – Nuclear Production and Assistant Plant Manager may be combined.

The Executive Director - Nuclear Production is responsible for the operation, maintenance, plant administration, and implementation of the fire protection program of Fermi 2. The Executive Director - Nuclear Production shall delegate in writing the succession to this responsibility during any absence.

Reporting to the Executive Director - Nuclear Production are the Assistant Plant Manager, Director – Nuclear Operations, the Director – Nuclear Maintenance, and the Director – Outage and Work Management.

Figures 13.1-3 and 13.1-4 are the organization charts for the sections reporting to the Executive Director - Nuclear Production; each classification in the figures represents a job position for one or more individuals. The functions, responsibilities, and authorities of plant personnel are described below.

13.1.2.2.1 Director – Nuclear Operations

The Operations Section is responsible for the operation of plant equipment and systems, and implementation of the fire protection program. The Director – Nuclear Operations is responsible for the activities of this section.

The Director – Nuclear Operations exercises overall managerial and supervisory responsibility for the startup testing and safe, reliable, and efficient operation of the plant and all associated equipment. It is the Director's responsibility to have a staff of trained and properly licensed personnel to accomplish the various plant responsibilities and to ensure that qualified personnel are available to fill the plant complement positions. Prior to operation, the Director – Nuclear Operations was responsible for the Fermi 2 startup and testing activities. The Operations Section is shown in Figure 13.1-4.

All operations, testing, or maintenance work must be approved either by the Director or by an assigned delegate, as established in procedures.

In the absence of the Director, the succession to the Director's responsibilities is documented in the form of organizational charts, functional descriptions, job descriptions for key personnel or in equivalent forms of documentation.

Reporting to the Director are the Operations Engineer and other support personnel as necessary. The Director – Nuclear Operations may also assume the functions and responsibilities of the Operations Engineer. When assuming these responsibilities, the Director – Nuclear Operations shall hold a senior reactor operator’s license.
The Operations Engineer is responsible for the overall operation of the plant equipment and systems. The Operations Engineer shall have a senior reactor operator's (SRO) license. As designated in procedures, the Operations Engineer or a delegate approves written work requests for equipment operation, maintenance, or tests. During the Operations Engineer's absence, a licensed SRO may be appointed to assume the duties and responsibilities of that position. Reporting to the Operations Engineer are the Shift Manager(s) and shift organization.

The Shift Manager(s) is responsible for and exercises supervisory control over the operating personnel on shift. The Shift Manager (or a designated individual during the Shift Manager’s absence from the control room) has control room command function. The Shift Manager is responsible for the overall operation of the plant during the absence of the Director – Nuclear

Operations, and the Operations Engineer. Each Shift Manager shall have an SRO license. Reporting to the Shift Manager is the Control Room Supervisor and Shift Technical Advisors.

The Control Room Supervisor assists the Shift Manager in duties as directed. Each Control Room Supervisor shall have an SRO license. Reporting to the Control Room Supervisor are the Licensed Nuclear Operators.

The Licensed Nuclear Operators manipulate the reactor controls and other controls and direct the activities of the Nuclear Operators. Normally, three Licensed Nuclear Operators are assigned to each operating shift. Each Licensed Nuclear Operator shall have a reactor operator's (RO) license.

The Nuclear Operators are responsible, under the direction of the Shift Manager, the Control Room Supervisor, or the Licensed Nuclear Operators, for operating auxiliary systems and for assisting in the refueling of the plant as directed. Among their regular duties are the operation of such plant equipment as pumps, turbine generator auxiliaries, blowers, radwaste systems, compressors, and auxiliary service equipment. Additional duties include radiation monitoring, recordkeeping, and general housekeeping.

Operations is responsible for implementing and coordinating the Fire Protection Program, including coordinating fire protection surveillances.

13.1.2.2.2 Director – Nuclear Maintenance

The Director – Nuclear Maintenance is responsible for the maintenance of the plant and all associated systems and equipment. Reporting to the Director – Nuclear Maintenance are Manager – Nuclear Maintenance and Manager – Nuclear Projects.

The Director – Nuclear Maintenance is responsible for the oversight of the Nuclear Maintenance and Nuclear Projects organizations. Duties for the Director – Nuclear Maintenance include strategic planning, strategic budget decisions for Capital and Operations and Maintenance (O&M) projects, and management of the accredited training program.

13.1.2.2.2.1 Manager – Nuclear Maintenance

The Manager – Nuclear Maintenance is responsible for the maintenance of the plant and all associated systems and equipment. Reporting to the Manager – Nuclear Maintenance are the Maintenance Superintendent(s).

The Manager – Nuclear Maintenance is responsible for the maintenance of plant structures, systems, and equipment. In this capacity, compliance with the Technical Specifications related to maintenance, written procedures, and work practices is ensured; and duties include the instrument spare parts, routine calibration, instrument and control troubleshooting, and the standards calibration program.

13.1.2.2.2.2 Manager – Nuclear Projects

The Manager – Nuclear Projects is responsible for oversite of the functional, schedule and budget performance for nuclear projects including all nuclear construction, security, engineering, and facility projects. Reporting to the Manager – Nuclear Projects is the Superintendent(s) – Nuclear Projects.

The Manger – Nuclear Projects provides leadership and oversight of personnel on all nuclear Capital and Operations and Maintenance projects. Supports the Director – Nuclear Maintenance with ensuring all work performed is in accordance with the applicable regulatory and operating license requirements, and the Nuclear Quality Assurance Program.

13.1.2.2.3 Assistant Plant Manager

NOTE: The positions of Executive Director – Nuclear Production and Assistant Plant Manager may be combined.

The Assistant Plant Manager is responsible for managing a portion of the Nuclear Production organization. The specific areas of responsibility are based on departmental performance and development needs. The Assistant Plant Manager is responsible for leading the managers of the following organizations/responsibility areas – Radiation Protection, Chemistry, Industrial Health and Safety, Human Performance and Medical Programs. Reporting to the Assistant Plant Manager are the Manager – Radiation Protection, Manager – Chemistry, and the Manager – Industrial Health and Safety. The Radiation Protection Manager reports directly to the Assistant Plant Manager regarding radiological control.

13.1.2.2.3.1 Manager - Radiation Protection

The Manager - Radiation Protection is responsible for the administration and supervision of the Radiation Protection Department. This department is responsible for radiological engineering, health physics, radiation protection, radiological effluents, ALARA programs, and radwaste (radwaste shipping, decontamination, and Onsite Storage Facility). Reporting to the Manager - Radiation Protection are the Radiation Protection Manager, and the General Supervisor – RP Technical Services and Support. The Manager may also assume the functions and responsibilities of the Radiation Protection Manager as described in subsection 13.1.2.2.3.1.1. In addition, the Manager may also assume the functions and responsibilities of the Manager – Chemistry as described in subsection 13.1.2.2.3.2.

The Manager - Radiation Protection assists the Fermi 1 Custodian. On the average, this activity will not require more than 100 work hours of effort each year.

13.1.2.2.3.1.1 Radiation Protection Manager

The Radiation Protection Manager, as described in NRC Regulatory Guides 1.8, 8.8 and 8.10, has the responsibility and authority to formulate and administer plant programs and procedures which ensure radiation protection for plant personnel, members of the public, and the environment. This position receives delegated authority from the Assistant Plant Manager in the area of radiological control, which includes radiation protection, radioactive effluents, radioactive waste transportation and disposal, and radiological health. The Radiation Protection Manager has direct access to the Site Vice President - Nuclear Generation to resolve questions related to the conduct of the radiation protection program. In the event the Radiation Protection Manager function is assigned to the Manager - Radiation Protection, an Assistant Radiation Protection Manager may be assigned to supervise the Radiation Protection Staff.

13.1.2.2.3.1.2 General Supervisor – RP Technical Services and Support

The General Supervisor – RP Technical Services and Support is responsible for maintaining the site within local, state, and federal environmental regulations, radiological health, radiological instrumentation matters, and reporting Fermi 2 compliance with established site procedures, company policies, and governing regulations.

13.1.2.2.3.2 Manager – Chemistry

The Manager – Chemistry is responsible for maintaining the chemical parameters of the plant within the requirements of the Technical Specifications; UFSAR; fuel warranty and industry guidelines. The Manager – Chemistry may also assume the functions and responsibilities of the Manager – Radiation Protection as described in subsection 13.1.2.2.3.1. The Manager – Chemistry evaluates results, reports, and laboratory techniques and is responsible for the following:

a. Overseeing the operation, maintenance, and calibration of, and providing technical support for, the plant chemical processing and water treatment equipment,
b. Directing the sampling of plant fluid systems, for the chemical laboratory, and for prescribing the procedures to be followed for sample preparation and analysis, and results reports.
c. Nonradiological environmental monitoring.

The functions and responsibilities of the Manager – Chemistry may be assumed by the Manager – Radiation Protection.

13.1.2.2.4 Director – Outage and Work Management

The Director – Outage and Work Management is responsible for the on-line work control, outage management, and reactor services at Fermi 2.

Reporting to the Director – Outage and Work Management are the Manager – On Line Work Management, Manager – Outage, and Manager – Reactor Services.

The functions, responsibilities, and authorities of these job positions are described below.

13.1.2.2.4.1 Manager – Online Work Management

NOTE: The positions of Manager – Online Work Management and Manager – Outage may be combined.

The Manager – Online Work Management is responsible for plant work management and planning services. Reporting to the Manager – Online Work Management are individuals responsible for assigning priority and planning, coordinating, and tracking all evaluation, design, and testing activities in support of plant operations. Also reporting to the Manager – Online Work Management are individuals responsible for reviewing and prioritizing all work requests, ensuring that work requests are completed as scheduled, and reviewing completed work requests. Also included are managing the 30-day, 7-day, and 48-hr schedules and coordinating near-term outage support.

Individuals reporting to the Manager – Online Work Management are also responsible for plant cost engineering, engineering planning, maintenance planning, developing work request packages, preparing management tracking reports, and for the day-to-day operation of the surveillance and performance scheduling and tracking.

13.1.2.2.4.2 Manager – Outage

NOTE: The positions of Manager – Online Work Management and Manager – Outage may be combined.

The Manager – Outage is responsible for outage management including outage programs and schedules, cost engineering, engineering planning, estimating plant modifications and generating outage reports. Reporting to the Manager – Outage are individuals responsible for developing and maintaining outage programs and schedules and assuming the lead role during outages. Also included is work scheduling and database input. Other support staff is responsible for the remainder of the Manager's outage responsibilities.

13.1.2.2.4.3 Manager – Reactor Services

The Manager – Reactor Services is responsible for all activities related to reactor vessel refueling and maintenance, and dry storage loading campaigns.

13.1.2.3 Director – Nuclear Technical Support – Project Management

The Director – Nuclear Technical Support – Project Management is responsible for the project management and engineering support functions of large nuclear related projects. Reporting to the Director – Nuclear Technical Support – Project Management is the Manager – Engineering Projects and Modifications.

13.1.2.3.1 Manager – Engineering Projects and Modifications

The Manager – Engineering Projects and Modifications may be delegated the responsibility for the project management of large plant modifications and engineering support functions associated with modifications of plant structures, systems and equipment. This responsibility includes the planning and management of the engineering scope and specifications, detailed design, procurement, installation and testing phases of the project. In this capacity, the Manager – Engineering Projects and Modifications has the responsibility and authority to utilize DTE personnel or retain qualified contract architects/engineers or consultants to implement the design development and control procedures under the jurisdiction of the Manager – Nuclear Design Engineering.

13.1.2.4 Director – Nuclear Engineering

The Director – Nuclear Engineering is responsible for design engineering, nuclear fuel design and management, strategic engineering, performance engineering, inservice inspection, modifications and configuration management, and procurement engineering. The Director – Nuclear Engineering is responsible for the formulation and effectiveness of the fire protection program. Reporting to the Director – Nuclear Engineering are Manager – Nuclear Design Engineering, Manager – Nuclear Strategic Engineering, Manager – Nuclear Performance Engineering, and Manager – Nuclear Tactical Engineering.

13.1.2.4.1 Manager – Nuclear Design Engineering

The Manager – Nuclear Design Engineering has the overall responsibility for the Fermi 2 plant configuration management program. The Manager – Nuclear Design Engineering is responsible for Engineering Projects and Modifications, and engineering support functions associated with modifications to plant structures, systems and equipment. This responsibility includes the planning and management of the engineering scope and specification, detailed design, procurement, installation and testing phases of the modification.

Within the context of Section 4.6.1 of ANSI N18.1-1971 (Selection and Training of Nuclear Power Plant Personnel), the Manager – Nuclear Design Engineering is equivalent to the "Engineer in Charge." In this capacity, the Manager – Nuclear Design Engineering has the responsibility and authority to assign DTE personnel or to retain qualified consultants to perform necessary design work, design reviews, incident evaluations, or safety analyses.

13.1.2.4.2 Manager – Nuclear Strategic Engineering

The Manager – Nuclear Strategic Engineering is responsible for the engineering functions related to the operation of the plant, including strategic engineering, preventive maintenance program, and technical and administrative procedures.

13.1.2.4.3 Manager – Nuclear Performance Engineering

The Manager – Nuclear Performance Engineering is responsible for the Inservice Inspection Program, equipment performance evaluation, equipment qualification program, fire protection program, and performance and inservice testing.

The Manager – Nuclear Performance Engineering is also responsible for nuclear fuel, including fuel cycle analysis, nuclear fuel accountability, uranium and enrichment accounting, core analysis, reactor dynamics, fuel design, fuel fabrication contract administration, fuel storage and shipment, fuel performance, and fuel burn-up.

The Manager – Nuclear Performance Engineering is also responsible for safe operating procedures as related to reactor core operating limits, fuel management, including maintaining records and specifying plant operations for maximum economic performance within the limits of the operating license, and procedures and documentation for fuel handling.

The Manager – Nuclear Performance Engineering is also responsible for all aspects of the Probabilistic Safety Assessment program including ownership and maintenance of the PSA model and the plant operating and plant shutdown risk assessment activities.

13.1.2.4.4 <u>Manager – Nuclear Tactical Engineering</u>

The Manager – Nuclear Tactical Engineering is responsible for Procurement Engineering and the Engineering Response Team.

13.1.2.5 <u>Other Managers in Figure 13.1-2</u>

13.1.2.5.1 <u>Manager - Nuclear Security</u>

The Manager - Nuclear Security is responsible for the physical security of DTE nuclear power plants and the facilities, material, equipment, and construction associated with them. The physical security responsibility includes developing and implementing the Physical Security Plan, the Safeguards Contingency Plan, the Security Personnel Training and Qualifications Plan, the Safeguards Information Protection Program, and security policy; conducting personnel screening for all personnel requiring unescorted access into the protected area; and implementing the access authorization and fitness for duty programs. The Manager - Nuclear Security also conducts investigations or initiates investigations of attempts to breach nuclear security, whether committed by a person employed at Fermi or a member of the public.

13.1.2.5.2 <u>Manager - Nuclear Performance Improvement</u>

The Manager – Nuclear Performance Improvement is responsible for administration of the plant Corrective Action Program, including trending and tracking of corrective action documents, administration of root cause analysis program and administration of operating experience, self-assessment and benchmarking programs.

13.1.2.5.3 <u>Manager - Nuclear Licensing</u>

The Manager - Nuclear Licensing is responsible for licensing activities, including regulatory and compliance support. The Manager - Nuclear Licensing provides the interface and communications with the NRC and other outside agencies, as assigned. The Manager – Radiological Emergency Response Preparedness as described in subsection 13.1.2.5.4 reports to the Manager – Nuclear Licensing.

13.1.2.5.4 <u>Manager – Radiological Emergency Response Preparedness</u>

The Manager – Radiological Emergency Response Preparedness is responsible for coordinating the activities of Emergency Planning.

13.1.2.6 Shift Crew Composition

NOTE: The titles Nuclear Shift Supervisor (NSS), Nuclear Assistant Shift Supervisor (NASS), and Nuclear Power Plant Operator (NPPO) have the same functional responsibilities as the titles Shift Manager (SM), Control Room Supervisor (CRS) and Nuclear Operator (NO), respectively.

During routine operations, the shift complement consists of one Shift Manager, one Control Room Supervisor, one Shift Technical Advisor/Operations Shift Engineer (OSE), three Licensed Nuclear Operators, five Nuclear Operators, and one Radiation Protection Technician. The Shift Manager, Control Room Supervisor, and Operations Shift Engineer must hold SRO licenses, and the Licensed Nuclear Operators must hold RO or SRO licenses. The Nuclear Operators are not licensed because they do not perform activities for which an RO license is required.

All core alterations shall be observed and directly supervised by either a licensed Senior Reactor Operator or licensed Senior Reactor Operator limited to fuel handling who has no other concurrent responsibilities during the operation. This is in addition to the normal Shift Crew Compliment during Mode 5.

The minimum crew composition of operators for normal routine operations consists of the following:

Position	Number of Personnel per shift	NRC License Requirements
Shift Manager (SM)	1	SRO
Control Room Supervisor (CRS)	1	SRO
Licensed Nuclear Operators (LNO)	3	RO or SRO
Nuclear Operators (NO)	5	None

The minimum shift crew requirements for the various modes is as follows:

Positions	Number of individuals required to fill position	
	Mode 1, 2 or 3	Mode 4 or 5
SM	1	1*
CRS	1	None
LNO	3	1
NO	5	1
STA/OSE	1	1

* Does not include the supervision of core alterations by the licensed SRO or the SRO limited to fuel handling.

Except for the Shift Manager, the shift crew composition may be one less than the minimum requirements for a period of time not to exceed 2 hours in order to accommodate unexpected absence of on-duty shift crew members provided immediate action is taken to restore the shift crew composition to within the minimum requirements. This provision does not permit any shift crew position to be unmanned upon shift change due to an oncoming shift crewman being late or absent.

The operating modes are the following:

Mode	Title	Reactor Mode Switch Position	Average Reactor Coolant Temperature (°F)
1	Power operation	Run	N/A
2	Startup	Refuel[a] or Startup/Hot Standby	N/A
3	Hot shutdown[a]	Shutdown	> 200
4	Cold shutdown[a]	Shutdown	≤ 200
5	Refueling[b]	Shutdown or Refuel	N/A

---

[a] All reactor vessel head closure bolts fully tensioned.

[b] One or more reactor vessel head closure bolts less than fully tensioned

The Shift Technical Advisors are required to have a Bachelor's Degree or equivalent in a scientific or engineering discipline from an accredited institution and 2 years of related nuclear experience. They complete an INPO-accredited Shift Technical Advisor training program. This program contains all of the SRO training materials and practical skills training that has been identified on a job task listing that is Fermi 2 specific. The Shift Technical Advisors are normally assigned to a shift and participate in the training cycle for licensed operator requalification.

The Operations Shift Engineers are required to meet the same qualifications as a Shift Technical Advisor and hold an SRO license.

The Operations Shift Engineer may be designated as the Control Room Supervisor on some shifts. This is in accordance with the NRC Policy Statement on Engineering Expertise on Shift (Reference 1).

The Shift Managers, Control Room Supervisors, Licensed Nuclear Operators, and Nuclear Operators are trained in the following areas of radiation protection:

a. Use of portable radiation detectors
b. Limits of exposure rates and accumulated doses
c. Use of protective barriers and signs
d. Use of protective clothing and breathing apparatus
e. Limiting contamination
f. Pertinent plant and federal regulations.

Shift chemistry technicians perform technical quantitative functions in chemistry, radiochemistry, and other areas. These technicians are qualified to meet the requirements of ANSI N18.1.

13.1.2.7 Qualification Requirements for Nuclear Plant Personnel

Regulatory Guide 1.8, Revision 1, September 1975, and ANSI N18.1 (1971) provide the regulatory criteria for the selection and training of Fermi 2 plant personnel. Regulatory Guide 1.8 endorses the criteria of ANSI N18.1 (1971), with the exception of the Radiation Protection Manager whose requirements are defined in the Regulatory Guide. Training and retraining for NRC-licensed operators is in compliance with 10 CFR 55.

For the purposes of complying with these requirements, the Technical Specifications, and 10 CFR 55, the following definitions apply to Fermi 2 personnel:

Plant Staff	All personnel reporting to the Site Vice President – Nuclear Generation or the Vice President – Engineering and Technical Support

Unit Staff	All personnel reporting to the Executive Director – Nuclear Production, including the Executive Director – Nuclear Production
Operations Staff	All personnel reporting to the Operations Engineer
Technical Staff	All personnel reporting to the Director - Nuclear Engineering

A Regulatory Qualifications List (RQL) is maintained and revised as required for changes in the regulatory requirements and plant staff personnel and titles. Using this list, qualified personnel can be selected for positions and the correct training and retraining programs can be maintained.
The qualification summaries, as required for plant staff affected by the RQL are maintained onsite and are available for review.

The resumes of the initial appointees to the managerial and supervising technical positions for Fermi 2 were included in the original FSAR.

13.2 TRAINING PROGRAM

13.2.1 Program Description

13.2.1.1 General

The objective of the training program for Fermi 2 is to provide fully trained operating, maintenance, and technical personnel. To accomplish this objective, the nuclear training program for Fermi 2 has been designed, and is being implemented, to meet the needs of the individual staff members. Each person receives training on the basis of background, previous training, and staff assignment.

Training for the following positions is derived from a systems approach to training and satisfies 10 CFR 50.120 requirements:

a. Non-licensed Operator

b. Shift Manager

c. Shift Technical Advisor/Operations Shift Engineer

d. Instrument and Control Technician

e. Electrical Maintenance Personnel

f. Mechanical Maintenance Personnel

g. Radiological Protection Technician

h. Chemistry Technician

i. Engineering Support Personnel

The overall training program for the plant staff is divided into the following four areas:

a. Training programs for reactor operator and senior reactor operator license candidates, as described in Subsection 13.2.1.2

b. Training programs for nonlicensed personnel, as described in Subsection 13.2.1.3

c. General employee training (Fermi 2 orientation), as described in Subsection 13.2.1.4

d. Fire-protection training, as described in Subsection 13.2.4.

The Director - Nuclear Training has overall responsibility for the training program and is also in charge of simulator activities and simulator training.

13.2.1.2 Training Program for Operator License Candidates

The training program for operator license candidates has been implemented in accordance with 10 CFR 55. The licensed operator training program was initially accredited by the Institute of Nuclear Power Operations (INPO) on December 18, 1985. This training program was developed using a systems approach to training.

13.2.1.3 Training Programs for Nonlicensed Personnel

13.2.1.3.1 General

Training suited to individual needs and backgrounds is given to nonlicensed personnel, such as supervisors, engineers, operators, technicians, and repairmen. Each course is described in more detail in the sections that follow. In all cases, various sections of the training for nonlicensed personnel may be omitted for those who have applicable experience.

13.2.1.3.2 Training of Chemistry Personnel

Selected chemical or chemical engineering personnel obtain specialized training presented by qualified personnel. In classroom and laboratory sessions, students receive instruction and practical experience that enable them to complete both radiochemical and chemical analyses for process control, waste disposal, effluent monitoring, and process and laboratory instrument calibrations and evaluations. The course work also covers material on interpreting and complying with the chemical and radiochemical aspects of the Technical Specifications, procedures, licenses, and plant warranties.

13.2.1.3.3 Training of Instrumentation and Control Personnel

Training for instrumentation and control personnel is divided into two portions: (1) classroom and (2) practical exercises. Classroom courses include instrumentation theory, procedures, and plant specific systems training. During the practical exercises portion, the trainee receives specific hands-on training that is most beneficial to his/her position on the staff. In addition, personnel will demonstrate the ability to use plant and maintenance administrative procedures.

13.2.1.3.4 Training for Mechanical and Electrical Maintenance Personnel

Mechanical and electrical journeymen for the plant are selected from other DTE facilities or from outside the company and have a minimum of 3 years of experience in one or more crafts. Their dexterity and ability in the basic skills of mechanical and electrical maintenance repair are shown by their previous experience.

As needed, personnel receive training in those skills required for the performance of work in radiological areas, the use of respiratory protection equipment, the use and/or maintenance of specific equipment, plant systems, and general employee training. In addition, personnel will demonstrate the ability to use plant and maintenance administrative procedures.

13.2.1.3.5 Training for Shift Technical Advisors

Training for shift technical advisors is designed to provide the knowledge to effectively perform assigned duties. Included is theoretical training in the sciences related to nuclear power plant operations and practical training in the design and procedures used at Fermi 2. In addition, simulator training is used to develop experience in transient responses.

13.2.1.3.6 Training for Radiation Protection Personnel

The Radiation Protection Technician Program provides training and qualification in the duty areas of dosimetry, instrument calibration, effluent monitoring, and radiation protection operations. Trainees receive training as needed in general employee training, position-required training, and continuing training. Personnel will also demonstrate the use of plant and/or Radiation Protection administrative procedures, as applicable.

13.2.1.3.7 Training for Quality Assurance Personnel

Quality assurance personnel must be certified in accordance with the applicable codes, regulations, and standards for the positions they hold.

As needed, personnel receive training in those skills required for the performance of work in radiological areas, the use of respiratory protection equipment, the use and/or maintenance of specific equipment, plant systems, and general employee training. In addition, personnel will demonstrate the ability to use plant and quality assurance administrative procedures.

13.2.1.3.8 Training for Nonlicensed Operators

The training program for nonlicensed operators provides the necessary knowledge and skills for the operators to perform their jobs. Included in the program are systems training course(s) and area qualifications. This training facilitates ensuring the reliability of plant systems and equipment. The training program consists of two phases as described below.

System Training. System training increases the nonlicensed operator's knowledge of the function and operation of plant systems. It ensures the safety and reliability of plant operation as a result of the integrated activities performed by licensed and nonlicensed operators. The objective of system training, which is provided in addition to area qualifications, is to give the non-licensed operator a concept of the overall operation of the system, the purpose of systems, the interrelationships of systems, and the operator's responsibilities relative to each system. Emphasis is placed on systems that can affect the safe operation or the safe shutdown of the plant. System training uses examinations to verify qualifications in each system. Examinations are used for requalification purposes to ensure that an optimum level of proficiency is maintained by the nonlicensed operator.

Area Qualifications. Checklists are developed and established by plant area and by job classification to familiarize the operators with the specific job tasks expected to be performed as part of the normal shift functions. Area qualifications are based on the following plant areas:

a. Turbine building

b. Reactor building

c. Radwaste building

d. Outside areas, consisting of:

    1. Residual heat removal building

    2. General service water and circulating water pump houses

3. Auxiliary boiler house
4. 120 KV and 345 KV switchyards

Satisfactory completion of each checklist item by each operator is documented by a fully qualified nuclear operator, a licensed nuclear operator, a control room supervisor, or a shift manager. Final completion of each area qualification checklist is approved by the Operations Engineer or his/her designee.

13.2.1.3.9 Training for Engineer Support Personnel

Technical personnel receive training to improve their overall knowledge of Fermi 2. This includes fundamental science topics, plant systems, and plant operations. They also receive general employee training. As needed, engineer support personal receive training on job-specific tasks and demonstrate a knowledge of organization specific procedures.

13.2.1.4 General Employee Training

13.2.1.4.1 Permanent Plant Personnel Training

All DTE employees permanently assigned (those assigned on a day-to-day basis) to the plant are trained as necessary in the following areas.

a. Appropriate plans and procedures, including plant procedures for security, radiological emergency, and reporting fires
b. Radiological health and safety, including applicable portions of 10 CFR 19 and 10 CFR 20
c. Industrial safety
d. Use of protective clothing and equipment
e. Quality assurance
f. Evacuation signals and routes
g. Fitness for duty

13.2.1.4.2 Temporary Plant Personnel Training

Temporary maintenance and service personnel (those who are not assigned to the plant on a day-to-day basis) are trained in the areas listed in Subsection 13.2.1.4.1 to the extent necessary to ensure the safe execution of their duties, or they are escorted by properly trained personnel as required.

13.2.1.4.3 Consultant, Vendor, and Contract Personnel

Consultant, vendor, and contract personnel who are required to perform duties at the plant receive indoctrination training in the areas listed in Subsection 13.2.1.4.1 to the extent necessary for the safe execution of their normal duties, or they are escorted by properly trained personnel as required.

13.2.1.4.4 Deleted

13.2.1.5 Responsible Individual

The Site Vice President - Nuclear Generation is responsible for ensuring that all plant staff members are trained appropriately to do their jobs. Authority is delegated to the individual managers of Nuclear Generation, who are responsible for specifically defining training requirements and for ensuring that their personnel have been trained according to said requirements.

The Director - Nuclear Training is responsible for administering, designing, developing, and implementing all training that has been determined to be required by the Site Vice President - Nuclear Generation or his/her delegate.

13.2.2 Retraining Program

A continuing requalification program for licensed operators and senior operators has been implemented in accordance with 10 CFR 55. The licensed operator requalification program was initially accredited by the Institute of Nuclear Power Operations (INPO) on December 18, 1985. This requalification program was developed using a systems approach to training.

13.2.3 Replacement Training

The purpose of the plant replacement training program is to ensure that replacement personnel satisfy the training requirements stipulated in ANSI N18.1-1971 for the various plant positions.

13.2.3.1 Licensed Personnel Replacement

Personnel selected to be in training for a reactor operator's or senior reactor operator's license are given formal technical training and practical on-the-job training. Subsection 13.2.1.2 identifies replacement training requirements.

13.2.3.2 Nonlicensed Personnel Replacement

Personnel filling positions not requiring an NRC reactor operator's or senior reactor operator's license receive training as outlined in Subsection 13.2.1.3.8.

13.2.3.3 Program Administration

The program is administered as described in Subsection 13.2.1.5.

13.2.4 Fire-Protection Training

13.2.4.1 Fire Brigade Training

13.2.4.1.1 General

The fire brigade (five 5-member teams) is trained in accordance with the NRC staff supplemental guidance, "Nuclear Plant Fire Protection Functional Responsibilities, Administrative Controls and Quality Assurance," dated August 29, 1977. Fire brigade members will receive instruction in the following topics:

a. Identification of the fire hazards and associated types of fires that could occur in the plant and an identification of the location of the hazards, including areas where breathing apparatuses are required, regardless of the size of the fire

b. Identification of the location of installed and portable fire-fighting equipment in each area and familiarization with plant layout, including access and egress routes to each area

c. Proper use of available equipment and the correct method of fighting each type of fire (electrical fires, fires in cables and cable trays, hydrogen fires, flammable liquids, waste debris fires, and record file fires)

d. Indoctrination in the plant fire-fighting plan, with coverage of each employee's responsibilities, including changes thereto

e. Proper use of breathing equipment, and communication, lighting, and ventilation equipment

f. Detailed review of the procedures, with particular emphasis on what equipment must be used in particular areas

g. Review of the latest modifications, additions, or changes to the plant, procedures, fire-fighting equipment, and the fire-fighting plan

h. Proper method of fighting fires inside buildings and tunnels.

Special instruction in directing and coordinating fire-fighting activities will be provided for fire brigade leaders.

Qualified personnel, experienced in fighting the types of fires that could occur in the plant and in using the types of equipment available in the plant, provide the instruction. Classroom training is repeated at a frequency of at least every 2 years.

13.2.4.1.2 Practice Sessions

Practice sessions are held at regular intervals not to exceed 1 year (Subsection 13.2.4.1.4). These sessions are held at a location sufficiently remote from the plant so as not to endanger safety-related equipment. These sessions provide practice in extinguishing actual fires and are conducted by DTE or other qualified personnel.

Practice sessions are also conducted that require fire brigade members to use protective equipment, including emergency breathing apparatus. These sessions need not include fire fighting. They are provided at regular intervals not to exceed 1 year (Subsection 13.2.4.1.4).

13.2.4.1.3 Fire Drills

Fire brigade drills are performed at the plant so that the fire brigade can practice as a team. Drills include the following.

a. The simulated use of equipment for the various situations and types of fires that could reasonably occur in each safety-related area

b. Conformance, where possible, to the established plant fire-fighting plans

c. Operating fire-fighting equipment where practical; this also includes self-contained breathing apparatus, communication equipment, and portable or installed ventilation equipment, when applicable.

The drills are performed at regular intervals not to exceed 90 days, with a grace period of 25 percent, for each fire brigade. The minimum number of fire brigade drills conducted within a period shall be equal to the number of operating shifts at the station. At least one drill per year will be performed on a backshift for each brigade. At least one drill per year for each fire brigade will be unannounced.

The drills are preplanned, evaluated, and critiqued to assess the effectiveness, the response time, the selection, the placement, and the use of equipment. An assessment is also made of the leaders' direction of the effort and each member's response.

At 3-year intervals, a randomly selected unannounced drill must be critiqued by qualified individuals independent of the Fermi 2 staff.

13.2.4.1.4 Periodicity of Fire Brigade Training

All training shall be performed within the time interval specified with

a. A maximum allowable extension not to exceed 25 percent of the training interval, but

b. The combined time interval for three consecutive training intervals shall not exceed 3.25 times the specified training interval.

13.2.4.1.5 Periodicity of Fire Drills Including the Offsite Fire Department

Periodically (once per calendar year) these drills will include offsite fire department personnel and will conform with the Fermi 2 plan for coordination with offsite fire departments.

13.2.4.1.6 Offsite Fire Departments

Training for the offsite fire departments is made available and includes training in basic radiation principles and practices, typical radiation hazards that may be encountered when fighting fires, and related plant procedures.

13.3 EMERGENCY PLANNING

Information for this section is contained in the Fermi 2 Radiological Emergency Response Preparedness Plan, submitted separately to the NRC on the Fermi 2 docket. This plan is periodically updated and current revisions are submitted to the NRC.

13.4 REVIEW AND AUDIT

13.4.1 General

During the construction of Fermi 2, the Edison quality assurance (QA) review and audit program complied with and exceeded the requirements of 10 CFR 50, Appendix B, QA Criteria for Nuclear Power Plants. The review and audit functions that Edison performed during construction are briefly addressed in Subsection 13.4.2 and more completely described in Section 17.1.

DTE uses a formal committee method to review testing and operation at Fermi 2. The review functions are carried out at two levels: one at the plant operations level and the second at the corporate level. The organizations responsible for reviews at these two levels are the Onsite Review Organization (OSRO) and the Nuclear Safety Review Group (NSRG), respectively. The OSRO reviews plant operations, administrative procedures that could affect nuclear safety, and tests and plans for future activities to assist and advise the Executive Director - Nuclear Production on the safe operation of the plant. The NSRG functions to provide an independent review of plant activities and reports to and advises the Senior Vice President and Chief Nuclear Officer as described in Subsection 13.4.3.2. In developing the essential elements of DTE's review program for tests and operations, which is discussed more fully in Subsection 13.4.3, DTE was guided by ANSI N18.7-1976, Administrative Controls and Quality Assurance for the Operational Phase of Nuclear Power Plants.

13.4.2 Review and Audit - Construction

Reviews and audits during the construction of Fermi 2 were part of the QA program described in Section 17.1. This program used a designated organizational unit to provide review and audit, the Project Management Organization, which met at least monthly for a review of construction work in progress. The Assistant Project Manager - Engineering was specifically assigned responsibility for design review. The Edison administrative and technical staffs reviewed design documentation (e.g., specifications, drawings, and design changes) for compliance with applicable codes, standards, good engineering practice, and overall design intent. Quality assurance for the project was the responsibility of the Director-Project Quality Assurance, who reported functionally to the Manager - Enrico Fermi 2 Project and administratively to the Manager - Quality Assurance. Quality Assurance performed vendor surveillance and review by witnessing significant check-points and overall vendor performance. Edison QA also systematically audited activities at the plant site to ensure that the required standards of quality were attained in all construction and installation work performed at the job site. These owner activities complied with the requirements of 10 CFR 50, Appendix B. The review and audit functions during the construction phase are more fully described in Section 17.1.

13.4.3 Review - Test and Operation

A review program has been established to ensure that the operation of the plant is in conformance with established requirements. Independent reviews by the Nuclear Safety

Review Group (NSRG) and reviews by the Onsite Review Organization (OSRO) are described in detail in Subsection 17.2.1.7.

13.4.3.1 Administration of the Onsite Review Organization

The OSRO is responsible for advising the Executive Director – Nuclear Production on all matters related to nuclear safety.

Onsite Review Organization membership, meeting frequency, meeting minutes, and subjects requiring OSRO review are described in Section 17.2 and covered in a written charter.

Procedure - The chairman of the OSRO has the authority to approve or disapprove proposals by the OSRO for nuclear-related matters that do not have safety implications. The OSRO Chairman, or designated alternate, may make a temporary change or authorize interim remedial action involving matters related to nuclear safety, as deemed necessary, provided the intent of the operating license or the Technical Specifications is not altered and the provisions of Subsection 13.5.2 are met.

In the review process, the item for review by the OSRO is placed on the agenda by the staff member initiating the item, who has seen that all necessary preliminary actions, such as the design review, and all necessary 10 CFR 50.59 reviews have been completed. The OSRO considers the item and votes approval or disapproval. The action taken by the OSRO is recorded in the minutes of the meeting. Should the proposed change require a license amendment prior to implementation, it is then forwarded to the NSRG for review, together with a report from the OSRO giving the basis for the findings.

Subjects that require the use of special technical skills may be handled by a subcommittee or task force composed of specialists in that field. When necessary, consultants are obtained to assist the subcommittee or task force in its deliberation. The members of the subcommittee or task force and the consultants are appointed by the OSRO Chairman.

13.4.3.2 Administration of the Nuclear Safety Review Group

The purpose of the NSRG is to provide independent review of facility operations as specified in Section 17.2. The NSRG reports to the Senior Vice President and Chief Nuclear Officer and acts for him in the review of the safety aspects of nuclear power plant operation.

Details concerning the membership requirements, areas of expertise, quorum requirements, review responsibilities and other administrative functions of the NSRG are given in Section 17.2.

13.4.3.3 Review of Operating Experience

Internal and external operating experience is reviewed and assessed to ensure that information pertinent to plant safety is supplied continually to operators and other appropriate personnel and is used for effecting design and procedural changes to correct generic or specific deficiencies and to enhance plant safety when warranted.

The review of externally generated operating experience shall be coordinated primarily by individuals in Nuclear Performance Improvement and Nuclear Design Engineering. These reviews include, but are not limited to, GE nuclear steam supply system (NSSS) reports;

INPO Significant Event Evaluation Information Network (SEEIN) reports such as SOERs and SERs, and NRC Bulletins, and Generic Letters.

The operating experience that is considered as warranting further evaluation is evaluated through the Corrective Action Program. The conclusions and recommendations are reviewed and documented. Recommendations, hardware and software modifications, procedures revisions, design changes, etc., resulting from the reviews are then implemented by the responsible groups within Nuclear Generation. Procedural changes are reviewed and approved by OSRO as applicable.

The Executive Director – Nuclear Production is responsible for ensuring that evaluations are performed for internally generated operating experience events. LERs are reviewed by OSRO and are distributed to appropriate groups for implementation or for information and to the NRC.

13.5 PROCEDURES

13.5.1 General

All safety-related operations at Fermi 2 are conducted in accordance with detailed written procedures. These procedures include the topics specified by Regulatory Guide 1.33 for compliance with the quality assurance (QA) requirements of 10 CFR 50, Appendix B and the applicable procedures required to implement the Fermi 2 commitments made in response to requirements of NUREG-0737. The procedures are implemented following the guidance provided in ANSI N18.7. The procedures related to nuclear safety are reviewed and approved prior to the initial use and periodically thereafter as described in Section 17.2.

The types of procedures used include the following:

a. Administrative Procedures

b. Technical Procedures, including:

    1. Operating Procedures
    2. Maintenance Procedures
    3. Reactor Engineering Procedures
    4. Radiation Protection
    5. Radiochemistry Procedures
    6. Fuel-Handling and Special Nuclear Materials Control and Accountability Procedures
    7. Fire Protection Implementing Procedures
    8. Radioactive-Materials-Handling Radwaste Procedures
    9. Environmental Procedures.
    10. Maintenance, Calibration, and Testing Procedures
    11. Surveillance Procedures

c. Radiological Emergency Response Preparedness Plan Procedures

d. Security Plan Procedures

Contract personnel were used to prepare the initial Fermi 2 procedures. Available plant personnel assisted with this work when training and preoperational testing workload permitted. The ultimate responsibility for the content and accuracy of the final operation procedures and any updating that becomes necessary is as shown below for the various documents. The Director – Strategic Business Operations is responsible for the distribution and upkeep of procedures.

The format varies with the different procedures, but each procedure generally contains the following.

a. Purpose

b. References

c. Description of the equipment involved

d. Prerequisites

e. Safety precautions

f. Valve status and checkoff

g. Step-by-step actions

h. Normal reactions

i. Monitoring requirements

j. Emergency actions or hold instructions.

A complete list of titles of all procedures is included in a procedure control system.

13.5.2 Temporary Changes

A temporary change to a procedure may be made provided that

a. The intent or format of the original procedure is not altered

b. The change is approved by two members of the plant management staff, at least one of whom holds a senior reactor operator's license

c. The change is documented, reviewed by the OSRO when required, and approved by the Executive Director – Nuclear Production or delegate within 14 days of implementation.

13.5.3 Conduct Manuals (Administrative Procedures)

The conduct manuals establish rules and instructions pertaining to the following:

a. Procedure adherence

b. Plant responsibilities and authorities

c. Review and audit programs

d. Reports and records

e. Equipment control and work permit procedures

f. Procurement and warehousing

g. Surveillance program

h. Plant security and visitor control

i. Standing or special orders (plant orders)

j. Radiation control standards procedures

k. Chemical-radiochemical procedures.

l. Shift and relief turnover procedure

Administrative Procedures are prepared under the direction of the appropriate director, or manager, who has the responsibility for their content and implementation. These procedures apply to all site activities and to all personnel at the site.

The procedure for shift and relief turnover consists in part of a checklist that is completed and signed by the oncoming and off-going Shift Managers and control room licensed nuclear operators.

The shift relief checklist is maintained in the control room by the control room operators.

13.5.4 Technical Procedures

Technical procedures shall be used to provide step-by-step sequences for performing technical work activities. The following subsections describe various types of technical procedures used at Fermi 2.

13.5.4.1 Operating Procedures

The preparation of the Operating Procedures is under the direction of the Director – Nuclear Operations. The implementation of these procedures mainly falls to the operating group and is performed under the direction of a licensed senior reactor operator or reactor operator. Procedures that are prepared include, but are not limited to, those in Regulatory Guide 1.33, Appendix A.

13.5.4.1.1 General Operating Procedures

The General Operating Procedures provide the necessary instructions for the integrated operation of all plant systems. Sign-offs are provided to ensure that necessary operating instructions, tests, and calibrations have been completed and are also used for confirming the completion of major steps in the proper sequence. General Operating Procedures are prepared under the direction of the Director – Nuclear Operations and implemented by Operations personnel.

13.5.4.1.2 System Operating Procedures

System Operating Procedures provide the necessary sequence of steps to properly operate a particular system, including the following, as necessary:

a. Normal operation

b. Startup operation

c. Shutdown operation

d. Standby operation

e. Automatic initiation

f. Manual initiation.

13.5.4.1.3 Alarm Response Procedures

Alarm Response Procedures provide guidance on actions to be taken by the control room operator when the alarm annunciators actuate. Each procedure contains the following:

a. The title of the annunciator

b. The actuating device

c. The setpoint(s) of the actuating device

d. The possible causes of the actuation

e. The immediate action to be taken by the operator and those actions which occur automatically

f. The subsequent action to be taken to return the system to its normal mode of operation, if necessary.

13.5.4.1.4 Abnormal Operating Procedures

Abnormal Operating Procedures provide operator guidance for stabilizing the plant or for restoring normal operating conditions following a perturbation.

13.5.4.1.5 Emergency Operating Procedures

Emergency Operating Procedures provide operator guidance to mitigate, reduce, or eliminate the consequence of an accident or potentially hazardous condition that has already occurred, to implement the emergency plan, or to prepare for possible hazardous natural occurrences.

13.5.4.2 Maintenance Procedures

Maintenance activities that affect the performance of safety- related equipment are preplanned and performed in accordance with written procedures, documented instructions, and drawings appropriate to the activity. Procedures for performing various categories of maintenance are prepared following the guidelines contained in Regulatory Guide 1.33, Appendix A. The Manager – Nuclear Maintenance is responsible for these procedures. Maintenance receives permission from the Shift Manager before performing maintenance on plant equipment. This ensures that the operability of redundant safety-related systems is maintained as required by the Technical Specifications.

13.5.4.3 Maintenance, Calibration, and Testing Procedures

Technical Procedures include the procedures necessary to provide periodic maintenance, calibration, and testing of plant instrumentation and components. These procedures have provisions for meeting surveillance schedules and for ensuring that measurement accuracies are adequate to keep parameters within operational and safety limits. Procedures for these tests and the control of measuring and test equipment used in conducting these tests are prepared in accordance with Regulatory Guide 1.33, Appendix A. The Manager – Nuclear Strategic Engineering, Manager – Nuclear Performance Engineering, and the Manager – Nuclear Maintenance are responsible for these procedures.

13.5.4.4 Reactor Engineering Procedures

Reactor Engineering Procedures provide guidance for activities associated with fuel and core management and nuclear performance evaluation. The Manager - Nuclear Performance Engineering is responsible for these procedures.

13.5.4.5 Radiation Protection Procedures

Procedures for personnel Radiation Protection are consistent with the requirements of 10 CFR Part 20 and are approved, maintained, and adhered to for all operations involving personnel radiation exposure. Radiation Protection Procedures describe the methods for personnel exposure control and monitoring; area radiation surveys; portable radiation surveys; portable radiation-monitoring equipment operation and calibration; emergency plan implementation; receipt, storage, and shipment of radioactive materials; and Radiation Protection training. The Manager - Radiation Protection is responsible for these procedures.

13.5.4.6 Radiochemistry Procedures

Radiochemistry Procedures describe the plant chemistry and radiochemistry program, the calibration and operation of plant chemistry and radiochemistry equipment, and the methods of analysis to implement this program. The Manager - Chemistry is responsible for these procedures.

13.5.4.7 Fuel-Handling and Special Nuclear Material Control and Accountability Procedures

Fuel-Handling Procedures specify all actions for core alterations and partial or complete refueling operations. Special Nuclear Material Control and Accountability Procedures define the methods for the control, accountability, and inventory of special nuclear material. The Manager - Nuclear Performance Engineering is responsible for ensuring that the requirements of the special nuclear material accountability program are implemented including the procedures governing special nuclear material greater than one gram. The Director – Nuclear Operations is also responsible fuel handling procedures.

13.5.4.8 Fire Protection Implementing Procedures

Fire Protection Implementing Procedures are developed to control the activities associated with the Fire Protection Program. These procedures include fire prevention, fire detection, confinement, suppression, extinguishment, and administrative controls. Procedures are available for fire brigade organization and training, fire inspection procedures, maintenance, and testing. The Director – Nuclear Operations is responsible for the implementation of the Fire Protection Program and ensures that the requirements for the Fire Protection Program are met.

13.5.4.9 Radioactive-Materials-Handling Radwaste Procedures

The Radioactive-Materials-Handling Radwaste Procedures describe the methods of operation and handling of liquid and solid radioactive waste. Radioactive waste from the floor, equipment, and chemical drains is included, plus the processing of sludges and liquids that result. The handling of dry compactible and noncompactible wastes is also included. Procedures for the implementation of the Process Control Program are also included in this group. The Director – Nuclear Operations and Manager – Radiation Protection are responsible for these procedures.

13.5.4.10 Environmental Procedures

The Environmental Procedures describe the environmental control programs, including whom to notify and what actions to take in the event of environmental incidents. Permits for the National Pollutant Discharge Elimination System are discussed, as are oil and chemical spills. The Manager – Chemistry is responsible for these procedures.

13.5.4.11 Surveillance Procedures

Surveillance Procedures provide the necessary steps to perform the required periodic testing of safety-related structures, systems, and components in accordance with Technical Specification requirements and/or the ASME Boiler and Pressure Vessel (B&PV) Code Section XI. Surveillance procedures require the Shift Manager's approval before performance of the surveillance. After completion of operability tests, the Shift Manager also reviews tests to verify that they have been successfully performed and meet the acceptance criteria cited in the surveillance procedure.

13.5.5 Radiological Emergency Response Preparedness Implementing Procedures

The Radiological Emergency Response Preparedness (RERP) Plan and Implementing Procedures are the responsibility of the Manager - RERP. The RERP Plan establishes and defines the criteria and concepts that are necessary to respond to and mitigate the consequences of radiological emergencies to safeguard plant personnel and protect the health and safety of the public. The RERP Implementing Procedures establish the organization, direction and control, overall response, and protective actions for an emergency at Fermi 2. RERP Implementing Procedures may be either administrative or technical procedures, depending upon content. The RERP Plan and Implementing Procedures are on file with the NRC.

13.5.6 Security Plan Procedures

Security Plan Procedures are the responsibility of the Manager -Nuclear Security working in conjunction with the Director – Nuclear Operations. Security procedures may be either administrative or technical, depending upon content. The implementation of the Security Plan Procedures is performed by Nuclear Security personnel under the direction of the Manager - Nuclear Security.

13.6 PLANT RECORDS

13.6.1 Plant History

The Director – Strategic Business Operations has overall responsibility for documents. Specific individuals within the Fermi Organization are assigned responsibility for the generation and control of documents within their purview. The preparation of written procedures and revisions thereto, and of other administrative records, is also included in the responsibilities of these individuals.

A recorded history of Fermi 2 documenting the design, engineering, construction, testing, operation, maintenance, and modification of the plant is maintained in accordance with 10 CFR 50, Appendix B, Section XVII, Quality Assurance Records.

13.6.2 Operating Records

Operating records and documents include appropriate log books, log sheets, data log output, and recorder charts covering the operation of the plant. These records are to include data sufficient to prepare operational information reports as required.

13.6.3 Events Records

In addition to the operating records that are maintained on a continuing basis, records of other occurrences that may be required to reconstruct significant events or satisfy statutory requirements are maintained for the life of the plant.

13.7 INDUSTRIAL SECURITY

13.7.1 Personnel and Plant Design

The Manager - Nuclear Security is directly responsible for the security at Fermi 2. This section describes, in general terms, the security measures that are in effect at Fermi 2 for protection against radiological sabotage. A detailed security plan, not for public disclosure, is made available to the NRC. The Fermi 2 Security Plan conforms to the requirements of 10 CFR 73.55, Requirements for Physical Protection of Licensed Activities in Nuclear Power Reactors Against Radiological Sabotage.

The security program is generally outlined in the Fermi 2 Physical Security Plan and is administered by the Manager - Nuclear Security. The security program at the plant is implemented by compliance with the criteria outlined in the Physical Security Plan.

The consequences of acts of radiological sabotage are minimized by the plant protective systems, including the nuclear safety features and engineered safety feature (ESF) systems incorporated in the plant design. The redundant protective systems and redundant ESF systems are described in detail in Chapters 6, 7, and 8. Also, fire protection equipment is located throughout the plant to minimize the effects of fire or explosion.

Plant operating, security, and staff personnel are screened to minimize potential security risks and to help ensure that reliable and emotionally stable personnel are selected for assignment in the plant. A background investigation, fitness for duty testing, and a psychological evaluation are performed for each employee who requires unescorted access to the Fermi 2 protected area. In addition, other DTE personnel and certain vendors or contractors, who have a need to be at the plant on a frequent basis, and whose personnel require unescorted access, are subject to the same pre-access screening. These people are issued photo-identification badges that permit unescorted access into the protected area. All other persons infrequently entering the protected area, such as certain subcontractors, vendor personnel, or visitors, are issued special badges that will provide limited and escorted access during their authorized visits.

Plant personnel in a management or supervisory capacity are advised of the necessity to recognize emotionally unstable personnel and to report abnormal behavior. A behavior observation program is established as required by 10 CFR 26.

A security training and qualification program is established for the purpose of developing and maintaining maximum proficiency of the Security Force personnel. In general, the guidelines in 10 CFR 73, Appendix B, are followed by the program. Security Force personnel are to be thoroughly familiar with all plant security procedures and are responsible for their implementation.

13.7.2 Security Plan

A detailed Physical Security Plan, Safeguards Contingency Plan, and Security Training and Qualification Plan are on file with the NRC.

Security procedures are issued to provide additional information for use by both the plant operating personnel and the plant security personnel in implementing the Physical Security Plan.

13.7.2.1 Access Control

The control of access into the protected area is accomplished with perimeter barriers and intrusion detection/assessment devices. An industrial-type security fence, properly lighted and cleared on both sides and contiguous with certain site buildings, forms the boundary of the protected area. The protected area barrier serves as a physical and psychological deterrent to entry. In addition, the protected area has intrusion detection alarms to detect entry into this area. Electronic equipment is used for the surveillance of the protected area perimeter fence. A vehicle barrier system is also in place to protect the plant from malevolent use of vehicles. A description of the vehicle barrier system is included in the Physical Security Plan.

Manned alarm stations are established to control and monitor alarms, personnel, vehicles, and materials entering and leaving the protected area. Specific responsibilities are assigned in the Physical Security Plan and by written procedures for the operation of these manned stations.

The control of materials into the protected area is covered by written procedures, which provide controls for articles carried by personnel as well as loads carried by vehicles.

Personnel access to vital buildings, rooms, and spaces, including the main control room, is controlled by a computer-based access control system. Access is granted by the need to enter specific areas. Portal protection of vital rooms, buildings, and structures is provided by locking devices and alarms. All alarms are self-checking and tamper-indicating.

The surveillance of vital areas is accomplished by periodic security patrols and by authorized operating personnel.

13.7.2.2 Control of Personnel by Categories

The control of authorized entry and movement is accomplished by a color-coded, conspicuously worn, photo-identification badge system. For permanent plant personnel and DTE employees who enter the plant frequently, a current access list is maintained and given to the Central Alarm Station and Secondary Alarm Station operators. Admission is granted to those persons who are positively identified and whose names appear on the approved access list. Access lists are reviewed and approved by a cognizant DTE manager or supervisor to ensure personnel on the list have a continued need for access.

For contractor, vendor, service personnel, or other authorized personnel not on the access authorization list, a visitor's badge is issued and an escort required. A visitor's log is maintained to show the name, date, time, purpose of visit, employment affiliation, citizenship, and name of individual to be visited.

13.7.2.3 Access Control During Emergencies

Requests for emergency aid are made either by site security personnel or by authorized plant operating personnel with such requests coordinated with security personnel to permit the required rapid access needed in emergency conditions. Procedures covering emergency access are referred to in the Physical Security or Safeguards Contingency Plans and are compatible with the Fermi 2 Radiological Plan.

13.7.2.4 Surveillance and Monitoring

Surveillance and monitoring of vital equipment, components, and areas are accomplished in accordance with administrative procedures and controls by the use of electronic equipment and remote-reading instruments to detect changes in ESF equipment. The inspection of nuclear fuel and radioactive materials upon receipt is in accordance with administrative controls and procedures.

13.7.2.5 Potential Security Threats

Nuclear security officers are armed and trained to respond as necessary as outlined in the site's Safeguards Contingency Plan in the event of situations affecting the security of the Fermi 2 plant. Fermi 2 security personnel have two independent means of communicating with local law enforcement agencies in order to summon aid. In addition, all on duty members of the security force are equipped with two-way portable radios if other means of communication are not available.

For any civil disorder, bomb threat, or other type of security threat, the Monroe County Sheriff's office and/or the Michigan State Police are notified and provide the necessary assistance. Any incidents involving attempted or actual breach of security controls or attempted acts of sabotage are reported to the NRC, in accordance with 10 CFR 73.71.

The Nuclear Security Organization evaluates all security incidents to determine if they are reportable to the NRC in accordance with 10 CFR 73.71. Those incidents found to be reportable are investigated and a report is developed. The report is reviewed by the Manager - Nuclear Security and the Site Vice President - Nuclear Generation before it is submitted to the NRC.

13.7.2.6 Administrative Procedures

The Physical Security Plan and implementing procedures are reviewed and approved and periodic reviews are performed according to the Physical Security Plan.

CHAPTER 14: INITIAL TESTS AND OPERATION

This chapter describes the initial testing and operating program conducted at Fermi 2. The program describes the manner in which the testing and initial operation was performed, controlled, and documented for the following four testing and initial operating phases:

a. Construction Test Phase - the period during which the Construction Manager had responsibility for activities. Construction tests were generally carried out before the energization of equipment. The transfer of jurisdiction over equipment and systems from the Construction Manager to the System Completion Organization (SCO) occurred at the end of this period

b. Checkout and Initial Operations Test Phase - the period during which the Edison Startup Group conducted checkout and initial operations (CAIO) tests, including initial equipment energizing, flushing and cleaning operations, initial calibration of instrumentation, electrical wiring and equipment tests, valve testing, and initial equipment and system operation. Hydrotesting (a construction test) was also conducted during this phase

c. Preoperational Test Phase - the period during which approved preoperational tests were performed. The preoperational testing was the responsibility of the Edison Startup Group

d. Startup Test Phase - the period beginning with preparation for fuel loading and extending through 100 percent power and warranty demonstrations, where the Edison Startup Test Phase Group has responsibility for startup testing. A detailed description of this test phase is provided in Subsection 14.1.3. The startup test phase is subdivided into four parts:

    1. Fuel-loading and open-vessel tests

    2. Initial heating to rated temperature and pressure

    3. Power testing from rated temperature and pressure to 100 percent of rated output

    4. Warranty demonstration.

The test program also encompassed cold functional testing, the Surveillance Testing Program, and hot functional testing.

The construction, CAIO, and preoperation test phases were not necessarily performed in series. Certain test activities were conducted in parallel, such as construction tests with CAIO tests and CAIO tests with preoperational tests. On ASME Code systems, the contractor maintained the responsibilities of the Installer through the ASME Code hydrotesting and N-stamping. Overall systems jurisdiction, however, was maintained by Edison's SCO in these situations. Figure 14.1-1 is an overall test program outline.

This test program closely adhered to Regulatory Guide 1.68 (11/73), "Preoperational and Initial Startup Test Programs for Water-Cooled Power Reactors," while recognizing the specific requirements of the construction codes (ASME Section III).

14.1 TEST PROGRAM

A comprehensive testing program was implemented at Fermi 2. This program was designed to ensure the following:

a. That the equipment and systems perform in accordance with General Design Criteria

b. That the plant is properly designed and constructed and is ready to operate in a manner that will not endanger the health or safety of the public

c. That the initial fuel loading is accomplished in a safe and efficient manner

d. That required verification of nuclear parameters is obtained

e. That the procedures for operating the plant are evaluated and demonstrated

f. That the operating staff is knowledgeable about the plant and procedures and fully prepared to operate the facility in a safe manner

g. That the plant achieves rated capacity while meeting all safety and environmental conditions.

Systems and components were tested and evaluated according to written and approved test procedures. An analysis of test results verified that each system or component performed satisfactorily. The written procedures for the initial tests and operation included objectives and prerequisites of the tests, initial conditions, precautions, the test method, acceptance criteria, return to normal status, and appropriate references.

During the preoperational and startup test phases, the permanent plant operating procedures, as described in Section 13.5, were used to support the preoperational and startup tests. The use of the plant system operating procedures in this manner enabled them to be verified and changed as necessary to become a safe, comprehensive set of system operating procedures.

14.1.1 Administrative Procedures (Testing)

The preoperational test program has been essentially completed for Fermi 2. All that presently (December 1988) remains is a small amount of testing to close out certain test items still open from previous testing on other systems.

The preoperational tests of the solid radwaste system were suspended in December 1987 because the system was unable to meet the design throughput values for ion-exchange resin waste streams. The objectives and test descriptions discussed in Subsection 14.1.3.2.17, as they apply to this system, will remain in effect should testing be resumed in the future.

The responsibilities and administrative controls necessary to complete this testing are defined in plant administrative procedures.

14.1.2 Administrative Procedures (Modifications)

(This section has been deleted.)

14.1.3 Preoperational Test Phase Objectives and Test Descriptions

14.1.3.1 General Objectives

(This section has been deleted.)

14.1.3.2 Discussion of Preoperational Tests

The preoperational test discussions that follow indicate the objectives, prerequisites, general test method, and acceptance criteria which formed the basis for the detailed preoperational test procedures. A listing of all preoperational tests, together with subsection and page references for use in locating a particular test discussion, follows under the heading "Preoperational Tests."

Systems that were not to be tested preoperationally were subjected to an acceptance test or a specific checkout and initial operations test. A list of acceptance tests that were performed follows the list of preoperational tests. After the list of acceptance tests is a list of specific checkout and initial operations tests that were used instead of acceptance tests.

PREOPERATIONAL TESTS

PREOPERATIONAL TESTS

Subsection Reference	Test Title
14.1.3.2.13	Core Spray System Preoperational Test
14.1.3.2.14	High Pressure Coolant Injection System Preoperational Test
14.1.3.2.15	Fuel Pool Cooling and Cleanup System Preoperational Test
14.1.3.2.16	Leak Detection System Preoperational Test
14.1.3.2.17	Liquid- and Solid-Radwaste System Preoperational Test

14.1.3.2.1 Feedwater Control System Preoperational Test

a. Test Objective - To verify proper operation of the feedwater control system

b. Prerequisites - The checkout and initial operations tests have been completed and the technical review committee (TRC) has reviewed and approved the test procedure and the initiation of testing. The control air system must be available and all feedwater control components should have an initial calibration in accordance with vendor's instructions

c. General Test Method - Verification of the feedwater control system capability is demonstrated by the proper, integrated operation of the following.

   1. Feedwater control instrumentation and interlocks
   2. Startup (low-flow) valve regulator
   3. Annunciators.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications.

14.1.3.2.2 Reactor Feedwater System Preoperational Test and Reactor Feedwater Pump Turbine Control System Preoperational Test

a. Test Objective - To verify the proper operation of the reactor feedwater pump turbine control system, including turbine support systems, controls, safety devices, and alarms and annunciators. Verify the proper operation of the reactor feedwater system valves and interlocks, and alarms and annunciators

b. Prerequisites - The checkout and initial operations tests have been completed, and the TRC has reviewed and approved the test procedure and the initiation of testing. The related support systems, the main turbine sealing steam, and the lube oil systems must have readiness verification. The Turbine Instruction Manual is reviewed in detail

c. General Test Methods - Verification of the reactor feedwater system and the turbine control system capability is demonstrated with actual and simulated signals by the proper, integrated operation of the following:

1. Automatic valves and interlocks
2. Alarms and annunciators
3. Lube-oil alarms and protective devices
4. Turbine hydraulic and lube oil system
5. Turbine turning gear and interlocks
6. Turbine trip and trip-reset system
7. Clean steam operation of north and south reactor feed pump turbine.

d. Acceptance Criteria - In addition to verification of operation of all system components, the turbine hydraulic and lube oil systems, turbine turning gear, and turbine trip and reset systems must be shown to be within their respective engineering design specifications.

14.1.3.2.3 Deleted (incorporated into Subsection 14.1.3.2.2)

14.1.3.2.4 Reactor Water Cleanup System Preoperational Test

a. Test Objective - To verify the operation of the reactor water cleanup (RWCU) system, including pumps, valves, and demineralizers

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. Anion and cation resin mixture is available. Reactor building closed cooling water system (RBCCWS) and control air must have readiness verification

c. General Test Methods - Verification of the RWCU system capability is demonstrated by the proper, integrated operation of the following:

1. Drain flow regulator flow interlocks
2. System and filter isolation and logic
3. Valve-operating sequence
4. Pump and related control and logic
5. Annunciators.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications. Total system filterability must be demonstrated similarly.

14.1.3.2.5 Standby Liquid Control System Preoperational Test

a. Test Objective - To verify the operation of the standby liquid control system (SLCS) including pumps, tanks, control, logic, and instrumentation

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. Relief valves are bench tested previously and other precautions relative to positive displacement pumps taken. The reactor pressure vessel (RPV) is available for injecting demineralized water

c. General Test Method - Verification of the SLCS capability is demonstrated by the proper, integrated operation of the following:

1. SLCS tank level instrumentation
2. Heaters and heat tracing
3. Alarms and logic
4. Relief valves
5. Pumps and related controls and logic
6. Flow testing with different flow paths
7. Injection of demineralized water by actual firing of squib valves
8. Volume and concentration limits according to the Technical Specifications.

d. Acceptance Criteria - All systems components must be either verified for proper operation, or demonstrated to be within their respective engineering design specifications.

14.1.3.2.6 Nuclear Boiler System Preoperational Test

a. Test Objective - To verify the proper operation of the nuclear boiler system, including the reactor vessel and containment isolation control logic, main steam isolation valves, automatic depressurization control logic, safety/relief valves (SRVs), and reactor vessel head leak detection system

b. Prerequisites - The checkout and initial operations tests have been completed as required and the TRC has reviewed and approved the test procedure and the initiation of testing

c. General Test Method - Verification of the system capability is demonstrated by integrated operation of the following portions of this system:

   1. Reactor vessel and containment isolation control including process sensors, logic channels, main steam isolation valves (MSIVs), drain valves, reactor water sample isolation valves, vacuum breakers, and pneumatic accumulators
   2. Automatic depressurization system (ADS) including sensors, logic channels, SRVs, manual controls, and pneumatic accumulators
   3. Non-ADS SRVs and associated manual controls
   4. Reactor head seal leak detection
   5. Annunciator and sequential operations recorder inputs
   6. Reactor head vent isolation valves
   7. Reactor vessel level instrument responses to actual water-level changes.

d. Acceptance Criteria - All system components must be verified for proper operation. The valves tested must meet required closing time maximum values. Logic response times where time delay devices are included must meet design values.

14.1.3.2.7 Residual Heat Removal System Preoperational Test

a. Test Objective - To verify the operation of the residual heat removal (RHR) system under its various modes of operation: standby, low pressure coolant injection (LPCI), shutdown cooling and vessel head spray, containment spray, suppression pool water cooling, and fuel pool cooling and cleanup (FPCC). Heat removal capabilities in certain modes are not verified

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. The RPV and recirculation loops are intact and capable of receiving water

c. General Test Method - Verification of the RHR system capability is demonstrated by the proper, integrated operation of the following:

   1. System isolation valve control and logic tests
   2. RHR pumps, motors, controls, and related logic features
   3. Automatic LPCI initiation logic
   4. Break detection loop selection logic

5. Verification of all flow paths. The time from initiation signal to full flow is verified similarly to be within design specifications
6. Demonstrate adequate net positive suction head (NPSH) with simulated suppression chamber inlet strainer 50 percent plugged
7. Alarms and annunciators.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications; system flow paths under various modes of operation must be demonstrated similarly.

The time from initiation signal to full flow is verified similarly to be within design specifications.

14.1.3.2.8 Reactor Core Isolation Cooling System Preoperational Test

a. Test Objective - To verify the operation of the reactor core isolation cooling (RCIC) system, valves, instrumentation, and control

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing

c. General Test Method - Verification of system capability is demonstrated with simulated signals by the proper, integrated operation of the following:

1. All valves and related controls, interlocks, and indicators
2. Manual and automatic initiation logic
3. Automatic isolation, including leak detection system logic
4. Turbine speed control, trip logic, instrumentation, and test mode
5. Barometric condenser condensate pump, and vacuum pump controls
6. Annunciators.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications.

14.1.3.2.9 Reactor Recirculation and Motor-Generator Sets Preoperational Test

a. Test Objective - To verify the operation of the reactor recirculation system, including pumps, and their associated motors and motor-generator (M-G) sets, valves, instrumentation, and controls. The rated conditions tests are conducted during the startup test program.

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. The RBCCWS must receive readiness verification. All required testing of equipment up to the operation of the recirculation pump has been completed, including operation of the M-G sets and fluid coupling, recirculation pump motor (uncoupled), and all control loops. Reactor internals which are in place are those which can satisfactorily withstand the pressure drops encountered during these tests. Means must be provided to monitor audible noise and vibration of the pumps

c. General Test Method - After prerequisite testing, verification of system capability is demonstrated by the proper, integrated operation of the following:

1. System valves

   (a) Operability

   (b) Opening and closing speed

   (c) Manual operation

   (d) Limit switch and torque switch operation

   (e) Position indicating lights.

2. Logic and interlocks

   (a) Recirculation pump trip with reactor low level and/or with reactor high pressure (anticipated transient without scram [ATWS]) recirculation pump runback with reactor low level and loss of feed pump

   (b) Recirculation flow limit for NPSH protection with low feedwater flow

   (c) Scoop tube positioner lockup with signal failure

   (d) M-G set drive motor lockout

   (e) M-G set drive motor circuit breaker trip

   (f) Circulating lube oil system

   (g) Annunciators.

3. Operational Testing

   (a) Single pump operation at minimum speed

   (b) Single and dual-pump operation at higher loop flows within flow and cavitation

   (c) Pump trips, including one- and two-pump drive motor breaker trips and a two-pump trip consistent with the ATWS pump trip. (In addition, the time delay for the field breaker trip will be confirmed)

   (d) Recirculating pump and piping vibration measurements

   (e) M-G set motor, coupler, and generator

   (f) Jet pump consistency.

d. Acceptance Criteria - Performance cannot be evaluated properly in the preoperational phase, and, therefore, no conclusions on performance can be reached until the system is tested during the power test program. Expected values of measured parameters will be tabulated before the test. Significant variations from these values will be investigated. All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specification.

14.1.3.2.10 Control Rod Drive Manual Control System Preoperational Test

a. Test Objective - To verify the operation of the reactor manual control system (RMCS), including relays, control circuitry, switches and indicating lights, and control valves

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. Associated primary coolant systems must be flushed

c. General Test Method - Verification of RMCS capability is demonstrated by the proper, integrated operation of the following:

    1. Control valve sensor and logic
    2. Rod blocks, interlocks, and alarms
    3. Control rod drive (CRD) position indication, alarms, and interlocks
    4. Alarms, annunciators, and system timer.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications.

14.1.3.2.11 Control Rod Drive Hydraulic System Preoperational Test

a. Test Objective - To verify the operation of the CRD hydraulic system, including CRD mechanisms, hydraulic control units (HCUs), hydraulic power supply, instrumentation, and controls

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. The CRD manual control system preoperational test (Subsection 14.1.3.2.10) must be completed on associated CRDs. The RBCCWS and control air system must receive readiness verification

c. General Test Method - Verification of CRD system capability is demonstrated by the proper, integrated operation of the following:

    1. Logic and interlocks
    2. CRD pumps and related controls and interlocks
    3. Flow controller, pressure control valves, and stabilizer valves
    4. Scram discharge level switches, and CRD position indication and alarms
    5. CRDs including latching and position indication

6. Scram testing of control rods at atmospheric pressure

7. Annunciators.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specification; full scram capability must be similarly demonstrated.

14.1.3.2.12 Fuel Handling and Vessel Servicing Equipment Preoperational Test

a. Test Objective - To verify the operation of the fuel handling and vessel servicing equipment, including tools used in the servicing of control rods and fuel assemblies, local power range monitors (LPRMs), and dry tubes. The test will also verify the operation of vacuum cleaning equipment, the refueling platform, the fuel preparation machine, and the service platform

b. Prerequisites - The checkout and initial operations tests have been completed as necessary, and the TRC has reviewed and approved the test procedure and the initiation of testing. Additionally, the refueling platform, fuel preparation machine, and fuel racks must be installed and operational; all slings and lifting devices must be certified at their design load, at least, by the vendor

c. General Test Method - Verification of the fuel handling and vessel servicing equipment is demonstrated by dry operation of the following equipment:

1. Cell disassembly tools

2. Channel replacement tools

3. Vacuum cleaning equipment

4. Interlocks and logic associated with the refueling and service platform

5. Refueling and service platforms.

d. Acceptance Criteria - The above tools must be verified for proper operation. In addition, logic and interlocks and grapple load cells must be either verified for proper operation or demonstrated to be within their respective engineering design specifications.

14.1.3.2.13 Core Spray System Preoperational Test

a. Test Objective - To verify the operation of the core spray system, including spray pumps, sparger ring, spray nozzles, controls, valves, and instrumentation

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. The RPV must be available and ready to receive water

c. General Test Method - Verification of core spray system capability is demonstrated by the proper, integrated operation of the following:

1. Logic and interlocks

2. Core spray system pumps, including auto initiation

3. Flow path verification
4. Annunciators
5. Adequate NPSH with simulated suppression chamber inlet strainer 50 percent plugged.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications; system flow rates and patterns and initiation time must be demonstrated similarly.

14.1.3.2.14 High Pressure Coolant Injection System Preoperational Test

a. Test Objective - To verify the operation of the high pressure coolant injection (HPCI) system, including turbine and related auxiliary equipment as available, vacuum pump, condensate pump, valves, instrumentation, and control

b. Prerequisites - The checkout and initial operations tests have been completed as necessary, and the TRC has reviewed and approved the test procedure and the initiation of testing

c. General Test Method - Verification of HPCI system capability is demonstrated with simulated signals by the proper, integrated operation of the following:

1. Automatic initiation
2. Automatic isolation, including leak detection and interlocks
3. Valve controls and interlocks
4. Turbine test mode and trip
5. Gland condenser condensate pump and vacuum pump, and interlocks
6. Alarms and annunciators.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications. All pump tests involving the HPCI main and booster pumps are deferred to the startup test phase.

14.1.3.2.15 Fuel Pool Cooling and Cleanup System Preoperational Test

a. Test Objective - To verify the operation of the fuel pool cooling and cleanup system (FPCCS), including valves, pumps, and demineralizer

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. The related support systems, the RBCCW, control air, and portions of the radwaste system must have readiness verification

c. General Test Method - Verification of the FPCCS is demonstrated by the proper, integrated operation of the following:

1. Control air-operated valves and related sequence logic

2. Flow path verification
3. Pumps, and their motors and related automatic controls, interlocks, and vacuum breaker verification
4. Demineralizer operation
5. Annunciators.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications; a total system operational capability must be demonstrated similarly.

14.1.3.2.16 Leak Detection System Preoperational Test

a. Test Objective - To summarize the test requirements and verify the leak detection test data for each of the nuclear systems

b. Prerequisites - The prerequisites are included in the preoperational test specifications for each of the nuclear systems listed below

c. General Test Method - As an integral part of each of the following system preoperational tests, the nuclear systems leak detection is verified by the proper operation of the leak detection features of the following nuclear systems:

1. RWCU
2. Nuclear boiler system
3. RHR
4. RCIC
5. HPCI
6. Radwaste system

d. Acceptance Criteria - The leak detection features of the nuclear systems must be verified for proper operation and shown to be within their respective engineering design specifications.

14.1.3.2.17 Liquid and Solid Radwaste System Preoperational Test

a. Test Objective - To verify the operation of the radwaste system, including pumps, filters and demineralizers, centrifuge, and solid-handling equipment

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. Additionally, laboratory facilities must be available to perform water quality tests

c. General Test Method - Verification of the radwaste system capability is demonstrated by the proper, integrated operation of the following:

1. System pumps under all normal possible flow paths and component operation
2. Isolation valve operation, including valve logic and leak detection sensors and related annunciators
3. Filters and demineralizers and related controls
4. Centrifuges and solid-handling equipment
5. Phase separator and waste sludge subsystems
6. Chemical waste and spent resin subsystems.

d. Acceptance Criteria - All system and subsystem components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications.

14.1.3.2.18 Reactor Protection System Preoperational Test

a. Test Objective - To verify the proper operation of the reactor protection system (RPS), including sensors, logic channels, scram relays, reset logic, and motor-generator power supplies

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. Checkout and initial operations tests of the MSIV limit switches must be complete. The CRD hydraulic system should have readiness verification

c. General Test Method - Verification of the RPS capability is demonstrated by the proper, integrated operation of the following.

1. M-G sets and associated voltage and underfrequency control logics
2. RPS input sensors including automatic bypass functions
3. Scram channel relay logic, including scram relays and manual scram switches
4. Mode switch functions and bypass time delays
5. Full scrams including CRDs if the CRD hydraulic system is available. Otherwise this verification is performed with the preoperational test of the CRD hydraulic system
6. Annunciator and sequential operations recorder inputs
7. RPS sensor initiation of reactor and containment isolation.

The method used for measuring the response times of initiating channels is described in Subsection 7.2.1.1.3.8.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to perform within their respective engineering design specifications; the RPS must demonstrate the ability to scram the reactor within a specified, maximum time. Each portion of the scram chain including sensors must meet a specified, maximum-allowable operating time.

14.1.3.2.19 Neutron Monitoring System Preoperational Test

a. Test Objective - To verify the operation of the neutron monitoring system (NMS), including startup, intermediate, power range detectors, rod block monitor (RBM), and related equipment

b. Prerequisites - The checkout and initial operations tests have been completed as required, and the TRC has reviewed and approved the test procedure at the initiation of testing. Additionally, all source range monitors (SRMs) and pulse preamplifiers, intermediate range monitors (IRMs) and voltage preamplifiers, and average power range monitors (APRMs) will have been calibrated per vendor's instructions

c. General Test Method - Verification of the NMS capability is demonstrated by the proper, integrated operation of the following.

   1. All SRM detectors, and their respective insert and retract mechanisms, and cables

   2. SRM channel, including pulse preamp, remote meter and recorder, trip logic, logic bypass and related lamps and annunciators, control system interlocks, refueling instrument trips, and power supply

   3. All IRM detectors and their respective insert and retract mechanisms and cables

   4. IRM channels, including voltage preamps, remote recorders, RMCS interlocks, RPS trips, annunciators and lamps, and power supplies

   5. All LPRM detectors and their respective cables, and power supplies

   6. All APRM channels, including trips, trip bypasses, annunciators and lamps, remote recorders, RMCS interlocks, RPS interlocks, and power supplies

   7. Recirculation flow bias signal, including flow unit, flow transmitters, and related annunciators, interlocks, and power supplies.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications; the ability of the system to interface properly with the reactor protection system must be demonstrated similarly.

14.1.3.2.20 Traversing In-Core Probe System Preoperational Test

a. Test Objective - To verify the operation of the traversing in-core probe (TIP) system, including the TIP detector, controls and interlocks, containment secure lamp, and squib circuits

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. Additionally, the TIP detector and dummy detector, ball valve time delay, core top and bottom limits, clutch, X-Y recorder, shear valves, and purge system are shown to be operational

c. General Test Method - With the exception of the shear valve which is not fired, verification of the TIP system is demonstrated by the proper, integrated operation of the following:

1. Indexer cross-calibration interlock
2. Shear valve monitor lamps
3. Drive motor manual control and override, automatic control and stop, and low speed control
4. TIP automatic detector withdrawal
5. Containment secure lamp and squib circuits
6. Ball valve control.

In addition, one explosive device is test fired to verify operability of the squib explosive channels. The squib valve firing circuit is checked by

(a) Jumpering pins to the valve actuators

(b) Operating the "fire" switch

(c) Measuring the current.

This test verifies wiring, operability of switch and interlocks, and capacity of the power supply. Continuity through the squib is monitored continuously by a "trickle" current

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications.

14.1.3.2.21 Rod Worth Minimizer System Preoperational Test

a. Test Objective - To verify the operation of the rod worth minimizer (RWM) system under its various modes of operation

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. The CRD system, RMCS, and rod position indication system are shown to be operational. The rod sequence control system (RSCS) is bypassed, computer diagnostic and special tests are completed, and fuel is not loaded

c. General Test Method - Proper operation of RWM hardware and program is demonstrated by successful completion of the following items using a rod test sequence loaded into computer memory

1. Proper indication of errors and application of rod blocks while operating between 100 percent and 50 percent rod density and the low-power setpoint
2. Proper indication of errors while operating between the low-power setpoint and the low-power alarm point
3. System initialization below the low-power setpoint, initialization between the low-power setpoint and the low-power alarm point, and initialization above the low-power alarm point
4. Rod test mode
5. RWM acceptance of a substitute rod position valve
6. Rod drift scan.

d. Acceptance Criteria - All system operations must be either verified or demonstrated to be within their respective engineering design criteria.

14.1.3.2.22 Process Radiation Monitoring System Preoperational Test

a. Test Objective - To verify the operation of all subsystems of the process radiation monitoring system (PRMS), both liquid and gaseous. The primary containment radiation monitoring subsystem preoperational test is reviewed in Subsection 14.1.3.2.50

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has approved the test procedure and the initiation of testing. Additionally, all component units, including the pulse preamplifiers, power supplies, indicator and trip units, sensors, and converters, are calibrated according to the vendor's instruction manuals; circuit continuity, insulation resistance, and high potentiometer tests will have been completed

c. General Test Method - Verification of the process PRMS is demonstrated by the proper, integrated operation of the components of all subsystems, including the following:

1. Air or water flow rates and operation of controls and alarms for all off-line subsystems
2. Operation accessibility and viability of all filter collectors (iodine and particulate) included in specified subsystems
3. Accessibility and operability of all grab sample portions, such as the offgas vial sampler
4. Sensors, preamps, cabling, channels, lamps, annunciators, trip units, recorders, sample racks, check sources, and interlocks.

d. Acceptance Criteria - All subsystem components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications.

14.1.3.2.23 Area Radiation Monitoring System Preoperational Test

a. Test Objective - To verify the operation of the area radiation monitoring system (ARMS), including sensors and channels, trip units, alarms, and recorder

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. Additionally, indicator and trip units, power supplies, and sensor/converters are calibrated according to the vendor's instruction manual

c. General Test Method - Verification of the ARMS capability is demonstrated by the proper, integrated operation of the following:

1. Sensor/converter and associated channels
2. Channel trip units
3. Alarm annunciators, lights, and beacons
4. Recorders.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications.

14.1.3.2.24 Process Computer Interface System Preoperational Test

a. Test Objective - To verify the operation of the process computer interface system, including computer inputs and printout

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. Additionally, computer diagnostic checks and programming are completed

c. General Test Method - Verification of the process computer interface system is demonstrated by proper operation of the following:

1. Analog input signals
2. Computer printout
3. Digital input signals
4. Digital output signals.

d. Acceptance Criteria - All system operations must be either verified or demonstrated to be within their respective engineering design specifications.

14.1.3.2.25 Rod Sequence Control System Preoperational Test

a. Test Objective - To verify the operation of the RSCS under its various modes of operation

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. Additionally, the self-test feature of the RSCS is verified

c. General Test Method - Verification of the RSCS is demonstrated by the proper operation of the following functions:

   1. Group fence blocks
   2. Full-in, full-out bypass blocks
   3. Group select blocks
   4. 50 percent rod density notch control logic
   5. 20 percent power notch control bypass (minimum)
   6. Illuminations and annunciation.

d. Acceptance Criteria - All system operations must be either verified, or demonstrated to be within their respective engineering design specifications; RSCS acceptance of an operator-initialized group reset must be demonstrated similarly.

14.1.3.2.26 Condensate System Preoperational Test

a. Test Objective - To verify the operation of the condensate system, including pumps, motors, controls and interlocks, feedwater heaters, control valves, condensers, and flow and pressure instrumentation. No attempt is made to verify design heat loads until nuclear steam is available

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. Related support systems (condensate makeup demineralizer, condensate storage, and control air) must have readiness verification

c. General Test Method - With the exception of the condensate polishing demineralizer, condensate storage, condenser vacuum, and condensate makeup demineralizer systems, which are the subjects of their own preoperational tests, verification of the condensate system capability is demonstrated by the proper, integrated operation of the following:

   1. Condenser pumps, motors, controls, and interlocks
   2. Offgas, steam-jet air ejector, and gland steam condensers, and their related water control valves
   3. System normal and emergency relief protection valves
   4. System minimum recirculation flow and bypass control valves
   5. Condenser hotwell level controls
   6. System normal and emergency makeup valves and control
   7. Heater feed pumps and bypasses, motors, controls, and interlocks

8. System flow and pressure instrumentation
9. Feedwater heaters and control valves
10. Reactor feed pump seal water injection and return pumps, motors, controls and logic
11. Annunciators.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications. Verification of system design heat loads is deferred until nuclear steam is available.

14.1.3.2.27 Condensate Polishing Demineralizer System Preoperational Test

a. Test Objective - To verify the operation of the condensate polishing demineralizer system, including demineralizers, pumps, motors, and automatic controls

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedures and the initiation of testing. The related support systems (condensate storage, condensate portions of radwaste, station air, and control air) must have readiness verification

c. General Test Method - Verification of the condensate polishing demineralizer system is demonstrated by the proper, integrated operation of the following:

1. Holding pumps, precoat pumps, and related automatic controls and interlocks
2. System flow, flow balance control, interlocks and override, and automatic valve operation
3. Demineralizers' automatic controls and valves
4. Resin precoat batch preparation subsystem, automatic sequencing, and tank agitators
5. Annunciators.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications; effective system filterability must be demonstrated similarly.

14.1.3.2.28 Condenser Vacuum System Preoperational Test

a. Test Objective - To verify the operation of the condenser vacuum system, including air-ejectors, and seal water and vacuum pumps

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. The related support systems (the condensate makeup demineralizer, condensate, condensate storage, general service water, control air, and radwaste systems) must have readiness verification

c. General Test Method - Total system performance cannot be verified until nuclear steam is available; functional verification of the condenser vacuum system capability is demonstrated by the proper operation of the following:

  1. Vacuum and seal water pumps automatic operation
  2. System automatic valve operation
  3. Water makeup system automatic operation
  4. Air-ejector system operation
  5. Annunciators.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications.

14.1.3.2.29 Condensate Storage System Preoperational Test

a. Test Objective - To verify the operation of the condensate storage system, including tanks, storage tank recirculating heat exchanger, pumps, reducing station, valves, instrumentation and controls

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. The related support systems (the condensate makeup demineralizer and demineralized water supply header) must have readiness verification

c. General Test Method - Verification of the condensate storage system capability is demonstrated by the proper, integrated operation of the following:

  1. System pumps, motors, and their related automatic controls, interlocks, and safety devices
  2. Condensate storage tank heat exchanger
  3. Automatic valve operation
  4. Annunciators.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications; the emergency capacity of the condensate storage tank must be demonstrated similarly.

14.1.3.2.30 Plant Process Sampling System (Liquid Radwaste) Preoperational Test

a. Test Objective - To verify the operation of the plant process sampling system (liquid radwaste), including valves and controls

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedures and the initiation of testing. The required support systems and demineralized water must have readiness verification. Additionally, portions of the radwaste system must have readiness verification

c. General Test Method - Verification of the plant process sampling system (liquid radwaste) is demonstrated by the ability of the system to draw samples from the following radwaste subsystems:

1. Chemical waste tank
2. Waste sample tanks
3. Liquid radwaste effluent
4. Waste collector system: waste-collector tank, etched-disk filter, oil coalescer, precoat filter, demineralizer
5. Floor drain collector system: collector tank, etched-disk filter, oil coalescer, precoat filter, demineralizer
6. Evaporator feed surge tank, evaporator drains, evaporator drains holdup tank, evaporator concentrates feed tank, evaporator distillate surge tank
7. Waste clarifier tank and condensate phase separators
8. Decant from centrifuge and distillate from extruder-evaporator
9. Centrifuge feed tank and spent resin slurry feed tank
10. Fuel pool filter-demineralizer.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications.

14.1.3.2.31 Plant Process Sampling System (Reactor) Preoperational Test

a. Test Objective - To verify the operation of the plant process sampling system (reactor), including sampling valves, isolation valves, pumps, motors, heat exchangers, and related equipment

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedures and the initiation of testing. The required support systems (control air, demineralized water, emergency equipment service water [EESW], and RBCCWS) must have readiness verification

c. General Test Method - Verification of the plant process sampling system (reactor) is demonstrated by the proper, integrated operation of the following:

1. Sampling lines and valve, automatic isolation valves, and the related sensors and indicators
2. Annunciators.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications. The ability of the system to draw samples from the reactor building equipment must be demonstrated.

14.1.3.2.32 Plant Process Sampling System (Turbine) Preoperational Test

a. Test Objective - To verify the operation of the plant process sampling system (turbine) including sampling valves, pressure regulators and reliefs, flow meter, monitor and recorder, pumps valve controls, and lights

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedures and the initiation of testing. Required support systems (demineralized water, turbine building closed cooling water system [TBCCWS], RBCCWS, condensate, circulating water, and condensate polishing demineralizer) must have readiness verification

c. General Test Method - Verification of the plant process sampling system (turbine) is demonstrated by the proper, integrated operation of the following:

   1. Sample lines pressure regulators, relief valves, and temperature baths

   2. Related sensors and indicators

   3. Condenser sample pump and motor

   4. Solenoid valve controls and indicator lights.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications. The ability of the system to draw samples from the turbine building equipment must be demonstrated.

14.1.3.2.33 Turbine Building Closed Cooling Water System Preoperational Test

a. Test Objective - To verify the operation of the TBCCWS, including pumps and associated motors, heat exchangers, makeup tank, valves, and instrumentation and control

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. The related support systems (condensate storage, and control air) must have readiness verification

c. General Test Method - Verification of the TBCCWS is demonstrated by the proper, integrated operation of the following:

   1. Pumps, motors, and associated controls, interlocks, and alarms

   2. Automatic makeup to head tank, and all control valve operation

   3. System flow through all heat exchangers and coolers

   4. Annunciators.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications. However, no attempt will be made to simulate design heat loads or design flow rates through the various coolers and heat exchangers.

14.1.3.2.34 Reactor Building Closed Cooling Water System Preoperational Test

a. Test Objective - To verify the operation of the RBCCWS, including pumps and associated motors, heat exchangers, makeup tank, valves, and instrumentation and control

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. The related support systems (condensate storage and control air) must have readiness verification

c. General Test Method - Verification of the RBCCWS capability is demonstrated by the proper, integrated operation of the following:

   1. Pumps, motors, and associated controls, interlocks, and alarms
   2. System flow through all heat exchangers and coolers
   3. Annunciators.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications. However, no attempt will be made to simulate design heat loads or design flow rates through the various coolers and heat exchangers.

14.1.3.2.35 Emergency Equipment Cooling and Service Water System Preoperational Test

a. Test Objective - To verify the operation of the emergency equipment cooling water (EECW) system, including pumps and motors, heat exchangers, makeup tanks, valves, and instrumentation and control

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. The related support systems (condensate storage, RBCCW, RHR service water system, RHR cooling towers, RHR reservoir, and control air) must have readiness verification

c. General Test Method - Verification of the EECW system is demonstrated by the proper, integrated operation of the following:

   1. Pumps, motors, and associated controls, interlocks, and alarms
   2. Automatic makeup to makeup tank, and control valve operation
   3. System flow through all heat exchangers and coolers
   4. Annunciators
   5. EECW pumps automatic start logic

6. Automatic isolation of nonessential RBCCW system cooling loads from the EECW system loads.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications. However, no attempt will be made to simulate design heat loads or design flow rates through the various coolers and heat exchangers.

14.1.3.2.36 Station and Control Air System Preoperational Test

a. Test Objective - To verify the operation of the station and control air systems, including station air compressors and their related motors and controls, aftercoolers and air receivers, control air compressors and their related motors and controls, and air drying equipment

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. The related support systems (the TBCCW and RBCCW) must have readiness verification

c. General Test Method - Verification of the station and control air system capability is demonstrated by the proper, integrated operation of the following:

1. Station air compressors and their motors and related controls, including loading and unloading
2. Aftercoolers, moisture separators, air receivers, and related solenoid-operated valves
3. Control air compressors and their related motors and automatic start loading and unloading controls
4. Air dryers and desiccant purge system blower, heater, and heat exchanger
5. Annunciators
6. System pressure decay test on noninterruptible control air.

d. Acceptance Criteria

1. All system components must be either verified for proper operation, or demonstrated to be within their respective engineering design specifications
2. Preoperational testing of the control air system is in accordance with Regulatory Guide 1.80 (June 1974).

14.1.3.2.37 Fire Protection System Preoperational Test

a. Test Objective - To verify the operation of the fire protection system, including normal and emergency water supplies, heat and smoke detection equipment and alarms, carbon dioxide systems, and Halon systems

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. The general service water (GSW) system must have readiness verification. Prior to test of the transformer deluge systems, upstream manual valves are closed

c. General Test Method - Verification of the fire protection system capability is demonstrated by the proper, integrated operation of the following:

1. Motor-driven fire pump and related automatic startup controls and alarms
2. Diesel-driven fire pump and related diesel automatic startup controls, alarms, automatic battery selector, and engine cooling water
3. Deluge and sprinkler systems solenoid valves and their related alarms and detectors
4. Main control room smoke detectors and alarms
5. Turbine building heat and smoke vents, outbuildings smoke and fire detectors, and diesel generator building smoke and fire detectors
6. Annunciators.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications.

14.1.3.2.38 Auxiliary Electrical Power System Preoperational Test

Contained in the auxiliary electrical power system are two engineered safety feature (ESF) load divisions (load groups), which are totally independent of one another. Within each division are two ESF power trains that can be tested individually without affecting the other train's buses or emergency diesel generator (EDG). The two divisions can be tested independently without affecting the alternate division's buses, EDGs, or redundant equipment. The tests are designed to prove the operability of the redundant systems and the availability of onsite power sources beyond l0 sec and to ensure proper loading for each EDG. The independence of divisions and redundancy of load groups will be verified to meet the requirements of Regulatory Guide 1.41 in the ECCS integrated test.

a. Test Objective - To verify the operation of the 4.16-kV/480-V ac power systems, including bus ties, transformers, switchgear, and related controls for

1. Load group assignments
2. Full load capability
3. Loss of offsite power.

b. Prerequisites - The checkout and initial operations tests have been completed, and the TRC has reviewed and approved the test procedure and the initiation of testing. The offsite l3.8-kV (l20-kV) and 345-kV preferred power supply sources must have readiness verification

c. General Test Method - Verification of the 4.l6-kV/480-V ac power systems is demonstrated by the proper, integrated operation on a divisional basis of the following:

1. 13.8-kV (120-kV) and 345-kV system service transformers and related controls
2. 13.8-kV source breaker and related controls
3. 4.16-kV buses and related controls
4. 4.16-kV tie breakers and related controls
5. 4.16-kV/480-V unit substations, including transformers
6. 480-V buses and related controls
7. 480-V motor control centers (MCCs) and related controls
8. 480-V load breakers and related controls
9. Load shedding - loss of offsite power and LOCA
10. Load sequencer operation
11. Annunciators.

Actual loading of the EDGs will be performed in the EDG system preoperational test (refer to Subsection 14.1.3.2.39)

d. Acceptance Criteria - All system components must be verified for proper load group assignment. All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications.

14.1.3.2.39 Emergency Diesel Generator System Preoperational Test

a. Test Objective - To verify the proper operation of the EDG system under all design test conditions. The testing will include diesel engines, related support equipment and controls; generators, related electrical switchgear and load-shedding devices; safety devices and alarms

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. The related support systems (the RHRSW and emergency diesel generator service water [EDGSW] system, EDG room ventilation system, auxiliary electrical system, 130/260-V dc system) must have readiness verification

c. General Test Method

1. Loss of Offsite Power - Simulate loss of offsite power and verify that the EDG system starts automatically
2. Loss of Offsite Power and LOCA - Simulate loss of offsite power and a LOCA condition and verify the proper operation of the load sequencer
3. Full-Load Test - Parallel the EDG to the offsite system and demonstrate operation for 2 hr at the 2-hr rating for the EDGs and continue operation for an additional 22 hr at the continuous rated load of the EDG

4. Hot Condition Test - Following the full-load test, repeat the loss of offsite power and LOCA test

5. Load Shed Test - Verify that voltage limits and overspeed limits are not reached when testing the loss of RHR pumps load and loss of complete rated load

6. Simulate Recovery - Verify that the EDG can be synchronized with offsite power to restore it to standby status, following the loss of offsite power tests, while the unit is connected to the emergency load

7. Reliability Test - Demonstrate 23 consecutive successful tests consisting of a manual start and load to 50 percent of continuous rating.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications; automatic startup and total load-carrying capability under emergency conditions must be demonstrated similarly.

14.1.3.2.40 120-V AC Instrument and Control Power System Preoperational Test

There are six l20-V ac instrument and control power supply systems. Three are located in each redundant electrical division; one from each division is used for ESF equipment. The tests are designed to prove the independence of the load groups of each instrument and control supply, to the requirements of Regulatory Guide 1.41.

a. Test Objective - To verify the operation of the l20-V ac instrument and control power system, including regulators, transformers, automatic switchgear, and related controls

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. The system supply transformers, transfer switches, and regulators must have readiness verification

c. General Test Method - Verification of the 120-V ac instrument and control power system capability is demonstrated by the proper, integrated operation of the following:

1. System supply transformers

2. Automatic transfer switchgear and respective controls

3. Regulators

4. Annunciators.

d. Acceptance Criteria - All system components must be verified for proper load group assignment. They must be either verified for proper operation or demonstrated to be within their respective engineering design specifications.

14.1.3.2.41 130/260-V DC Power System Preoperational Test

The 130/260-V dc power system consists of two divisional redundant and one balance-of-plant (BOP) 130/260-V battery charger load group combinations. The divisional dc systems used for ESF loads are redundant and independent of each other and of the BOP dc system.

The tests are designed to prove the independence of the systems and their load groups and to verify the supply and operability of the required load throughout the entire designed battery load period during the design-basis event. This includes verification of the operability of Class 1E dc loads that are required to operate at reduced battery voltage conditions. The requirements of Regulatory Guide 1.41 for the two divisional 130/260-V dc power systems for redundancy and load group assignment will be verified in the integrated ECCS test.

a. Test Objective - To verify the operation of the 130/260-V dc power system, including batteries, battery chargers, distribution panels, ground detectors, and alarms

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. The ac supply power, batteries, and system components must have readiness verification

c. General Test Method - Verification of the 130/260-V dc power system is demonstrated by the proper, integrated operation of the following:

   1. Battery chargers: 480-V ac-130-V dc, and related controls
   2. Batteries
   3. Ground detectors
   4. DC power distribution panels
   5. Annunciators.

d. Acceptance Criteria - Required system components must be verified for proper operation at the reduced dc system voltage encountered when they are required to operate or must have been qualification-tested previously to a lower voltage. Total battery capacities under specified discharge rates must be demonstrated similarly.

14.1.3.2.42 24/48-V DC Power System Preoperational Test

There are two, independent 24/48-V dc power systems. Each system can be tested independently without affecting the other. The tests are designed to prove their ability to perform as designed. The requirements of Regulatory Guide 1.41, for independence and proper load group assignment, are verified in the integrated ECCS preoperational test.

a. Test Objective - To verify the operation of the 24/48-V dc power system, including batteries, battery chargers, distribution panels, and alarms

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. The ac supply power, batteries, and system components must have readiness verification

c. General Test Method - Verification of the 24/48-V dc power system is demonstrated by the proper, integrated operation of the following.

   1. Battery chargers: 120-V ac-24-V dc, and their 480/120-V ac supply transformers
   2. Batteries
   3. DC power distribution panels, including under-voltage relays
   4. Annunciators.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications; total battery capacities under specified discharge rates must be demonstrated similarly.

14.1.3.2.43 Primary Containment Leak Rate Preoperational Test

a. Test Objective - To determine the leak rates of the primary containment, containment penetrations, MSIVs, and the drywell to suppression pool vacuum breakers

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. Permanent plant air supply or a portable air compressor with filters and valves, pressure and temperature sensors, flow meters, and soap bubble and ultrasonic leak detection equipment must be available. Functional tests of isolation valves described in the nuclear boiler preoperational test (14.1.3.2.6) and vacuum breakers described in the containment vacuum breakers preoperational test (14.1.3.2.66) must be completed

c. General Test Method - Leak rates are determined by leak rate testing of the following:

   1. Local leak rate test of primary containment penetrations
   2. Local leak rate test of primary containment isolation valves and each torus to reactor building vacuum breaker and isolation valve
   3. Local leak rate tests of the MSIV
   4. Overall containment integrated leakage
   5. Integrated leakage test - drywell to suppression pool.

d. Acceptance Criteria - All leak rates from penetrations, valves, and overall containment must be shown to be within the limits specified in 10 CFR 50, Appendix J. Leakage from the drywell to suppression pool vacuum breakers shall be within the limits specified in the Technical Specifications.

14.1.3.2.44 Reactor Building Crane Preoperational Test

a. Test Objective - To verify the operation of the reactor building crane to design load

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing

c. General Test Method - Verification of the reactor building crane is demonstrated by the proper, integrated operation of the following:

   1. Limit switches
   2. Interlocks
   3. Motors and their related controls
   4. No-load, full-load, and overload conditions tests.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications, at both no-load and overload conditions.

14.1.3.2.45 Reactor Building Heating and Ventilation System Preoperational Test

a. Test Objective - To verify the operation of the reactor building heating and ventilation system, including filters, heaters, supply and exhaust fans, essential cooling coil units, and controls

b. Prerequisites - The checkout and initial pperations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing

c. General Test Method - Verification of the reactor building heating and ventilation system is demonstrated by the proper, integrated operation of the following:

   1. Fresh air intake louvers and filters
   2. Air intake heater and controls
   3. Supply and exhaust air fans and their related motors and controls
   4. Secondary containment isolation logic
   5. System shutoff and modulating dampers
   6. Annunciators
   7. Essential cooling coil units
      (a) ECCS pump rooms
      (b) Control center air conditioning system (CCACS) equipment room
      (c) Thermal recombiner cubicles

(d) Control air compressor areas

(e) EECWS equipment areas

(f) SGTS rooms

(g) Essential switchgear rooms

(h) Essential battery rooms.

8. Reactor building booster exhaust fans

9. Reactor building unit heaters.

d. Acceptance Criteria - All system components including air flow balancing must be either verified for proper operation or demonstrated to be within their respective engineering design specifications.

14.1.3.2.46 Main Control Room Heating, Ventilation, and Air Conditioning Systems Preoperational Test

a. Test Objective - To verify the operation of the main control room heating, ventilation, and air conditioning (HVAC) systems and their related heaters, chillers, fans, chlorine detection, and radiation monitoring response action and controls

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. The related support systems (the RBCCW, and control air) must have readiness verification

c. General Test Method - Verification of the main control room HVAC systems is demonstrated by the proper, integrated operation of the following:

1. Refrigeration compressors, condensers, and evaporators

2. Chilled water pump and motor and associated controls

3. Chiller control panel and thermostatic controls

4. Cooling coils and fans

5. Multizone air conditioners, including electronic air cleaners, filters, heaters, and coolers, humidifiers, and all related thermostats, humidistats, and controls

6. Indicating lights and alarms

7. Emergency recirculation fans and motors, and filters

8. All air-operated valves and dampers

9. Return air fans and related controls

10. Deleted

11. Annunciators

12. Deleted

13. Radiation monitoring response action
14. CCACS equipment room.

d. Acceptance Criteria - All system components including air flow balancing must be either verified for proper operation or demonstrated to be within their respective engineering design specifications.

14.1.3.2.47 Standby Gas Treatment System Preoperational Test

a. Test Objective - To verify the operation of the SGTS, including system exhaust fans, decay heat removal fans, filters, air heaters, charcoal adsorber unit, isolation valves, and their controls

b. Prerequisites - The checkout and initial operation tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. The control air system must have readiness verification

c. General Test Method - Verification of the SGTS is demonstrated by the proper, integrated operation of the following:

1. Exhaust fans and their related motors and controls
2. Decay heat removal fans and their related motors and controls
3. Charcoal adsorber carbon dioxide fire protection system
4. Air heater and its controls
5. Charcoal adsorber heater and controls
6. Alarms and annunciators.

d. Acceptance Criteria

1. All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications
2. Preoperational testing is in accordance with Regulatory Guide l.52 (June l973), Regulatory Position, C5b, C5c, and C6.

14.1.3.2.48 Drywell Cooling System Preoperational Test

a. Test Objective - To verify the operation of the drywell cooling system, including coolers, blowers, motors, and related logic and controls. Heat load performance of the system is checked during the startup test program

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing

c. General Test Method - Verification of the drywell cooling system capability is demonstrated by the proper, integrated operation of the following:

1. Cooling coils and flow balance valves

2. Cooling fans and their motors and related controls
3. Motor logic circuitry and protective features
4. Annunciator alarms.

d. Acceptance Criteria - All system components including air flow balancing must be either verified for proper operation or demonstrated to be within their respective engineering design specifications.

14.1.3.2.49 Primary Containment Atmosphere Control Preoperational Test

a. Test Objective - To verify the operation of the primary containment atmosphere control system, including nitrogen inerting, purging, primary containment pneumatic supply, and pressure control systems

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. The auxiliary steam system must have readiness verification

c. General Test Method - Verification of the primary containment atmosphere control system capability is demonstrated by the proper, integrated operation of the following:

1. Nitrogen storage tank pressure valve and controller, pressure relief valves, and instrumentation
2. Electric vaporizer and pressure buildup coil
3. Automatic pneumatic supply line containment isolation valves, sensors, and controls
4. Primary containment pneumatic supply isolation valves, controls, and interlocks
5. Temperature control and valve controllers
6. Nitrogen receivers pressure monitors and alarms
7. Steam vaporizer and controls
8. Primary containment purging valves, controls, and interlocks
9. Primary containment pressure control valves, makeup valves, vent valves, and controls
10. Annunciators.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications.

14.1.3.2.50 Primary Containment Monitoring System Preoperational Test

a. Test Objective - To verify the operation of the primary containment monitoring system, including valves, monitoring sensors and channels, and temperature, pressure, and level monitors

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing

c. General Test Method - Verification of the primary containment monitoring system capability is demonstrated by the proper, integrated operation of the following:

   1. Isolation valves and sample pumps

   2. Primary containment atmosphere monitoring system, including filters, detectors, recorders and meters, alarms, and channels

      (a) Hydrogen-oxygen subsystem, including analyzers, recorders, and alarms

      (b) RMS, including gaseous detector and related monitoring, recording, and annunciating equipment.

   3. Temperature, pressure, and level subsystems, including pressure transmitters and recorders, thermocouples and recorders, and level transmitters and recorders.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications.

14.1.3.2.51 Secondary Containment Leak Rate Preoperational Test

a. Test Objective - To measure the secondary containment leak rate

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. The SGTS and reactor building heating and ventilation system must have readiness verification

c. General Test Method - Verification of the secondary containment boundary integrity is demonstrated by the leak rate testing of the overall secondary containment

d. Acceptance Criteria

   1. The ability of the SGTS to maintain the design negative pressure under containment isolation conditions must be demonstrated

   2. The SGTS must be able to draw down the secondary containment pressure to -0.25 in. of water under accident conditions within 10 minutes.

14.1.3.2.52 Turbine Building Heating and Ventilation System Preoperational Test

a. Test Objective - To verify the operation of the turbine building heating and ventilation system, including filters, heaters, supply and exhaust fans, and related controls

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing

c. General Test Method - Verification of the turbine building heating and ventilation system capability is demonstrated by the proper, integrated operation of the following:

   1. Fresh air intake louvers, filter, heater, and controls
   2. Supply and exhaust air fans and their related motors and controls
   3. Booster fan and propeller fans and their motors and controls
   4. System shutoff and modulating dampers
   5. Condensate return tanks and condensate return pumps and their related controls and interlocks
   6. Offgas adsorber room air conditioning units and controls
   7. Turbine building unit heaters.

d. Acceptance Criteria - All system components including air flow balancing must be either verified for proper operation or demonstrated to be within their respective engineering design specifications.

14.1.3.2.53 Radwaste Building Heating and Ventilation System Preoperational Test

a. Test Objective - To verify the operation of the heating and ventilation system for the radwaste building, Health Physics lab, and radwaste control room

b. Prerequisites - The checkout and initial operations tests have been completed, and the TRC has reviewed and approved the test procedure and the initiation of testing. The related support systems (the auxiliary steam, control air, and condensate makeup demineralizer) must have readiness verification

c. General Test Method - Verification of the heating system is demonstrated by the proper, integrated operation of the following:

   1. Radwaste building supply and exhaust fans, steam heater, chiller, and associated controls and interlocks
   2. Health Physics lab and radwaste control room supply and exhaust fans, heater and chiller, and associated controls and interlocks
   3. Health Physics lab fume hood exhaust fan and controls
   4. Radwaste building battery room air conditioning unit

5. Radwaste building booster exhaust fans
6. Radwaste building unit heaters.

d. Acceptance Criteria - All system components including air flow balancing must be either verified for proper operation or demonstrated to be within their respective engineering design specifications.

14.1.3.2.54 Communication and Evacuation Alarm System Preoperational Test

a. Test Objective - To verify the operation of the communication and evacuation alarm system, including the two-way radio, hi-com, telephone, hard-wired headset, and emergency alarm

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing

c. General Test Method - Verification of the communication and evacuation system capability is demonstrated by the proper, integrated operation of the following:

1. Two-way radio system, including base station, monitor receivers, selected portable transmitter/receivers, and base station speaker
2. Hi-com, including amplifiers, speakers, microphones, tone generator, signal relays, and control switches
3. System Supervisor's system
4. Hard-wired headset system and selected headsets
5. Emergency alarm system and alarm devices.

d. Acceptance Criteria - All permanently installed system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications. Proper operation of portable components (headsets and transceivers) will be by random sample and documented in the preoperational test.

14.1.3.2.55 Seismic Monitoring System Preoperational Test

a. Test Objective - To verify the operation of the seismic monitoring system, including accelerometers and recorders

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing

c. General Test Method - Verification of the seismic monitoring system capability is demonstrated by the proper integrated operation of the following:

1. Triaxial accelerometers
2. Signal conditioners and magnetic tape recorders

3. Seismic trigger and logic
4. Strip-chart recorder
5. Alarm circuits and annunciators
6. Batteries.

d. Acceptance Criteria - All system components must either be verified for proper operation or demonstrated to be within their respective engineering design specifications. Accelerometer signal input is simulated with a signal generator.

14.1.3.2.56 Residual Heat Removal Complex Heating and Ventilation System Preoperational Test

a. Test Objective - To verify the operation of the RHR complex heating and ventilation system, including heaters, supply fans, and instrumentation and controls

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing

c. General Test Method - Verification of the RHR complex heating and ventilation system is demonstrated by the proper, integrated operation of the following:

1. Diesel generator room, switchgear room and pump room fans, motors, and related controls and logic
2. Pump room temperature monitor and fan logic
3. Unit heaters and controls.

d. Acceptance Criteria - All system components including air flow balancing must be either verified for proper operation or demonstrated to be within their respective engineering design specifications.

14.1.3.2.57 Residual Heat Removal Complex Service Water Systems Preoperational Test

a. Test Objective - To verify the operation of the RHRSW, EESW, and EDGSW systems, including pumps, fans, motors, cooling towers, and valves

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing

c. General Test Method - Verification of the RHR complex service water systems capability is demonstrated by the proper, integrated operation of the following:

1. RHRSW, EDGSW, and EESW pumps, motors, controls, and logic
2. RHRSW, EDGSW, and EESW pumps at minimum submergence level without vortexing
3. RHRSW, DGSW, and EESW pumps for 100 hr at rated flow

4. Pump minimum flow valves to tower basin
5. Cooling tower fans, motors, and controls, and spray nozzles
6. Cooling tower control valves
7. Pressure sensors, indicators, and annunciators.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications; no attempt is made to simulate design heat loads.

14.1.3.2.58 Condensate Makeup Demineralizer System Preoperational Test

a. Test Objective - To verify operation of the condensate makeup demineralizer system including pumps, motors, demineralizers, storage tanks, controls, interlocks, and alarms

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. The related support systems (the control air, potable water, and auxiliary steam systems) must have readiness verification

c. General Test Method - Verification of the condensate makeup demineralizer system capability is demonstrated by the proper, integrated operation of the following:

1. System pumps, motors, and the related automatic controls, interlocks, and safety devices
2. Demineralizer train alarms, stops, interlocks, and automatic controls
3. Acid and caustic storage tanks automatic controls, and heating; demineralized water tank controls
4. Annunciators.

d. Acceptance Criteria - All system components must be verified for proper operation and shown to be within their respective engineering design specifications.

14.1.3.2.59 General Service Water System Preoperational Test

a. Test Objective - To verify the operation of the GSW system, including GSW pumps and motors, traveling screens, circulating water reservoir makeup pumps and motors, and GSW pump strainers with motors, valves, and instrumentation and control

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing

c. General Test Method - Verification of the GSW system capability is demonstrated by the proper, integrated operation of the following:

1. GSW pumps, motors, and their controls, interlocks, and alarms
2. Traveling screens, motors, and their controls, interlocks, and alarms
3. Circulating water reservoir makeup pumps, motors, and controls
4. GSW pump strainer controls
5. Annunciators.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications; however, no attempt is made to simulate design heat loads or design flow rate through the various heat exchangers until nuclear steam is available.

14.1.3.2.60 Circulating Water System Preoperational Test

a. Test Objective - To verify the operation of the circulating water system, including pumps and motors, chemical subsystems, cooling towers, and screens

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. The GSW and control air systems must have readiness verification

c. General Test Method - Total system performance cannot be verified until full-power operation. Functional verification of the circulating water system is demonstrated by the proper operation of the following:

1. Circulating water pumps and related motors, pump and motor cooling, discharge valve operation, automatic controls and trips
2. Cooling tower isolation and bypass valves
3. Reservoir decanting pumps and related controls and interlocks
4. Chemical injection equipment
5. Annunciators.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications. Heat load performance is deferred until the power test program.

14.1.3.2.61 Offgas System Preoperational Test

a. Test Objective - To verify the operation of the offgas system, including pumps, motors, fans, gas treatment equipment, and instrumentation and control

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. Demineralized water and control air systems must have readiness verification

c. General Test Method - Verification of the offgas system capability is demonstrated by the proper, integrated operation of the following:

1. All motor-operated pumps, compressors, and fans and their related controls and logic
2. System instrumentation
3. System valves
4. Annunciators
5. Demonstrate offgas system gas-handling ability by introducing control air into the system at rated flow
6. Krypton gas test to verify design delay time.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications. The Krypton gas test will verify design delay time.

14.1.3.2.62 Main Turbine Electro-Hydraulic Control System Preoperational Test

a. Test Objective - To verify the operation of the electrohydraulic control (EHC) system, including speed governor equipment, reactor pressure control equipment valves, and instrumentation and control

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. Turbine cannot be tested until nuclear steam is available, but functional verification is performed. The EHC system and hydraulic fluid cooling system must have readiness verification

c. General Test Method - Verification of the EHC system is demonstrated by the proper, integrated operation of the following:

1. Hydraulic fluid pumps, motors, and their controls; fluid test valve; and fluid heaters, coolers, fans, and their respective controls, alarms, and annunciators
2. Stop valves, control valves, intercept valves, and bypass valves opening, closing, and logic
3. Wide-range runup control
4. Onload testing of turbine valves
5. Narrow-range speed governor and reactor pressure control equipment (using signal generator).

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications.

14.1.3.2.63 Thermal Recombiner System Preoperational Test

a. Test Objective - To verify the operation of the thermal recombiner system, including reaction chamber, separator, blower, related valves, and instrumentation and control

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. No attempt is made to simulate design heat loads

c. General Test Method - Verification of the thermal recombiner system capability is demonstrated by the proper, integrated operation of the following:

   1. Blower and controls
   2. Heater chamber and controls
   3. Reaction chamber and controls
   4. Water spray cooler and separator
   5. Instrumentation, valves, and annunciators.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications.

14.1.3.2.64 System Vibration and Expansion Preoperational Test

a. Test Objective - To verify proper installation and load adjustment of the piping support system, and to verify that fluid systems and their supports are not subject to excessive deflections and vibrations caused by normal and abnormal hydrodynamic transients

b. Prerequisites - The checkout and initial operations tests for the affected systems have been completed and the TRC or Onsite Review Organization (OSRO) has reviewed and approved the test procedure and the initiation of testing. The specific system tested must have readiness verification

c. General Test Method - Verification of acceptable performance is demonstrated by the following tasks:

   1. Check all hangers and snubbers for proper position and load indication after the system is filled with fluid or drained as appropriate to the system service
   2. Check for abnormal deflection or sag of piping
   3. Conduct vibration surveys during system operation and record and evaluate deflection and vibration data. A detailed discussion of the vibration operational test program is presented in Subsection 3.9.1.1. Table 3.9-1 presents a list of the systems to be tested. Certain vibration surveys will be performed after fuel load as part of the startup test program.

d. Acceptance Criteria - The piping system and its support system must be verified to be within established engineering design limits. The detailed acceptance criteria are provided in Subsection 3.9.1.1.

14.1.3.2.65 Primary Containment, Secondary Containment, and Auxiliary Building Equipment Drains and Floor Drains Preoperational Test

a. Test Objective - To verify the operation of the isolation valves in the drain lines that interconnect the two corner rooms of each division located in the subbasement

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. The sump pumps in the reactor building and primary containment must have readiness verification

c. General Test Method - The proper operation of the floor drains is demonstrated by closure of the valves in the floor drain and equipment drain lines that interconnect the corner rooms

d. Acceptance Criteria - All flood control isolation valves shall be verified to close on hi-hi sump water level.

14.1.3.2.66 Containment Vacuum Breakers Preoperational Test

a. Test Objective - To verify the proper adjustment and operation of the containment vacuum breakers, including the drywell-to-torus and torus-to-reactor building vacuum breakers and the torus-to-reactor building isolation valves. (Individual vacuum breaker leakage is measured as part of the primary containment leak-rate preoperational test)

b. Prerequisites - The Checkout and Initial Operations Tests have been completed as required, and the TRC has reviewed and approved the test procedure and the initiation of testing

c. General Test Method - Verification of the vacuum breaker functionability is demonstrated by the following:

   1. Opening force tests on each vacuum breaker

   2. Operability tests of the vacuum breakers using the air operators

   3. Measurement of the close switch setpoint gap on the vacuum breakers

   4. Operability tests on the torus-to-reactor building isolation valves.

d. Acceptance Criteria - During operability tests, valve closing times, position indicating instrumentation, and the torus-to-reactor building isolation valve opening differential pressure meet the respective engineering design specifications. The vacuum breaker opening force measurement is less than the equivalent force exerted by the design opening differential pressure. The opening gap at the close switch setpoint is adjusted to less than, or equal to, 0.03 in.

14.1.3.2.67 Emergency Lighting System Preoperational Test

The emergency lighting system is designed to provide minimum adequate lighting during loss of normal lighting. The tests are designed to prove the independence of load groups of the emergency lighting system. The tests are designed to meet the requirements of Regulatory Guide l.4l.

a. Test Objective - To verify the operation of the emergency lighting system, including transformers, automatic transfer switchgear, and the related controls

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing. The system supply transformers, automatic transfer switches, and dc systems must have readiness verification

c. General Test Method - Verification of the emergency lighting system capability is demonstrated by the proper, integrated operation of the following:

   1. System supply transformers
   2. Automatic transfer switchgear and respective controls
   3. The lighting fixtures
   4. Annunciators.

d. Acceptance Criteria - All system components must be verified for proper load group assignment. All system components must be either verified for proper operation, or demonstrated to be within their respective engineering design specifications.

14.1.3.2.68 Personnel Monitoring, Survey Instruments, and Laboratory Equipment Preoperational Test

a. Test Objective - To verify proper operation of personnel monitoring, survey instruments, and the laboratory equipment

b. Methodology - Site procedures of chemistry and health physics are used to preoperationally test and verify the proper operation of personnel monitoring, survey instruments, and the laboratory equipment described in Section 12.3. This testing is performed by chemistry and health physics personnel. Test results are reviewed by group supervisors and maintained as a plant record. This program is described in the Plant Operating Manual and is audited by Quality Assurance. Although this program is somewhat different from other preoperational tests, the intent of Regulatory Guide 1.68 is fulfilled.

14.1.3.2.69 Reactor System Hydrostatic Preoperational Test

a. Test Objective - The test objective is to demonstrate the pressure-retaining integrity of the RPV and all connecting piping welds out to, and including, the welds connecting the first isolation valve in each connecting pipe

b. Prerequisites - The checkout and initial operations tests have been completed as necessary, and the TRC has reviewed and approved the test procedure and the initiation of testing. The related support system must be operable

c. General Test Method - The RPV hydrostatic test includes heatup, pressurization, inspection, and depressurization requirements

d. Acceptance Criteria - The test demonstrates zero leakage at all welded connections at test pressure.

14.1.3.2.70 Main Steam Line Isolation Valve Leakage Control System Preoperational Test

a. Test Objective - To verify the operation of the MSIV leakage control system, including controls, instrumentation, and all active components

b. Prerequisites - The checkout and initial operations tests have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing

c. General Test Method - Verification of system capability is demonstrated by the proper, integrated operation of the following:

1. System logic, interlocks, and timers
2. All valves and related controls and instrumentation, including the pressure regulators
3. Pressure and flow monitoring devices
4. Local and remote indication
5. Proper system response to the loss of each of the leakage control system air supplies
6. Proper system response will be functionally tested by manual initiation of each division using the applicable Plant Operating Procedure under conditions that simulate actual service conditions.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications.

14.1.3.2.71 Reactor Internals Flow-Induced Vibration Preoperational Test

a. Test Objective - To detect damage or excessive wear, loose parts, or other unacceptable vibration that could result from assembly errors or undesirable deviation from the previously qualified prototype plant. The test is performed consistent with the requirements of Regulatory Guide 1.20

b. Prerequisites - The reactor recirculation system must have readiness verification. Core support structures and components, fuel support castings, surveillance specimen holders and specimens, jet pumps, spargers, shroud head, steam separator, and reactor vessel head are installed during the flow test.

Temporary hardware is removed, and control rod blades either removed or fully redrawn

The core matrix must be empty; fuel assemblies, incore instrumentation tubes, and neutron source rods are not installed

c. General Test Method - Prior to the recirculation system flow excitation testing, a preliminary, internal, visual inspection of the vessel and components takes place. All or part of this inspection is by normal, visual fabrication inspection. After the preliminary visual inspections, the reactor recirculation system is operated at rated volumetric core flow for a minimum of 35 hr. Each reactor recirculation loop is operated independently for a minimum of 14 hr. The flow testing sequence is not important as long as the above flow conditions, totaling a minimum of 63 hr, are accumulated at some time between the preflow and postflow vessel internal inspection

   Following completion of the flow testing, a reactor vessel water sample taken at bottom vessel drain line will be examined for wear products. The vessel will be drained, and the areas examined in the preflow inspection examined again

d. Acceptance Criteria - There must be no evidence of defects, loose parts, or wear resulting from the flow test. Flush cloths used for the bottom vessel drain sample must show no more than a slight particle speckling. Results of the vibration test are submitted to the NRC in accordance with Regulatory Guide 1.20.

14.1.3.2.72 Remote Shutdown Preoperational Test

a. Test Objective - To verify that systems to be used during a shutdown operation from outside the control room at the remote shutdown panel are operable in the manner in which they would be used during a shutdown

b. Prerequisites - The checkout and initial operations tests for the systems associated with the remote shutdown panel have been completed and the TRC has reviewed and approved the test procedure and the initiation of testing for each affected individual system

c. General Test Method - Verification of remote shutdown capability is demonstrated by the proper operation of the following:

   1. Individual system or component preoperational tests associated with the remote shutdown panel

   2. Each valve, pump, and logic that is controlled from the remote shutdown panel

   3. Instruments at the remote shutdown panel displaying plant parameters

   4. Annunciator alarms.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their engineering design specifications. Operation of all valves and pumps must be satisfactory. Analog instruments at the remote shutdown panel displaying plant parameters must mimic the corresponding main control room instruments.

14.1.3.2.73 Torus Water Management System Preoperational Test

a. Test Objective - To verify the operation of the torus water management system (TWMS), including pumps, valves, and controls and instrumentation

b. Prerequisites - The checkout and initial operations tests have been completed, and the TRC has reviewed and approved the test procedure and initiation of testing. The condenser must be available and ready to receive water. The torus must be available and contain water

c. General Test Method - Verification of TWMS capability is demonstrated by the proper, integrated operation of the following:

   1. Alarm and logic verification

   2. Pump performance and functional tests.

d. Acceptance Criteria - All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications; a total system operational capability must also be demonstrated.

14.1.3.2.74 Postaccident Sampling System Preoperational Test

a. Test Objective - The purpose of this test is to demonstrate proper operation of the postaccident sampling system. Specific objectives are to demonstrate the following:

   1. The ability to obtain a gas or liquid sample from the correct sample source

   2. The proper operation of the sample system control logic, including interlocks

   3. The proper operation of the sample panel graphic display lights.

b. Prerequisites - The checkout and initial operations tests have been completed, and the TRC has reviewed and approved the test procedure and the initiation of testing. The required support systems RHR system, reactor recirculation system, and RBCCWS must have readiness verification

c. General Test Method - Verification of the postaccident sampling system is demonstrated by the proper, integrated operation of the following.

   1. Sampling lines and sample isolation valves

   2. All sensing devices

   3. All motor-, solenoid-, and nitrogen-operated valves in the control panel, sample station, and piping station

   4. All control logic and interlocks

   5. Gas sample chiller

6. Gas sample heat tracing
7. All indicator lights and annunciators.

In addition, all cask and sample vial positioners shall be operated to verify ability to align with the sample station and to perform their functions in obtaining the desired liquid or gas sample.

d. Acceptance Criteria

1. All system components must be either verified for proper operation or demonstrated to be within their respective engineering design specifications
2. The postaccident sampling system shall be capable of obtaining both a gas and a liquid sample.

14.1.4 Fuel Load and Initial Operation - Startup Test Phase

At the time of fuel loading, the preoperational test results for all completed tests were approved by the TRC, and access control was established, and the startup test phase began. The startup test phase begins with preparation for fuel loading and extends to the completion of the warranty demonstration. This phase is subdivided into the following four parts:

a. Fuel loading and open vessel tests
b. Initial heatup
c. Power tests
d. Warranty demonstration.

This section describes each of the parts of the startup test phase, the tests to be conducted and their sequence, the administrative methods to be used for procedure and test control, and the functions of the Edison Startup Test Phase Group. Normal plant personnel responsibilities, authorities, and qualifications are given in Chapter 13. The startup test phase and all associated testing activities adhere closely to Regulatory Guide 1.68, "Preoperational and Initial Startup Test Programs for Water-Cooled Power Reactors."

The overall objectives of the startup test phase are as follows:

a. To achieve an orderly and safe initial core loading
b. To perform all testing and measurements necessary to determine that the approach to initial criticality and the subsequent power ascension are accomplished safely and orderly
c. To conduct low-power physics tests sufficient to ensure that physics design parameters have been met
d. To conduct initial heatup and hot functional testing so that hot integrated operation of all systems is shown to meet design specifications
e. To conduct an orderly and safe power ascension program, with requisite physics and systems testing, to ensure that the plant operating at power meets design intent

f. To conduct a successful warranty demonstration program.

Tests conducted during the startup test phase consist of major plant transients, stability tests, and a remainder of tests that are directed toward demonstrating correct performance of the nuclear boiler and numerous auxiliary plant systems while at power. Certain tests may be identified with more than one part of the startup test phase. Table 14.1-1 shows a general view of the startup test phase program and should be considered in conjunction with Figure 14.1-2, which shows, graphically, the various test areas as a function of core thermal power and flow.

14.1.4.1 Fuel Loading and Open Vessel Tests

Fuel loading began when the preoperational testing program described in Subsection l4.l.3 had been completed to the maximum extent practical and when the TRC and the augmented OSRO approved the initial fuel loading.

14.1.4.2 Initial Heatup

The heatup testing phase has been completed at Fermi 2. All required tests were completed successfully. A more detailed discussion of the testing performed during this period is given in the test abstracts (Subsection 14.1.4.8), which were applicable for this phase of testing.

14.1.4.3 Power Tests

Many of the tests of the power test phase are repeated several times at different test levels. Table 14.1-1 and Figure 14.1-2 show, in general, the planned order of execution for the full series of tests.

Coolant chemistry tests and radiation surveys are made at each principal test level to preserve a safe and efficient power increase. The effect of control rod movement on other parameters (e.g., electrical output, steam flow, and neutron flux level), is examined for different power conditions. Following the first reasonably accurate heat balance, the APRMs and IRMs are readjusted if necessary.

At major power levels, the LPRMs and APRMs are calibrated. Completion of the process computer checkout is made for all variables, and the various options are compared with independent calculations as soon as significant power levels are available. Further tests of the RCIC and the HPCI systems are made with and without injection into the RPV.

Collection of data from the system expansion tests is completed for those piping systems that had not previously reached full operating temperatures. The axial and radial power profiles are explored fully by means of the TIP system at representative power levels during power ascension.

Core performance evaluations are made at selected test points above the 10 percent power level; the work involves the determination of core thermal power, maximum linear heat generation rate, and minimum critical power ratio (MCPR).

Overall plant stability in relation to minor perturbations is shown by the following group of tests:

a. Pressure regulator setpoint change

b. Pressure regulator failure

c. Feedwater system setpoint change

d. Flow control setpoint change.

The category of major plant transients includes full closure of all the MSIVs, fast closure of turbine generator control/stop valves, loss of the main generator and offsite power, feedwater system heating loss, trip of a feedwater pump, and a recirculation pump trip. The plant transient behavior is recorded for each test, and the results are compared with the predicted design performance.

A test is made of the safety/relief valves (SRVs) in which leaktightness and general operability are demonstrated. At selected major power levels, the jet pump flow instrumentation is calibrated. The local control loop performance, based on the drive motor, fluid coupler, generator, drive pump, jet pumps, and control equipment, is checked. Vibration testing is conducted at several power conditions as the operating power level is raised.

Heat load performance of certain fluid and ventilation systems is demonstrated. These systems were tested previously during the preoperational test phase to demonstrate their operability and their ability to meet safety criteria, but could not be tested for heat load performance until normal plant operating conditions were available. The demonstration of heat load performance includes tuning of system controls and base line data acquisition for future performance evaluation. These continuations of preoperational tests will be treated, for administrative control purposes, as separate tests conducted in parallel with the startup tests.

14.1.4.4 Warranty Demonstration

The warranty test phase consists of a demonstration in which the steaming rate and steam quality are shown to comply with contractual obligations. This demonstration includes a 100-hr full-power run.

14.1.4.5 Startup Test Procedure Preparation, Approval, and Modification

Startup Test Procedures are prepared by Edison or their designated agents. These procedures are based on GE-supplied Startup Test Specifications and other source documents. Draft startup test procedures are reviewed by the Edison Startup Test Phase Group, then submitted to the augmented OSRO for review and approval.

Minor modifications to the approved procedures can be made if the modification does not change the intent of the test. The responsible Startup Test Phase Engineer and an Edison Senior Reactor Operator (SRO) can provide approval of the minor modifications. Minor changes are handled administratively in a manner similar to normal plant procedures as described in Section 13.5.

Major modifications to the approved procedures are those that change the intent of the startup test or that will change safety margins already approved. Such proposed modifications must undergo review and approval of the augmented OSRO prior to test performance. Major changes to procedures required after the start of testing necessitate a halt of the test until the augmented OSRO reviews and approves the proposed major modifications. If Startup Test Specification Level 1 Criteria are involved in the major change, the GE Site Operations Manager may be required to obtain approval of the intended change from GE Engineering.

14.1.4.6 Startup Test Execution

Startup test performance and supervision is the responsibility of the Startup Test Phase Engineer and plant personnel who obtain technical direction, where applicable, from the GE Operations Shift Engineers and Test Design and Analysis Shift Test Engineers. Startup Test Phase Engineers are assigned to follow startup tests on a shift basis.

All startup tests are performed according to approved startup test procedures.

14.1.4.7 Startup Test Results Approval and Approvals for Power Escalation

All startup tests are documented by the responsible Startup Test Phase Engineer. The test report is reviewed by the Startup Engineer - Test phase or his delegate before submittal to the augmented OSRO and Plant Manager for approval.

During startup testing, many of the tests are repeated several times at different test levels or test conditions. These test conditions are used for convenience to define the basic plant conditions of core power and core flow.

The sequence in which each test condition must be performed is shown below. An exception to this sequence is Test Condition 4, which may be conducted any time after the completion of Test Condition 3.

Individual tests within each test condition may be performed in any desired sequence. However, all testing within each test condition must be completed before proceeding to the next test condition except for justifiable exceptions approved by the augmented OSRO and Plant Manager.

Most of the test conditions are shown in terms of reactor power versus core flow on Figure 14.1-2. The test condition designations and sequence are further defined as follows:

<u>Test Conditions</u>

a. Pre fuel-load tests, fuel-load tests, and open vessel tests
b. Heatup testing
c. Test Condition 1
d. Test Condition 2
e. Test Condition 3
f. Test Condition 4 (may be performed at any time following Test Condition 3)
g. Test Condition 5
h. Test Condition 6 and warranty run tests.

Prior to initiating each test condition, the augmented OSRO reviews the test results of the previous test condition. It determines that the results are adequate and present no safety hazards to personnel, equipment, or the general public, and that any test exceptions have been properly dispositioned. The augmented OSRO presents its findings and recommendations to the Plant Manager. The Plant Manager, when satisfied that the test results are proper and that the conditions required for the next test condition of startup testing are available, will give approval to advance in the testing sequence.

14.1.4.8 General Discussion of Startup Tests

The startup test program is specified on the following pages. The general sequence planned can be obtained from Table 14.1-1. Start at the left side of the page and move to the right. The sequence of tests in a column is as follows:

a. Core performance analysis

b. Steady-state testing

c. Control system tuning

d. Major transients.

In describing the objectives of a test, an attempt is made to identify those operating and safety-oriented characteristics of the plant which are being explored.

Where applicable, a definition of the relevant acceptance criteria for the test is given and is designated either Level l or Level 2. A Level 1 criterion normally relates to the value of a process variable assigned in the design of the plant, component systems, or associated equipment. If a Level 1 criterion is not satisfied, the plant will be placed in a suitable hold-condition until resolution is obtained. Tests compatible with this hold- condition may be continued. Following resolution, applicable tests must be repeated to verify that the requirements of the Level 1 criterion are now satisfied.

A Level 2 criterion is associated with expectations relating to the performance of systems. If a Level 2 criterion is not satisfied, operating and testing plans would not necessarily be altered. The measurements and analytical techniques used for the predictions would be investigated.

Acceptance criteria values presented in the following test descriptions will be verified against the approved Technical Specifications prior to Startup Test Procedure performance. Where differences exist, the Technical Specifications shall take precedence.

A detailed and specific startup test procedure is written for each of the startup tests. The startup test procedure is the document which provides detailed instruction for each test when performed by the test personnel. A list of the startup tests presently planned, together with subsection sequence for use in locating a particular test discussion, follows.

STARTUP TESTS

Subsection	Test Title
14.1.4.8.1	Chemical and Radiochemical

STARTUP TESTS

Subsection	Test Title
14.1.4.8.2	Radiation Measurements
14.1.4.8.3	Fuel Loading
14.1.4.8.4	Full Core Shutdown Margin
14.1.4.8.5	Control Rod Drive System
14.1.4.8.6	Source Range Monitor Performance and Control Rod Sequence
14.1.4.8.7	Water Level Reference Leg Temperature Measurement
14.1.4.8.8	Intermediate Range Monitor Performance
14.1.4.8.9	Local Power Range Monitor Calibration
14.1.4.8.10	Average Power Range Monitor Calibration
14.1.4.8.11	Process Computer
14.1.4.8.12	Reactor Core Isolation Cooling System
14.1.4.8.13	High Pressure Coolant Injection System
14.1.4.8.14	Selected Process Temperatures
14.1.4.8.15	System Expansion
14.1.4.8.16	(Not Applicable)
14.1.4.8.17	Core Performance
14.1.4.8.18	Steam Production (Deleted)
14.1.4.8.19	(Not Applicable)
14.1.4.8.20	Pressure Regulator
14.1.4.8.21	Feedwater System
14.1.4.8.22	Turbine Valve Surveillance
14.1.4.8.23	Main Steam Isolation Valves
14.1.4.8.24	Relief Valves
14.1.4.8.25	Turbine Stop Valve and Control Valve Fast Closure Trips
14.1.4.8.26	Shutdown From Outside the Control Room
14.1.4.8.27	Flow Control
14.1.4.8.28	Recirculation System

STARTUP TESTS

Subsection	Test Title
14.1.4.8.29	Loss of Turbine-Generator and Offsite Power
14.1.4.8.30	Steady-State Vibration
14.1.4.8.31	Recirculation System Flow Calibration
14.1.4.8.32	Reactor Water Cleanup System
14.1.4.8.33	Residual Heat Removal System
14.1.4.8.34	Piping System Dynamic Response Testing

14.1.4.8.1 Chemical and Radiochemical

Purpose

The principal objectives of this test are to secure information on the chemistry and radiochemistry of the reactor coolant, and to determine that the sampling equipment, procedures, and analytic techniques are adequate to supply the data required to demonstrate that the chemistry of all parts of the entire reactor system meet specifications and process requirements.

Specific objectives of the test program include evaluation of fuel performance, evaluations of filter-demineralizer operations by direct and indirect methods, confirmation of condenser integrity, demonstration of proper steam separator-dryer operation, measurement and calibration of the offgas system, and calibration of certain process instrumentation. Data for these purposes are secured from a variety of sources: plant operating records, regular routine coolant analysis, radiochemical measurements of specific nuclides, and special chemical tests.

Description

Prior to fuel loading, a complete set of chemical and radiochemical samples is taken to ensure that all sample stations are functioning properly, and to determine initial concentrations. Subsequent to fuel loading, during reactor heatup and at each major power level change, samples are taken and analyzed to determine the chemical and radiochemical quality of primary coolant, the amount of radiolytic gas in the steam, gaseous activities leaving the air ejectors, decay times in the offgas lines, and performance of filter-demineralizers. Calibrations are made on monitors in the stack, liquid waste system, and liquid process lines.

Criteria

Level 1

Chemical factors defined in the Technical Specifications and Fuel Warranty must be maintained within the limits specified. The activity of gaseous and liquid effluents must conform to license limitations. Water quality must be known at all times and remain within the guidelines of the Water Quality Specifications.

Level 2

Not applicable.

14.1.4.8.2 Radiation Measurements

Purpose

The purposes of this test are to determine the background radiation levels in the plant environs prior to operation for base data on activity buildup, and to monitor radiation at selected power levels to ensure the protection of personnel during plant operation.

Description

A survey of natural background radiation throughout the plant site is made prior to fuel loading. Subsequent to fuel loading, during reactor heatup and at major levels during the initial power ascension program, gamma radiation level measurements, and, where appropriate, thermal and fast neutron dose-rate measurements, are made at significant locations throughout the plant. All potentially high radiation areas are surveyed.

Criteria

Level 1

The radiation doses of plant origin and the occupancy times of personnel in radiation zones shall be controlled consistent with the guidelines of the standards for protection against radiation outlined in 10 CFR 20, "Standards for Protection Against Radiation," and NRC General Design Criteria.

Level 2

Not applicable.

14.1.4.8.3 Fuel Loading

Purpose

The purpose of this test is to load fuel safely and efficiently to the full core size.

Description

Prior to fuel loading, control rods and neutron sources and detectors are installed and tested. Fuel loading begins at the center of the core and proceeds radially to the fully loaded configuration. Control rod functional tests, subcriticality checks, and shutdown margin demonstrations are performed periodically during the loading.

Criteria

Level 1

The partially loaded core must be subcritical by at least 0.38 percent $\Delta k/k$ with the analytically determined strongest rod fully withdrawn.

Level 2

Not applicable.

14.1.4.8.4 Full Core Shutdown Margin

Purpose

The purpose of this test is to demonstrate that the reactor is subcritical throughout the first fuel cycle with any single control rod fully withdrawn.

Description

This test is performed in the fully loaded core in the Xenon-free condition. The shutdown margin is measured by withdrawing the control rods until criticality is reached. If criticality is not reached with in-sequence control rods in the configuration corresponding to the required shutdown margin reactivity, the shutdown margin is satisfied. Additional in-sequence control rods are then withdrawn until the reactor is critical. The difference between the measured K_{eff} and the calculated K_{eff} for the in-sequence critical will be applied to the calculated shutdown margin to obtain the true shutdown margin.

Criteria

Level 1

The shutdown margin of the fully loaded core with the analytically determined strongest rod withdrawn must be at least 0.38 percent $\Delta k/k$ plus an additional margin for exposure.

Level 2

Criticality should occur within ±1.0 percent $\Delta k/k$ of the predicted critical.

14.1.4.8.5 Control Rod Drive System

Purpose

The purposes of the CRD system test are to demonstrate that the CRD system operates properly over the full range of primary coolant temperatures and pressures from ambient to operating, and to determine the initial operating characteristics of the entire CRD system.

Description

The CRD tests performed during the open vessel, heatup, and power test parts of the startup test program are designed as an extension of the tests performed during the preoperational CRD system tests. Thus, after it is verified that all CRDs operate properly when installed, they are tested periodically during heatup to ensure that there is no significant binding caused by thermal expansion of the core components. A list of all CRD tests to be performed during startup testing is given in Table 14.1-2.

Criteria

Level 1

Each CRD must have a normal withdrawal speed less than, or equal to, 3.6 in./sec, indicated by a full 12-ft stroke in greater than, or equal to, 40 sec. The mean scram time of all operable

CRDs with functioning accumulators must not exceed the following times (scram time is measured from the time the pilot scram valve solenoids are deenergized).

Position Inserted From Fully Withdrawn	Scram Time (sec)
46	0.358
36	1.096
26	1.860
06	3.419

The mean scram time of the three fastest CRDs in a two-by-two array must not exceed the following times (scram time is measured from the time the pilot scram valve solenoids are deenergized):

Position Inserted From Fully Withdrawn	Scram Time (sec)
46	0.379
36	1.161
26	1.971
06	3.624

Level 2

Each CRD must have a normal insertion or withdrawal speed of 3.0 ± 0.6 in./sec, indicated by a full 12-ft stroke in 40 to 60 sec. With respect to the CRD friction tests, if the differential pressure variation exceeds 15 psid for a continuous drive-in, a settling test must be performed. In this case, the differential settling pressure should not be less than 30 psid, nor should it vary by more than 10 psid over a full stroke.

14.1.4.8.6 Source Range Monitor Performance and Control Rod Sequence

Purpose

The purpose of this test is to demonstrate that the operational sources, source range monitor (SRM) instrumentation, and rod withdrawal sequences provide adequate information to achieve criticality and increase power in a safe and efficient manner. The effect of typical rod movements on reactor power will be determined.

Description

The operational neutron sources will be installed and SRM count rate data will be taken during rod withdrawals to critical and compared with stated criteria on signal and signal count-to-noise count ratio. A withdrawal sequence has been calculated that completely specifies control rod withdrawals from the all-rods-in condition to the rated power configuration.

Movement of rods in a prescribed sequence is monitored by the rod worth minimizer (RWM) and rod sequence control system (RSCS), which will prevent out-of-sequence withdrawal. Also, not more than two rods may be inserted out of sequence. As the withdrawal of each rod group is completed through Test Condition 1 (see Figure 14.1-2), the electrical power, steam flow, control valve position, and average power range monitor (APRM) response are recorded.

Criteria

Level 1

There must be a neutron signal count-to-noise count ratio of at least 2:1 on the required operable SRMs or fuel-loading chambers. The minimum count rate, as defined by the Technical Specifications, must be met on the required operable SRMs or fuel-loading chambers.

Level 2

Not applicable.

14.1.4.8.7 Water Level Reference Leg Temperature Measurement

Purpose

The purpose of this test is to measure the reference leg temperature and recalibrate the instruments if the measured temperature is different from the value assumed during the initial calibration.

Description

To monitor the reactor vessel water level, four level instrument systems are provided. These are the following:

a. Shutdown (floodup) range

b. Narrow range

c. Wide range

d. Fuel (core level) range.

These systems are used, respectively, as follows:

a. Water level measurement, cold shutdown conditions

b. Feedwater flow and water level control functions, hot operating conditions

c. Safety functions, hot operating conditions

d. Safety functions, postaccident conditions.

This test will be done at rated temperature and pressure and under steady-state conditions and will verify that the reference leg temperatures of the instruments are the values assumed during initial calibration. If not, the instruments will be recalibrated using the measured value.

Criteria

Level 1

Not applicable.

Level 2

The difference between the actual reference leg temperature(s) and the value(s) assumed during initial calibration shall be less than that amount that will result in a scale endpoint error of 1 percent of the instrument span for each range.

14.1.4.8.8 Intermediate Range Monitor Performance

Purpose

The purpose of this test is to adjust the intermediate range monitor system (IRMS) to obtain an optimum overlap with the SRM and APRM systems.

Description

Initially, the IRM system is set to maximum gain. After the APRM calibration, the IRM gains are adjusted to optimize the IRM overlap with the SRMs and APRMs.

Criteria

Level 1

Each IRM channel must be on scale before the SRMs exceed their rod block setpoint. Each APRM must be on scale before the IRMs exceed their rod block setpoint.

Level 2

Not applicable.

14.1.4.8.9 Local Power Range Monitor Calibration

Purpose

The purpose of this test is to calibrate the LPRM system.

Description

The LPRM channels are calibrated to make the LPRM readings proportional to the neutron flux in the LPRM water gap at the chamber elevation. Calibration factors are obtained through the use of either an off-line or a process computer calculation that relates the LPRM reading to average fuel assembly power at the chamber height.

Criteria

Level 1

Not applicable.

Level 2

Each LPRM reading will be within 10 percent of its calculated value.

14.1.4.8.10 Average Power Range Monitor Calibration

Purpose

The purpose of this test is to calibrate the APRM system.

Description

Generally a heat balance is made each shift and after each major power level change. Each APRM channel reading is adjusted to be consistent with the core thermal power as determined from the heat balance. During heatup, a preliminary calibration is made by adjusting the APRM amplifier gains so that the APRM readings agree with the results of a constant heatup rate heat balance. The APRMs will be recalibrated in the power range by a heat balance as soon as adequate feedwater indication is available.

Criteria

Level 1

The APRM channels must be calibrated to read equal to, or greater than, the actual core thermal power. Technical Specification and fuel warranty limits on APRM scram and rod block shall not be exceeded. In the startup mode, all APRM channels must produce a scram at less than, or equal to, 15 percent of rated thermal power. Recalibration of the APRM system is not necessary from a safety standpoint if at least two APRM channels per RPS trip circuit have readings greater than, or equal to, core power.

Level 2

If the above criteria are satisfied, then the APRM channels will be considered to be reading accurately if they agree with the heat balance to within (+7, -0) percent of rated power.

14.1.4.8.11 Process Computer

Purpose

The purpose of this test is to verify the performance of the process computer under plant operating conditions.

Description

Computer system program verifications and calculational program validations at static and at simulated dynamic input conditions are tested preoperationally at the computer supplier's site and following delivery to the plant site. Following fuel loading, during plant heatup, and the ascension to rated power, the nuclear steam supply system (NSSS) and the balance-of-plant (BOP) system process variables sensed by the computer as digital or analog signals will become available. Verify that the computer is receiving correct values of sensed process variables, and that the results of performance calculations of the NSSS programs are correct. At steady-state power conditions the Dynamic System Test Case will be performed.

Criteria

Level 1

Not applicable.

Level 2

Programs OD-1, P1, and OD-6 are considered operational when

a. The MCPR calculated by the BUCLE computer code and the process computer either

    1. Are in the same fuel assembly and do not differ in value by more than 2 percent, or

    2. For the case in which the MCPR calculated by the process computer is in a different assembly than that calculated by the BUCLE code, for those two assemblies, the MCPR and the critical power ratio (CPR) calculated by the two methods shall agree within 2 percent.

b. The maximum linear heat generation rate calculated by the BUCLE code and the process computer either

    1. Are in the same fuel nodes and do not differ in value by more than 2 percent, or

    2. For the case in which the maximum linear heat generation rate calculated by the process computer is in a different node than that calculated by the BUCLE code, for those two nodes, the maximum linear heat generation rate and the linear heat generation rate calculated by the two methods shall agree within 2 percent.

c. The maximum average planar linear heat generation rate calculated by the BUCLE code and the process computer either

    1. Are in the same fuel nodes and do not differ in value by more than 2 percent, or

    2. For the case in which the maximum average planar linear heat generation rate calculated by the process computer is in a different node than that calculated by the BUCLE code for those two nodes, the maximum average planar linear heat generation rate and the average planar linear heat generation rate calculated by the two methods shall agree within 2 percent.

d. The local power range monitor system gain adjustment factors calculated by BUCLE and the process computer agree to within 2 percent.

The remaining programs will be considered operational on the successful completion of the static and dynamic testing.

14.1.4.8.12 Reactor Core Isolation Cooling System

Purpose

The purpose of this test is to verify the proper operation of the reactor core isolation cooling (RCIC) system over its expected operating pressure range.

Description

The RCIC system test consists of two parts: injection to the CST and injection to the reactor vessel.

The CST injections consist of manual and automatic mode starts at 150 psig and near rated reactor pressure conditions. The pump discharge pressure during these tests is throttled to be 100 psi above reactor pressure. The initial testing is for demonstrating operability and making initial controller adjustments. This is followed by vessel injections beginning with cold RCIC hardware. Cold is defined as a minimum of 3 days without any kind of RCIC operation.

The vessel injections verify the adequacy of the startup transient and also include steady-state controller adjustments. Two consecutive vessel injections starting from cold conditions and with the same equipment settings are necessary to demonstrate system reliability.

After final controller settings are determined, CST injections are done with initially cold RCIC equipment. These runs provide a benchmark for future surveillance testing.

A demonstration of an extended operation of 30 minutes of continuous running or until the pump and turbine oil temperature is stabilized, is scheduled at a convenient time during the test program.

Criteria

Level 1

The average pump discharge flow must be equal to, or greater than, 100 percent-rated value after 50 sec have elapsed from initiation on all auto start at any reactor pressure between 150 psig and rated. With pump discharge at any pressure between 250 psig and 100 psi above rated pressure, the required flow is 600 gpm. (The 100 psi is a conservatively high value for line losses. The measured value may be used if available.)

The RCIC turbine shall not trip or isolate during auto or manual starts. If any Level 1 criteria are not met, the reactor will be allowed to operate only up to a restricted power level defined in the Startup Test Procedure.

Level 2

The turbine gland seal condenser system shall be capable of preventing steam leakage to the atmosphere. The DP switch for the RCIC steam supply line high-flow isolation trip shall be adjusted to actuate at 300 percent of the maximum required steady-state flow, with the reactor assumed to be near the pressure for main relief valve actuation. For small speed or flow changes in either manual or automatic mode, the decay ratio of each recorded RCIC system variable must be less than 0.25.

To provide a margin on the overspeed trip and isolation, the first and subsequent speed peaks on the transient start shall not exceed the rated speed of the RCIC turbine by more than 5 percent.

14.1.4.8.13 High Pressure Coolant Injection System

Purpose

The purpose of this test is to verify the proper operation of the high pressure coolant injection (HPCI) system over its expected operating pressure range.

Description

The HPCI system test consists of two parts: injection to the CST and injection to the reactor vessel.

The CST injections consist of manual and automatic starts at 150 psi and at rated reactor pressure. The pump discharge pressure during these tests is throttled to 100 psi above reactor pressure. The initial testing is for demonstrating operability and making initial controller adjustments. This is followed by vessel injections beginning with cold HPCI hardware. Cold is defined as a minimum of 3 days without any kind of HPCI operations.

The vessel injections verify the adequacy of the startup transient and also include steady-state controller adjustments. Two consecutive vessel injections starting from cold conditions with the same equipment settings are necessary to demonstrate system reliability.

After final controller settings are determined, CST injections are done with initially cold HPCI equipment. These runs provide a benchmark for future surveillance testing.

A demonstration of an extended operation of 30 minutes of continuous running or until pump and turbine oil temperature is stabilized, is scheduled at a convenient time during the test program.

Criteria

Level 1

The average pump discharge flow must be equal to, or greater than, the 100 percent-rated value with a system response time of less than or equal to 30 sec as defined in the Technical Specifications at any reactor pressure between 150 psig and rated. With pump discharge at any pressure between 250 psig and 100 psi above rated pressure, the flow should be at least 5000 gpm. (The 100 psi is a conservatively high value for line losses. The measured value may be used if available.) The HPCI turbine shall not trip or isolate during auto or manual starts.

Level 2

The turbine gland seal condenser system shall be capable of preventing steam leakage to the atmosphere. The delta P switch for the HPCI steam supply line high flow isolation trip shall be adjusted to actuate at 300 percent of the maximum required steady-state flow with reactor assumed to be near the pressure for main relief valve actuation. For small speed or flow changes in either manual or automatic mode, the decay ratio of each recorded HPCI system variable must be less than 0.25.

The margin to avoid the overspeed trip shall be at least 10 percent of the nominal overspeed trip setpoint of 5000 rpm during all auto starts of the HPCI system.

14.1.4.8.14 Selected Process Temperatures

Purpose

The purposes of this procedure are to establish the proper setting of the low speed limiter for the recirculation pumps to avoid coolant temperature stratification in the reactor pressure vessel (RPV) bottom head region, to provide assurance that the measured bottom head drain temperature corresponds to bottom head coolant temperature during normal operations, and to identify any reactor operating modes that cause temperature stratification.

Description

During initial heatup while at hot-standby conditions, the bottom drain line temperature, recirculation loop suction temperature, and applicable reactor parameters are monitored as the recirculation pump flow is slowly lowered to minimum stable flow. The parameters above are recorded during pump trips as well. The effects of cleanup flow, CRD flow, and power level are investigated as operational limits allow. Utilizing these data, it can be determined if coolant temperature stratification occurs when the recirculation pumps are on and if so, what minimum pump speed will prevent it. A comparison of recirculation loop coolant temperature with bottom drain line temperature when core flow is 100 percent will be performed.

Criteria

Level 1

The reactor recirculation pumps shall not be started nor flow increased unless the coolant temperatures between the steam dome and bottom head drain are within 145°F. The recirculation pump in an idle loop must not be started, active loop flow must not be raised, and power must not be increased unless the idle loop suction temperature is within 50°F of the active loop suction temperature. If two pumps are idle, the loop suction temperature must be within 50°F of the steam dome temperature before pump startup.

Level 2

During operation of two recirculation pumps at rated core flow, the bottom head temperature as measured by the bottom drain line thermocouple should be within 30°F of the recirculation loop temperatures.

14.1.4.8.15 System Expansion

Purpose

The purpose of this procedure is to verify that major piping of the NSSS and related auxiliary systems is free and unrestrained with regard to thermal expansion, and to verify that the thermal movement of the piping and associated support system components is consistent with the analytical predictions of the piping system stress analyses.

Description

Observations and/or recordings of the thermal expansion movements of key points on the piping of the NSSS and related auxiliary systems are made as the piping systems are brought initially from ambient to operational temperature. The points ordinarily chosen to be monitored will be those points in each piping system that are expected to exhibit relatively large thermal deflections and/or experience large thermally induced stresses, as predicted by the piping system stress analysis.

Pipe position will be recorded or logged at the ambient, intermediate, and maximum expected temperature points described above.

One or more of the following methods of monitoring piping system thermal movement will be employed, depending on practicality and accessibility limitations:

a. Actual observation of piping system thermal behavior by a member or delegate of the Edison Startup Group

b. Installation of local mechanical recording devices (scratch or dial gages)

c. Installation of remote-indicating movement measuring devices (linear variable differential transformers and Lanyard potentiometers) used in conjunction with suitable indicating/recording instruments installed in accessible locations.

Extent of Testing

The piping systems subjected to thermal expansion test verification are listed in Table 3.9-1. Detailed discussion concerning thermal expansion testing is presented in Subsection 3.9.1.1.

Criteria

Acceptance criteria for this test are presented in Subsection 3.9.1.1.5.

14.1.4.8.16 (Not Applicable)

14.1.4.8.17 Core Performance

Purpose

a. To evaluate the core thermal power

b. To evaluate the following core performance parameters:

   1. Maximum linear heat generation rate (MLHGR)

   2. Minimum critical power ratio (MCPR)

   3. Maximum average planar linear heat generation rate (MAPLHGR).

Description

The core performance evaluation is employed to determine the principal thermal and hydraulic parameters associated with core behavior. These parameters are

a. Core flow rate

b. Core thermal power level

c. MLHGR

d. MCPR

e. MAPLHGR.

Those core performance parameters listed are evaluated as described below.

a. Core flow rate is read from the total core flow recorder in the control room, and a correction curve is used if necessary. During some transients, core DP will be used as an indication of core flow

b. Core thermal power is determined from a detailed reactor heat balance

c. The MLHGR is determined using the LPRM system, axial power distribution information, and calculated fuel assembly local power distribution information

d. The value of MAPLHGR in the core shall be restricted to the limits given in the Technical Specifications

e. The MCPR of a fuel assembly depends on the fuel assembly flow, the total fuel assembly power, the fuel assembly average exposure, the core inlet subcooling, and the fuel assembly peak axial power factor and location.

Criteria

Level 1

The MLHGR during steady-state conditions shall not exceed the allowable heat flux as specified in the Technical Specifications.

The steady-state MCPR shall be maintained greater than, or equal to, the value specified in the Technical Specifications.

The MAPLHGR shall not exceed the limits given in the Technical Specifications.

Steady-state reactor power shall be limited to full rated maximum values on or below the design flow control line.

Core flow should not exceed its rated value.

Level 2

Not applicable.

14.1.4.8.18 Steam Production (Deleted)

This subsection has been deleted because the test is performed only for warranty demonstration purposes unrelated to safety. The test will be conducted as a demonstration test.

14.1.4.8.19 (Not Applicable)

14.1.4.8.20 Pressure Regulator

Purpose

a. To determine the optimum settings for the pressure control loop by analysis of the transients induced in the reactor pressure control system by means of the pressure regulators

b. To demonstrate the takeover capability of the backup pressure regulator on failure of the controlling pressure regulator and to set spacing between the setpoints at an appropriate value

c. To demonstrate smooth pressure control transition between the control valves and bypass valves when the reactor generates more steam than is used by the turbine.

Description

The pressure setpoint is decreased rapidly and then increased rapidly by up to 10 lb/in.^{2}, and the response of the system will be measured in each case. It is desirable to accomplish the setpoint change in less than 1 sec. At specified test conditions, the load limit setpoint is set so that the transient is handled by control valves, bypass valves, or both. The backup regulator is tested by simulating a failure of the operating pressure regulator so that the backup regulator takes over control. The response of the system is measured and evaluated and regulator settings are optimized. The matrix of test mode and conditions is tabulated below.

		Test Condition Number				
Mode	Input	1	2	3	5	6
CV	Setpoint	No	Yes	Yes	Yes	Yes
CV	Fail to back up	No	Yes	Yes	No	Yes
BPV	Setpoint	Yes	Yes	No	Yes	Yes
BPV	Fail to back up	Yes	Yes	No	No	Yes
	Recirc. modes	Manual	Manual	Manual	Manual	Manual

Criteria

Level 1

The decay ratio must be less than 1.0 for each process variable that exhibits oscillatory response to pressure regulator changes.

Level 2

In all tests the decay ratio must be less than or equal to 0.25 for each process variable that exhibits oscillatory response to pressure regulator changes when the plant is operating above the lower limit setting of the master flow controller.

Pressure control deadband, delay, etc., shall be small enough for steady-state limit cycles, if any, to produce turbine steam flow variations no larger than 0.5 percent of rated flow.

During the simulated failure of the controlling pressure regulator along the 100 percent rod line (Figure 14.1-2), if the setpoint of the backup pressure regulator is optimally set, the backup regulator shall control the transient so that the peak neutron flux or peak vessel pressure remains below the scram settings by 7.5 percent and 10 lb/in.^{2}, respectively.

After a pressure setpoint adjustment, the time between the setpoint change and the occurrence of the pressure peak shall be 10 sec or less. (This applies to pressure setpoint changes made with the recirculation system in the master or local manual control mode.)

14.1.4.8.21 Feedwater System

Purpose

a. To adjust the feedwater control system for acceptable reactor water level control

b. To demonstrate stable reactor response to subcooling changes

c. To demonstrate the capability of the automatic core flow runback feature to prevent low water level scram following the trip of one feedwater pump

d. To demonstrate adequate response to feedwater heating loss

e. To determine the maximum feedwater runout capability.

Description

Reactor water level setpoint changes of approximately 3 to 6 in. will be used to evaluate and adjust the feedwater control system settings for all power and feedwater pump modes. The level setpoint changes will also demonstrate core stability to subcooling changes. One of two operating feedwater pumps will be tripped and the automatic flow runback circuit will act to drop power to within the capacity of the remaining pump. The worst single- failure case of feedwater temperature loss will be performed and the resulting transients recorded between 80 and 90 percent power and near full core flow rate. Data will be taken between 50 and 100 percent power to allow determination of the maximum feedwater runout capability.

Criteria

Level 1

The response of any level-related variable to any test input change, or disturbance, must not diverge during the setpoint changes.

For the feedwater temperature loss test, the maximum feedwater temperature decrease due to a single-failure case must be less than or equal to 100°F. The resultant MCPR must be greater than the fuel thermal safety limit.

For the feedwater temperature loss test, the increase in simulated heat flux cannot exceed the predicted Level 2 value by more than 2 percent. The predicted value will be based on the actual test values of feedwater temperature change and power level.

The feedwater flow runout capability must not exceed the assumed value in the FSAR.

Level 2

Level control system-related variables may contain oscillatory modes of response. In these cases, the decay ratio for each controlled mode of response must be less than or equal to 0.25, as a result of the setpoint change testing.

A scram must not occur from low water level following a trip of one of the operating feedwater pumps. There should be a greater than 3-in. water-level margin to scram for the feedwater pump trip.

For the feedwater temperature loss test, the increase in simulated heat flux cannot exceed the predicted value referenced to the actual feedwater temperature change and power level, which will be taken from the Transient Safety Analysis Design Report.

The average rate of response of the feedwater actuator to large (>20 percent of pump flow) step disturbances shall be between 10 to 25 percent of pump rated feedwater flow per second. This average response rate will be assessed by determining the time required to pass linearly through the 10 percent and 90 percent response points of the flow transient.

The dynamic flow response of each feedwater actuator (turbine or valve) to small (<10 percent) step disturbances shall be the following:

a. Maximum time to 10 percent of a step disturbance ≤1.1 sec

b. Maximum time from 10 to 90 percent of a step disturbance ≤1.9 sec

c. Peak overshoot (percentage of step disturbance) ≤15 percent.

14.1.4.8.22 Turbine Valve Surveillance

Purpose

To demonstrate acceptable procedures and maximum power levels for surveillance testing of the main turbine control and stop valves without producing a reactor scram.

Description

Individual main turbine control and stop valves are tested routinely during plant operation as required for turbine surveillance testing. At several test points, the response of the reactor is observed and the maximum possible power level for performance of these tests along the 100 percent load line established.

First actuation should be between 45 and 65 percent power, and be used to extrapolate to the next test point between 70 and 95 percent power and, ultimately, to the maximum power test condition, with ample margin to scram. Note proximity to APRM flow bias scram point. Each valve test is manually initiated and reset. The rate of valve stroking and the timing of the close-open sequence is such that the minimum practical disturbance is introduced.

If it is later decided to do bypass valve surveillance testing at power (present plans are to test these valves only when the plant is shut down), then these valves will be tested in the same manner as described above for control and stop valves.

Criteria

Level 1

Not applicable.

Level 2

Peak neutron flux must be at least 7.5 percent below the scram trip setting. Peak vessel pressure must remain at least 10 $lb/in.^2$ below the high-pressure scram setting. Peak heat flux must remain at least 5.0 percent below its scram trip point.

Peak steam flow in the high-flow lines must remain 10 percent below the high-flow isolation trip setting.

14.1.4.8.23 Main Steam Isolation Valves

Purpose

a. To check functionally the main steam line isolation valves (MSIVs) for proper operation at selected power levels

b. To determine reactor transient behavior during and after simultaneous full closure of all MSIVs

c. To determine isolation valve closure time.

Description

At selected power levels, both slow and fast single-valve closure is performed. A test of the simultaneous full closure of all MSIVs is performed at a level greater than or equal to 95 percent of rated thermal power. Should an inadvertent full closure of the MSIVs occur at a lower power level (≥70 percent), credit may be taken for this test if supporting analysis shows that the results can be extrapolated to the higher power condition. Correct performance of the RCIC (if L2 is reached) and relief valves is shown. Reactor process variables are monitored to determine the transient behavior of the system during and following the main steam line (MSL) isolation.

The MSIV closure times are determined from the MSL isolation data by multiplying the time increment between deenergizing the solenoids and actuation of the MSIV closed light by an extrapolation factor. The extrapolation factor will correct the time obtained to that of full closure and will be calculated for each MSIV based on previous, direct measurement data of valve full stroke length and actual position indicating switch actuation points.

The times to be determined are (a) the time from deenergizing the solenoids until the valve is 100 percent closed (t_{sol}) and (b) the valve stroke time (t_s). Time t_{sol} equals the interval from deenergizing the solenoids until the valve reaches 90 percent closed plus 1/8 times the interval from 10 to 90 percent closure. Time t_s equals the interval from when the valve starts to move until it is 100 percent closed and is based on the interval from 10 to 90 percent closure and linear valve travel from 0 to 100 percent closure.

Criteria

Level 1

The MSIV stroke time (t_s) shall be no faster than 3.0 sec (average of the fastest valve in each steam line) and for any individual valve 2.5 sec $\leq t_s \leq$ 5 sec. Total effective closure time for any individual MSIV shall be t_{sol} plus the maximum instrumentation delay time and shall be ≤5.5 sec.

The positive change in vessel dome pressure occurring within 30 sec after the simultaneous full closure of all MSIVs must not exceed the Level 2 criteria by more than 25 psi. The positive change in simulated heat flux shall not exceed the Level 2 criteria by more than 2 percent of rated value.

Flooding of the main steam lines shall not occur following the full MSIV closure test.

The reactor must scram during the full simultaneous MSIV closure test to limit the severity of the neutron flux and simulated fuel surface heat flux transient.

Level 2

During full closure of individual valves, peak vessel pressure must be at least 10 psi below scram, peak neutron flux must be at least 7.5 percent below scram, and steam flow in individual lines must be at least 10 percent below isolation trip setting. The peak heat flux must be at least 5 percent less than its trip point. The reactor shall not scram or isolate as a result of individual valve testing.

The relief valves must reclose properly (without leakage) following the pressure transient resulting from the simultaneous MSIV full closure.

The positive change in vessel dome pressure and simulated heat flux occurring within the first 30 sec after the closure of all MSIV valves must not exceed the predicted values in the Transient Safety Analysis Design Report. Predicted values will be referenced to actual test conditions of initial power level and dome pressure and will use beginning of life nuclear data. The predicted values will be corrected for the appropriate measured parameters.

After the full MSIV closure, the initial action of the RCIC and HPCI shall be automatic if L2 is reached, with RCIC capable of establishing an average pump discharge flow equal to or greater than 600 gpm within the first 50 sec after automatic initiation and HPCI capable of establishing an average pump discharge flow equal to or greater than 5000 gpm with a system response time of less than or equal to 30 sec as defined in the Technical Specifications.

If the low-low set pressure relief logic functions after the simultaneous full MSIV closure test, the open/close actions of the safety/relief valves (SRVs) shall occur within ±20 psi of the low-low set design setpoints. The total number of opening cycles, for the SRVs opening on low-low setpoint, after initial blowdown is not to exceed four times during the initial 5 minutes following isolation. If any SRVs open as a result of this test, only one valve may reopen after the first blowdown.

Recirculation pump trip shall be initiated if L2 is reached after the MSIV full closure test.

14.1.4.8.24 Relief Valves

Purpose

The purposes of this test are (a) to verify that the relief valves function properly (can be opened and closed manually), (b) to verify that the relief valves reseat properly after operation, and (c) to verify that there are no major blockages in the relief valve discharge piping.

Description

A functional test of each SRV shall be made as early in the startup program as practical. This is normally the first time the plant reaches 250 psig. The test is then repeated at rated reactor pressure. Bypass valve response is monitored during the low-pressure test, and the electrical output response is monitored during the rated pressure test. The test duration will be about 10 sec to allow turbine valves and tailpipe sensors to reach a steady state.

The tailpipe sensor response will be used to detect the opening and subsequent closure of each SRV. The bypass valve and MWe responses will be analyzed for anomalies indicating a restriction in an SRV tailpipe.

Valve capacity will be based on certification by ASME code stamp and the applicable documentation being available in the onsite records. Note that the nameplate capacity/pressure rating assumes that the flow is sonic. This will be true if the back-pressure is less than 55 percent of inlet pressure. The GE design specification requires the backpressure to be less than 40 percent of the inlet pressure, and present designs have backpressures on the order of 30 percent of the inlet pressures. The methods of calculating line losses and pressure drops are reliable enough to ensure that the 15 to 25 percent conservatism in the design more than offsets any slight inaccuracies in the calculation. A major blockage of the line would not necessarily be offset, and it should be determined that none exists through the bypass valve response signatures.

Vendor bench test data of the SRV opening responses will be available onsite for comparison with design specifications.

Criteria

Level 1

There should be a positive indication of steam discharge during the manual actuation of each valve.

Level 2

Variables related to the pressure control system may contain oscillatory modes of response. In these cases, the decay ratio for each controlled mode of response must be less than or equal to 0.25.

The temperature measured by thermocouples on the discharge side of the valves shall return to within 10°F of the temperature recorded before the valve was opened. If pressure sensors are available, they shall return to their initial state on valve closure.

During the 250 psig functional test, the steam flow through each relief valve, as measured by the initial and final bypass valve position, shall not differ by more than 10 percent from the average relief valve steam flow as measured by bypass valve position.

During the rated pressure test, the steam flow through each relief valve as measured by change in MWe is not to differ by more than 0.5 percent of rated MWe from the average of all the valve responses.

14.1.4.8.25 Turbine Stop Valve and Control Valve Fast Closure Trips

Purpose

To demonstrate the response of the reactor and its control systems to protective trips in the turbine and generator.

Description

The turbine stop valves and the main generator breakers are tripped at selected reactor power levels. Several reactor and turbine operating parameters are monitored to evaluate the response of the bypass valves, the relief valves, and the reactor protection system (RPS). In addition, the peak values and change rates of reactor steam pressure and heat flux are determined. The ability to ride through a load rejection within bypass capacity without a scram is demonstrated.

A turbine/generator trip is performed at Test Condition 6. Should an inadvertent turbine/generator trip occur at a lower power level (≥70 percent), credit may be taken for this test if supporting analysis shows that the results can be extrapolated to the higher power condition. Both line circuit breakers and the generator field breaker will open, and all the turbine valves will close at the maximum rate.

Criteria

Level 1

For turbine/generator trips, there should be a delay of no more than 0.1 sec following the beginning of control or stop valve closure before the beginning of bypass valve opening. The bypass valves should be opened to a point corresponding to greater than or equal to 80 percent of their capacity within 0.3 sec from the beginning of control or stop valve closure motion.

Flooding of the main steam lines shall not occur following the turbine/generator trips.

The positive change in vessel dome pressure occurring within 30 sec after either generator or turbine trip must not exceed the Level 2 criteria by more than 25 psi.

The positive change in simulated heat flux shall not exceed the Level 2 criteria by more than 2 percent of rated value.

Level 2

There shall be no MSIV closure in the first 3 minutes of the transient, and operator action shall not be required in that period to avoid the MSIV trip.

The positive change in vessel dome pressure and in simulated heat flux that occur within the first 30 sec after the initiation of either generator or turbine trip must not exceed the predicted values in the Transient Safety Analysis Design Report.

For the turbine/generator trip within the bypass valves capacity, the reactor shall not scram for initial thermal power values less than or equal to 25 percent of rated.

If the low-low set pressure relief logic functions, the open/ close actions of the SRVs shall occur within +20 psi of their design setpoints. If any SRVs open, only one valve may reopen after the first blowdown.

14.1.4.8.26 Shutdown From Outside the Control Room

Purpose

To demonstrate that the reactor can be brought from a normal, initial, steady-state power level to the hot shutdown condition and to verify that the plant has the potential for being safely cooled from hot shutdown to cold shutdown conditions from outside the control room using the remote shutdown panel.

Description

Hot Shutdown Demonstration:

The reactor will be shut down following a simulated main control room evacuation. The reactor will be scrammed, from outside the main control room, from a power level sufficiently high for the plant systems to be in normal operating configurations with the turbine generator in operation.

Reactor vessel water level and pressure will be controlled from a location outside the main control room. All other non-safety- related activities that would not be required during an actual remote shutdown will be performed from the main control room.

Data will be obtained at locations outside the control room to verify that the plant has achieved hot standby status and that the plant can be maintained in the stable hot standby condition.

This portion of the test will be performed with the minimum shift complement.

Cold Shutdown Demonstration:

The potential capability for cold shutdown will be demonstrated by partially cooling down the plant in the hot standby condition using controls and instrumentation located outside the control room. Cooldown can then proceed using normal procedures and operating modes from the control room to the point at which the shutdown cooling mode of residual heat removal (RHR) can be initiated. Operation of the RHR system in the shutdown cooling mode will then be initiated and controlled from outside the control room. Reactor coolant temperature will be partially reduced at a rate that will not exceed Technical Specifications limits. This demonstration will use additional personnel who can be made available to the plant before cooldown is initiated.

Approved operating procedures will be available for performance of a remote shutdown, including procedures for conducting all portions of the startup test.

Criteria

Level 1

Not applicable.

Level 2

During the cold shutdown demonstration, the reactor must be brought to the point where cooldown is initiated and under control.

During the simulated control room evacuation and hot shutdown demonstration, the reactor vessel pressure and water level are controlled using equipment and controls outside the control room.

14.1.4.8.27 Flow Control

Purpose

a. To determine the correct gain settings for the individual recirculation controllers

b. To demonstrate plant response to changes in circulation flow in both local manual and master manual mode

c. To set the limits of range of operation for the recirculation pumps.

Description

The testing of the recirculation flow control system follows a "building block" approach while the plant is ascending from low to high power levels. The time responses of the individual pump flow loops and speed loops will be optimized by adjusting the gains of the controllers. By far, the most extensive testing will be performed along the mid-power load line where most of the systems' final adjustments are determined.

Criteria

Level 1

The transient response of any variable related to the recirculation system to any test input must not diverge.

Level 2

The decay ratio of the speed loop response shall be <0.25 at any speed.

Flow control system limit cycles (if any) must produce a turbine steam flow variation no larger than ±0.5 percent of the rated steam flow value.

The APRM neutron flux trip avoidance margin shall be ≥7.5 percent, and the heat flux trip avoidance margin shall be ≥5.0 percent as a result of the recirculation flow control maneuvers.

14.1.4.8.28 Recirculation System

Purpose

a. To verify that the feedwater control system can satisfactorily control the water level without a resulting turbine trip/scram and obtain actual pump speed/flow

b. To verify recirculation pump startup under pressurized reactor conditions

c. To obtain recirculation system performance data

d. To verify that no recirculation system cavitation occurs in the operable region of the power flow map.

Description

The reactor coolant recirculation system consists of the reactor vessel and two piping loops. Each loop contains a centrifugal recirculation pump and two isolation valves located in the drywell and 10 jet pumps in parallel situated in the reactor downcomer. Each recirculation pump takes suction from the reactor downcomer and discharges through a manifold system to the nozzles of the 10 jet pumps. Here the flow is augmented by suction flow from the downcomer and delivered to the reactor inlet plenum.

A potential threat to plant availability is the high water level turbine trip scram caused by the level upswell that results after an unexpected trip of one recirculation pump. The change in core flow and resultant power decrease causes void formation, which the level-sensing system senses as a rise in water level. The one pump trip test is to prove that the water level will not rise enough to threaten a high-level trip of the main turbine or the feedwater pumps, while the pump restart demonstrates the adequacy of the restart procedure at the highest possible reactor power level.

Steady-state data will be collected several times during the startup test program in order to obtain a complete record of recirculation system performance.

Both the jet pumps and the recirculation pumps will cavitate at conditions of high flow and low power, where net positive suction head (NPSH) demands are high and little feedwater subcooling occurs. However, the recirculation pumps will automatically run back to minimum speed when feedwater flow decreases to 20 percent and the maximum recirculation flow is normally limited by the upper limit of the master flow controller which corresponds to the pump speed for rated flow at rated power. It will be verified that these limits are sufficient to prevent operation where recirculation pump or jet pump cavitation occurs.

Criteria

Level 1

The response of any level-related variables during pump trips must not diverge.

Level 2

The simulated heat flux margin to avoid a scram shall be greater than or equal to 5.0 percent during the one pump trip recovery.

The APRM margin to avoid a scram shall be greater than or equal to 7.5 percent during the one pump trip recovery.

During the noncavitation verification, runback logic shall have settings adequate to prevent operation in areas of potential cavitation.

During the one pump trip, the reactor water level margin to avoid a high-level trip (L8) shall be greater than or equal to 3.0 in.

14.1.4.8.29 Loss of Turbine Generator and Offsite Power

Purpose

a. To determine the reactor transient performance during the loss of the main generator and all offsite power

b. To demonstrate acceptable performance of the station electrical supply system.

Description

The loss-of-auxiliary-power test will be performed with the generator at least l0 percent of rated electrical output. The proper response of reactor plant equipment and automatic switching equipment, as well as the proper switching of loads to the diesel generator, will be checked.

Suitable provisions are made to facilitate continuous indicating and recording capability throughout the duration of the test (variables of interest are power, core flow, vessel pressure, and reactor water level).

The transient is extended for a minimum of 30 minutes.

Criteria

Level 1

The RPS, the diesel generator, RCIC, and HPCI must function properly without manual assistance. The HPCI and/or RCIC system action, if necessary, shall keep the reactor water level above the initiation level of low-pressure core spray, low pressure coolant injection (LPCI), and automatic depressurization systems.

Level 2

If the low-low set pressure relief logic functions, the open/ close actions of the SRVs shall occur within ±20 psi of their design setpoints. If any SRVs open, only one may reopen after the first blowdown.

14.1.4.8.30 Steady-State Vibration

Purpose

To determine the vibration characteristics of the primary pressure boundary piping (NSSS) and engineered safety feature (ECCS) piping systems for vibrations induced by recirculation flows, hot two-phase forces, and hot hydrodynamic transients; and to demonstrate that flow-induced vibrations, similar in nature to those expected during normal and abnormal operation, will not cause damage and excessive pipe movement and vibration.

Description

The systems subjected to the piping vibration testing during the startup test phase are listed in Table 3.9-1.

A complete, detailed discussion of the piping vibration and dynamic effect test program is presented in Subsection 3.9.1.1.

Criteria

Acceptance criteria for this test are presented in Subsection 3.9.1.1.5.

14.1.4.8.31 Recirculation System Flow Calibration

Purpose

To perform a complete calibration of the installed recirculation system flow instrumentation.

Description

During the testing program at operating conditions that allow the recirculation pumps to be operated at the speeds required for rated flow at rated power, the jet pump flow instrumentation is adjusted to provide correct flow indication based on the jet pump flow. After the relationship between drive flow and core flow is established, the flow-biased APRM/RBM system will be adjusted to match this relationship.

Criteria

Level 1

Not applicable.

Level 2

Jet pump flow instrumentation is adjusted so that the jet pump total flow recorder provides a correct core flow indication at rated conditions.

The APRM/RBM flow-bias instrumentation is adjusted to function properly at rated conditions.

The flow control system shall be adjusted to limit maximum core flow to 102.5 percent of rated flow by limiting motor-generator (M-G) set scoop tube position.

14.1.4.8.32 Reactor Water Cleanup System

Purpose

To demonstrate specific aspects of the mechanical operability of the reactor water cleanup (RWCU) system.

Description

With the reactor at rated temperature and pressure, process variables are recorded during steady-state operation in three modes as defined by the system process diagram: blowdown, hot standby, and normal. A comparison of the bottom head flow indicator and the RWCU inlet flow indicator will be made.

Criteria

Level 1

Not applicable.

Level 2

The temperature at the tube side outlet of the nonregenerative heat exchangers shall not exceed 130°F in the blowdown mode and shall not exceed 120°F in the normal mode.

The pump available NPSH is 13 ft or greater during the hot shutdown with loss of RPV recirculation pumps mode defined in the process diagrams.

The bottom head flow indicator will be recalibrated against the RWCU flow indicator if the deviation is greater than 25 gpm.

The cooling water supplied to the nonregenerative heat exchangers shall be less than 6 percent above the flow corresponding to the heat exchangers' capacity (as determined from the process diagram) and the existing temperature differential across the heat exchangers. The outlet temperature shall not exceed 180°F.

14.1.4.8.33 Residual Heat Removal System

Purpose

To demonstrate the ability of the RHR system to remove residual and decay heat from the nuclear system so that refueling and nuclear servicing can be performed.

Description

During the first suitable reactor cooldown, the shutdown cooling mode of the RHR system will be demonstrated. The torus cooling mode will also be demonstrated, if necessary.

Criteria

Level 1

Not applicable.

Level 2

The RHR system is capable of operating in the suppression pool cooling and shutdown cooling modes at the flow rates and temperature differentials indicated on the process diagrams.

14.1.4.8.34 Piping System Dynamic Response Testing

Purpose

To verify that piping system structural behavior under probable transient loadings is acceptable and within the limit predicted by analytical investigations.

Description

The following piping systems and dynamic transient events are evaluated by test during the startup testing sequence:

a. Behavior of the feedwater system piping from the feedwater pump discharge to the containment penetration following a trip of a feedwater pump

b. Behavior of the HPCI system piping from the HPCI pump discharge to the feedwater system tee connection in the steam tunnel after a rapid start of the HPCI pump turbine

c. Behavior of the main steam piping from the turbine stop valve to the containment penetration after a turbine stop valve and control valve fast closure trip. This test will be conducted during an inadvertent turbine trip after the startup test program is completed

d. Selected main steam SRV discharge piping during SRV operation

e. Recirculation piping for a pump trip at 100 percent-rated flow.

The tests described above have been selected for the following reasons:

a. The transient phenomena identified are normal/upset transients that may be reasonably expected to occur during the life of the plant

b. The transients described are already planned during the system's tests to confirm system and equipment behavior in accordance with design

c. Evaluation of the results of these tests will aid in confirming that use of present design rules and stress analysis requirements produces system designs that are adequate for anticipated transient events.

The vibration surveys conducted during these transient events make up one portion of the piping vibration test program presented in Subsection 3.9.1.1.

Criteria

Acceptance criteria for this test are presented in Subsection 3.9.1.1.5.

14.2 AUGMENTATION OF STAFF IN INITIAL TESTS AND OPERATIONS

14.2.1 Description of Augmented Staff

Since the normal complement of plant operating personnel was insufficient in number to staff the initial test and operation program, Edison augmented the staff for this initial test period, primarily with General Electric and English Electric test personnel.

The responsibility for the completion of the startup test program lies with the Edison Startup Test Phase Group, which is part of the Nuclear Production Organization. The detailed description of the organization, personnel qualifications, and responsibilities for the Startup Test Phase Group is covered by plant administrative procedures.

CHAPTER 15: ACCIDENT ANALYSIS

15.0 GENERAL

The original Final Safety Analysis Report (FSAR) was submitted in support of the Detroit Edison Company's (Edison) application for a license to operate Fermi 2, a 3293-MWt nuclear power plant, at the Enrico Fermi Atomic Power Plant site on the western shore of Lake Erie, at Lagoona Beach, Monroe County, Michigan. The Updated Final Safety Analysis Report (UFSAR) was prepared in response to 10 CFR 50.71(e).

The design power rating (emergency core cooling system [ECCS] design basis) for Fermi 2 is 3486 MWt, with a turbine-generator design gross electrical output at the generator terminals of 1235 MWe and a net electrical output of approximately 1170 MWe.

On September 9, 1992, the NRC issued Amendment 87 to the Fermi 2 operating license authorizing a change in the thermal power limit from 3293 MWt to 3430 MWt, a 4.2 percent increase in thermal power (References 1 and 2). This changed the new electrical capacity from 1093 MWe to 1139 MWe, or an increase of 46 MWe.

During RF05 the LP Steam Path was replaced by a GE designed LP Steam Path with a higher efficiency. This changed the designed net electrical capacity from 1139 MWe to 1150 MWe, or an increase of 11 MWe.

During RF07, the HP Steam Path was replaced by a GE designed HP Steam Path with a higher efficiency. However, the gross generator output will not exceed the present 1217 MWe.

The Fermi Power Uprate Program followed the GE Nuclear Energy guidelines and evaluations for BWR power plants (References 3, 4 and 5).

Fermi 2 specific analyses and evaluations were performed, consistent with the generic guidelines, for systems and components that might be affected to ensure their capability to support the increase in power output and steam flow. Since the analyses are described in detail in the UFSAR, revisions have been made to reflect power uprate, as appropriate.

Cycle 3 was used as the representative fuel cycle for power uprate. The radiological consequences were calculated for the transient and accident analyses as applicable. Direct or statistical allowance for 2 percent power uncertainty was included in the analysis. The data has been updated for Cycle 7 fuel. Since the radiological consequences for Cycle 3 are bounding, the base calculations remain unchanged.

For Fermi 2, the limiting events for each limiting transient category were analyzed to determine their sensitivity to core flow, feedwater temperature, and cycle exposure. The results of these analyses developed the new licensing basis for transient analyses at uprated power. No changes to the basic characteristics for any of the limiting events were caused by power uprate.

The radiological doses resulting from several postulated accidents were reanalyzed for uprated conditions using methods recommended in the NRC Standard Review Plan (NUREG-0800, Chapter 15). The whole body dose and thyroid dose at the exclusion area, low population zone and, where appropriate, for the main control room were calculated.

In addition, feedwater line break, Section 15.6.6, air ejector line break, Section 15.7.1, liquid and solid radwaste system failure, Section 15.7.3, and gaseous radwaste failure, Section 15.11 were evaluated for impact due to power uprate. The feedwater line break is not affected by power uprate since it was analyzed based upon Technical Specification radiation levels which are not changing. The other accidents (originally analyzed based on a reactor thermal power level of 3430 MWt) were conservatively reanalyzed assuming a 2 percent increase in radiation releases which results in only minor increases in dose.

The results from all the reanalyses are significantly below the 10 CFR 100 guidelines and confirm the validity of the generic evaluation conclusions in Reference 3.

Fermi 2 has chosen to reanalyze the radiological consequences associated with a control rod drop accident, Section 15.4.9, a fuel handling accident, Section 15.7.4, and the design basis loss of coolant accident, Section 15.6.5, utilizing the guidance in Regulatory Guide 1.183, *Alternative Radiological Source Terms for Evaluating Design Basis Accidents at Nuclear Power Reactors*. The guidelines of 10 CFR 50.67 are applicable to the radiological consequences of these accidents. The results from these analysis are below the 10 CFR 50.67 guidelines.

On February 10, 2014, the NRC issued Amendment 196 to the Fermi 2 operating license authorizing a change in the thermal power limit from 3430 MWt to 3486 MWt, a 1.64 percent increase in thermal power and a 1.88 percent increase in steam flow. This changed the net electrical capacity from 1150 MWe to approximately 1170 MWe (Reference 13). This power uprate was performed in accordance with 10 CFR 50, Appendix K and reflects the improvement in feedwater flow measurement. The Fermi 2 Measurement Uncertainty Recapture (MUR) power uprate followed the GE generic guidelines and evaluations for BWR plants provided in GEH Topical Report NEDC-32938P-A, "Generic Guidelines and Evaluations for General Electric Boiling Water Reactor Thermal Power Optimization," Revision 2, May 2003 (Reference 18). The analyses performed at 102% of the pre-MUR licensed thermal power (3430 MWt) remain applicable at the MUR uprated thermal power (3486 MWt) because the 2% uncertainty factor discussed in Regulatory Guide 1.49 is effectively reduced by the improvement feedwater flow measurements.

In general, the Hydrogen Water Chemistry (HWC) system does not affect any of the events analyzed in chapter 15. It is not an initiator for these events, nor is it required to mitigate any of these events or to shut down the reactor or any systems. Any accident or transient which results in a reactor scram, offgas flow restriction (valves not fully open), or a loss of power, will automatically shut down the HWC system. Once the HWC system is stopped, then the rest of the event proceeds as described in the following sections of chapter 15. The presence of the HWC system will not affect the offsite radiological consequences of any of the analyzed events primarily due to the short half-life of isotope N-16. After two minutes (approximately 15 half lives), any potential N-16 source will have decayed to insignificant levels. Since the transport time out to a building stack and then to the site boundary is typically greater than two minutes, the offsite dose consequences are negligible, when compared to the other potentially-released isotopes. Therefore, the increased N-16 levels caused by HWC operation will not affect any of the accidents described herein.

Chapter 15 through Section 15.8 is presented in the format of Regulatory Guide 1.70, Revision 2 (Reference 6). This was the standard method chosen by GE to present the accident analysis for all safety analysis reports circa 1975. The analyses included in Sections 15.9 through 15.16, with the exception of 15.11, were not reanalyzed for power uprate because they were no longer required by Revision 2/3 of the Regulatory Guide, nor are they presently required by the Standard Review Plan, NUREG-0800.

The safety analysis is based on the General Electric (GE) report, General Electric Standard Application for Reactor Fuel (GESTAR II), described in Reference 7. GESTAR II represents generic information relative to the GE fuel design and analysis and consists of a description of the fuel design and fuel thermal-mechanical, nuclear, and thermal-hydraulic analyses bases. It provides information and methods used to determine reactor limits that are independent of a plant-specific application. Plant-specific information and the transient and accident methods used are given in the United States supplement. Proposed changes to GESTAR II are submitted to the appropriate regulatory body for review and approval. A listing of NRC approved amendments are provided in GESTAR II. All approved changes are incorporated as a revision to the text.

The postulated most limiting transients and accidents were analyzed, consistent with the fuel design, as described in Chapter 4. This Chapter examines the effects of anticipated process disturbances and postulated component failures to determine their consequences and to evaluate the capability built into the plant to control or accommodate such failures and events.

The scope of the situations analyzed includes anticipated operational occurrences (AOOs) (expected) (e.g., loss of electrical load), off-design abnormal (unexpected) transients that induce system operations condition disturbances, postulated accidents of low probability (e.g., the sudden loss of integrity of a major component), and finally hypothetical events of extremely low probability (e.g., an anticipated transient without the operation of the entire control rod drive system).

The Fermi 2 design is intended to be valid for the licensed life of the plant. The supplemental cycle-specific safety analysis assures that the plant can be operated safely and not pose any undue risk to the health and safety of the public. This is accomplished by demonstrating that radioactive releases from the plant for normal operation, AOOs, and postulated accidents meet applicable regulations.

Fermi 2 plant operation must meet various safety requirements defined in the Code of Federal Regulations. To evaluate the safety impact, fuel lattice physics calculations and 3-D simulation, transient, and accident evaluations were performed. The NRC approved methodologies described in GESTAR II were used to license the following combination of operating states (References 2 and 8 through 13):

a. Operation in the maximum extended operating domain with both the turbine bypass and moisture separator reheater in service

b. Operation in the maximum extended operating domain with either the turbine bypass or moisture separator reheater out-of-service

c. Operation in the maximum extended operating domain with both the turbine bypass and moisture separator reheater out-of-service.

d. Operation in the maximum extended operating domain with pressure regulator out-of-service.

Operation in the extended domain includes the maximum extended load line limit region and increased core flow with flow between 83 percent and 105 percent of rated flow at rated power (3486 MWth); feedwater heaters out-of-service and final feedwater temperature reduction with feedwater temperature between -50°F and +5°F of rated; and single loop operation.

The core-wide nuclear and thermal reactivity characteristics when combined with the rest of the plant systems and equipment determines the normal steady-state operation, transient and accident performance of the plant.

The performance of the anticipated operational occurrences (moderate frequency events) were evaluated with the methodologies described in GESTAR II. The limiting events analyzed are determined by a sensitivity study described in Reference 7 that examines the impact of minimum critical power ratio (MCPR) due to the change in fuel design. Based on results of the study, several limiting events have been identified and analyzed using the appropriate input parameters. The MCPR results of these limiting transients form the basis of the MCPR operating limits. Implementation of these MCPR operating limits in the Core Operating Limits Report ensures that the MCPR safety limit for normal conditions (dual loop operation) and for single loop operation will not be exceeded during the most severe anticipated operational occurrences.

15.0.1 Analytical Objective

The spectrum of postulated initiating events is divided into categories based on the type of disturbance and the expected frequency of the initiating occurrence; the limiting events in each combination of category and frequency are quantitatively analyzed. The plant safety analysis evaluates the ability of the plant to operate within regulatory guidelines, without undue risk to the public health and safety.

15.0.2 Analytical Categories

Transient and accident events contained in this report are discussed in individual categories as required by Reference 6. The cycle-specific input parameters and results of the events are summarized in Tables 15.0-1, 15.0-2, 15.0-3, and Reference 15. Each event evaluated is assigned to one of the following applicable categories.

a. Decrease in Core Coolant Temperature

   Reactor vessel water (moderator) temperature reduction results in an increase in core reactivity. This could lead to fuel cladding damage

b. Increase in Reactor Pressure

   Nuclear system pressure increase threatens to rupture the reactor coolant pressure boundary (RCPB). Increasing pressure also collapses the voids in the core moderator, thereby increasing core reactivity and power level which threaten fuel cladding due to overheating

c. Decrease in Reactor Core Coolant Flow Rate

A reduction in the core coolant flow rate threatens to overheat the cladding as the coolant becomes unable to adequately remove the heat generated by the fuel

d. Reactivity and Power Distribution Anomalies

Transient events included in this category are those that cause rapid increases in power due to increased core flow disturbance events. Increased core flow reduces the void content of the moderator, increasing core reactivity and power level

e. Increase in Reactor Coolant Inventory

Increasing coolant inventory could result in excessive moisture carryover to the main turbine, feedwater turbines, etc.

f. Decrease in Reactor Coolant Inventory

Reductions in coolant inventory could threaten the fuel as the coolant becomes less able to remove the heat generated in the core

g. Radioactive Release From a Subsystem or Component

Loss of integrity of a radioactive containment component is postulated

h. Anticipated Transients Without Scram (ATWS)

Anticipated transient without scram (ATWS) means an anticipated operational occurrence (e.g., loss of power to all recirculation pumps, tripping of the turbine generator set, isolation of the main condenser, loss of all offsite power, etc.) followed by the failure of the reactor trip portion of the protection system. The systems used to mitigate the postulated ATWS events are recirculation pump trip (RPT), alternate rod insertion (ARI), and standby liquid control (SLC). These systems are required to meet 10 CFR 50.62.

15.0.3 Event Evaluation

15.0.3.1 Identification of Causes and Frequency Classification

Situations and causes that lead to the analyzed initiating events are described within the categories designated above. The frequency with which each event occurs is summarized on the basis of available operating plant history for the transient event. Events for which inconclusive data exist are discussed separately within each event section.

Each initiating event within the major groups is assigned to one of the following frequency groups:

a. Incidents of moderate frequency - incidents that may occur during a calendar year to once per 20 years for a particular plant. These events are referred to as anticipated (expected) operational transients

b. Infrequent incidents - incidents that may occur during the life of the particular plant (spanning once in 20 years to once in 100 years). These events are referred to as abnormal (unexpected) operational transients

c. Limiting faults - occurrences that are not expected to occur but are postulated because their consequences may result in the release of significant amounts of radioactive material. These events are referred to as design basis (postulated) accidents.

15.0.3.1.1 Unacceptable Results for Incidents of Moderate Frequency (Anticipated [Expected] Operational Transients)

The following are considered unacceptable safety results for incidents of moderate frequency (anticipated operational transients):

a. A release of radioactive material to the environs that exceeds the limits of 10 CFR 20

b. Reactor operation induced fuel cladding failure

c. Nuclear system stresses in excess of those allowed for the transient classification by applicable industry codes

d. Containment stresses in excess of those allowed for the transient classification by applicable industry codes.

15.0.3.1.2 Unacceptable Results for Infrequent Incidents (Abnormal [Unexpected] Operational Transients)

The following are considered unacceptable safety results for infrequent incidents (abnormal operational transients):

a. Release of radioactivity that results in dose consequences that exceed a small fraction of 10 CFR 100

b. Fuel damage that would preclude resumption of normal operation after a normal restart

c. Generation of a condition that results in consequential loss of function of the reactor coolant system

d. Generation of a condition that results in a consequential loss of function of a necessary containment barrier.

15.0.3.1.3 Unacceptable Results for Limiting Faults (Design Basis [Postulated] Accidents)

The following are considered unacceptable safety results for limiting faults (design basis accidents):

a. Radioactive material release that results in dose consequences that exceed the guideline values of 10 CFR 100 or 10 CFR 50.67 for DBA-LOCA and fuel handling accident

b. Failure of fuel cladding that cause changes in core geometry, such that core cooling would be inhibited

c. Nuclear system stresses in excess of those allowed for the accident classification by applicable industry codes

d. Containment stresses in excess of those allowed for the accident classification by applicable industry codes when containment is required

e. Radiation exposure for limiting faults other than DBA-LOCA or fuel handling accident to plant operations personnel in the main control room in excess of 5 rem whole body, 30 rem inhalation, and 75 rem skin

f. Radiation exposure to operations personnel in the main control room in excess of 5 rem TEDE.

15.0.3.2 Sequence of Events and Systems Operations

Each transient or accident is discussed and evaluated in terms of the following.

a. A step-by-step sequence of events from initiation to final stabilized condition

b. The extent to which normally operating plant instrumentation and controls are assumed to function

c. The extent to which plant and reactor protection systems are required to function

d. The credit taken for the functioning of normally operating plant systems

e. The operation of engineered safety systems that are required.

In analyzing anticipated operational transients, some non safety grade pieces of equipment are assumed to operate. The most limiting transient that takes credit for this equipment is the excess feedwater event. The plant operating equipment that plays a significant role in mitigating this event (feedwater controller failure, open to maximum demand; Subsection 15.1.2) is the turbine bypass system and the Level 8 high water level trip (closes turbine stop and control valves). To ensure an acceptable level of performance for Fermi 2, surveillance requirements for both the bypass valves and feedwater Level 8 trip are included in the Technical Specifications.

15.0.3.2.1 Single Failures or Operator Errors

This subsection discusses a very important concept pertaining to the application of single failure and operator error analyses of the postulated events. Single active component failure criteria have been required and successfully applied on past NRC approved docket applications to design basis accident categories <u>only</u>. Reference 6 implies that a single failure and operator error requirement should be applied to transient events (high, moderate, and low probability occurrences) as well as accident (very low probability) situations.

Although Fermi 2 may well be able to tolerate the application of single failures or operator errors to transient events, this analysis does not consider such failures. At the time the construction permit for Fermi 2 was issued, such analyses were not a requirement.

The transients and accidents in this Chapter have been evaluated by the more restrictive old allowances and limits than those of the event categorization presently in effect. Most events postulated for consideration are the results of single equipment failures <u>or</u> single operator errors that have been postulated during any normal or planned mode of plant operation. The types of operational single failures and operator errors considered as initiating events are identified in Subsection 15.0.3.2.2.

Accidents Events. For accidents analyzed, all immediate short term functions are automatic. No operator action is therefore required to mitigate the event consequences for the first 10 minutes. Ten minutes has been judged to be ample time for an operator to assess the situation, determine trends of temperature and pressure, and decide whether containment cooling or suppression pool cooling should be initiated, or whether some other action is more appropriate.

For ECCS evaluation, the post accident period during which no credit is taken for operator action was selected to be 20 minutes, because 20 minutes allows more than enough time for the automatic emergency core cooling systems to have initiated their design function. Specific operator actions would depend on the extent of the primary system break, but in no case is action required in less than 10 minutes, and in general, a longer time (20 minutes or more) would likely be available (Subsection 6.3.2.15.1).

The possible variables that must be considered after the reactor water level has been automatically restored to a safe condition can best be judged and acted upon by trained, licensed operators using information displayed in the control room in conjunction with symptom oriented emergency procedures and guidelines. Because of the large number of variables to be considered, the operator should not be bound to respond to prescriptive instructions, but will respond to the symptoms as they exist.

Operational Transient Events. For all operational transients, no operator action is required to prevent the fuel from exceeding safety design basis limits.

Operator action is expected and used in order to

a. Maintain the plant in a steady-state condition

b. Initiate safe and orderly shutdown.

If the operator is unsuccessful in achieving normal plant status, he will be guided by the symptom oriented emergency procedures that are developed from the BWR Owners Group generic guidelines submitted to the NRC.

Effect of Single Failures or Operator Errors

Accident Events. The effect of single failures or operator errors has been considered in analyzing postulated accidents. Accidents involving an entire spectrum of primary system breaks are covered in Section 6.3.

Operational Transient Events. The use of the single failure or operator error criteria has not been a design basis requirement for Fermi 2. However, information provided to address Item II.K.3.44 of NUREG-0737 demonstrates that, for Fermi 2, adequate core cooling is maintained for any operational transient with the worst single failure.

The generic analysis performed by GE (Reference 14) for the BWR Owners Group of the adequacy of core cooling for transients with single failure is applicable to Fermi 2.

The anticipated transients in Regulatory Guide 1.70, Revision 3, were reviewed from a core cooling viewpoint. The loss of feedwater event was identified to be the most limiting transient that would challenge core cooling. The BWR is designed so that the high pressure makeup or inventory maintenance systems or heat removal systems are independently capable of maintaining the water level above the top of the active fuel given a loss of feedwater. The detailed analyses showed that even with the worst single failure in combination with the bounding loss of feedwater event, the core still remains covered.

Even with more degraded conditions involving four stuck open relief valves in addition to the worst transient with the worst single failure, studies showed that the core remains covered and adequate core cooling is available during the whole course of the transient. It has been concluded that for Fermi 2 anticipated transients (including transients that result in a stuck open relief valves) combined with the worst single failure and assuming proper operator actions, the core remains covered.

15.0.3.2.2 Initiating Events

The following types of operational single failures and operator errors are considered as initiating events.

a. The undesired opening or closing of any single valve (a check valve is not assumed to close against normal flow)

b. The undesired starting or stopping of any single component

c. The malfunction or maloperation of any single control device

d. Any single electrical component failure

e. Any single operator error.

Operator error is defined as an active deviation from written operating procedures or nuclear plant standard operating practices. A single operator error is the set of actions that is a direct consequence of a single erroneous decision. The set of actions is limited as follows:

a. Those actions that could be performed by one person

b. Those actions that would have constituted a correct procedure had the initial decision been correct

c. Those actions that are subsequent to the initial operator error and have an effect on the designed operation of the plant, but are not necessarily directly related to the operator error.

Examples of single operator errors are as follows:

a. An increase in power above the established flow control power limits by control rod withdrawal in the specified sequences

b. The selection and complete withdrawal of a single control rod out of sequence

c. An incorrect calibration of an average power range monitor

d. Manual isolation of the main steam lines as a result of operator misinterpretation of an alarm or indication.

15.0.3.3 Core and System Performance

15.0.3.3.1 Introduction

Section 4.4, Thermal and Hydraulic Design, is a description of the various fuel failure mechanisms. Avoidance of unacceptable results 1 and 2 for incidents of moderate frequency is verified statistically with consideration given to data, calculation, manufacturing, and operating uncertainties. An acceptable criterion was determined to be that 99.9 percent of the fuel rods in the core would not be expected to experience boiling transition (see Reference 1). This criterion is met by demonstrating that transients do not result in a minimum critical power ratio (MCPR) of less than the Safety Limit Minimum Critical Power Ratio (SLMCPR) as stated in the Core Operating Limits Report. (Initial core SLMCPR was 1.06)

The steady-state operating limit is determined as follows:

a. The change in the critical power ratio, ΔCPR, that would result in the safety limit CPR value is calculated for each event. These calculations use the most limiting axial power shape and the results represent the most limiting ΔCPRs for the allowable operating range (e.g. maximum extended load line limit analysis, increased core flow, partial feedwater heating, single loop operation, and various equipment out of service). The results are exposure and fuel type dependent.

b. For nonpressurization events, the ΔCPR value is added to the safety limit CPR value to obtain the event based minimum CPR, MCPR.

c. For pressurization events the MCPR is determined by the safety limit CPR and the ΔCPR in conjunction with correction factors. The correction factors are explained in Subsection 4.4.4.1.

The results are given in Reference 15 for the limiting transients.

The operating limit MCPR is the maximum value of the event based MCPRs calculated from the transient analysis. Maintaining the MCPR operating limit at or above this operating limit ensures that the safety limit CPR is never violated.

Section 4.4 describes the various fuel failure mechanisms and establishes fuel damage limits for various plant conditions. Avoidance of fuel cladding damage and release of radioactive material in excess of 10 CFR 100 or 10 CFR 50.67 (as applicable) limits during or as a result of abnormal operational transients is verified by demonstrating that abnormal operational transients do not result in a MCPR of less than safety limit CPR. If the MCPR remains above the safety limit CPR, no fuel failures result from the transient, and thus the radioactivity released from the plant cannot be increased over the operating conditions existing prior to the transient. Maintaining a MCPR greater than safety limit CPR is a sufficient but not a necessary condition to ensure that no fuel damage occurs. This is discussed in Section 4.4.

Avoidance of catastrophic failure of fuel cladding in design basis accidents is shown by demonstrating that fuel cladding temperatures remain below the fragmentation temperature of 2200°F or fuel enthalpies remain below 280 cal/g (Subsection 4.3.3).

For situations in which fuel damage is sustained, the extent of damage is determined by correlating fuel energy content, cladding temperature, fuel rod internal pressure, and cladding mechanical characteristics.

These correlations are substantiated by fuel rod failure tests and are discussed in Section 4.4, Thermal and Hydraulic Design, and Section 6.3, Emergency Core Cooling Systems.

15.0.3.3.2 Input Parameters and Initial Conditions for Analyzed Events

In general, the events analyzed have values for input parameters and initial conditions as specified in Table 15.0-1. Analyses which assume data inputs different than these values are designated accordingly in the appropriate event discussion.

15.0.3.3.3 Initial Power/Flow Operating Constraints

The analyses basis for most of the transient safety analyses is the rated thermal power at 105 percent rated core flow. This operating point is the apex of a bounded operating power/flow map which, in response to classified anticipated operational occurrences (AOOs), will yield the minimum thermal margins of any operating point within the bounded map.

Any other constraint which may truncate the bounded power/flow map must be observed, such as the recirculation valve and pump cavitation regions, the licensed power limit and other restrictions such as pressure and thermal margin criteria.

The upper operating power/flow limit of a reactor is predicated on the operating basis of the analysis and the corresponding constant rod pattern line. This boundary may be truncated by the licensed power and the MCPR operating limit.

Certain localized events are evaluated at other than the above mentioned conditions. These conditions are discussed as they pertain to the appropriate event.

15.0.3.3.4 Evaluation of Results

The results of the transient analyses are provided for each event and the critical parameters are shown in Reference 15 (peak neutron flux, heat flux, and MCPR responses). The transient responses for these events are presented in figures of Reference 15. The MCPR values provided in Reference 15 are used to generate the operating limit MCPR values for the licensed operating states in the Core Operating Limits Report (COLR). COLR presents these limits as a function of assumed scram speed.

In order to address all of the credible transient events in these eight analytical categories (refer to Subsection 15.0.2), the transients were based on the analysis of a spectrum of approximately 25 events, assignable to one of these categories. The relative and absolute severity of the consequences of the events are generally plant-specific and often cycle-specific as well. Most of the events result in fairly mild plant disturbances. Thus, only a few events are severe enough to be potentially limiting. Furthermore, although the most limiting event may differ from plant to plant and reload to reload, it is General Electric's experience that the most limiting transients can always be expected to come from the same selected group of transient events. Therefore, most of the events analyzed need not be reanalyzed or reassessed for cycle-specific core licensing application. The selected group of limiting events consists of:

a. Generator Load Rejection (without bypass),

b. Turbine generator trip (without bypass),

c. Feedwater controller failure,

d. Pressure Regulator Failure – Closed (when backup pressure regulator is out of service),

e. Loss of Feedwater Heating, and

f. Rod Withdrawal Error at Power

Subsequent AOO analyses verified the results of the above sensitivities. Descriptions of the typical analyses performed for the above limiting events are discussed in the following subsections.

15.0.3.3.4.1 Analysis Uncertainties

Model uncertainties are documented in Chapter 4, Subsection 4.4.4.1.2.6.

15.0.3.4 Barrier Performance

This section primarily evaluates the performance of the reactor coolant pressure boundary (RCPB) and the containment system during transients and accidents. During transients that occur with no release of coolant to the primary containment, only RCPB performance is considered. If release to the primary containment occurs, as in the case of limiting faults, then challenges to the primary containment are evaluated as well. Similarly, if the release occurs outside the primary containment, as in the case of limiting faults, then the challenges to the secondary containment (reactor building) are evaluated (Subsection 3.6.2).

Avoidance of excessive RCPB stresses during abnormal operational transients and accidents is assessed by comparing peak internal pressure with the overpressure transient allowed by the applicable industry code. The only significant areas of interest for internal pressure damage are the high pressure portions of the nuclear system primary barrier (the reactor pressure vessel (RPV) and the high pressure pipelines attached to the RPV). The overpressure, below which no damage can occur, is taken as the pressure increase over design pressure allowed by the ASME Boiler and Pressure Vessel (B&PV) Code Section III, Class 1. This code permits pressure transients up to 10 percent over design pressure (1375 psig = 110 percent x 1250 psig). It can be concluded that the high pressure portion of the nuclear system process barrier meets the design requirement if peak nuclear system pressure remains below 1375 psig.

An analysis performance measurement, discussed in Subsection 4.3.3, is used to evaluate whether nuclear system process barrier damage occurs as a result of reactivity accidents. If peak fuel enthalpy remains below 280 cal/g, no nuclear system process barrier damage results from nuclear excursion accidents.

Containment Damage

Containment integrity during accidents is maintained by ensuring that containment stresses do not exceed those allowed for accidents by applicable industry codes (ASME B&PV Code Section III, Class B, Nuclear Vessel 1968, including 1969 Summer Addenda).

Radioactive Barrier Mechanical Design

Design basis accidents are used in determining the sizing and strength requirements of many of the essential nuclear system components. Comparing accidents considered in this section with those used in the mechanical design of equipment reveals that either the applicable accidents are the same or that the accident in this section results in less severe stresses than those assumed for mechanical design. Damage to any of the radioactive material barriers, as a result of accident initiated fluid impingement and jet forces, is considered in those parts of the UFSAR that describe the mechanical design features of systems and components.

15.0.3.5 Radiological Consequences

In this Chapter, the consequences of radioactivity release during the three types of events: (a) incidents of moderate frequency (anticipated operational transients), (b) infrequent incidents (abnormal operational transients), and (c) limiting faults (design basis accidents), are considered. For all events whose consequences are limiting, a detailed quantitative evaluation is presented. For nonlimiting events a qualitative evaluation is presented or results are referenced from a more limiting or enveloping case or event.

For limiting faults, 2 hr radiation doses were calculated for the site exclusion area boundary, and 30 day doses were calculated for the low population zone boundary. The calculated doses were compared against the NRC dose criteria set forth in 10 CFR 100 or 10 CFR 50.67, as applicable. All of this work has been done according to guidelines issued over the years by the NRC and contained in various Regulatory Guides (e.g., 1.3, 1.4, 1.5, 1.25, 1.98 and 1.183). The maximum doses would result from a LOCA, and this was therefore the bounding accident (Subsection 15.6.5). Regulatory Guide 1.3 clearly states that its assumptions are acceptable to the NRC for use in evaluating the design basis LOCA for a BWR and in comparing the consequent doses against the 10 CFR 100 guidelines. The release of radioactivity and subsequent sources for the bounding accident are as indicated in Regulatory Guide 1.3. The source of offsite radioactivity for those accidents analyzed in accordance with Regulatory Guide 1.3 is the standby gas treatment system; estimates of releases from this system are based on the postulated primary containment leak rate of 0.5 percent per day.

Regulatory Guide 1.183 provides for selective evaluation of the radiological consequences of design basis accidents given that the accidents that were previously analyzed are completely superceded by the new analysis, completely reanalyzed utilizing the assumptions in Regulatory Guide 1.183, and that the results are within the limits of 10 CFR 50.67. The assumptions pertaining to Regulatory Guide 1.183 and the limits of 10 CFR 50.67 cannot be applied to any existing analysis. Therefore, the discussions of the radiological consequences of the accidents not analyzed in accordance with Regulatory Guide 1.183 remain unchanged. The sources of offsite radioactivity for accidents analyzed in accordance with Regulatory Guide 1.183 are leakage of ECCS piping and components that recirculate suppression pool water outside of primary containment, MSIV leakage, standby gas treatment system, and secondary containment bypass leakage.

The ECCS leakage is limited to a maximum of 5 gpm for the entire 30 days of the DBA LOCA. Two percent of the iodine is assumed to become airborne and is released as 97 percent elemental and 3 percent organic. The drywell and wetwell are projected to leak at their design leakage of 0.5 percent of their atmospheric contents by weight for the first 24 hours and 0.25 percent of their atmospheric contents by weight for the remaining 29 days. No credit is taken for secondary containment draw down for 15 minutes after the 2 minute gap release. Secondary containment bypass leakage is limited to 10 percent of the primary containment leakage and is modeled as a ground release at the TBHVAC stack. Credit is not taken for deposition in the bypass leakage pathway. The MSIVs are projected to leak 250 scfh total (100 scfh maximum in one line) for the first 24 hours and 50 percent of that for the remaining 29 days. A portion of elemental and aerosol iodine is credited to plate out in the main steam piping. However, no credit is taken for deposition in the broken steam line upstream of the inboard MSIV. Credit is taken for the main steam piping to cool to increase the mechanism for iodine plate out.

Generator Load Rejection without Bypass	BOC to MOC1	83 to 105	Turbine Bypass Feedwater Heaters
Generator Load Rejection without Bypass	MOC1 to MOC2	83 to 105	Turbine Bypass Feedwater Heaters
Generator Load Rejection without Bypass	MOC2 to EOC	83 to 105	Turbine Bypass Feedwater Heaters
Generator Load Rejection without Bypass	BOC to EOC	83 to 105	Turbine Bypass Moisture Separator Reheaters Feedwater Heaters
Control Rod Withdrawal Error	BOC to EOC	83 to 105	This event is independent of equipment out of service options
Pressure Regulator Failure Downscale	BOC to EOC	83 to 105	One Pressure Regulator

Notes

A. The analysis either covers or is independent of the identified out-of-service equipment. The OLMCPR adequately bounds the operating condition with the identified out-of-service equipment. The turbine generator and load rejection events are required to be analyzed without the turbine bypass; therefore, this event still needs to be considered when operating with turbine bypass. Normal operation with or without operation of MEOD and Final Feedwater Temperature Reduction of 50F. The analysis bounds the operation with this out-of-service equipment for a total of 100F feed water temperature reduction.

B. The required OLMCPR values are generated utilizing GE GEMINI or TRACG methods. Statistical mean value distributed control rod scram times are used in the analysis. Event unique adders are used to generate the required OLMCPR for Tau = 0 and Tau = 1 scram times. Tau is defined in the Core Operating Limits Report. OLMCPR values and limiting transients are found in Reference 15.

REHEATER AND DRAINS SYSTEM

15.1 DECREASE IN REACTOR COOLANT TEMPERATURE

Four transients are evaluated under the decrease in reactor coolant temperature analytical category:

a. Loss of feedwater heating

b. Feedwater controller failure

c. Pressure regulator failure

d. Inadvertent safety relief valve opening.

Of the above identified transients, only feedwater controller failure and loss of feedwater heating transients have cycle specific analyses performed. A qualitative prescription of results is described for those events determined to be nonlimiting from a core performance standpoint.

15.1.1 Loss of Feedwater Heating

15.1.1.1 Identification of Causes and Frequency Classification

15.1.1.1.1 Identification of Causes

A feedwater heater can be lost in at least two ways:

a. Steam extraction line to the heater is closed

b. Feedwater is bypassed around the heater.

The first case produces a gradual cooling of the feedwater. In the second case, the feedwater bypasses the heater and no heating of the feedwater occurs. In either case, the reactor vessel receives cooler feedwater. The maximum number of feedwater heaters that can be tripped or bypassed by a single event represents the most severe transient for analysis considerations. This event has been conservatively estimated to incur a loss of up to 100°F of the feedwater heating capability of the plant and causes an increase in core inlet subcooling. This increases core power due to the negative void reactivity coefficient.

The design basis of the loss of feedwater heating event requires that no single failure or operator action can result in a loss of more than 100°F in feedwater inlet temperature. Therefore, the existing transient is conservative for Fermi 2.

The single failure or operator error event that could cause the greatest reduction in feedwater temperature is the inadvertent bypassing of half the feedwater flow around Heaters 3, 4, and 5. There are two separate parallel strings of Heaters 3, 4, and 5, each sized to handle half the total feedwater flow, and a bypass line also sized to limit flow to half capacity. A 100 percent feedwater flow can be maintained by opening the bypass line and then shutting off the flow through one of the half sized heater strings. Such an action would cause a reduction in the final feedwater temperature that is significantly less than the 100°F design criterion established for this system.

In the unlikely event that a drop in feedwater temperature in excess of 100°F occurs, and assuming no operator action, the decrease in the minimum critical power ratio (MCPR) and increase in reactor power would be limited, because a scram would occur from high thermal power and thus no significant reductions in fuel thermal margin would occur. The scram might occur marginally sooner for greater temperature drops. After scram, no further increases in power occur.

The effects of this transient have been reviewed within the maximum extended operating domain described in Section 15.0. The most limiting loss of feedwater heating transient with respect to MCPR is performed at 100 percent rated power, minimum core flow at rated power and a 100ºF reduction in inlet feedwater temperature. The analysis at rated power does not credit the simulated thermal power scram.

The above discussion concerns a transient with a sudden feedwater temperature drop of 100°F. Steady-state operation with partial feedwater heating should also be considered because such operation might occur during maintenance or as a result of a decision to operate with lower feedwater temperature near end-of-cycle (EOC).

There are two distinct periods of concern when operating with partial feedwater heating:

a. Before EOC. Reducing the feedwater temperature before EOC may occur during routine maintenance. The peak pressures will be lower because of the reduced steam production. However, the magnitudes of the DCPR are still transient event dependent and, therefore, evaluation is conducted to ensure that the licensing bases are bounded. The plant is licensed to operate with a 50°F reduction in feedwater temperature.

b. After EOC. Operating with reduced feedwater temperature may occur as a result of an extended fuel cycle. The basis for the plant safety analysis has covered this operating condition. The plant is licensed to operate with a 50°F reduction in feedwater temperature during cycle extension.

15.1.1.1.2 Frequency Classification

The probability of this event (sudden 50°F drop) is considered low enough to warrant being categorized as an infrequent incident. However, because of the lack of a sufficient frequency data base, this transient disturbance is analyzed as an incident of moderate frequency.

This event is analyzed under worst case conditions of a 100°F loss and at full power. A reduction of feedwater temperature of 100°F at high power has never been reported, although smaller decreases have occurred. The probability of occurrence of this event is, therefore, regarded as small.

15.1.1.2 Sequence of Events and Systems Operation

15.1.1.2.1 Sequence of Events

This slow transient event results in the reactor core receiving colder feedwater up to a reduction of 100°F. This collapses the void content in the core thus increasing the core power due to the negative void coefficient.

15.1.1.2.2 Systems Operation

In establishing the expected sequence of events and simulating plant performance, it was assumed that normal functioning occurred in the plant instrumentation and controls, plant protection, and reactor protection systems.

The simulated thermal power trip (STPT) scram is the primary protection system trip in mitigating the consequences of this event.

Required operation of engineered safeguard features is not expected for either of these transients.

15.1.1.3 Core and System Performance

15.1.1.3.1 Mathematical Model

The quasi-steady-state nature of this transient enables this slow transient to be analyzed using the 3-dimensional, coupled nuclear thermal-hydraulics core simulator computer model as described in detail in Reference 1. This model calculates the changes in power level; power distribution; core flow; exposures; reactor thermal-hydraulic characteristics; and critical power ratio with spatially varying voids, control rods, burnable poisons, and other variables under steady-state conditions. For this transient, the time for reactivity insertion is greater than the fuel thermal time constant and the core hydraulic-transport times. Therefore, the steady-state representation before and after the transient is adequate. This computer model has been qualified and approved by the NRC for application with this transient.

15.1.1.3.2 Input Parameters and Initial Conditions

The 100 percent power, minimum core flow at rated power, and partial feedwater heating represents the bounding conditions for the analysis. The transient is simulated by programming a change in feedwater enthalpy corresponding to a 100°F loss in feedwater heating.

15.1.1.3.3 Qualitative Results

A scram on high thermal power may or may not occur for a 100°F loss event since it has been shown that the power increase for a 100°F loss event is very close to the high thermal power scram setpoint. Vessel steam flow and the initial system pressure remains relatively constant or increases slightly.

The analysis evaluated at 100 percent power, minimum core flow at rated power, and partial feedwater heating bounds all power, flow and feedwater temperature conditions. This subcooling perturbation event is not significantly affected by initial power, flow, and feedwater temperature conditions. The operability of the turbine bypass system and the moisture separator reheater does not affect the results of this event.

For reload cores, an evaluation is performed to determine if this transient could potentially alter the cycle MCPR operating limit. The results are reported in the cycle-specific supplemental reload licensing report.

15.1.1.3.4 Consideration of Uncertainties

Important factors (such as reactivity coefficient, scram characteristics, and magnitude of the feedwater temperature change) are assumed to be at the worst configuration so that any deviations seen in actual plant operation reduce the severity of the event.

15.1.1.4 Barrier Performance

The consequences of this event do not result in any temperature or pressure transient in excess of the criteria for which the fuel, pressure vessel, or containment are designed; therefore, these barriers maintain their integrity and function as designed.

15.1.1.5 Radiological Consequences

Since this event does not result in any fuel failures or any release of primary coolant to either the secondary containment or the environment, there are no radiological consequences associated with this event.

15.1.2 Feedwater Controller Failure, Open to Maximum Demand

The Feedwater Controller Failure, open to maximum demand event represents the most limiting event in this analytical category.

15.1.2.1 Identification of Causes and Frequency Classification

15.1.2.1.1 Identification of Causes

This event is postulated on the basis of a single failure of a control device, specifically one that can directly cause an increase in coolant inventory by increasing the feedwater flow.

The most severe applicable event is a feedwater controller failure during maximum flow demand. The feedwater controller is forced to its upper limit at the beginning of the event.

15.1.2.1.2 Frequency Classification

This event is considered to be an incident of moderate frequency.

15.1.2.2 Sequence of Events and Systems Operation

15.1.2.2.1 Sequence of Events

The excess feedwater flow increases the water level to the high level reference point, at which time the feedwater pumps and the main turbine are tripped and a scram is initiated.

15.1.2.2.2 Systems Operation

To properly simulate the expected sequence of events, the analysis of this event assumes normal functioning of plant instrumentation and controls, plant protection, and reactor protection systems, with the exception of the fact that four Group 1 relief valves are assumed to remain closed. Important system operational actions for this event are the high level tripping of the main turbine, turbine stop valve scram trip initiation, feedwater pump trip, bypass valve opening, and low water level initiation of the reactor core isolation cooling (RCIC) system and the high pressure coolant injection (HPCI) system. Initiation of RCIC and HPCI maintains long term water level control following tripping of feedwater pumps.

In addition to the turbine bypass flow after the turbine trip, the steam flow through the moisture separator reheater line is also available for the first 3 seconds after turbine trip during the transient. The Fermi 2 system is unique in that the main steam flow normally flows to this moisture separator reheater and it is not shut off by the stop or control valves.

The moisture separator reheater and drains system is shown in Chapter 15, Figure 15.0-3. A line carries a portion of the main steam from the main steam manifold to the tube side of two moisture separator reheaters where condensation occurs. The heat given up superheats the shell side fluid, which is the steam source for the low pressure turbine. The condensed fluid passes through the moisture separator reheater seal tank, Heater 6, Heater 5, the flash tanks, the drain pumps, and then is directly injected into the main feedwater line.

Outlet valves on the seal tank and Heater 6 are controlled by their respective levels. High water level in these vessels also opens bypass valves to the condenser.

The moisture separator reheater flow characteristics are modeled as shown in Chapter 15, Figure 15.0-2. The total flow ramps off to about 8.0 percent flow at 200 msec after turbine trip. After reaching about 8.0 percent flow, it becomes constant until 2 seconds have elapsed. After 2 seconds, the flow ramps off linearly to zero at approximately 3 seconds. The analysis of reheater steam flow is discussed in more detail in Chapter 10, Subsection 10.4.4.

15.1.2.3 Core and System Performance

15.1.2.3.1 Mathematical Model

The predicted dynamic behavior of this event is evaluated using the TRACG computer model described in Reference 1.

TRACG is designed to predict the transient behavior associated with a BWR. This model has been qualified by extensive comparison of its predicted results with actual BWR test data. Some of the significant features of the model are:

a. TRACG has a multi-dimensional, two-fluid model for the reactor thermal hydraulics and a three dimensional reactor kinetics model. The models simulate a large variety of test and reactor configurations to allow for detailed, realistic simulation of a wide range of BWR phenomena.

b. TRACG uses a two-fluid model, with six conservation equations for both the liquid and gas phases.

c. The two-fluid conservation equations contain a mixing term to account for turbulent mixing and molecular diffusion.

d. TRACG solves the heat conduction equation for the fuel rods in cylindrical geometry and for structural material in slab geometry TRACG heat conduction modeling uses a gap conductance model and couples the heat transfer between the fuel rod and the coolant.

e. The TRACG code has had the GEXL heat transfer correlation installed.

f. TRACG uses basic component models as building blocks to construct physical models. The components modeled include the pipe, pump, valve, tee, channel, jet pump, steam separator, steam dryer, vessel, upper plenum, heat exchanger, and break and fill as boundary conditions.

g. TRACG uses a first-principle mechanistic model for the steam separator validated against full-scale performance test data for two-stage and three-stage steam separators.

15.1.2.3.2 Input Parameters and Initial Conditions

The transient is simulated by programming an upper limit failure in the feedwater system so that 114.8 percent of nuclear boiler rated (NBR) feedwater flow occurs at the operating pressure. An additional 5 percent higher flow rate conservatism is assumed in the analysis to allow for feedwater flow uncertainty.

The 114.8 percent maximum flow used is a valid input because the Fermi 2 feedwater system is designed to supply 112.8 percent flow to the reactor at design sparger pressure. This flow is basically controlled by changing the speed of the two steam driven feed pump turbines. Each turbine drive has an independent, redundant electrohydraulic speed control system that responds to feedwater demands from the level control logic system (Chapter 7, Subsection 7.7.1.3). The controlled speed range of each feed pump is adjusted during startup such that a maximum flow demand signal to both pumps will produce a maximum flow of 114.8 percent at nominal pressure. The adjustment of each of the pump speed control spans results in an adequate margin for flow control at rated power and also maximizes the resolution of the control system over the control system operating range. Each turbine speed control is redundant, and any internal failure generally causes the turbine to fail to minimum speed by design. If a particular turbine fails to a high speed, the remaining turbine would be controlled to a lower speed and maintained at that level automatically by the level control system.

Thus, a failure of the common feedwater demand signal to the power supply voltage level was assumed to produce a flow of 114.8 percent which was evaluated for this transient. Replacement of the feedwater control system (FWC) with a digital feedwater control system (DFCS) has eliminated this common element whose proposed failure to power supply voltage level could affect both feedwater pumps to create this high flow condition. The DFWC hardware has separate modules for each feed pump drive. However, this transient bounds that created by any credible failure with the DFWC and is therefore a valid analysis of the system's ability to respond to any proposed failure.

Because each of the two feed pump drives has been adjusted to produce a pump speed that delivers 114.8 percent feedwater flow at nominal pressure at maximum feedwater demand, the calibration will preclude the need for any further corrective actions to meet the design value of flow subsequent to a single failure.

Typical, cycle-specific feedwater controller failure cases analyzed include the following:

a. Operation with turbine bypass and moisture separator reheater operable, and feedwater heaters inoperable at 100 percent power, 105 percent core flow

b. Operation with moisture separator reheater operable with turbine bypass and feedwater heaters inoperable at 100 percent power, 105 percent core flow

c. Operation with feedwater heaters, turbine bypass and moisture separator reheater inoperable at 100 percent power, 105 percent core flow.

15.1.2.3.3 Qualitative Results

Results of the cycle-specific analyses are presented in Chapter 15.0 Reference 15. The operating limits for these analyses are presented in Chapter 15.0 Reference 15. The following subsections present qualitative results of the cases described in Subsection 15.1.2.3.2. Tables 15.1.2-1 through 15.1.2-3 list the typical sequence of events for these cases.

15.1.2.3.3.1 100 Percent Power, 105 Percent Core Flow, 50°F Feedwater Temperature Reduction with Bypass and Moisture Separator Reheater Flow

The high water level turbine trip and feedwater pump trip occur at about 16 sec. Scram occurs simultaneously from stop valve closure and limits the neutron flux peak and fuel thermal transient so that no fuel damage occurs. The turbine bypass system opens to limit peak pressure in the steam line, and the nuclear system process barrier pressure limit is not endangered.

The bypass valves subsequently close to reestablish pressure control in the vessel during shutdown. The level will gradually drop to the low level isolation reference point, activating the RCIC and HPCI systems for long term level control.

15.1.2.3.3.2 100 Percent Power, 105 Percent Core Flow, 50°F Feedwater Temperature Reduction Without Bypass and With Moisture Separator Reheater Flow

The high water level turbine trip and feedwater pump trip occur at about 16 seconds. Reactor scram occurs immediately thereafter which limits the peak neutron flux and fuel thermal transient so that no fuel damage occurs. This analysis is also conservatively applied to the operating condition without moisture separator reheater, but with turbine bypass operable and with partial feedwater heating. This analysis represents the limiting transient for the operational condition without turbine bypass or moisture separator reheater flow and with partial feedwater heating, and provides the basis for the Core Operating Limits Report MCPR operating limit curve.

15.1.2.3.3.3 100 Percent Power, 105 Percent Core Flow, 50°F Feedwater Temperature Reduction Without Bypass and Moisture Separator Reheater Flow

The high water level turbine trip and feedwater pump trip occurs at about 16 seconds. Reactor scram occurs immediately thereafter which limits the peak neutron flux and fuel thermal transient so that no fuel damage occurs. This analysis represents the limiting transient for operation without bypass and moisture separator reheater flow and provides the basis for the Core Operating Limits Report MCPR operating limit curve.

15.1.2.3.4 Consideration of Uncertainties

Important analytical factors (such as void and scram reactivity coefficients) have been adjusted statistically so that any deviation in the actual plant parameters will produce a less severe transient.

15.1.2.4 Barrier Performance

The consequences of this event do not result in any temperature or pressure transient in excess of the criteria for which the fuel, pressure vessel, or containment are designed; therefore these barriers maintain their integrity and function as designed.

15.1.2.5 Radiological Consequences

While the consequence of this event does not result in fuel failure, it does result in the discharge of normal coolant activity to the suppression pool through safety relief valve (SRV) operation. Since this activity is contained in the primary containment, there will be no exposure to operating personnel.

Since this event does not result in an uncontrolled release to the environment, the plant operator can choose to leave the activity bottled up in the primary containment or discharge it to the environment under controlled meteorological and release conditions. If purging of the primary containment is chosen, the release will have to be in accordance with the established Technical Specifications; therefore, this event, at the worst, would only result in a small increase in the yearly integrated exposure level.

Table 15.1.2-1 Typical Sequence of Events for Feedwater Controller Failure at 100% Power, 105% Core Flow, 50°F Feedwater Temperature Reduction with Bypass and Reheater Flow[(a)]

Estimated Time (sec)	Event
0	Simulated failure of 114.8 percent upper limit on feedwater flow is initiated.
15.9	L8 vessel level setpoint trips main turbine and feedwater pumps.
15.9	Turbine trip initiates closure of turbine stop valves and fast closure of turbine control valves.
15.9	Turbine trip initiates bypass operation.
15.9	Main turbine stop valves reach 90 percent-open position and initiate a reactor scram trip.

15.1.3 Pressure Regulator Failure, Open to Maximum Demand

15.1.3.1 Identification of Causes and Frequency Classification

15.1.3.1.1 Identification of Causes

The total steam flow rate to the main turbine, resulting from a pressure regulator malfunction, is limited by a maximum flow limiter imposed at the turbine controls. This limiter is set to limit maximum steam flow to approximately 112.8 percent nuclear boiler rated.

If either the controlling pressure regulator or the backup regulator fails to the open position, the turbine admission valves can be fully opened, and the turbine bypass valves can be partially opened until the maximum steam flow is established.

15.1.3.1.2 Frequency Classification

This transient disturbance is categorized as an incident of moderate frequency.

15.1.3.2 Sequence of Events and Systems Operation

15.1.3.2.1 Sequence of Events

Table 15.1.3-1 lists the typical sequence of events. Section 15.1.3.3.3 describes the potential for an alternate sequence of events that is also considered.

15.1.3.2.2 Systems Operation

To properly simulate the expected sequence of events, the analysis of this event assumes normal functioning of plant instrumentation and controls, plant protection, and reactor protection systems except as described below.

Initiation of high pressure coolant injection (HPCI) and reactor core isolation cooling (RCIC) system functions will occur when the vessel water level reaches the L2 setpoint. Normal startup and actuation can take approximately 30 sec (up to 60 sec) before effects are realized. If these events occur, they will follow some time after the primary concerns of fuel thermal margin and overpressure effects have occurred and are expected to be less severe than those already experienced by the system.

15.1.3.3 Core and System Performance

15.1.3.3.1 Mathematical Model

Only a qualitative evaluation is provided.

15.1.3.3.2 Input Parameters and Initial Conditions

This transient is simulated by setting the controlling regulator output to a high value, which causes the turbine admission valves to open fully and the turbine bypass valves to open partially. Since the controlling and backup regulator outputs are gated by a high value gate, the effect of such a failure in the backup regulator would be exactly the same. A regulator failure with 127.6 percent steam flow was simulated as a worst case, since 112.8 percent is the normal maximum flow limit.

15.1.3.3.3 Qualitative Results

For the pressure regulator failure (open) transient, the water level rises to the high level trip setpoint in 2.1 sec and initiates trip of the main turbine and feedwater turbines. Closure of the turbine stop valves initiates scram.

Reactor high level trip limits the duration and severity of the depressurization so that no significant thermal stresses are imposed on the nuclear system process barrier. No significant reductions in fuel thermal margins occur. Because the rapid portion of the transient results in only momentary depressurization of the nuclear system, the nuclear system process barrier is not threatened by high internal pressure for this pressure regulator malfunction.

These qualitative evaluations were performed using the REDY model which predicted that reactor water level would swell during the pressure regulator failure (open) transient. As described in Reference 2, more recent evaluations with improved transient models (e.g., ODYN and TRACG) have determined that the reactor water level swell may not be sufficient to reach the high water level setpoint. In this case, the depressurization would be terminated by main steam isolation valve (MSIV) closure at the low pressure isolation setpoint. Reactor scram would then occur due to MSIV closure. There is no challenge to fuel cladding integrity as the critical power ratio increases during the transient. However, to avoid the potential for reactor steam dome pressure to decrease below the range associated with the Technical Specification Safety Limits prior to the reactor power level decrease due to reactor scram, a methodology was developed in Reference 3 to address this issue. This methodology was adopted, and in Reference 4 the reactor steam dome pressure associated with the Technical Specification Safety Limits was reduced and the low pressure isolation setpoint was increased. With these changes, fuel cladding integrity is ensured and Technical Specification Safety Limits are maintained regardless of whether the pressure regulator failure (open) transient is terminated by the water level increase or by the low pressure isolation setpoint being reached.

15.1.3.3.4 Consideration of Uncertainties

If the maximum flow limiter is set higher or lower than normal, faster or slower loss in nuclear steam pressure will result. The rate of depressurization may be limited by the bypass capacity, but it is unlikely that this will happen. For example, the turbine valves will open to the valves wide open state, admitting slightly more than the rated steam flow; and with the limiter in this analysis set to fail at 127.6 percent, it is expected that something less than 23.5 percent would be bypassed. Therefore, this is not a limiting factor on this plant. If the rate of depressurization does change, it will be terminated by the low turbine inlet pressure trip setpoint.

For the pressure regulator failure (open) transient, depressurization occurs after initiation of the event, which results in voiding action of the core and then reduces the core power, maintaining high thermal margin. The impact on the minimum critical power ratio (MCPR) and peak vessel pressure for the case with a scram from low turbine inlet pressure (a scram caused by main steam isolation valve (MSIV) closure) due to a lower depressurization rate is insignificant. Because this is a relatively mild transient, an opening to maximum (127.6 percent) is assumed.

If the depressurization rate is not large enough, the sensed vessel water level trip setpoint (L8) may not be reached, and a turbine feedwater pump trip will not occur in the transient. In this case the turbine inlet pressure will drop below the low pressure isolation setpoint, and the expected transient signature will conclude with an isolation of the main steam lines. The reactor will be shut down by the scram initiated from main steam isolation valve closure. Therefore, the plant response to a less limiting depressurization is addressed by the alternate sequence of events described in Section 15.1.3.3.3.

15.1.3.4 Barrier Performance

The consequences of this event do not result in any temperature or pressure transient in excess of the criteria for which fuel, pressure vessel, or containment are designed; therefore, these barriers maintain their integrity and function as designed.

15.1.3.5 Radiological Consequences

The consequences of this event do not result in any fuel failure.

Table 15.1.3-1 Typical Sequence of Events for Pressure Regulator Failure, Open To Maximum Demand*

Estimated Time (sec)	Event
0	Simulate maximum limit on steam flow to main turbine.
0.1	Main turbine bypass starts to open.
2.1	L8 vessel level setpoint trips main turbine and feedwater pumps.
2.1	Reactor scram trip is actuated from main turbine stop valve position switches.

* See Section 15.1.3.3.3 for description of a potential alternate sequence of events that is also considered.

15.1.4 Inadvertent Safety/Relief Valve Opening

Inadvertent opening of an SRV can lead to two possible events. First, the valve may open and reclose. This event has no significant effect on plant operation. Second, the valve may open and stick in the open position. This is the more limiting case and results in the plant transient discussed below.

15.1.4.1 Identification of Causes and Frequency Classification

15.1.4.1.1 Identification of Causes

Cause of inadvertent opening is malfunction of the valve or an operator initiated opening. Opening and closing circuitry at the individual valve level (as opposed to groups of valves) is subject to a single failure impact. It is therefore simply postulated that a failure occurs and the event is analyzed accordingly. Detailed discussion of the valve is provided in Chapter 5.

15.1.4.1.2 Frequency Classification

This transient disturbance is categorized as an infrequent incident, but because of the lack of a comprehensive data base, it is being analyzed as an incident of moderate frequency.

15.1.4.2 Sequence of Events and Systems Operation

15.1.4.2.1 Sequence of Events

Table 15.1.4-1 lists the sequence of events for this transient.

15.1.4.2.2 Systems Operation

In this transient, the analysis assumes normal functioning of plant instrumentation and controls, specifically, the relief valve discharge line temperature sensors, suppression pool temperature sensors, and the level control systems. Additionally, minimum reactor and plant protection systems, emergency core cooling system (ECCS) flow, and residual heat removal (RHR) pool cooling are required. No credit is taken for the functioning of normal operation plant systems other than as defined above.

15.1.4.3 Core and System Performance

15.1.4.3.1 Mathematical Model

Only a qualitative evaluation is provided.

15.1.4.3.2 Input Parameters and Initial Conditions

It is assumed that the reactor is operating at an initial power level corresponding to 105 percent of rated steam flow conditions when an SRV is inadvertently opened. Flow through the valve at normal plant operating conditions stated above is approximately 870,000 lb/hr. Table 5.2-5 contains SRV set pressures and capacities.

15.1.4.3.3 Qualitative Results

The opening of an SRV allows steam to be discharged into the suppression pool. The sudden increase in the rate of steam flow leaving the reactor vessel causes a mild depressurization transient.

The pressure regulator senses the nuclear system pressure decrease; within a few seconds it closes the turbine control valve far enough to stabilize reactor vessel pressure at a slightly lower value, and reactor power settles at nearly the initial power level. Thermal margins decrease only slightly through the transient, and no fuel damage results from the transient. The MCPR is essentially unchanged; therefore, the safety limit margin is unaffected.

The analysis assumed the initial suppression pool temperature is 95°F, maximum.

a. For a fully stuck open SRV, the suppression pool temperature Technical Specifications limit of 110°F is reached in about 6 minutes. Thus, the operator would be required to initiate a reactor scram approximately 6 minutes after the occurrence of the stuck open relief valve

b. If the plant shutdown is delayed, the suppression pool temperature would continue to rise at a rate of about 2°F/minute. At 10 minutes after the occurrence of the stuck open relief valve, the reactor is assumed to be scrammed. The suppression pool temperature would be less than 120°F. Fermi 2 has T-quenchers; therefore, no adverse effect on safety is expected

   The maximum allowable suppression pool temperature is limited by the net positive suction head for ECCS pumps and is discussed in Subsection 6.3.2.14

15.1.4.4 Barrier Performance

As discussed above, the transient resulting from a stuck open relief valve is a mild depressurization within the range of normal load following and therefore without significant effect on reactor coolant pressure boundary (RCPB) and containment design pressure limits.

15.1.4.5 Radiological Consequences

While the consequence of this event does not result in fuel failure, it does result in the discharge of normal coolant activity to the suppression pool via SRV operation. Since this activity is contained in the primary containment, there will be no exposure to operating personnel. Since this event does not result in an uncontrolled release to the environment, the plant operator can choose to leave the activity bottled up in the containment or discharge it to the environment under controlled meteorological and release conditions. If purging of the primary containment is chosen, the release will have to be in accordance with the established Technical Specifications; therefore, this event, at the worst, would result in only a small increase in the yearly integrated exposure level.

Table 15.1.4-1 Typical Sequence of Events for Inadvertent Safety/Relief Valve Opening

Estimated Time (min)	Event
0	Initiate opening of one SRV, which remains open throughout the event.
6	Operator actuates scram on high suppression pool temperature.
10	Operator attempts to close valve unsuccessfully.
15	The reactor pressure vessel (RPV) water level reaches L2; the HPCI and RCIC systems are actuated.
20	Operator activates RHR and initiates normal plant shutdown.
300	Shutdown is completed.

15.2 INCREASE IN REACTOR PRESSURE

Seven transients are evaluated under the increase in reactor pressure analytical category:

a. Pressure regulator failure - closed

b. Generator load rejection

c. Turbine generator trip

d. Main steam isolation valve closure

e. Loss of condenser vacuum

f. Loss of alternating current power

g. Loss of feedwater flow

Only the turbine generator trip, generator load rejection, and pressure regulator failure – closed with backup pressure regulator out of service transients in this analytical category are analyzed for cycle-specific analysis. A qualitative prescription of results is described for those events determined to be nonlimiting from a core performance standpoint.

15.2.1 Pressure Regulator Failure - Closed

15.2.1.1 Identification of Causes and Frequency Classification

15.2.1.1.1 Identification of Causes

Two identical pressure regulators are provided to maintain primary system pressure control. They independently sense pressure just upstream of the main turbine stop valves and compare it with two separate setpoints to create proportional error signals that produce each regulator output. The regulator with the highest output controls the main turbine control valves. (Note: The lowest pressure setpoint gives the largest pressure error and thereby the largest regulator output.) The backup regulator is set 5 psi higher, giving a slightly smaller error and a slightly smaller effective output of the controller.

It is assumed for the purposes of this transient analysis that a single failure occurs that erroneously causes the controlling regulator to close the main turbine control valves and thereby increases reactor pressure. If this occurs, the backup regulator is ready to take control.

15.2.1.1.2 Frequency Classification

This event is treated as a moderate frequency event.

15.2.1.2 Sequence of Events and Operator Actions

15.2.1.2.1 Sequence of Events

Postulating a failure of the primary or controlling pressure regulator in the closed mode, as discussed in Subsection 15.2.1.1.1, will cause the valves to close momentarily. The pressure will increase because the reactor is still generating the initial steam flow. The backup regulator will reopen the valves and reestablish steady-state operation above the initial pressure equal to the setpoint difference of 5 psi.

15.2.1.2.1.1 Identification of Operator Actions

The operator will verify that the backup regulator assumes proper control.

15.2.1.2.1.2 The Effect of Single Failures and Operator Errors

The nature of the first assumed failure produces a slight pressure increase in the reactor until the backup regulator gains control. Because no other action is significant in restoring normal operation if the backup regulator fails at this time (the second assumed failure), the control valves will start to close, raising reactor pressure to the point where a flux or pressure scram trip will be initiated to shut down the reactor. At rated power, this event is less severe than the turbine trip where stop valve closure occurs.

For the pressure controller failure - closed transient, a single failure is assumed to occur that erroneously causes the main controlling regulator to close the main turbine control valves, thereby increasing reactor pressure. If this occurs, the backup regulator is ready to take control. The probability of the concurrent failure of the backup regulator and the primary regulator is low enough such that the event combination is classified as an infrequent event. Nevertheless, a quantitative evaluation of this assumed transient (failure of the backup regulator) at rated power was made using TRACG.

15.2.1.3 Core and System Performance

The disturbance is mild, similar to a pressure setpoint change, and no significant reductions in fuel thermal margins occur. This transient is much less severe than the generator and turbine trip transients described in Subsections 15.2.2 and 15.2.3. However, the pressure regulator failure – closed event with backup pressure regulator out of service is potentially limiting for reloads and plant modifications. During this event, pressure regulator demand is forced to zero, which causes the full closure of turbine control valves at the normal servo rate as well as inhibit the opening of the turbine bypass valves; thereby increasing reactor power and pressure. The event is terminated when the reactor scrams on high pressure or high neutron flux.

15.2.1.3.1 Mathematical Model

Only a qualitative evaluation is provided except TRACG methodology is used for the backup pressure regulator out of service analysis (see Section 15.1.2.3.1).

15.2.1.3.2 Input Parameters and Initial Conditions

Only a qualitative evaluation is provided.

15.2.1.3.3 Qualitative Results

The response of the reactor during this regulator failure is such that the pressure at the turbine inlet increases quickly, less than 2 sec or so, because of the sharp closing action of the turbine control valves that reopen when the backup regulator gains control. This pressure disturbance in the vessel is not expected to exceed flux or pressure scram trip setpoints.

15.2.1.4 Barrier Performance

As noted above, the consequences of this event do not result in any temperature or pressure transient in excess of the criteria for which the fuel, pressure vessel, or containment are designed; therefore, these barriers maintain their integrity and function as designed.

15.2.1.5 Radiological Consequences

Because this event does not result in any additional fuel failures or any release of primary coolant to either the secondary containment or to the environment, there are no radiological consequences associated with this event.

15.2.2 Generator Load Rejection

Either the generator load rejection without bypass event or the turbine generator trip without bypass event (Subsection 15.2.3) are the most limiting events in this analytical category.

15.2.2.1 Identification of Causes and Frequency Classification

15.2.2.1.1 Identification of Causes

The turbine control valves (TCVs) will close under servo action initiation as a result of turbine shaft acceleration whenever electrical grid disturbances occur that result in significant loss of electrical load on the generator. The turbine control valves are required to close as rapidly as possible to prevent excessive overspeed of the turbine generator rotor. Closure of the main turbine control valves will cause a sudden reduction in steam flow, which in turn will result in an increase in system pressure and reactor shutdown.

15.2.2.1.2 Frequency Classification

This transient is categorized as an incident of moderate frequency. Fermi 2 has an uncommon bypass system because of its English Electric turbine. Additional information on the Fermi 2 bypass system is provided in Subsection 10.4.4.

15.2.2.2 Sequence of Events and Systems Operation

15.2.2.2.1 Sequence of Events

A loss of generator electrical load from high power conditions initiates a fast closure of the turbine control valves which results in a rapid pressurization in the reactor vessel, causing a collapse of steam voids that rapidly increases the neutron flux. The fast closure of the turbine control valves initiates the reactor scram and terminates the event.

15.2.2.2.2 Systems Operation

The TCV fast closure signal is generated independently in each valve control logic and wired directly into the reactor protection system (RPS). The signal to the RPS is generated simultaneously with the de-energizing of the solenoid dump valves, which produces control valve fast closure. Therefore, when TCV fast closure occurs, a scram trip signal is initiated.

The pressure relief system, which operates the relief valves independently when system pressure exceeds relief valve instrumentation setpoints, is assumed to function normally during the time period analyzed with the exception of the fact that four Group 1 relief valves are assumed to remain closed.

All plant control systems maintain normal operation unless specifically designated to the contrary. The steam flow through the moisture separator reheater line as described in Subsection 15.1.2.2.2, is included in the analysis, except as noted.

15.2.2.3 Core and System Performance

15.2.2.3.1 Mathematical Model

The predicted dynamic behavior of this event is evaluated using the TRACG computer model described in Reference 1 (see details in Subsection 15.1.2.3.1).

15.2.2.3.2 Input Parameters and Initial Conditions

These analyses are evaluated, unless otherwise noted, with the plant conditions in Table 15.0-1.

The turbine control system power/speed acceleration rate detects load rejection before a measurable speed change takes place.

The closure characteristics of the TCVs are assumed such that the valves operate in the full arc (FA) mode and have a full stroke closure time, from fully open to fully closed, of 0.220 seconds. The valves are assumed to be at an intermediate position at 100 percent power so they close faster than 0.220 seconds causing a more severe pressure transient.

Fermi 2 valves have a near linear flow versus stroke characteristic. In sensitivity studies the initial control valve position at less than wide open and the reactor operating at full power were considered. These studies indicate that the smaller control valve opening does not result in a significant increase change in CPR.

Auxiliary power would normally be independent of any turbine generator overspeed effects.

A reactor scram is initiated simultaneously with the de-energizing of the solenoid dump valves. This produces the TCV fast closure.

When comparing a lower power case with a full power case for generator load rejection transient with a full stroke TCV closure, the severity of the event remains relatively unchanged. This is because the pressurization effect of reduced steam flow rate and shorter

TCV closure time balance each other. Consequently, ΔMCPR and peak vessel pressure during a load rejection transient at low power are expected to be about the same as during a full power transient.

For the Fermi 2 turbine design, the control valves are at an intermediate position at rated reactor pressure and a steam flow equivalent to rated nuclear boiler rating (NBR). In the case of the TRACG analysis, evaluated for the turbine generator trip transient, an intermediate position of the control valves is assumed to exist initially and corresponds to an actual valve travel time of less than 0.220 seconds.

In the evaluation of the generator load rejection transient, the closure characteristics of the TCVs are assumed to be in the full arc mode. That is, the valves operate in the full arc mode and have a full stroke closure time of 0.220 seconds from fully open to fully closed. Sensitivity studies show that TCV closure times less than the assumed 0.220 sec do not result in unacceptable increases in delta CPR or reactor peak pressure. For example, if the TCV closure time were 0.15 sec, the peak surface heat flux would increase by approximately 1 percent and the peak vessel pressure by only about 1 psi. The change in CPR for the turbine trip transient and the generator load rejection transient are close with the generator load rejection transient normally being more severe. However, this transient is confirmed each fuel cycle so the results of the analysis can be found in the most current Supplemental Reload Licensing Report.

The following generator load rejection without bypass cases are typically analyzed for cycle-specific analysis:

a. Operation with moisture separator reheater and feedwater heaters operable at 100 percent power, 105 percent flow at EOC.

b. Operation without moisture separator reheater and with feedwater heaters operable at 100 percent power, 105 percent flow, at EOC.

15.2.2.3.3 Qualitative Results

Because of Fermi 2 special design features, (Chapter 10, Subsection 10.4.4) the turbine generator trip transient is typically bounded by this transient.

A generator load rejection with failure of the bypass system typically bounds the corresponding turbine trip transient due to the following Fermi 2 specific design features:

a. Recirculation pumps are powered through auxiliary transformers from outside power sources and are independent of turbine generator overspeed effects

b. A reactor scram is initiated simultaneously with the de-energizing of the solenoid dump valves, which produces the TCV fast closure. The TCVs are at an intermediate position so they close faster than the full open closure time of 0.220 seconds. Therefore, the pressure transient is larger.

Therefore, the generator load rejection transient bounds the turbine trip transient discussed in Subsection 15.2.3 typically. However, this transient is confirmed each fuel cycle so the results of the analysis can be found in the most current Supplemental Reload Licensing Report.

15.2.2.3.4 Consideration of Uncertainties

Important analytical factors, such as void and scram reactivity coefficients, have been adjusted statistically at a given cycle exposure so that any deviation in the actual plant parameter will produce a less severe transient.

15.2.2.4 Barrier Performance

The consequences of the analyzed events do not result in any temperature or pressure transient in excess of the criteria for which the fuel, pressure vessel, or containment are designed; therefore, these barriers maintain their integrity and function as designed.

15.2.2.5 Radiological Consequences

While the consequence of this event does not result in fuel failures, it does result in the discharge of normal coolant activity to the suppression pool via safety/relief valve (SRV) operation. Since this activity is contained in the primary containment, there will be no exposure to operating personnel. Since this event does not result in an uncontrolled release to the environment, the plant operator can choose to leave the activity bottled up in the containment or discharge it to the environment under controlled meteorological and release conditions. If purging of the containment is chosen, the release will have to be in accordance with established Technical Specifications; therefore, this event, at the worst, would result in only a small increase in the yearly integrated exposure level.

Table 15.2.2-1 TYPICAL SEQUENCE OF EVENTS FOR GENERATOR LOAD REJECTION, WITHOUT TURBINE BYPASS AND WITH MOISTURE SEPARATOR REHEATER FLOW AT MOC[(a)]

Estimated Time (sec)	Event
(-)0.015	Turbine generator detects loss of electrical load when CM and CF open.
0	Turbine generator trip logic initiates turbine control valve (TCV) fast closure.
0	Turbine bypass valves fail to operate.
0	TCV Fast control valve closure logic simultaneously initiates scram trip.
0.2	Turbine control valves are fully closed.
1.2	High pressure pump trip setpoint is reached.
1.5	Recirculation pumps trip because of high pressure.

Table 15.2.2-1 TYPICAL SEQUENCE OF EVENTS FOR GENERATOR LOAD REJECTION, WITHOUT TURBINE BYPASS AND WITH MOISTURE SEPARATOR REHEATER FLOW AT MOC[(a)]

15.2.3 Turbine Generator Trip

Either the generator load rejection without bypass event (Subsection 15.2.2) or the turbine generator trip without bypass event are the most limiting events in this analytical category.

15.2.3.1 Identification of Causes and Frequency Classification

15.2.3.1.1 Identification of Causes

A variety of turbine or nuclear system malfunctions will initiate a turbine trip. Some examples are low condenser vacuum and reactor high water level. Both turbine generator trip and load rejection will initiate the closure of turbine stop valves and the fast closure of the turbine control valves (TCV).

15.2.3.1.2 Frequency Classification

This transient is categorized as an incident of moderate frequency. In defining the frequency of the this event, turbine generator trips that occur as a by product of other transients, such as loss of condenser vacuum or reactor high level trip events, are not included. However, spurious low vacuum or high level trip signals that cause an unnecessary turbine generator trip are included in defining the frequency. To get an accurate event-by-event frequency breakdown, this type of division of initiating causes is required.

15.2.3.2 Sequence of Events and Systems Operation

15.2.3.2.1 Sequence of Events

This event results in a rapid pressurization in the reactor vessel causing a collapse of steam void that rapidly increases the neutron flux. The fast closure of the turbine control/stop valve initiates the reactor scram and terminates the event.

15.2.3.2.2 Systems Operation

All plant control systems maintain normal operation unless specifically designated to the contrary. The steam flow through the moisture separator reheater line as described in Subsection 15.1.2.2.2, is included in this analysis with the reheater operational. The turbine bypass is assumed to be out-of-service for all the analyses.

A turbine generator trip signal closes both the stop and control valves at the maximum closure rate of 0.220 sec for full valve travel. Each set of valves is wired in a preassigned logic to cause a reactor scram upon closure. For the stop valve function, a limit switch at a valve position of 10 percent closed from full open is used. A control valve fast closure signal is generated independently in each valve control logic and wired directly into the reactor protection system (RPS). The signal to the RPS is generated simultaneously with the de-energizing of the solenoid dump valves, which produce the control valve fast closure.

In the analyses, it is assumed that both sets of turbine valves are closed on turbine generator trip demand, but as an added conservatism the scram is assumed to occur as a result of the stop valve closure. The trip, which is anticipated by the control valve fast closure signal to the RPS, has been considered. For analytical purposes, the reactor trip occurs 0.02 seconds after the turbine generator trip as the stop valve reaches the 10 percent closed position. Credit is taken for successful operation of the RPS.

The pressure relief system, which operates the relief valves independently when system pressure exceeds relief valve setpoints, is assumed to function normally during the time period analyzed with the exception of the fact that four Group 1 relief valves are assumed to remain closed.

15.2.3.3 Core and System Performance

15.2.3.3.1 Mathematical Model

The predicted dynamic behavior of this event is evaluated using the TRACG computer model described in Reference 1 (see details in Subsection 15.1.2.3.1).

15.2.3.3.2 Input Parameters and Initial Conditions

These analyses are evaluated, unless otherwise noted, with the plant conditions in Table 15.0-1.

Turbine stop valve full stroke closure time is assumed to be 0.220 sec.

A reactor scram is initiated by position switches on the stop valves when the valves are less than 90 percent open. This stop valve scram trip signal is automatically bypassed when the reactor is below 29.5 percent NBR power level.

A reactor scram signal is also initiated by the fast closure of turbine control valves. A 30-msec delay of this scram signal is conservatively assumed.

The following turbine generator trip without bypass cases are typically analyzed for cycle-specific analysis:

a. Operation with moisture separator reheater and feedwater heaters operable at 100 percent power, 105 percent flow at EOC.

b. Operation without moisture separator reheater and with feedwater heaters operable at 100 percent power, 105 percent flow, at EOC.

15.2.3.3.3 Qualitative Results

Results of the cycle-specific analyses are presented in Chapter 15.0 Reference 15. The MCPR operating limits for these analyses are presented in Chapter 15.0 Reference 15. The following subsections present the results of the cases described above. Tables 15.2.3-1, 15.2.3-2 and 15.2.3-3 list the typical sequence of events for these cases.

15.2.3.3.3.1 100 Percent Power, 105 Percent Flow with Moisture Separator Reheater and Feedwater Heaters Operable at MOC

This analysis typically represents a non-limiting transient for normal operation early in the cycle. The Core Operating Limits Report and Table 15.0-3 describe the limiting transients for each operating cycle.

15.2.3.3.3.2 100 Percent Power, 105 Percent Flow with Moisture Separator Reheater and Feedwater Heaters Operable at EOC

This transient is typically bounded by the generator load rejection without bypass with moisture separator reheater and feedwater heaters operable at EOC. The Core Operating Limits Report and Table 15.0-3 describe the limiting transients for each operating cycle.

15.2.3.3.3.3 100 Percent Power, 105 Percent Flow with Moisture Separator Reheater Inoperable and Feedwater Heaters Operable at EOC

This transient is more severe than the turbine generator trip without bypass since no credit is taken for the passive steam bypass flow through the moisture separator reheater. The high pressure pump trip setpoint is reached and the recirculation pumps trip about 0.1 seconds earlier, and the Group 1, 2 and 3 relief valves are actuated about 0.2 seconds earlier than in the turbine generator trip without bypass transient. The Core Operating Limits Report and Table 15.0-3 describe the limiting transients for each operating cycle.

15.2.3.3.4 Consideration of Uncertainties

Important analytical factors, such as void and scram reactivity coefficients, have been adjusted statistically at a given cycle exposure so that any deviation in the actual plant parameter will produce a less severe transient.

15.2.3.4 Barrier Performance

The consequences of the analyzed events do not result in any temperature or pressure transient in excess of the criteria for which the fuel, pressure vessel, or containment are designed; therefore, these barriers maintain their integrity and function as designed.

15.2.3.5 Radiological Consequences

While the consequences of this event do not result in fuel failure, there is discharge of normal coolant activity to the suppression pool via SRV operation. Since this activity is contained in the primary containment, there will be no exposure to operating personnel. Since this event does not result in an uncontrolled release to the environment, the plant operator can choose to leave the activity bottled up in the containment or discharge it to the environment under controlled meteorological and release conditions. If purging of the primary containment is chosen, the release will have to be in accordance with established Technical Specifications; therefore, this event, at the worst, would result in only a small increase in the yearly integrated exposure level.

Table 15.2.3-1 TYPICAL SEQUENCE OF EVENTS FOR TURBINE GENERATOR TRIP WITHOUT BYPASS AT 100% POWER, 105% FLOW, RATED FEEDWATER TEMPERATURE WITH REHEATER FLOW AT MOC[(a)]

Estimated Time (sec)	Event
0	Turbine generator trip initiates fast closure of turbine control valves.
0	Turbine generator trip of load rejection initiates closure of main stop valves.
0	Turbine bypass valves fail to operate.

Table 15.2.3-1 TYPICAL SEQUENCE OF EVENTS FOR TURBINE GENERATOR TRIP WITHOUT BYPASS AT 100% POWER, 105% FLOW, RATED FEEDWATER TEMPERATURE WITH REHEATER FLOW AT MOC[(a)]

Estimated Time (sec)	Event
0.02	Main turbine stop valves reach 90 percent open position and initiate reactor scram trip.
0.03	Fast closure of turbine control valves initiaties a reactor scram trip.
0.2	Turbine control valves are fully closed.
1.3	High pressure pump trip setpoint is reached
1.6	Recirculation pumps trip because of high pressure.
1.7	Group 1 relief valves are actuated.
1.9	Group 2 relief valves are actuated.
2.0	Reheater flow starts to decay.
2.1	Group 3 relief valves are actuated.
3.0	Reheater flow decays to zero.

1.6	Group 2 relief valves are actuated.
1.7	Group 3 relief valves are actuated.

15.2.4 Main Steam Isolation Valves Closure

15.2.4.1 Identification of Causes and Frequency Classification

15.2.4.1.1 Identification of Causes

Various steam line and nuclear system malfunctions, or operator actions, can initiate main steam isolation valves (MSIV) closure. Examples are low steam line pressure, high steam line flow, high steam line radiation, low water level, or manual action.

15.2.4.1.2 Frequency Classification

15.2.4.1.2.1 Closure of All Main Steam Isolation Valves

This event is categorized as an incident of moderate frequency. To define the frequency of this event as an initiating event and not the by product of another transient, only the following contribute to the frequency: manual action (purposely or inadvertently); spurious signals, such as low pressure, low reactor water level, low condenser vacuum, and the like; and finally, equipment malfunctions, such as faulty valves or operating mechanisms. Depending on reactor conditions, a closure of one MSIV may cause an immediate closure of all the other MSIVs. If this occurs, it is also included in this category. During the MSIV closure, position switches on the valves provide a reactor scram if the valves in three or more main steam lines are less than 90 percent open (except for interlocks which permit proper plant startup). Protection system logic, however, permits the test closure of one valve without initiating scram from the position switches.

15.2.4.1.2.2 Closure of One Main Steam Isolation Valve

This event is categorized as an incident of moderate frequency. One MSIV at a time may be manually closed for testing purposes. Operator error or equipment malfunction may cause a single MSIV to be closed inadvertently. If reactor power is greater than about 80 percent when this occurs, a high flux or high steam line flow scram may result (if all MSIVs close as a result of the single closure, the event is considered a closure of all MSIVs).

15.2.4.2 Sequence of Events and Systems Operation

15.2.4.2.1 Sequence of Events

Table 15.2.4-1 lists the typical sequence of events.

15.2.4.2.2 Systems Operation

15.2.4.2.2.1 Closure of All Main Steam Isolation Valves

The MSIV closures initiate a reactor scram trip via position signals to the protection system. Credit is taken for successful operation of the protection system. The pressure relief system, which initiates opening of the relief valves when system pressure exceeds relief valve setpoints, is assumed to function normally during the time period analyzed. All plant control systems maintain normal operation, unless specifically designated to the contrary.

15.2.4.2.2.2 Closure of One Main Steam Isolation Valve

A closure of a single MSIV at any given time will not initiate a reactor scram. This is because the valve position scram trip logic is designed to accommodate single valve operation and testability during normal reactor operation at limited power levels. Credit is taken for the operation of the pressure and flux signals to initiate a reactor scram. All plant control systems maintain normal operation, unless specifically designated to the contrary.

15.2.4.3 Core and System Performance

15.2.4.3.1 Mathematical Model

Only a qualitative analysis is provided.

15.2.4.3.2 Input Parameters and Initial Conditions

Only a qualitative evaluation is provided.

The MSIVs close in 3 to 5 sec. The worst case, the 3-sec closure time, is assumed in this analysis.

Position switches on the valves initiate a reactor scram when the valves are less than 90 percent open. Closure of these valves inhibits steam flow to the feedwater turbines terminating feedwater flow.

Valve closure indirectly causes a trip of the main turbine and generator. Because of the loss of feedwater flow, water level within the vessel decreases sufficiently and initiates the high pressure coolant injection (HPCI) and reactor core isolation cooling (RCIC) systems.

15.2.4.3.3 Qualitative Results

15.2.4.3.3.1 Main Steam Isolation Valves, Position Scram

For the simultaneous isolation of all main steam lines while the reactor is operating at rated NBR, the neutron flux reaches a peak, then drops below its initial power value.

15.2.4.3.3.2 Closure of One Main Steam Isolation Valve

Only one isolation valve is permitted to be closed at a time for testing purposes to prevent scram. Normal test procedure requires an initial power reduction to approximately 80 to 90 percent of design conditions to avoid high flux scram, high pressure scram, or full isolation from high steam flow in the live lines. With a 3-sec closure of one main steam isolation valve during rated power conditions, the steam flow disturbance raises vessel pressure and reactor power enough to initiate a high neutron flux scram. This transient is considerably milder than the full power case. No quantitative analysis is furnished for this event. However, no significant change in thermal margins is experienced, and no fuel damage occurs. Peak pressure remains below SRV setpoints.

Inadvertent closure of one or all of the isolation valves while the reactor is shut down will produce no significant transient. Closures during plant heatup (operating state D) will be less severe than the maximum power cases (maximum stored and decay heat) discussed in Subsection 15.2.4.3.3.1.

15.2.4.3.4 Consideration of Uncertainties

Uncertainties in these analyses involve protection system settings, system capacities, and system response characteristics. In all cases, the most conservative values are used in the analyses.

a. Slowest allowable control rod scram motion is assumed

b. Scram worth shape for all-rod-out conditions is assumed

c. Minimum specified valve capacities are utilized for overpressure protection

d. Setpoints of the SRVs are assumed to be at least 1 percent higher than the valve's nominal setpoint.

15.2.4.4 Barrier Performance

15.2.4.4.1 Closure of All Main Steam Isolation Valves

The nuclear system relief valves begin to open at approximately 2.7 sec after the start of isolation. The valves close sequentially as the stored heat is dissipated, but continue to discharge the decay heat intermittently.

15.2.4.4.2 Closure of One Main Steam Isolation Valve

No significant effect is imposed on the reactor coolant pressure boundary (RCPB) since, if closure of the valve occurs at an unacceptably high operating power level, a flux or pressure scram will result. The main turbine bypass system will continue to regulate system pressure via the other three live steam lines.

15.2.4.5 Radiological Consequences

While the consequences of this event do not result in fuel failures, there is discharge of normal coolant activity to the suppression pool via SRV operation. Since this activity is contained in the primary containment, there will be no exposure to operating personnel. Since this event does not result in an uncontrolled release to the environment, the plant operator can choose to leave the activity bottled up in the primary containment or discharge it to the environment under controlled meteorological and release conditions. If purging of the primary containment is chosen, the release will have to be in accordance with established Technical Specifications; therefore, this event, at the worst, would result in only a small increase in the yearly integrated exposure level.

Table 15.2.4-1 TYPICAL SEQUENCE OF EVENTS FOR MAIN STEAM ISOLATION VALVES, POSITION SCRAM

Estimated Time (sec)	Event
0	Initiate closure of all MSIVs.
0.3	MSIVs reach 90 percent open.[a]
0.3	MSIV position trip scram is initiated.
2.7	Group 1 relief valves open due to pressure relief setpoint action.[b]
2.8	High pressure pump trip setpoint is reached.
3.1	Recirculation pumps are tripped due to high pressure.
11.5	Group 1 pressure relief valves close.
15+	Relief valves open and close as required for pressure relief.
53	HPCI/RCIC systems flow enters vessel to maintain water level (not simulated). Note HPCI rated flow may occur later if the maximum analyzed response time of 60 sec is assumed.

---

[a] The change in position scram setpoint to 85 percent open has no significant impact on delta CPR or peak pressure.

[b] The change in allowable SRV setpoint tolerances from ±1% to ±3% has no impact on delta CPR because minimum MCPR occurs before SRV opening.

15.2.5 Loss of Condenser Vacuum at Two Inches per Second

15.2.5.1 Identification of Causes and Frequency Classification

15.2.5.1.1 Identification of Causes

Various system malfunctions that can cause a loss of condenser vacuum through some single equipment failure are designated in Table 15.2.5-1.

15.2.5.1.2 Frequency Classification

This event is categorized as an incident of moderate frequency.

15.2.5.2 Sequence of Events and Systems Operation

15.2.5.2.1 Sequence of Events

Table 15.2.5-2 lists the typical sequence of events.

15.2.5.2.2 Systems Operation

In establishing the typical sequence of events, it was assumed that normal functioning occurred in the plant instrumentation and controls, and in plant protection and reactor protection systems. Tripping functions incurred by sensing main turbine condenser vacuum pressure are designated in Table 15.2.5-3.

15.2.5.3 Core and System Performance

15.2.5.3.1 Mathematical Model

Only a qualitative analysis is provided.

15.2.5.3.2 Input Parameters and Initial Conditions

Only a qualitative evaluation is provided.

A reactor scram is initiated by position switches on the stop valves when the valves are less than 90 percent open. This stop valve scram trip signal is automatically bypassed when the reactor is below 29.5 percent NBR power level.

The analysis presented here is a hypothetical case with a conservative 2-in. Hg/sec vacuum decay rate. Thus, the bypass system is available for several seconds, since the bypass is signaled to close at a vacuum level of about 10 in. Hg less than the stop valve closure.

15.2.5.3.3 Qualitative Results

Under this hypothetical 2-in. Hg/sec vacuum decay condition, the turbine bypass valve and MSIV closure will follow main turbine and feedwater turbine trips about 5 sec after they initiate the transient. For Fermi 2, the minimum period of time (5 sec) between the turbine trip and the isolation of MSIV is based on the maximum rate of vacuum loss in Table 15.2.5-1 (24-in. Hg/min or 0.4 in. Hg/sec) that was estimated at the time of the original licensing of the plant. This transient, therefore, is similar to a normal turbine trip with bypass. The effect of MSIV closure tends to be minimal, since the closure of main turbine stop valves and subsequently the bypass valves has already shut off the main steam line flow. It is assumed that the plant is initially operating at rated NBR power conditions. Safety relief valves open to limit the pressure rise, then sequentially reclose as the stored energy is dissipated.

15.2.5.3.4 Consideration of Uncertainties

The reduction or loss of vacuum in the main turbine condenser will sequentially trip the main and feedwater turbines and close the MSIVs and bypass valves. While these are the major events occurring, other resultant actions will include scram (from stop valve closure) and bypass opening with the main turbine trip. Because the protective actions are actuated at various levels of condenser vacuum, the severity of the resulting transient is directly dependent upon the rate at which the vacuum pressure is lost. Normal loss of vacuum due to loss of cooling water pumps or steam jet air ejector problems produces a very slow rate of loss of vacuum: minutes, not seconds (see Table 15.2.5-1). If corrective actions by the reactor operators are unsuccessful, then simultaneous trips of the main and feedwater turbines, and ultimately complete isolation by closing the bypass valves (opened with the main turbine trip) and the MSIVs, will occur.

A faster rate of loss of the condenser vacuum will reduce the anticipatory action of the scram and the overall effectiveness of the bypass valves, since they will be closed more quickly.

Other uncertainties in these analyses involve protection system settings, system capacities, and system response characteristics. In all cases, the most conservative values are used in the analyses.

a. Slowest allowable control rod scram motion is assumed

b. Scram worth shape for all-rod-out conditions is assumed

c. Minimum specified valve capacities are utilized for overpressure protection

d. Setpoints of the SRVs are assumed to be at least the upper limit of Technical Specifications for all valves.

15.2.5.4 Barrier Performance

The overpressure transient is below the reactor coolant pressure boundary transient pressure limit of 1375 psig. A comparison between the turbine trip with bypass failure at high power shows the similarities between these two transients. The prime differences are the loss of feedwater and main steam isolation, and the resulting low water level trips.

15.2.5.5 Radiological Consequences

While the consequence of this event does not result in fuel failures, it does result in the discharge of normal coolant activity to the suppression pool via SRV operation. Since this activity is contained in the primary containment, there will be no exposure to operating personnel. Since this event does not result in an uncontrolled release to the environment, the plant operator can choose to leave the activity bottled up in the primary containment or discharge it to the environment under controlled meteorological and release conditions. If purging of the primary containment is chosen, the release will have to be in accordance with established Technical Specifications; therefore, this event, at the worst, would result in only a small increase in the yearly integrated exposure level.

TABLE 15.2.5-1 TYPICAL RATES OF DECAY FOR CONDENSER VACUUM

Cause		Estimated Vacuum Decay Rate
1.	Failure or isolation of steam-jet air ejectors	<1 in. Hg/minute
2.	Loss of sealing steam to shaft gland seals	≈1 to 2 in. Hg/minute
3.	Opening of vacuum breaker valves	≈2 to 12 in. Hg/minute
4.	Loss of one or more circulating water pumps	≈4 to 24 in. Hg/minute

TABLE 15.2.5-2 TYPICAL SEQUENCE OF EVENTS FOR LOSS OF CONDENSER VACUUM AT 2 INCHES PER SECOND

Estimated Time (sec)	Event
-2.5	Initiate simulated loss of condenser vacuum at 2 in. Hg per sec.
0.0	Low condenser vacuum main turbine trip is actuated.
0.0	Low condenser vacuum feedwater trip is actuated.
0.02	Main turbine trip initiates reactor scram.
2.0	Moisture separator reheater flow starts to decay.
2.9	Group 1 relief valves' setpoints are actuated.
5.0	Reheater flow decays to zero.
5.0	Low condenser vacuum initiates MSIV closure.

TABLE 15.2.5-2 TYPICAL SEQUENCE OF EVENTS FOR LOSS OF CONDENSER VACUUM AT 2 INCHES PER SECOND

Estimated Time (sec)	Event
5.0	Low condenser vacuum initiates bypass valve closure.
9.8	Group 1 relief valves close.
15.0	Water level drops to L2 initiating recirculation pump trip and the startup sequence for HPCI/RCIC.
20+	Relief valve opens and closes as required to maintain pressure relief.
45	HPCI/RCIC system flow enters vessel to maintain water level (not simulated). Note: HPCI injection will take longer assuming the maximum analyzed response time of 60 sec.

TABLE 15.2.5-3 TRIP SIGNALS ASSOCIATED WITH LOSS OF CONDENSER VACUUM

Vacuum (in. Hg)	Protective Action Initiated
27 to 28	Normal vacuum range
20	Main turbine trip and feedwater turbine trip (stop valve closures)
10	MSIV closure and bypass valve closure

15.2.6 Loss of Alternating Current Power

15.2.6.1 Identification of Causes and Frequency Classification

15.2.6.1.1 Identification of Causes

Loss of all grid connections can result from major shifts in electrical loads, loss of loads, lightning, storms, wind, and the like, which contribute to electrical grid instabilities. These instabilities will cause equipment damage if unchecked. Protective relay schemes automatically disconnect electrical sources and loads to mitigate damage.

15.2.6.1.2 Frequency Classification

This transient disturbance is categorized as an incident of moderate frequency.

15.2.6.2 Sequence of Events and Systems Operation

15.2.6.2.1 Sequence of Events

Table 15.2.6-1 lists the typical sequence of events.

15.2.6.2.2 Systems Operation

This event, unless otherwise stated, assumes and takes credit for normal functioning of plant instrumentation and controls, and plant protection and reactor protection systems.

The reactor is subjected to a complex sequence of events when the plant loses all external ac power. Estimates of the responses of the various reactor systems (assuming loss of all grid connections) provide the following simulation sequence:

a. The recirculation pumps are tripped at a reference time, t = 0, with normal coastdown times. Also, at t = 0 a generator load rejection is initiated. This load rejection immediately causes the TCVs to close and causes a scram

b. At approximately 2 sec, independent MSIV closure and scram are initiated due to loss of power to the respective solenoids

c. At approximately 4 sec, feedwater pump trips are initiated.

Operation of the HPCI and RCIC system functions is not simulated in this analysis. Their operation occurs at some time beyond the primary concerns of fuel thermal margin and overpressure effects of this analysis.

Fermi 2 has no direct isolation signal derived from the loss of all grid connections. However, the MSIV closure analysis assumes that the valves start to close 2 sec after the loss of offsite power.

The MSIV isolation logic is supplied with 120-V ac power derived from the RPS motor generator (MG) sets. Because the drive motor of each MG set is de-energized when there is a loss of offsite power, each MG set output will trip as the output voltage and/or the frequency decays. This trip occurs approximately 2 sec after the initial loss of power to the MG set. Each MSIV actuator is equipped with ac- and dc-operated solenoid valves to prevent the inadvertent closure of an isolation valve on the loss of a single ac-power feed and to permit online testing of the isolation logic.

15.2.6.3 Core and Systems Performance

15.2.6.3.1 Mathematical Model

Only a qualitative analysis is provided.

15.2.6.3.2 Input Parameters and Initial Conditions

Only a qualitative evaluation is provided.

15.2.6.3.3 Qualitative Results

Loss of all grid connections essentially takes on the characteristic response of a full load rejection with turbine bypass operable. The generator load rejection wihout turbine bypass operable is discussed in Subsection 15.2.2.

15.2.6.3.4 Consideration of Uncertainties

The most conservative characteristics of protection features are assumed. Any deviations in actual plant performance are expected to make the results of this event less severe.

Following main steam line isolation, the reactor pressure is expected to increase until the SRV setpoint is reached. At this time the valves operate in a cyclic manner to discharge the decay heat to the suppression pool.

15.2.6.4 Barrier Performance

Safety/relief valves open in the pressure relief mode of operation as the pressure increases beyond their setpoints. The pressure in the dome is well below the vessel pressure limit of 1375 psig.

15.2.6.5 Radiological Consequences

While the consequences of this event do not result in fuel failure, the event does result in the discharge of normal coolant activity to the suppression pool via SRV operation. Since this activity is contained in the primary containment, there is no exposure to operating personnel. Since this event does not result in an uncontrolled release to the environment, the plant operator can choose to leave the activity bottled up in the primary containment or discharge it to the environment under controlled meteorological and release conditions. If purging of the primary containment is chosen, the release will have to be in accordance with established Technical Specifications; therefore, this event, at the worst, will result in only a small increase in the yearly integrated exposure level.

Table 15.2.6-1 TYPICAL SEQUENCE OF EVENTS FOR LOSS OF ALL GRID CONNECTIONS

Estimated Time (sec)	Event
(-)0.01	Loss of grid causes turbine generator to detect a loss of electrical load.
0	Control valve fast closure is initiated.

Table 15.2.6-1 TYPICAL SEQUENCE OF EVENTS FOR LOSS OF ALL GRID CONNECTIONS

Estimated Time (sec)	Event
0	Turbine generator power load unbalance trip initiates main turbine bypass system operation.
0	Recirculation system pump motors are tripped.
0.03	Fast control valve closure initiates a reactor scram trip.
0.1	Turbine bypass valves open.
0.2	Turbine control valves are fully closed.
2.0	MSIVs start to close.
2.6	Group 1 SRVs actuate.
2.8	Group 2 SRVs actuate.
3.0	Emergency diesel generator (EDG) starts.
4.0	Feedwater turbine trips off.
10.5	Group 1 SRVs close.
12.0	Sensed water level reaches Level 3. Containment isolation is initiated.
13.0	EDG breaker close.
60	Sensed water level reaches Level 2. HPCI/RCIC systems are initiated.
120	Core water level is reestablished.

15.2.7 Loss of Feedwater Flow

15.2.7.1 Identification of Causes and Frequency Classification

15.2.7.1.1 Identification of Causes

A loss of feedwater flow could occur from pump failures, feedwater controller failures, operator errors, or reactor system variables, such as high vessel water level (L8) trip signal.

15.2.7.1.2 Frequency Classification

This transient disturbance is categorized as an incident of moderate frequency.

15.2.7.2 Sequence of Events and Systems Operation

15.2.7.2.1 Sequence of Events

Table 15.2.7-1 lists the typical sequence of events.

15.2.7.2.2 Systems Operation

Loss of feedwater flow results in a reduction of vessel inventory, which causes the vessel water level to drop. The first corrective action is the low level (L3) scram trip actuation. The RPS responds within 1 sec after this trip to scram the reactor. The low level (L3) scram trip function meets single failure criterion.

Containment isolation, when it occurs, also initiates a main steam isolation valve position scram trip signal as part of the normal isolation event. The reactor, however, is already scrammed and shut down by this time.

Credit is taken for operation of the SRV (low setpoint) to remove decay heat, since the bypass becomes ineffective due to main steam line isolation.

15.2.7.3 Core and System Performance

15.2.7.3.1 Mathematical Model

Only a qualitative analysis is provided.

15.2.7.3.2 Input Parameters and Initial Conditions

Only a qualitative evaluation is provided.

15.2.7.3.3 Qualitative Results

Feedwater flow terminates in approximately 5 seconds and subcooling decreases, causing a reduction in core power level and pressure. As power level is lowered, the turbine steam flow starts to drop off because the pressure regulator is attempting to maintain pressure for the first 7 sec or so. Water level continues to drop until the vessel level (L3) scram trip setpoint is reached, whereupon the reactor is shut down. As the vessel water level drops to the L2 trip setpoint, the recirculation system is tripped, and HPCI and RCIC operation is initiated (not simulated). Minimum critical power ratio remains considerably above the safety limit, since increases in heat flux are not experienced.

15.2.7.3.4 Consideration of Uncertainties

End-of-cycle scram characteristics are assumed. This transient is most severe from high power conditions because the rate of level decrease is greatest and the amount of stored and decay heat to be dissipated is highest.

Operation of the RCIC or HPCI systems is not included in the simulation of the first 50 sec of this transient, since startup of these pumps occurs in the latter part of this time period; therefore, these systems have no significant effects on the results of this transient.

15.2.7.4 Barrier Performance

The consequences of this event do not result in any temperature or pressure transient in excess of the criteria for which the fuel, pressure vessel, or containment are designed; therefore, these barriers maintain their integrity and function as designed.

15.2.7.5 Radiological Consequences

The consequences of this event do not result in any fuel failure.

TABLE 15.2.7-1 TYPICAL SEQUENCE OF EVENTS FOR LOSS OF ALL FEEDWATER FLOW

Estimated Time (sec)	Event
0	Trip of all feedwater pumps is initiated.
3.6	Recirculation flow is run back to the low end of the flow control range.
5.0	Feedwater flow decays to zero.
6.8	Vessel water level (L3) trip initiates scram trip.
25.5	Vessel water level (L2) trip initiates containment isolation. (The low water level MSIV closure setpoint is at L1).
25.5	Vessel water level (L2) trip initiates HPCI and RCIC operation (not simulated, however).
28.5	The MSIVs are fully closed.[a]

[a] The low water level MSIV closure has been changed from L2 to L1. However, no significant impact on peak pressure and thermal margin will result from the change. Therefore, no reanalysis is required.

15.2 INCREASE IN REACTOR PRESSURE

REFERENCES

1. General Electric Co., "General Electric Standard Application for Reactor Fuel, GESTAR II," NEDE-24011-P-A, (Latest Approved Revision as identified in the COLR).

15.3 DECREASE IN REACTOR COOLANT SYSTEM FLOW RATE

Three transients are evaluated under this analytical category:

a. Recirculation pump trip

b. Recirculation flow control failure

c. Recirculation pump seizure

None of these transients are analyzed on a cycle-specific basis. A qualitative description of results is provided for each event determined to be nonlimiting with respect to core performance.

15.3.1 Recirculation Pump Trip

15.3.1.1 Identification of Causes and Frequency Classification

15.3.1.1.1 Identification of Causes

Recirculation pump motor operation can be tripped off by design for intended reduction of other transient core and reactor coolant pressure boundary effects as well as randomly by unpredictable operational failures. Intentional tripping will occur in response to the following:

a. Reactor vessel water level L2 setpoint trip

b. Failure to scram high pressure setpoint trip

c. Motor branch circuit overcurrent protection

d. Motor overload protection

e. Suction block valve not fully open.

Random tripping will occur in response to the following:

a. Operator error

b. Loss of electrical power source to the pumps

c. Equipment or sensor failures and malfunctions which initiate the above intended trip response.

15.3.1.1.2 Frequency Classification

The trip of one or two recirculation pump(s) is categorized as one of moderate frequency.

15.3.1.2 Sequence of Events and Systems Operation

15.3.1.2.1 Sequence of Events

15.3.1.2.1.1 Trip of One Recirculation Pump

Table 15.3.1-1 lists a typical sequence of events.

15.3.1.2.1.2 Trip of Both Recirculation Pump Motors

Table 15.3.1-2 lists a typical sequence of events.

15.3.1.2.2 Systems Operation

Analysis of these events assumes normal functioning of plant instrumentation and controls and of plant protection and reactor protection systems. Specifically, these transients take credit for vessel level (L8) instrumentation to trip the turbine. Reactor scram is tripped from the turbine stop valves. High system pressure is limited by operation of the pressure relief valve system.

15.3.1.3 Core and System Performance

15.3.1.3.1 Mathematical Model

Only a qualitative evaluation is provided.

15.3.1.3.2 Input Parameters and Initial Conditions

Only a qualitative evaluation is provided.

Pump motors and pump rotors are normally simulated with minimum specified rotating inertias.

The design jet pump efficiency is used in the analysis. However, the minimum pump inertia (lower bound) is used in the analysis for conservatism so that the actual pump flow coastdown rate is slower than the calculated values.

The actual pump motor rotating inertia must meet the inertia requirement in the design specification.

15.3.1.3.3 Qualitative Results

15.3.1.3.3.1 Trip of One Recirculation Pump

No scram is initiated directly by pump trip. The vessel water level swell due to rapid flow coastdown may reach the high level trip, thereby shutting down the main turbine and feed pump turbines and indirectly initiating scrams as a result of the main turbine trip. Thermal-hydraulic instabilities may result from a pump trip and are mitigated by the Oscillating Power Range Monitor (OPRM) or other Operator actions. Subsequent events, such as main steam line isolation and initiation of reactor core isolation cooling (RCIC) and high pressure coolant injection (HPCI) systems occurring late in this event, have no significant effect on the results. This is not a limiting transient and the consequences do not result in any fuel failures.

15.3.1.3.3.2 Trip of Both Recirculation Pumps

No scram is initiated directly by pump trip. The vessel water level swell due to rapid flow coastdown is expected to reach the high level trip, thereby shutting down the main turbine and feed pump turbines and indirectly initiating scrams as a result of the main turbine trip. Subsequent events, such as main steam line isolation and initiation of RCIC and HPCI systems occurring late in this event, have no significant effect on the results. This is not a limiting transient and the consequences do not result in any fuel failures.

15.3.1.3.4 Consideration of Uncertainties

Initial conditions chosen for these analyses are conservative and tend to force analytical results to be more severe than expected under actual plant conditions.

Actual pump and pump motor drive line rotating inertias are expected to be somewhat greater than the minimum design values assumed in this simulation. Actual plant deviations regarding inertia are expected to lessen the severity as analyzed. Minimum design inertias were used as well as the least negative void coefficient, since the primary interest is in the flow reduction.

15.3.1.4 Barrier Performance

15.3.1.4.1 Trip of One Recirculation Pump

The results indicate a final reduction in system pressures from the initial conditions. Therefore, the reactor coolant pressure boundary (RCPB) barrier is not threatened.

15.3.1.4.2 Trip of Both Recirculation Pumps

The results indicate that peak pressures stay well below the 1375 psig limit allowed by the applicable code. Therefore, the RCPB is not threatened.

15.3.1.5 Radiological Consequences

The consequences of this event do not result in any fuel failure.

TABLE 15.3.1-1 TYPICAL SEQUENCE OF EVENTS FOR TRIP OF ONE RECIRCULATION PUMP MOTOR

Estimated Time (sec)	Event
0	Trip of one recirculation pump is initiated.
4.5	Vessel water level (L8) trip initiates turbine trip.[a]
4.5	Feedwater pumps are tripped off.
4.5	Turbine trip initiates bypass operation.
4.5	Reactor scram is initiated.
6.5	Moisture separator reheater flow starts to decay.
9.5	Reheater flow decays to zero.
20.0	Core flow and power level stabilize at new equilibrium conditions.

[a] A level 8 trip is not normally expected after the trip of a single recirculation pump. The table presents the worst-case scenario.

TABLE 15.3.1-2 TYPICAL SEQUENCE OF EVENTS FOR TRIP OF BOTH RECIRCULATION PUMP MOTORS

Estimated Time (sec)	Event
0	Trip of both recirculation pumps is initiated.
3.1	Vessel water level (L8) trip initiates turbine trip.
3.1	Feedwater pumps are tripped off.
3.1	Turbine trip initiates bypass operation.
3.1	Turbine trip initiated reactor scram trip.
5.1	Moisture separator reheater flow starts to decay.
8.1	Moisture separator reheater flow decays to zero.
20.0	Core flow and power level stabilize at new equilibrium conditions.
190.0	Vessel water (L2) setpoint is reached (not simulated).
220.0	The HPCI and RCIC flow enters vessel (not simulated).

15.3.2 Recirculation Flow Control Failure - Decreasing Flow

15.3.2.1 Identification of Causes and Frequency Classification

15.3.2.1.1 Identification of Causes

Failure of an individual recirculation motor generator (MG) set speed control signal (one per loop) or failure of the positioning control of an individual scoop tube positioner can result in a rapid flow decrease in only one recirculation loop.

15.3.2.1.2 Frequency Classification

This transient disturbance is categorized as an incident of moderate frequency.

15.3.2.2 Sequence of Events and Systems Operation

15.3.2.2.1 Sequence of Events

A typical sequence of events for this transient is similar to and can never be more severe than that listed in Table 15.3.1-1 for the trip of one recirculation pump.

15.3.2.2.2 Systems Operation

Normal plant instrumentation and control is assumed to function. Credit is taken for scram in response to vessel high water level (L8) trip if it occurs. This is true for both the single and master controller failure events.

15.3.2.3 Core and System Performance

15.3.2.3.1 Mathematical Model

Only a qualitative evaluation is provided.

15.3.2.3.2 Input Parameters and Initial Conditions

Only a qualitative evaluation is provided. Typically a less negative void coefficient is used for these analyses.

15.3.2.3.3 Qualitative Results

In the case of failure of one control demand signal, the scoop tube positioners are designed so that the flow change rate limit is determined by the individual stroking rate, which is approximately 25 percent/sec. This case is similar to the trip of one recirculation pump, evaluated in Subsection 15.3.1.3.3.1, and is less severe than the transient that results from the simultaneous trip of both recirculation pumps.

15.3.2.3.4 Consideration of Uncertainties

Initial conditions chosen for these analyses are conservative and tend to force analytical results to be more severe than otherwise expected. These analyses, unlike the pump trip series, will be unaffected by deviations in pumps, pump motor, and drive line inertias, since it is the flow demand signal that causes rapid recirculation decrease.

15.3.2.4 Barrier Performance

The barrier performance considerations for these events are the same as those discussed in the section on recirculation pump trips.

15.3.2.5 Radiological Consequences

The consequences of this event do not result in fuel failure.

15.3.3 Recirculation Pump Seizure

15.3.3.1 Identification of Causes and Frequency Classification

The seizure of a recirculation pump is considered in philosophical, probability, and functional senses as a design basis accident event. It has been evaluated as a very mild accident in relation to other design basis accidents, such as the LOCA. The analysis has been conducted with consideration to a single or two loop operation.

The recirculation pump is designed to very rigid standards and codes. It is very well instrumented, monitored, and controlled to ensure safe and orderly operation. It is designed to meet strict seismic and environmental conditions. It is protected from external disturbances that could negate its inherent capabilities to preclude a self destruction (seizure or shaft impairment). Refer to Subsection 5.5.1 for specific mechanical considerations and to Chapter 7 for electrical aspects.

The seizure event postulated certainly would not be the mode failure of such a device. Safe shutdown components (e.g., electrical breakers, protective circuits) would preclude an instantaneous seizure event.

15.3.3.1.1 Identification of Causes

The case of recirculation pump seizure represents the extremely unlikely event of instantaneous stoppage of the pump motor shaft of one recirculation pump. This event produces a very rapid decrease of core flow as a result of the large hydraulic resistance introduced by the stopped rotor.

15.3.3.1.2 Frequency Classification

This event is considered to be a limiting fault in its category but it results in effects that can easily satisfy more frequent event limits (i.e., infrequent incident classification).

15.3.3.2 Sequence of Events and Systems Operation

15.3.3.2.1 Sequence of Events

Table 15.3.3-1 lists the typical sequence of events.

15.3.3.2.2 Systems Operation

To properly simulate the expected sequence of events, the analysis of this event assumes normal functioning of plant instrumentation and controls and plant protection and reactor protection systems. Operation of safe shutdown features, although not included in this simulation, is expected to be utilized to maintain adequate water level.

15.3.3.3 Core and System Performance

15.3.3.3.1 Mathematical Model

Only a qualitative evaluation is provided.

15.3.3.3.2 Input Parameters and Initial Conditions

Only a qualitative evaluation is provided.

For the purpose of evaluating consequences to the fuel thermal limits, this transient event is assumed to occur as a consequence of an unspecified, instantaneous stoppage of one recirculation pump shaft while the reactor is operating at rated NBR power. Also, the reactor is assumed to be operating at thermally limited conditions.

The void coefficient is adjusted to the most conservative value, that is, the least negative value.

15.3.3.3.3 Qualitative Results

Core coolant flow drops rapidly. The MCPR does not decrease significantly before fuel surface heat flux begins dropping enough to restore greater thermal margins. The level swell produces a trip of the main and feedwater turbines, and stop valve closure scram. Since, after MCPR occurs, heat flux decreases much more rapidly than the rate at which heat is removed by the coolant, the scram conditions impose no threat to thermal limits. Additionally, the bypass valves limit the pressure well within the range allowed by the ASME vessel code. Therefore the reactor coolant pressure boundary is not threatened by overpressure. The consequences from the event are rather mild even if this is classified as a moderately frequent event.

15.3.3.3.4 Consideration of Uncertainties

Considerations of uncertainties are included in the GETAB analysis.

15.3.3.4 Barrier Performance

Opening the bypass valves limits the pressure well within the range allowed by the ASME vessel code. Therefore the reactor coolant pressure boundary is not threatened by overpressure.

15.3.3.5 Radiological Consequences

The consequences of this event do not result in fuel failure.

15.3.3.6 Recirculation Pump Seizure With Coincident Loss of Offsite Power

The recirculation pump seizure accident with coincident loss of offsite power is similar to the transient discussed in Subsection 15.2.6 (loss of ac power) except that the feedwater is tripped earlier and the core flow coastdown is faster. Thus, actual expected core power response of this postulated accident is less severe than that evaluated in Subsection 15.2.6 due to the faster core flow coastdown. No fuel failure is expected. Failure of nonsafety grade equipment would not make the core performance and/or radiological consequences of this postulated accident more limiting than the LOCA addressed in the UFSAR. Therefore, no additional evaluations are considered necessary.

The recirculation pump seizure accident was reviewed on a generic basis by the utility Licensing Review Group (LRG) and the NRC as LRG issue RSB-21. The issue was satisfactorily resolved with the commitment to perform Technical Specifications surveillance on the applicable nonsafety grade equipment involved (Level 8 trip and turbine bypass system) and with the knowledge that generic analyses had been performed by GE to show that nonreliance on the nonsafety grade equipment did not significantly affect the overall safety analysis (the postulated accident was still bounded by other analyzed accident scenarios).

TABLE 15.3.3-1 TYPICAL SEQUENCE OF EVENTS FOR SEIZURE OF ONE RECIRCULATION PUMP MOTOR

Estimated Time (sec)	Event
0	Single pump seizure is initiated.
2.6	Vessel level (L8) trip initiates turbine trip.
2.6	Feedwater pumps are tripped off.
2.6	Turbine trip initiates bypass operation.
2.6	Turbine trip initiates reactor scram trip.
4.6	Moisture separator reheater flow starts to decay.
6.4	Vessel water level reaches Level 3 (L3) setpoint.
7.6	Moisture separator reheater flow decays to zero.
65.0	Vessel water reaches Level 2 (L2) setpoint (not simulated).
75.0	The HPCI and RCIC flow enters the vessel (not simulated).

15.4 REACTIVITY AND POWER DISTRIBUTION ANOMALIES

15.4.1 Rod Withdrawal Error - Low Power

15.4.1.1 Control Rod Removal Error During Refueling

15.4.1.1.1 Identification of Causes and Frequency Classification

The event considered here is inadvertent criticality caused by the complete withdrawal or removal of the most reactive rod during refueling. The probability of occurrence of the initial causes alone is considered low enough to warrant the categorization of this event as an infrequent incident, since there is no postulated set of circumstances that results in an inadvertent rod withdrawal error while in the refuel mode.

15.4.1.1.2 Sequence of Events and Systems Operation

15.4.1.1.2.1 Initial Control Rod Removal

During refueling operations, safety system interlocks provide assurance that inadvertent criticality does not occur because a control rod has been removed or is withdrawn in coincidence with another control rod.

15.4.1.1.2.2 Fuel Insertion With Control Rod Removed

To minimize the possibility of loading fuel into a cell containing no control rod, all control rods are required to be fully inserted when fuel is being loaded into the core. This requirement is backed up by refueling interlocks on rod withdrawal and movement of the refueling platform. When the mode switch is in the refuel position, the interlocks prevent the platform from being moved over the core if a control rod is withdrawn and fuel is on the hoist. Similarly, if the refueling platform is over the core and fuel is on the hoist, control rod motion is blocked by the interlocks.

15.4.1.1.2.3 Second Control Rod Removal

When the platform is not over the core (or fuel is not on the hoist), and the mode switch is in the refuel position, only one control rod can be withdrawn. Any attempt to withdraw a second rod results in a rod block by the refueling interlocks. Since the core is designed to meet shutdown requirements with the highest worth rod withdrawn, the core remains subcritical even with one rod withdrawn.

15.4.1.1.2.4 Control Rod Removal Without Fuel Removal

Finally, the design of the control rod, which incorporates the velocity limiter, does not physically permit the upward removal of the control rod without the simultaneous or prior removal of four adjacent fuel bundles. This precludes any hazardous condition.

15.4.1.1.3 Core and System Performance

Since the probability of inadvertent criticality during refueling is precluded, the core and system performance was not analyzed. However, withdrawal of the highest worth control rod during refueling results in a positive reactivity insertion, but not enough to cause criticality. This is verified experimentally by performing shutdown margin checks (see Subsection 4.3.2 for a description of the methods and results of the shutdown margin analysis). Additional reactivity insertion is precluded by interlocks (see Subsection 7.6.1.1). As a result, no radioactive material is ever released from the fuel; it is therefore unnecessary to assess any radiological consequences.

No mathematical models are involved in this event. Input parameters or initial conditions are not required, as there are no results to report. Consideration of uncertainties is not appropriate.

15.4.1.1.4 Barrier Performance

The barrier performance was not evaluated for this event, since it is highly localized and does not result in any change in the core pressure or temperature.

15.4.1.1.5 Radiological Consequences

Radiological consequences were not evaluated for this event, since no radioactive material is released from the fuel.

15.4.1.2 Continuous Rod Withdrawal During Reactor Startup

15.4.1.2.1 Identification of Causes and Frequency Classification

The probability of occurrence of initial causes or errors alone in this event is low enough to warrant its being categorized as an infrequent incident. The probability of further development of this event is extremely low because it is contingent upon the failure of the rod worth minimizer (RWM) concurrent with a high worth, out-of-sequence rod selection contrary to procedure, coupled with lack of operator response to the RWM continuous alarm annunciations prior to safety system actuation.

15.4.1.2.2 Sequence of Events and System Operation

Before the continuous rod withdrawal during reactor startup is possible, the first part of the sequence of events presented in Table 15.4.1.2-1 must occur.

The RWM constraints on the control rod sequences prevent the continuous withdrawal of an out-of-sequence rod during the reactor startup. With the RWM inoperable a second licensed operator or other technically qualified member of the unit technical staff who is present at the reactor control console verifies the control rod movement compliance with the prescribed control rod pattern. The RWM is programmed to the banked position withdrawal sequence (BPWS) to reduce control rod worths to a value that would be acceptable in the event of a control rod drop accident (see Subsection 15.4.9). The generic analyses for the continuous control rod withdrawal transient in the startup range are included in Reference 1.

As generically described in Reference 2, the range of application of BPWS is between 100 percent control rod density (all rods in) and the low power set point, i.e., 10 percent of rated core power. In this low power range the control rods are effectively withdrawn in the form of stepped bank patterns. Because the control rods are withdrawn in the banked patterns, the incremental rod worth is maintained at low values such that the resultant peak fuel enthalpies due to the continuous withdrawal of an out-of-sequence control rod is less than the licensing basis of 170 cal/g.

The generic analysis of the continuous control rod withdrawal transient in the startup range are included in Reference 1. Table 15.4.1.2-1 shows the sequence of events for the continuous rod withdrawal transient considered.

15.4.1.2.3 Core and System Performance

The performance of the RWM forces adherence to the BPWS constraints applied to control rod withdrawals, thus eliminating the rod withdrawal error in the low power range as a transient of any concern.

The methods and design basis used for performing the detailed analyses for this transient are documented in Reference 1.

15.4.1.2.4 Barrier Performance

An evaluation of the barrier performance was not made for this event, since this is a highly localized event with no significant change in core temperature or pressure.

15.4.1.2.5 Radiological Consequences

An evaluation of the radiological consequences is not required for this event, since no radioactive material is released from the fuel.

TABLE 15.4.1.2-1 TYPICAL SEQUENCE OF EVENTS FOR CONTINUOUS ROD WITHDRAWAL DURING REACTOR STARTUP

Estimated Elapsed Time (sec)	Event
-	The reactor is critical and operating in the startup range.
>0	The operator selects and withdraws an out-of-sequence control rod at the maximum normal drive speed of 3.6 ips.
4	Both the RWM and operator check off system fail to block the selection (selection error) and continuous withdrawal (withdrawal error) of the out-of-sequence rod.
4-8	The reactor scram is initiated by the intermediate range monitor (IRM) system or the average power range monitor (APRM) system.
5-9	The prompt power burst is terminated by a combination of Doppler and/or scram feedback.
10	The transient is finally terminated by the scram of all rods, including the control rod being withdrawn.

15.4.2 Rod Withdrawal Error at Power

The control rod withdrawal error at power condition has been identified in GESTAR II (Reference 3) as one of the more likely events to limit operation from MCPR consideration; therefore, it is typically analyzed on a cycle-specific basis.

15.4.2.1 Identification of Causes and Frequency Classification

15.4.2.1.1 Identification of Causes

While operating in the power range in a normal mode of operation, the reactor operator makes a procedural error and withdraws a high worth control rod until the rod block monitor (RBM) system inhibits further withdrawal.

15.4.2.1.2 Frequency Classification

The probability of this event is considered low enough to warrant its categorization as an infrequent incident. However, because of the lack of sufficient frequency data base, this transient disturbance is analyzed as an incident of moderate frequency until its frequency can be further evaluated and justified.

15.4.2.2 Sequence of Events and Systems Operation

15.4.2.2.1 Sequence of Events

The sequence of events for this transient is presented in Table 15.4.2-1. No operator actions are required during this event; however, operator actions expected to occur are shown in the table. This event results in a local power increase due to a reactivity rise from the decrease in control rod poison material. The rod block monitoring system blocks the further withdrawal of the error control rod and terminates the event.

15.4.2.2.2 Systems Operation

This event is localized to a small portion of the core. Therefore, although reactor control and instrumentation is assumed to function normally, credit is taken only for the RBM system. A discussion of the event follows.

While operating in the power range in a normal mode of operation (except as noted in Subsection 15.4.2.3.2), the reactor operator makes a procedural error and withdraws a control rod until the RBM system inhibits further withdrawal.

Under most normal operating conditions, no operator action is required when a rod withdrawal error is made with average rod worth, since the transient that would occur would be very mild. If the local power increase is excessive when a high worth rod is withdrawn, the nearby local power range monitors (LPRM) would detect this phenomenon and sound an alarm. The operator is suppose to acknowledge this alarm and take appropriate action to rectify the situation.

If the rod withdrawal error were severe enough, and the operator continues to withdraw the control rod, the RBM system would block further withdrawal of the control rod before the fuel cladding integrity safety limit is reached.

15.4.2.2.3 Rod Block Monitor System Operation

The RBM system is designed to automatically block control rod withdrawal that could violate the MCPR safety limit during a control rod withdrawal error transient. Upon operator selection of a control rod, the system begins comparing RBM signals to predefined trip levels. The RBM signals consist of the average of selected B, C, and D level local power range monitor (LPRM) in-core signals in the strings immediately surrounding the selected control rod normalized to 100%. An increase in the RBM signal during rod withdrawal indicates a local power increase, and a corresponding local thermal margin decrease. The rod block trip levels are established such that the thermal margin decrease will be less than available margin. If an upscale rod block is received (rod withdrawal permissive removed), the operator verifies that he is in compliance with fuel thermal limits before resetting the rod block trip. Once reset, the RBM system reinitializes and allows further control rod withdrawal consistent with design basis thermal margin reduction increments.

The RBM has three upscale trip levels which vary as a step function of core power. Each trip level is enforced over a range of core power levels, with the highest trip corresponding to the lowest power and the lowest trip corresponding to the highest power. This allows longer withdrawals at low power where thermal margins are high, and only short withdrawals at high power. The trip levels and their corresponding power level ranges can be changed based on the thermal margin reported in the cycle specific Supplemental Reload Licensing Report. The core power input used to automatically select the applicable RBM trip is provided by the Average Power Range Monitoring (APRM) system.

15.4.2.3 Core and System Performance

15.4.2.3.1 Mathematical Model

For this transient, the reactivity insertion rate is very slow; therefore, it is adequate to assume that the core has sufficient time to equilibrate (i.e., that both the neutron flux and heat flux are in phase). With the use of the above assumption, this transient is calculated by using a steady-state, three-dimensional, coupled, nuclear thermal hydraulics computer program. All spatial effects are included in the calculation.

The primary output from this code, in addition to the basic nuclear parameters, is as follows: the variation of the linear heat generation rate (LHGR); the variation of the minimum critical power ratio (MCPR); the total reactor power; and the variation of the in-core instruments during the transient. A detector response code uses the instrument responses to predict the rod block monitor action under the specified condition for the rod withdrawal error.

The analytical methods and assumptions used in evaluating the consequences of this accident are considered to provide a realistic, yet conservative, assessment of the consequences.

15.4.2.3.2 Input Parameters and Initial Conditions

The number of possible rod withdrawal error (RWE) transients is extremely large because of the number of control rods and the wide range of core characteristics and power levels. With the improved RBM system, the RBM response is well correlated to MCPR response. Because of this, a statistical analyses is performed based on the large amount of data available from past reload, and a generic set of bounding values of DCPR as a function of RBM setpoints is established. Also, additional analyses may be supplemented to further assure that the generic statistical result is applicable.

The generic rod withdrawal error database was drawn from actual plant states and covered the spectrum of plant designs, fuel designs and power densities. Relevant cases were selected with minimum margins to MCPR and MAPLHGR limits in bundles near deep control rods to yield meaningful results. For each RWE case, the analytical outputs (MCPR, MAPLHGR, LPRM readings, and gross core power as a function of error rod position) became inputs to the statistical analysis. Furthermore, numerous simulated RWEs were generated from each rod pattern case by randomly varying the initial position of the error rod and the location and number of failed LPRMs. From these simulated RWEs (per each rod pattern case), the mean and standard deviation and components of the standard deviation were calculated for each RBM setpoint. Here the RBM setpoint is the permissible change of local power as computed by the RBM assigned LPRMs for the selected control rod. All these were used to determine the mean and standard deviation of the entire database.

The final RBM setpoints are determined with the requirement that there is 95% confidence that 95% of the RWE consequence will be bounded if the required MCPR is 1.20, 1.25, 1.30, or 1.35. This statistical analyses conclude that the RWE transients can be protected by three RBM protective settings in three power ranges. See Reference 6 for more details on the bounding MCPR value or for more details of this statistical analysis.

This event is localized to a small portion of the core. Therefore, although reactor control and instrumentation is assumed to function normally, credit is taken only for the RBM system. A discussion of the event follows.

While operating in the power range in a normal mode of operation (except as noted in Subsection 15.4.2.3.2), the reactor operator makes a procedural error and withdraws a control rod until the RBM system inhibits further withdrawal.

Under most normal operating conditions, no operator action is required when a rod withdrawal error is made with average rod worth, since the transient that would occur would be very mild. If the local power increase is excessive when a high worth rod is withdrawn, the nearby local power range monitors (LPRM) would detect this phenomenon and sound an alarm. The operator is suppose to acknowledge this alarm and take appropriate action to rectify the situation.

If the rod withdrawal error were severe enough, the RBM system would sound alarms, at which time the operator would acknowledge the alarms and take corrective action. Even for extremely severe (i.e., those involving highly abnormal control rod patterns or operating conditions in which it is assumed that the operator ignores all alarms and warnings and continues to withdraw the control rod), the RBM system would block further withdrawal of the control rod before the fuel reached the point of boiling transition or the 1 percent plastic strain limit imposed on the clad.

15.4.2.3.3 Qualitative Results

To assure the rod withdrawal error transients are acceptable, the RBM setpoints meet the following requirements:

Let required MCPR = 1.25 at rated conditions

Power Range	Analytical Limit	(permissible change of local power)
> 85 – 100%	110.2%	
> 65 - 85%	115.2%	
> 30 – 65%	120%	

15.4.2.3.4 Consideration of Uncertainties

The uncertainties are included in the statistical analyses.

15.4.2.4 Barrier Performance

The barrier performance was not evaluated for this event, since this is a localized occurrence with very little change in the gross core characteristics. Typically, an increase in total core power is less than 5 percent, and the changes in pressure are negligible.

15.4.2.5 Radiological Consequences

An evaluation of the radiological consequences is not required for this event, since no radioactive material is released from the fuel.

TABLE 15.4.2-1 TYPICAL SEQUENCE OF EVENTS - ROD WORTH EVENT IN POWER RANGE

Approximate Elapsed Time (sec)	Event
0	Core is assumed to be operating at rated conditions.
0	Operator selects and withdraws the maximum worth control rod.
1	The total core power and the local power in the vicinity of the control rod increase.
5	The LPRM system indicates excessive localized peaking.
5	The operator ignores warning and continues withdrawal.
15	The RBM system indicates excessive localized peaking.
15	The operator ignores warning and continues withdrawal.
20	The RBM system initiates a rod block inhibiting further withdrawal.

TABLE 15.4.2-1 TYPICAL SEQUENCE OF EVENTS - ROD WORTH EVENT IN POWER RANGE

Approximate Elapsed Time (sec)	Event
40	Reactor core stabilizes at higher core power level.
60	Operator reinserts control rod to reduce core power level.
80	Core stabilizes at rated conditions.

15.4.3 Control Rod Maloperation (System Malfunction or Operator Error)

This event is included in the evaluation cited in Subsections 15.4.1 and 15.4.2.

15.4.4 Abnormal Startup of Idle Recirculation Pump

15.4.4.1 Identification of Causes and Frequency Classification

15.4.4.1.1 Identification of Causes

This action results directly from the operator's manual action to initiate pump operation. It assumes that the remaining loop is already operating.

15.4.4.1.1.1 Normal Restart of Recirculation Pump at Power

This transient is categorized as an incident of moderate frequency.

15.4.4.1.1.2 Abnormal Startup of Idle Recirculation Pump

This transient is categorized as an incident of moderate frequency.

15.4.4.2 Sequence of Events and Systems Operation

15.4.4.2.1 Sequence of Events

Table 15.4.4-1 lists the typical sequence of events.

15.4.4.2.2 Systems Operation

This event assumes and takes credit for normal functioning of plant instrumentation and control as well as plant protection and reactor protection systems. In particular, credit is taken for high flux scram to terminate the transient. No engineered safety feature (ESF) action occurs as a result of the transient.

15.4.4.3 Core and System Performance

15.4.4.3.1 Mathematical Model

Only a qualitative evaluation is provided.

15.4.4.3.2 Input Parameters and Initial Conditions

When starting an idle loop with one pump already running, Technical Specifications require heating the idle recirculation loop to within 50°F of core inlet temperature prior to loop startup, to be consistent with the assumptions of the reactor vessel nozzle and reactor recirculation system ASME Upset category stress analysis and partial power fuel thermal limit analyses.

The idle recirculation pump suction valve is open, but the pump discharge valve is closed. The idle pump fluid coupler is at a setting that approximates 50 percent generator speed demand.

15.4.4.3.3 Qualitative Results

Following the transient response to the incorrect startup of a cold, idle recirculation loop, the pump begins to move and a flow surge from the jet pump diffusers causes the core inlet flow to rise sharply. The neutron flux peak would reach the fixed average power range monitor (APRM) flux setpoint and reactor scram is initiated. Nuclear system pressures do not increase significantly. The water level does not reach either the high or low level setpoints prior to APRM high flux scram.

After the initiation of the startup of the idle recirculation loop pump transient, the core flow increases and thus reduces the void fraction in the core. Because of the negative void reactivity coefficient, the void reactivity increases and causes the neutron flux to increase. The increase of power level then produces more void and reduces the void reactivity and the neutron flux. This is not a limiting transient.

15.4.4.3.4 Consideration of Uncertainties

This transient is evaluated for an initial power level much higher than that expected for the actual event. The much slower thermal response of the fuel mitigates the effects of the rather sharp neutron flux spike; and even in this high range of power, no threat to thermal limits is possible.

15.4.4.4 Barrier Performance

No evaluation of barrier performance is required for this event, because no significant pressure increases are incurred during this transient.

15.4.4.5 Radiological Consequences

An evaluation of the radiological consequence is not required for this event, since no radioactive material is released from the fuel.

TABLE 15.4.4-1 TYPICAL SEQUENCE OF EVENTS FOR STARTUP OF IDLE RECIRCULATION LOOP

Approximate Elapsed Time (sec)	Event
0	Start pump motor.
8	Startup loop flow reverses.
10	Reactor high flux scram is initiated.
13	Turbine control valves start to close upon falling turbine pressure.
20	Turbine control valves fully close. Turbine pressure is below pressure regulator setpoints.
> 45	Core inlet flow and vessel pressure settle at a new steady state.

15.4.5 Recirculation Flow Control Failure With Increasing Flow

15.4.5.1 Identification of Causes and Frequency Classification

15.4.5.1.1 Identification of Causes

Failure of an individual recirculation motor generator (MG) set speed control signal (one per loop) system (maximum demand) or failure of the positioning control of an individual scoop tube positioner can result in a rapid flow increase in only one recirculation loop.

15.4.5.1.2 Frequency Classification

This transient disturbance is classified as an incident of moderate frequency.

15.4.5.2 Sequence of Events and Systems Operation

15.4.5.2.1 Sequence of Events

Table 15.4.5-1 lists the typical sequence of events.

15.4.5.2.2 Systems Operation

The analysis of this transient assumes and takes credit for normal functioning of plant instrumentation and controls and the reactor protection system. Operation of engineered safeguards is not expected.

15.4.5.3 Core and System Performance

15.4.5.3.1 Mathematical Model

Only a qualitative evaluation is provided.

15.4.5.3.2 Input Parameters and Initial Conditions

In each of these transient events, the most severe transient results when initial conditions are established for operation at the low end of the rated flow control rod line.

Maximum change in speed control occurs with failure of one of the MG set speed controllers. A rapid swing of the coupler is simulated at its maximum rate of 25 percent/sec.

15.4.5.3.3 Qualitative Results

Even with the worst recirculation flow control failure, the changes in nuclear system pressure are not significant with regard to overpressure. Pressure decreases over most of the transient. The rapid increase in core coolant flow causes an increase in neutron flux, which initiates a reactor APRM high flux scram. The MCPR remains above the safety limit and no radioactive material is released from the fuel. This is not a limiting event.

15.4.5.3.4 Consideration of Uncertainties

Some uncertainties in void reactivity characteristics, scram time, and worth are expected to have less serious outcomes than those simulated here.

15.4.5.4 Barrier Performance

This transient results in a very slight increase in reactor vessel pressure and therefore represents no threat to the reactor coolant pressure boundary (RCPB).

15.4.5.5 Radiological Consequences

An evaluation of the radiological consequences is not required for this event, since no radioactive material is released from the fuel.

TABLE 15.4.5-1 TYPICAL SEQUENCE OF EVENTS FOR RECIRCULATION FLOW CONTROLLER FAILURE WITH INCREASING FLOW

Approximate Elapsed Time (sec)	Event
0	Simulate failure of single loop control.
1.5	Reactor high flux scram trip is initiated.
5	Turbine control valves start to close upon falling turbine pressure.
14	Turbine control valves fully close. Turbine pressure is below pressure regulator setpoints.

TABLE 15.4.5-1 TYPICAL SEQUENCE OF EVENTS FOR RECIRCULATION FLOW CONTROLLER FAILURE WITH INCREASING FLOW

Approximate Elapsed Time (sec)	Event
55	Vessel water level reaches Level 8 (L8) setpoint.
55	Feedwater pumps are tripped off.
>100	Core inlet flow and vessel pressure settle at a new steady state.

15.4.7 Misplaced Bundle Accident

15.4.7.1 Identification of Causes and Frequency Classification

15.4.7.1.1 Identification of Causes

The event discussed in this section is the improper loading of a fuel bundle and subsequent operation of the core. Analysis is performed for the initial core, and reload cores through Cycle 21, where the resultant CPR response may establish the operating limit MCPR.

Three errors must occur for this event to take place in the initial core loading. First, a bundle must be misloaded into a wrong location in the core. Second, the bundle that was supposed to be loaded where the mislocation occurred also has to be put in an incorrect location. Third, the two misplaced bundles have to be overlooked during the core verification process performed following initial core loading. For reload cores, only two errors must occur.

15.4.7.1.2 Frequency of Occurrence

This unlikely event occurs when a fuel bundle is loaded into the wrong location in the core. It is assumed that the bundle is misplaced to the worst possible location and that the plant is operated with the mislocated bundle. This event is categorized as an infrequent incident on the basis of the following data: expected frequency is 0.004 events per operating cycle.

The above number is based upon past experience. The only misloading events that have occurred in the past were in reload cycles where only two errors are necessary. Therefore, the frequency of occurrence for initial cores is even lower, since three errors must occur concurrently. There has never been a loading error in an initial core.

15.4.7.2 Sequence of Events and Systems Operation

15.4.7.2.1 Sequence of Events

The postulated sequence of events for the misplaced bundle accident is presented in Table 15.4.7-1.

15.4.7.2.2 Systems Operation

A fuel loading error may result in a reduction in thermal margin during power operations. For the analysis reported here, detection occurs when offgas radiation levels rise. No corrective operator action or automatic protection system functioning occurs to prevent the event.

15.4.7.2.3 Effect of Single Failure and Operator Errors

This analysis already represents the worst case (i.e., operation of a misplaced bundle with three single operator errors [SOEs]).

15.4.7.3 Core and System Performance

15.4.7.3.1 Mathematical Model

A three-dimensional BWR simulator model would be used to calculate the core performance resulting from this event. The misplaced bundle accident is a steady-state event, and the BWR simulator easily models this situation. This model is described in detail in Reference 3.

15.4.7.3.2 Input Parameters and Initial Conditions

15.4.7.3.2.1 Initial Core

The initial core consists of three bundle types with average enrichments that are high, medium, or low, with correspondingly different gadolinia concentrations. The fuel bundle loading error involves interchanging a bundle of one enrichment with another bundle of a different enrichment. The following fuel loading errors can be conceived for an initial core:

a. A high enriched bundle is misloaded into a low enriched bundle location

b. A medium enriched bundle is misloaded into a low enriched bundle location

c. A low enriched bundle is misloaded into a high enriched bundle location

d. A low enriched bundle is misloaded into a medium enriched bundle location

e. A medium enriched bundle is misloaded into a high enriched bundle location

f. A high enriched bundle is misloaded into a medium enriched bundle location.

Since all low enriched bundles are located on the core periphery, the two possible fuel loading errors consisting of the misloading of high or medium enriched bundles into a low enriched bundle location (i.e., types 1 and 2) are not significant. In these cases, the higher reactivity bundles are moved to a region of lower importance, resulting in an overall improvement in performance.

The third type of fuel loading error, as identified above, results in the largest enrichment mismatch. However, it does not result in an unacceptable operating consequence. Consider a fuel bundle loading error at beginning of cycle (BOC) with the low enriched bundle (which should be loaded at the periphery) interchanged with a high enriched bundle located adjacent to a local power range monitor (LPRM) and predicted to have the highest LHGR and/or lowest CPR in the core. After the loading error has occurred and has gone undetected, it is assumed, for purposes of conservatism, that the operator uses a control pattern that places the limiting bundle in the four bundle array containing the misplaced bundle on thermal limits as recorded by the LPRM. As a result of loading the low enriched bundle in an improper location, the average power in the four bundles decreases. Normally, the reading of the LPRM will show a decrease in thermal flux due to the decreased power; however, in this case, an increase in the thermal flux occurs due to decreased neutron absorption in the low enriched bundle. The effects of the softer neutron spectrum due to the decreased thermal absorption are larger than the power depression effect of the lower fission rate, resulting in a net increase in instrument reading. Thus, a fuel loading error of this kind does not result in undetected reductions in thermal margins during power operations.

The fourth and fifth types of fuel loading errors are of the same kind (lower enrichment into higher enrichment) as the third type, and also do not result in a nonconservative operating error.

The fuel bundle loading error with greatest impact on thermal margin is of the sixth type, which occurs when a high enriched bundle is interchanged with a medium enriched bundle located away from an LPRM. Since the medium and high enrichment bundles have a corresponding medium and high gadolinia content, the maximum reactivity difference occurs at end of cycle (EOC), where the gadolinia is burned out. After the loading errors are made and have gone undetected, the operator assumes that the mislocated bundle is operating at the same power as the instrumented bundle in the mirror image location and operates the plant until EOC. For the purpose of conservatism, it is assumed that the mirror image bundle is on thermal limits as recorded by the LPRM. As a result of placing the instrumented bundle on limits, the mislocated bundle violates the Technical Specifications operating MCPR limit.

A misoriented bundle loading error, i.e., rotated 180°, is of no consequence for C-lattice BWR plants. The C-lattice configuration has equal size gaps on all four sides of the bundle; thus rotation will have no effect on the maximum R-factor. Similar to the D-lattice, the bundle in a C-lattice configuration will tilt axially due to the channel buttons at the top of the level assembly. Contrary to the D-lattice, where the tilting tends to mitigate the effect of a rotation, the R-factor increases slightly for the C-lattice. The net effect for the C-lattice is a CPR of less than 0.05.

15.4.7.3.2.2 <u>Reload Cores</u>

For reload cores, the loading error involves the mislocation of at least two fuel bundles. One location is loaded with a bundle which would potentially operate at a lower critical power than it would otherwise. The other location would operate at a higher critical power. The low critical power location could have less margin to boiling transition than other bundles in the core.

15.4.7.3.3 <u>Qualitative Results</u>

The generic radiological analysis in GESTAR Amendment 28 (Reference 3) assumes no fuel melt occurs as a result of this event. The incident would be like a fuel assembly operating with one or more leaking fuel rods. However, to bound the consequences for this event, a conservative assumption that all fuel rods in the misplaced fuel assembly and the four face adjacent fuel assemblies will experience instantaneous failure.

15.4.7.3.4 Consideration of Uncertainties

In order to account for any uncertainties, major input parameters of the bounding analysis are taken as the worst case, that is, (a) the bundle is placed in a location with the highest LHGR and/or the lowest CPR in the core, (b) the bundle is assumed to fail and cause 4 four face adjacent bundles to fail, (c) all fuel rods fail in the five failed bundles, and (d) the radial peaking factor is high.

15.4.7.4 Barrier Performance

An evaluation of the barrier performance was not made for this event, since it is a very mild and highly localized event. No perceptible change in the core pressure would be observed.

15.4.7.5 Radiological Consequences

Using the generic guidance of GESTAR Amendment 28, the offsite radiological dose and the control room dose are within Amendment 28 limits. Offsite dose is less than 2.5 Rem TEDE and the control room dose is less than 5 Rem TEDE.

TABLE 15.4.7-1 TYPICAL SEQUENCE OF EVENTS FOR THE MISPLACED BUNDLE ACCIDENT

1. During the core loading operation, a bundle is loaded into the wrong core location.
2. Subsequently, the bundle designated for this location is incorrectly loaded into the location of the previous bundle.
3. During core verification procedure, the two errors are not observed.
4. The plant is brought to full power operation with subsequent failure of a primary fuel assembly and adjacent fuel assemblies.
5. The fuel failure is detected by the offgas radiation monitors.

15.4.9 Control Rod Drop Accident

15.4.9.1 Identification of Causes and Frequency Classification

15.4.9.1.1 Identification of Causes

The control rod drop accident (CRDA) is the result of a postulated event in which a high worth control rod is inserted out-of-sequence into the core. Subsequently, it becomes decoupled from its drive mechanism. The mechanism is withdrawn, but the decoupled control rod is assumed to be stuck in place. At a later optimum moment, the control rod suddenly falls free and drops out of the core. This action results in the removal of large negative reactivity from the core, which in turn results in a localized power excursion.

A more detailed discussion is given in Reference 7 and 8.

15.4.9.1.2 Frequency Classification

The CRDA is categorized as a limiting fault because it is not expected to occur during the lifetime of the plant; if postulated to occur, however, it has consequences that include potential for the release of radioactive material from the fuel.

15.4.9.2 Sequence of Events and Systems Operation

15.4.9.2.1 Sequence of Events

Before the CRDA is possible, the first part of the sequence of events presented in Table 15.4.9-1 must occur.

To limit the worth of the rod that would be dropped in a banked position withdrawal sequence (BPWS) operating mode, the RWM is used below the low power setpoint to enforce the BPWS. The RWM is programmed to follow the BPWS, which are generically defined in Reference 2. For BPWS, the effective withdrawal is in the form of (stepped) defined bank patterns.

15.4.9.2.2 System Operation

The unlikely set of circumstances described above makes possible the rapid removal of a control rod. The dropping of the rod results in high reactivity in a small region of the core. For large, loosely coupled cores, this action should result in a highly peaked power distribution and subsequent operation of shutdown mechanisms. Significant shifts in the spatial power distribution would occur during the course of the excursion.

The rod worth minimizer (RWM) limits the worth of any control rod that could be dropped by regulating the withdrawal sequence. This system prevents the movement of an out-of-sequence rod in the 100 percent control rod density to the preset low power level; the RWM will allow only BPWS mode withdrawals or insertions.

The RWM or second operator check off system is assumed to operate throughout the event. The second operator check off system provides similar protection as the RWM if the RWM was not functioning and the second operator check off system conducted.

This excursion is terminated by automatic safety features of inherent shutdown mechanisms. Therefore, no operator action during the excursion is required. Although other normal plant instrumentation and controls are assumed to function, no credit is taken for their operation in the analysis of this event.

15.4.9.3 Core and System Performance

15.4.9.3.1 Mathematical Model

Techniques and models used to analyze the control rod drop accident (CRDA) are documented in References 1, 7, 8, and 9. The information in these documents has been used for the development of design approaches to make the consequences of CRDA acceptable.

The rod worth and scram worth are determined by using the BWR simulator model described in Chapter 4, Subsection 4.3. The Doppler coefficient is calculated by using the methods described in References 1, 2, and 7.

15.4.9.3.2 Input Parameters and Initial Conditions

The core at the time of the CRDA is assumed to be at the point in cycle that results in the highest control rod worth, to contain no xenon, to be in a hot startup condition, and to have the control rods positioned such that the highest incremental control rod worth encountered occurs next. The removal of xenon, which competes well for neutron absorptions, increases the fractional absorptions, or worth, of the control rods.

15.4.9.3.3 Qualitative Results

Adherence to BPWS reduces control rod worth such that the postulated control rod drop accident is well under the design criterion of 280 cal/gm. Reference 10 provides a statistical evaluation of BPWS control rod accident analyses. The results show that, in all cases, the peak fuel enthalpy in a CRDA would be much less than the 280 cal/gm design limit even with a maximum incremental rod worth corresponding to 95 percent probability at the 95 percent confidence level. Based on these results, it was proposed to the NRC, and subsequently found acceptable, to delete the CRDA from the standard GE BWR reload package for the BPWS plants (References 2 and 11).

15.4.9.4 Barrier Performance

An evaluation for the barrier performance was not made for this accident, since this is a highly localized event with no significant change in the gross core temperature or pressure.

15.4.9.5 Radiological Consequences

The design basis analysis is consistent with the requirements of 10 CFR 50 and in accordance with Regulatory Guide 1.183 (Reference 19). The analytical results were evaluated against the criteria contained in 10 CFR 50.67. Two release paths were considered: the original NRC Standard Review Plan 15.4.9 (Reference 12) condenser release and a forced release via the offgas system (i.e. steam-jet air ejector (SJAE) discharge through a series of sand filters and charcoal beds). Specific parametric values used in the evaluation are presented in Table 15.4.9-2 and Table 15.4.9-3. The specific models, assumptions, and programs used for computer evaluation are described in Reference 18.

The design basis analysis also meets the requirements of NEDO-31400A (Reference 20), which provided a basis for elimination of reactor scram and MSIV closure associated with main steam line high radiation (Reference 23). In addition to the analysis described in this subsection, NEDO-31400A required the alarms associated with the main steam line radiation monitor subsystem (Subsection 11.4.3.8.2.3) and offgas 2-minute delay pipe radiation monitor subsystem (Subsection 11.4.3.8.2.13) to be set at 1.5 times the "full power background." These alarm setpoints allow for prompt sampling of the reactor coolant to determine sources of contamination and the need for corrective actions. Determination of the "full power background" is described in Subsections 15.4.9.5.4 and 15.4.9.5.5 below.

15.4.9.5.1 Fission Product Release From Fuel

Table 15.4.9-4 provides a summary of pre-accident core activities. No credit is assumed for source term decay prior to reactor startup. The number of failed fuel rods is assumed to be 1,200 rods for the bounding case of 10x10 GE14 fuel (Reference 17). The breached fuel gap is assumed to release 10 percent of the core inventory of noble gases and iodine, and 12 percent of the core inventory of alkali metals. The percentage of breached fuel that melts is assumed to be 0.77 percent, releasing 100 percent of the noble gases, 50 percent of the iodine, and 25 percent of the alkali metals contained in the melted fuel fraction.

15.4.9.5.2 Fission Product Transport to the Environment

The activity released from the fuel from either the gap or from fuel pellets is assumed to be instantaneously mixed with the reactor coolant within the pressure vessel and 100 percent of all noble gases, 10 percent of the iodines, and 1 percent of alkali metal nuclides are transported to the turbine/condenser. Of the activity that reaches the turbine and condenser, 100 percent of the noble gases, 10 percent of the iodines, and 1 percent of the alkali metal nuclides are available for release to the environment. The accident release duration is 24 hours and no credit is taken for MSIV closure, nor SJAE shutdown, prior to 24 hours.

Two release paths were considered: delayed release from the main condenser and a forced release from the offgas system due to the continued operation of the SJAEs.

The main condenser is assumed to release the post-CRDA activity to the turbine building at a rate of 1% per day. No credit is taken for dilution or holdup within the turbine building; however, radioactive decay during holdup in the condenser is credited. The condenser activity released to the environment is assumed to exit via the turbine building ventilation stack.

The evaluation of a release via the offgas system from the SJAEs assumes that the MSIVs do not close and that steam flow continues for approximately 24 hours before this path is isolated. The SJAEs are placed into operation once sufficient steam is available above approximately 2.5 percent power. The offgas system delivers noncondensable gases in the main condenser to a series of sand filters which remove particulates and a series of charcoal adsorber beds that retain iodine and holdup the noble gases to allow the natural decay process to significantly reduce activities prior to release to the environment via the reactor building exhaust stack.

Upon detection of high radiation by the main steam line radiation monitors (MSLRM) (see Subsection 11.4.3.8.2.3), the reactor water sample system is automatically isolated, the condenser mechanical vacuum pumps and line valves are automatically tripped, and the gland seal exhausters are automatically tripped. As a result of crediting these automatic trips and isolations, release through these pathways are not considered in the analysis. Above 10 percent reactor power, control rod reactivity worth is reduced such that the effects of a postulated rod drop are not sufficient to cause significant fuel damage (Figure 3-9 of Reference 7) and the automatic trips are not required. To minimize the potential for spurious gland seal exhauster trips that could result in a malfunction of the turbine gland sealing system, the exhauster trip is automatically bypassed above the low power setpoint associated with the rod worth minimizer (see Subsection 7.7.1.3.3.5). No automatic bypass of the condenser vacuum pump trip is provided since vacuum pumps are not operated above 10 percent reactor power.

15.4.9.5.3 Results

The calculated exposures from the Reference 18 design basis analysis are presented in Table 15.4.9-5 and are well within the guidelines of 10 CFR 50.67. Note the design basis analysis is based on an 18-month GE14 fuel cycle. The consequences of this accident have also been evaluated for the GNF3 24-month equilibrium core source term in Reference 14. The GE14 18-month results bound the GNF3 based accident. While the number of damaged rods is the same for both accidents, there are fewer effective rods per bundle for GE14; thus, the fraction of core damage is larger for GE14.

15.4.9.5.4 Evaluation of the Impact of Hydrogen Water Chemistry

The operation with HWC will increase radiation doses in the main steam lines due to carryover of Nitrogen N-16. For a 4 ppm final feedwater dissolved hydrogen concentration, the background radiation levels in the main steam lines may increase by a factor of up to eight (8). Therefore, the MSLRM will see an increase in the normal operating radiation levels while the reactor is at power. The MSLRMs have a high radiation alarm, trip, and isolation functions with setpoints based on an increased radiation level relative to the operating background to provide an early detection of gross release of fission products from fuel failures. Fermi 2 takes credit for the MSLRM initiated trip and isolation functions in the event of a control rod drop accident (CRDA). The MSLRM allowable value is specified in the Fermi 2 Technical Specifications as 3.6 times "full power background" with a nominal setpoint specified in the Technical Requirements Manual of three times "full power background."

As part of the HWC implementation at Fermi 2, it has been decided to keep the MSLRM allowable value at 3.6 times the "full power background" as stated in the Technical Specifications. However, the redefined "full power background" will include the effects of hydrogen injection. By redefining the "full power background" to include the effects of hydrogen injection, the MSLRM setpoint will have to be adjusted due to an increase in the "full power background" radiation levels. An increase in the "full power background" radiation level by a factor of up to eight (8) may thus require an MSLRM setpoint adjustment. However, by redefining the "full power background" to include the effects of hydrogen injection, the wording in the Technical Specifications and Technical Requirements Manual need not be changed.

The MSLRMs provide signals which isolate the reactor water sample system, trip condenser mechanical vacuum pumps, and trip gland seal exhausters when elevated (i.e. high-high) radiation levels are detected in the main steam lines. However, the only accident which takes credit for the MSLRM trip and isolation signals is the Control Rod Drop Accident (CRDA).

During this accident, the primary function of the MSLRM trip and isolation signals is to limit the potential fission product release pathways. During a CRDA, the reactor scram signal would be initiated by the neutron monitoring system.

The evaluation of the proposed MSLRMs setpoint adjustment (to account for background radiation change due to the HWC) from three times the "full power background" without the HWC to three times the "full power background" with HWC performed by GENE (Ref. 15) has concluded that such a change will not affect the radiological consequences of the CRDA, which are given in Table 15.4.9-5. GENE's evaluation of the design basis accident indicates that the adjusted MSLRM setpoint for HWC is still a fraction of the dose rate expected as a result of CRDA. Thus though the adjusted setpoint due to HWC may be higher by a factor of up to eight, a CRDA would still be detected by the MSLRMs, whether HWC is operating or not. Therefore on the basis of this evaluation, it is concluded that plant operation with or without hydrogen injection is justified for a MSLRM setpoint of up to 30 R/hr.

15.4.9.5.5 Evaluation of Impact of On-Line Noble Chem™ and Hydrogen Water Chemistry

On-Line Noble Chem™ (OLNC) injects a noble metal compound into reactor feedwater. This provides a catalytic environment that promotes the recombining of hydrogen and oxygen in the reactor coolant in the reactor and recirculation piping. OLNC works in conjunction with Hydrogen Water Chemistry (HWC) for controlling intergranular stress corrosion cracking (IGSCC). The catalytic nature of the OLNC process allows the use of lower hydrogen injection rates when compared to HWC alone. The lower hydrogen injection rates will result in lower amounts of N-16 being carried over into the main steam lines lowering the "full power background" radiation dose in the vicinity of the lines.

The reactor water sample system isolation, condenser mechanical vacuum pump trip, and gland seal exhauster trip functions of the main steam line radiation monitors (MSLRM) are specified in the Fermi 2 Technical Specifications. The Technical Requirements Manual specifies the setpoint as three times "full power background." The definition of "full power background" at the time of HWC implementation included the effects of hydrogen injection. As hydrogen will continue to be injected, that definition remains valid.

As part of OLNC implementation the MSLRM setpoints are adjusted to reflect the full power background radiation at the new hydrogen injection rates. Reference 15 concludes that plant operation is justified for a MSLRM setpoint of up to 30 R/hr. As the setpoints for OLNC with lower hydrogen injection rates will be lower than the setpoints for HWC alone, the evaluation in Reference 15 bounds the conditions for OLNC with lower hydrogen injection rates.

TABLE 15.4.9-1 TYPICAL SEQUENCE OF EVENTS FOR CONTROL ROD DROP ACCIDENT

Approximate Elapsed Time (sec)	Event
-	Reactor is at a control rod pattern corresponding to maximum increment rod worth.
-	The Rod Worth Minimizer or operators are functioning within constraints of banked position withdrawal sequence (BPWS). The control rod that will result in the maximum incremental reactivity worth addition at any time in core life under any operating condition while employing the BPWS becomes decoupled from the control rod drive.
-	Operator selects and withdrawals the drive of the decoupled rod along with the other required control rods assigned to the banked-position group such that the proper core geometry for the maximum incremental rod worth exists.
-	Decoupled control rod sticks in the fully inserted position.
0	Control rod becomes unstuck and drops at the maximum velocity determined from experimental data (3.11 fps).
< 1 sec	Reactor goes on a positive period and initial power burst is terminated by the Doppler reactivity feedback.
-	The average power range monitor system (APRM) 120% power signal scrams reactor (conservative; in startup mode APRM scram would be operative + intermediate range monitor).
< 5 sec	Scram terminates accident.

15.5 INCREASE IN REACTOR COOLANT INVENTORY

Only one transient was evaluated under the increase in reactor coolant inventory analytical category. However, this event may not always be analyzed on a cycle-specific basis, since it is normally bounded by the loss of feedwater heater event.

15.5.1 Inadvertent High Pressure Coolant Injection Startup

The inadvertent high pressure coolant injection (HPCI) activation or startup transient behaves similarly to the loss of feedwater heating event (Subsection 15.1.1). The high pressure coolant injection pumps are inadvertently started and the cold water injection results in an increase in inlet subcooling (or decrease in temperature) and a consequent increase in power.

15.5.1.1 Identification of Causes and Frequency Classification

15.5.1.1.1 Identification of Causes

Manual startup of the high pressure coolant injection (HPCI) system is postulated for this analysis; i.e., operator error is postulated.

15.5.1.1.2 Frequency Classification

This transient disturbance is categorized as an incident of moderate frequency.

15.5.1.2 Sequence of Events and Systems Operation

15.5.1.2.1 Sequence of Events

Table 15.5.1-1 lists the typical sequence of events. Similar to the loss of feedwater heating transient, this event results in the reactor core receiving colder water through the feedwater sparger. The reactor vessel initially receives an excess of feedwater flow (as during the feedwater controller failure) until the feedwater flow is reduced by the water level controls. The subcooling of the feedwater along with the excess flow result in an increase in core inlet subcooling which is usually less than that produced by the LFWH event. The increase in core inlet subcooling collapses the void content in the core, thus increasing the core average power due to the negative void coefficient. The increased subcooling also produces a power distribution change, shifting the axial distribution towards the bottom of the core. Because of this axial shift, voids begin to build up at the bottom again which acts as a negative feedback to the void collapsing process. Additional negative reactivity (doppler feedback) is applied when the fuel temperature increases. This feedback moderates the core power increase. This event also tends to flatten the radial power distribution.

The HPCI event is a relatively slow event. The reactor core power is essentially in steady state throughout the transient. The core power typically reaches its maximum value during the first half minute of the transient. This is attributable to the core inlet subcooling transient brought about by the excess feedwater flow.

15.5.1.2.2 Systems Operation

To properly simulate the expected sequence of events, the analysis of this incident assumes normal functioning of plant instrumentation and controls, specifically of the pressure regulator and the vessel level control that respond directly to this event.

Required operation of engineered safeguards, apart from what is described, is not expected for this transient event. The system is assumed to be in the manual flow control mode of operation.

15.5.1.3 Core and System Performance

15.5.1.3.1 Mathematical Model

The quasi-steady-state nature of this transient allows analysis using the 3-dimensional, coupled nuclear thermal-hydraulics core simulator model described in Reference 1. This model calculates changes in power level, power distribution, core flow, exposures, reactor thermal-hydraulic characteristics, and critical power ratio with spatially varying voids, control rods, burnable poisons, and other variables under steady-state conditions. For this transient, the time for reactivity insertion is greater than the fuel thermal time constant and core hydraulic-transport times. Therefore, the steady-state representation of the event's initial, final, and peak power state is adequate.

As described in Reference 2, the loss of feedwater heating event is demonstrated to be bounding by comparing the increase in core inlet subcooling due to feedwater temperature reduction from HPCI plus the increase in core inlet subcooling due to the excess feedwater from HPCI to the increase in core inlet subcooling for the LFWH event. If the HPCI increase is less than the LFWH increase, then the LFWH is bounding.

The enthalpy of the high pressure cold water supplied to the vessel, $h_{sparger}$, is determined by performing an energy balance on the feedwater line just downstream of the point of HPCI injection. Based on $h_{sparger}$, the core inlet subcooling due to feedwater temperature reduction from HPCI can be determined from an energy balance on the reactor vessel. The increase in core inlet subcooling due to the excess feedwater from HPCI is determined using the REDY point dynamic transient model described in Reference 1. The core inlet subcooling due to LFWH can be determined from an energy balance on the reactor vessel based on the post-event feedwater enthalpy.

If the HPCI event is not bounded by the loss of feedwater heating event, the cycle specific results are determined using the REDY point dynamic transient model described in Reference 1.

The REDY model is designed to predict associated transient behavior of this reactor. This model has been improved and verified through extensive comparison of its predicted results with actual BWR test data. Some of the significant features of the model are presented below.

a. A point kinetic model is assumed with reactivity feedbacks from control rods (absorption), voids (moderation), and Doppler (capture) effects.

b. The fuel is represented by three four-node cylindrical elements, each enclosed in a cladding node. One of the cylindrical elements is used to represent core average power and fuel temperature conditions, providing the source of Doppler feedback. The other two are used to represent hot spots in the core, and to simulate peak fuel center temperature and cladding temperature.

c. Four primary system pressure nodes are simulated representing the core exit pressure, vessel dome pressure, steam line pressure (at a point representative of the SRV location), and turbine inlet pressure.

d. The active core void fraction is calculated from a relationship among core exit quality, inlet subcooling, and pressure. This relationship is generated from multi-node core steady-state calculations. A second-order void dynamic model, with the void boiling sweep-time calculated as a function of core flow and void conditions, is also utilized.

e. Principal controller functions, such as feedwater flow, recirculation flow, reactor water level, pressure, and load demand, are represented, together with their dominant nonlinear characteristics.

f. The ability to simulate necessary reactor protection system functions is provided.

15.5.1.3.2 Input Parameters and Initial Conditions

The bounding conditions for this analysis are 100 percent power and maximum subcooling. The transient is simulated by programming a change in feedwater enthalpy corresponding to the maximum subcooling condition.

The water temperature of the HPCI system was assumed to be 40°F. Inadvertent startup of the HPCI system provides the greatest auxiliary source of cold water into the vessel. For the inadvertent HPCI startup transient, the lowest HPCI injection temperature of 40°F and a minimum enthalpy of 8 Btu/lb are used. The lower the HPCI injection temperature, the greater the subcooling increase. To inject at a temperature lower than 40°F, the operator would have to fail to use the heater to maintain the condensate tank temperature above 40°F. This would violate procedural requirements the operator is required to follow.

A higher HPCI temperature would still result in a water level considerably below the setpoint of the Level 8 trip and would result in a lower increase in heat flux.

15.5.1.3.3 Qualitative Results

If the cycle-specific analyses are required to be performed, then the results are documented in the cycle-specific supplemental reload licensing report. Table 15.5.1-1 lists the typical sequence of events.

The simulated transient event begins with the introduction of cold water into the feedwater sparger. Within 5 sec, the full HPCI flow is established at approximately 20 percent of the rated feedwater flow rate. Delays were not considered because they are irrelevant to the analysis.

Addition of cooler water to the core causes the neutron flux to increase. No violation of fuel limits occurs as a result of this event.

15.5.1.3.4 Consideration of Uncertainties

Important analytical factors, such as the feedwater temperature change, have been assumed to be at the worst conditions so that any deviations in the actual plant parameters will produce a less severe transient. Additionally, the HPCI flow rate is assumed to be 10 percent greater than its rated capacity.

15.5.1.4 Barrier Performance

A slight pressure reduction from initial conditions occurs; therefore no further evaluation is required, as reactor coolant pressure boundary (RCPB) margins are maintained.

15.5.1.5 Radiological Consequences

Since no radioactivity is released during this event, a detailed evaluation is not required.

Estimated Time (sec)	Event
0	The HPCI cold water injection is simulated.
5	Full flow is established for HPCI.

15.6 DECREASE IN REACTOR COOLANT INVENTORY

Four events are evaluated under the decrease in reactor coolant inventory analytical category:

a. Instrument line pipe break

b. Steam system pipe break outside containment

c. Loss of coolant accident inside containment

d. Feedwater line break outside containment

None of these events are analyzed on a cycle-specific basis. A qualitative description of results is provided for those events determined to be nonlimiting from a core performance standpoint.

15.6.2 Instrument Line Pipe Break

There is no specific event or circumstance identified that results in the failure of an instrument line. First, the line is constructed seismically so that it will not fail. Second, if the line did fail, the check valves provided would prevent flow out of the break. However, for the sake of conservatism and for the purpose of evaluating a small line rupture, the failure of an instrument line is assumed to occur between the check valve and the primary containment. This highly unlikely failure is postulated only for the sake of presenting an analysis of the consequences of a small line rupture.

This event involves a postulated small steam line or liquid line pipe break inside or outside primary containment but within a controlled release structure. To bound the event, it is assumed that a small instrument line instantaneously and circumferentially breaks at a location where it may not be possible to isolate it and where immediate detection is not automatic or apparent. This event is far less limiting than the postulated events in Subsections 15.6.4, 15.6.5, and 15.6.6.

This postulated event represents the envelope evaluation for small line failure inside and outside containment, relative to sensitivity to detection.

Though beyond the design basis for Fermi 2, the NRC requested an analysis of an accident scenario that assumed a break of a reactor water level sensing line coincident with a single failure in the remaining instrumentation. The results of such an evaluation concluded that adequate time is available to allow proper mitigating actions to be taken to negate the effects of this scenario.

15.6.2.1 Identification of Causes and Frequency Classification

15.6.2.1.1 Identification of Causes

No specific event or circumstance is identified that results in the failure of an instrument line. These lines are designed to meet high quality engineering standards and strict seismic and environmental requirements. However, for the purpose of evaluating the consequences of a small line rupture, the failure of an instrument line is assumed.

15.6.2.1.2 Event Description

A circumferential rupture of an instrument line that is connected to the primary coolant system is postulated to occur outside the drywell but inside the secondary containment. This failure results in the release of primary system coolant to the secondary containment structure until the reactor is depressurized. This event could conceivably occur also in the drywell. However, the associated effects would not be as significant as those from a failure in the secondary containment.

15.6.2.1.3 Frequency Classification

This event is categorized as a limiting fault.

15.6.2.2 Sequence of Events and Systems Operation

15.6.2.2.1 Sequence of Events

The typical sequence of events for this accident is shown in Table 15.6.2-1.

15.6.2.2.2 Systems Operation

Normal plant instrumentation and controls are assumed to be fully operational during the entire plant transient to ensure positive identification of the break and safe shutdown of the plant. Minimum reactor and plant protection system operations are assumed for the analysis, e.g., minimum emergency core cooling system (ECCS) flow and pool cooling capability. As a consequence of the accident, the reactor is scrammed and the reactor vessel cooled and depressurized over a 5-hr period.

15.6.2.3 Core and System Performance

15.6.2.3.1 Qualitative Summary - Results

Instrument line breaks, because of their small size, are substantially less limiting from a core and system performance standpoint than the events examined in Subsections 15.6.4, 15.6.5, and 15.6.6. Consequently, instrument line breaks are considered to be bounded specifically by the steam line break (Subsection 15.6.4). Details of this calculation, including those pertinent to core and system performance, are discussed in detail in Subsection 15.6.4.

Since instrument line breaks result in a slower rate of coolant loss and are bounded by the calculations referenced above, the results presented here are qualitative rather than quantitative. Since the rate of coolant loss is slow, an orderly reactor system depressurization follows reactor scram, and the primary system is cooled down and maintained without ECCS actuation. No fuel damage or core uncovering occurs as a result of this accident.

15.6.2.3.2 Quantitative Results

Instrument line breaks, because of their small size, are substantially less limiting from a core and system performance standpoint than is the steam line break outside containment. Similarly, instrument line breaks are considered within the spectrum considered in ECCS performance calculations discussed in detail in Subsection 6.3.3. Therefore, all information concerning ECCS models employed, input parameters, and detailed results for a more limiting (steam line break) event may be found in Section 6.3.

15.6.2.3.3 Consideration of Uncertainties

The approach to conservative analysis of this event is discussed in detail for a more limiting case in Section 6.3.

15.6.2.4 Barrier Performance

15.6.2.4.1 General

The release of primary coolant through the orificed instrument line could result in an increase in secondary containment pressure and the potential of isolation of the normal ventilation system. The following assumptions and conditions are the basis for the mass loss during the 5-hr reactor shutdown period of this event.

a. Shutdown and depressurization are initiated 10 minutes after break occurs

b. Normal depressurization and cooldown of reactor pressure vessel occur

c. Line contains a 1/4-inch diameter flow restricting orifice inside the drywell

d. Moody critical blowdown flow model (Reference 1) is applicable, and flow is critical at the orifice.

The total integrated mass of fluid released into the secondary containment via the break during the blowdown is 25,000 lb. Of this total, 6000 lb flashes to steam. Release of this mass of coolant results in a containment pressure that is well below the design pressure.

15.6.2.4.2 Outside Containment Structure Effects

Refer to Subsection 3.6.2, Pipe Break Outside Containment.

15.6.2.5 Radiological Consequences

While the NRC has developed a standard review plan for this event, a specific regulatory guide calculation method has not been issued to specify unique design-basis assumptions. For this reason, only the realistic bases will be provided.

This analysis is bases on a realistic, but still conservative, assessment of this accident. A circumferential rupture of an instrument line that is connected to the primary coolant system is postulated to occur outside of the drywell. Operator action is assumed to occur at 10 minutes. Therefore, for 10 minutes, primary coolant flows into the reactor building at the maximum rate. At 10 minutes the reactor building is isolated, the standby gas treatment system (SGTS) is initiated, and the reactor is taken through a normal shutdown over a 5.4 hr period. It is assumed that saturated water flows into the instrument line, therein resulting in the maximum iodine release to the reactor building. If the water is subcooled, then there will be less flashing; and if the line connects to partially vaporized coolant, the activity level in the fluid will be less than in the saturated liquid due to steam carryover considerations. During the first 10 minutes prior to operator action, the activity releases from the break are based on coolant iodine concentrations which correspond to the Technical Specification maximum equilibrium concentration of 0.2 microcuries/gm dose-equivalent ^{131}I. After 10 minutes the coolant is assumed to contain additional iodine activity as a consequence of the release of "spiking activity" from the fuel during depressurization of the vessel. The specific models, assumptions, and program used for computer evaluation are described in Reference 2. Specific values of parameters used in the evaluation are presented in Table 15.6.2-2. The leakage path used in these calculations is shown in Figure 15.6.2-1.

15.6.2.5.1 Fission Product Release From Fuel

The quantity of activity released as a consequence of reactor scram and vessel depressurization is based in part on measurements during plant shutdowns (Reference 2). These measurements have been used to develop an empirical model that predicts, during the depressurization transient, ^{131}I releases of 0.42 Ci/ bundle for a 50 percent probability value to 2.14 Ci/bundle for the 95 percent probability value. For the purpose of this evaluation, the 95th percentile values are used. The release of other iodine isotopes is considered to be inversely proportional to the fission yields. For example, the 95th percentile spike activity for ^{132}I is:

$$^{132}\mathrm{I} = \frac{(2.14)\left(\mathrm{F}_{\gamma}\ ^{132}\mathrm{I}\right)}{\mathrm{F}_{\gamma}\ ^{132}\mathrm{I}}$$

These releases are assumed to occur from all 764 bundles. It is assumed that when depressurization is initiated at time 10 minutes, 15% of the total available spiking activity is immediately released to the reactor coolant. At any subsequent time, it is assumed that the cumulative fractional release to the coolant of the remaining 85% of spiking activity is equal to the fractional reduction in vessel pressure at that time.

15.6.2.5.2 Fission Product Release to the Environment

Fifty percent of the iodine activity in the coolant which flashes to steam is assumed to be removed by plateout in the reactor building, leaving 50% airborne. The activity airborne in the reactor building is presented in Table 15.6.2-3.

The activity airborne in the reactor building is assumed to be uniformly mixed in the air volume and released unfiltered to the environment through the ventilation system via the roof vent for the first 10 minutes. After initiation of the SGTS (at 10 minutes), flow to the environment is at the rate of 100 percent per day. The integrated isotopic activity released to the environment is presented in Table 15.6.2-4.

15.6.2.5.3 Results

The calculated exposures are presented in Table 15.6.2-5. The results are well below 10 CFR 100 requirements.

15.6.3 DELETED IN PREVIOUS REVISION

15.6.4 Steam System Piping Break Outside Containment

This event involves the postulation of a large steam line pipe break outside primary containment. It is assumed that the largest steam line instantaneously and circumferentially breaks at a location downstream of the outermost isolation valve. The plant is designed to immediately detect such an occurrence, to initiate isolation of the main steam lines, and to actuate the necessary protective features. This postulated event represents the envelope evaluation of steam line failures outside primary containment.

15.6.4.1 Identification of Causes and Frequency Classification

15.6.4.1.1 Identification of Causes

A main steam line break is postulated without identification of the cause. These lines are designed to high quality engineering codes and standards and to restrictive seismic and environmental requirements. However, for the purpose of evaluating the consequences of a postulated large steam line rupture, the failure of a main steam line is assumed to occur.

15.6.4.1.2 Frequency Classification

This event is categorized as a limiting fault.

15.6.4.2 Sequence of Events and Systems Operation

15.6.4.2.1 Sequence of Events

Accidents that result in the release of radioactive materials directly outside the primary containment are the results of postulated breaches in the reactor coolant pressure boundary or the steam power conversion system boundary. A break spectrum analysis for the complete range of reactor conditions indicates that the limiting fault event for breaks outside the containment is a complete severance of one of the four main steam lines. The sequence of events and approximate times required to reach the event are given in Table 15.6.4-1.

15.6.4.2.2 Systems Operation

A postulated guillotine break of one of the four main steam lines outside the primary containment results in mass loss from both ends of the break. The flow from the upstream side is initially limited by the flow restrictor upstream of the inboard isolation valve. Flow from the downstream side is initially limited by the total area of the flow restrictors in the three unbroken lines. Subsequent closure of the MSIVs further limits the flow when the valve area becomes less than the limiter area and finally terminates the mass loss when the full closure is reached. A discussion of plant and reactor protection system action and ESF action is given in Sections 6.3, 7.2, and 7.3. Figure 15.6.4-1 is a schematic of the steam flow system and the location of the break; and Figure 15.6.4-2 is the leakage path for the steam line break.

15.6.4.3 Core and System Performance

Quantitative results for this event (including mathematical models, input parameters, and consideration of uncertainties) are given in Section 6.3. The temperature and pressure transients that result from this accident are insufficient to cause fuel damage.

15.6.4.3.1 Input Parameters and Initial Conditions

Refer to Section 6.3 for initial conditions.

15.6.4.3.2 Results

There is no fuel damage as a consequence of this accident. Refer to Section 6.3 for ECCS analysis.

15.6.4.3.3 Consideration of Uncertainties

Sections 6.3 and 7.3 contain discussions of the uncertainties associated with the ECCS performance and the containment isolation system, respectively.

15.6.4.4 Barrier Performance

Since this break occurs outside the primary containment, barrier performance within the primary containment envelope is not applicable. Details of the results of this event can be found in Subsection 3.6.2, Pipe Break Outside Containment.

15.6.4.5 Radiological Consequences

The design basis analysis is based on NRC Standard Review Plan 15.6.4 and Regulatory Guide 1.5. The specific models, assumptions, and program used for computer evaluation are described in Reference 3. Specific values of parameters used in the evaluation are presented in Table 15.6.4-2. The design basis analysis is documented in Reference 12.

15.6.4.5.1 Fission Product Release From Fuel

There is no fuel damage as a result of this accident. The only activity available for release from the break is that present in the reactor coolant and steam lines prior to the break. In accordance with the Standard Review Plan 15.6.4, two cases have been analyzed. For Case 1, the analysis was performed for continued full power operation with a maximum equilibrium coolant concentration of 0.2 μCi/gm dose equivalent I-131. For Case 2, a maximum coolant concentration of 4.0 μCi/gm dose equivalent I-131 is used. This is based on a preaccident iodine spike caused by power changes. It was also conservatively assumed that the offgas release rate (after 30 minutes decay) was 350,000 μCi/sec (as modified by the methodology in Reference 3), and that noble gas activity was discharged into the environment for 10.5 seconds, up to full MSIV closure. The iodine concentration in the reactor coolant is given by (μCi/gm):

	Case 1	Case 2
^{131}I	0.074	1.47
^{132}I	0.67	13.4
^{133}I	0.49	9.89
^{134}I	1.34	26.8
^{135}I	0.73	14.7

Because of its short half-life, N-16 is not considered in the analysis.

15.6.4.5.2 Fission Product Transport to the Environment

The transport pathway is a direct unfiltered release to the environment. The MSIV detection and closure time of 10.5 sec results in a discharge of approximately 112,000 pounds from the break. Assuming that all the activity in this discharge becomes airborne, the release of activity to the environment is presented in Table 15.6.4-3.

15.6.4.5.3 Results

The calculated exposures for the design-basis analysis are presented in Table 15.6.4-4 and are a small fraction of the guidelines of 10 CFR 100.

15.6.5 Loss-of-Coolant Accidents (Resulting From Spectrum of Postulated Piping Breaks Within the Reactor Coolant Pressure Boundary) Inside Containment

This event involves the postulation of a spectrum of piping breaks inside primary containment varying in size, type, and location. The break type includes steam lines and/or liquid process system lines. This event is also coupled with severe natural environmental conditions, including earthquakes.

The event has been analyzed quantitatively in Sections 6.2, 6.3, 7.1, 7.3, 7.6, and 8.3. Therefore, the following discussion provides only new information not presented in the subject sections. All other information is covered by cross referencing.

The postulated event represents the envelope evaluation for liquid or steam line failures inside containment.

15.6.5.1 Identification of Causes and Frequency Classification

15.6.5.1.1 Identification of Causes

There are no realistic, identifiable events that would result in a pipe break inside the containment of the magnitude required to cause a LOCA coincident with a safe shutdown earthquake (SSE) plus single active component failure criteria requirements. The subject piping is designed to meet strict engineering codes and standards criteria, and to withstand severe seismic and environmental conditions. However, since such an accident provides an upper limit estimate to the resultant effects for this category of pipe break, it is evaluated without identification of the causes.

15.6.5.1.2 Frequency Classification

This event is categorized as a limiting fault.

15.6.5.2 Sequence of Events and Systems Operation

15.6.5.2.1 Sequence of Events

Following the pipe break and scram, the low low water level or high drywell pressure signal will initiate the HPCI system at time 0 plus approximately 30 sec. Note that HPCI injection may take as long as 60 sec assuming the maximum analyzed response time; however, this analysis does not depend on HPCI response time. The MSIV will begin closing on the low

low low level signal at time 0 plus approximately 0.5 sec. Additionally, the low low low water level or high drywell pressure signal will initiate the core spray system at time 0 plus approximately 30 sec and the low pressure coolant injection (LPCI) system at time 0 plus approximately 77 sec.

15.6.5.2.2 Systems Operation

Accidents that could result in the release of radioactive fission products directly into the containment are the results of postulated nuclear system, primary coolant pressure boundary pipe breaks. Sections 6.2 and 6.3 examine the possibilities for all pipe break sizes and locations, including the severance of small process system lines, the main steam lines upstream of the flow restrictors, and the recirculation loop pipe lines. The most severe nuclear system effects and the greatest release of radioactive material to the containment result from a complete circumferential break of one of the two recirculation loop pipe lines. In the case where a recirculation pipe breaks, all of the main steam lines are available for iodine deposition and the dose consequences are not maximized. In order to maximize the potential radioactive consequences, a steamline is assumed to break upstream of an inboard MSIV with a degraded ECCS and the maximum release of radioactive material to the containment. This deterministic sequence of events maximizes the dose consequences of a DBA LOCA and is discussed in Section 15.6.5.5. The minimum required functions of any reactor and plant protection system are discussed in Sections 6.2, 6.3, 7.3, 7.6, and 8.3.

15.6.5.3 Core and System Performance

15.6.5.3.1 Mathematical Model

The analytical methods and associated assumptions used in evaluating the consequences of this accident are considered to provide ultraconservative assessment of the expected consequences of this very improbable event. The details of these calculations, their justification, and bases for the models are developed in Sections 6.2, 6.3, 7.3, 7.6, and 8.3.

15.6.5.3.2 Input Parameters and Initial Conditions

Input parameters and initial conditions used for the analysis of this event are given in Table 6.3-6.

15.6.5.3.3 Results

Results of this event are given in detail in Sections 6.2 and 6.3. The temperature and pressure transients resulting from this accident are insufficient to cause perforation of the fuel cladding. Therefore, no fuel damage results from this accident. The containment integrity is maintained. Postaccident tracking instrumentation and control is ensured. Continued long term core and containment cooling is demonstrated. Radiological effects are minimized and kept within limits. Continued operator control and surveillance are examined and guaranteed.

15.6.5.3.4 Consideration of Uncertainties

This event was conservatively analyzed; see Sections 6.2, 6.3, 7.3, 7.6, and 8.3. In order to account for uncertainties in the accident, additional conservative assumptions were utilized in the analysis to maximize the dose consequences:

a. MSIV leakage is through the three shortest main steam lines. No leakage is assumed in the longest main steam line

b. The outboard steam lines are assumed to be at 554 F for the first 8 hours and decrease in four steps to 289 F at 96 hours

c. The inboard steam piping remains at 554 F through the duration of the accident

d. No hold up or deposition is credited in the secondary containment bypass leakage pathway

e. No mixing or hold up is credited in the secondary containment

f. The release points at the SGTS stack and the TBHVAC stack are modeled as ground level releases.

15.6.5.4 Barrier Performance

The design basis for the containment is to maintain its integrity and to experience normal stresses after the instantaneous rupture of the largest single primary system piping within the structure while also accommodating the dynamic effects of the pipe break at the same time an SSE is occurring. Therefore, any postulated LOCA does not result in exceeding the primary containment design limit. For details and results of the analyses, see Sections 3.6, 3.9, and 6.2.

15.6.5.5 Radiological Consequences

A schematic of the transport pathway is shown in Figure 15.6.5-1.

Edison's analysis of the radiological consequences of the design basis LOCA is consistent with the requirements of 10 CFR 50 and in accordance with Regulatory Guide 1.183. The analytical results were evaluated against the criteria contained in 10 CFR 50.67. Each criterion and fundamental assumption used in the analysis is, in itself, appropriately conservative. These criteria and assumptions, however, are used collectively and will likely result in substantially overestimating the potential exposures.

Among the assumptions that are used is that the primary containment is postulated to leak at a rate of 0.5 percent per day for the first 24 hours after the start of the postulated accident, then at a reduced rate of 0.25 percent per day for the remainder of the 30-day event.

The methods, assumptions, and conditions used to evaluate this accident are in accordance with those guidelines set forth in the NRC Standard Review Plan 15.0.1 and Regulatory Guide 1.183. The specific models, assumptions, and computer code used to evaluate this event on the bases of the above criteria are presented in References 7, 8 and 9. Specific values of parameters used in this evaluation are presented in Table 15.6.5-1.

15.6.5.5.1 Fission Product Release From Fuel

It is assumed, per Regulatory Guide 1.183 guidance, that core fission products are released consistent with the values shown in Table 15.6.5-1. Core activity at the start of the DBA-LOCA is an End-of-Cycle (EOC) condition with a core average burnup of 38.235 GWD/MTU, and based on an average initial enrichment of 4 percent. EOC is conservative in that I-131 is maximized. The powers model for natural deposition (incorporated in the RADTRAD code) is used, consistent with NUREG/CR-6604 and Regulatory Guide 1.183 methodology (Reference 7) to credit post-LOCA plateout in the drywell.

Activity deposited in containment can potentially be carried to the suppression pool. In order to assure that dissolved iodines remain in solution, the suppression pool water pH is maintained above 7 using sodium pentaborate injected into the reactor vessel using the Standby Liquid Control System. The SLCS is manually initiated, and injection is required to be complete within approximately 6 hours. The sodium pentaborate will reach the suppression pool through ECCS injection and spill through the break. The amount of sodium pentaborate solution that is required for the SLCS reactivity control function, and controlled per Technical Specifications, is sufficient to assure that the pH remains above 7 for the 30-day accident duration. For primary containment isolation purposes, the activity from the damaged core is assumed to begin to be released into the containment at 121 sec following the accident. This timing assumption recognizes conclusions derived from the source term studies described in NUREG-1465, Regulatory Guide 1.183 and Reference 4. During a DBA LOCA, the drywell and torus air volumes are uniformly mixed due to steam action driving the drywell volume into the suppression pool. However, for the first 2 hours of this accident it is conservatively assumed that no mixing between the drywell and suppression pool occurs. This concentrates the source term in the drywell air volume increasing the dose consequences to personnel. After 2 hours, the drywell and torus air volumes are modeled to instantaneously and homogeneously mix. Natural deposition of iodine particulate (aerosol) is credited in the primary containment utilizing the Powers natural deposition algorithm. No credit is taken for either suppression pool scrubbing or for the use of containment sprays.

15.6.5.5.2 Fission Product Transport to the Environment

The transport pathway consists of leakage from the primary containment to the secondary containment by several different mechanisms, as well as discharge to the environment through the standby gas treatment system (SGTS) at an elevated location and modeled as a ground level release. The SGTS filter efficiency for iodine removal is assessed as 99 percent. The assumed mechanisms for leakage from the primary containment are discussed below.

a. Containment leakage

The design basis leak rate of the primary containment and its penetrations to the secondary containment is 0.5 percent per day, reduced to 0.25 percent per day at 24 hours for the remaining duration of the accident. Ninety percent of the activity in the secondary containment escapes to the environment via SGTS which has a 99 percent efficiency. Ten percent of the activity in the secondary containment bypasses SGTS. The bypass leakage is released through the TBHVAC stack and modeled as a ground release. The duration of exfiltration during the drawdown of the secondary containment is 15 minutes after the 2-minute gap release. No credit is taken for mixing and holdup within the secondary containment structure. Figure 15.6.5-1 is an illustration of the release path to the environment.

b. Leakage from engineered safety feature (ESF) components outside the primary containment, which is filtered by the SGTS. The ECCS leakage is limited to 5 gpm for the 30-day duration of the accident. Two percent of the iodine is assumed to become airborne and is released as 97 percent elemental and 3 percent organic.

c. An MSIV leakage rate totaling 250 scfh, with a maximum of 100 scfh in one main steam line. The worst case single failure is a failure of an outboard MSIV to close in the broken line with the highest flow and shortest length outside primary containment. To credit activity removal in a main steam line, a steam line is modeled as two well mixed deposition nodes, as the formulations in AEB 98-03, Appendix A (Reference 8) are used. The settling velocity for aerosol particulate nuclides is a median velocity based on a Monte Carlo analysis; only horizontal piping is credited, and the aerosol settling area is assumed to be only the bottom half of this piping. For elemental iodine, the entire volume and inside surface area is available for deposition, the deposition velocity from the Cline report of Reference 9 was used because gravitational settling is not an applicable transport mechanism. No organic iodine removal is credited. There is no iodine removal credited in the broken steam line upstream of the inboard MSIV. Time dependent pipe wall temperatures are applied to the piping downstream of the inboard MSIV.

Shutdown cooling operation during the 30-day period after a LOCA would involve recirculation of the emergency core coolant water stored in the suppression pool. The emergency core cooling systems used would be the core spray system to cool the reactor core and the RHR system to remove the heat from the emergency coolant. Reactor core cooling with the core spray system is described in Subsection 6.3.2.2.3. Containment cooling with the RHR system is described in Subsection 5.5.7.3.3.

There is no storage of emergency coolant in these systems except in the suppression pool.

The two redundant core spray loops are not connected. The redundant RHR divisions are cross connected for LPCI injection with an isolation valve.

Non seismic piping systems connected to the core spray or RHR systems are seismically qualified up to the first seismic constraint beyond the isolation valve that separates the safety related and non seismic portions of the piping system, as discussed in Section 3.7.3.13. Relief valves on both the RHR and core spray systems discharge back to the suppression pool. The RHR heat exchanger vent lines also drain back to the suppression pool.

The ECCS pump manufacturer's design criteria and technical manuals state that expected leakage for the pump seals is essentially zero. Experience has shown that occasionally seals have a slight leakage when first started; after a short period, this leakage usually ceases.

Edison believes the leakage from the ECCS pump seals to be essentially zero. Industry-wide experience has shown no significant leakage through such pump seals. In spite of this experience and the pump manufacturer's design criteria, which strongly indicate the expected leakage through the seals to be insignificant, the radiological consequences of leakage of water from the emergency cooling water systems have been examined. Hence, in accordance with Appendix B of NRC Standard Review Plan 15.6.5, leakage of ECCS was assumed and a conservative leakage rate of 5-gpm was assigned. It was further assumed that 98 percent of ECCS coolant remains in an unflashed state and that SGTS filter efficiency is 99 percent. The resulting activity in the secondary containment thus undergoes reduction by a factor of five thousand before its release to the environment.

The iodine released to the primary containment includes 95 percent cesium iodine, 4.85 percent elemental iodine, and 0.15 percent organic forms. The assumption of this specification is predicated on maintaining the suppression pool pH 7.0 or higher. At pH below 7.0, elemental iodine may evolve from the water pool and invalidate this specification. The standby liquid control system (SLC) will be used to establish and maintain the pH of the suppression pool at 7.0 or higher. Operators will be directed to initiate SLC when high radiation levels and LOCA symptoms are detected in the primary containment. Due to the mixing action of the ECCS in the RPV, the suppression pool pH control will be effective within 6 hours.

15.6.5.5.3 Results

The calculated exposures for the design basis analysis are presented in Table 15.6.5-4 and are well within the guidelines of 10 CFR 50.67. Dose associated with coolant activity release in the first 121 sec of the accident is not included in this table. Its contribution to the accident dose is insignificant (on the order of 2 rem thyroid at the Exclusion Area Boundary). The control room dose analysis is found in Appendix 15A.

15.6.6 Feedwater Line Break Outside Containment

For the purpose of evaluating large liquid process line pipe breaks outside containment, the failure of a feedwater line is assumed to evaluate the response of the plant design to this postulated event. The postulated break of the feedwater line, which is the largest liquid line outside the containment, provides the envelope evaluation relative to this type of occurrence. The break is assumed to be instantaneous, circumferential, and downstream of the outermost isolation valve.

A more limiting event from a standpoint of core performance evaluation, feedwater line break inside containment, has been quantitatively analyzed in Section 6.3, Emergency Core Cooling Systems. Therefore, the following discussion provides only new information not presented in Section 6.3. All other information is covered by cross referencing to appropriate subsections in Chapter 6.

15.6.6.1 Identification of Causes and Frequency Classification

15.6.6.1.1 Identification of Causes

A feedwater line break is assumed without identification of the cause. The subject piping is designed to meet engineering codes and standards and severe seismic environmental requirements.

15.6.6.1.2 Frequency Classification

This event is categorized as a limiting fault.

15.6.6.2 Sequence of Events and Systems Operation

15.6.6.2.1 Sequence of Events

The typical sequence of events is shown in Table 3.6-6.

15.6.6.2.2 Systems Operation

The feedwater system operation is described in Subsection 3.6.2.2.2.

15.6.6.3 Core and System Performance

15.6.6.3.1 Qualitative Summary

The accident evaluation qualitatively considered in this subsection is considered to be a conservative and enveloping assessment of the consequences of the postulated failure (i.e., severance) of one of the feedwater piping lines external to the containment. The accident is postulated to occur at the input parameters and initial conditions given in Table 6.3-6.

15.6.6.3.2 Qualitative Results

The feedwater line break outside containment is less limiting than either the steam line breaks outside containment (analysis presented in Section 6.3 and Subsection 15.6.4) or the feedwater line break inside containment (analysis presented in Subsection 6.3.3). It is far less limiting than the design basis accident (the recirculation line break analysis presented in Subsections 6.3.3 and 15.6.5).

The reactor vessel is isolated on level 1 water level. HPCI, which activates at level 2, restores the reactor water level to normal elevation. The fuel is covered throughout the transient, and there are no pressure or temperature transients sufficient to cause fuel damage.

15.6.6.3.3 Consideration of Uncertainties

This event was conservatively analyzed, and uncertainties were adequately considered (see Section 6.3 for details).

15.6.6.4 Barrier Performance

Accidents that result in the release of radioactive materials outside the primary containment are the results of postulated breaches in the reactor coolant pressure boundary or the steam power conversion system boundary. A break spectrum analysis for the complete range of reactor conditions indicates that the limiting fault event for breaks outside containment is a complete severance of one of the main steam lines as described in Subsection 15.6.4.

15.6.6.5 Radiological Consequences

The analysis is based on a conservative assessment of this accident. The accident evaluation considered is an assessment of the consequences of a failure of the feedwater piping external to containment for the specific Fermi 2 system.

Specific values of parameters used in the evaluation are presented in Table 15.6.6-1. A schematic diagram of the break and the leakage path for this accident is shown in Figures 15.6.6-1 and 15.6.6-2.

15.6.6.5.1 Fission Product Release

There is no fuel damage as a consequence of this accident. In addition, an insignificant quantity of activity (compared to that existing in the main condenser hotwell prior to occurrence of the break) is released from the contained piping system prior to isolation closure.

In order to estimate the upper bounds of the dose consequences, it was assumed that the maximum Fermi Technical Specification limit for the primary coolant iodine concentration (0.2 microcuries per gram of dose equivalent I-131) exists at the time of the accident. In accordance with NUREG-0016 (Revision 1), an iodine carryover factor of 0.004 (0.4 percent carryover) was taken between the reactor coolant and the condenser hotwell. Noble gas activity in the condensate is negligible, since the air ejectors remove essentially all noble gas from the condenser.

15.6.6.5.2 Fission Product Transport to the Environment

The transport pathway consists of liquid release from the break, carryover to the turbine building atmosphere due to flashing and partitioning, and unfiltered release to the environment through the turbine building ventilation system.

Of the 1,484,907 lb of condensate released from the break, 237,779 lb flashes to steam, with an assumed iodine carryover of 100 percent. Of the activity remaining in the unflashed liquid, 5 percent is assumed to become airborne. Normally, all feedwater reaching the break location will have passed through condensate demineralizers that have a 90 percent iodine removal efficiency. However, as a result of the increased feedwater flow caused by the break, differential pressure across the demineralizers is assumed to initiate flow through the demineralizer bypass line. This bypass line then carries 15 percent of the total flow, resulting in an effective iodine removal efficiency for all flow of 76.5 percent.

Taking no credit for holdup, decay, or plate out during transport through the turbine building, the resultant release of dose- equivalent I-131 activity to the environment is 0.026 curie. The entire release is assumed to take place within 2 hr of the occurrence of the break.

15.6.6.5.3 Results

The calculated exposures for the realistic analysis are presented in Table 15.6.6-2 and are a small fraction of 10 CFR 100 guidelines.

TABLE 15.6.4.-1 TYPICAL SEQUENCE OF EVENTS FOR STEAM LINE BREAK OUTSIDE OF CONTAINMENT

Estimated Time (sec)	Event
0	Guillotine break of one main steam line occurs outside primary containment.
0.5	High steam line flow signal initiates closure of main steam line isolation valve.
<1.0	Reactor begins scram.
≤10.5	Main steam line isolation valves are fully closed.
15	Safety/relief valves open on high vessel pressure. The valves open and close to maintain vessel bottom pressure less than 1375 psi.
30	The RCIC and HPCI would initiate on low low water level (RCIC is considered unavailable; HPCI is assumed single failure and therefore would not be available).
80	Reactor water level inside shroud begins to drop slowly because of loss of steam through the safety/relief valves. Reactor bottom pressure remains less than 1375 psi.
555	ADS receives signal to initiate on low water level (level 1) signal. ADS bypass timer starts.
1155	All ADS timers timed out. ADS valves actuate. Vessel depressurizes rapidly.
1430	Low pressure ECCS systems are initiated. Reactor fuel is partially uncovered.
1475	Core is effectively reflooded and clad temperature heatup is terminated. There is no fuel rod failure. (Reference to Subsection 6.3.3)

15.7 RADIOACTIVE RELEASE FROM SUBSYSTEMS AND COMPONENTS

Three events were evaluated under the radioactive release from subsystem and component analytical category:

a. Failure of main turbine steam air ejector lines

b. Hypothetical liquid and solid radwaste system accident

c. Fuel handling accident

None of these events are analyzed on a cycle-specific basis. A qualitative description of results is provided for those events determined to be nonlimiting from a core performance standpoint.

15.7.1 Failure of Main Turbine Steam Air Ejector Lines

This event involves a postulated break in the delay line downstream of the main turbine steam air ejector line.

15.7.1.1 Identification of Causes

An evaluation of those events that could cause a failure of the air ejector line indicates that a seismic event more serious than the system is designed to withstand is the only event that could rupture the lines. The lines are designed to withstand the effects of a hydrogen explosion.

The seismic induced failure is considered the most probable and most severe that the system is designed to prevent or accommodate. The seismic failure is the only conceivable event that could cause significant system damage.

The equipment and piping are designed to contain any hydrogen-oxygen detonation that has a reasonable probability of occurring. A detonation is not considered a possible failure mode.

The system is reasonably isolated from other systems or components that could cause any serious interaction or failure. The only credible event that could result in the release of significant activity to the environment is an earthquake.

An event more severe than the design requirements of the offgas system is arbitrarily assumed to occur, resulting in the failure of the offgas system. The design basis, description, and performance evaluation of the subject system are given in Section 11.3.

15.7.1.2 Sequence of Events and Systems Operation

15.7.1.2.1 Sequence of Events

It is assumed that the incident occurs while the reactor is operating at 3499 MWt. It is assumed that the delay line leading from the steam-jet air ejector to the offgas treatment system fails. This results in activity normally processed by the offgas treatment system being discharged directly to the turbine building and subsequently through the ventilation system to the environment. This failure results in a signal of loss of flow to the offgas system. Table 15.7.1-1 presents the typical sequence of events.

15.7.1.2.2 Systems Operation

In analyzing the postulated steam air ejector line failure, no credit is taken for the operation of plant and reactor protection systems, or engineered safety features. Credit is taken for functioning of normally operating plant instruments and controls and other systems only in assuming the following:

a. Capability to detect the failure itself is indicated by an alarmed increase in radioactivity levels seen by the area radiation monitoring system and in an alarmed loss of flow in the offgas system

b. Capability to isolate the system and shut down the reactor

c. Operational indicator and annunciators in the main control room.

15.7.1.3 Core and System Performance

The postulated failure results in a system isolation necessitating reactor shutdown because of loss of vacuum in the main condenser.

15.7.1.4 Barrier Performance

The postulated failure is the break of the delay line downstream of the steam-jet air ejector. No credit is taken for performance of secondary barriers.

15.7.1.5 Radiological Consequences

The NRC provides specific guidelines for the evaluation of this accident in Regulatory Guide 1.98.

15.7.1.5.1 Fission Product Release

It is assumed that the reactor is operating at 3499 MWt with a steam flow of 1.52 x 10^7 lb/hr. The noble gas release rate at the steam-jet air ejector was assumed to be 350,000 µCi/sec (at 30-minute delay) for a period of 30 days prior to the accident. The reactor water concentrations in mCi/g for iodine were assumed to be the following:

^{131}I	0.047
^{132}I	0.43
^{133}I	0.32
^{134}I	0.86
^{135}I	0.47

The iodine activity per pound of steam is assumed to be 2 percent of the iodine activity per pound of reactor coolant. An additional iodine decontamination factor of 200 is assumed to exist between the condenser water and the offgas piping. No credit for plate-out in the turbine building is assumed.

The design-basis noble gas release rate is 350,000 μCi/sec at 30 minutes. However, for this accident the mix is assumed to be approximately 7 sec old at the time of release. Therefore, the noble gas release rate at the break location is approximately 4.9 x 10^6 μCi/sec.

It is assumed that the steam-jet air ejector continues to operate for a period of 1 hr after the accident. Activation gases are neglected. The total radioactive release from the break is assumed to be released over a 1-hr period. Table 15.7.1-2 presents the parameters used in this analysis. A schematic diagram of the break and the leakage path for this accident is shown in Figure 15.7.1-1.

15.7.1.5.2 Fission Product Release to the Environment

The total activity released to the environment during the 1-hr period is shown in Table 15.7.1-3 and is well below 10 CFR 100 limits.

15.7.1.5.3 Results

The calculated exposures for the design basis analysis are presented in Table 15.7.1-4 and are well below 10 CFR 100 limits.

15.7.3 Hypothetical Liquid and Solid Radwaste System Accident Analysis

15.7.3.1 Problem

The purpose of the accident analysis for the liquid radwaste system is to determine the consequences of a hypothetical uncontrolled release of radioactive liquids from the system. Regulatory Guide 1.143 and Standard Review Plan 15.7.3 require that the analysis assess the effects of this release on the health and safety of the public. It is assumed that the initiating event for the accident is a seismic induced total failure of the liquid radwaste system. This assumption is conservative in comparison with the requirements of Regulatory Guide 1.29. Subsection 15.7.3.2 describes the basic method of the analysis, and Subsection 15.7.3.3 describes the source terms used in the analysis. Subsections 15.7.3.4 and 15.7.3.5 describe the liquid pathway analysis and the atmospheric pathway analysis, respectively. For the power uprates, the data was evaluated at 3499 MWt which resulted in an approximate 2 percent increase in the radiological values.

The pathways considered in evaluating the consequences of the accident are (a) releases to the atmosphere of radioiodines from the spilled liquid and (b) contamination of the potable water supply by transport of radionuclides in the ground water. The sources and characteristics of radioactive contamination of the potable water supply are identified in the analysis and traced through the course of the accidental release to Lake Erie via the site ground water aquifer. The resulting hypothetical radioactivity level was determined at the location of the release to Lake Erie and at the City of Monroe public water supply intake. For the atmospheric release pathway, the controlling dose would be the inhalation thyroid dose to a maximally exposed individual (or a child located at the exclusion radius).

The liquid and solid radwaste system, as described in Chapter 11, is the basis for determining the amounts and types of contaminated liquids contained in the radwaste system at the time of the hypothetical event.

15.7.3.2 Basic Methodology

It is first assumed that all radwaste tanks that contain liquids are filled to full rated capacity (i.e., above the tank overflow point). It is then assumed that an earthquake takes place and that the seismic event causes simultaneous ruptures of all the radwaste tanks, releasing their contents to the basement floor of the radwaste building. A list of these tanks, their volumes, and their contents is given in Table 15.7.3-1.

For the liquid pathway analysis, it is assumed that a massive failure of the basement floor occurs as a result of the seismic event. Since the normal ground water level is above the top of the basement floor of the radwaste building, the initial flow will be into the radwaste building until the water levels are equalized. It is assumed (Subsection 2.4.13.3) that water will enter the radwaste building for a 3- to 4-week period. During this time, equipment can be mobilized for pumping, storage, processing, and disposal of the radioactive liquid. However, credit for these actions is not taken in this analysis. It is also assumed that spilled radwaste liquid will be diluted by at least a factor of 10 to 1 by the incoming ground water. This dilution factor is based on the ratio of the total spilled liquid volume to the available free volume, when considering the radwaste basement as the holding basin.

After the water levels are equalized, it is conservatively assumed that the diluted liquid containing the radwaste will move into and through the aquifer at the same rate of flow and in the same direction as the existing ground water in the aquifer. The direction of movement will be to the east at a rate of 0.24 ft/day, as described in Subsection 2.4.13.2. The length of time required for the liquid to travel the 460-ft distance from the radwaste building to the Lake Erie shoreline is 1920 days.

The total time required for the spilled liquid to reach the water of Lake Erie is calculated as follows:

25.5 days	-	for water levels to equalize
1920.0 days	-	to travel to Lake Erie
40.0 days	-	to move upward through till and lake bottom
1985.5 days		TOTAL

In determining the radionuclide concentration entering Lake Erie, only the credit for dilution occurring in the radwaste building and decay in transit was taken. Although there are other factors that lower the radionuclide concentrations entering the lake, they were not applied to this analysis. These factors are the sorption and ion exchange processes that occur in the soil while the radionuclides in the ground water are transported from the radwaste building to the lake.

For the atmospheric pathway analysis, the inhalation thyroid dose to a maximally exposed individual (or a child located at the exclusion radius) was calculated on the basis of the iodine isotopes released from the failed tanks. It is conservatively assumed that the gaseous iodine partition factor for cold radwaste liquid is 0.01; regulatory guidance allows a partition factor of 0.001 for determining expected releases. The resulting gaseous radioiodine releases are given at the bottom of Table 15.7.3-1. The inhalation thyroid dose was calculated using the

0-1 hr, 5-percentile meteorology, $\chi/Q = 1.52 \times 10^{-4}$ sec/m^3 (see Table 2.3-27), a breathing rate of 1.7×10^{-4} m^3/sec (for a child), and the methodology of Regulatory Guide 1.109.

15.7.3.3 Source Terms

A summary of source-term radionuclides is given in Table 15.7.3-1. It shows the isotopic radioactive source terms in each tank.

15.7.3.3.1 Primary Coolant Activity

The concentrations of the various isotopes in the primary coolant activity (PCA) during normal plant operation are shown in Table 15.7.3-2. These concentrations are based on the data provided in NUREG-0016, Revision 1 (BWR-GALE Code; see Reference 1). The concentrations correspond to a failed fuel level of a noble gas release rate of 50,000 mCi/sec at 30 minutes decay (equivalent to the 15-mCi/sec/MWt value called for in Section 15.7.3 of the Standard Review Plan). The tritium concentration is based on a production rate of 0.03 Ci/MWt, half of which is entrained in the liquid radwaste stream. This rate is also based on data presented in the BWR-GALE Code (Reference 1). The resulting concentrations entering the radwaste system tanks are conservatively assumed to be 0.01 mCi/g.

15.7.3.3.2 Radwaste System Activities

The activities accumulated in the radwaste system inventory at the time of the event are based on the normal operational throughput rates of the radwaste system. The system is assumed to be operating at equilibrium and processing at the normal level. The detailed results described herein assume that the mode of radwaste system operation includes evaporators, the asphalt extruder solidification system, and the etched-disk filter/oil coalescer train are in service. Alternative calculations were made for the overall operational mode of precoat filters in combination with vendor processing and with the evaporators not in service. This latter mode produced airborne and Lake Erie isotopic concentrations which were lower than the first assumed mode. The activities are based on expected normal levels at the particular stage of the tank in the decontamination process. The basic normal radioactivity inputs to the radwaste system (e.g., collector tanks and phase separators) are based on the flow rates listed in the process flow diagram (Figure 11.2-15), along with their corresponding fractions of primary coolant activity (see Table 15.7.3-3). The fractions of primary coolant activity of the effluents from the floor drain collector, waste collector, and chemical waste tanks are determined by the weighted average of the composite streams entering the tanks.

The isotopic concentrations within the radwaste system have been determined on the basis of the normal input streams and the processing equipment decontamination factors listed in Table 15.7.3-4. The computer code CORN (Concentration of Radionuclides; see Reference 2) was used to generate the activity values for the 16 radwaste tanks assumed to fail (see Table 15.7.3-1). This program calculates the specific isotopic concentration in effluent streams and processing equipment by accounting for the buildup and decay of all influent isotopes as they flow through the system, including the contribution of radioactive daughter products. The concentrations of each nuclide vary depending on the various phases of waste processing incurred by the fluids contained in each tank and on the waste retention times. The isotopic concentrations for all powdered and bead resin sludges, etched disk filter backwashes, and evaporator concentrates were calculated on the basis of the buildup and decay of isotopes within the particular piece of process equipment.

The concentrations for the chemical waste tank, condensate phase separators, waste clarifier tank, waste surge tank, spent resin tank, chloride waste tank, centrifuge feed tank, and spent resin slurry feed tank are based on fractions of PCA. The factor of 0.02 for the chemical waste tank and the chloride waste tank is based on guidance from Reference 1 (BWR-GALE Code), Table 1-4. The table specifies this fraction of PCA for the lab drains and chemical lab waste activities, which are the plant input sources of these tanks. The other tank activities derived from PCA use a 0.002 factor, which is also based on Table 1-4 of Reference 2. The table specifies this factor for the cleanup phase separator decant, which is conservatively the highest radioactive input to each of these tanks.

The analysis assumes that all identified radionuclides are soluble in water and that those radionuclides trapped in the process resins by ion exchange remain within the resins and are not available for further transport. The analysis also assumes that for those tanks normally containing bead and powdered resin sludge (e.g., phase separators and feed tanks) the heavy, immobile sludge component is not available for transport to the aquifer. The remaining liquid component is represented by the values in Table 15.7.3-1.

The final source term analysis consisted of computing an average isotopic concentration for the accident (weighted according to each tank volume and concentration). These concentrations are listed in the second from last column of Table 15.7.3-1.

15.7.3.4 Liquid Pathway Analysis

As previously described, the liquid pathway analysis assumes a factor of 10 water dilution before the radioactivity leaves the radwaste basement and enters the aquifer. The resultant average diluted radionuclide concentrations (listed in the last column of Table 15.7.3-1) are, therefore, the aquifer entrance concentrations. Further attenuation through the aquifer is provided by the radioactive decay which occurs during the 1985.5-day travel time.

The concentration of each radionuclide as it enters Lake Erie is therefore calculated as follows:

$$\begin{bmatrix}\text{Concentration}\\ \text{entering Lake Erie}\end{bmatrix} = \begin{bmatrix}\text{Concentration}\\ \text{entering aquifer}\end{bmatrix} \times \exp\left[\frac{-0.693 \times \text{travel time}}{\text{Half-life}}\right]$$

The resultant concentrations from the liquid pathway were calculated at the closest intake of potable water from Lake Erie, which is at Monroe. There are no wells or other intakes for public water consumption between the site and the City of Monroe intake. The radionuclide concentrations attributable to this postulated accident at the potable water intake were assumed to be reduced by a factor of 77 due to dilution by lake water. (See Appendix B-3, Section III, of the Environmental Report.)

The isotopes, along with their half-lives, their average concentrations (C) in the tank before the release, their concentrations upon entering Lake Erie, and their concentrations at the potable water intake, are listed in Table 15.7.3-5. The average concentrations at the Monroe intake are compared with the maximum permissible concentrations (MPC) specified in Appendix B of 10 CFR 20. A summation ratio is obtained of the concentrations of the isotopes considered significant at the Monroe intake to the MPC for that isotope. Only those isotopes with concentrations greater than 10^{-15} $\mu Ci/cm^3$ were considered significant. The results produce a final ratio ($\sum$ C/MPC) of 0.0031, which is well within the NRC requirements in Appendix B of 10 CFR 20. These values are shown in Table 15.7.3-6.

15.7.3.5 Atmospheric Pathway Analysis

The thyroid dose from inhalation by a maximally exposed individual (or a child located at the exclusion radius) was calculated using the methodology of Regulatory Guide 1.109 and a χ/Q value based on the 0-1 hr, 5-percentile meteorology (see Table 2.3-27). The quantity of radioiodine released to the atmosphere was calculated by multiplying the weighted average concentrations by the total tank volume and the conservative partition factor of 0.01.

The inhalation dose to the maximally exposed individual from radioiodines released to the atmosphere by this liquid spill is 5.12 x 10^{-4} rem to the thyroid of a child.

15.7.4 Fuel-Handling Accident

15.7.4.1 Identification of Causes and Frequency Classification

15.7.4.1.1 Identification of Causes

Accidents that result in the release of radioactive materials directly to the containment can occur when the drywell is open. A survey of the various conditions that could exist when the drywell is open reveals that the greatest potential for the release of radioactive material occurs when the drywell head and reactor vessel head have been removed. In this case, radioactive material released as a result of fuel failure is available for transport directly to the containment.

Various mechanisms for fuel failure under this condition have been investigated. With the current fuel design the refueling interlocks, which impose restriction on the movement of refueling equipment and control rods, prevent an inadvertent criticality during refueling operations. In addition, the reactor protection system can initiate a reactor scram in time to prevent fuel damage for errors or malfunctions occurring during planned criticality tests with the reactor vessel head off. It is concluded that the accident that could result in the release of the most significant quantities of fission products to the containment during this mode of operation is the one resulting from the accidental dropping of a fuel bundle onto the top of the core. This accident bounds postulated fuel handling accidents that may occur over the fuel chute, over the spent fuel pool, or over the fuel preparation machine containing a fuel bundle.

This event occurs under non-operating conditions for the fuel. The key assumption of this postulated occurrence is the inadvertent mechanical damage to the fuel rod cladding as a consequence of the fuel bundle being dropped on the core while in the cold condition. Therefore, fuel densification considerations do not enter into or affect the accident results.

15.7.4.1.2 Frequency Classification

This event is categorized as a limiting fault.

15.7.4.2 Sequence of Events and Systems Operation

15.7.4.2.1 <u>Sequence of Events</u>

From a radiological viewpoint, the most severe fuel handling accident is the dropping of a fuel assembly onto the top of the core. The sequence of events is as follows:

	Event	Approximate Elapsed Time
a.	Fuel assembly is being handled by refueling equipment. The assembly and mast drops onto the top of the core	0
b.	Some of the fuel rods in both the dropped assembly and reactor core are damaged, resulting in the release of gaseous fission products to the reactor coolant and eventually to the reactor building atmosphere	0
c.	The reactor building ventilation radiation monitoring system alarms to alert plant personnel, isolates the ventilation system, and starts operation of the SGTS	< 1 Minute
d.	Operator actions begin	< 5 Minute

15.7.4.2.2 <u>Systems Operation</u>

Normally, operating plant instrumentation and controls are assumed to function, but credit is taken only for the isolation of the normal ventilation system and the operation of the SGTS. Operation of other plant or reactor protection systems or ESF systems is not expected.

The radiation monitor provided to detect a fuel-handling accident is described in Subsection 11.4.3.8.2.11. The monitor has a full scale step response of 3 sec or less. Prior to the elimination of response time testing requirements, the Fuel Pool Ventilation Radiation monitor response time requirement was 500 msec or 0.5 sec. An elapsed time of 2 sec from detection of radiation to trip contact operation is included in the analysis.

Following a fuel handling accident, the reactor building ventilation isolation valves are designed to be 90 percent closed in 1 sec and 100 percent or fully closed in 3 sec. A 2-sec margin is judged necessary to account realistically for operating conditions throughout the life of the plant, resulting in an assumed full closure time of 5 sec. Therefore, the elapsed time from detection to valve full-closure is 7 sec.

The transit time from the worst case (shortest path – 153.7 ft long) ventilation exhaust grill to the ventilation inboard isolation valve is 2.7 sec. This time is based on a maximum velocity of 57.6 fps with the isolation valve fully open. This is the highest velocity section of the duct run. The minimum duct transit time predicted, based on actual duct velocities, is 3.5 sec.

Assuming undegraded plant equipment, if a release occurs at the worst case exhaust grill, there is no expected release of the exhaust air to the environment. However, there is conservatism included in the assumed 2-sec detector response time and a 2-sec margin is added to the specified isolation valve stroke time for purposes of accounting for realistic conditions throughout the life of the plant.

The potential 4.3 sec of radioactivity release before SGTS actuation does not appreciably affect the analytical results given in this subsection. Even if no credit is given for isolation of the reactor building and actuation of the SGTS, the resultant calculated offsite doses (thyroid dose only is affected) are still a small fraction of those permitted by 10 CFR 50.67. The initial unfiltered release has a greater potential to affect onsite (operator) dose, however the results presented in this section demonstrate that the GDC19 criteria are still satisfied even without credit for the operation of the CREFS.

15.7.4.3 Core and System Performance

15.7.4.3.1 Mathematical Model

The analytical methods and associated assumptions used to evaluate the consequences of this accident are considered to provide a realistic, yet conservative, assessment of the consequences. The kinetic energy acquired by a falling fuel assembly may be dissi-pated in one or more impacts. To estimate the expected number of failed fuel rods in each impact, an energy approach is used.

The fuel assemblage is expected to impact on the reactor core at a small angle from the vertical, possibly inducing a bending mode of failure on the fuel rods of the dropped assembly. It is assumed that each fuel rod resists the imposed bending load by a couple consisting of two equal, opposite concentrated forces. Therefore, fuel rods are expected to absorb little energy prior to failure as a result of bending.

The energy absorption on successive impacts is estimated by considering a plastic impact. Conservation of momentum under a plastic impact shows that the fractional kinetic energy absorbed during impact is

$$1 - \frac{M_1}{M_1+M_2}$$

where M_1 is the impacting mass and M_2 is the struck mass.

15.7.4.3.2 Input Parameters and Initial Conditions

Three assumptions are used in the analysis of this accident.

a. The assemblage (fuel assembly plus NF-500 mast) is dropped from 34.0 feet (the maximum height allowed by the fuel handling equipment).

b. The entire amount of potential energy, including the energy of the entire assembly falling to its side from a vertical position (referenced to the top of the reactor core), is available for application to the fuel assemblies involved in the accident. This assumption neglects the dissipation of some of the mechanical energy of the falling fuel assembly in the water above the core and requires that the grapple head and three sections of the telescoping mast to remain attached to the falling assembly.

c. None of the energy associated with the dropped fuel assembly is absorbed by the fuel material (UO_2).

d. All fuel rods, including tie rods, were assumed to fail by 1 percent strain in compression, the same mode as ordinary fuel rods. For the fuel designs considered here, there is no propensity for preferential failure of tie rods.

15.7.4.3.3 Results

Because of the complex nature of the impact and the resulting damage to fuel assembly components, a rigorous prediction of the number of failed rods is not possible. For this reason, a simplified energy approach was taken and numerous conservative assumptions were made to assure a conservative estimate of the number of failed rods. The approach, which is described in NEDE-24011-P-A (Reference 13) is demonstrated below for the 9x9 fuel rod array bundle.

The number of failed rods was determined by balancing the energy of the dropped assemblage against the energy required to fail a rod. The wet weight of the dropped bundle is 562 pounds for the 9x9 fuel rod array bundle (617 pounds for the 7x7 fuel rod array bundle) and the wet weight of the grapple mast and head is 619 pounds. The drop distance is 34 feet. The total energy to be dissipated by the first impact is

$$E = (562 \text{ lb} + 619 \text{ lb}) (34 \text{ ft}) = (40{,}154 \text{ ft-lb}).$$

One half of the energy was considered to be absorbed by the falling assembly and one half by the four impacted assemblies.

No energy was considered to be absorbed by the fuel pellets (i.e., the energy was absorbed entirely by the non-fuel components of the assemblies). The energy available for clad deformation was considered to be proportional to the mass ratio:

$$\frac{\text{mass of cladding}}{(\text{mass of assembly} - \text{mass of fuel pellets})}$$

and is equal to a maximum of 0.510 for the fuel designs considered here.

The energy absorbed by the cladding of the four impacted assemblies is therefore

$$(20{,}077 \text{ ft} - \text{lbs})(0.510) = 10{,}239 \text{ ft} - \text{lbs}$$

Each rod that fails is expected to absorb approximately 200 ft-lb before cladding failure, based on uniform 1 percent plastic deformation of the cladding.

The number of rods failed in the four impacted assemblies is

$$N_F = \frac{(10{,}239 \text{ ft}-\text{lb})}{(200 \text{ ft}-\text{lb})} = 51 \text{ rods}$$

The dropped assembly was considered to impact at a small angle from vertical, subjecting all the fuel rods in the dropped assembly to bending moments. The fuel rods are expected to absorb little energy prior to failure as a result of bending. For this reason, it was assumed that all the rods in the dropped assembly fail. The total number of failed rods on <u>initial</u> impact was 74 + 51 = 125.

The assembly was assumed to tip over and result in a second impact horizontally on the top of the core from a height of one bundle length, approximately 160 inches. The remaining available energy was used to predict the number of additional rod failures. The available energy was calculated by assuming a linear weight distribution in the assembly with a point load at the top of the assembly to represent the fuel grapple weight.

$$
\begin{aligned}
E_2 &= W_G\,H_G + \int_0^{H_B} (W_B/H_B)\,y\,dy \\
&= W_G\,H_G + (0.5)\,W_B\,H_B \\
&= (619\text{ lb})(160/12) + (0.5)(562)\,(160/12) \\
&= 12{,}000\text{ ft-lb}
\end{aligned}
$$

As before, the energy was considered to be absorbed equally by the falling assembly and the impacted assemblies and the fraction available for clad deformation was 0.510. The energy available to deform clad in the impacted assemblies was

$$E_C = (0.5)(12{,}000\ ft-lb)\,(0.510) = 3{,}060\text{ ft}-\text{lb}$$

and the number of failures in the secondarily-impacted assemblies was

$$N_F = \frac{(3{,}060\text{ ft}-\text{lb})}{(200\text{ ft}-\text{lb})} = 15\text{ rods}$$

Since the rods in the dropped assembly were considered to have failed in the initial impact, the total failed rods in both impacts is 125 + 15 = 140.

Similar calculations can be performed for both the 7x7 and 8x8 fuel rod array bundles. The corresponding results indicate 111 failed rods for the 7x7 fuel rod array bundle and 117 failed rods for the 8x8 fuel rod array bundle.

Applied to the 10x10 fuel designs currently used in the Fermi 2 fuel cycle, the number of failed rods associated with a 34-ft drop is less than 166 fuel pins for a drop of a GE14 assembly (Reference 14) and less than 169 pins for a GNF3 bundle.

15.7.4.4 Barrier Performance

The reactor coolant pressure boundary and primary containment are assumed to be open. The transport of fission products from the secondary containment is discussed in Subsections 15.7.4.5.1 and 15.7.4.5.2 below.

15.7.4.5 Radiological Consequences

The original Fermi 2 design basis analysis evaluated drops of 7x7, 8x8, and 9x9 fuel types based on the guidance in the NRC Standard Review Plan 15.7.4 and Regulatory Guide 1.25. The Fermi 2 Fuel Handling Accident was subsequently re-analyzed in accordance with the methods and assumptions of NRC Regulatory Guide 1.183, Alternate Source Term, in order to establish a basis for distinguishing between secondary containment and control room isolation and filtration system operability requirements during the movement of irradiated fuel depending on whether or not the fuel is considered recently irradiated. The operability of ESF systems and subsystems previously required to mitigate the radiological consequences of fuel handling accidents is not necessary after a sufficient post-shutdown decay period has elapsed. Prior to this decay period, the fuel is classified as recently irradiated and operability requirements for systems and subsystems supporting secondary containment and control room integrity and filtration apply to the movement of fuel over the spent fuel pool and reactor vessel.

The analysis documented in Reference 8 evaluates the radiological consequences associated with the drop of a recently irradiated fuel bundle and also determines the duration of the post-shutdown decay period after which GNF3 and GE14 10x10 fuel bundle types would no longer be considered as recently irradiated. Dose calculations defining the required delay period for the 7x7, 8x8, and 9x9 fuel bundle types are not performed. These bundle designs have been long since retired hence their source terms have decayed sufficiently that their associated consequences are bounded by the 10x10 bundle design currently used in the Fermi 2 fuel cycle. As a result, the discussion of the radiological consequences associated with the 7x7, 8x8, and 9x9 fuel types hereafter has been deleted from Section 15.7.4.

The re-analysis of the Fermi Fuel Handling Accident provided an opportunity to take advantage of the Alternate Source Term (AST) as defined in NRC Regulatory Guide 1.183 (Reference 7). This regulatory guide contains a set of assumptions, methodologies, and acceptance criteria (different from Regulatory Guide 1.25) that may be used to evaluate the radiological consequences associated with the Chapter 15 design basis accidents. Concerning the Fuel Handling Accident, the new guidance has the advantage of smaller gap fractions, and larger pool decontamination factor (DF), and dose criteria that replace both the 10 CFR 50.100 whole body and thyroid dose limits with a limit on Total Effective Dose Equivalent (TEDE) based on 10 CFR 50.67.

The ability to credit the new AST assumptions depends on the burnup and operating history of the fuel. Specifically, use of the AST non-LOCA gap fractions is predicated on the assumptions of a peak rod average burnup up to 62 GWD/MTU and a peak rod average Linear Heat Generation Rate (LHGR) not exceeding 6.3 kW/ft for exposures above 54 GWD/MTU (Reference 7, Table 3). Thus, the ability of the fuel in a given cycle to meet the Reference 7 criteria is required to be verified prior to applying the definition of recently irradiated during refueling operations.

Reference 8 determines the radiological consequences associated with fuel handling accidents where the AST assumptions are valid considering both the drop of a recently irradiated fuel bundle 24 hours following a plant shutdown, and at a later time when the fuel is considered to be no longer recently irradiated. Based on the damage estimates for GE14 and GNF3 described in Subsection 15.7.4.3.3 above, the drop of the GE14 fuel type results in damage to a larger fraction of the core: 1.93 assembles for GE14 vs 1.91 assemblies for GNF3.

Since the GE14 fuel is still present while the fuel cycle is transitioned to a full core of GNF3, the analysis of consequences is conservatively based on the GE14 damage estimate and a common source term that is bounding for both fuel types (Reference 15). In addition, the core source term has been determined conservatively using a cycle exposure corresponding to a 24-month cycle.

The specific models, assumptions, and program used for computer evaluation are described in References 7 through 11. Specific values of parameters used in the evaluation are presented in Table 15.7.4-1.

15.7.4.5.1 Fission Product Release From Fuel

The core fission product inventory for the bounding (GNF3) fuel design has been determined by GEH (Reference 15) for each isotope (i) of interest in units of Curies per

Megawatt using an ORIGEN 2 based approach as specified in Regulatory Guide 1.183. The source term associated with the fuel damaged in a drop is determined as follows:

$$S_i\left(\frac{Ci}{MW}\right) x\ Core\ Power\ (MW)\ x\ \frac{\#\ Fuel\ Pins\ Damaged}{\#\ Fuel\ Pins\ in\ Core}$$

The fission product inventory of a core average rod is adjusted by the radial peaking factor to establish the inventory of each damaged rod. Only the fraction of the source term located inside the "gap" region of each rod is assumed to be released to the pool. The specific fractions applied are stipulated by Regulatory Guide 1.183 (AST) for fuel that has been confirmed to satisfy the AST limits on LHGR versus fuel exposure.

15.7.4.5.2 Fission Product Transport to the Environment

For fuel handling accidents involving recently irradiated fuel, the transport pathway is assumed to consist of mixing in the fuel pool, migration from the pool to the secondary containment atmosphere, and release to the environment through the SGTS. (It is possible for a slight amount of radioactivity to escape to the environment before initiation of the SGTS if no credit is given for nonsafety related dampers and the outboard safety related damper is assumed to fail open. See Subsection 15.7.4.2.2.) All of the noble gas and 0.5 percent of the iodines in the fuel gap released to the pool are assumed to become airborne in the secondary containment.

The airborne activity is released from the refuel floor to the environment over a 2-hr period after filtration by the SGTS (99 percent removal efficiency for iodine). The release of activity to the environment is presented in Table 15.7.4-2. The analyses that define when irradiated fuel becomes no longer "recently irradiated", assume no credit for SGTS, CCHVAC makeup filtration, or CREF recirculation filtration of iodine species. The analysis does assume that the source term on the refuel floor is released to the outside environment and enters the control room via the more limiting of the normal or emergency makeup air intakes, not via building internal ducts and pathways. The most likely release point is the RBHVAC exhaust stack. However, the Reference 8 analysis established a bounding secondary containment-to-control room atmospheric dispersion factor that did not correspond to a release via the RBHVAC exhaust stack. The analysis conservatively assumed the release is from the reactor building, south side ground level doors.

When the CREF and CCHVAC ductwork is breached in support of maintenance, the assumptions on the transport path of the source term are preserved through the application of administrative controls that are implemented prior to creating a breach to ensure that the transport of the fuel handling accident source term into the control room via the breach is not a credible possibility.

15.7.4.5.3 Results

The calculated exposures for the re-analyzed original design basis analysis (i.e., a drop of recently irradiated fuel 24-hours post-shutdown) presented in Table 15.7.4-3 are well below the guidelines of 10 CFR 50.67. Refueling procedures have been updated in accordance with License Amendment 141 to require the reactor to have been subcritical for at least 60 hours prior to movement of irradiated fuel. Consequently, the analysis based on 24 hours post-shutdown remains conservative. The calculated exposures for the design basis accident which defines the required post-shutdown delay period after which irradiated fuel is no longer considered recently irradiated presented in Table 15.7.4-4 establish a required post-shutdown delay after which irradiated GE14 and GNF3 fuel may be declared no longer recently irradiated to be approximately 6.3 days (151 hours), based on a maximum control room operator 30-day integrated dose of 5 rem TEDE. The Table 15.7.4-4 results show that the control room operator dose consequences associated with drops of fuel that is not recently irradiated fuel without secondary containment and control room isolation and filtration bound those of the original design basis accident.

15.7.4.5.4 Evaluation of the Impact of Uprated Power Operation and Extended Fuel Burnup

The analysis of the radiological consequences of the Fuel Handling Accident involving recently irradiated 9x9 fuel, which is no longer used at Fermi, that does not meet the AST burnup specifications are based on NRC Standard Review Plan 15.7.4 and Regulatory Guide 1.25. The assumptions given in Regulatory Guide 1.25 related to the release of radioactive material from the fuel and fuel storage facility as a result of a fuel handling accident, however, are only valid for fuel with an average burnup for the peak assembly of 25000 MWD/MTU or less (which corresponds to a peak local burnup of about 45000 MWD/MTU).

In a report prepared for the NRC by Pacific Northwest Laboratory (PNL) entitled "Assessment of the Use of Extended Burnup Fuel in Light Water Power Reactors," NUREG/CR-5009, dated February 1988, PNL examined the changes that could result in the NRC design-basis accident (DBA) assumptions contained in various Standard Review Plan Sections and Regulatory Guides as a result of extended fuel burnup (up to 60,000 MWD/MTU). PNL concluded, and the NRC Staff subsequently agreed, that the only DBA which could be affected by the extended fuel burnup would be the potential thyroid doses that could result from a fuel handling accident. The PNL report estimated that the calculated iodine gap-release fraction for fuel with extended burnup would be 20 percent greater for some high power fuel designs than the assumed value of 0.10 stated in Regulatory Guide 1.25. Thus, the calculated thyroid doses resulting from a fuel handling accident with extended burnup fuel could be 20 percent higher than those estimated using Regulatory Guide 1.25. The results of this report were later used as the basis for an NRC Environmental Assessment published in the Federal Register (53 FR 6040).

In response to an NRC Staff question concerning Detroit Edison's submittal for Power Uprate (License Amendment 87), Detroit Edison noted in a February 24, 1992 letter to the NRC its plans to use fuels enriched to a maximum of 5.0 percent by weight of Uranium-235 and fuel burnup levels not exceeding a maximum rod average burnup of 60,000 MWD/MTU. The letter also stated that these values of fuel enrichment and burnup were bounded by the NRC Environmental Assessment and that the conclusions made in the Environmental Assessment were applicable to Fermi 2. The NRC Staff subsequently agreed with Detroit Edison's statement that the conclusions of the Environmental Assessment published in the Federal Register (53 FR 6040) are applicable to Fermi 2, and that the use of extended burnup fuels within the limit specified above will have no significant adverse radiological or non-radiological impacts, and will not significantly affect the quality of the human environment.

During the course of its review of the Detroit Edison submittal for Power Uprate (License Amendment 87), the NRC Staff reevaluated the fuel handling accident for Fermi 2 using the uprated power level. The calculated 2-hour thyroid dose at the exclusion boundary was determined to remain less than 1 rem. Similarly, the low population zone thyroid and whole-body doses would be expected to remain less than 0.1 rem for the fuel handling accident. The staff concluded that the potential increased doses resulting from DBA with extended burnup levels of up to 60,000 MWD/MTU, met the acceptance criteria provided in Standard Review Plan Section 15.7.4, and will remain within the dose guidelines described in 10 CFR Part 100. Consequently, the staff concluded that the changes proposed by Detroit Edison with respect to the use of fuel with Uranium-235 enrichments up to 5 percent and burnup not exceeding 60,000 MWD/MTU were acceptable.

The Alternate Source Term described in Regulatory Guide 1.183, considers fuel burnup up to 62,000 MWD/MTU peak rod average. Thus, the AST assumptions on peak rod average exposure bound the Fermi 2 extended burnup granted in License Amendment 87; however, the Regulatory Guide 1.183 (Table 3 Footnote 11) also places a restriction on Linear Heat Generation Rate that must also be satisfied in order for the non-LOCA AST gap fractions to be valid. GE 10x10 fuel types are not expected to challenge the burnup limitations specified in Regulatory Guide 1.183 and the AST gap fractions are applied. GE11 9x9 and prior fuel types, which are no longer present in the active Fermi 2 fuel cycle, have resided in the spent fuel pool sufficiently long that these designs are no longer formally evaluated for drop consequences.

TOTAL CURIES OF IODINE IN THE SPILLED LIQUID:

I-129 = 3.619E-10
I-131 = 1.304E-01
I-132 = 1.985E+00
I-133 = 1.681E+00
I-134 = 3.288E+00
I-135 = 1.681E+00

TOTAL CURIES OF IODINE ASSUMED TO BE RELEASED TO THE ATMOSPHERE:

I-129 = 3.619E-12
I-131 = 1.304E-03
I-132 = 1.985E-02
I-133 = 1.681E-02
I-134 = 3.288E-02
I-135 = 1.681E-02

* Tank is not considered operational per Note in UFSAR Section 11.2.1.
** Two of the Waste Sample Tanks have volume of 24,300 gallons, and the third has volume of 21,100 gallons.
# Pre-2005 values are more limiting than Post 2005 values. For conservatism, Pre-2005 values are continued to be used in dose calculations. As such, the dose calculation for liquid tank failure analysis remains unchanged.

TABLE 15.7.3-3 FRACTIONS OF PRIMARY COOLANT ACTIVITY DURING NORMAL PLANT OPERATION FOR RADWASTE SOURCE

Source	Fraction
Equipment drains	
Drywell	1.00
Reactor building	0.1
Radwaste building	0.1
Turbine building	0.001
Floor drains	
Drywell	0.001
Reactor building	0.001
Radwaste building	0.001
Turbine building	0.001
Lab drains, chemical waste	0.02
Cleanup phase separator decantation	0.002
Condensate phase separator decantation[a]	2×10^{-6}

[a] Assumed to be equal to condensate demineralizer backwash water.

TABLE 15.7.3-4 DESIGN-BASIS DECONTAMINATION FACTORS FOR RADWASTE EQUIPMENT

Equipment	Soluble Isotopes	Insoluble Isotopes
Etched-disk filter	1	10
Precoat filter	1	10
Oil coalescers (3 in series)	1	10
Radwaste demineralizer[a]	100(10)	10(10)
Radwaste evaporator	1,000	10,000
Extruder/evaporator	1,000	1,000
Centrifuge	67	67
Phase separators[b] (sludge effluent)	1	1
Reactor water cleanup condensate filter-demineralizers	100	100

[a] Values in parentheses are for the second demineralizer in series.

[b] All activity entering the phase separators has been assumed to exit via the sludge letdown line.

χ/Q main control room (sec/m^3) 0-2 hours Note 11	3.65E-03 Note 4 Note 8		4.25E-03 Note 7

Notes:

1. No credit for reduced CREF filtration and isolation.

2. Fraction accounts for partial length rods in dropped assembly. All impacted rods assumed to be full length. Drop over RPV (approx. 34 ft) bounds drop over spent fuel pool (approx. 6 ft).

3. SGTS exhaust stack-to-control room χ/Q calculated in Reference 8 using ARCON96 (Reference 10) assuming zero-velocity vent release. See Reference 8 for a complete description of the inputs and methodology used to calculate the χ/Q values used in the FHA analysis.

4. This SGTS stack χ/Q value is different than that used to calculate the control room operator dose in UFSAR Section 15.A. Both values were calculated using reviewed and approved methodologies. The value used for the FHA was calculated in Reference 8 using the same methodology used to evaluate other secondary containment release points. No credit assumed for SRP 6.4 factor of 4 reduction in χ/Q for control room dual air inlet configurations.

5. EPA Federal Guidance Reports 11 and 12 (References 11 and 12)

6. Rate of release conservatively based on a refuel floor volume of 950,000 ft^3 and an assumed air removal rate of 95,000 cfm. The normal rate of ventilation supplied by RBHVAC is approximately 33,000 cfm. 95,000 cfm effectively releases the source term within one-hour. (99.75 percent after one hour, >99.99 percent after two hours)

7. Secondary containment-to-control room χ/Q representing releases via locations other than SGTS calculated in Reference 8 using ARCON96 (Reference 10). See Reference 8 for a complete description of the inputs and methodology used to calculate the χ/Q values used in the FHA analysis.

8. The analysis of the 24-hour FHA involving recently irradiated fuel includes the effects of an initial period of unfiltered release via the RBHVAC stack. UFSAR Section 15.7.4.2.2 describes a 4.3 second period of unfiltered release; however, the Reference 8 analysis conservatively evaluated a 7.2 second unfiltered release. The χ/Q assigned to this release path was 4.05E-3 s/m^3 based on a value of 4.03E-3 s/m^3 calculated in the Reference 8 analysis.

9. GE11 9x9 fuel is no longer used in Fermi 2 fuel cycles. All GE11 fuel has been discharged to the spent fuel pool, is no longer recently irradiated, and satisfies the Reference 7 burnup restriction.

10. All analyses of dose consequences are performed based on GE14 Effective Number of Damaged Bundles.

11. The EAB dose is calculated as the worst 2-hour dose at the EAB boundary. The control room and LPZ doses are conservatively computed assuming 0-2 hr χ/Q persists for the 30-day duration of accident.

12 This breathing rate is assigned to the EAB, LPZ, and main control room. In addition, the control room is assigned the following occupancy factors 1.0 (0-24 hrs), 0.6 (24-48 hrs), and 0.4 (48-120 hrs).

13. Accidents involving recently irradiated fuel have been reviewed and approved assuming the FHA drop occurs 24 hours post-shutdown. This is consistent with UFSAR Section 9.1.4.3.2; however, the expanded capacity of the spent fuel pool approved under License Amendment 141 requires the initial removal of fuel from the core to the spent fuel pool to be delayed for 60 hours.

TABLE 15.7.4-2 FUEL-HANDLING ACCIDENT (DESIGN-BASIS ANALYSIS) ACTIVITY RELEASED TO THE ENVIRONMENT (CURIES)

I-134	60280		
I-135	51570	2.575E-05	1.565E+01
Te-131	24250		
Te-131m	4000		
Te-132	38620		

[1] Initial release from pool to reactor builidng.
[2] Release to Environment following 2-hr if SGTS filtration not credited.
[3] GE11 9x9 fuel is no longer used in Fermi 2 fuel cycles and is not included above. All GE11 fuel has been discharged to the spent fule pool, is no longer recently irradiated, and satisifies the Reference 7 burnup restriction.
[4] With the exception of tellurium, blank entries represent radionuclides considered in source term that decay so rapidly they are essentially not present at the time of the assumed start of the accident. Tellurium is not present because it is assigned a zero gap fraction. (See Table 15.7.4-1).
[5] Kr-85 core source term doubled to enable use of a single value of Noble Gas gap fraction.

TABLE 15.7.4-3 FUEL-HANDLING ACCIDENT (DESIGN-BASIS ANALYSIS) RADIOLOGICAL EFFECTS (DROPS INVOLVING RECENTLY IRRADIATED FUEL 24 HOURS POST-SHUTDOWN[d])

Drop of 10x10 Recently Irradiated Fuel Bundle

	TEDE Dose (rem)	Regulatory Limit
Main Control Room	0.309	(30-day – 5.0 rem)
Exclusion Area (915 m)	0.169	(2-hr – 6.3 rem)
Low-population zone (4827 m)	0.040	(30-day – 6.3 rem)

Drop of 10x10 Fresh Fuel Bundle over Recently Irradiated Fuel

	TEDE Dose (rem)	Regulatory Limit
Main Control Room	4.025	(30-day – 5.0 rem)
Exclusion Area (915 m)	0.028	(2-hr – 6.3 rem)
Low-population zone (4827 m)	0.065	(30-day – 6.3 rem)

[a] 10x10 Recently Irradiated fuel is assumed to meet exposure limitations necessary for use of Reference 7, Table 3 AST non-LOCA gap fractions.

[b] Use of GE11 9x9 fuel was discontinued at the end of Cycle 14 (October 2010). All GE11 fuel has been discharged to the spent fuel pool, is no longer recently irradiated, and satisfies the Reference 7 burnup restriction. In consideration of the significant period of source term decay to which the discharged GE11 (9x9) fuel has been subjected and given the large degree to which the radiological consequences of a drop of GE11 fuel are bounded by those of the 10x10 fuel designs currently in use, GE11 (9x9) results are no longer computed for presentation in this section.

[c] Results above assume no credit for CREF filtration. Credit for SGTS filtration is assumed for the drop of recently irradiated fuel (see Table 15.7.4-1), but is not assumed for the drop of fresh fuel.

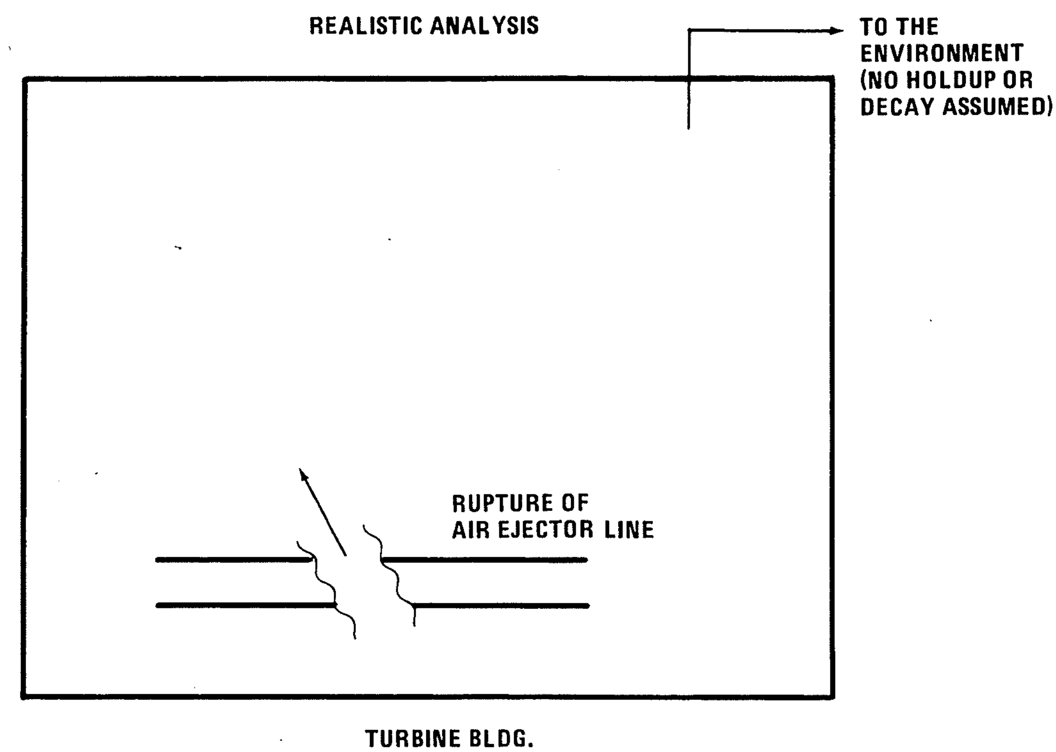
[d] Refueling procedures have been updated in accordance with License Amendment 141 to require the reactor to have been subcritical for at least 60 hours prior to movement of irradiated fuel. Consequently, the analysis based on 24 hours post-shutdown remains conservative.

TABLE 15.7.4-4 FUEL-HANDLING ACCIDENT (ANALYSIS DEFINING "RECENTLY IRRADIATED") RADIOLOGICAL EFFECTS

10 x 10 AST Fuel Rods (6.3 day delay)

	TEDE Dose (rem)	
Main Control Room	4.726	(30-day Reg. Limit 5.0)
Exclusion Area (915 m)	0.267	(2-hr Reg. Limit 6.3)
Low-population zone (4827 m)	0.062	(30-day Reg. Limit 6.3)

Note GE11 9x9 fuel was discontinued at the end of Cycle 14 (October 2010). All GE11 fuel has been discharged to the spent fuel pool, is no longer recently irradiated, and satisfies the Reference 7 burnup restriction. Considering the significant period over which the source term has decayed, consequences associated with the 10x10 fuel types currently in use bound the GE11 consequences to a large degree. For this reason, the results of postulated drops of GE11 fuel type are no longer presented in this chapter.



Fermi 2

UPDATED FINAL SAFETY ANALYSIS REPORT

FIGURE 15.7.1-1

LEAKAGE PATH FOR MAIN TURBINE STEAM AIR EJECTOR LINE FAILURE

15.8 ANTICIPATED TRANSIENTS WITHOUT SCRAM (ATWS)

In order to ease the severity of the consequences of the failure of the scram protection system following an anticipated transient, the NRC has imposed 10 CFR 50.62 requirements for all BWR owners.

15.8.1 ATWS Rule 10CFR50.62

Anticipated transients are transients expected to occur during the life of the plant. Anticipated transients without scram (ATWS) are those extremely low probability events in which an anticipated transient occurs and is not followed by an automatic reactor shutdown (scram) when required. The postulation of the "normal scram" failure in ATWS can only be deduced if more than one "single failure criteria" is assumed.

The NRC has since established the requirements to further reduce the risk to the public from such a postulated event. These requirements are specified in 10CFR50.62, "Requirements for Reduction of Risk from Anticipated Transients Without Scram (ATWS) Events for Light Water Cooled Nuclear Power Plants." For the BWR, 10CFR50.62 requires an alternate rod insertion (ARI) system, a manual standby liquid control system (SLCS), and an automatic recirculation pump trip (RPT) function.

The BWR Owners Group had prepared a topical report on the subject of ATWS and discussed the details of the design option how 10CFR50.62 is satisfied. Reference 1 is the NRC approved topical report. Detroit Edison is a member of the Owners Group and the Fermi 2 design is consistent with that discussed in Reference 1. ATWS was previously evaluated at the 3430 MWt power level (Reference 2). ATWS was previously analyzed with a 3% SRV drift and reviewed as acceptable by the NRC in Reference 3. For the GNF3 new fuel introduction and in support of fuel cycle lengths up to 24 months, ATWS was evaluated at current licensed thermal power and found to meet the ATWS acceptance criteria (Reference 4).

Details of the Fermi 2 ARI can be found in Chapters 4 and 7, Subsections 4.5.2.2 and 7.6.1.18; details of the SLCS and enriched boron can be found in Chapter 4, Subsection 4.5.2.4; and details of ATWS-RPT can be found in Chapter 7, Subsection 7.7.1.2.3.1.

15.9 FAILURE OF THE COOLANT REGULATING INSTRUMENTATION - CORE COOLANT TEMPERATURE INCREASE

This accident was not reevaluated for the Fermi 2 power uprates.

Four coolant regulating instrumentation failures have been identified which can cause a power-coolant mismatch. These events are

a. Core coolant temperature increase

b. Feedwater controller failure

c. Recirculation flow control failure with decreasing flow

d. Recirculation flow control failure with increasing flow.

The analytical methods and assumptions used in evaluating the consequences of these accidents are considered to provide a conservative assessment of the consequences. The NRC has not issued guidelines for evaluating these accidents.

Event a., core coolant temperature increase, is addressed in this section while events b., c., and d. are addressed in Subsections 15.1.2, 15.3.2, and 15.4.5, respectively.

15.9.1 Identification of Causes

15.9.1.1 Starting Conditions and Assumptions

The reactor is going through normal shutdown and cooldown when the residual heat removal (RHR) shutdown cooling system fails.

15.9.1.2 Event Description

Loss of RHR shutdown cooling capability during reactor shutdown and cooldown results in a core coolant temperature increase.

15.9.2 Analysis of Effects and Consequences

15.9.2.1 Methods, Assumptions, and Conditions

An event that can directly cause reactor pressure vessel (RPV) water temperature increase is one in which the energy removal rate is less than the decay heat rate addition. The applicable event is loss of RHR shutdown cooling. This event can occur only during the low pressure portion of a normal reactor shutdown and cooldown when the RHR system is operating in the shutdown cooling mode.

15.9.2.2 Results and Consequences

For most single failures that could result in a loss of shutdown cooling, no unique safety actions are required. In these cases, shutdown cooling is simply reestablished using other normal shutdown cooling equipment. In cases where the RHR system shutdown cooling suction line becomes inoperative, a unique requirement for cooling arises. In operating states in which the RPV head is off, the RHR system LPCI mode can be used to maintain water level. During operating conditions in which the RPV head is on, the system can be pressurized, and the low pressure cooling system, relief valves (manually operated), and RHR system suppression pool cooling mode can be used to maintain water level and remove decay heat.

15.9.2.3 Consideration of Uncertainties

The multiplicity of operator actions available to mitigate the effects of this transient ensure that reactor cooldown can be accomplished.

15.10 INTERNAL AND EXTERNAL EVENTS

These events were not reevaluated for the Fermi 2 power uprates.

The internal accidents to be considered in Subsection 15.10.1 are those that develop from fires in parts of the plant. Specific initiating events are not postulated.

Fires may be initiated from many sources. However, very few flammable materials are used in the plant. Even though fires are postulated to occur for the purpose of accident analysis, the actual probability of a fire is negligible due to both the absence of the combustion process and the low temperatures found in the plant.

External events, such as floods, storms, and earthquakes, are discussed in Subsection 15.10.2. Section 2.4 gives a detailed description of possible floods and storms at the Fermi site. That section also defines the probable maximum flood and the probable maximum meteorological event.

A complete description of the Fermi site seismological characteristics is given in Section 2.5. Response spectra are given for both the operating basis earthquake (OBE) and the safe shutdown earthquake (SSE).

The fire protection system is described in Subsection 9.5.1.

15.10.1 Internal Event Evaluation

A complete description of the Fermi 2 fire protection features is in Subsection 9.5.1, and a fire hazards analysis for safety-related areas is provided in the Fire Protection Program Description/Analysis Program.

15.10.2 External Event Evaluation

Floods, storms, and earthquakes are evaluated in this subsection.

15.10.2.1 Identification of Causes

15.10.2.1.1 Floods

Section 2.4 gives a detailed description of floods, flood parameters, and events concurrent with flooding for the Fermi site. This section also describes the probable maximum flood.

15.10.2.1.2 Storms

Refer to Section 2.3 for a detailed description of storms and other meteorological events concurrent with storms for the Fermi site. Also included in Section 2.4 is a description of the probable maximum flood.

For a description of the wind and tornado design parameters for all Category I structures and components, refer to Section 3.3.

15.10.2.1.3 Earthquakes

Refer to Section 2.5 for a complete description of the Fermi site seismological characteristics and history. Included are the response spectra for both the safe shutdown earthquake (SSE) and the operating basis earthquake (OBE).

15.10.2.2 Analysis of Effects and Consequences

15.10.2.2.1 Floods

Neither the plant ESF systems nor the safe shutdown capability of the reactor will be impaired by flooding of the Fermi site. All Category I structures are conservatively designed to behave elastically and remain functional and watertight under the effects of the probable maximum flood and wind generated waves specified in Sections 2.4 and 3.4. Refer to Section 3.8 for a discussion of the design of Category I structures. As mentioned in Subsection 3.4.1, the design stillwater flood elevation of the probable maximum flood is conservatively increased to 1.1 ft above the predicted probable maximum flood elevation specified in Section 2.4.

The reactor building, auxiliary building, and the RHR complex incorporate the flood protection measures specified in Subsection 3.4.4, to ensure that the effects of the probable maximum flood will not penetrate the exterior boundaries of these structures.

15.10.2.2.2 Storms

All Category I structures and components are designed or suitably protected to remain functional for all credible meteorological events, including the probable maximum meteorological event and the tornado, whose parameters are specified in Subsection 3.3.2.

Superficial damage may be sustained by miscellaneous plant property and nonseismic structures during the postulated tornado. However, this damage will not impair the plant ESF systems nor the safe shutdown capabilities of the reactor.

All roofs are properly sealed, pitched, and drained to prevent water from entering the building. Similarly, the reactor building superstructure siding above the fifth floor has sealed joints. As mentioned in Section 3.3, the metal siding will be assumed to blow away when the wind velocity exceeds 200 mph. However, the superstructure steel framing is designed to behave elastically for the tornado postulated in Subsection 3.3.2. Should this unlikely event occur and expose the refueling floor, the safe shutdown capabilities of the reactor would not be impaired.

A meteorological station has been constructed on the Fermi site and is maintained by Edison. Meteorological data, such as temperature, barometric pressure, and wind velocity and direction, are recorded to keep plant personnel informed of current meteorological conditions.

15.10.2.2.3 Earthquakes

All Category I structures, components, and equipment are designed to remain functional during an SSE. The seismic analysis and design for Category I structures are in accordance with Sections 3.7 and 3.8, respectively. Some cracking of the reactor building exterior walls may occur during an SSE, but large, predominantly open cracks are not expected. Therefore, leakage of water into the reactor building through cracks will not occur.

Active earthquake recording instrumentation (triaxial accelerometers) are provided to measure the basic ground motion time history acceleration, as well as the seismic motion of the primary containment elements (including the base of the RPV pedestal). The recording system will be energized when a seismic trigger senses acceleration above a preset limit. This signal will be sent over shielded cables for permanent recording and data reduction, and will alert facility operators to the fact that an earthquake has occurred.

In addition to active instrumentation, passive sensors (triaxial spectrum recorders) are provided to measure various ground motion and in-structure response spectra.

The recorded data will be examined immediately, and the plant will be evaluated as described in Section 3.7.4.4, and operation will not be resumed until analysis and/or necessary refurbishing of all critical structures, systems, and components is completed. If examination shows that the SSE validation level is exceeded, further rigorous investigation will commence. If permanent deformation or evidence of material yield is encountered, appropriate repairs will be affected before startup.

Refer to Subsection 3.7.4 for a complete description of the seismic instrumentation.

15.11 FAILURE OF THE GASEOUS RADWASTE SYSTEM

15.11.1 Identification of Causes

An evaluation of those events which could cause a gross failure in the offgas system has resulted in the identification of a seismic event more severe than the one for which the system is designed as being the only conceivable event which could cause significant damage.

15.11.2 Starting Conditions and Assumptions

Equipment and piping are designed to contain any explosion which has a reasonable probability of occurring. Therefore, an explosion is not considered a possible failure mode. The equipment vaults are not accessible during normal operation. Therefore, an operator induced failure is not considered reasonable. The only credible event that could result in the release of significant activity to the environment is an earthquake.

15.11.3 Event Description

An event more severe than the design requirements of the offgas system is arbitrarily assumed to occur, resulting in the failure of the offgas system. The sequence of events following this failure is as follows:

	Events	Approximate Elapsed Time
a.	Event begins. System fails	0
b.	Noble gases are released	0
c.	Area radiation alarms alert plant personnel.	< 1 minute

15.11.4 Analysis of Effects and Consequences

15.11.4.1 Realistic Evaluation Methods

The analytical methods and associated assumptions used in evaluating the consequences of this accident are considered to provide a realistic, yet conservative, assessment of the consequences. In some instances very conservative assumptions are made in accordance with Regulatory Guide l.29 to show that the offgas system does not require Category I design.

15.11.4.1.1 Methods, Assumptions, and Conditions

The reactor is assumed to be operating at 3499 MWt for a period of time sufficient to cause an equilibrium inventory to be accumulated in the offgas system.

The activity in the offgas system is based on the following conditions:

a. 40 scfm air inleakage

b. l02,000 μCi/sec noble gas after 30-minute delay

c. Six charcoal beds

d. Removal of daughter products by equipment:

  1. Catalytic recombiner - 100 percent (iodine)

  2. Offgas condenser - l00 percent

  3. Aftercooler - l00 percent

  4. Precooler - l00 percent

  5. Holdup pipe - l00 percent

  6. Chiller - l00 percent

  7. Sandfilter - l00 percent.

e. Operating times

  l. Charcoal beds - l0 years

  2. Afterfilter - l0 years.

The radionuclide inventories for each component in the offgas system, as well as the total system inventories, are listed in Table 11.3-2. Table 15.11-1 presents the parameters used in this accident analysis.

15.11.4.1.2 Results and Consequences

Fuel Damage

There is no fuel damage as a result of this accident.

Fission Product Release From Fuel

There is no fission product release from the fuel as a result of this accident.

Fission Product Release to the Environment

It is conservatively assumed that l00 percent of the iodine and 10 percent of the noble gases in each component of the offgas system are released to the environment. Table 15.11-2 lists the total isotopic releases from this accident. The assumption that 10 percent of the noble gases in the offgas system is released is indeed a conservative one. Approximately 99 percent of the noble gas activity is contained in the charcoal adsorbers. The only credible failure that could result in the release of a significant amount of noble gases would be the loss of carbon from a charcoal adsorber. The circumferential failure of the steel structure surrounding the charcoal bed would be such an accident. However, only 10 to 15 percent of the carbon in the bed would be released.

Measurements made at KRB indicated that the offgas is about 30 percent richer in krypton than air. As a result, when the carbon is exposed to the air, the krypton absorbed by the carbon eventually obtains equilibrium with the noble gases in the air. However, the first few inches of carbon will blanket the underlying carbon from the air. Therefore, a 10 percent loss of noble gases from the beds is conservative because of the small fraction of carbon exposed to the air.

Radiological Effects

The radiological effects for this accident are based on the total system activities summarized in Table 15.11-2. The resultant radiological exposures are presented in Table 15.11-1. These doses are based on conservative dispersion data (5 percentile site meteorology) to conform with Regulatory Guide 1.29 assumptions. The resulting exposures are a small fraction of the guideline values of 10 CFR 100 and the limits for radiation exposure specified in Regulatory Guide 1.29.

15.12 MALFUNCTION OF TURBINE GLAND SEALING SYSTEM

This malfunction was not reevaluated for the Fermi 2 power uprates:

15.12.1 Loss of Vacuum in the Gland Steam Condenser

The gland steam condenser is self sealing and during normal operation, noncondensables are removed from the gland steam condenser by one of two gland steam condenser blowers. In the event the operating blower malfunctions, the backup blower will automatically assume the gas removal requirements. Assuming loss of both blowers, vacuum will be lost in the gland steam condenser. The pressure in the gland steam exhaust header will increase to greater than atmospheric, allowing sealing steam to escape into the turbine building.

15.12.2 Analysis of Effects and Consequences

In the event of loss of vacuum in the gland steam condenser, the gland sealing steam pressure will begin to increase in the exhaust header. This will result in blowing sealing steam into the atmosphere around the glands (on the third floor of the turbine building). This pressure buildup will be alarmed in the main control room. Main control room personnel will then correct the situation and ensure vacuum is restored in the gland steam condenser. The gland sealing system is not required for a safe reactor shutdown, nor can its failure adversely affect the operation of safety systems required for a safe reactor shutdown. It is an ALARA (as low as reasonably achievable) and a personnel safety concern for personnel near the turbine.

15.13 SHUTDOWN COOLING MALFUNCTION DECREASING TEMPERATURE

This malfunction was not reevaluated for the Fermi 2 power uprates.

At design power conditions, no conceivable single failure type malfunction is possible in the shutdown cooling system that can cause a temperature reduction.

If the reactor were critical or near critical, a very slow increase in reactor power could result. A shutdown cooling malfunction leading to a moderator temperature decrease could result from misoperation of the cooling water controls for the RHR system heat exchangers. The resulting temperature decrease would cause a slow insertion of positive reactivity into the core. If the operator did not act to control the power level, a high neutron flux reactor scram would terminate the transient without fuel damage and without any measurable increase in nuclear system pressure.

15.14 LOSS OF SERVICE WATER SYSTEM

This event was not reevaluated for the Fermi 2 power uprates.

The residual heat removal service water (RHRSW), the emergency equipment service water (EESW), and the emergency diesel generator service water (EDGSW) systems supply cooling water, either directly or indirectly, to all ESF equipment. Subsections 6.3.2.2.6, 9.2.5, and 9.5.5 describe these systems.

15.14.1 Identification of Causes

The loss of the service water systems listed above can be caused by loss of the service water pump, loss of electrical power, loss of the service water piping, loss of the heat exchanger, or loss of control circuits. The EESW system has a temperature regulator valve that fails open. The RHRSW system uses a manually controlled globe valve for flow control. The EDGSW systems do not have regulating valves.

15.14.1.1 Starting Conditions and Assumptions

This accident is analyzed using the following assumptions:

a. Prior to this event the reactor turbine is operating normally at full design reactor power (3292 MWt)

b. The DBA occurs: namely, the circumferential sudden break of a reactor recirculation loop pipe occurs

c. A complete loss of normal power occurs simultaneously with the recirculation pipe break

d. The EDGs start normally

e. The ECCS, HPCI, ADS, LPCI, and core spray systems start and operate normally

f. The RHRSW system is manually started and valved into the RHR heat exchangers between 10 and 30 minutes after ECCS initiation to limit the suppression pool temperature to less than l85°F.

15.14.1.2 Event Description

An individual loss of an EDGSW system will cause loss of only the particular EDG that it cools. The EDG loss will cause loss of only the loads for that particular generator because the Fermi 2 essential power system consists of four independent buses. The loss of the EESW system will cause loss of the emergency equipment cooling water (EECW) system in that division. This loss will cause the eventual loss of the ESF equipment in the particular division cooled by the EECW system.

Loss of the RHRSW system will cause loss of the RHR heat exchanger in that division. For a worst-case assumption, the EDGSW, EESW, and RHRSW systems are assumed to fail simultaneously in the same division coincident with the LOCA. The EDGs will start and load in both divisions. The EDGs without service water will operate approximately 3 minutes before overheating. The remaining division is unaffected.

The EECW system will start and isolate from the nonessential reactor building closed cooling water system (RBCCWS). This system will operate because it is a closed condensate system but will not be able to reject heat to the EESW system. When the EDGs in the division fail (from loss of EDGSW), the equipment serviced by the EECW will stop running. Thus, the EECW will no longer be needed. The remaining division is unaffected.

The RHRSW system failure will not allow the operator to use the RHR heat exchanger in that division. The remaining heat exchanger is unaffected.

15.14.2 Analysis of Effects and Consequences

15.14.2.1 Methods, Assumptions, and Conditions

In analyzing the failure of one division of the RHRSW system, it is assumed that the other division of service water is operable. This meets the single failure criterion (General Design Criterion 44). There are no common mode failures that can cause failure of both divisions of essential service water systems.

15.14.2.2 Results and Consequences

The failure of one divisional service water system results in no effect on the remaining divisional system. No additional operator action is required to initiate the remaining division. The loss of any service water subsystem and a single failure coincident with a LOCA will cause eventual loss of the division, but the effect is not as great as an immediate loss of one emergency power division coincidental with a LOCA. The consequences then reduce to the LOCA accident which assumes one division ESF equipment loss.

15.15 LOSS OF ONE (REDUNDANT) DIRECT CURRENT SYSTEM

This event was not reevaluated for the Fermi 2 power uprates.

15.15.1 Identification of Causes

Loss of one entire redundant dc system would be the result of a total loss of one of the batteries, plus the loss of the full capacity battery chargers or dc distribution panels. This could be due to a fire, hydrogen explosion, or equipment failure. However, the probability of each is very low because of the noncombustible nature of the room and the battery room ventilation requirements of six air changes per hour.

It would be more likely to lose one redundant battery due to the short circuiting of a cell or series of cells, hydrogen explosion within a cell, faulty fuse, or several other possible but rare events. Battery damage would not preclude the use of the charger for handling the normal loads unless it, too, were involved in the event. Any fault in the main distribution cabinet affecting the dc bus would cause the loss of only one division of the dc system.

15.15.1.1 Starting Conditions and Assumptions

The reactor is initially operating at l00 percent of rated power (3292 MWt).

15.15.1.2 Event Description

Loss of the ESF Division I 130/260-V dc battery would result in the loss of availability of the RCIC system and several motor operated containment outboard isolation valves. Loss of the ESF Division II 260-V dc system would eliminate the availability of the HPCI system and also remove motive power from several containment outboard isolation valves.

Since the 130-V dc supply for each ESF is derived from the 260-V dc center tapped battery, loss of the 260-V dc battery would eliminate control power to the ESF division of switchgear serviced from that particular l30-V dc system. Other pertinent effects would be a loss of diesel generator control, loss of control power to dc relays of the RHR and core spray systems, and loss of dc power to one reactor protection system (RPS).

Loss of one 48/24-V dc system would eliminate one redundant system of stack gas monitors, startup range neutron monitors, and process radiation monitors.

15.15.2 Analysis of Effects and Consequences

Assuming that a fire or other event rendered one dc system inoperative, the second redundant system would provide the capability of a safe shutdown.

The operation of the RCIC system is not essential to safe shutdown. Therefore, the loss of the RCIC system, due to the loss of the ESF Division I 260-V dc battery, would not prevent safe shutdown. Loss of motive power to the outboard isolation valves would not be critical, even if they should be needed, since each line is backed up with a redundant ac-operated isolation valve inside the containment.

A loss of an ESF Division II dc power system would remove the HPCI system should an incident occur in which the vessel did not depressurize. The HPCI system is, however, backed up by the automatic depressurization system (ADS), which has its power supply from the ESF Division I l30-V dc system. Thus, in the event of loss of all ESF Division II dc power, the ADS would depressurize the reactor, and the LPCI and core spray systems would provide adequate core cooling. Emergency diesel generators, RHR and core spray pump control, and RPS power are all redundant.

Loss of the 48/24-V dc system would have no significant effect because all indication is backed up with indication from the redundant division.

15.16 LOSS OF INSTRUMENT AIR SYSTEM

This event was not reevaluated for the Fermi 2 power uprates.

15.16.1 Identification of Causes

Equipment malfunctions or operator errors can initiate loss of instrument air supply system pressure.

15.16.1.1 Starting Condition and Assumptions

The station air compressor is loaded automatically to maintain 100 psi in the receiver tanks. The station air header automatic isolation valves are open, and the standby station air compressor is ready to automatically start.

15.16.1.2 Event Description

If the instrument air supply continues to decrease after falling pressure has initiated an automatic start of the standby station air compressor, the main control room will receive an alarm and the third station air compressor will be manually started.

15.16.2 Analysis of Effects and Consequences

15.16.2.1 Effects

Decreasing plant air pressure automatically shuts off plant air supply to equipment requiring station air and starts the control air compressors. An alarm occurs in the control room due to the control air compressor auto start. A sustained decrease in air pressure will cause isolation of both divisions of noninterruptible control air from the nonessential (non safety related) systems and components resulting in their associated equipment and systems being considered inoperative. In such a case, equipment or systems requiring station or interruptible control air go to a fail safe position or have qualified accumulators which automatically isolate to maintain the equipment in a safe condition. Isolation of the noninterruptible control air initiates an alarm in the main control room.

15.16.2.2 Analysis

The safety related portion of the instrument air system is the noninterruptible control air. Noninterruptible control air (NIAS) is supplied through two separate, fully qualified, distribution systems (Division I and II). Each division consists of a compressor, after cooler, filters, dryer, receiver tank, and distribution piping.

Reliability of the system (NIAS) is maintained by the fact that (1) equipment and piping is seismically qualified, (2) control air compressors and dryers are automatically electrically fed off the emergency diesel generators on loss of offsite power, (3) the system is automatically isolated on low header pressure or loss of offsite power, and (4) receiver tanks are capable of maintaining the system pressure at an acceptable level for the short duration transition period of the loss of offsite power event (See Table 8.3-5) until the compressors' electrical load is picked up by the diesel generators on loss of offsite power.

Based on the above, noninterruptible control air will provide the required instrument air on loss of station and/or interruptible air. Therefore, essential equipment will have the necessary control air available to perform their safety function through NIAS or accumulators.

APPENDIX 15A: DOSE CALCULATION MODELS AND SPECIFIC CALCULATIONAL VALUES

For a LOCA, the dose calculations have been re-evaluated as indicated in Section 15.6.5.5 using Alternative Source Terms (AST). The LOCA atmospheric dispersion factors for AST offsite doses were derived as per Section 2.3.4, with onsite (Main Control Room, modeled as a zero velocity vent release) AST dispersion factors derived as per Notes 4 and 7 to Table 15.7.4-1 for the AST Fuel Handling Accident analyses. The resulting LOCA AST atmospheric dispersion factors are provided in Section 15.6.5, replacing those discussed in Section 15A.1 and Table 15A-2 below. The resulting AST LOCA doses are shown in Section 15.6.5.

15A.1 OFFSITE TOTAL BODY AND THYROID DOSES (PRE-AST TREATMENT)

The whole-body and beta skin doses at the site boundary and low population zone have been calculated by the semi-infinite cloud model

$$D_{WB} = \sum_{i=1}^{n} \sum_{j=1}^{m} R_{ij} \frac{\chi}{Qj} DCF_i \qquad (15A\text{-}1)$$

where

D_{WB} = whole-body dose for time period of interest, rem

R_{ij} = integrated release of i^{th} isotope over j^{th} time interval, curies

$\frac{\chi}{Qj}$ = atmospheric dispersion factor to location of interest for j^{th} time interval, sec/m^3

DCF_i = dose conversion factor for i^{th} isotope, $\left[\frac{rem - m^3}{Ci - s}\right]$

The values of DCF_i has been evaluated in accordance with Regulatory Guide 1.3 as

$$DCF_i \ (0.25\bar{\Sigma}\gamma)_i, \text{for whole body dose} \qquad (15A\text{-}2)$$

$$DCF_i \ (0.23\bar{\Sigma}\beta)_i, \text{for skin dose} \qquad (15A\text{-}2a)$$

where

$\bar{\Sigma}\beta$ = average beta energy

$\bar{\Sigma}\gamma$ = average gamma energy

The values of $\bar{\Sigma}_{\beta}$ and $\bar{\Sigma}_{\gamma}$ used in the calculations are presented in Table 15A-1 (Reference 1).

Fermi site meteorological data collected from the 60-meter tower over the period June 1, 1974, to May 31, 1975, were used to calculate the short-term χ/Q values used in the accident analyses. Values of χ/Q for the site boundary and low-population zone are presented in Table 15A-2. The 5 percentile χ/Q for the appropriate time interval was used for the dose calculations.

Thyroid doses at the site boundary and low-population zone have been calculated by the model

$$D_{TH} = \sum_{i=1}^{n} \sum_{j=1}^{m} R_{ij} \frac{\chi}{Qj} B_j \frac{D\infty}{A} \tag{15A-3}$$

where

D_{TH} = thyroid dose commitment from exposure during time period of interest, rem

B_j = breathing rate during j^{th} time interval, m^3/sec

$\left(\frac{D\infty}{A}\right)_i$ = thyroid dose commitment conversion factor from i^{th} isotope $\left(\frac{rem}{Ci}\right)$

The values of B_j used in the calculations are in accordance with Regulatory Guide 1.3. The values of B_j for the appropriate time intervals are

Time Interval	B_j (m^3/sec)
0-8 hr	3.47×10^{-4}
8-24 hr	1.75×10^{-4}
>24 hr	2.32×10^{-4}

The values of $\left(\frac{D\infty}{A}\right)_i$ are presented in Table 15A-1 (Reference 2).

CHAPTER 17: QUALITY ASSURANCE

To ensure that the design and construction of the Enrico Fermi Atomic Power Plant Unit 2 (Fermi 2) were in conformance with applicable regulatory requirements and the established design bases, the Detroit Edison Company (Edison), as plant owner, established and implemented a Quality Assurance (QA) program that satisfied the requirements of Appendix B to 10 CFR 50.

Edison, acting as its own Architect-Engineer (A-E), designed major portions of the plant and procured the nuclear steam supply system (NSSS) and the remainder of the plant structures, systems, and components. Edison was assisted in its design effort by the assignment of certain tasks to qualified engineering firms. Administration and control of site erection and construction contractors were assigned to a Construction Manager.

Edison imposed the applicable requirements of Appendix B to 10 CFR 50 on the NSSS vendor, on the engineering firms involved, on the vendors who supplied plant items, and on the contractors who erected and constructed plant structures, systems, and components.

The Edison QA program and its implementation during the plant design, procurement, construction, and testing phases are described in Section 17.1.

The Edison QA program for plant preoperational testing, startup, operation, maintenance, and modification is described in Section 17.2.

17.1 DETROIT EDISON QUALITY ASSURANCE DURING DESIGN AND CONSTRUCTION

Edison established a QA program to control the design, procurement, manufacturing, installation, construction, inspection, and testing of the safety-related structures, systems, and components of Fermi 2.

The organization and procedures that implemented the program are described herein. Also included is a brief description of the corporate organization.

17.1.1 Organization for Quality Assurance

17.1.1.1 Corporate Organization

That part of Detroit Edison, down to the department level, having corporate responsibilities for quality-related activities for Fermi 2 is shown in Figure 17.1-1. More information on the corporate organization is located in Chapter 13 of the original FSAR.

The President, as chief operating officer, had overall responsibility for engineering, construction, operation, and maintenance of Edison's plants and for system development and interconnection. He was also responsible for establishing corporate policies, goals, and objectives on quality assurance matters. The management functions discussed below reported to him.

A Group Vice President was responsible for those Edison organizational units that provided for the planning, engineering, construction, operation, maintenance, and technical support of the company's power plants and electrical facilities. Vice Presidents of Planning and

Research, Operations, and Engineering and Construction reported to the Group Vice President.

The Vice President - Nuclear Operations, with overall responsibility for the operation, maintenance, and operational quality assurance for the Fermi 2 plant, reported to the President.

A Group Vice President responsible for administrative functions and the division organizations reported to the President.

The Manager - Quality Assurance, who was responsible for quality assurance at the corporate level, reported to the President.

17.1.1.2 Project Organization

The Vice President - Fermi 2 Project reported directly to the President. He had overall responsibility for the completion of construction and startup testing of the Fermi 2 project.

The Manager of the Project was responsible for the design, procurement, and construction activities for the project. He was supported by the Project Management Organization described herein.

The Manager - Startup, who was also Manager - Nuclear Operations, was responsible for the testing activities performed by the Startup Organization, including the checkout and initial operational testing, which was subject to the requirements of the QA program described in this section of the UFSAR.

Project functions were organized into five principal groupings, with the head of each group reporting to the Manager of the Project. The organizational structure of the Project Management Organization is shown in Figure 17.1-2. All groups except Project Engineering were located at the site. Project Engineering maintained an organizational unit at the site.

The Assistant Project Manager - Engineering had overall responsibility for administration and technical direction of the Project Engineering Organization.

The Technical Director provided technical direction to the Fermi 2 project and was assisted by a group of System Engineers and the Project Licensing Engineer in performing his duties, which included

a. Ensuring that safety reviews, safety analyses, and design reviews were conducted

b. Defining and controlling the technical scope of the project

c. Performing licensing activities

d. Ensuring compliance with technical regulatory requirements

e. Ensuring correctness of conceptual design documents and functional system descriptions

f. Ensuring adequacy of test criteria, procedures, and results

g. Identifying safety-related plant structures, systems, and components.

The Director - Project Design had overall responsibility for ensuring the adequacy of design performed by Project Engineering and various design contractors. Among his principal duties were the following:

a. Preparation, review, approval, and control of project design documents, including design instructions, system diagrams, drawings, specifications, design change notices, field modification requests, and purchase requisitions
b. Review and control of design documents produced by design contractors
c. Establishment of requirements and acceptance criteria for testing plant structures, systems, and components
d. Preparation of vendor document lists
e. Technical review of submitted vendor documents.

The Director - Project Engineering Assurance had responsibility for ensuring that the design activities of Project Engineering were adequately controlled and that the design achieved the plant quality objectives. Among his duties were:

a. Ensuring that design control procedures were prepared and implemented
b. Assisting Project QA in audits of Project Engineering activities and design contractors
c. Reviewing design documents for quality criteria
d. Ensuring that Project Engineering personnel were properly trained
e. Ensuring the adequacy of computer codes.

The Director - Project Field Engineering had overall responsibility for design activities performed at the site and for acting as the representative of Project Engineering. His principal duties included:

a. Reviewing and determining disposition of deviation disposition requests, design change requests, and field modification requests
b. Interpreting engineering specifications and drawings
c. Designing electrical conduit, cable trays, and supports
d. Designing small-bore process piping, instrument lines, and supports
e. Verifying or modifying design of large-bore supports
f. Reviewing contractor procedures for technical requirements
g. Providing as-built information for ASME Section III, Class 1, piping systems
h. Reviewing drawings prepared by contractors at the site
i. Interfacing with the Construction Manager's area superintendents through the area engineers.

Project Engineering was assisted by a number of A-Es and engineering consultants, namely:

Sargent & Lundy. Sargent & Lundy (S&L) was contracted to perform the civil, structural, and architectural design of the reactor building, prepare specifications for the primary containment vessel, perform certain electrical design tasks, and conduct piping system analyses. This work was performed as an extension of the Edison design effort and was subject to the same QA procedures and controls as those established for Edison's design efforts, including documented design reviews.

By a second contract, S&L had total responsibility for design of the residual heat removal (RHR) system. This included preparing design documents, procurement documents, and an approved bidders list; reviewing bids received by Edison; recommending contract awards; and reviewing contractor or vendor submittals (e.g., drawings, manufacturing and inspection plans, QA programs, and QA documentation) and recommending that they be approved or revised. S&L's QA program, as described in Topical Report SL-TR-1A, was implemented for this contract.

Stone & Webster. Stone & Webster (S&W) was contracted to assist Edison in the design area. A number of identified tasks were assigned, varying from total engineering responsibility, as in the case of the security system, to supplying personnel to work on Edison premises under direct Edison supervision. Work performed at the S&W offices was in accordance with applicable provisions of the S&W Standard Quality Assurance Program, 1-74A.

Giffels and Associates. Work performed by Giffels and Associates (G&A) was an extension of the Edison design effort. G&A received both design criteria and direction from Edison, and G&A work was subject to review and final approval by Edison.

NUS Corporation. NUS Corporation (NUS) acted as engineering consultant to perform calculations of pressure response in the annular space between the reactor pressure vessel (RPV) and sacrificial shield and for the redesign of the radwaste system. In addition, NUS provided environmental and licensing services for the project. Work was performed under the NUS QA program.

NUTECH. NUTECH acted as engineering consultant and was assigned three tasks: designing torus modifications; performing various tasks associated with the GE Mark I Owners Group; and reviewing the environmental qualifications of electrical equipment. Work was performed in accordance with the requirements of the NUTECH QA program.

The Site Manager, who was also an Assistant Project Manager, had overall responsibility at the site for directing construction activities and for completion and turnover of plant systems to the Startup Organization. Reporting to him were the Project Construction Superintendent; the Daniel International Project Manager; the Bechtel Project Manager; and the Director of System Completion.

The Project Construction Superintendent and his staff assisted the Site Manager in carrying out his duties involving construction activities.

Daniel International Corporation (DIC) was the Construction Manager for the project. The DIC Project Manager reported to the Project Management Organization through the Site

Manager. DIC was responsible for supervision of construction and for administration of the site installation and construction contracts awarded by Edison. In addition, DIC was responsible for construction engineering and implementation of the storage and preservation program for equipment, stored or installed.

Responsibilities of contractors at the site varied from having a complete QA program with an independent QA organization, to providing a work force and a limited-scope QA program.

Contractors providing their own inspection were structured organizationally so as to ensure the independence of inspectors from those directly responsible for the work.

If a contractor was required to provide an individual with responsibility for ensuring effective implementation of its corporate QA program, that individual reported to a responsible offsite corporate management level.

The Bechtel Power Corporation (Bechtel) was contracted as the Maintenance Contractor for the operational phase of the plant but was also assigned certain construction tasks. The Bechtel Project Manager on construction matters reported to the Site Manager. Bechtel's work was performed in accordance with Edison procedures or procedures developed by Bechtel and approved by Edison. Inspection of work was by Project QA.

The Director of Systems Completion was responsible for accomplishing turnover of systems from contractors to Edison, completing punchlist items for each turned-over system, coordinating the checkout and initial operations testing by the Startup Organization of Nuclear Operations, performing system hydros, and finally turning over systems to the Startup Organization for preoperational testing.

The Project Materials Director was the General Purchasing Department's representative on the Project Management Organization. He and his staff were responsible for all contracts, including purchasing and expediting activities for Project Management Organization procurements. Additionally, the Project Materials Director was responsible for purchase of materials for Nuclear Operations and operation of warehousing facilities at the site, including the receipt of materials and equipment purchased by Edison.

The Director of Project Controls was responsible for establishment and administration of project cost and scheduling programs. Activities of his department were not subject to requirements of the QA program.

The Project QA Director reported administratively to the Manager - Quality Assurance, but on project-related matters, he reported to the Manager of the Project. The Project QA Director was responsible for ensuring establishment and effective implementation of the project QA program by Edison and its suppliers and contractors and for coordinating project activities involving the interface with the Region III Office of the NRC. With two Assistant Project QA Directors, he provided administrative and technical direction to Project QA. The Project QA Director had stated authority to initiate action to stop work when significant quality problems existed and to bring about their resolution on a timely basis.

The organizational structure of Project QA is shown in Figure 17.1-3. The organization was located both at the site and at the Engineering Construction Center (ECT) at Troy, Michigan.

The Procurement QA Section of Project QA was responsible for activities associated with procurement of materials and equipment for the project. Included in its activities were the following:

a. Coordination on preparation of source surveillance plans with the General Purchasing Department, Inspection Division
b. Review of Edison procurement documents for items important to safety
c. Acceptance of supplier QA manuals
d. Audit of supplier QA programs
e. Maintenance of the approved suppliers list
f. Receiving inspections and supplier QA records review for procured items
g. Evaluation of vendors'/suppliers' performance
h. Participation in American Society of Mechanical Engineers surveys
i. Surveillance over material control practices in the warehouses.

The Construction QA Section of Project QA was responsible for auditing and surveillance of Edison and contractor activities at the site subject to requirements of the QA program for the project. Among its principal activities were the following:

a. Review and acceptance of contractor QA programs and procedures
b. Audit of onsite contractor QA programs
c. Audit of Edison and Construction Management groups at the site
d. Surveillance of contractor activities for compliance with procedures and quality requirements
e. Coordination of onsite NRC inspections by nonresident inspectors and preparation of responses to inspection reports
f. Reporting 50.55(e) deficiencies to the NRC and coordination and preparation of written reports
g. Review and approval of conditional releases
h. Preparation of management reports
i. Initiation of stop-work action when required
j. Preparation of contractor performance evaluations
k. Audit and surveillance of balance-of-plant construction activities
l. Investigation of significant quality problems and determination of corrective actions
m. Coordination of trend analyses.

The Finish Construction and Maintenance QA Section of Project QA was responsible for the surveillance and inspection of work performed by Bechtel, Plant Maintenance, and contractors who did not furnish inspection personnel. Among its principal activities were

a. Contractor maintenance and construction procedures review
b. Inspection planning
c. Development of inspection procedures and checklists
d. Maintenance and finish construction inspection and surveillance
e. Maintenance nondestructive-examination (NDE) activities
f. System completion and turnover monitoring and documentation review
g. Verification of completion of NRC commitments (hardware)
h. Review of project master punchlist
i. Verification of completion of punchlist items.

Engineering QA, located at Troy, Michigan, was responsible for monitoring and auditing activities associated with Project Engineering. Among its principal activities were the following:

a. Audit and surveillance of Project Engineering activities and support A-Es
b. Review of selected project procedures for offsite activities
c. Review of procurement specifications
d. Review of Edison-ECT procurement documents for QA Level I items
e. Preparation of responses to NRC bulletins, etc.

The Operational Assurance Section of Project QA was responsible for audit, surveillance, and inspection of activities and document review involving systems turned over to the Startup Organization for checkout and initial operations testing, including support activities performed by Nuclear Operations organizations. Among its principal activities were the following:

a. Inspection of startup tests
b. Surveillance of startup activities
c. Review of startup test procedures
d. Review of test results documentation
e. Coordination of nonconformance reports resulting from testing activities
f. Initiation of stop-work action when appropriate
g. Performance of trend analyses.

The Inspection Division of the General Purchasing Department provided qualified personnel to perform vendor surveillance, including inspection of hardware and release of materials and equipment for shipment. They also provided the expertise necessary to perform facilities surveys when potential bidders were being qualified. The participation of Inspection Division personnel in the project was coordinated through Project QA. Certain vendor surveillance and inspection was contracted to qualified outside organizations to augment Edison's vendor surveillance personnel.

Quality Control (QC) and technical specialists, such as metallurgists, NDE specialists, welding engineers, construction inspectors, and others from various Edison departments, were available to the project to participate in evaluation of manufacturing, installation, and construction problems and in audits of vendor and contractor activities. Efforts of QC and technical specialists in the latter role were coordinated through Project QA.

The Startup Organization was responsible for conducting testing of plant equipment and systems, beginning with the checkout and initial operations testing and proceeding through preoperational tests. Managerial and administrative controls for testing programs were prescribed in the Startup Manual.

Nuclear Production was responsible for the tagging of systems and components turned over to Edison jurisdiction from the contractors, for operating such systems and components, and for directing the maintenance and refurbishment programs.

Administration Services of Nuclear Operations was assigned responsibility by the Project Management Organization for the operation of the Document Control Center at the site and the QA records vault.

General Electric Company (GE), as the NSSS supplier, was a major participant in the Fermi 2 project. The official interfaces between the Edison and GE organizations were the GE project managers and Edison's Manager of the Project; at the working level, there were numerous interfaces. Review of designs was coordinated through the Assistant Project Manager - Engineering; audit and surveillance of GE's QA program and related activities were coordinated through the Director of Project QA; GE's involvement with licensing of the plant was coordinated by the Project Licensing Engineer; at the site, GE provided technical consultation and supervision in erection, testing, and operation of the NSSS through its Site Resident Manager and staff of technical and startup specialists and QC representatives. The Site Resident Manager and his staff coordinated their activities through the DIC Project Manager, the Edison Startup Engineer, and Project QA.

17.1.2 The Quality Assurance Program

In order to establish the highest degree of functional integrity and reliability for those structures, systems, and components that prevent or mitigate the consequences of postulated accidents that could cause undue risk to the health and safety of the public, Edison implemented a QA program, either directly or through its vendors and contractors, to meet the requirements of Appendix B to 10 CFR 50.

The objectives of this program were to ensure that:

a. Applicable regulatory criteria, codes, standards, and design bases were correctly translated into drawings, specifications, procedures, and instructions

b. Systems, components, and materials fabricated or tested in a manufacturer's facility conformed to drawings, specifications, procedures, and instructions

c. Structures, systems, and components constructed and tested at the Fermi site conformed to drawings, specifications, procedures, and instructions

d. Provisions were made for documenting and retaining information on quality-related activities performed on those structures, systems, and components whose satisfactory performance was necessary to meet plant safety and availability objectives.

The QA program, as defined in the QA manual, contained established written policies that were intended to (1) aid in achieving the program objectives, and (2) satisfy the requirements of each of the 18 criteria of Appendix B to 10 CFR 50.

In accordance with these policies, written procedures were established and implemented during the design, procurement, manufacturing, installation, construction, inspection, and testing phases of the project to delineate:

a. The structure, responsibilities, and functions of the corporate organization relative to QA

b. The Project Management Organization established by Edison for effective management of the project

c. The project personnel responsible for certain QA functions, and to define the responsibilities, duties, and authorities of persons and organizations performing QA functions

d. The responsibilities and methods to ensure that plant design was appropriately controlled in process and that its adequacy was verified and documented

e. The responsibilities and methods for evaluation and dispositioning of changes, deviations, and incidents affecting the plant configurations as defined in the approved design documents to ensure that such changes, deviations, and incidents were adequately controlled and did not compromise the design intent

f. The responsibilities and methods for receiving, identifying, filing, distributing, maintaining, and reporting status of project documents to ensure that such documents were adequately controlled

g. The control of procurement documents to ensure that requirements referenced or included therein for material, equipment, and services procured by Edison, or by its vendors and contractors, conformed to the requirements of the procurement documents

h. The identification and control of material, parts, and components to ensure the use or installation of only correct and accepted items

i. That the activities affecting quality were prescribed by appropriate written instructions, procedures, or drawings and were accomplished in accordance with these documents

j. That special processes were performed in accordance with qualified procedures and only by qualified personnel

k. That a program for inspection of activities affecting quality was established and executed to verify conformance to the documented instructions, procedures, and drawings prescribing a given activity

l. That a documented test program was established and implemented to demonstrate that structures, systems, and components performed satisfactorily in service

m. The control, calibration, and periodic adjustment of tools, gages, instruments, and other measuring and test equipment used to verify conformance to established requirements

n. Controls for the handling, storage, shipping, cleaning, packaging, and preservation of material and equipment to ensure the maintenance of quality from source through installation or use

o. Requirements, methods, and responsibilities for indicating inspection, test, and operating status of the plant structures, systems, and components

p. Methods of controlling items, services, or activities that do not conform to requirements

q. Methods to ensure that appropriate and prompt corrective action was taken when conditions adverse to quality were identified

r. That sufficient records were provided and maintained to furnish documentary evidence of the quality of items and of those activities affecting quality

s. That a comprehensive system of planned and documented audits was carried out to verify compliance with all aspects of the QA program, and to assess the effectiveness of the program; and further, to require that management review the audit results and take necessary action to correct deficiencies.

Those structures, systems, and components covered by the Edison QA program and the programs of vendors and contractors were indicated in the column titled "Quality Assurance Requirements" in Table 3.2-1 of the original FSAR.

The major organizations participating in the project and involved in the QA program, including their designated functions, are discussed in Subsection 17.1.1 and are summarized in the following paragraphs.

Edison, as plant owner, established and implemented a QA program in accordance with the requirements of Appendix B to 10 CFR 50. Edison performed the major part of the plant design; the preparation of procurement documents; the procurement of systems, materials, equipment, and services exclusive of the scope of supply of the NSSS; source inspection; site receiving inspection; and the site QA and certain QC functions not delegated to contractors.

General Electric, the NSSS supplier, was responsible for the design, procurement, manufacture, inspection, and predelivery testing of the components within its scope of supply and for providing technical direction and instructions for the installation and testing of the NSSS components and systems.

Daniel International Corporation was responsible for construction management at the site.

General Electric Company and the A-Es established and implemented QA programs that satisfied the applicable requirements of Appendix B to 10 CFR 50 as defined in the procurement documents. These programs were reviewed and accepted by Edison. The proper implementation of these programs was ensured by the performance of planned and periodic audits, with reaudits as necessary, by Edison Project QA.

Materials and components that were not supplied by GE were procured by Edison from qualified vendors. These vendors, with varying responsibilities for design, procurement, assembly, manufacture, inspection, and testing, established and implemented QA programs as required by the procurement documents. The QA programs of these vendors were reviewed and accepted by Edison QA, and their implementation was verified by planned and periodic audits.

Site installation and construction contractors established and implemented QA/QC programs commensurate with responsibilities and in accordance with contract requirements. The programs were reviewed and accepted by Edison QA.

The Fermi 2 QA policies, procedures, and instructions were contained in the project QA manual and in the project procedures manual.

The requirements and practices delineated in these manuals applied to the Project Management Organization, Project QA personnel, the Construction Management Organization, and Edison personnel or organizational groups who had any responsibilities for the project. Controlled copies of the manuals were distributed to these organizations and personnel.

Certain procedures in the manuals concerned work activities that were performed by others rather than Edison. In such cases, the requirements delineated in these procedures were imposed on the vendors, contractors, and A-Es performing the activities. The implementation of these requirements was verified by planned and periodic audits conducted by Project QA.

17.1.3 Design Control

Edison established and implemented procedures that delineated the design process from initiation through final approval and release, and determined that design activities were carried out in a planned and controlled manner, and that plant design adequacy was verified and documented.

The established procedures defined for participating design groups were:

a. Responsibilities, authority, reporting paths, and lines and methods of communication

b. Method of identifying and controlling design interfaces, including procedures for review, approval, release, distribution, and revision of documents involving interfaces.

The established procedures also delineated specific requirements and methods to ensure:

a. That applicable regulatory criteria and the design bases including codes and standards, as specified in the Preliminary Safety Analysis Report (PSAR), were correctly translated into design documents

b. That appropriate quality standards were specified and included in design documents. Quality standards include codes and industry standards, and must include appropriate quantitative or qualitative acceptance criteria for determining that activities were satisfactorily accomplished

c. That selection and review for suitability of application of materials, parts, equipment, and processes that are essential to the safety-related functions of items were accomplished

d. That proper attention was given to constructibility, accessibility for inservice inspection, maintenance, repair, and delineation of acceptance criteria for inspections and tests

e. That adequacy of design was verified and documented

f. That adequacy of a design was verified or checked by the performance of design reviews, by the use of alternate or simplified calculational methods, or by the performance of a suitable testing program

g. That the verifying or checking process was performed by individuals or groups other than those who performed the original design

h. That, as a minimum, verifying or checking consisted of reviewing the design, spot checking the calculations or analyses, and assessing the results against the original design bases and functional requirements

i. That design verification documents identified the verification method utilized

j. That the method and scope of the design verification selected depended upon:

    1. Importance and complexity of design

    2. Degree of standardization

    3. The state of the art

    4. Similarity with previously proven designs.

k. That standardized or previously proven designs were carefully reviewed for applicability

l. That formal design reviews, normally consisting of a detailed check of the complete design, were performed. Personnel from Edison engineering, QA, operating, and construction departments or from a consulting engineering organization participated in these design reviews

m. That the adequacy and compatibility of the seismic design performed by vendors were evaluated by a third-party reviewer

n. That where necessary the adequacy of the final design was verified by documented qualification testing of the item or part under the most adverse design conditions

o. That design changes, including field changes, and deviations from design requirements were processed in accordance with established configuration control procedures

p. That design review documentation was filed and maintained with the controlled project QA records

q. That errors and deficiencies in the design process were determined, documented, and dispositioned, and that corrective actions were determined and implemented

r. That the applicable QA requirements of Appendix B to 10 CFR 50 were defined in the procurement documents for the NSSS vendor, and for the design tasks delegated to A-Es

s. That Project QA conducted planned and periodic audits of the Edison design process and of the design processes of others.

17.1.4 Configuration Control

Edison established and implemented procedures that delineated the responsibilities and methods for the evaluation and disposition of changes, deviations, and incidents affecting the plant configuration as defined in the approved design documents to ensure that such changes, deviations, and incidents were adequately controlled and did not compromise the design intent.

The established procedures contained provisions to ensure:

a. That Project Engineering was responsible for configuration control and for preparation of the required procedures

b. That changes, deviations, or incidents were classified as Type I or Type II; that configuration control procedures delineated the specific criteria for classifying and the responsibility for processing each type

c. That Type I was assigned to changes, deviations, or incidents that affected a characteristic or process that is essential to the safety-related function of an item. A listing of the systems, structures, and components that have a safety-related function was included in the configuration control procedures

d. That Type I was also assigned to changes, deviations, and incidents that do not involve a safety-related item but would

    1. Involve significant re-engineering of an approved design

    2. Affect a characteristic or process that is essential to the availability of the plant

    3. Have a major impact on plant cost or schedule

    4. Affect in-plant safety of operating personnel.

e. That Type II was assigned to changes, deviations, and incidents that did not meet the criteria for Type I

f. That coordination and implementation of the configuration control procedures at the construction site were the responsibility of Field Engineering

g. That changes to approved design documents initiated within Project Engineering were processed in accordance with the configuration control procedures

h. That changes to Edison-approved design documents by vendors, deviations accepted by vendors, and reported incidents occurring in vendor shops, of the Type I classification, were subject to review and concurrence by Project Engineering in accordance with the configuration control procedures

i. That the dispositioning of Type I changes, deviations, and incidents was by those who approved the original design, or by others to whom the responsibility was delegated; their approval was necessary before the disposition could be implemented. The evaluation and disposition were subject to the same requirements for control and documentation as specified for the original design in the design control procedures

j. That changes, deviations, and incidents occurring at the job site were referred to Field Engineering for review and action

k. That the evaluation and disposition of changes, deviations, and incidents were documented and the records retained in the project file.

17.1.5 Procurement Document Control

Edison, acting as its own Architect-Engineer, prepared the technical requirements for the majority of the procurement documents for materials, equipment, and services for the plant. Edison delegated this function to S&L for the RHR complex and the primary containment vessel.

Edison's established procedures were in effect to implement the preparation, review, approval, and control of procurement documents to ensure that the requirements included and/or referenced therein for material, equipment, and services procured for the plant agreed with the design intent and were sufficient to ensure adequate quality.

The established procedures defined the following responsibilities with respect to procurement documents:

a. The Director of Materials Control had the responsibility to coordinate the preparation and administration of procurement document control procedures

b. Project Engineering had the responsibility to prepare, or to delegate the preparation of, the technical content of procurement documents

c. Project QA had the responsibility to prepare, and ensure the inclusion of, the applicable QA requirement

d. Project QA had the responsibility to review the procurement documents to ensure compliance with the requirements of the procedures

e. Changes and/or deviations must have been approved by Project Engineering and Project QA.

The procedures included provisions to ensure that the procurement documents:

a. Were reviewed and that applicable regulatory requirements, design bases, quality requirements, and other requirements were included and/or referenced therein

b. Included requirements for vendors and contractors to provide QA programs in accordance with the identified requirements for QA and the elements of the program applicable to the items or services to be performed, for review and acceptance by Project QA, prior to the initiation of any activity

c. Included, as applicable, basic technical requirements including drawings, specifications, codes, and industrial standards with applicable revision data, test and inspection requirements, and special instructions and requirements such as for designing, fabrication, cleaning, erecting, packaging, handling, shipping, and field storage conditions

d. Included the right of access to vendor and contractor facilities and records for source inspection and audits by Edison and/or its agent

e. Provided for documentation requirements, identifying the documents to be prepared, submitted, maintained, stored, or made available for review, such as drawings, specifications, procedures, procurement documents, manufacturing and testing plans, inspection and test records, personnel and procedures qualifications records, and material, chemical, and physical test results

f. Included instructions for record retention and storage

g. Provided for extending applicable QA requirements to the vendor's or contractor's lower tier suppliers, and including Edison's or its agent's right of access to lower tier suppliers' facilities and records

h. Provided that changes and/or revisions were subject to the same reviews and approvals as the original document.

17.1.6 Instructions, Procedures, and Drawings

The Edison QA program contained provisions to ensure that activities affecting quality were prescribed by appropriate written instructions, procedures, or drawings and that the activities were accomplished in accordance with these documents.

Instructions, procedures, and/or drawings that prescribed quality-affecting activities delineated the method and sequence by which an activity was to be performed, and included appropriate quantitative or qualitative acceptance criteria for determining that the activity had been satisfactorily performed.

Contractors and/or vendors responsible for an activity were required to provide the necessary instructions, procedures, and/or drawings for the accomplishment of the activity.

These documents included as much detail as necessary to properly supplement information given in approved design documents in order that the quality-affecting activity was appropriately described.

The prepared documents were reviewed and approved by responsible personnel in the contractor's or vendor's organization, in accordance with QA program requirements, prior to performing the activity.

Edison may have required contractors or vendors to submit instructions, procedures, and/or drawings to Edison for review and concurrence prior to undertaking the activity. This requirement was established on the basis of the importance of the activity to plant safety or availability.

Project QA performed audits to ensure that approved and appropriate instructions, procedures, and/or drawings were used by Edison personnel and its vendors and contractors in performing any activity that may have affected quality.

Design control, configuration control, and document control procedures were followed in the preparation, receipt, identification, review, approval, processing of changes and deviations, retention and filing, retrieval, distribution, and control of instructions, procedures, and/or drawings.

17.1.7 Document Control

Edison established and implemented procedures to delineate the responsibilities and methods for receiving, identifying, filing, distributing, maintaining, and reporting the status of project documents to determine that such documents were adequately controlled.

The established procedures contained provisions to ensure:

a. That Edison had the overall responsibilities for document control and was responsible for the preparation of the necessary procedures for such control

b. That Edison had the responsibility for site control of documents and was responsible for the preparation of the necessary procedures for such control

c. That Edison had the responsibility for control of documents that recorded evidence of performance of activities affecting quality

d. That an identification system was established and implemented to permit the identification of documents with plant structures, systems, and components. All technical documents were assigned an identification code within the system

e. That documents were received at a central location at both the Edison office and the job site, and that the receipt was recorded

f. That document filing systems were such as to permit ready retrieval of both current and historical documents by reference to the identification system; and that access to the files was controlled to provide security from fire, water, and other hazards

g. That documentation distribution was made in accordance with distribution lists and controlled so that copies of the latest approved documents were available at the place and time needed

h. That documents superseded by revised issues and preliminary or other status drawings not approved for construction or fabrication, were controlled to prevent their inadvertent use

i. That prior to general distribution or release of a document, it had an identification number assigned to it

j. That distribution was accompanied by a transmittal letter, a copy of which, together with a record copy of the document, was maintained in the file

k. That file maintenance procedures established the retention time and final disposition of project documents

l. That a system of document reporting was established and implemented to provide periodic information about the document file; and that this report contained the following information as a minimum:

   1. Document control identification number
   2. Status
   3. Title or description of document
   4. Originator of document
   5. Status date
   6. Originator's identification number
   7. Originator's revision number.

m. That a master list of the current revision number of approved design documents was distributed periodically to the authorized distribution list

n. That document review and change and configuration controls were performed in accordance with the established procedures for design control, configuration control, and procurement document control

o. That documents controlled included, but were not limited to, design specifications; design instructions; design calculations; bills of materials; design, manufacturing, construction, and installation drawings; QA program manuals; QA procedures and instructions, checklists, and audits; procurement documents; manufacturing inspection and testing instructions; meeting minutes; accident reports; inspection reports; design change notices; deviation disposition reports; and correspondence

p. That the procurement documents delineated the requirements for document control that vendors and contractors must have met.

17.1.8 Control of Purchased Material, Equipment, and Services

Edison established and implemented procedures to ensure that safety-related material, equipment, and services procured by Edison, its vendors, and contractors conformed to the requirements of the approved procurement documents.

The established procedures contained provisions to ensure:

a. That quotations to furnish material, equipment, and services were solicited from qualified bidders

b. That criteria for qualification considered Edison's experience with the bidder, the bidder's reputation and experience in the field and in the nuclear industry, QA capability, and other facts, as appropriate

c. That qualification of bidders not on the approved bidders list was accomplished by a detailed evaluation that included assessment of the bidder's management capability, financial resources, plant facilities, technical capability, and QA program. To assist in the evaluation process, Edison representatives, including QA personnel, visited the contractor's or vendor's facilities, when deemed necessary and appropriate

d. That bidders proposing to furnish items or services important to plant safety or availability submitted their QA manual or an adequate description of their QA plan and procedures for review and concurrence by Edison

e. That the procurement documents delineated the documentation required to be furnished by the successful bidders as objective evidence of compliance with the procurement document requirements

f. That bids that were not responsive to the QA requirements of the procurement documents were rejected

g. That a source surveillance program was established and that this program required that:

    1. Vendors furnished Edison with sufficient information concerning their manufacturing and inspection plans to permit Edison to plan and implement a source surveillance plan

    2. Project QA coordinated establishment of the surveillance plan with the Inspection Division of the General Purchasing Department

    3. The surveillance plan included inspection of items, witnessing of tests or processes, and audits of vendor's QA program

    4. Material or equipment requiring source inspection in accordance with the surveillance plan was inspected for conformance to the procurement requirements

    5. This inspection verified that quality documentation existed and was complete

    6. An item could not be accepted if it did not conform to the procurement document requirements

    7. An item could not be accepted if the quality documentation did not comply with the procurement document requirements.

h. That site-receiving inspection of items was performed upon receipt in accordance with a documented receiving inspection plan

i. That items that had been inspected and accepted at the source were inspected at the site for shipping damage, correctness of identification, and proper quality documentation

j. That items that had not been inspected at the source had their quality verified by the review of submitted test reports, inspection, user tests, or other means as identified in the inspection plan

k. That documentary evidence that safety-related items conformed to procurement document requirements was available at the site prior to use or installation of such items

l. That documentary evidence was sufficient to identify that specific requirements, such as codes, standards, and specifications were met by the procured item. (This requirement could be satisfied by having available at the site copies of the purchase specification, purchase order, and a written certification of conformance to procurement requirements)

m. That Project QA verified the validity of certifications of conformance by vendor audits.

17.1.9 Identification and Control of Material, Parts, and Components

Edison established and implemented procedures to identify and control safety-related materials, parts, and components to ensure the use or installation of only correct and accepted items.

The procedures contained provisions to ensure:

a. That the procurement documents required that equipment and/or components be identified at the source, prior to shipping, in accordance with the plant identification system

b. That the procurement documents specified when there was a requirement for traceability of materials, parts, or components to their quality documentation

c. That the procurement documents required vendors to identify items in accordance with the plant identification system

d. That the procurement documents stated that the verification of the correct identification of items and their records was a condition for acceptance of the item

e. That source and receiving inspection planning included the verification of the correct identification of items and their records

f. That physical identification was used to the greatest extent possible for relating an item at any stage of work to an applicable drawing, specification, and/or other pertinent technical document

g. That where physical identification was impractical, physical separation, procedural control, or other appropriate means were employed

h. That identification could be either on the item or on records traceable to the item, as appropriate

i. That consideration was given to ensure that the location and method of identification did not affect the function or quality of the item being identified

j. That contractors established and implemented onsite procedures for the identification and control of materials, parts, and components.

17.1.10 Control of Special Processes

Edison established and implemented procedures to determine that special processes were performed in accordance with qualified procedures by qualified personnel.

Special processes were defined as those metallurgical, chemical, and other processes where assurance of the process quality was dependent largely on the inherent skill of the operator and on the control of the process parameters, and could not be ensured by direct inspection of the work alone. These included, but were not limited to, welding, heat treating, cadwelding, chemical cleaning, and nondestructive examination.

The established procedures contained provisions to ensure:

a. That Project Engineering, or its agent, established the requirements for special processes and for identifying these processes in drawings, specifications, procedures, and/or instructions, in accordance with applicable codes, standards, specifications, criteria, regulatory requirements, and other special requirements

b. That contractors and vendors, onsite and in manufacturing and production facilities, performed special processes with the use of qualified personnel and procedures that were in accordance with the design documents and applicable codes and standards as defined in the procurement documents

c. That documentation on procedure and personnel qualification was submitted to Edison, or its agent, for review and concurrence when required by the procurement documents

d. That equipment and procedures utilized in the performance, control, and inspection of special processes were qualified prior to use in accordance with approved engineering documents and identified codes and standards

e. That controlled conditions for accomplishing a special process were maintained

f. That personnel performing a special process were qualified by proper training and/or testing prior to performing the task, and that they were certified if so required by code or other requirements

g. That documentation was maintained for currently qualified personnel, processes, or equipment in accordance with the requirements of the design documents, applicable codes and standards, and the procurement documents

h. That the necessary qualifications of personnel, procedures, or equipment were defined in applicable design and procurement documents for special processes not covered by existing codes or standards, or where quality requirements exceeded the requirements of established codes and standards

i. That qualification documentation was made available to Edison, or its agents, and to recognized representatives of regulatory agencies

j. That qualifications documentation was regularly reviewed and audited by Project QA to ensure that personnel qualifications had not expired and that equipment and processes were properly qualified.

17.1.11 Inspection

Edison established and executed a program for inspection activities affecting quality to verify conformance to the approved instructions, procedures, and drawings prescribing a given activity.

The established procedures contained provisions that required:

a. That inspection planning included the identification and responsibility for performing and documenting inspections

b. That inspections were performed by individuals other than those who performed an activity and who were appropriately qualified as prescribed by code, specification, or other applicable document

c. That the current status of the qualifications of those who performed inspections was documented and maintained

d. That audits of inspection equipment were conducted to ensure that the equipment was within calibration to perform inspections requiring such equipment

e. That examination, measurement, or tests of items processed were performed after each work operation if deemed necessary to ensure quality

f. That when samples were used to verify the acceptability of a group of items, the documented sampling procedure was based on recognized standard practices and provided justification for the selected procedure

g. That inspection planning prescribed the need for monitoring processing methods and personnel when inspection of the finished product was impractical or inconclusive; and that both inspection and process monitoring were utilized when necessary for adequate control

h. That vendors maintained integrated manufacturing and inspection plans that were reviewed by Edison to establish an agreed-upon set of notification points, including mandatory inspection hold points, beyond which work could not proceed without acceptance by Edison

i. That Edison's General Purchasing Department Inspection Division, or its agent, was responsible for the inspection of vendor's activities in accordance with an inspection plan developed as a part of an overall vendor surveillance program

j. That when mandatory inspection hold points, beyond which work must not proceed until signed off by Edison or its agent, were required, they were indicated in appropriate vendor documents before work was initiated

k. That site contractors having first-level inspection responsibility prepare their inspection plans for review by Project QA and that Project QA establish notification and mandatory inspection hold points beyond which work could not proceed until approved by Project QA

l. That site contractors who furnished only labor prepare limited-scope QA plans and that inspection of their work was performed by Project QA.

17.1.12 Test Control

Edison established and implemented a documented test program in accordance with written controlled procedures to demonstrate that safety-related structures, systems, and components performed satisfactorily in service.

The procedures contained provisions to ensure:

a. That tests were performed at vendor facilities or at the job site, in accordance with written test procedures that included or referenced the requirements and acceptance limits contained in applicable design documents

b. That Project Engineering and responsible vendors provided test instructions, requirements, and acceptance criteria

c. That vendors and contractors were required to perform acceptance tests, prototype qualification tests, proof tests prior to installation, and performance tests, when prescribed by applicable design and engineering documents referenced in the procurement documents

d. That when tests were conducted in vendor facilities, the vendor prepared the test procedure for review and approval by Edison

e. That the Startup Organization, or its designated agents, prepared the acceptance, preoperational, and startup testing procedures

f. That the test specification and/or procedure included criteria that had been reviewed and found acceptable by the Project QA Organization, and that the Project QA Organization audited the performance of the testing activity to ensure that the established criteria had been satisfied

g. That test procedures included provisions to ensure that:

    1. Prerequisites for the test had been met

    2. Adequate instrumentation was available and used

    3. Necessary monitoring was performed.

h. That test prerequisites included, but were not limited to:

    1. Appropriate checklists and test report forms

    2. Calibrated instrumentation

    3. Adequate and appropriate equipment

    4. Trained, licensed, and/or certified personnel, as appropriate

    5. Test equipment in good condition

    6. Items to be tested that were in good condition

    7. Suitable environmental conditions

8. Mandatory hold points, as appropriate, for witnessing of tests by Edison personnel, or its agents, for tests performed at vendor facilities and at the site

9. Provisions for data acquisition, evaluation, and storage.

i. That test results were documented, reviewed, and evaluated by responsible personnel to establish that the test requirements and acceptance criteria had been satisfied

j. That nonconformances, when they occurred, were documented and resolved by the responsible organization. The resolutions and corrective actions, if required, were approved by the appropriate Edison personnel and the approval documented

k. That the acceptance status of the component or system tested was identified in accordance with established procedures.

17.1.13 Control of Measuring and Test Equipment

Edison established and implemented procedures for the control, calibration, and periodic adjustment of tools, gages, instruments, and other measuring and test equipment used to verify conformance to established requirements.

The established procedures contained provisions to ensure:

a. That vendors and contractors implemented written procedures for the control and calibration of tools, measuring and test equipment, and devices used in the manufacture, fabrication, assembly, and testing of an item

b. That inspection, test, and work procedures included provisions to ensure that tools, gages, instruments, and other measuring and testing equipment and devices used in activities affecting quality were of the proper range, type, and accuracy to verify conformance to established requirements

c. That inspection, measuring, and test equipment was controlled, calibrated, adjusted, and maintained at prescribed intervals, or prior to use, with calibration performed against acceptable standards

d. That qualified contractors calibrated, adjusted, and maintained measuring and testing equipment and instrumentation used during installation, construction, and acceptance testing

e. That the calibration status, date of calibration, and recall date were displayed prominently on each device, wherever possible, or on records traceable to the device

f. That controls were provided that prevent the use, by unauthorized personnel, of calibrated tools, gages, instruments, and other measuring and test equipment

g. That records of the calibration history were maintained and included such information as:

1. Calibration procedures and standards

2. Identification
3. Calibration data
4. Calibration recall date
5. Instrument characteristics condition at calibration
6. Control measures to prevent unauthorized use.

h. That contractors provided and maintained the calibration status and records of tools, gages, and other measuring and testing devices used by them at the job site

i. That when discrepancies in measuring and test equipment were found, a nonconformance report was issued. The report must include complete identification of the equipment and description of the work or item on which the out-of-calibration equipment was used. The recommended corrective action must include the requirement for a review of the materials, fabricated items, and/or components previously checked with the out-of-calibration equipment to determine if applicable quality standards had been met.

17.1.14 Handling, Storage, and Shipping

Edison established and implemented written work instructions and inspection procedures to control the handling, storage, shipping, cleaning, packaging, and preservation of material and equipment, to establish the maintenance of quality from source through installation or use.

The established procedures contained provisions that ensured that:

a. Project Engineering established and included in procurement documents the requirements for handling, cleaning, preservation, packaging, shipping, and storage of materials and equipment in conjunction with vendors and the Construction Manager at the site

b. Instructions were included in the procurement documents concerning marking and labeling for packaging, shipment, and storage of items. Marking must have been sufficient to identify, maintain, and preserve the shipment, including the indication of the presence of special environments or the need for special control

c. Project QA personnel reviewed the procurement documents for the inclusion of instructions to vendors to provide information on handling, cleaning, preservation, marking and labeling, packaging, shipping, and storage of the product supplied

d. Vendors, in their shops, and contractors at the site, provided and controlled special handling tools and equipment necessary to maintain safe and adequate handling of critical, sensitive, perishable, or high-value items. Special handling tools and equipment, including but not limited to lifting devices, cables, hooks, slings, cranes, and their appurtenances such as brakes and safety devices, were inspected and tested by qualified personnel in accordance with written procedures at specified times, to verify that the tools and equipment were adequately maintained and were suitable for the intended use

e. Edison Inspection Division personnel, or its agent, verified that the shipping requirements were met prior to release of an item for shipment

f. The Construction Manager prepared and implemented procedures at the job site in accordance with identified requirements for receiving, storing, and preserving materials and equipment

g. When necessary for particular items at the site, special coverings, special equipment, and special protective environments, such as inert gas, and specific moisture-content levels, were specified through Project Engineering, and were provided by the Construction Manager, and their existence and presence were verified by Project QA

h. Project QA established surveillance plans to assess and document onsite compliance with the handling, cleaning, preserving, and storing procedures

i. Nonconformances were reported, corrective actions specified, and monitoring performed to establish compliance with required corrective actions

j. Project QA reviewed the documentation furnished with items received at the site so that the contractor complied with the requirements noted therein.

17.1.15 Inspection, Test, and Operating Status

Edison procedures were in effect to delineate the requirements, methods, and responsibilities for indicating inspection, test, and operating status of the plant structures, systems, and components during manufacturing, installation, testing, and operation.

The established procedures included provisions to ensure that:

a. The inspection and test status of items in vendor shops or at the site was identified, where practicable, by use of stamps, tags, labels, or other suitable means and on records traceable to the item

b. Vendors implemented, in their shops, a system for indicating the inspection, test, and operating status of an item

c. Stamps, tags, labels, or other means of marking were in an approved format and that they conveyed by their color, shape, design, or other characteristic a uniform, unambiguous message

d. Nuclear Production established procedures for the control of test and operating status indicators including the authority for application and removal of tags, markings, labels, and stamps

e. The operating status of systems and components was clearly indicated by suitable means to prevent inadvertent operation and/or hazard to personnel

f. The status indication system did not allow bypassing of inspections, tests, and other critical operations.

17.1.16 Nonconforming Materials, Parts, Components, Services, and Activities

Edison established and implemented procedures to delineate the methods of controlling materials, parts, components, services, or activities that did not conform to established requirements.

The established procedures contained provisions to ensure that:

a. Vendors had in effect acceptance procedures for the control of nonconforming items that included delineation of the vendor's method of identification, segregation, documentation, and evaluation of nonconforming items

b. Edison approval was required on vendor dispositions that

   1. Accepted the nonconforming item "as is"

   2. Allowed rework or repair by a procedure that had not received prior approval by Edison.

c. Upon identification of a nonconformance, contractors at the site suspended the affected work until the nonconformance was evaluated if

   1. The continuance of the work would cover up the nonconformance and make its correction difficult

   2. The nonconformance was caused by the work procedure and continuing the procedure would increase the extent or severity of the nonconformance.

d. Nonconforming items, where practical, were segregated from acceptable material in a controlled access location; when this was not practicable, control of the nonconforming item was maintained by tagging, marking, or other clear means of identification

e. Reports of nonconforming items, services, or activities were dispositioned in accordance with configuration control procedures

f. Occurrence of nonconforming items, services, or activities was reported to affected organizations

g. Nonconforming items were repaired or reworked in accordance with documented procedures, and that, before the acceptance of such repaired or reworked items, they were reinspected in accordance with documented applicable inspection plans and procedures

h. Nonconforming items that were rejected were removed from the work location in vendor shops, and from the job location during construction

i. Documentation for items that had been repaired, reworked, or accepted "as is" described the change, waiver, or nonconformance that had been accepted and denoted the as-built condition

j. Reports of onsite nonconforming items or services were filed in the Project QA office, with copies forwarded to Field Engineering for disposition.

17.1.17 Corrective Action

Edison established and implemented written procedures to ensure that appropriate and prompt corrective action was taken when conditions adverse to quality were identified.

The established procedures contained provisions to ensure that:

a. QA and QC personnel promptly identified and reported on conditions adverse to quality, such as failures, malfunctions, deficiencies, nonconformances, defective material and/or equipment, and procedural nonconformances

b. The reports on conditions adverse to quality were submitted to Field Engineering for action in accordance with established configuration control procedures

c. Corrective action was taken as soon as practical

d. The technical aspects of conditions adverse to quality were resolved by Project Engineering

e. Project Engineering concurred with or rejected solutions provided by vendors or site contractors

f. Project QA determined the cause of significant conditions adverse to quality and that corrective action was taken to preclude repetition

g. Nonconformances to approved project procedures and instructions were reported to Project QA for action

h. Responsible management of the affected vendor or contractor was promptly notified and made aware of the problem and the required corrective action

i. When conditions adverse to quality existed at the site that required prompt action, and the required corrective measures were not taken by responsible supervision when properly notified, the Project QA Director exercised stop-work authority in the affected area

j. Identification of significant conditions adverse to quality, the cause of the condition, and the corrective action taken were documented and reported to appropriate levels of management by Project QA.

17.1.18 Quality Assurance Records

Edison established and implemented requirements that ensured that sufficient records were provided and maintained to furnish documentary evidence of the quality of items and of those activities affecting quality.

Established procedures contained provisions that ensured that:

a. The Document Control Center had the overall responsibility for receiving, filing, and maintaining QA records during and until completion of construction

b. Project QA was responsible for reviewing QA records generated or received at the site

c. QA record requirements, including type and content, were identified in procurement documents

d. Requirements and responsibilities for record transmittal, retention, and maintenance subsequent to the completion of construction were established and documented by written procedures

e. Required QA records included as-built drawings, operating logs, and the results of reviews, inspections, tests, audits, monitoring of work performances, nonconformances, corrective action reports, and materials analyses

f. QA records contained data on the qualification of personnel, procedures, and equipment involved in the quality-related activity

g. The inspection and test reports included identification of the inspector or data recorder, the type of observation made, the test or measurement equipment used, the results, their acceptability, and the disposition of any deviations found

h. Records were identifiable as to structure, system, component, and/or materials, were retrievable, and were secured against loss by theft, fire, or deterioration

i. Vendors or contractors who retained QA records must have met Edison's requirements on retention, and that the records were made available for use by Edison, or its agent, on demand

j. Procurement documents included the requirement that vendors or contractors notify Edison when they intended to dispose of their retained QA records so that Edison could be permitted to take possession of the records

k. Edison was responsible for all QA records, whether retained by Edison or its vendors or contractors

l. Permanent records, such as as-built drawings, and other records required for the operation, maintenance, inservice inspection, or plant maintenance, were retained and maintained for the life of the plant

m. Planned and periodic audits were conducted by Edison and its vendors and contractors to ensure compliance with the requirements for record maintenance and retention.

17.1.19 Audits

Edison established a comprehensive system of planned and documented audits to verify compliance with all aspects of the Project QA program and to assess its effectiveness. Responsible management had the responsibility to review the audit results and to take necessary action to correct deficiencies.

Audits of the program were performed to:

a. Provide an objective evaluation of compliance with established requirements, methods, and procedures

b. Assess progress in assigned tasks

c. Determine the adequacy of QA program performance

d. Verify the implementation of recommended corrective action.

The Project QA Director was responsible for ensuring that periodic audits of the project QA program or any portion of it, as deemed necessary, were conducted and the findings reported to responsible management.

Project QA conducted planned and periodic audits of the QA programs of vendors and contractors and reported findings to the Manager of the Project, the Project QA Director, and responsible management of the area audited.

Audits were performed in accordance with written procedures and/or checklists by appropriately trained personnel having no direct responsibilities in the area audited. Audits were scheduled and conducted on the basis of the status and safety importance of the activity being performed.

Audits included an objective evaluation of:

a. Quality assurance practices, procedures, and instructions
b. The effectiveness of program implementation
c. Conformance to policy directives.

Audits also included an evaluation of:

a. Work areas
b. Activities
c. Processes
d. Items
e. Documents and records, and their storage and retrievability.

Audits were initiated early enough to ensure effective implementation of QA programs at the beginning of design, procurement, manufacturing, installation, construction, and testing activities.

Audits were scheduled when one or more of the following conditions existed:

a. When it was necessary to determine the acceptability of a vendor's or contractor's QA program prior to award of a purchase order or contract
b. When, after the award of a purchase order or contract, it was appropriate to determine that a vendor or contractor was implementing his QA program
c. When significant changes were made in functional areas of the QA program, including significant organizational changes and/or procedural revisions
d. When it was suspected that safety, performance, or reliability of the item was in jeopardy because of deficiencies and nonconformances in the QA program
e. When a systematic and independent assessment of program effectiveness or item quality, or both, was considered necessary
f. When it was considered necessary to verify the implementation of required corrective actions.

Suppliers, vendors, and contractors who were providing safety-related materials, components, or services were contractually required to conduct audits as part of their QA programs.

PROJECT QUALITY ASSURANCE ORGANIZATION

17.2 QUALITY ASSURANCE PROGRAM FOR PLANT OPERATION

The DTE Electric Company (DTE) operational quality assurance (QA) program is based on American National Standards Institute (ANSI) Standard N18.7-1976, "Administrative Controls and Quality Assurance for the Operational Phase of Nuclear Power Plants," as modified by Regulatory Guide 1.33 as addressed in Appendix A of the UFSAR. The program is structured and implemented in accordance with the guidance of the ANSI standards referenced therein and the associated regulatory guides that endorse them. Compliance with this guidance ensures a comprehensive QA program and an effective implementation of that program for compliance with the requirements of Appendix B to 10 CFR 50 and Appendix A to Branch Technical Position (BTP) APCSB 9.5-1, "Guidelines for Fire Protection for Nuclear Power Plants."

NOTE: When a position is not filled, reporting order will be to the next higher position.

17.2.1 Organization

The organizational structure, responsibilities, authorities, and functions of the nuclear organization (Nuclear Generation) are described in this subsection. Those corporate organizational units that support the operation and maintenance of the plant and perform activities subject to the requirements of the QA program are also described. Those organizational units include Supply Chain as discussed in Subsection 17.2.7.

The DTE corporate organization is described in Subsection 13.1.1. That portion of the corporate organization that is involved with activities subject to the QA program is shown in Figure 17.2-1.

17.2.1.1 Senior Vice President and Chief Nuclear Officer (CNO)

The Senior Vice President and Chief Nuclear Officer reports to the President and Chief Executive Officer, DTE Energy. The CNO has responsibility for the overall administration of DTE Nuclear power. The CNO is the ultimate Management Authority for establishing QA Policy and responsibility for the quality assurance function. Reporting to the CNO are the Director – Nuclear Oversight, the Site Vice President – Nuclear Generation, Vice President – Engineering and Technical Support, Director – Strategic Business Operations, and the Nuclear Safety Review Group (NSRG) Chairman. The Senior Vice President and Chief Nuclear Officer is also responsible for the Employee Concerns Program.

17.2.1.1.1 Director – Nuclear Oversight

The Director – Nuclear Oversight is responsible for establishing a sustainable oversight model for Fermi. This includes responsibility for Quality Assurance. Reporting to the Director – Nuclear Oversight is the Manager – Nuclear Quality Assurance.

17.2.1.1.1.1 Manager - Nuclear Quality Assurance

The Manager - Nuclear Quality Assurance is responsible for (1) ensuring the establishment and effective implementation of the Nuclear Generation Quality Assurance Program; (2) monitoring and evaluating the implementation of the Quality Assurance Program within Nuclear Generation by conducting planned and periodic audits; (3) reporting the audit findings to the Site Vice President – Nuclear Generation and Vice President – Engineering and Technical Support; (4) providing direction on Quality Assurance matters to the Executive Director - Nuclear Production; (5) recommending solutions to identified quality problems and verifying implementation of solutions for NQA identified problems which are significant conditions adverse to quality; and (6) issuing action to stop work when appropriate. The Manager - Nuclear Quality Assurance reports to the Director – Nuclear Oversight.

The Manager - Nuclear Quality Assurance has the authority and the responsibility to initiate action to suspend any activity, except reactor operation, if he/she discovers or suspects that a deviation from the QA program has occurred or is developing; nonconformances that appear to warrant suspension of reactor operation, including startup or power generation, will be reported to the Executive Director - Nuclear Production immediately.

The Manager - Nuclear Quality Assurance will meet the following qualifications:

Education: Bachelor Degree in Engineering or related science or the equivalent in practical experience.

Experience: Four years experience in the field of quality assurance, or equivalent number of years of nuclear plant experience in a supervisory or management position preferably at an operating nuclear plant or a combination of the two. At least one year of this four years experience shall be nuclear power plant experience in the implementation of the quality assurance program. Six months of the one year experience shall be obtained within a quality assurance organization.

An additional year of quality assurance program implementation experience may be substituted for six months experience within a quality assurance organization. The equivalent in practical experience to a Bachelor Degree in Engineering or related science is an additional four years experience in the fields of quality assurance, engineering or nuclear plant experience.

The review of implementing QA procedures and the review of nonconformance and corrective action documents covering significant conditions adverse to quality and safety and selected nonsignificant conditions adverse to quality is performed by Nuclear QA.

The NQA organization supports other units within Nuclear Generation to provide the required quality assurance functions.

17.2.1.1.1.1.1 Nuclear Quality Assurance Responsibilities

The Manager - Nuclear Quality Assurance and his/her staff are responsible for the following activities:

a. Performing surveillances of selected plant operations and maintenance and modification activities, Design Engineering, Tactical Engineering and Strategic

Engineering activities, instrument and control activities, transporting of radioactive material, fire protection and other activities which implement the QA program.

b. Review of maintenance and modification procedures, and inspection of maintenance and modification work.

c. Performance of nondestructive testing and examinations or review of its results.

d. Evaluation of inspection and surveillance results.

e. Review of selected engineering related documents.

f. Evaluation of existing and emerging issues and problems having safety significance.

g. Ensuring the content and adequacy of quality program requirements are included in the Fermi Conduct Manuals.

h. Performing audits and surveillances of Nuclear Generation units implementing the QA program.

i. Perform audits and surveillances of the corrective action process.

j. Performing audits and surveillances of onsite and offsite engineering organizations including contractors.

k. Performing supplier audits, source surveillances and commercial grade surveys.

l. Maintenance and issuance of an approved suppliers list.

m. Performing audits and surveillances of the procurement process.

n. Performing special assigned tasks.

17.2.1.1.2 Corporate Support

Corporate Support functions are described in Section 13.1.1.3.2.

17.2.1.1.3 Director – Strategic Business Operations

The functions of the Director – Strategic Business Operations are described in Subsection 13.1.1.3.3.

17.2.1.1.4 Vice President – Engineering and Technical Support

The Vice President – Engineering and Technical Support reports to the Senior Vice President and Chief Nuclear Officer and also has access to the President and Chief Executive Officer, DTE Energy for the reporting of nuclear safety problems. This individual has responsibility for the administration of engineering, including engineering aspects of the fire protection program, and technical support organizations. Reporting to the Vice President – Engineering and Technical Support are the Director – Nuclear Engineering, the Director – Nuclear Technical Support – Project Management, and the Manager – Nuclear Licensing. Supply Chain has a functional relationship to the Vice President – Engineering and Technical

Support. Additional detailed description of those organizations reporting to the Vice President – Engineering and Technical Support is provided in Section 17.2.1.2.

17.2.1.1.5 Site Vice President - Nuclear Generation

The Site Vice President - Nuclear Generation reports to the Senior Vice President and Chief Nuclear Officer and also has access to the President and Chief Executive Officer, DTE Energy for the reporting of nuclear safety problems. The authority and responsibilities of the Site Vice President - Nuclear Generation are discussed in Subsection 13.1.1. He/she has the overall responsibility for the implementation of the QA program and the fire protection program by Nuclear Generation. He/she is assisted by the Executive Director – Nuclear Production, the Manager – Nuclear Security, the Manager – Nuclear Performance Improvement, and the Director – Nuclear Training.

Additional detailed description of those organizations reporting to the Site Vice President – Nuclear Generation is provided in Section 17.2.1.2.

17.2.1.2 Organizations and Positions Reporting to the Site Vice President – Nuclear Generation and the Vice President – Engineering and Technical Support

17.2.1.2.1 Executive Director - Nuclear Production

NOTE: The titles of Plant Manager and Executive Director - Nuclear Production have the same functional responsibility

The Executive Director - Nuclear Production is responsible for the operation, maintenance, and plant administration of Fermi 2 and for the implementation of quality-related procedures and implementing the fire protection program. A detailed description of the Executive Director - Nuclear Production's organization, including responsibilities, authorities, duties, and qualifications for all key staff positions, is given in Subsection 13.1.2.

17.2.1.2.2 Director – Nuclear Technical Support – Project Management

The functions of the Director – Nuclear Technical Support – Project Management are described in Subsection 13.1.2.3.

17.2.1.2.3 Director – Nuclear Engineering

The Director – Nuclear Engineering is responsible for design engineering, including nuclear fuel design and management, strategic engineering, inservice inspection, performance engineering, procurement engineering, and modifications and configuration management in support of plant operations. The Director - Nuclear Engineering is responsible for the formulation and effectiveness of the fire protection program. Reporting to the Director – Nuclear Engineering are Manager – Nuclear Design Engineering, Manager - Nuclear Strategic Engineering, Manager - Nuclear Performance Engineering, and Manager – Nuclear Tactical Engineering.

17.2.1.2.3.1 Manager – Nuclear Design Engineering

The Manager – Nuclear Design Engineering has the overall responsibility for the Fermi 2 plant configuration management program. The Manager – Nuclear Design Engineering is responsible for Engineering Projects and Modifications, and engineering support functions associated with modifications to plant structures, systems and equipment. This responsibility includes the planning and management of the engineering scope and specification, detailed design, procurement, installation and testing phases of the modification. Nuclear Quality Assurance advises the Manager – Nuclear Design Engineering on Quality Assurance matters.

17.2.1.2.3.2 Manager – Nuclear Strategic Engineering

The Manager – Nuclear Strategic Engineering is responsible for strategic engineering.

17.2.1.2.3.3 Manager – Nuclear Performance Engineering

The Manager – Nuclear Performance Engineering is responsible for inservice inspection, including nondestructive examination activities or review of the results, the equipment qualification program, the fire protection program, nuclear fuel, reactor engineering, and probabilistic risk assessment (PSA).

17.2.1.2.3.4 Manager – Nuclear Tactical Engineering

The Manager – Nuclear Tactical Engineering is responsible for Procurement Engineering, including functions of approving procurement documents to ensure that technical and quality requirements are imposed for safety-related or important to safety applications, providing technical support for quality-related supplier oversight, providing evaluations for equivalent part replacements, performing design changes to plant components, and receiving and inspecting safety-related material and supplies.

The Manager – Nuclear Tactical Engineering is also responsible for the Engineering Response Team, including functions of assisting Operations and Maintenance with emergent plant issues, providing technical evaluations for degraded equipment, and performing replacement part evaluations in addition to design changes to plant systems.

The Manager – Nuclear Tactical Engineering has a functional relationship to the Manager – Nuclear Design Engineering, who has overall responsibility for the Fermi 2 plant configuration management program, for the approval of design changes to plant systems and components.

17.2.1.2.4 Director – Nuclear Training

The Director - Nuclear Training is responsible for developing and implementing training programs in support of the safe and efficient operation of the plant. The Director - Nuclear Training also provides the support for licensed operator medical issues.

The training program is described in Section 13.2.

17.2.1.2.5 Other Managers in Figure 17.2-1

17.2.1.2.5.1 Manager – Nuclear Licensing

The Manager - Nuclear Licensing is responsible for nuclear licensing activities, ensuring compliance with regulatory requirements. The Manager or the operating authority is responsible for communications with the NRC regional office on reportable deficiencies for activities covered by the Nuclear QA Program. The Manager – Radiological Emergency Response Preparedness as described in subsection 17.2.1.2.5.4 reports to the Manager – Nuclear Licensing.

17.2.1.2.5.2 Manager – Nuclear Security

The functions of the Manager – Nuclear Security are described in Subsection 13.1.2.5.1.

17.2.1.2.5.3 Manager – Nuclear Performance Improvement

The Manager – Nuclear Performance Improvement is responsible for administration of: 1) the plant Corrective Action Program, including trending and tracking of corrective action documents; 2) the root cause analysis program; 3) benchmarking and self-assessment programs; and 4) internal and external operating experience to provide for early detection of conditions potentially adverse to nuclear safety.

17.2.1.2.5.4 Manager – Radiological Emergency Response Preparedness

The Manager – Radiological Emergency Response Preparedness is responsible for coordinating the activities of Emergency Planning.

17.2.1.3 Review Organizations

The membership, meeting frequency, minutes, quorum, and other details of the NSRG and the OSRO are described in this subsection. These review organizations, which provide a technical review of plant maintenance and operation, have been established in accordance with the criteria listed below. The membership of the NSRG and the OSRO will be supplemented by DTE personnel or consultants as necessary.

17.2.1.3.1 Onsite Review Organization (OSRO)

17.2.1.3.1.1 Function

The OSRO shall function to advise the Executive Director - Nuclear Production on all matters related to nuclear safety as described in Subsection 17.2.1.3.1.6.

17.2.1.3.1.2 Composition

The OSRO membership shall be composed of a minimum of 6 but not more than 11 plant management representatives whose responsibilities include the functional areas of: operations, maintenance, radiation protection, engineering/technical support and quality assurance. All members shall be appointed in writing by the OSRO chairman. The qualifications of each OSRO member shall meet or exceed the requirements and recommendations of Section 4.2 or 4.3 of ANSI N18.1-1971 and the OSRO chairman shall meet or exceed the requirements of Section 4.2.4 of ANSI N18.1-1971.

17.2.1.3.1.3 Alternates

The Chairman may designate in writing other members who may serve as the Vice Chairman of the OSRO. Alternates may be designated for specific OSRO members. No more than two alternates shall participate as voting members in OSRO activities at any one time. All alternate members shall be appointed in writing by the OSRO Chairman.

17.2.1.3.1.4 Meeting Frequency

The OSRO shall meet periodically and as situations demand as convened by the OSRO Chairman or a Vice Chairman.

17.2.1.3.1.5 Quorum

The quorum of the OSRO necessary for the performance of the OSRO responsibility and authority provisions of this section (17.2.1.3.1) shall consist of the Chairman or Vice Chairman and four members including alternates.

17.2.1.3.1.6 Responsibilities

The OSRO shall be responsible for:

a. Review of Plant Administrative Procedures and changes thereto that could affect nuclear safety;

b. Review of all proposed tests and experiments that affect nuclear safety;

c. Review of all proposed changes to Appendix A Technical Specifications;

d. Review of all proposed changes or modifications to unit systems or equipment that affect nuclear safety. OSRO review of plant modifications which require a 10 CFR 50.59 Evaluation meet the requirements for this review;

e. Review of the 10 CFR 50.59 Evaluations for plant procedures and changes thereto completed under the provisions of 10 CFR 50.59;

f. Review of events reportable under 10 CFR 50.73;

g. Review of unit operations to detect potential hazards to nuclear safety;

h. Performance of special reviews, investigations, or analyses and reports thereon as requested by the Executive Director - Nuclear Production or the Nuclear Safety Review Group;

i. Review of every unplanned onsite release of radioactive material to the environs including the preparation and forwarding of reports covering evaluation, recommendations and disposition of the corrective action to prevent recurrence to the Site Vice President - Nuclear Generation and to the Nuclear Safety Review Group;

j. Review of changes to the Process Control Program, the Offsite Dose Calculation Manual, and major modifications to the Radwaste Treatment Systems; and

k. Review of all Licensing Change Requests (LCRs) for proposed changes to the Fire Protection Program, Security Plans and the RERP Plan.

17.2.1.3.1.7 Actions for Events Reportable Under 10 CFR 50.73

Each event reportable under 10 CFR 50.73 shall be reviewed by OSRO, and the results of this review shall be submitted to the NSRG and the Site Vice President - Nuclear Generation.

17.2.1.3.1.8 Written Communication

The OSRO shall:

a. Recommend in writing to the Executive Director - Nuclear Production approval or disapproval of items considered under Subsection 17.2.1.3.1.6.a through d prior to their implementation,

b. Render determinations in writing to the Nuclear Safety Review Group with regard to whether or not each item considered under Subsection 17.2.1.3.1.6.a through e requires a License Amendment prior to implementation,

c. Provide written notification within 24 hours to the Site Vice President - Nuclear Generation and the Nuclear Safety Review Group of disagreement between the OSRO and the Executive Director - Nuclear Production; however, the Executive Director - Nuclear Production shall have responsibility for resolution of such disagreements pursuant to Technical Specification 5.2.1b.

17.2.1.3.1.9 Records

The OSRO shall maintain written minutes of each OSRO meeting that, at a minimum, document the results of all OSRO activities performed under the responsibility provisions of this subsection.

Copies shall be provided to the Site Vice President - Nuclear Generation and the Nuclear Safety Review Group.

17.2.1.3.2 Nuclear Safety Review Group (NSRG)

17.2.1.3.2.1 Function

The NSRG shall function to provide independent review of designated activities in the areas of:

a. Nuclear power plant operations,

b. Nuclear engineering,

c. Chemistry and radiochemistry,

d. Metallurgy,

e. Nondestructive testing,

f. Instrumentation and control,

g. Radiological controls,

h. Mechanical and electrical engineering, and

i. Quality assurance practices.

The NSRG shall report to and advise the Senior Vice President and Chief Nuclear Officer on those areas of responsibility in Subsections 17.2.1.3.2.7 and 17.2.1.3.2.8.

17.2.1.3.2.2 Composition

The Senior Vice President and Chief Nuclear Officer shall appoint members to the NSRG and shall designate from this membership a Chairman and at least one Vice Chairman. The membership shall collectively possess experience and competence to provide independent review in the areas listed in Subsection 17.2.1.3.2.1. The Chairman and Vice Chairman shall have nuclear background in engineering or operations and shall be capable of determining when to call in experts to assist the NSRG review of complex problems. All members shall have at least a bachelor’s degree in engineering or related sciences or at least 10 years of responsible power plant experience of which a minimum of 3 years shall be nuclear power plant experience. The Chairman shall have at least 10 years of professional level management experience in the power field and each of the members shall have at least 5 years of cumulative professional level experience in one or more of the fields listed in Subsection 17.2.1.3.2.1.

17.2.1.3.2.3 Alternates

All alternate members shall be appointed in writing by the NSRG Chairman to serve on a temporary basis; however, no more than two alternates shall participate as voting members in NSRG activities at any one time.

17.2.1.3.2.4 Consultants

Consultants shall be utilized as determined by the NSRG Chairman to provide expert advice to the NSRG.

17.2.1.3.2.5 Meeting Frequency

The NSRG shall meet at least twice per year.

17.2.1.3.2.6 Quorum

The quorum of the NSRG necessary for the performance of the NSRG review functions of this subsection shall consist of the Chairman or his/her designated alternate and at least one half of the remaining NSRG members, with a minimum of four, of whom two may be alternates. No more than a minority of the quorum shall have line responsibility for operation of the unit.

17.2.1.3.2.7 Review

The NSRG shall be responsible for the review of Subsection 17.2.1.3.2.7.a through i:

a. Post facto review of 10 CFR 50.59 Evaluations for (1) changes to procedures, equipment, facilities or systems and (2)tests or experiments completed under the provision of 10 CFR 50.59 to verify that such actions did not require a License Amendment prior to implementation;

b. Proposed changes to procedures, equipment, or systems which involve a License Amendment prior to implementation as defined in 10 CFR 50.59;

c. Proposed tests or experiments which involve a License Amendment prior to implementation as defined in 10 CFR 50.59;

d. Proposed changes to Technical Specifications or the Operating License;

e. Violations of codes, regulations, orders, Technical Specifications, license requirements, or of internal procedures or instructions having nuclear safety significance;

f. Significant operating abnormalities or deviations from normal and expected performance of unit equipment that affect nuclear safety;

g. Events reportable under 10 CFR 50.73;

h. All recognized indications of an unanticipated deficiency in some aspect of design or operation of structures, systems, or components that could affect nuclear safety; and

i. Reports and meeting minutes of the OSRO.

17.2.1.3.2.8 Audits

Audits of unit activities shall be performed under the cognizance of the NSRG. These audits shall encompass topics listed in Subsection 17.2.18.5.

17.2.1.3.2.9 Records

Records of NSRG activities shall be prepared, approved, and distributed as indicated below:

a. Minutes of each NSRG meeting shall be prepared, approved, and forwarded to the Senior Vice President and Chief Nuclear Officer promptly following each meeting.

b. Reports of reviews encompassed by Subsection 17.2.1.3.2.7 shall be prepared, approved, and forwarded to the Senior VicePresident and Chief Nuclear Officer promptly following completion of the review.

c. Audit reports encompassed by Subsection 17.2.1.3.2.8 shall be forwarded to the Senior Vice President and Chief Nuclear Officer and to the management positions responsible for the areas audited within 30 days after completion of the audit by the auditing organization.

17.2.2 Nuclear Quality Assurance Program

The Nuclear QA program established for plant operations applies to all quality-related activities associated with the structures, systems, and components identified as safety related. The QA programs for fire protection and the Independent Spent Fuel Storage Installation (ISFSI) are part of the overall QA program. The program is designed to comply with the requirements of Appendix B to 10 CFR 50, NRC regulatory guides, and the endorsed ANSI standards that are used in structuring the program and in developing procedures to implement it. In all cases the required implementation procedures are established before the initiation of a given activity and must comply with the governing QA program.

Application of the 10 CFR 50, Appendix B QA program to activities conducted under 10 CFR 71 is limited to procurement, maintenance, repair and use of transportation packages for shipment of radioactive materials. Design, fabrication, assembly, and modification of shipping casks will not be conducted under this QA program.

17.2.2.1 Corporate QA Policies, Goals, and Objectives

The Senior Vice President and Chief Nuclear Officer has the ultimate authority for establishing QA policy. He/she is assisted by the Manager - Nuclear Quality Assurance in establishing goals and objectives.

17.2.2.1.1 Policies

QA policies are the following:

a. The operation and maintenance of the power plant shall be managed in accordance with a comprehensive QA program

b. The QA program shall be structured to comply with the requirements of regulations, codes, and company policies

c. Mandatory QA program requirements shall be established for all company and contractor personnel who oversee and/or perform activities that may affect safety or plant availability.

17.2.2.1.2 Goals

QA goals are the following:

a. Achieve safe and efficient operation

b. Achieve maximum plant availability within economic and safety limitations.

17.2.2.1.3 Objectives

QA objectives are to provide assurance that:

a. Plant design modifications are performed in accordance with regulatory requirements, codes, and standards to ensure a safe and reliable plant

b. Materials and services for the plant are procured as specified in design documents

c. Plant structures, systems, and components are constructed, maintained, and repaired to design standards

d. Plant structures, systems, and components are inspected to verify compliance with design requirements

e. Plant structures, systems, and components are tested to verify continued performance to design requirements

f. Adequate documentation is provided as objective evidence of quality and as required for plant operation and maintenance

g. No alterations are made to the facility which constitute a change from the current Technical Specifications except as allowed by 10 CFR 50.54(x) and (y) under emergency conditions. Other necessary alterations are made only after formal revision to the Technical Specifications.

The Fermi Conduct Manuals, approved and made mandatory by management, are the chief means of communicating the policies, goals, and objectives stated above to Nuclear Generation. Indoctrination sessions will also aid in furthering understanding. See Subsection 17.2.2.7 for further details.

17.2.2.2 Program Documentation

The Nuclear QA program is described in this section of the UFSAR (17.2) and is supported by Fermi Conduct Manuals and implementing procedures. QA Program elements applied to ISFSI are described in UFSAR Appendix 17.2A. This quality assurance program description (QAPD) and changes thereto shall be approved by the Senior Vice President and Chief Nuclear Officer after review by the Manager - Nuclear Quality Assurance.

17.2.2.2.1 Fermi Conduct Manuals

The Fermi Conduct Manuals address the QA program and other programs associated with the operation, maintenance, and modification of Fermi 2 and the activities of support organizations. These conduct manuals are organized by function and are divided into chapters which represent administrative implementing procedures.

Fermi Conduct Manuals are endorsed by DTE management in the QA management policy statement, and reflect commitments to meet the applicable regulatory requirements for safe operation, as well as provide for ensuring reliability of operation. These Conduct Manuals are approved by Fermi management and are the basis for the overall management program for Nuclear Generation. The Conduct Manuals are also applicable, as appropriate, to other DTE departments, suppliers, and contractors who furnish materials, equipment, or services that can affect the safe and reliable operation of Fermi 2.

Fermi Conduct Manuals identify the requirements and implementing procedures that management has mandated to be followed. Conduct Manuals applicable to the QA program describe responsibilities and principal duties for the performance of specific quality-related activities and the QA requirements applicable to those activities. These Fermi Conduct Manuals are approved by the Executive Director – Nuclear Production after review by the management of affected organizations. The Executive Director – Nuclear Production may delegate approval authority in writing for specific types of procedures to a management representative responsible for the functional area.

Conduct Manuals are controlled documents and are handled as described in Subsection 17.2.6. Revisions will be made, as appropriate, and will be subject to the same review and approval required for the original issue. Controlled copies of the manual are issued to identified personnel. Holders of the manual are required to keep it updated as revisions are issued and to be familiar with its applicable contents.

A matrix showing the 18 criteria of 10 CFR 50, Appendix B, QA Regulatory Guides and endorsed ANSI standards, and the conduct manuals implementing these criteria is shown in The QA Conduct Manual.

17.2.2.3 Program Elements

The Nuclear QA program implemented in the Fermi Conduct Manuals has the following major elements:

a. Definition of responsibility and authority of those involved in the implementation of the QA program during maintenance, modification, and operation of the plant

b. Identification of items and activities covered by the program and the extent of the applicability of the program, based on the safety-related importance of the item or activity

c. Verification and documentation of quality by personnel with sufficient independence and organizational freedom to effectively control quality

d. Performance of activities affecting quality in accordance with written instructions, procedures, or drawings

e. Indoctrination and training of personnel performing activities affecting quality to the extent required to ensure their proficiency

f. Identification and verification of compliance with requirements of applicable codes, standards, design documents, and regulations

g. Performance of activities affecting quality under suitably controlled conditions

h. Documentation of the satisfactory completion of activities and of the quality of an item

i. Regular review by management, outside of Nuclear QA, as directed by the Site Vice President – Nuclear Generation, to assess the status and adequacy of the QA program

j. Review of proposed changes to the QA program to determine if the proposed change requires prior review and acceptance by the NRC.

17.2.2.4 Program Applicability

The requirements of the Nuclear QA program are to be applied to quality-related activities involving safety-related structures, systems, and components. The safety-related structures, systems, and components are identified in Table 3.2-1 of the UFSAR and in the Central Component Computer Data Base (CECO). Procedures describe how changes are made to CECO.

The requirements of the QA program are applicable to the fire protection program and are applied to the extent consistent with safety. Therefore, Sections 17.2.6, 17.2.8, 17.2.9, 17.2.12 and 17.2.13 are not applicable to the fire protection program.

The requirements of the QA program are applicable to the ISFSI program and are applied to the extent consistent with safety. Elements of the QA program applicable to the ISFSI program are delineated in Appendix 17.2.A.

QA program procedures require that the development, control, and use of computer programs are performed in accordance with implementing procedures that incorporate applicable QA requirements to ensure the adequacy of the design and use of these programs.

17.2.2.5 QA Programs of Others

The QA program for Nuclear Generation includes requirements that a contractor providing items, work, or services involving safety-related structures, systems, or components must establish and maintain a prescribed QA program in compliance with the applicable requirements of Appendix B to 10 CFR 50. The specific QA requirements that the contractor program must satisfy are specified in the procurement documents. The program is subject to review and concurrence by Nuclear QA before work is started. The program may be reviewed by another utility provided that an agreement has been established to ensure that DTE's QA requirements have been satisfied. The results of the review will be provided to DTE.

17.2.2.6 Resolution of Disputes

Disputes between Nuclear QA personnel and others are to be referred for resolution to personnel who have the responsibility and authority to make the final decision. On technical matters, the dispute is referred to those in the organization who have the responsibility and expertise to make the decision; e.g., on problems involving the welding process, the Welding Engineer is the arbiter. Disputes involving operating procedures that cannot be resolved with the responsible organization are to be referred to the OSRO for resolution. In the event the OSRO and the Executive Director - Nuclear Production are in disagreement, resolution shall be obtained as described in Subsection 17.2.1.3.1.8.c. Disputes on QA program requirements specified in the Fermi Conduct Manuals are to be referred through the Manager - Nuclear Quality Assurance to the Senior Vice President and CNO as necessary.

17.2.2.7 Indoctrination and Training of Personnel

Personnel whose responsibilities and duties involve quality- related activities will participate in formal indoctrination and training programs conducted by Nuclear Training. These programs, in conjunction with training provided within the plant organizations, are designed to make personnel knowledgeable of the requirements of the Nuclear QA program, including purpose and scope, and the implementing procedures applicable to their work.

Periodic reviews will be scheduled to maintain a high level of understanding and knowledge of the Nuclear QA program. Special training sessions will be established for personnel requiring specialized skills in the performance of their work. The proficiency of such personnel will be established by appropriate examination, reexamination, and certification as required by codes, standards, and regulations. Files for formal training programs will include the objective, the content of training, the list of attendees, the date of attendance, and records of satisfactory completion. See Subsection 13.2.1 for further details.

17.2.2.8 Regulatory Guides and ANSI Standards

The operational QA program is intended to comply with the requirements of 10 CFR 50.55a, Part g; 10 CFR 50, Appendix B; Branch Technical Position (BTP) APCSB 9.5-1, Appendix A; 10CFR72, Subpart G and appropriate regulatory guides as addressed in Appendix A. The program is structured and implemented in accordance with ANSI N18.7-1976, "Administrative Controls and Quality Assurance for the Operational Phase of Nuclear Power Plants," the ANSI standards referenced therein, and the regulatory guides that endorse them as addressed in Appendix A.

Those structures, systems, and components that are addressed by regulatory guides endorsing American Society of Mechanical Engineers (ASME) codes are listed in Section 3.2.

17.2.3 Design Control

Technical Organization is responsible for the engineering scope of modifications to plant structures, systems, and equipment. Design documents (e.g., drawings, calculations, specifications, procedures, and instructions) originating from or released for review by this group will contain the required regulatory requirements, quality standards, and design bases in accordance with NRC licensing requirements. Design activities may include calculations, analysis, materials selection, equipment arrangement and layout, and specification of test and inspection criteria essential to the safety-related functions of structures, systems, and components. Those design activities performed by individuals within DTE organizations are controlled by design control procedures.

Design control procedures satisfy the applicable QA requirements for design activities as specified in ANSI N45.2.11-1974 and as modified by Regulatory Guide 1.64 as addressed in Subsection A.1.64. Any organization performing design work for DTE must have similar requirements in its procedures before its QA program can be accepted.

To ensure that the design is adequate and that the above requirements and procedures are satisfied, designs are internally verified by the originating organization. This internal verification of adequacy may be accomplished either by a design review, by alternative calculation methods, or by the establishment of a suitable test program. Where a test program is used to verify the adequacy of a specific design feature in lieu of other verification or checking processes, it will include suitable qualification testing of a prototype unit under the most adverse design conditions. Those proposed changes in the facility which involve changes to the Technical Specifications or require a License Amendment prior to implementation as defined in 10 CFR 50.59(c)(2) shall also be reviewed by NSRG. Minutes of each NSRG meeting are prepared and approved.

Design controls have been established to assure that applicable fire protection program guidelines and requirements are included in design and procurement documents and that deviations are controlled. Field changes and design deviations that affect the intent of the modification shall be subject to the same level of controls, reviews, and approvals that were applicable to the original document. Quality standards are specified in the design documents such as appropriate fire protection codes and standards. Deviations or changes from these standards are individually approved. New designs and plant modifications, including fire protection systems, are reviewed by qualified personnel to assure inclusion of appropriate fire protection requirements.

All documentary material reviewed is identified. Copies of minutes are distributed to the originating organization.

During the design reviews, particular attention will be given to ensure that:

a. Appropriate quality standards are contained in the documents and clearly delineated

b. The technical information for the materials, components, equipment, and processes is contained in the documents and is suitable for the intended applications. This information will include, as applicable, the physics, seismic, radiation, hydraulics, thermal, strength, and accident analyses used; the compatibility of design for inservice inspection, maintenance, and repair; and the acceptance criteria for inspections and tests. Performance history and failure data on installed components will be considered when similar components are intended for installation as part of a system or structure modification

c. Design interfaces, when more than one organization has participated in the design, are compatible and consistent with the overall design bases and existing systems

d. In the selection of standard commercial or previously approved items with safety-related functions, a review is performed to determine if the characteristics of the item satisfy the requirements of the application

e. The inspection requirements per Subsection 17.2.10 are included and adequate

f. Errors and deficiencies discovered in the design as a result of the reviews are documented and disposition is assigned. A feedback system of corrective action, by distribution of the review comments to the responsible organization, is used to prevent repetitive errors or deficiencies in the design process.

Changes to the basic documents, including field changes as a result of modifications, which affect the technical adequacy of the design, will receive reviews and approvals comparable to the original basic documents. Editorial changes may be made with the approval of the responsible Nuclear Design Engineering Supervisor or other designated persons. Copies of editorial changes will be routed to the participating design organization and the Information & Procedures organization.

17.2.4 Procurement Document Control

17.2.4.1 General

Design documents are used in the procurement of plant materials, equipment, and services to properly define the technical and quality requirements for each procured item. Procurement packages are prepared or initiated by the responsible individual in accordance with established purchase requisition procedures.

The procurement package originator is responsible for ensuring that the applicable specifications, drawings, test requirements, inspection requirements, special process requirements, codes, standards, and regulatory requirements for safety-related items are specified or referenced in the procurement documents. The procurement packages are reviewed by Procurement Engineering to ensure (or provide) inclusion of appropriate technical, QA, and documentation requirements, DTE's right of access, and the control of nonconformances.

The procurement document planning, preparation, review, approval, and control process is performed in accordance with procedures prepared by the responsible organizations. Procurement document control procedures require that changes to procurement documents be subject to the same controls as the original document. Procurement document control procedures satisfy applicable QA requirements described in ANSI N45.2.13-1976 as modified by Regulatory Guide 1.123 as addressed in Subsection A.1.123.

Procurement documents for fire protection materials, equipment, and services are reviewed, approved and documented by qualified personnel to verify the adequacy of fire protection and quality requirements. This review assures that fire protection and quality requirements are correct; that there are adequate acceptance and rejection criteria; and that the procurement document has been properly prepared, reviewed, and approved.

The provisions which ensure that procurement documents contain DTE's right of access to supplier's facilities and records for source inspection and audits are delineated in the Fermi Conduct Manuals.

17.2.4.2 Procurement of Commercial Quality Items

Procurement of safety-related equipment, parts, and materials at Fermi 2 is in compliance with the plant's design requirements and commitments and is consistent with 10 CFR 50, Appendix B. These items may on occasion be procured commercial quality as replacements in safety-related systems. The criteria used for these commercial-quality procurements are consistent with the definition of commercial-grade items for use in safety-related systems contained in 10 CFR 21.

Safety-related items procured as Commercial Quality require specific engineering evaluations to establish engineering criteria and verification requirements prior to hardware acceptance. The development of engineering criteria includes critical performance characteristics and environmental and seismic requirements. Critical performance characteristics evaluate the item's form, fit, and function. Environmental requirements evaluate humidity, temperature, pressure, and radiation fields in which the hardware is expected to function under normal and accident conditions. Seismic requirements necessitate a need to evaluate the items for operation during and after a seismic event. Verification requirements are developed to ensure that established critical performance characteristics and environmental and seismic requirements are met.

Verification of product quality may be accomplished by sampling. The verification process includes visual inspection, analysis/ justification, or testing, either nondestructive or destructive, before release for installation. Other methods that can be used include commercial grade survey of the supplier or source verification. Commercial grade surveys will not be employed as the basis for accepting items from suppliers with undocumented commercial quality control programs or with programs that do not effectively implement their own necessary controls. Commercial grade surveys will not be employed as the basis for accepting items from distributors unless the survey includes the part manufacturer(s) and the survey confirms adequate controls by both the distributor and the part manufacturer (s). Surveys are led by Nuclear QA personnel. Under certain circumstances, equipment, parts, or materials can be verified by post installation testing.

Other verification activities are performed at the direction of Fermi 2 Procurement Engineering and overseen by Nuclear Quality Assurance in accordance with the Fermi 2 Quality Assurance Program with the exception that some source verifications are performed by QA.

Documentation resulting from engineering evaluations and hardware verifications is designed to be auditable and become permanent plant procurement records. It may also be used to replicate generic or specific engineering evaluations during subsequent procurements.

Nuclear QA will ensure that such requirements are included in the detailed procedures. Independent audits by Nuclear QA will ensure compliance with the established procedures.

17.2.5 Instructions, Procedures, and Drawings

Activities affecting quality are performed in accordance with approved instructions, procedures, or drawings. These documents include the necessary limits and tolerances on materials, equipment, processes, and procedures for all activities from design through operation. Also included are qualitative or quantitative acceptance criteria to ensure that important operations have been accomplished satisfactorily. The basis for determining the need for procedures and their content is consistent with the requirements of ANSI N18.7-1976 and Regulatory Guide 1.33 as addressed in Subsection A.1.33.

Documents established to ensure that activities affecting quality are accomplished in accordance with applicable codes, standards, specifications, and drawings include the following:

a. Fermi Conduct Manuals, including administrative implementing procedures and NQA procedures

b. Technical procedures, including, but not limited to: Operating procedures, radiation protection procedures, maintenance and modification procedures, periodic calibration and test procedures, special test procedures, and fuel handling procedures

c. Inspections, tests, administrative controls, fire drills and training that govern the fire protection program are prescribed in instructions, procedures or drawings and accomplished in accordance with these documents.

Nuclear Generation unit supervisors are responsible for ensuring compliance to procedures by personnel under their direction. Independent auditing by Nuclear QA will further ensure and verify onsite compliance with the approved procedures. The activities of DTE support organizations and vendors or contractors are also audited by Nuclear QA to verify compliance with requirements.

17.2.5.1 Technical Review and Control

17.2.5.1.1 Activities

Procedures required by Technical Specification 5.4, and other procedures which affect plant nuclear safety, including those governing the fire protection program, as determined by the Plant Manager, and changes thereto, shall be prepared by a qualified individual/organization.

17.2.5.1.2 Review

17.2.5.1.2.1 Procedure Review

Each procedure or procedure change prepared in accordance with 17.2.5.1.1, and each plant administrative procedure and changes thereto, shall be reviewed for technical adequacy by a qualified individual other than the individual that prepared the procedure or change thereto. Each such review shall include a determination of whether or not additional, cross-disciplinary review is necessary. If deemed necessary, such review(s) shall be performed by personnel of the appropriate discipline. Procedures governed by the fire protection program shall be reviewed to assure proper inclusion of fire protection requirements.

17.2.5.1.2.2 Procedures Required by Technical Specification 5.4.1.c and 5.5.1

Each procedure required by Technical Specification 5.4.1.c and 5.5.1, or changes thereto, shall be reviewed by the Manager -Radiation Protection or his/her designee. The Environmental Program Coordinators (an alternate title may be designated for this position) will review any changes pertaining to Technical Specification 5.4.1.c. These reviews may be performed in lieu of, or in addition to, those required by 17.2.5.1.2.1 above.

17.2.5.1.3 10 CFR 50.59 Evaluations

When required by 10 CFR 50.59, a 10 CFR 50.59 Evaluation to determine whether or not a License Amendment is involved shall be included in the review. Pursuant to 10 CFR 50.59, NRC approval of items requiring License Amendments prior to implementation shall be obtained prior to approval of the procedure or procedure change.

17.2.5.1.4 Qualifications

Individuals performing the reviews and evaluations in accordance with 17.2.5.1.2.1 through 17.2.5.1.3 above shall meet or exceed the qualifications stated in Sections 4.2 or 4.4 of ANSI N18.1-1971 for the appropriate discipline, and shall be members of the plant staff previously designated in writing by the Executive Director - Nuclear Production.

17.2.5.1.5 Records

Written records of reviews and evaluations performed in accordance with items 17.2.5.1.2.1 through 17.2.5.1.3 above, including recommendations for approval or disapproval, shall be prepared and maintained.

17.2.5.2 Review and Approval Process and Temporary Change Process

17.2.5.2.1 Plant Administrative Procedures

Each plant administrative procedure, and changes thereto, shall be reviewed in accordance with 17.2.5.1.2 and 17.2.1.3.1.6 and approved by the Executive Director – Nuclear Production prior to implementation, and shall be reviewed periodically thereafter as set forth in administrative procedures. The Executive Director – Nuclear Production may delegate approval authority in writing for specific types of procedures to a management representative responsible for the functional area.

17.2.5.2.2 Plant Procedures Required by Technical Specification 5.4.1

Each plant procedure required by Technical Specification 5.4.1, other than administrative procedures, and changes thereto, shall be reviewed in accordance with 17.2.5.1 and approved by the Executive Director – Nuclear Production prior to implementation and shall be reviewed periodically thereafter as set forth in administrative procedures. The Executive Director – Nuclear Production may delegate approval authority in writing for specific types of procedures to a management representative responsible for the functional area.

17.2.5.2.3 Temporary Changes

Temporary changes to procedures of Technical Specification 5.4.1 may be made provided:

a. The intent of the original procedure is not altered;

b. The change is approved by two members of the unit management staff, at least one of whom holds a Senior Operator license on Fermi 2; and

c. The change is documented, and reviewed and approved in accordance with either 17.2.5.2.1 or 17.2.5.2.2 above, as appropriate, within 14 days of implementation.

17.2.5.3 Process Control Program (PCP)

The PCP shall be approved by the Commission prior to implementation.

17.2.5.3.1 Changes to the PCP

a. Shall be documented and records of reviews performed shall be retained as required by Subsection 17.2.17.4.3n. This documentation shall contain:

   1. Sufficient information to support the change together with the appropriate analyses or evaluations justifying the change(s) and

   2. A determination that the change will maintain the overall conformance of the solidified waste product to existing requirements of Federal, State, or the applicable regulations.

b. Shall become effective after review and acceptance by the OSRO and the approval of the Executive Director - Nuclear Production.

17.2.6 Document Control

Documents defining the performance of quality-related activities are controlled to ensure that only current and correct information is used at the work location. Such documents include, but are not limited to, the following:

a. Design specifications, calculations, and analyses

b. Design, manufacturing, and construction drawings

c. Procurement documents

d. Fermi Conduct Manuals

e. Technical procedures

f. Nonconformance and design-change documents.

Such documents are drafted, reviewed, and approved by appropriate individuals or groups to ensure that the documents are adequate and that they include appropriate quantitative or qualitative acceptance criteria for determining that prescribed activities have been accomplished satisfactorily. Nuclear QA reviews such documents either directly or by audits and surveillances as appropriate for the type of document to ensure the inclusion of QA program requirements. The appropriate review and approval process is described in administrative procedures. The issuance of approved documents is made in accordance with established distribution lists.

Changes to such documents will meet the same requirements as the original document and will be reviewed and approved by the same organizations that performed the original review and approval, unless this responsibility is specifically delegated by these organizations to another qualified responsible organization.

Supervisors are responsible for ensuring that the correct revisions of necessary documents are being used to accomplish work.

During inspection, surveillance, and audit activities, Nuclear QA will verify that required documents such as drawings, specifications, instructions, or procedures are available at the work location.

The Director – Strategic Business Operations is responsible for maintaining and making available a document control system that identifies the current revision of procedures, specifications, drawings, procurement documents, and other such quality-related documents. The requirements for retaining and storing the quality-related documentation required above and other historical records are described in Subsection 17.2.17.

17.2.7 Control of Purchased Material, Equipment, and Services

Individuals designated by procedure approve the placement of contracts based on the analysis and recommendation of the appropriate Nuclear Generation organizational units. The evaluation of the QA capabilities of such vendors and contractors is the responsibility of Nuclear QA.

Supply Chain is responsible for supplier selection and bid evaluations. Requisitions are routed to Nuclear Generation and/or Supply Chain management personnel responsible for the issuance of purchase orders. The technical and quality requirements are transferred from the requisition to the purchase order. Procurement personnel review the purchase order for correctness prior to releasing the order to the vendor.

Three types of QA evaluation of a contractor or vendor are possible. One of these three may be used as appropriate to the level of quality required. They are as follows:

a. Desk Review - Evaluation of contractor or vendor QA capabilities accomplished by the review of pertinent information submitted by the contractor or vendor; quality history records of previous performance; documented review of audit reports by other utilities, or other similar methods. Included are ASME accreditation of an N Stamp, NA, NPT, and NV Stamps and associated Certificates of Authorization accepting the ASME accreditation of holders of the aforementioned in lieu of a separate evaluation of the programmatic adequacy of a supplier's documented QA program.

b. Facility Evaluation - Evaluation of a vendor's QA capabilities conducted at their facility, including

   1. Preaward evaluation of vendor QA system and implementation

   2. Preaward surveillance of vendor products, processing, or service and related documentation in accordance with requirements of the applicable purchase contract

   3. Inprocess evaluations.

c. Commercial grade calibration and/or testing services may be procured from commercial laboratories based on the laboratory's accreditation to ISO/IEC-17025 by an Accreditation Body (AB) which is a signatory to the International

Laboratory Accreditation Cooperation (ILAC) Mutual Recognition Arrangement (MRA) provided each of the conditions in the following list are met. The ILAC accreditation process cannot be used as part of the commercial grade dedication process of Nondestructive Examination (NDE) or Nondestructive Testing (NDT) services in lieu of performing a commercial grade survey.

1. A documented review of the supplier's accreditation is performed and includes a verification of the following:
   a) The calibration or test laboratory holds accreditation by an accrediting body recognized by the ILAC MRA. The accreditation encompasses ISO/IEC-17025:2017, "General Requirements for the Competence of Testing and Calibration Laboratories."
   b) For procurement of calibration services, the published scope of accreditation for the calibration laboratory covers the needed measurement parameters, ranges, and uncertainties.
   c) For procurement of testing services, the published scope of accreditation for the test laboratory covers the needed testing services including test methodology and tolerances/uncertainties.
   d) The laboratory has achieved accreditation based on an on-site accreditation assessment by the selected AB within the past 48 months. The laboratory's accreditation cannot be based on two consecutive remote accreditation assessments.
2. The purchase documents require that:
   a) The service must be provided in accordance with their accredited ISO/IEC-17025:2017 program and scope of accreditation.
   b) As found calibration data must be reported in the certificate of calibration when calibrated items are found to be out of tolerance (for calibration services only).
   c) The equipment/standards used to perform the calibration must be identified in the certificate of calibration (for calibration services only).
   d) Subcontracting of these accredited services is prohibited.
   e) The customer must be notified of any condition that adversely impacts the laboratory's ability to maintain the scope of accreditation.
   f) Performance of the services listed on this order is contingent on the laboratory's accreditation having been achieved through an on-site accreditation assessment by the AB within the past 48 months.
   g) Additional technical and quality requirements, as necessary, based upon a review of the procured scope of services, which may include,

but are not necessarily limited to, tolerances, accuracies, ranges, and industry standards.

3. It is validated, at receipt inspection, that the laboratory's documentation certifies that:

   a) The contracted calibration or test service has been performed in accordance with their ISO/IEC-17025:2017 program, and has been performed within their scope of accreditation.

   b) The purchase order's requirements are met.

After evaluation, the approved sources are placed on a current list of approved suppliers. Additions and deletions to the list are made by Nuclear QA.

To ensure that material and equipment fabrication is in accordance with procurement requirements, Nuclear Generation or Supply Chain inspection personnel perform source verification of vendor activities, which includes witnessing significant fabrication checkpoints, validity of vendor-supplied documentation, and overall vendor performance as appropriate to the purchased item. The surveillance activities are accomplished in accordance with approved procedures.

Suppliers shall be required, as part of the purchase order, to furnish, as a minimum, a certificate of conformance or compliance that identifies the item provided and specifically itemizes the quality requirements of the procurement documents that it meets. In some instances inspections and audits of records will be used to verify the credibility of the certification.

One of the provisions in the procurement document shall require a supplier to submit to DTE requests for the disposition of all nonconformances to DTE specified requirements. In addition, the supplier shall be required to document the disposition of nonconformances to their own requirements. Those dispositions that resulted in "accept as is" or "repair" shall be described in the submitted documentation. See Subsection 17.2.16 for corrective actions in the case of nonconformances.

After receipt and before the storage of a material, part, or component, inspection is accomplished by qualified personnel as necessary to ensure that the material, equipment, fire protection items, or service is adequately identified and complies with the specifications delineated in the associated procurement documents. These inspections and subsequent identification of status are performed in accordance with material receiving and inspection procedures.

Documentation of the inspection will be prepared. A necessary condition for acceptance is the receipt of the QA records identified in the procurement documents verifying that the specified quality requirements have been met. An item is considered nonconforming until sufficient quality documentation has been provided. Procedures permit the conditional release of material lacking the specified QA records, provided the item can be readily removed if necessary. Functional testing may be performed on materials installed under conditional release; however, these materials are not to be placed in service unless a technical evaluation has been performed and documented in accordance with approved procedures including a 10 CFR 50.59 review.

Following a satisfactory receiving inspection, the receiving inspection report, and required documentation of tests, certificates of conformance or compliance and other specified requirements are retained to provide documentary evidence of compliance. If a nonconforming item is found during the inspection, the item is retained in a hold area or otherwise controlled area pending resolution.

The procurement of spare or replacement parts for structures, systems, and components is subject to QA program controls, codes, and standards and to technical requirements equal to or better than the original technical requirements as necessary to preclude the repetition of defects.

For specific criteria applying to commercial grade items refer to Subsection 17.2.4.2.

17.2.8 Identification and Control of Materials, Parts, and Components

Safety-related materials (including consumables), parts, and components (including partially fabricated subassemblies) are identified in a manner that allows traceability to the documentation that verifies the acceptability of the items to the extent specified in the procurement documents. The identification system is used to preclude the use of nonconforming materials, parts, and components. Identification must not adversely affect the function or quality of the item identified. Vendor-supplied items are identified and documented by the manufacturer in a manner consistent with applicable codes and as specified in the procurement documents. Materials, parts, and components manufactured or modified by DTE are identified, documented, and controlled.

When safety-related items are received, the items are inspected according to inspection procedures. Incorrect or defective materials, parts, and components will be identified with a tag or other appropriate means and handled in accordance with Subsection 17.2.15 to preclude inadvertent use before proper disposition. Identification and control of materials, parts, and components at the site is prescribed by, and implemented in accordance with, approved procedures.

17.2.9 Control of Special Processes

Special processes used in the course of maintenance, modification, and testing of the plant are controlled to ensure that they are accomplished in a satisfactory manner. Examples of special processes include, but are not necessarily limited to, the following:

a. Chemical cleaning

b. Application of protective coatings

c. Plating

d. Heat treatment

e. Metal joining, such as brazing, soldering, and welding

f. Nondestructive examinations.

Implementing procedures establish the methods for controlling and accomplishing the special processes. These procedures include the following:

a. Training, testing, and qualification requirements of onsite personnel engaged in accomplishing or inspecting special process operations

b. Certification or qualification of equipment and procedures used in the performance of special processes at the site

c. Certification and audit of vendor and contractor special fabrication process equipment, procedures, and personnel

d. Documentation of process results, procedures, personnel qualifications, and equipment certifications.

Implementing procedures define the requirements for the control of special processes to ensure that they are accomplished by qualified personnel in accordance with approved procedures, codes, and specifications. These procedures also require the documentation of personnel qualifications, equipment, special process procedures used, and acceptance/rejection criteria. Supervisors are responsible for ensuring that personnel, equipment, and special processes under their supervision, direction, or use are qualified to accomplish a particular onsite activity. These qualifications are established in accordance with the applicable codes, specifications, and standards.

Offsite special process activities will be performed in accordance with approved procedures and procurement document requirements, and by qualified personnel.

Specific procedures for special processes are prepared by the plant personnel or DTE support organizations. Qualification records of all personnel, procedures, and equipment and copies of procedures for special processes are maintained and controlled in accordance with approved procedures. Personnel performing nondestructive examinations will be qualified and certified in accordance with the requirements of ASNT SNT-TC-1A or ANSI/ASNT-CP-189 (applicable year as specified by the ISI-NDE program) and additional requirements set forth in applicable codes, standards, and specifications.

17.2.10 Inspection

Inspections are required to ensure that maintenance, repair, or modification work has been satisfactorily accomplished. Administrative procedures require that maintenance, repair, or modification procedures be submitted for review by Nuclear QA. Nuclear QA, in conjunction with other Nuclear Generation units, establishes the need for inspection, inspection personnel, and documentation and incorporates such information into plans or procedures. Such procedures include criteria for determining which inspections are required and how they are sequenced. Nuclear QA personnel are also required to prepare inspection plans and checklists from information obtained from original design documents to determine which inspections are required and the acceptance and rejection criteria. If the responsible design organization establishes additional requirements or criteria, these must also be included in the inspection checklists. Inspections are accomplished using procedures, instructions, and/or checklists that contain at least the following:

a. Acceptance and rejection criteria

b. Identification of those individuals responsible for performing the inspection activity

c. Description of the method of inspection, examination, measurement, or test of materials or processes necessary to be performed to ensure quality

d. Requirements for inspection equipment and instruments

e. Identification of required witness and/or hold points

f. Results of inspection activity

g. Identification of inspection subject

h. Signoff signature or controlled stamp showing evidence of completion and verification of the inspection

i. Identification of required procedures, drawings, specifications, and revisions.

If inspection of the work is impossible or disadvantageous, indirect control by the monitoring of processing methods, equipment, and personnel is provided. Both inspection and process monitoring are provided when necessary to ensure adequate control.

The inspection program also includes:

a. Periodic inspections of fire protection systems, breathing equipment and emergency lighting to assure the acceptable conditions of these items

b. Periodic inspections of materials subject to degradation such as fire stops, seals and fire retardant coatings to assure that such items have not been damaged or deteriorated.

With the exception of inservice inspection (ISI), receiving inspection, and source inspection inspectors personnel qualified to perform inspections normally will be from Nuclear QA or from onsite support organizations and will be under the control of DTE. Contract inspectors may be used, if required, for special-purpose inspections. Personnel qualified to perform inspections will:

a. Not have performed any of the activities being inspected

b. Have satisfactorily completed the qualification requirements and be certified as specified by procedures that incorporate the requirements of ANSI N45.2.6-1978 as modified by Regulatory Guide 1.58 and Subsection A.1.58 or the requirements of ASNT SNT-TC-1A or ANSI/ASNT CP-189, as applicable per Section 17.2.9

c. Be currently qualified and so designated on a qualified inspectors list approved by management.

If contractors perform special-purpose inspections, such as inservice inspections, they perform such work under the control of onsite supervision. Responsible onsite supervision ensures that contractor personnel, equipment, and procedures are properly qualified and adequate to perform the inspection.

Activities affecting fire protection will be inspected by NQA personnel or other personnel who are independent of the activity being inspected to verify conformance with documented installation drawings and test procedures for accomplishing the activities. Inspection personnel will be knowledgeable in the design and installation requirements for fire protection to the extent necessary to perform the inspection.

If an inspection reveals that a nonconformance has occurred, the inspector has the authority to initiate action to suspend further activity until the nonconformance is resolved. All nonconformances are reported and acted on in accordance with Subsection 17.2.15.

The results of each inspection are documented. The appropriate Nuclear QA Supervisor is responsible for the review of the results following completion of an activity to ensure that inspections were properly performed and documented. Maintenance of inspection records is described in Subsection 17.2.17.

Each vendor is required to establish and implement an inspection program to ensure that requirements of purchase orders are met. DTE personnel perform selective surveillance inspections to evaluate progress, monitor processes, and verify adherence to specifications and codes during fabrication in the vendor's shop. Specific attention is paid to the quality of workmanship, finishes, cleaning procedures and facilities, the interface setup of connections, and the adequacy and cleanliness of shop assembly and test areas. A system of mandatory hold points is established for critical operations and inspections to permit DTE to witness such operations and inspections.

17.2.11 Test Control

Preoperational and startup test programs were established and completed in accordance with the guidance provided in Regulatory Guide 1.68, as described in the Startup Manual.

Onsite test activities following plant startup are controlled by the implementation of approved test procedures. These procedures are prepared by the organization responsible for a given test activity, technically reviewed by Nuclear Generation staff, and approved by the Executive Director - Nuclear Production or designee in accordance with approved administrative procedures. Test control at the plant provides assurance that appropriate tests are conducted on structures, components, systems, or parts of systems in accordance with design documents, codes, and Technical Specifications. Tests within the scope of this subsection include periodic tests and those tests required as a result of modification, maintenance, or repair of safety-related items.

Following modification, repair or replacement, sufficient testing is performed to demonstrate that fire protection equipment in support of nuclear safety-related equipment areas will perform satisfactorily in service and that design criteria are met. Written test procedures for installation tests are prepared by the responsible engineering group and incorporate the requirements and acceptance limits contained in applicable design documents.

Implementing procedures describe the criteria used to determine which systems, structures, and components require testing and when such testing should be performed. When systems, structures, and components have been repaired, modified, or replaced, proof tests, operational tests, or other special tests are performed as required by NRC regulations and other applicable codes and standards to demonstrate satisfactory performance of the affected equipment. The responsible supervisor ensures that test procedures are prepared for the required tests and that each test procedure complies with applicable design documents, codes, and specifications. Nuclear QA reviews test procedures through inspections, surveillances, and audits.

Each test procedure includes the following as applicable:

a. Test procedure approval sheet

b. Purpose or objective

c. References

d. Prerequisites and precautions, such as suitable and controlled plant conditions for testing, adequate test equipment and instrumentation (including accuracy and calibration requirements), and completeness of item to be tested

e. Special test equipment and materials

f. The body of the procedure, including the delineation of test requirements and acceptance criteria contained in applicable design and procurement documents

g. Radiological control requirements

h. Data sheets, including provisions for signoff of prerequisites

i. Valve and electrical system lineup sheets for test and return to normal conditions

j. Hold points for inspection and witnessing.

The responsible section head or supervisor is responsible for the overall conduct and review of onsite tests. He/she assigns a qualified lead person and qualified personnel under the lead person to perform tests.

The lead person makes certain that test equipment has the proper accuracy and is properly calibrated and that each test is conducted under proper environmental conditions. Tests are conducted, documented, and results are reviewed by the lead person/qualified personnel. Additionally, the Shift Manager (SM) reviews tests to ensure that the results meet the requirements and acceptance criteria of the applicable test procedures.

Nuclear QA reviews test results through inspections, surveillances, or audits. Test records are maintained as described in Subsection 17.2.17.

Safety-related components and equipment may be tested in the vendor's shop before shipment, as required, to verify that they meet the contract drawings and specifications, and to ensure that the required quality is achieved. Tests are conducted in an environment in which shop conditions and activities do not interfere with test results. DTE requires that vendor-conducted shop tests be conducted in accordance with written test procedures. These procedures define in detail the step-by-step operations for demonstrating each feature of specified performance and provide such information as measuring and test equipment used, specifying range, accuracy, and type. The test data sheet provides space for actual test results and is traceable to the acceptance criteria. Space is provided for the signature and title of the person performing the test.

When appropriate, DTE personnel may witness the testing of items in a vendor's shop to ensure compliance with test procedures and specification requirements. The opportunity to witness will be established and coordinated with the vendor.

17.2.12 Control of Measuring and Test Equipment

The control of measuring and test equipment is implemented by specific procedures that describe calibration techniques, frequency requirements, and control of all the instruments and standards used in the measurement, inspection, and monitoring of safety-related components, systems, and structures. Control is used to ensure that tools, gages, instruments, and other measuring and test devices are calibrated to required accuracies against reference and transfer standards traceable to nationally recognized standards. Where national standards do not exist, the basis for calibration is documented in accordance with approved procedures. The DTE organization, supplier, or contractor responsible for testing materials, parts, assemblies, and end products ensures that the specified controls are implemented. Frequently used testing and measuring equipment will be checked for accuracy on a specified routine basis. Testing and measuring equipment used only on an infrequent basis will be checked before use.

Procedures require that testing and measuring equipment be stored in suitable locations and environments and be used only by personnel trained in their proper use and care. The calibration control documentation indicates the source and traceability of calibration, including the date of last calibration. The records also provide identification and traceability for all measuring equipment by a serial number or other suitable means. The responsible supervisor ensures the maintenance of records that indicate the complete status of measuring and test equipment under calibration control. Procedures provide for investigations to be conducted and documented to determine the validity of previously made measurements when measuring or test equipment is found to be out of calibration, and also require the repair or replacement of instruments found to be consistently out of calibration.

The section heads or supervisors of the organizations using measuring and test equipment are responsible for the establishment, implementation, and effectiveness of their calibration program. Procedures describe calibration methods, calibration frequencies, and the use of calibration stickers or tags on equipment indicating the next calibration date.

Calibration frequencies are based on required accuracy, purpose, extent of usage, stability characteristics, and other conditions that affect measurement. Calibrating standards have equal or greater accuracy than the equipment being calibrated. Those standards having equal accuracy must be adequate for the requirements, and such determination is documented and authorized by cognizant staff personnel.

17.2.13 Handling, Shipping, and Storage

Requirements for packaging, handling, cleaning, storing, and shipping safety-related materials, components, and systems are specified in procurement, shipping, and design documents in order to prevent damage, loss, or deterioration by environmental conditions such as temperature or humidity. These requirements are in accordance with applicable codes, standards, specifications, and manufacturer's recommendations. The procurement documents include, as applicable, the requirements for the following:

a. Cleaning and preparation of materials

b. Packaging container requirements

c. Identification and cautionary markings

d. Protection against weathering and corrosion

e. Environmental conditions for shipping and storage

f. Safe-handling requirements.

Plant section heads and supervisors are responsible for ensuring that safety-related items are handled, cleaned, stored, preserved, protected, packaged, and shipped by qualified individuals in accordance with specified codes, standards, and procedures. Procedures are established to control the storage (including shelf life) of chemicals, reagents, lubricants, and other consumable materials. Nuclear QA conducts audits to ensure that items are adequately protected and handled.

On receipt of materials and components, special requirements and protective environment, including inert-gas atmospheres, specific moisture content levels, and temperature levels, are verified and documented. During subsequent storage and before installation or use, these special requirements are maintained and will be verified by documented routine inspection in accordance with approved procedures.

Special handling equipment, cranes, and rigging are examined and tested as required by procedures before the handling of important or large items. Detailed handling instructions are prepared for items requiring special handling because of size, weight, susceptibility to shock damage, or importance. Nonconformances concerned with the handling, shipping, and storage of safety-related items will be controlled as described in Subsection 17.2.15.

17.2.14 Inspection, Test, and Operating Status

The QA program requires that contractors, suppliers, and onsite organizations indicate the inspection, test, and operating status of structures, components, systems, or parts of systems by a suitable means of identification and in the plant records. This prevents the inadvertent use of nonconforming, inoperative, or malfunctioning systems, structures, or components, and verifies that required inspections or tests have been performed.

Personnel safety and proper equipment operation are paramount in conducting inspections and tests associated with plant maintenance and operation. Written procedures describe the process for tagging and documenting the status of valves, breakers, and related controls for inspection, test, or maintenance.

Procedures describe methods for altering the sequence of required tests, inspections, and other operations important to safety so that appropriate reviews and approvals are performed.

The Technical Specifications establish the requirements for safety-related items necessary for the safe operation of the plant, including provisions for periodic and nonperiodic tests and inspections of various instruments, structures, components, systems, or parts of systems. Periodic tests may be operational tests or tests following maintenance; nonperiodic tests may be tests following repairs or modifications. The Technical Requirements Manual establishes requirements for fire protection items.

Schedules and methods for periodic testing of fire protection systems and components have been developed and documented. Fire protection equipment in support of nuclear safety related equipment areas is tested periodically to assure that the equipment will properly function and continue to meet the design criteria. Test results are documented, evaluated and reviewed for acceptability.

The Shift Manager is responsible for maintaining sufficient knowledge of the plant status and the status of tests or inspections in progress to ensure safe plant operation. The Shift Manager will ensure that personnel performing onsite tests or inspections keep him/her or the Licensed Nuclear Operator in charge of the main control room advised of the current status of tests or inspections in progress that could affect any safety-related activity.

Supply Chain, assisted by Procurement Engineering as needed, is responsible for correct status indication of equipment and material in storage.

Administrative procedures require that Nuclear QA review maintenance, modification, repair, special tests, and plant technical procedures for performing radwaste processing and shipping as specified by Nuclear QA. Other procedures are reviewed during audits and surveillances as appropriate. Nuclear QA keeps routinely informed of scheduled plant activities to ensure that they can plan to perform and document inspections and be prepared to review, monitor, or audit work and test activities and any critical operations to ensure compliance with specified requirements.

17.2.15 Nonconforming Material, Parts, or Components

Written procedures govern the discovery, identification, documentation, segregation, review, notification, and disposition of nonconforming conditions identified during maintenance and operation. Materials and equipment that deviate from approved specifications, codes, drawings, or other applicable documents are considered nonconforming items. Until proper disposition has been made, Supply Chain, assisted by Procurement Engineering as needed, is responsible for such items in storage being clearly identified with appropriate tags or other appropriate measures to indicate unacceptable status and segregated, if possible, to prevent inadvertent use or installation for maintenance or operation of the plant.

When nonconforming items are found or suspected, the items are controlled to preclude further activity pending resolution of the adverse condition. A nonconformance document is originated and processed to the organization responsible for determining cause and recommending corrective action. Nuclear QA is notified of the condition. The nonconformance document has provisions for identifying and describing the nonconforming item, the cause, when appropriate, proposed corrective action, and approval by responsible supervision, actual corrective action taken and acknowledgment by responsible supervisory personnel, and closeout action, including any required inspections or tests and acknowledgment by Nuclear QA.

Corrective action will be proposed by qualified organizations and approved by supervisory personnel having responsibility for dispositioning the nonconforming item.

Copies of completed nonconformance documents are maintained as described in Subsection 17.2.17.

The acceptability of rework, repair, or replacement of materials, parts, components, systems, and structures is verified by inspecting and testing the item for conformance with its original requirements or acceptable alternatives. The inspection and test records are documented and become part of the QA records for the item.

Nuclear QA periodically analyzes quality data obtained from the review of nonconformance documents including nonconformance documents issued as a result of inspection reports, surveillance reports, and audit reports. This analysis, including the determination of quality trends is reported to appropriate management and supervisory personnel for their review, assessment and appropriate action.

17.2.16 Corrective Action

Measures are established to ensure that conditions adverse to quality, such as failures, malfunctions, deficiencies, deviations, defective material and equipment, and nonconformances, are promptly identified and corrected. In the case of a significant condition adverse to quality or safety, procedures require that the cause be determined and corrective action be taken to preclude recurrence, and that the significant condition, its cause, and the corrective action be documented. Significant conditions affecting nuclear safety shall be reported to the Executive Director - Nuclear Production and the NSRG Chairman. Nuclear QA reviews all corrective action documents which delineate significant conditions adverse to quality or safety and some corrective action documents for other conditions adverse to quality to determine, when appropriate, that the root cause of the problem is identified and corrective action is adequate.

The QA requirements in procurement documents or contracts require the vendor or contractor not only to identify material or parts that do not conform to the procurement requirements, but also to determine and correct the causes for the condition adverse to quality.

When vendors furnish products that do not conform to the requirements of the applicable purchase contract, Nuclear QA conducts a reappraisal of the vendor's QA program when appropriate. Results of the reappraisal, together with a request for specific corrective actions, are transmitted to the vendor. If the vendor does not improve their QA program and products as requested, Nuclear QA may remove the vendor from the list of approved suppliers.

Licensing or the operating authority as appropriate is responsible for communications with the NRC Regional Office on reportable deficiencies for activities covered by the Nuclear QA program.

17.2.17 Quality Assurance Records

Copies of pertinent documentation, including available design, procurement, fabrication, inspection, deficiencies and corrective action, test, audit, and construction reports; reviews, material analysis, and monitoring of work performance; qualification of personnel, procedures, and equipment; drawings, specifications, calibration procedures, and reports; pertinent operating logs; maintenance and modification procedures and related inspection results; reportable occurrences; and other records required by Subsection 17.2.17.4 are available at the plant. Storage facility environmental conditions will be maintained to protect the records from deterioration. Redundant storage, where practical, is provided offsite to preclude the loss of records through fire, flood, or theft.

17.2.17.1 Plant Records

The Nuclear QA records and documents are filed and maintained by the Director – Strategic Business Operations, who is responsible for maintaining permanent records of the design documents developed during the plant operating, maintenance, and modification phases. These records will provide the historical reference necessary for maintenance, modification, and operation of the plant. Procedures define the necessary practices for the collection, storage, and maintenance of plant Nuclear QA records in accordance with the requirements of ANSI N45.2.9-1974, as endorsed by Regulatory Guide 1.88, and as addressed in Subsection A.1.88.

17.2.17.2 Support Organization Records

Support organizations that perform work for the plant in the areas of design, procurement, maintenance, modification, and testing will document such work and forward records to the Director – Strategic Business Operations for permanent filing and for ensuring that the records are identifiable and retrievable. Records for offsite support organizations are specified in procurement documents.

17.2.17.3 Vendor or Contractor QA Records

Vendors or contractors who exercise the option to retain QA records will comply with the following requirements:

a. Meet DTE's requirements on collection, storage, and maintenance of records

b. Make records available on demand for use by DTE or its agent

c. Inform DTE of any intent to dispose of QA records and permit DTE to take possession of records in accordance with agreed-upon terms.

17.2.17.4 Record Retention

17.2.17.4.1 Minimum Retention Periods

In addition to the applicable record retention requirements of Title 10, Code of Federal Regulations, the following records shall be retained for at least the minimum period indicated.

17.2.17.4.2 Record Retention - Five Years

The following records shall be retained for at least 5 years:

a. Records and logs of unit operation covering time interval at each power level,

b. Records and logs of principal maintenance activities, inspections, repair, and replacement of principal items of equipment related to nuclear safety,

c. All Reportable Events,

d. Records of surveillance activities, inspections, and calibrations required by the Technical Specifications,

e. Records of changes made to the procedures required by Technical Specification 5.4.1,

f. Records of sealed source and fission detector leak tests and results,

g. Records of annual physical inventory of all sealed source material of record.

17.2.17.4.3 Record Retention - Duration of Operating License

The following records shall be retained for the duration of the unit Operating License:

a. Records and drawing changes reflecting unit design modifications made to systems and equipment described in the Final Safety Analysis Report,

b. Records of new and irradiated fuel inventory, fuel transfers, and assembly burnup histories,

c. Records of doses received by all individuals for whom monitoring was required,

d. Records of gaseous and liquid radioactive material released to the environs,

e. Records of transient or operational cycles for those unit components identified in Technical Specification Table 5.5.5,

f. Records of reactor tests and experiments, if applicable.

g. Records of training and qualification for current members of the unit staff,

h. Records of inservice inspections performed pursuant to the Technical Specifications,

i. Records of quality assurance activities required by ANSI N45.2.9-1974.

j. Records of reviews performed for changes made to procedures or equipment or reviews of tests and experiments pursuant to 10 CFR 50.59,

k. Records of meetings of the OSRO and NSRG,

l. Records of the service lives of all hydraulic and mechanical snubbers required by Technical Requirements Manual Sections 3.7.9 and 5.1 including the date at which the service life commences and associated installation and maintenance records,

m. Records of analyses required by the radiological environmental monitoring program that would permit evaluation of the accuracy of the analysis at a later date. This should include procedures effective at specified times and QA records showing that these procedures were followed,

n. Records of reviews performed for changes to the Offsite Dose Calculation Manual and Process Control Program,

o. Records of radioactive shipments.

17.2.18 Audits

Within DTE, the implementation of a comprehensive system of planned and periodic audits is the responsibility of Nuclear QA.

Nuclear QA provides a direct audit function of the implementation of the QA program. These audits are performed to verify compliance with all aspects of the QA program, including audits of vendors and service contractors.

17.2.18.1 Audit Personnel

Audit personnel are qualified in accordance with ANSI N45.2.23-1978 and Regulatory Guide 1.146 (August-1980) and are provided appropriate training to ensure that they are competent to perform the required audits. The proficiency of audit personnel is maintained by active participation in the audit process and/or by participation in training or orientation programs.

Audits and evaluations of selected subjects may be conducted by using technical specialists from outside the NQA organization. Technical specialists, who occasionally serve as audit team members, will receive indoctrination and/or training appropriate for the audit function performed.

17.2.18.2 Vendor and Service Contractor Audits

Nuclear QA, supported by technical specialists when appropriate, performs audits, source verification, and commercial grade surveys of vendors and service contractors to verify and evaluate their QA programs, procedures, and/or activities, to ensure that they are meaningful and are effectively complying with all aspects of the QA program and procurement requirements. Nuclear QA also verifies that the vendors and contractors review and audit the QA programs of their suppliers as required.

Nuclear QA performs audits or surveillances of special-purpose inspections, such as inservice inspections, performed by contractors to ensure that the inspection work is being properly performed.

Audits are conducted in accordance with established procedures and by personnel having no direct responsibilities in the areas being audited. Audits, source verifications, and commercial grade surveys performed by other nuclear utilities may be accepted as satisfying DTE's criteria based on a documented evaluation of the report. Evaluation may be performed and documented by another utility provided that an agreement has been established that DTE’s scope of supply will be included. The results of the evaluation will be provided to DTE.

Source verification (surveillance or source surveillance) shall be commensurate with the relative importance, complexity, and quantity of the items or service procured and the vendor’s quality performance. In-process and final surveillance requirements of vendor products shall be determined in advance and performed to assure conformance with procurement document requirements. Remote source surveillance is allowed as an adequate dedication or acceptance process when a pandemic or similar state of emergency has been declared restricting access or travel to and/or from vendor locations affected by the declaration. The remote source surveillance will be in accordance with EPRI’s April 2020

Final Report 3002019436, “Remote Source Verification During a Pandemic or Similar State of Emergency: Screening Criteria and Process Guidance” to screen for eligibility, plan, perform using real time video, and document.

When purchasing commercial grade calibration or testing services from a laboratory holding accreditation by an Accreditation Body (AB) which is a signatory to the International Laboratory Accreditation Cooperation (ILAC) Mutual Recognition Arrangement (MRA), commercial grade surveys need not be performed provided each of the conditions in the following list are met. The ILAC accreditation process cannot be used as part of the commercial grade dedication process of Nondestructive Examination (NDE) or Nondestructive Testing (NDT) services in lieu of performing a commercial grade survey.

1. A documented review of the supplier’s accreditation is performed and includes a verification of the following:
    a) The calibration or test laboratory holds accreditation by an accrediting body recognized by the ILAC MRA. The accreditation encompasses ISO/IEC-17025:2017, “General Requirements for the Competence of Testing and Calibration Laboratories.”
    b) For procurement of calibration services, the published scope of accreditation for the calibration laboratory covers the needed measurement parameters, ranges, and uncertainties.
    c) For procurement of testing services, the published scope of accreditation for the test laboratory covers the needed testing services including test methodology and tolerances/uncertainties.
    d) The laboratory has achieved accreditation based on an on-site accreditation assessment by the selected AB within the past 48 months. The laboratory’s accreditation cannot be based on two consecutive remote accreditation assessments.
2. It is validated, at receipt inspection, that the laboratory’s documentation certifies that:
    a) The contracted calibration or test service has been performed in accordance with their ISO/IEC-17025:2017 program, and has been performed within their scope of accreditation.
    b) The purchase order’s requirements are met.

Audit results are reported to the Manager - Nuclear Quality Assurance, the management of the organization audited, and the affected DTE organizations. DTE requires written reports from each organization on the measures taken to correct deficiencies and prevent recurrence. Appropriate follow-up, including reaudits, is made to determine that nonconformances are effectively corrected and that the corrective action precludes repetitive occurrences.

17.2.18.3 Nuclear Generation Audits

Nuclear QA is responsible for independent audits of Nuclear Generation unit activities to verify compliance with the QA program and to assess its effectiveness. The activities audited include those described in the governing procedures that apply to the plant and onsite support organizations.

Copies of the audit report are distributed to appropriate Nuclear Generation management, including the CNO, the Site Vice President - Nuclear Generation, Vice President – Engineering and Technical Support, the Manager - Nuclear Quality Assurance and affected organizations. The NSRG receives a copy of reports of audits for which the NSRG has responsibility to review.

If a condition adverse to quality is discovered that may affect the safe operation of the plant, it will be brought to the attention of the Executive Director - Nuclear Production, in accordance with Subsection 17.2.16. After an audit of an organization has been completed, the appropriate Nuclear Generation manager is responsible for a written report of the corrective action taken in response to any nonconforming conditions identified in the audit report. Appropriate follow-up by Nuclear QA, including reaudits, is made to determine that significant conditions adverse to quality and selected nonsignificant conditions adverse to quality are effectively corrected and that corrective action precludes repetitive occurrences. Other nonsignificant conditions adverse to quality identified during audits are followed up during the next audit of the activity.

Nuclear QA will verify that the correct revisions of procedures, drawings, and other documents are being used when performing an activity affecting quality. This will be accomplished during inspections, surveillances, and audits.

17.2.18.4 Nuclear Safety Review Group

The NSRG is responsible for review as specified in Subsections 17.2.1.3.2.7 and 17.2.1.3.2.8. In addition to these activities, the NSRG will review such other activities as have been established in its charter.

17.2.18.5 Scope and Schedule of Audits

The scope and schedule of audits to be performed will be established by Nuclear QA in coordination with the responsible organizations in accordance with the requirements of the Nuclear QA program. Audit schedules will indicate the activity to be audited and the minimum frequency, and will assign the primary responsibility for the performance of the audit. The audit schedule will be reviewed and revised periodically by Nuclear QA in coordination with the responsible organizations to make certain that coverage and schedule reflect current activities.

A prominent factor in developing and revising audit schedules will be performance in the subject area. The audit schedule will be revised so that weak or declining areas get increased audit or surveillance coverage and strong areas receive less coverage. A maximum interval is set to ensure that all areas receive periodic audit coverage.

Audit schedules shall be based on the month in which the audit starts. For audits scheduled once per 24 months, a 25% grace period beyond the original 24-month completion date may be applied. The maximum time between specific 24-month audits shall not exceed 30 months. Likewise, audits on an annual (12 month) frequency shall not exceed 15 months, except for audit frequencies defined by regulation such as the Emergency and Security plans where the audit intervals are defined and use of extension periods is not allowed.

When an audit interval extension greater than one month is used, the next audit for that particular audit area will be scheduled from the original anniversary month rather than the month of the extended audit.

The following internal Nuclear generation areas will be audited at least once per 24 months, except where a specific frequency is specified by regulation:

a. The conformance of unit operation to provisions contained within the Technical Specifications and applicable license conditions.

b. The performance, training and qualifications of the entire unit staff.

c. The results of actions taken to correct deficiencies occurring in unit equipment, structures, systems, or method of operation that affect nuclear safety at least once per 12 months.

d. The performance of activities required by the Operational Quality Assurance Program to meet the criteria of Appendix B, 10CFR Part 50.

e. The fire protection programmatic controls including the implementing procedures by qualified licensee QA personnel.

f. The fire protection equipment and program implementation, utilizing either a qualified offsite licensee fire protection engineer(s) or an outside independent fire protection consultant. An outside independent consultant should have the qualification for membership in the Society of Fire Protection Engineers as the grade of member; an equivalency of an experienced Fire Protection Engineer not employed by the licensee. An outside independent fire protection consultant shall be utilized at least every third year.

g. Any other area of unit operation considered appropriate by the Nuclear Safety Review Group, the CNO or the Site Vice President-Nuclear Generation.

h. The radiological environmental monitoring program and the results thereof.

i. The OFFSITE DOSE CALCULATION MANUAL and implementing procedures.

j. The PROCESS CONTROL PROGRAM and implementing procedures for processing and packaging of radioactive wastes.

k. The performance of activities required by the Quality Assurance Program to meet the provisions of Regulatory Guide 1.21, Revision 1, June 1974 and Regulatory Guide 4.1, Revision 1, April 1975. (Radioactive Effluents and Environmental Monitoring)

l. The Safeguards Contingency Plan and Security Program (as specified by regulation, and the 25% grace period does not apply).

m. Access Authorization (as specified by regulation).

n. Fitness for Duty (as specified by regulation).

o. Emergency Preparedness (as specified by regulation, and the 25% grace period does not apply).

p. Radiological Protection (as specified by regulation).

q. Fitness for Duty Laboratory.

r. Station Blackout.

s. Nonradiological Environmental Protection Program.

t. Independent Spent Fuel Storage Installation (ISFSI)

Audits are initiated as early as practicable in the life of the activity, consistent with the schedule for accomplishing the activity, to ensure the timely implementation of QA requirements. Audit scope and schedules are established based on the status and importance of the activities performed to ensure the adequacy of, and conformance with, the Nuclear QA program.

Regularly scheduled audits are supplemented by audits for one or more of the following conditions:

a. When it is necessary to assess the capability of a contractor's QA program before awarding a contract or purchase order

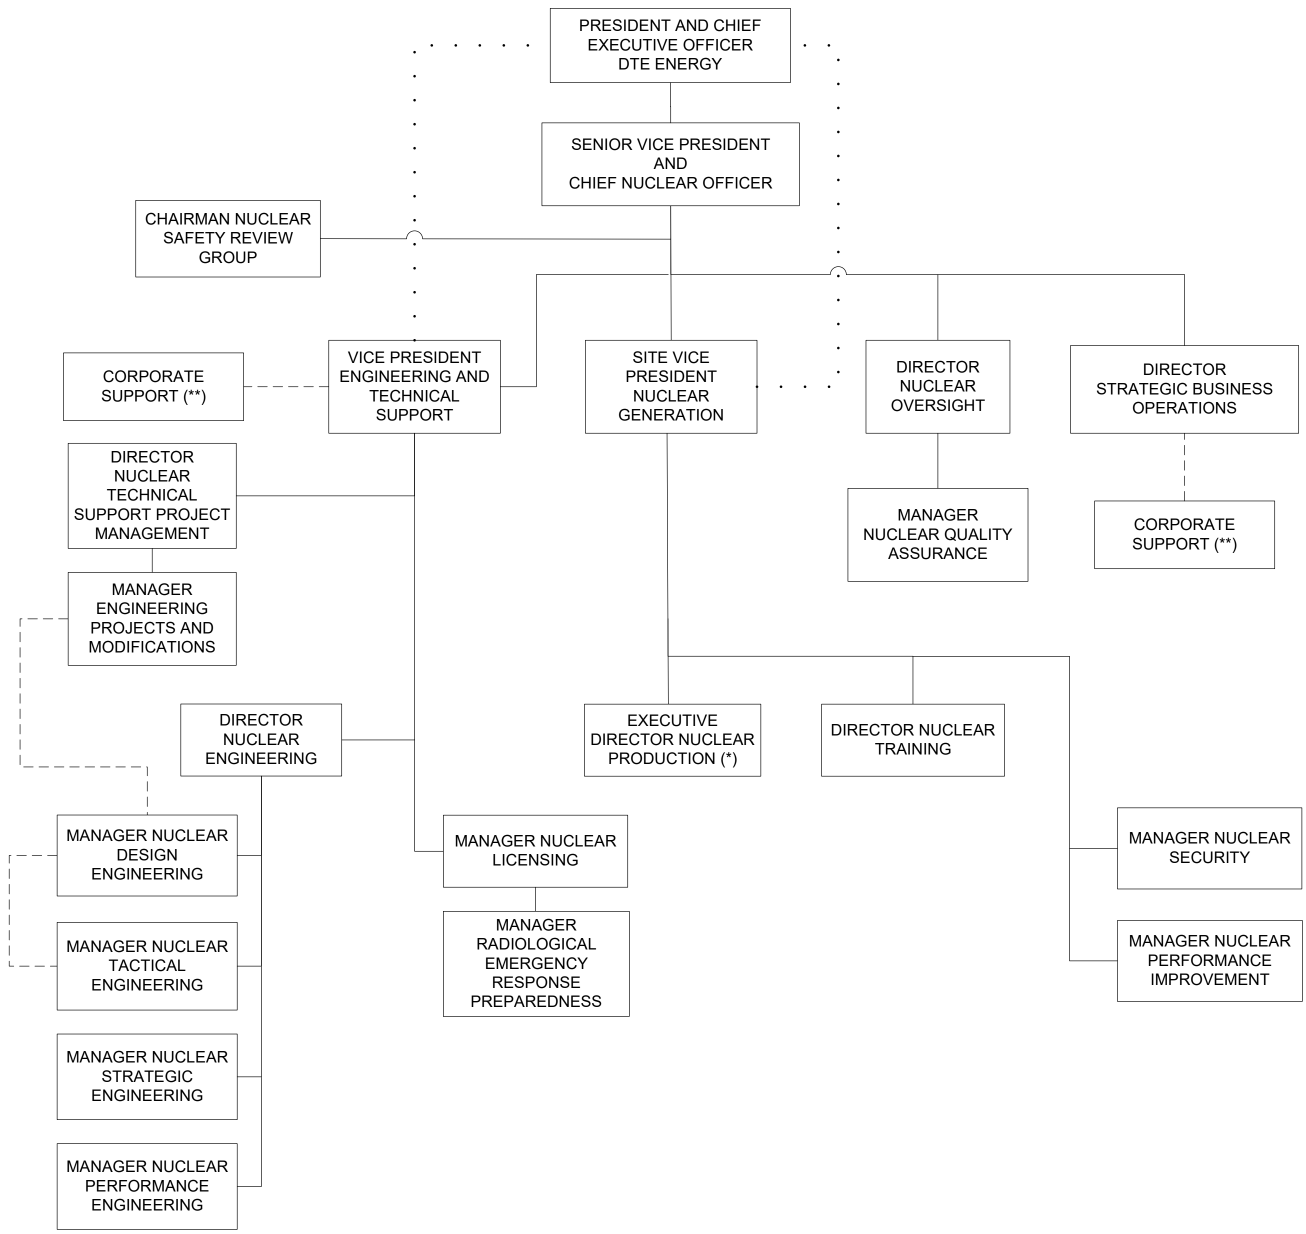
b. When, after the award of a contract, sufficient time has elapsed for implementing the QA program and it is appropriate to determine that the organization is adequately performing the functions as defined in the quality assurance program, codes, standards, and other contract documents

c. When significant changes are made in functional areas of the QA program, such as significant reorganization or procedure revisions

d. When it is suspected that the quality of the item is in jeopardy because of deficiencies in the QA program.

e. When a systematic, independent assessment of program effectiveness is considered necessary

f. When necessary to verify implementation of required corrective action.



. . . . . . Signifies Direct Access

\- - - - - - Signifies Functional Relationship

(*) For details of the Nuclear Production organization, see Figures 13.1-2 and 13.1-3.

(**) When corporate support organizations perform quality-related activities for Fermi 2, such activities are performed under the Fermi 2 Quality Assurance Program.

NOTE: When a position is not filled, reporting order will be the next higher position.

Fermi 2
UPDATED FINAL SAFETY ANALYSIS REPORT

FIGURE 17.2-1
CORPORATE/NUCLEAR GENERATION ORGANIZATION INVOLVED IN THE QUALITY ASSURANCE PROGRAM FOR OPERATION

17.2A QUALITY ASSURANCE OF THE INDEPENDENT SPENT FUELSTORAGE INSTALLATION

This Appendix describes the administrative controls and the quality assurance (QA) program applied to important-to-safety (ITS) structures, systems and components associated with the Fermi 2 Nuclear Plant Independent Spent Fuel Storage Installation (ISFSI) to assure conformance to regulatory requirements and the design bases. This program is an extension of the quality assurance program described in Section 17.2, modified to address 10 CFR 72 Subpart G items specific to ISFSI and related support activities.

The QA program described in Section 17.2 is applicable to ISFSI items classified as ITS Category A. Specific aspects of the QA program are applied to ITS Categories B and C items as specified in the individual subsections.

The following definitions are applicable to the Fermi 2 Nuclear Plant Quality Assurance Program:

ITS structures, systems, and components are those features of ISFSI whose function is to:

a. Maintain the conditions required to store spent fuel safely,

b. Prevent damage to the spent fuel container during handling, or storage, or

c. Provide reasonable assurance that spent fuel can be received, handled, packaged, stored, and retrieved without undue risk to the health and safety of the public.

The definition of ITS safety categories below are based on NUREG/CR-6407, "Classification of Transportation Packaging and Dry Spent Fuel Storage System Components According to Importance to Safety."

1. Category A – ITS Category A items include structures, components, and systems whose failure could directly result in a condition adversely affecting public health and safety. The failure of a single item could cause loss of primary containment leading to release of radioactive material, loss of shielding, or unsafe geometry compromising criticality control.
2. Category B - ITS Category B items include structures, components, and systems whose failure or malfunction could indirectly result in a condition adversely affecting public health and safety. The failure of a Category B item, in conjunction with failure of an additional item, could result in an unsafe condition.
3. Category C – ITS Category C items include structures, components, and systems whose failure or malfunction would not significantly reduce the packaging effectiveness and would not be likely to create a situation adversely affecting public health and safety.

The QA program, as described in the following identified UFSAR subsections, is applied to ITS Category A, B, and C items unless modified by the description below:

17.2.1 Organization

The corporate organization established to support operation of Fermi 2 Nuclear Plant also functions to support operation of the Fermi 2 Nuclear Plant ISFSI.

Additional offsite support is provided by the storage system vendor.

Some plant personnel who perform 10 CFR 50.59 evaluation reviews also perform the corresponding ISFSI evaluation reviews under 10 CFR 72.48.

17.2.2 Nuclear Quality Assurance Program

QA program requirements are applied to the ISFSI and support structures, systems, and components using a graded approach based on the ISFSI item classification. The program requirements that apply to QA ITS Category A, B and C are identified in table 17.2A-1. Items identified as not important to safety (NITS) are excluded from the QA program.

The plant organization has the same responsibilities as described in paragraph 17.2.1.3 and subsection 17.2.2 for ITS Category A items.

17.2.3 Design Control

Design control measures for ITS Category A and Category B items are applied where appropriate per the controls in subsection 17.2.3. Additional review concerns that are specific to the ISFSI are criticality physics, shielding, and features to facilitate decontamination.

The designs of ITS Category C items specify procurement, inspection, and testing at a level appropriate for the importance of the function performed.

17.2.4 Procurement Document Control

A graded approach is applied through the use of a multi-level procurement classification system based upon the end-use of each item or service. Items procured as ITS Category A items are controlled as described in subsection 17.2.4. ITS Category A items procured as commercial grade are controlled by the existing commercial grade dedication program. ITS Categories B or C items are procured as appropriate for function and safety importance, and are excluded from the provisions of 10 CFR 21.

17.2.5 Instructions, Procedures, and Drawings

17.2.6 Document Control

17.2.7 Control of Purchased Material, Equipment, and Service. (CAT A)

17.2.8 Identification and Control of Materials, Parts, and Components. (CAT A)

17.2.9 Control of Specific Processes. (CAT A & B)

17.2.10 Inspection. (CAT A & B)

17.2.11 Test Control. (CAT A & B)

17.2.12 Control of Measuring and Test Equipment. (CAT A & B)

17.2.13 Handling, Shipping , and Storage, (CAT A)

17.2.14 Inspection, Test, and Operating Status. (CAT A)

17.2.15 Nonconforming Material, Parts, and Components. (CAT A & B)

17.2.16 Corrective Action

17.2.17 QA Records

Records pertaining to design, fabrication, erection, testing, maintenance, and use of ITS items are maintained for the duration of the General License granted under Subpart K of 10 CFR 72 for the specific storage system.

17.2.18 Audits

Audits are performed on a frequency not to exceed 24 months for quality activities related to the operation and maintenance of the ISFSI.

Regarding ISFSI the QA program, as described in the following identified UFSAR subsections, is applied to only ITS Category A and B items as follows.

A.1 DIVISION 1 APPLICABLE REGULATORY GUIDES

A.1.1 REGULATORY GUIDE 1.1 (November 1970), NET POSITIVE SUCTION HEAD FOR EMERGENCY CORE COOLING AND CONTAINMENT HEAT REMOVAL SYSTEM PUMPS

Fermi 2 conforms to the regulatory position in this guide. The net positive suction head (NPSH) margin has been adequately established as being conservative.

The analysis establishing the adequacy of the NPSH margin is found in response to Question 2.8.3f of Amendment 17 to the Fermi 2 FSAR.

For details refer to Subsection 6.3.2.14.

A.1.2 REGULATORY GUIDE 1.2 (November 1970), THERMAL SHOCK TO REACTOR PRESSURE VESSELS

The reactor pressure vessel (RPV) of the Fermi 2 plant will behave in a nonbrittle manner under loss-of-coolant conditions. This position is based on NEDO-10029, "An Analytical Study on Brittle Fracture of GE-BWR Vessel Subject to the Design Basis Accident."

For details refer to Subsection 5.4.4.

A.1.3 REGULATORY GUIDE 1.3 (June 1974, Revision 2), ASSUMPTIONS USED FOR EVALUATING THE POTENTIAL RADIOLOGICAL CONSEQUENCES OF A LOSS OF COOLANT ACCIDENT FOR BOILING WATER REACTORS

Regulatory Guide 1.3 is no longer the basis for Fermi 2 Loss of Coolant Accident radiological consequence analysis. Alternative Source Term (AST) analysis per Regulatory Guide 1.183 has replaced the original Regulatory Guide 1.3 based analysis and discussed in Section 15.6.5 and 15.7.4.

A.1.4 REGULATORY GUIDE 1.4 (June 1974, Revision 2), ASSUMPTIONS USED FOR EVALUATING THE POTENTIAL RADIOLOGICAL CONSEQUENCES OF A LOSS OF COOLANT ACCIDENT FOR PRESSURIZED WATER REACTORS

Regulatory Guide 1.4 does not apply to Fermi 2, which is a BWR.

A.1.5 REGULATORY GUIDE 1.5 (March 1971), ASSUMPTIONS USED FOR EVALUATING THE POTENTIAL RADIOLOGICAL CONSEQUENCES OF A STEAM LINE BREAK ACCIDENT FOR BOILING WATER REACTORS

The analyses of the effects of a steam line break accident are discussed in Subsection 15.6.4. The analysis is in conformance with the regulatory position of this guide.

A.1.6 REGULATORY GUIDE 1.6 (March 1971), INDEPENDENCE BETWEEN REDUNDANT STANDBY (ONSITE) POWER SOURCES AND BETWEEN THEIR DISTRIBUTION SYSTEMS

To provide the assurance of protection from releases of radioactivity by maintenance of fission product barrier integrity under accident conditions, the electrical power supply system to the emergency core cooling systems and operational reactor coolant pressure boundary (RCPB) protection systems must be sufficient in capacity and redundancy to supply service to vital functions at all times from onsite power. In addition, General Design Criterion (GDC) 17 of Appendix A to 10 CFR 50 requires sufficient independence and testability of the onsite electrical power system to perform under single-failure conditions.

The Fermi 2 plant onsite power system consists of four emergency diesel generator (EDG) units separated into two divisions. Each division containing two EDGs will supply power to its own radial load. The capacity of each division (two EDGs; 2850 kW/unit) and required capacities and preoperational design loads are listed in the tables of Subsection 8.3.1.1.8.1. Either divisional pair of diesel generator units will be capable of supplying loads needed for safe reactor shutdown as Position 1 of the guide requires.

To comply with Position 2, each division is connected to an independent offsite power source; Division I through transformers to the 120-kV electrical system grid and Division II through the 345-kV grid.

Fermi 2 has identified the residual heat removal (RHR) system as vital to the protection of the fission product barrier. This system does not comply with Position 1 of the guide. The RHR electrical system automatically transfers loads between divisions (if necessary) during a LOCA. Due to the special nature of the above automatic transfer, all feeds to and from the motor control center (MCC) are run exclusively in conduit in order to maintain divisional integrity.

Position 3 of the guide specifies that dc load groups have battery and battery chargers to energize them. The Fermi 2 dc systems consist of two loads. Within each division are two 130- V dc control batteries in series, thus producing 260-V dc emergency power feed capacity. To provide independence of battery and charger combinations, the system incorporated into the dc system has a charger for each 130-V dc battery and one standby battery charger per division. In conjunction, the dc instrument system consists of one 48/24-V battery per division with two 24-V dc chargers per division and a standby charger. As a result, the battery and charger system combination relies on no automatic connections to other redundant dc loads.

No automatic load transfers are to be performed with the exception of certain RHR-related loads as noted above. There do exist manually operated electrical and physical interlocked maintenance ties between the two ac power supply divisions. During operating conditions, both breakers at each end of the ties are kept open and racked out of their operating position. In compliance with Position 4, this interlock arrangement prevents operator inadvertent error, which might imperil standby power source availability.

The Fermi 2 design uses two divisions of ac sources each with redundant motor-generator sets, i.e., two EDGs per division. This redundancy ensures reliability and satisfies the need for protection against common-mode failures and single failures required in Position 5.

For additional information, refer to Subsections 8.3.1.1.4 and 8.3.1.1.8.1.

A.1.7 REGULATORY GUIDE 1.7 (March 2004, Revision 3), CONTROL OF COMBUSTIBLE GAS CONCENTRATIONS IN CONTAINMENT

Fermi 2 originally complied with the guidance in Regulatory Guide 1.7, Revision 2. The NRC amended 10 CFR 50.44, "Standards for combustible gas control system in lightwater-cooled power reactors" on October 16, 2003 to eliminate the requirements for hydrogen recombiners. The hydrogen recombiner Technical Specification requirements were subsequently removed by License Amendment 159, dated March 15, 2004. Regulatory Guide 1.7, Revision 3, was issued in March 2007 to reflect the amended 10 CFR 50.44.

Fermi 2 complies with guidance set forth in this regulatory guide.

As it is no longer required for compliance with tis regulatory guide, the Combustible Gas Control System (CGCS) has been retired in place with its electrical circuits de-energized and fluid process piping isolated from primary containment with redundant locked-closed isolation valves as described in Subsection 6.2.5. Combustible gas control of the primary containment is provided by inerting the primary containment with nitrogen, see Section 9.3.6. For descriptions of the hydrogen/oxygen monitoring system, see Subsection 7.6.1.

A.1.8 REGULATORY GUIDE 1.8 (September 1975, Revision 1), PERSONNEL QUALIFICATION AND TRAINING

With regard to Revision 1 to Regulatory Guide 1.8 (September 1975), Fermi 2 is in conformance.

A.1.9 REGULATORY GUIDE 1.9 (December 1979, Revision 2), SELECTION, DESIGN, AND QUALIFICATION OF DIESEL GENERATOR UNITS USED AS STANDBY (ONSITE) ELECTRICAL POWER SYSTEMS AT NUCLEAR POWER PLANTS

The guidelines presented in Regulatory Guide 1.9, Revision 2, apply to nuclear power plants whose construction permit applications were docketed after December 1979. Because the application for Fermi 2 was docketed in 1969, the revised versions of the guidelines do not apply to Fermi 2.

The EDGs for Fermi 2 are acceptable as discussed on page 31 of the AEC Staff Safety Evaluation Report of May 17, 1971. The Fermi 2 design conforms to the regulatory guide positions except those in paragraphs C.4, C.5, C.7, C.9, and C.11 of Regulatory Guide 1.9 (December 1979, Revision 2). Exceptions taken to Positions C.4, C.5, C.7, C.9, and C.11 are described below, along with Edison's compliance with Position C.14.

Exception To Position C.4

Preoperational tests have validated the starting and load- accepting capability of the EDGs. Minor deviations from the Regulatory Guide recommendations are noted below but they do not impair the ability of the EDGs to perform their design functions.

System analyses performed by Colt and Detroit Edison produced results close to the recommended limit of 75% in this position. As a result, pre-operational testing was utilized to ensure successful operation in lieu of analytical comparison to the 75% limit. The pre-operational test results, shown in Table 8.3-8, identified that the first voltage dip associated with the RHR pump start did decrease below 75%, but subsequent voltage dips, such as for the CS pump start, did not. The original excitation systems (Portec) were replaced with new excitation systems (Basler). System analysis by Coltec with the new excitation systems predicted voltage dips below 75% for the RHR pump start. Testing performed during refueling outages since the replacement has shown that voltage dips associated with the RHR pump start have sometimes been below the 75% value of this position as well as below those from the pre-operational test results. Similarly, testing has shown that the voltage dip associated with the CS pump start has at times decreased below 75%. The continued successful testing during refueling outages with the identified voltage dips ensures the adequacy of the EDG performance during large-motor starting transients even when voltage dips below the 75% value associated with this position. Voltage dips, while not an acceptance criteria of the testing, are monitored to identify potential for EDG or other equipment degradation. Revision 2 to Regulatory Guide 1.9 maintains the same voltage dip limits of 75 percent and a frequency limit of 95 percent as did Revision 1.

The recovery time of the original regulatory guide was relaxed somewhat in Revision 1. The original regulatory guide required voltage recovery to 10 percent of nominal and frequency to 2 percent of nominal within 45 percent of each load sequence. The revised regulatory guide now allows the recovery in 60 percent of each load sequence. Preoperational test results showed that all loading frequencies, with the exception of the RHR pumps (Table 8.3-8), were within the allowed recovery times.

Fermi 2 is also in compliance with the overspeed trip requirements of this position.

<u>Exception To Position C.5</u>

The Fermi 2 EDGs were purchased to meet IEEE 323-1971, which was acceptable when they were purchased in February 1973.

<u>Exception To Position C.7</u>

Fermi 2 meets most of the requirements of this position. The EDG protective trips are automatically bypassed (except for overspeed and generator differential, in accordance with Position C.7). In addition, the crankcase overpressure and low lube-oil pressure trips, although not bypassed, require coincidental signals to trip, again in accordance with Position C.7. Fermi 2 also has a start failure relay trip which, during the startup of the unit, does not require coincidental signals to trip. (Once the unit is up to speed, two speed contacts bypass the relay.) This approach, as presented in Subsection 8.3.1.1.12.2 and Table 8.3-12 is in compliance with EICSB 17 of the Standard Review Plan (SRP) and was found acceptable in the interim safety evaluation report, NUREG-0314.

The bypass circuits are initiated by either relay ESA or ESB, such that a single failure will not prevent a bypass of the trips.

The bypass function is testable and the emergency mode operation of the EDG is annunciated in the main control room. Any trip that is bypassed will still annunciate in the control room. Fermi 2 does not have manual reset of the trip bypass but the trip bypass automatically resets when the emergency start signals are picked up.

<u>Exception To Position C.9</u>

This position suggests the use of the 1975 version of IEEE 344 for the seismic qualification program. The Fermi 2 seismic qualification followed the 1971 version of IEEE 344, which was current when the equipment was purchased in February 1973.

Exception To Position C.11

Position C.11 suggests that the EDG site-acceptance tests and periodic tests conform with Sections 6.5 and 6.6 of IEEE 387-1977 and be supplemented by Regulatory Guide 1.108. The Fermi 2 EDGs were tested to the performance requirements of Regulatory Guide 1.108, but not necessarily all of the requirements of IEEE 387-1977.

Position C.13

Position C.13 is not applicable to Fermi 2.

Compliance With Position C.14

The Fermi 2 preoperational test procedures were developed to meet Regulatory Guide 1.108, Revision 1. Regulatory Guide 1.108, Section C.2.a.(3), requires a demonstration run of 22 hr at the continuous rating (2850 kW) and 2 hr at the 2-hr rating (3135 kW). Position C.14 in Regulatory Guide 1.9 is basically the same requirement as Regulatory Guide 1.108 except that the test sequence is different and must be continuous. Regulatory Guide 1.9 now calls for a warm-up run at the continuous rating until equilibrium temperatures are reached, then a 2-hr run at the 2-hr load and a subsequent 22-hr run at the continuous rating. Since this position reflects the current NRC position, Edison has run the preoperational test in accordance with Position C.14.

A.1.10 REGULATORY GUIDE 1.10 (January 1973, Revision 1), MECHANICAL (CADWELD) SPLICES IN REINFORCING BARS OF SEISMIC CATEGORY I CONCRETE STRUCTURES

The Fermi 2 procedures are in conformance with the overall objectives and intent in Regulatory Guide 1.10. A minor exception to the detailed practices set forth in the guide is that the Fermi 2 procedures require (1) each splice operator to be qualified by at least one test splice at each anticipated splice position and (2) a test program similar in quality to the one which is specified in the guide. However, it relies heavily on the use of companion or "sister" splicing, rather than "production" splice testing, to qualify the production splices. The procedure requires production testing in the event of companion test failures.

For details refer to Subsection 3.8.4.6.6.

This Regulatory Guide has since been withdrawn (as of July 1981).

A.1.11 REGULATORY GUIDE 1.11 (Supplement, February 1972), INSTRUMENT LINES PENETRATING PRIMARY REACTOR CONTAINMENT

The design of Fermi 2 satisfies GDC 55 and 56 of 10 CFR 50, Appendix A, as well as Regulatory Guide 1.11 and the Supplement to this regulatory guide issued in February 1972. By the use of a single automated excess flow check valve and shutoff valve external to the primary containment wall and a flow restriction orifice, internal to the primary containment wall, the isolation of the penetration line ports takes place. Normally open, the excess flow check valves close automatically and indicate the actuation on the control room panel on occurrence of a line break. These "N" stamp valves are designed to conservative requirements for seismic testing and close with a 2.5-gpm maximum reverse flow rate. Design operating pressure is 1250 psig at 575°F.

For design details refer to Subsection 6.2.4.2.5.

A.1.12 REGULATORY GUIDE 1.12 (April 1974, Revision 1), INSTRUMENTATION FOR EARTHQUAKES

The seismic instrumentation program described in Subsection 3.7.4 meets the intent of Regulatory Guide 1.12, Revision 1. The system conceived and designed for the Fermi facility was documented in January of 1972, prior to the issuance of Regulatory Guide 1.12. In June 1975, the Fermi project reviewed this earthquake recording system for compliance with the requirements of Regulatory Guide 1.12, Revision 1, and concluded that the intent of the requirements was satisfied. In May 1996, the recording system was upgraded with a digital recorder. The upgrade was reviewed for compliance with the requirements of Regulatory Guide 1.12, Revision 1, and concluded that the intent of the requirements was satisfied.

The Fermi 2 earthquake recording system does not contain a triaxial seismic switch, a triaxial response spectrum switch, or any triaxial peak accelerographs. The intent of the Regulatory Guide requirements for this equipment is fulfilled, however, by installed triaxial active time history accelerographs and passive response spectra recorders.

A seismic trigger set at 1/8 of the horizontal operating-basis earthquake (OBE) zero period acceleration level indicates to control room personnel that a seismic event has occurred. Active on-line playback apparatus and extracted triaxial response spectra data provide information allowing a decision to be made expeditiously regarding facility shutdown.

High frequency acceleration data from the 18 response spectrum recorders at the Fermi facility provides significant peak acceleration information for representative reactor equipment, reactor piping, and other Category I equipment and Category I facility structures.

A.1.13 REGULATORY GUIDE 1.13 (December 1975, Revision 1), FUEL STORAGE FACILITY DESIGN BASIS

The design of the Fermi 2 fuel storage facility does not conform fully to certain regulatory positions in this guide. Edison has incorporated alternative solutions to ensure that the design of this facility is adequate. The Fermi 2 reactor building crane meets single-failure criteria and is therefore acceptable by the revised (Revision 1) guide. The design basis of the facility versus the regulatory positions is discussed below.

Edison has done a very careful analysis of the probability of a missile generated by cyclonic winds damaging the pool or the fuel. The results of the study show that in view of the extremely low probability of a tornado-borne missile damaging fuel, neither the added complexity to plant operation nor the cost of a fuel pool cover is warranted. Based on its own independent assessment (AEC letter of June 11, 1974, W. R. Butler (AEC) to H. Tauber (Edison)), the AEC waived the requirement to provide tornado protection of the spent fuel pool on the basis of the low probability of a tornado, the lower likelihood that objects could be lifted to the elevation of the fuel pool and become missiles, and the expectation that where spent fuel damage were to occur, the associated offsite exposure radiological consequences would be likely within 10CFR100 limits.

The reactor building crane is designed to standards of complete redundancy of fail-safe systems. Hooks, cables, brakes, and motors are redundant; drums are fail-safe. Edison takes the position that this solution is superior to the area-interlock method suggested in the regulatory guide. The reactor building crane is described in Subsection 9.1.4.2.2.

Coolant can be added to the pool from the condensate storage tanks (up to 100 gpm), or from the RHR system. The RHR system, including storage, and the cross-tie piping between the RHR system and the fuel pool diffusers, are designed to Category I requirements.

The justification for the design for fuel pool makeup is as follows: the pool, which is a Category I structure, incorporates a very high integrity stainless steel liner; therefore, a large leak is very unlikely. Consequently, the time from initiation of the low-level alarm until the water reaches the top of the fuel is in units of hours. Should the fill line be unusable at this time, numerous alternatives are available to get water into the pool, such as the use of the fire-fighting system or connection of a fire hose to the RHR system. These alternatives can be employed within the time available.

The fuel storage facility is described in Subsections 3.1.2.6, 9.1.1.1, 9.1.2.1, 9.1.3.1, and 9.1.4.1.

A.1.14 REGULATORY GUIDE 1.14 (August 1975, Revision 1), REACTOR COOLANT PUMP FLYWHEEL INTEGRITY

Regulatory Guide 1.14 does not apply to Fermi 2 since BWRs do not use reactor coolant pumps and BWR reactor recirculation coolant pump motors do not have inertia flywheels.

A.1.15 REGULATORY GUIDE 1.15 (December 1972, Revision 1), TESTING OF REINFORCING BARS FOR SEISMIC CATEGORY I CONCRETE STRUCTURES

Fermi 2 is in conformance with the guide except for a departure relating to the requirement to test one bar for each bar size from every 50 tons or fraction thereof from each heat. Edison Specification No. 3071-16, "Concrete Reinforcement," requires that the reinforcing steel conform to ASTM A 615-72, which requires bar testing on a "per heat" basis without regard to heat tonnage.

This Regulatory Guide has since been withdrawn (as of July 1981).

A.1.17 REGULATORY GUIDE 1.17 (June 1973), PROTECTION OF NUCLEAR POWER PLANTS AGAINST INDUSTRIAL SABOTAGE

The Fermi 2 Physical Security Plan is not designed to conform specifically to Regulatory Guide 1.17.

The Fermi 2 Physical Security Plan conforms to 10 CFR 73, Section 73.55, "Requirements for Physical Protection of Licensed Activities in Nuclear Power Reactors Against Industrial Sabotage." The guidelines of NUREG-0908, Acceptance Criteria for the Evaluation of Nuclear Power Reactor Security Plans (August 1982), were used to develop the plan.

A.1.18 REGULATORY GUIDE 1.18 (December 1972, Revision 1), STRUCTURAL ACCEPTANCE TEST FOR CONCRETE PRIMARY REACTOR CONTAINMENTS

Regulatory Guide 1.18 does not apply since Fermi 2 utilizes a steel primary reactor containment.

A.1.19 REGULATORY GUIDE 1.19 (August 1972, Revision 1), NON-DESTRUCTIVE EXAMINATION OF PRIMARY CONTAINMENT LINER WELDS

Regulatory Guide 1.19 does not apply since there is no primary containment liner in the Fermi 2 power plant.

A.1.20 REGULATORY GUIDE 1.20 (May 1976, Revision 2), COMPREHENSIVE VIBRATION ASSESSMENT PROGRAM FOR REACTOR INTERNALS DURING PREOPERATIONAL AND INITIAL STARTUP TESTING

The Fermi 2 vibration program for the reactor internals includes provisions for confirmatory instrumented vibration tests as suggested in this guide. The Tennessee Valley Authority Browns Ferry, Unit 1, reactor was the prototype reactor and was to be tested according to the BWR Prototype Vibrational Testing Program.

Complete details of the program were developed and are available for review by the NRC prior to the performance of scheduled preoperational functional tests.

Refer to Subsection 3.9.1.3 for additional discussion on the testing of reactor internals.

A.1.21 REGULATORY GUIDE 1.21 (June 1974, Revision 1), MEASURING, EVALUATING, AND REPORTING RADIOACTIVITY IN SOLID WASTE AND RELEASES OF RADIOACTIVE MATERIALS IN LIQUID AND GASEOUS EFFLUENTS FROM LIGHT-WATER-COOLED NUCLEAR POWER PLANTS

The Fermi 2 design complied with the first issue of Regulatory Guide 1.21. Changes to the guide in Revision 1 have caused some features of the plant design to be in possible noncompliance.

Areas of possible noncompliance do not affect the ability to safely shut down the reactor. Automatic termination of releases from the condenser offgas system on detection of high activity has not been provided. Edison's reason for noncompliance with this aspect of Regulatory Guide 1.21 is based on Edison's compliance with Appendix I to 10 CFR 50 taking priority. A brief summary of the considerations involved follows.

Paragraph 20.1(c) of 10 CFR 20 states

> Persons engaged in activities under licenses issued by the Nuclear Regulatory Commission . . . make every reasonable effort to maintain radiation exposures, and releases of radioactive materials in effluents to unrestricted areas, as low as is reasonably achievable. The term ‘as low as is reasonably achievable’ means as low as is reasonably achievable taking into account the state of technology, and the

economics of improvements in relation to benefits to the public health and safety, and other societal and socioeconomic considerations, and in relation to utilization of atomic energy in the public interest.

Public use of a dependable energy source, although a seldom- emphasized consideration of the "as low as is reasonably achievable" requirement, is part of the regulation and must receive equal emphasis.

Section IV of Appendix I to 10 CFR 50, which contains numerical guidance for technical specifications and limiting conditions for operation, states that the licensee is permitted the flexibility of operation, compatible with considerations of health and safety, to ensure that "the public is provided a dependable source of power even under unusual operating conditions that <u>may temporarily result in releases higher than such numerical guides</u> for design objectives . . ." (emphasis added). Edison regards this type of operating flexibility to be warranted in light of the restrictive nature of Appendix I. Continued operation of licensed facilities in this manner will <u>not</u> decrease the protection from radiation established by existing regulations. The Commission has clearly emphasized that the Appendix I guides are not radiation protection standards, but are a quantitative expression of meaning of the "as low as is reasonably achievable" requirement. The Commission's standards are in 10 CFR 20 and remain unchanged by Appendix I to 10 CFR 50.

Edison complied with the radiation protection standards for limiting potential doses to the public contained in 10 CFR 20 prior to elaborate additions to the condenser offgas system. It procured the condenser offgas system to satisfy the then proposed Appendix I to 10 CFR 50 to reduce activity releases to the "as low as practicable" level, and not because the health and safety of the public were endangered.

Guidance on technical specifications and limiting condition for operation contained in Appendix I requires (among other things) that the licensee implement a program of corrective action should material actually released during any calendar quarter result in a calculated exposure exceeding twice the annual design objective. This essentially means that a licensee shall take corrective action to limit activity releases well before any individual could receive an exposure above the limiting values of 10 CFR 20. The action taken by a licensee in compliance with Appendix I (and monitored by the Commission) inherently ensures that the limiting doses of 10 CFR 20 will not be exceeded. Automatic isolation of the condenser offgas system would ultimately result in a turbine trip and the potential loss of electrical power to some members of the public. This is not only unnecessary, but should be avoided in order to comply with all aspects of Appendix I.

Clearly, automatic termination of the offgas system operation at the restrictive levels contained in Appendix I is inconsistent with an objective of Appendix I to ensure that the public is provided a dependable source of power even under unusual operating conditions that may temporarily result in releases higher than the design objective.

Automatic termination of offgas system operation required by Regulatory Guide 1.21 is outside the scope of the regulatory guide and inconsistent with the operational flexibility permitted by Appendix I. Compliance with this particular aspect of the regulatory guide should not take priority over the requirements of Appendix I.

In summary, the corrective action the operator would take to comply with the requirements of Appendix I would limit the resultant doses to a value well below the historically accepted safe limits specified in 10 CFR 20. Automatic termination of the condenser offgas system operation would not provide the operator with the option of reducing power nor permit activity releases temporarily higher than those associated with the almost immeasurably small doses of Appendix I, which the Commission expressly expected would be exceeded to permit the necessary flexibility in compliance with Appendix I in its entirety.

The Fermi 2 Technical Specifications and Offsite Dose Calculation Manual implement the intent of this Regulatory Guide.

A.1.22 REGULATORY GUIDE 1.22 (February 1972), PERIODIC TESTING OF PROTECTION SYSTEM ACTUATION FUNCTIONS

The current Fermi 2 provisions for periodic testing of protection system actuation functions conform to the requirements of this guide.

Refer to Subsections 7.2.1.1, 7.2.2.2, 7.3.1.2, 7.6.1.1, 7.6.1.2, 7.6.1.4, 7.6.1.7, 7.6.1.8, 7.6.1.14, 7.6.1.15, 7.6.2.1, 7.6.2.2, 7.6.2.3, 7.6.2.4, 7.6.2.7, 7.6.2.8, 7.6.2.9, 7.6.2.12, 7.6.2.13, and 7.6.2.15.

A.1.23 REGULATORY GUIDE 1.23 (February 1972), ONSITE METEOROLOGICAL PROGRAMS

The Fermi 2 onsite meteorological programs fulfill the requirements of this guide except for the section on instrument accuracy. The Fermi 2 meteorological data acquisition system meets the system accuracy requirements of proposed Revision 1 (September 1980) to Regulatory Guide 1.23.

For details on the Fermi 2 meteorological program, refer to Subsection 2.3.3.6.

A.1.24 REGULATORY GUIDE 1.24 (March 1972), ASSUMPTIONS USED FOR EVALUATING THE POTENTIAL RADIOLOGICAL CONSEQUENCES OF A PRESSURIZED WATER REACTOR RADIOACTIVE GAS STORAGE TANK FAILURE

Regulatory Guide 1.24 does not apply since Fermi 2 is a BWR.

A.1.25 REGULATORY GUIDE 1.25 (March 1972), ASSUMPTIONS USED FOR EVALUATING THE POTENTIAL RADIOLOGICAL CONSEQUENCES OF A FUEL HANDLING ACCIDENT IN THE FUEL HANDLING AND STORAGE FACILITY FOR BOILING AND PRESSURIZED WATER REACTORS

The analysis of the fuel-handling accident, as discussed in Subsection 15.7.4, is in conformance with the regulatory position of this guide. Regulatory Guide 1.25 assumptions regarding the pool iodine decontamination factor and gap fractions (except as modified per License Amendment 87 based on NUREG/CR-5009) apply to the analysis of 9x9 fuel that does not meet the Regulatory Guide 1.183 limitations on fuel burnup. Fuel handling accidents involving fuel that meets the Regulatory Guide 1.183 (Table 3, Footnote 11) burnup specifications are analyzed in accordance with the NRC's Alternate Source Term and; thus, do not conform to this regulatory guide.

A.1.26 REGULATORY GUIDE 1.26 (February 1976, Revision 3), QUALITY GROUP CLASSIFICATIONS AND STANDARDS FOR WATER-, STEAM-, and NUCLEAR POWER PLANTS

The Fermi 2 design is not in full conformance with the requirements of this guide. The design is based on the commitment in the PSAR as accepted by the AEC-DL in the Safety Evaluation Report (SER) Section 3.3.3, page 16. The Fermi 2 project considers the extent to which the design conforms to this guide to be adequate.

For details refer to Subsection 3.2.2.

A.1.27 REGULATORY GUIDE 1.27 (January 1976, Revision 2), ULTIMATE HEAT SINK FOR NUCLEAR POWER PLANTS

The design of the Fermi 2 RHR Complex conforms with the requirements of GDC 44 of 10 CFR 50, Appendix A, by providing assurance of system redundancy for safe removal of reactor decay heat after emergency shutdown and during accident conditions. Fermi 2 meets regulatory guide position 1 by providing 6,598,000 gallons of water at 1 foot below grade level to permit safe cooldown requirements over a 7-day period. This period includes time needed to evaluate the situation and take corrective action to initiate replenishment activities if necessary.

The ultimate heat sink system was originally sized to provide sufficient cooling for 30 days following an accident without make-up water addition to the RHR reservoir. Regulatory Guide 1.27 states that a UHS capacity of less than 30 days may be acceptable if it can be demonstrated that replenishment can be effected to ensure the continuous capability of the sink to perform its safety functions, taking into account the availability of replenishment equipment and the limitations that may be imposed on freedom of movement following an accident.

The Fermi 2 UHS design evolved long before the post-TMI improvements in Emergency Preparedness. These improvements are reflected in the Detroit Edison Radiological Emergency Response Preparedness Plan. One of the objectives of this program is effective and timely implementation of emergency measures. Detroit Edison now has the resources of the Emergency Response Organization to rapidly identify the need for reservoir replenishment and to direct procurement of material and field implementation. This change significantly improves the ability to provide reservoir replenishment within 7 days as it relates to resolving problems associated with freedom of movement following an accident or occurrence of severe natural phenomena.

The 7-day make-up provision for the RHR reservoir is consistent with the 7-day make-up provisions allowed for replenishment of the diesel generator fuel supply. Therefore, this period of time is sufficient to recover from the effects of natural phenomena such as tornado, storm, earthquake or flood and restore site access for replenishment activities.

Make-up will be provided by the normal make-up system or using RHR Complex fire hoses. If these systems are not available, temporary equipment will be used. The necessary pumps and hoses are commercially available from many sources and that seven days is sufficient time to procure and install the equipment. The water source will be either Lake Erie, the Fermi 1 discharge canal, the circulating water reservoir, the on-site Quarry Lake or Swan Creek. The temperature and quality of make-up water is maintained to ensure that the service water systems and cooling towers perform as required. Siphon of the reservoir is prevented by ensuring that hoses are not placed into the reservoir water.

The 7-day supply calculations utilize the Marley design and test data for cooling tower drift and evaporative water losses. As discussed in Section 9.2.5.3.3, water losses due to leakage and EECW makeup from the reservoir are assumed. In addition, both divisions of EDGs, RHR, EECW/EESW, EDGSW, and RHRSW cooling towers are assumed to be operating maximizing heat load to the reservoir and maximizing evaporative and drift losses. Constant historical worst-case meteorological data is used to compute evaporative water losses. The 7-day supply also assumes initial reservoir level at the technical specification limit of 580' - 0" versus the normal operations level of between 582'-0" and 583'-0" which provides additional conservatism.

In regard to Position 2 of the Regulatory Guide, the Fermi 2 RHR heat sink is designed to withstand the most severe natural phenomenon such as the safe-shutdown earthquake (SSE), tornado, hurricane, flood, or drought. In addition, other less severe phenomena and reasonably probable combinations of less severe phenomena have been accounted for in the safety analysis.

The primary components of man-made structures in the RHR heat sink complex are the RHR cooling towers. In the ultimate heat sink design calculations, the 1972 ASHRAE Handbook Fundamentals ambient air wet bulb temperature of 76°F and dry bulb temperature of 92°F are used. These design temperatures represent values that have been equaled or exceeded by only 1% of the total hours of the months of June through September. These conditions are assumed to be continuous over the 7-day period.

The Technical Specification limit for cooling tower reservoir temperature is 80°F. To calculate the peak suppression pool temperature following DBA/LOCA, an energy balance calculation was used to determine the post-LOCA RHRSW temperature increase as a function of time from the initial condition of 80°F to the cooling tower maximum return design temperature of 90°F. The temperature profile, which is nonlinear, was conservatively bounded by a linear profile with the initial temperature of 80°F increasing in a linear way to 90°F over an 8-hour period. Using the conditions outlined in Regulatory Guide 1.1 (November 1970), adequate NPSH margin is provided for pumps taking suction from the suppression pool.

Regulatory Position 3 requires redundant sources of water, both of which must be capable of meeting the requirements of Position 1. In cases where an extremely low probability of failure due to natural phenomena of a single source is demonstrated, this requirement may be waived. In addition, Technical Specifications, including provisions for actions taken in the event of the threat of partial loss of capability of the ultimate heat sink, must be reviewed. The Fermi 2 design of the ultimate heat sink provides a highly reliable single water source of Category I design. This source is located below grade and is composed of two separate reservoirs connected by redundant 10-inch penetrations. The design allows either redundant division of the RHRSW, EESW or EDGSW systems to use the entire volume of water in the two reservoirs. The 7-day water supply is thus met even after considering any single failure. In the event of a seismic disturbance and failure that causes development of a crack, only water stored above ground-water elevation will be lost. The 7-day water supply includes allowance for a below grade crack in both reservoir basins. The RHR complex of diesel generators, cooling towers, RHRSW, EESW and EDGSW systems, and auxiliaries is redundant.

For details refer to Subsection 9.2.5.2.

A.1.28 REGULATORY GUIDE 1.28 (February 1979, Revision 2), QUALITY ASSURANCE PROGRAM REQUIREMENTS (DESIGN AND CONSTRUCTION)

The Fermi 2 quality assurance (QA) program complies with ANSI N45.2-1977 and the requirements of Revision 2 of this regulatory guide.

For details on the QA program, refer to Chapter 17.

A.1.29 REGULATORY GUIDE 1.29 (September 1978, Revision 3), SEISMIC DESIGN CLASSIFICATION

The Fermi 2 design is in conformance with the requirements of Regulatory Guide 1.29. Refer to Subsection 3.2.1 for a listing of safety-related structures, systems, and components that are designed to withstand the effects of an SSE.

A.1.30 REGULATORY GUIDE 1.30 (August 1972), QUALITY ASSURANCE REQUIREMENTS FOR THE INSTALLATION, INSPECTION, AND TESTING OF INSTRUMENTATION AND ELECTRIC EQUIPMENT

The Fermi 2 QA program is in conformance with this guide.

For details refer to Chapter 17.

A.1.31 REGULATORY GUIDE 1.31 (April 1978, Revision 3), CONTROL OF FERRITE CONTENT IN STAINLESS-STEEL WELD METAL

Stainless steel systems and components for Fermi 2 were fabricated by GE or Dravo and include the following:

a. Reactor recirculation system

b. Control rod drive (CRD) hydraulic return

c. CRD housing to flange

d. Reactor core isolation cooling (RCIC) system (suction from condensate storage).

Since these systems and components were ordered prior to the inception of Regulatory Guide 1.31, welds were not specifically tested for delta ferrite. Welds made by GE were made with long- standing procedures that had been proven adequate for consistently producing satisfactory, fissure-free welds. In addition, welds produced in five BWRs using the same procedures as used on Fermi 2 equipment were tested and found to contain a minimum of 3 percent delta ferrite. In addition, stainless steel welds made by Dravo were made using weld filler metal containing 5 to 15 percent delta ferrite. Similar welds made by Dravo using the same procedures were inspected and found to consistently contain a minimum of 3 percent delta ferrite.

In view of the above, Edison does not plan a delta ferrite inspection program on previously fabricated stainless steel components and systems. In addition, since Regulatory Guide 1.31 and Branch Technical Position (BTP) MTEB 5.1 were issued, a considerable amount of attention has been given to delta ferrite control. Programs have been undertaken to determine not only the effects of delta ferrite on fissure sensitivity but also the effects of welding parameters on delta ferrite formation. Programs included analysis of laboratory-produced welds as well as statistical analysis of welds in actual components and systems.

These programs indicated that fissuring is minimized when as little as 3 percent delta ferrite is present. Additional amounts of delta ferrite do not further reduce fissure susceptibility.

It has also been shown that the delta ferrite in a resultant weld can be controlled by controlling the chemistry of the weld metal. Weld metals containing approximately 5 percent delta ferrite will produce welds with a minimum of 3 percent delta ferrite. Accordingly, for all future fabrication and installation of austenitic stainless steel components and systems, Edison will control delta ferrite formation as follows:

a. Each heat of austenitic stainless steel (A-No. 8 analysis of ASME Section IX, QW 442) bare wire and each heat or lot of austenitic stainless steel covered electrodes will be purchased in accordance with the applicable requirements of ASME Code Sections II and III as well as DECo Specification 3071-370

b. All austenitic stainless steel weld materials of the A-No. 8 analysis will also be specified to contain a minimum ferrite number of 8FN. The ferrite number will be determined by both chemical analysis and magnetic measurements performed by the filler metal manufacturer on an undiluted weld pad, with the exception that the ferrite number for A-No. 8 filler metals of SFA Specification 5.9 that are used with the gas tungsten arc welding (GTAW) process need only be determined by chemical analysis. Welding of the coupon shall be as specified in the applicable SFA specification.

c. Completed final welds will not be inspected for ferrite content.

The controls used for Fermi 2 are now consistent with industrial practices and Regulatory Guide 1.31.

A.1.32 REGULATORY GUIDE 1.32 (February 1977, Revision 2), CRITERIA FOR SAFETY RELATED ELECTRIC POWER SYSTEMS FOR NUCLEAR POWER PLANTS

The Fermi 2 design conforms to the requirements of Revision 1 to this guide, with the exception of Parts 1d, 1e, and 2b. These sections required compliance with Regulatory Guides 1.75 and 1.93. For discussions of those guides, see the applicable sections of this appendix.

For details refer to Sections 8.2 and 8.3.

A.1.33 REGULATORY GUIDE 1.33 (February 1978, Revision 2), QUALITY ASSURANCE PROGRAM REQUIREMENTS (OPERATION)

Fermi 2 is in conformance with the requirements of Regulatory Guide 1.33, with the following exceptions:

a. The Quality Assurance program as described in Subsection 17.2.7 permits the conditional release of material lacking the specified quality assurance records, provided the item can be readily removed. The program allows for functional testing on conditionally released materials that have been installed; however, they will not be placed in service unless a technical evaluation has been performed and documented, and appropriate 10 CFR 50.59 review in accordance with 10 CFR 50.59 has been performed.

b. Exception is taken from the audit program scope and frequency of audits described in Regulatory Guide 1.33 and ANSI N18.7-1976 as endorsed by Regulatory Guide 1.33. The provisions in the Quality Assurance Program described in Subsection 17.2.18 govern the audit program. When differences exist between Regulatory Guide 1.33 and the UFSAR, the latter shall take precedence.

c. When purchasing commercial grade calibration or testing services from a laboratory holding accreditation by an Accreditation Body (AB) which is a signatory to the International Laboratory Accreditation Cooperation (ILAC) Mutual Recognition Arrangement (MRA), procurement documents are not required to impose a quality assurance program consistent with ANSI N45.2-1977. Alternative requirements described in UFSAR Appendix A, A.1.123, for Regulatory Guide 1.123 may be implemented in lieu of imposing a quality assurance program consistent with ANSI N45.2-1977. In addition, the following exception will be taken to ANSI N18.7: When purchasing commercial grade calibration or testing services from a laboratory holding accreditation by an accrediting body recognized by the ILAC MRA, the procurement documents are not requires to impose a quality assurance program consistent with ANSI N45.2-1977. Alternative requirements described in UFSAR, Appendix A, for Regulatory Guide 1.123 may be implemented in lieu of imposing a quality assurance program consistent with ANSI N45.2-1977.

An exception is taken to the review of all plant procedures every two years. Instead, non-routine procedures (procedures such as emergency operating procedures, abnormal operating procedures, procedures which implement the emergency plan, and Security and other procedures that are implemented as a result of an event) shall be reviewed at least every two years and revised as appropriate. On a biennial basis, continue to audit a sample of routine procedures and immediately review procedures following an unusual incident or plant modification. Routine plant procedures that are used at least biennially receive scrutiny by knowledgeable individuals during work activities and are updated, as necessary, to assure adequacy of controlled activities. Plant policy requires that the job be stopped and the procedure revised or the situation resolved prior to work continuing if the procedure cannot be implemented as written. Routine plant procedures that have not been used for two years will be reviewed before use to determine if changes are necessary or desirable.

Exception is also taken to full compliance with some of the regulatory guides listed in Section C.2 of Regulatory Guide 1.33. The Fermi 2 position on regulatory guides listed in Section C.2 is stated elsewhere in this appendix.

A.1.34 REGULATORY GUIDE 1.34 (December 1972), CONTROL OF ELECTROSLAG WELD PROPERTIES

Electroslag welding has been performed only on the turbine shielding wall in the field for Fermi 2. Although Edison specifications did not specifically prohibit it, no use of electroslag welding on core support structures or ASME Class 1 or 2 vessels or components can be identified. Most of those components that would be expected to have electroslag welding were completed and fabricated before this guide was issued.

A.1.35 REGULATORY GUIDE 1.35 (January 1976, Revision 2), INSERVICE SURVEILLANCE OF UNGROUTED TENDONS IN PRE- STRESSED CONCRETE CONTAINMENT STRUCTURES

This guide does not apply to Fermi 2, which does not use a concrete containment.

A.1.36 REGULATORY GUIDE 1.36 (February 1973), NONMETALLIC THERMAL INSULATION FOR AUSTENITIC STAINLESS STEEL

The Fermi 2 design is in conformance with the requirements of this regulatory guide.

For details refer to Subsection 5.2.3.3.

A.1.37 REGULATORY GUIDE 1.37 (March 1973), QUALITY ASSURANCE REQUIREMENTS FOR CLEANING OF FLUID SYSTEMS AND ASSOCIATED COMPONENTS OF WATER-COOLED NUCLEAR POWER PLANTS

Fermi 2 is in conformance with the requirements of 10 CFR 50, Appendix B. The plant startup task force is responsible for activities to ensure system cleanliness and flushing with the objective of meeting the intent of ANSI N45.2.1.

For details refer to Subsection 17.1.9 and Chapters 13 and 14.

A.1.38 REGULATORY GUIDE 1.38 (May 1977, Revision 2), QUALITY ASSURANCE REQUIREMENTS FOR PACKAGING, SHIPPING, RECEIVING, STORAGE, AND HANDLING OF ITEMS FOR WATER-COOLED NUCLEAR POWER PLANTS

During the initial design and construction phase, the Fermi 2 project conformed to 10 CFR 50, Appendix B, but not with the measures required to comply with this guide.

The Fermi 2 project procedure was to require each manufacturer to work by written packaging and handling procedures that had been reviewed and approved by Edison, and to supply storage instructions that were followed for onsite storage. These measures are similar to the requirements in ANSI N45.2.2-1972. This standard, however, contained some provisions that were not feasible to implement on Fermi 2 because of the date of issue; specifically,

a. Each specific item covered by the standard (all QA level I items) was required to be classified into one of four levels (A through D). Classification of those items already on order or delivered to the job site prior to issuance of the guide was not feasible for the Fermi 2 project

b. There were numerous minor requirements that would require significant investigation to ensure compliance, both at the job site and at the vendors' facilities. These include, but were not necessarily limited to, the requirement that all tarpaulin be fire retardant, that nonmetallic caps and plugs be brightly colored, and that all hoisting equipment meet the requirements of either ANSI B30.2.0, B30.5, B30.6, or A10.5, as appropriate

c. Inspection, examination, and testing personnel were required to be qualified in accordance with ANSI N45.2.6. The Fermi 2 position on this is stated in the conformance review of Regulatory Guide 1.58.

The operational QA program complies with the requirements of this regulatory guide.

A.1.39 REGULATORY GUIDE 1.39 (September 1977, Revision 2), HOUSEKEEPING REQUIREMENTS FOR WATER-COOLED NUCLEAR POWER PLANTS

The Fermi 2 project was in conformance with the regulatory position of this guide during the construction phase. Procedures were written for the regulation of site area, site preparation, and fire prevention and protection, as required by ANSI N45.2.3-1973. During the operational phase, the Fermi 2 Quality Assurance program is based on ANSI Standard N18.7-1976, “Administrative Controls and Quality Assurance for the Operational Phase of Nuclear Power Plants”, as modified by Regulatory Guide 1.33. Housekeeping controls during the operational phase are in conformance with Regulatory Guide 1.33.

A.1.40 REGULATORY GUIDE 1.40 (March 1973), QUALIFICATION TESTS OF CONTINUOUS-DUTY MOTORS INSTALLED INSIDE THE CONTAINMENT OF WATER-COOLED NUCLEAR POWER PLANTS

There are no continuous-duty motors inside the drywell of the Fermi 2 plant to which this guide applies.

A.1.41 REGULATORY GUIDE 1.41 (March 1973), PREOPERATIONAL TESTING OF REDUNDANT ONSITE ELECTRIC POWER SYSTEMS TO VERIFY PROPER LOAD GROUP ASSIGNMENTS

The Fermi 2 testing program, described in Subsection 8.3.1, is in conformance with the requirements of this guide.

A.1.43 REGULATORY GUIDE 1.43 (May 1973), CONTROL OF STAINLESS STEEL WELD CLADDING OF LOW-ALLOY STEEL COMPONENTS

The requirements in this guide primarily concern fabrication of the RPV. Fermi 2 is in conformance with the requirements of this guide.

For details refer to Section 5.4.

A.1.44 REGULATORY GUIDE 1.44 (May 1973), CONTROL OF THE USE OF SENSITIZED STAINLESS STEEL

Fermi 2 is not in complete conformance with the regulatory position as stated in this guide. Intergranular corrosion tests were not performed for each welding procedure to be used for welding material having a carbon content greater than 0.03 percent.

The corrosion tests are not considered necessary because the essential variables used in welding procedures at Fermi 2 were based on recommendations made by GE following extensive research. Furthermore, intergranular stress corrosion cracking (IGSCC) countermeasures have been applied to the extent practical. Steps were taken to minimize sensitization by control of welding procedures and the adverse effects of the limited sensitization offset by IGSCC countermeasures.

For details refer to Subsections 5.2.3 and 5.2.5.

A.1.45 REGULATORY GUIDE 1.45 (May 1973), REACTOR COOLANT PRESSURE BOUNDARY LEAKAGE DETECTION SYSTEMS

To ensure the safety of the public, GDC for Nuclear Power Plants, Criterion 30, Appendix A of 10 CFR 50, requires all plants to provide a means for detecting and identifying the locations of the sources of reactor coolant leakage from the RCPB. The Fermi 2 design, in conformance with Regulatory Position 1 of Guide 1.45, effectively identifies, classifies, and collects sources of leakage to monitor and control individual leakage flow rates, as well as total flow rates.

Sources of leakage can be classified as identified and unidentified. Position 2 of this guide requires that unidentified sources be collected and monitored with a flow rate accuracy of 1 gpm. This sensitivity requirement is attained on the Fermi design by the drywell floor drain sump level rate-of-change monitor.

Regulatory Position 3 requires a minimum of three separate detection systems in the design. These sensing systems must include a sump level and flow monitor and an airborne particulate radioactivity monitor. In addition, either an air cooler condensate flow rate or airborne gaseous radioactivity monitoring system must be included in the design. All global (i.e., general area) systems must use humidity, temperature, or pressure conditions of the containment atmosphere as the alarm setpoint indicator. The Fermi 2 design conforms with these system requirements by providing monitoring of sump level and flow, airborne gaseous radioactivity, and a supplementary drywell floor level monitor. Specific monitored parameters are sump level, sump level flow, airborne particulate matter, airborne gaseous radioactivity, primary containment pressure and temperature, low reactor water level, high steam flow indications, and drywell local temperature.

Regulatory Position 4 requires detection of intersystem leakage utilizing methods of radioactivity monitoring and abnormal water levels or flow in local RCPB regions. Intersystem leakage can be detected in the following systems: RHR service water, general service water, and reactor building closed cooling water systems. With the exception of the general service water, all of these systems use radioactivity level indication as the monitoring parameter. In addition, abnormal water levels or flow are also monitored. Thus Fermi 2 complies with Position 4 of the guide.

The sensitivity and response time for each leakage detection system for unidentified leakage is required by Position 5 to match the 1 gpm-or-less standard of Position 3 in less than 1 hr after the onset of the leak. As stated previously, the Fermi 2 designed detection system guarantees detection of flows with this precise accuracy limit.

Position 6 of the guide specifies that leakage detection systems should be capable of performing their functions during and following seismic events not requiring plant shutdown. The sump level analog monitor will remain functional when exposed to the SSE. In addition, the steam leak detection systems, which utilize temperature detectors and excess steam flow differential pressure measurements, are to withstand SSE conditions. The primary containment pressure and reactor water level systems are also Category I components. Thus, with the exception of the sump level detection (for sump pump control) and the airborne radioactivity monitoring systems, Fermi 2 complies with the intent of Position 6.

Regulatory Position 7 requires that each leakage detection system have a capability for independent activation of response alarms within the control room. In addition, the control room is required to contain indicators from each system. These indicators are required to be calibrated and metered in units that allow operators to convert measurements into common leakage equivalent. Equipment used in the Fermi 2 design provides for control room alarms and indicators. Such design will allow common equivalent leakage procedures to be developed.

Position 8 requires designed equipment to readily permit testing for operability and calibration during plant operation. All leakage detection systems of Fermi 2 except the sump level can be periodically tested and calibrated during plant operation. The reactor level and drywell pressure lines are designed to allow calibration of switch setpoints by application of calibration pressures to switch actuators. The sump level switch operation can be observed during normal operation, and comparison between sets of switches can be used for calibration. The flow within the sumps using differential pressure transmitters can be calibrated. Calibration of the primary containment drain pumps can also be accomplished outside the drywell during operation.

Position 9 states that Technical Specifications with limiting conditions for both identified and unidentified leakage should include the availability of various instrument types during plant operation and the spectrum of coverage each instrument provides. The Fermi 2 Technical Specifications for leakage detection systems include the information necessary to comply with Position 9.

For details on system specifications, refer to Subsection 5.2.7.

A.1.46 REGULATORY GUIDE 1.46 (May 1973), PROTECTION AGAINST PIPE WHIP INSIDE CONTAINMENT

The Fermi 2 design meets the intent of this regulatory guide.

For details, refer to Subsection 3.6.1.

A.1.47 REGULATORY GUIDE 1.47 (May 1973), BYPASSED AND INOPERABLE STATUS INDICATION FOR NUCLEAR POWER PLANT SAFETY SYSTEMS

The Fermi 2 design does not comply with this regulatory guide.

This guide describes an acceptable method of complying with the requirements of Section 4.13 of IEEE 279-1971, and Criterion XIV of Appendix B to 10 CFR Part 50. Fermi 2 implements this requirement of IEEE 279-1971 through the design of subject systems to provide continuous indication in the event that the protective action of some part of the protection system has been bypassed or deliberately rendered inoperative. The conformance of these designs is described in UFSAR Section 1.6, 7.1, 7.2 and 7.3. The requirements of 10 CFR 50, Appendix B, Criterion XIV, are met through proven administrative controls that establish measures for indicating the operating status of structures, systems, and components of the nuclear power plant to prevent inadvertent operation.

A.1.48 REGULATORY GUIDE 1.48 (May 1973), DESIGN LIMITS AND LOADING COMBINATIONS FOR CATEGORY I FLUID SYSTEM COMPONENTS

Fermi 2 does not conform to this regulatory guide.

The Fermi 2 Category I pressure-retaining components are designed pursuant to 10 CFR 50, Paragraph 50.55a, which invokes the compliance with ASME Code Section III.

For details refer to Section 5.5.

A.1.49 REGULATORY GUIDE 1.49 (December 1973, Revision 1), POWER LEVELS OF NUCLEAR POWER PLANTS

Fermi 2 nuclear power plant design is in conformance with Regulatory Guide 1.49. The licensed power level of 3430 MWt for this plant is below the 3800-MWt limit set forth in this guide.

This Regulatory Guide has since been withdrawn (as of June 2007)..

A.1.50 REGULATORY GUIDE 1.50 (May 1973), CONTROL OF PREHEAT TEMPERATURE FOR WELDING OF LOW-ALLOY STEEL

Fermi 2 is in conformance with this guide except for Regulatory Position 2. All low-alloy steel welds, except for ASME Section III, Class 3, 4-in.-and-less diameter piping, are examined by nondestructive testing methods for detection of cracks and other defects prior to or following the application of postweld heat treatment.

A.1.52 REGULATORY GUIDE 1.52 (March 1978, Revision 2), DESIGN, TESTING, AND MAINTENANCE CRITERIA FOR POSTACCIDENT ENGINEERED-SAFETY-FEATURE ATMOSPHERE CLEANUP SYSTEM AIR FILTRATION AND ADSORPTION UNITS OF LIGHT-WATER-COOLED NUCLEAR POWER PLANTS

General Design Criteria 19, 41, 42, 43, and 61 in Appendix A of 10 CFR 50, "General Design Criteria for Nuclear Power Plants," cover the design of atmosphere cleanup systems to safeguard public health and safety. Regulatory Guide 1.52 states acceptable methods for complying with these criteria for the control center and secondary containment filtration systems.

The Fermi 2 control center emergency air filtration system design as described in Section 6.4 conforms to most positions in this guide except for the lack of redundancy of passive components. Other items which do not strictly conform are identified in the following table; overall functional performance is adequate.

The standby gas treatment system (SGTS) design, discussed in Section 6.2 does not strictly conform to all guide positions, but its overall functional performance is adequate. The specific conformances to the positions of Regulatory Guide 1.52 are given in the compliance evaluation for the control center filtration system and SGTS, which follows.

CONFORMANCE OF VENTILATION SYSTEMS WITH RESPECT TO THE POSITIONS OF REGULATORY GUIDE 1.52

Regulatory Position	Control Center Filtration System	Standby Gas Treatment System		
1.0 Environmental Design Criteria				
a. Each ESF atmosphere cleanup system is based on maximum conditions resulting from DBA.	Yes	No. Parameters are listed below:		
			Fermi 2	R.G. 1.52
		Maximum influent temperature	153°F	180°F
		Average radiation levels:		
		Airborne	Not specified	10^5 rads/hr
		Iodine buildup	Not specified	10^9 rads
		Average airborne iodine:		
		Elemental	0.35 mg/m^3	10.0 mg/m^3

CONFORMANCE OF VENTILATION SYSTEMS WITH RESPECT TO THE POSITIONS OF REGULATORY GUIDE 1.52

Regulatory Position	Control Center Filtration System	Standby Gas Treatment System
		Methyl iodine and particulate iodine 0.035 mg/m^3 1.0 mg/m^3
b. System design based on 30-day integrated dose after a DBA in the vicinity of the adsorber section, using Regulatory Guides 1.3, 1.4, and 1.25 radiation source assumptions	Yes	No. A total integrated dose for the charcoal was not used in Fermi 2 SGTS specifications. There are no data for removal efficiency after 10^9 rads exposure. Evans* determined removal efficiency loss is <0.1 percent for KI_3-impregnated carbon. Relative humidity was less than 90 percent for exposure of 10^9 rads from a radiation field of 1.5 x 10^7 rads/hr.
c. Adsorber design based on concentration and relative abundance of iodine as assumed in Regulatory Guides 1.3, 1.4, and 1.25	Yes	Yes. Average airborne elemental and methyl radioiodine release was 1300 g in secondary containment, after DBA. CVI simulation** of SGTS module shows 99.99 percent removal of airborne methyl iodine concentration of 0.035 mg/m^3
d. Compatibility of atmosphere cleanup system with other ESF systems	Yes	System designed to withstand post-LOCA environment and function normally in conjunction with other ESF systems
e. Components of systems designed for both the lowest and highest predicted temperatures	Yes	Yes. All compartments are heated and cooled by Category I equipment during DBA

2.0 System Design Criteria

* A. G. Evans, "Effect of Intense Gamma Radiation on Radioiodine Retention by Activated Carbon," Proceedings of the Twelfth AEC Air Cleaning Conference, pp. 401-414

** D. P. Siegwarth and M. Siegler, Detroit Edison Standby Gas Treatment System Gasketless Filter Test Series, General Electric Company (private), NEDC-12431, Class III, July 1973.

CONFORMANCE OF VENTILATION SYSTEMS WITH RESPECT TO THE POSITIONS OF REGULATORY GUIDE 1.52

	Regulatory Position	Control Center Filtration System	Standby Gas Treatment System
a.	Required redundancy for atmosphere cleanup systems designed and installed to limit doses after DBA. Includes both active and passive components	No. The recirculation and makeup filter system is provided with redundancy of active components only. The recirculation and makeup filter system is provided with redundancy of fans, dampers, heaters, and controls. The passive components, such as ductwork, filter housings, filter, and moisture separator, are not redundant.	No. Previous requirements for SGTS did not specify this feature. Single stacks and ductwork penetrating the reactor building were not associated with any failure mechanisms at that time. Fermi 2 design has common discharge on RB roof and common inlet in secondary containment.
b.	Physical separation of redundant atmosphere cleanup system with missile protection	Yes, except for nonredundant passive components.	Yes. Active components are protected.
c.	Atmosphere cleanup system designed as Category I	Yes	Yes
d.	ACS pressure surge protection	No. Location of the recirculation and makeup air filter system is external to secondary containment. There are no anticipated pressure surges of significant magnitude that could cause damage to any of the filter system components. Thus no pressure relief valves are included in the overall system design.	No. The maximum system pressure is 20.0 in. H_2O. There are no relief valves in the STGS system except in the charcoal adsorber section, which may be overpressurized by CO_2.
e.	Atmosphere cleanup system construction materials must effectively perform under exposure to high radiation levels.	Yes, even though superfluous.	Yes
f.	Limiting flow rate for a single cleanup train of 30,000cfm.	Yes	Yes. Four parallel filter elements, each rated at 1000 scfm, are used.
g.	Atmosphere cleanup system instrumentation to signal, alarm, and record pressure drops, flow rates in the control room	Recirculation and makeup air filter system will be instrumented to alarm in the main control room for large pressure drop. The system flow rate can only be measured locally.	Design provides local signal and alarms for pressure. Flow is recorded, and low flow is alarmed in the main control room.

CONFORMANCE OF VENTILATION SYSTEMS WITH RESPECT TO THE POSITIONS OF REGULATORY GUIDE 1.52

	Regulatory Position	Control Center Filtration System	Standby Gas Treatment System
h.	Electrical distribution and power supply conforming to IEEE standards	Yes	Yes
i.	Automatic activation of ESF atmosphere cleanup systems	Yes	Yes
j.	Unit replacement capability of filter to protect workers from exposure to radiation in accordance with Regulatory Guide 8.8	No. However, unit will be disassembled in largest segments compatible with handling equipment and access availability	Removal of SGTS as a unit is required by the guide. This is impossible for the Fermi SGTS for two reasons: (1) the SGTS fans are mounted separately from the main skid, and (2) the main skid was final assembled on the fifth floor of the auxiliary building from components. Removal as a single unit is not physically possible. Replacement of SGTS is <u>not</u> necessary to remove the SGTS, it can be cut into the segments in which it was shop fabricated for removal.
k.	Protection of outdoor air intakes from weather and contamination.	Yes	Not applicable.
l.	Atmosphere cleanup system housing and ductwork limitations on maximum total leakage rate in accordance with ANSI N509-1976, duct and housing leak tests performed in accordance with ANSI N510-1975	No. Maximum total leakage rate determined in accordance with ANSI N509-1980. Duct and housing leak test developed and implemented using ANSI N510-1980 as guidance.	Fermi 2 criterion for measuring housing integrity is the housing differential pressure. It shall not decrease more than 4 in. H_2O in 5 minutes with initial internal pressure of 20 in. H_2O. In addition, SGTS must maintain the secondary containment at a net negative pressure of 0.25 in. H_2O with respect to the atmosphere.
3.0	<u>Component Design Criteria and Qualification Testing</u>		
a.	Demister performance and qualification requirements to 5.4 ANSI N509-1976	No. Demisters designed in accordance with MSAR 71-45	Fermi 2 SGTS demisters are not designed to ANSI N509. However, they are designed to the functionally similar requirements of Savannah River Laboratory Report DP-812.
b.	Air heaters designed to 5.5 ANSI N509-1976	No. The heaters are designed to reduce the relative humidity to 70 percent.	A prototype heating element will not be qualified under DBA conditions. A heater certified for heating capacity only will be used. The heaters, however, are designed to reduce the relative humidity of the incoming air to 70 percent (maximum) under the worst-expected conditions during postulated accident conditions.

CONFORMANCE OF VENTILATION SYSTEMS WITH RESPECT TO THE POSITIONS OF REGULATORY GUIDE 1.52

	Regulatory Position	Control Center Filtration System	Standby Gas Treatment System
c.	Prefilter material must withstand radiation levels and environmental conditions during a DBA, designed to 5.3 ANSI N509-1976.	No. Materials will withstand the radiation levels and environmental conditions in accordance with ANSI N509-1980.	No. Materials will withstand the radiation levels and environmental conditions in accordance with ANSI N509-1980.
d.	HEPA filter requirements to 5.1 ANSI N509-1976	No. HEPA filter requirements are in accordance with ANSI N509-1980.	No. HEPA filter requirements are in accordance with ANSI N509-1980.
e.	Design and construction requirements and materials for filter and adsorber mounting frames in accordance with 5.6.3 ANSI N509-1976	No. Designed in accordance with 4.3 ORNL-NSIC-65.	Regulatory Guide 1.52 requires HEPA filter separators to be made of corrosion-resistant unpainted steel. Fermi 2 HEPA filters have aluminum separators. HEPA demister, and prefilter frames are made of carbon steel.
f.	Design and construction requirements for filter and adsorber bank arrangements in accordance with 4.4 ERDA 76-21	No. Designed in accordance with 4.4 ORNL-NSIC-65.	No. Designed in accordance with 4.4 ORNL-NSIC-65
g.	Housing steel conformance to 5.6 ANSI N509-1976.	No. Designed in accordance with 4.5 ORNL-NSIC-65	No. Designed in accordance with 4.5 ORNL-NSIC-65
h.	Water drain recommendations in accordance with 4.5.8 ERDA-76-21	No. Designed in accordance with 4.5 ORNL-NSIC-65	No. Designed in accordance with 4.5 ORNL-NSIC-65

CONFORMANCE OF VENTILATION SYSTEMS WITH RESPECT TO THE POSITIONS OF REGULATORY GUIDE 1.52

	Regulatory Position	Control Center Filtration System	Standby Gas Treatment System
i.	Removal of gaseous iodine by adsorber material.	No. Demonstration and certification of the radiation stability of the carbon used in the adsorber will not be performed. Outside air intake radiation levels are low. Thus insignificant loss in carbon performance will take place. Each new replacement batch of impregnated activated carbon used in the adsorber section will meet the qualification and batch test results summarized in Table 5.1 of ANSI/ASME N509-1980- except for Methyl Iodine Penetration at 30°C, 95% RH. ANSI/ASME N509-1980 requires 3% penetration, maximum. Fermi 2's replacement carbon will be tested in accordance with ASTM D3803-1989 to a more stringent acceptance value of 1% penetration, maximum.	No. Seismic efficiency and certification of charcoal for design radiation will not be part of Fermi 2 testing procedures. Seismic analysis will be by calculation only, although some interments will be tested on a shaker table. Past testing experience (see footnote b in 1.0(c.)) will be considered valid for charcoal tests. Testing of new activated carbon will be performed in accordance with ASTM D3803-1989 at 30°C, 95% RH showing less than 1.0% penetration for methyl iodine.
j.	Design of adsorber cells in accordance with 5.2 ANSI N509-1976	No. Gasketless charcoal adsorber design is used in accordance with ANSI N509-1976	No. Gasketless charcoal adsorber design is used in accordance with ANSI N509-1976
k.	Fire prevention in adsorber from auto-ignition by water sprays	No. Entering air into the makeup and recirculation filter is outside air mixed with the discharge from the 99 percent efficiency SGTS, and the resulting radioactivity-induced heat in the adsorbent from this air is not expected to be sufficient for adsorbent auto-ignition	A CO_2 fire protection system is provided instead of the water spray system. Fermi 2 SGTS fire protection system functions to detect and limit charcoal temperatures to values well below the ignition limit and precludes the possibility of charcoal ignition. The ignition temperature of charcoal is 625°F. Fermi 2 CO_2 system will automatically activate at 310°F
l.	System fans provided with rated flow capacity to 5.7 and 5.8 ANSI N509-1976	No. Designed in accordance with 2.7 ORNL-NSIC-65	No. Designed in accordance with 2.7 ORNL-NSIC-65

CONFORMANCE OF VENTILATION SYSTEMS WITH RESPECT TO THE POSITIONS OF REGULATORY GUIDE 1.52

	Regulatory Position	Control Center Filtration System	Standby Gas Treatment System
m.	Atmosphere cleanup system fans on blower designed to operate under environmental conditions postulated	Yes	Yes
n.	Ductwork conformance with 5.10 of ANSI N509-1976	No. Ductwork conforms to the intent of ANSI N509-1980 for all areas of duct construction and testing. The duct construction characteristics are as follows: (1) Transverse companion angles are stitch welded on exterior of the duct, and the duct is bent or formed over the angle. (2) Longitudinal seams are mechanical-lock type and externally brazed with sealant applied to internal duct surfaces. In addition, sealant has been applied externally to the seam to enhance low leakage characteristics	No. The ductwork conforms to the intent of ANSI N509-1980 for all areas of duct construction and testing.
o.	Design configuration to minimize hazards	Yes	Yes
p.	Dampers designed to 5.9 ANSI N509-1976	No	No
4.0	Maintenance		
a.	Easy access to components in accordance with 4.7 ANSI N509-1976 and 23.8 ERDA 76-21.	No. Designed in accordance with 2.5 ORNL-NSIC-65	Fermi 2 SGTS entrance doors are about 5 ft high and probably will require a man to bend over. This is not considered a hindrance for proper maintenance.
b.	Definite mounting frame separation distance (3ft).	No. Minimum 3 ft spacing has not been provided. Components are accessible for maintenance without entering the unit housing by the use of access doors.	Sufficient spacing for component maintenance is provided even though the recommended 3ft is not always provided.
c.	Permanent test probes with external connections in accordance with 4.11 ANSI N509-1976	No. Permanent test probes provided but not necessarily in accordance with ANSI N509-1976.	No. Fermi 2 has no permanent test probes and/or manifolds, only couplings in the doors for DOP and Freon connections.

CONFORMANCE OF VENTILATION SYSTEMS WITH RESPECT TO THE POSITIONS OF REGULATORY GUIDE 1.52

	Regulatory Position	Control Center Filtration System	Standby Gas Treatment System
d.	Periodic operation of standby atmosphere cleanup system	No. Periodic operation is performed in accordance with Regulatory Guide 1.52 Revision 3, Position 6.1, per License Amendment No. 192.	No. Periodic operation is performed in accordance with Regulatory Guide 1.52 Revision 3, Position 6.1, per License Amendment No. 192.
e.	ACS components installed after active construction	Yes	Yes
5.0	In-Place Testing Criteria		
a.	Visual inspection before testing in accordance with 5 ANSI N510-1975	No. Visual inspection in accordance with ANSI N510-1980	No. Visual inspection in accordance with ANSI N510-1980
b.	The airflow distribution should be tested initially and after maintenance that affects distribution	Yes	Yes
c.	The in-place DOP test for HEPA filters should be in accordance with ANSI N510-1975 and occur initially and periodically thereafter	No.* In place DOP test in accordance with ANSI N510-1980 to confirm a penetration of less than 1.0 percent ± 10 percent rated flow. This meets Generic Letter 83-13.	No. In place DOP test in accordance with ANSI N510-1980.
d.	Bypass leakage testing of the activated carbon adsorber section should be in accordance with ANSI N510-1975	No. Bypass leakage testing in accordance with ANSI N510-1980 for a halogenated hydrocarbon refrigerant test gas to confirm a penetration less than 1.0 percent at ± 10 percent rated flow. This meets Generic Letter 83-13.	No. Bypass leakage testing in accordance with ANSI N510-1980 for a halogenated hydrocarbon refrigerant test gas.

* A silicone sealant is used as a permanent seal in HVAC ductwork.

CONFORMANCE OF VENTILATION SYSTEMS WITH RESPECT TO THE POSITIONS OF REGULATORY GUIDE 1.52

Regulatory Position	Regulatory Position	Regulatory Position
6.0 Laboratory Testing Criteria for Activated Carbon	Yes. Both the make-up and recirculation activated carbon adsorbers have been assigned a decontamination efficiency of 95 percent each. This results in a combined efficiency of 99.75 percent for the make-up air supply. Laboratory testing acceptance criteria are based on 95 percent efficient adsorbers. Laboratory testing of used activated carbon will be performed in accordance with ASTM 0383-1989 at 30°C, 70% RH showing a Methyl Iodine penetration of less than 1.0%. This is with a 2-in. bed for the emergency make-up filter train; and a 4-inch bed for the emergency recirculation air filter train. Verification of the above will be done within 31 days after removal.	Yes. (As justified below) A sample of the SGTS charcoal is removed from the adsorber by vertically inserting a “grain thief.” Charcoal removed in this manner will provide a sample possessing essentially the same characteristics of the bed and has advantages over the parallel-canister-type sample arrangement required by Regulatory Guide 1.21. The “grain thief” sample device withdraws a sample that has experienced (1) the same volume, (2) same flow rate, and (3) same exposure to contaminants as the charcoal in the bed. The parallel-canister arrangement has several disadvantages that are avoided by the present design. (1) Air will likely flow through the canister at a different rate than it flows through the bed. This will cause inconsistency in the amount of contamination or loss of efficiency between the sample and the charcol bed; (2) The parallel-canister sample arrangement will require a gasketed seal on the canister that may deteriorate and cause charcoal adsorber bypass; and (3) A parallel-canister sample arrangement will provide the potential for charcoal adsorber bypass if a sample canister is removed and not replaced or if the canister holder is not properly sealed with a cover and gasket. Laboratory testing of used activated carbon will be performed in accordance with ASTM 03803-1989 at 30°C, 70% RH showing a methyl iodide penetration of less than 0.100%. This is in accordance with ASTM 03803-1989 with a 6-inch bed. Verification of the above will be done within 31 days after removal.

The areas of noncompliance do not, either singly or in combination, reduce the high level of reliability of these systems for protecting the health, safety, and welfare of the public. The areas of noncompliance are essentially subjective in nature, and noncompliance does not functionally impair the performance of either system.

A.1.53 REGULATORY GUIDE 1.53 (June 1973), APPLICATION OF THE SINGLE-FAILURE CRITERION TO NUCLEAR POWER PLANT PROTECTION SYSTEMS

Under Section 50.55a, "Codes and Standards," of "Licensing of Production and Utilization Facilities" of 10 CFR 50, the regulatory staff requires the use of IEEE-279-1971 section 4.2 (ANSI N42.7-1972) issued in the Institute of Electrical and Electronic Engineers Criteria for

Nuclear Power Plant Protection Systems. This standard requires that any single failure of a protection system component will not alter proper protective actions at the system level.

The Fermi 2 reactor protection system (RPS) complies with Regulatory Guide 1.53 by meeting the single-failure criterion. In compliance with the positions of the guide the RPS uses redundant sensors and system logic to ensure that failure of a sensing element, decision logic, or an actuator unit will not impair other redundant system functions. Thus any single failure will not prevent or initiate protective action. The RPS employs separate channels in which a fault affecting one channel will not prevent other channels from operating. In addition, facilities exist for testing the RPS so that equipment can be operated in various test modes to confirm operability.

For details refer to Subsection 7.2.2.

A.1.54 REGULATORY GUIDE 1.54 (June 1973), QUALITY ASSURANCE REQUIREMENTS FOR PROTECTIVE COATINGS APPLIED TO WATER-COOLED NUCLEAR POWER PLANTS

The coatings used in the Fermi 2 containment are described in Subsection 6.2.1.6 and are listed in Table 6.2-8. Not all the coatings used on surfaces within the drywell and suppression pool (wetwell) are "qualified" in terms of compliance to the recommendations of Regulatory Guide 1.54. The unqualified coatings, however, have been evaluated and have been determined to have no adverse effect on the reliable performance of the plant under normal or abnormal conditions, and it is considered that the intent of Regulatory Guide 1.54 has been fulfilled.

The Plasite 7155 suppression pool (wetwell) coatings and the coatings applied to the concrete surfaces of the drywell conform to the recommendations of Regulatory Guide 1.54 and are considered fully qualified.

The Carboguard 6250 N suppression pool and torus vent header interior coating conforms to the recommendations of Regulatory Guide 1.54 (1973) with the following exceptions:

- ASTM D5139-10, endorsed by Revision 2 of Regulatory Guide 1.54, was used for surface preparation of test panels instead of ANSI N101.2-1972.
- ASTM D4082-10, endorsed by Revision 2 of Regulatory Guide 1.54, was used for radiation testing instead of ANSI N5.12-1974.
- ASTM D3912-10, endorsed by Revision 2 of Regulatory Guide 1.54, was used for chemical resistance testing instead of ANSI N5.12-1974.
- ASTM D3911-08, endorsed and supplemented by Revision 2 of Regulatory Guide 1.54, was used for evaluation of design basis accident test panels instead of ANSI N101.2-1972.
- ASTM E84, endorsed by Revision 2 of Regulatory Guide 1.54, was used for cure requirements of fire evaluation panels instead of ANSI N101.2-1972.
- There are small areas where Carboguard 6250 N coating was applied to small stainless steel components and welds or where Carboguard 6250 N overlaps Plasite 7155 coating in the suppression pool interior surfaces. These areas are considered

unqualified and tracked as indicated in Table 6.2-8. Additionally, there are small areas in the torus vent header interior vacuum breaker and downcomer penetrations where Carboguard 6250 N coating overlaps Plasite 7155 coating. DBA testing has been performed to simulate this overlap condition in order to provide reasonable assurance that, when properly applied and maintained, the coating will not detach under normal or accident conditions per ASTM D7491-08.

The unqualified Carboguard 6250 N coating areas have been evaluated and have been determined to have no adverse effect on the reliable performance of the plant under normal or abnormal conditions. The alternative standards endorsed by Revision 2 of Regulatory Guide 1.54 have been evaluated relative to the design basis standards. It is concluded that they provide an acceptable qualification basis for the Carboguard 6250 N coating at Fermi 2, and it is considered that the intent of Regulatory Guide 1.54 (1973) has been fulfilled.

Most of the coating on the drywell reactor coolant pressure boundary and the drywell primary structural steel (Carboline Carbozinc 11) was applied prior to the issuance of Regulatory Guide 1.54 and ANSI N101.4, in accordance with the accepted industry standards of that time. This coating system has a long record of reliable service in operating BWRs under a variety of adverse conditions.

The Carbozinc 11 coating has also been subjected to extensive design-basis accident (DBA) testing using a variety of application techniques. The conditions under which failure of the coating could occur and its failure mode have been evaluated (Subsection 6.2.1.6). The coating has been found to present no threat to the reliable performance of the plant under normal or abnormal circumstances.

In 1984, the commercial name of the Carbozinc 11 coating was changed to Carbozinc 11 SG. Consequently, in cases where repairs to the original Carbozinc 11 coating were needed after 1984, Carbozinc 11 SG was used.

A.1.55 REGULATORY GUIDE 1.55 (June 1973), CONCRETE PLACEMENT IN CATEGORY I STRUCTURES

The Fermi 2 procedures conform to the requirements of this guide.

For details refer to Sections 3.8 and 17.1.

A.1.56 REGULATORY GUIDE 1.56 (July 1978, Revision 1 for Comment), MAINTENANCE OF WATER PURITY IN BOILING WATER REACTORS

Fermi 2 chemistry procedures have been developed in conformance with this guide. For details, refer to Subsections 5.5.8, 9.3.2, and 10.4.6.1.2.

A.1.57 REGULATORY GUIDE 1.57 (June 1973), DESIGN LIMITS AND LOADING COMBINATIONS FOR METAL PRIMARY REACTOR CONTAINMENT SYSTEM COMPONENTS

The Fermi 2 containment was purchased, designed, and constructed in accordance with ASME Code Section III, 1968, and is not in conformance with the requirements of this guide, which are based on ASME Code Section III, 1971. Physical changes could not be made without major construction schedule impact.

For details refer to Section 3.8.

A.1.58 REGULATORY GUIDE 1.58 (September 1980, Revision 1), QUALIFICATION OF NUCLEAR POWER PLANT INSPECTION, EXAMINATION, AND TESTING PERSONNEL

The established design and construction QA program, which predates the development of ANSI N45.2.6-1973, was not committed to be in compliance with Regulatory Guide 1.58. Rather, it met the intent of the endorsed ANSI standard.

Inspection and examination personnel of site contractors have been qualified to the requirements of ANSI N45.2.6-1973. Inspection personnel of Project Quality Assurance who performed first-level inspection were also qualified to the same standard.

Edison test personnel, who are part of the Startup Organization and who perform the Checkout and Initial Operations and Preoperational testing, have been qualified to requirements that exceed the requirements of ANSI N45.2.6-1978.

During operations, the provisions of ANSI N45.2.6-1978 apply only to QA/QC inspectors. With two exceptions, the Edison operational QA program conforms to Regulatory Guide 1.58, Revision 1.

(1) For plant inspection, examination, and testing personnel, a grace period of 90 days beyond the maximum one-year cycle is allowed for the completion of at least one inspection or examination.

(2) Edison's exception to NRC Position C.6, regarding the educational requirements, is based on the concern that these requirements, when applied to contractors and vendors, would disqualify fully qualified inspection personnel who have demonstrated the ability to perform but lack the education. The ability to perform should be the only criterion.

A.1.59 REGULATORY GUIDE 1.59 (August 1977, Revision 2), DESIGN BASIS FLOODS FOR NUCLEAR POWER PLANTS

The analytical methods for assessment of design-basis floods at the Fermi 2 site differ in some areas from those presented in Regulatory Guide 1.59, Revision 2. The methods employed for Fermi 2 were reviewed by the NRC staff and were determined to be acceptable. (Refer to NUREG-0314, Sections 2.4 and 3.4.)

A.1.60 REGULATORY GUIDE 1.60 (December 1973, Revision 1), DESIGN RESPONSE SPECTRA FOR SEISMIC DESIGN OF NUCLEAR POWER PLANTS

The Fermi 2 design is not in conformance with the recommendations of this guide. The DBE (now called the SSE) for this plant was defined in 1971; it was reviewed by the AEC/DRL in May 1971, and judged to be reasonable and conservative by the staff and consultants. The seismic environment required in Revision 1 by the AEC sets criteria which in some cases are up to 50 percent more conservative than those used in Fermi 2 design. The following table shows the comparison of design response spectra. Although the Fermi 2 design is not in conformance with the specific numerical requirements of this guide, the discrepancy between recommended response spectra of Revision 1 and the design of Fermi 2 does not have any significant impact on reactor safety.

COMPARISON OF DESIGN RESPONSE SPECTRA

I. Horizontal OBE (2 percent damping)

Parameter	Control Point	Fermi 2	Regulatory Guide 1.60
Acceleration (g)	A	0.08	0.08
Acceleration (g)	B	0.14	0.28
Acceleration (g)	C	0.17	0.34
Displacement (in.)	D	5.0	7.2

II. Horizontal SSE (5 percent damping)

Parameter	Control Point	Fermi 2	Regulatory Guide 1.60
Acceleration (g)	A	0.15	0.15
Acceleration (g)	B	0.18	0.39
Acceleration (g)	C	0.22	0.47
Displacement (in.)	D	7.5	11.0

For details on seismic design bases, refer to Subsections 3.7.1.1, 3.7.1.3, 3.7.2.1, 3.7.2.2, 3.7.2.6, 3.7.3.6, 3.7.3.15, 3.7.3.16, 3.7.4.4, and 3.7.5.2.

In response to a request from the NRC Geosciences Branch, a site-specific earthquake ground response spectrum (essentially per Regulatory Guide 1.60 pegged at 0.15g horizontal) was developed, and structures, systems, and components required for cold shutdown were reassessed for the effect of this site-specific earthquake (see Subsections 2.5.2.11 and 3.7.1.2.1).

A.1.61 REGULATORY GUIDE 1.61 (October 1973), DAMPING VALUES FOR SEISMIC DESIGN OF NUCLEAR POWER PLANTS

The Fermi 2 design conforms to the required damping values for Category I structures, components, and systems. Thus, these structures, components, and systems will remain functional in the event of an SSE as required by Appendix A to 10 CFR 100, "Seismic and Geologic Siting Criteria," and 10 CFR 100, "Reactor Site Criteria." A comparison of model damping values as an analysis of viscous damping for elastic spectral or time-history dynamics has shown that Fermi 2 values are lower than Regulatory Guide 1.61 specifications. Therefore, the Fermi 2 design meets the guide requirements. The following table displays the comparison of guide and Fermi 2 project damping values for each division of structure or component required by the guide except prestressed concrete structures, which Fermi 2 does not have. In addition, specific values of damping are given for the RPV, CRD housing, fuel, and coupling drywell-building values. Fermi 2 damping values are conservatively two to four times lower than the regulatory guide requirements except in the case of bolted steel structures. The comparison shows compliance with Position 1 of the guide.

Therefore due to the lower damping values, Position 2 requiring documented test data of dynamic seismic analysis is not applicable. The use of lower damping values is conservatively incorporated into the Fermi 2 design, thus avoiding an underestimation of vibration amplitudes and dynamic stresses. As a result, Position 3 of the guide has been complied with.

DAMPING VALUES

Item	Percent of Critical: Operating-Basis Earthquake (1/2 SSE)		Safe-Shutdown Earthquake	
	Fermi 2	R.G. 1.61	Fermi 2	R.G. 1.61
General				
Equipment and large (12 in.) diameter piping	0.5	2.0	1.0	3.0
Small-diameter piping (12 in.)	0.5	1.0	1.0	2.0
Welded and H.S. bolted steel framed structures	2.0	2.0	5.0	4.0
Bolted and riveted steel framed structures	5.0	4.0	10.0	7.0
Welded structural assemblies (equipment and supports)	2.0		4.0	
Reinforced concrete structures	2.0	4.0	5.0	7.0
Specific				
Reactor pressure vessel	2.0		2.0	
CRD housing	3.5		3.5	
Fuel	7.0		7.0	
Drywell-building (coupled)	2.0		5.0	

For details on the seismic analysis, refer to Subsections 3.7.3.6 through 3.7.3.16, and 3.7.5.1 through 3.7.5.4.

A.1.62 REGULATORY GUIDE 1.62 (October 1973), MANUAL INITIATION OF PROTECTIVE ACTIONS

The Fermi 2 system design is in partial conformance with this guide.

The isolation system does not have a single manual pushbutton that actuates all valves closed. A manual switch is available to close each individual valve.

The automatic depressurization system (ADS) cannot be actuated manually at the system level. Manual actuation is available at the component level.

Manual initiation of the low pressure coolant injection (LPCI) system is not available at the system level. However, since a low reactor pressure interlock prevents the premature opening of the injection valves from either manual or automatic initiation, actuation at the component level is considered adequate.

The core spray system cannot be actuated by a single manual switch. Manual switches are available in the main control room to actuate the individual system components.

The high pressure coolant injection (HPCI) system cannot be actuated by a single manual switch. Manual switches are available in the main control room to actuate the individual components of the system.

A.1.63 REGULATORY GUIDE 1.63 (July 1978, Revision 2), ELECTRIC PENETRATION ASSEMBLIES IN CONTAINMENT STRUCTURES FOR LIGHT-WATER-COOLED NUCLEAR POWER PLANTS

The guidelines presented in Regulatory Guide 1.63, Revision 2, apply to nuclear power plants for which construction permit applications were docketed after December 30, 1977. The application for Fermi 2 was docketed in 1969 and, as such, is exempt from the guidelines of Regulatory Guide 1.63. However, the Fermi 2 design complies with the intent of Regulatory Guide 1.63 (October 1973, Revision 0). For details, refer to Subsections 6.2.1.2.1.5, 6.2.1.4.1.1, and 8.3.1.3.

A.1.64 REGULATORY GUIDE 1.64 (June 1976, Revision 2), QUALITY ASSURANCE REQUIREMENTS OF THE DESIGN OF NUCLEAR POWER PLANTS

The NRC regulatory staff has accepted ANSI Standard N45.2.11-1974, "Quality Assurance Requirements for the Design of Nuclear Power Plants," as an acceptable method of complying with the Commission's regulations in regard to Design Control. The initial issue of Regulatory Guide 1.64, which endorsed a draft version of ANSI N45.2.11, was published in October 1973, approximately a year after the issuance of the QA Manual. Later revisions of Regulatory Guide 1.64 were published in February 1975, and June 1976. Regulatory Guide 1.64, Revision 1, endorsed the approved ANSI Standard N45.2.11-1974, and was applicable to submittals docketed after April 1, 1975. Regulatory Guide 1.64, Revision 2, clarified the limitations on performance of "independent design verification" by supervisors, and was applicable to submittals docketed after July 15, 1976.

The current Fermi 2 QA Program was planned to meet the requirements of 10 CFR 50, Appendix B. It includes the elements of Design Control necessary for approval at the time it was submitted. To retrofit to the requirements of Regulatory Guide 1.64, Revision 2, was not feasible, and to modify the Design Control program for the remainder of the design and construction phase would have been disruptive.

During the operational phase, design activities will be required to comply with ANSI N45.2.11 as endorsed by Regulatory Guide 1.64, Revision 2.

A.1.65 REGULATORY GUIDE 1.65 (October 1973), MATERIALS AND INSPECTIONS FOR REACTOR VESSEL CLOSURE STUDS

The Fermi 2 design and inspection procedures are in conformance with the requirements of this guide except those in Regulatory Positions 2b, 2e, and 3.

Studs were examined in accordance with the requirements of ASME Boiler and Pressure Vessel Code Section III, N-325 (1968 edition plus 1969 Addendum (Summer) in effect at time of contract). Bored blank nuts were ultrasonically examined by both the longitudinal and shear wave methods. Shear wave examination on the nuts was performed in both the axial and circumferential directions.

Regulatory Position 3 recommends provision for adequate corrosion protection during venting and filling of the vessel, and while the head is removed. General Electric supplies thread protectors that prevent stud damage, but stud holes are not plugged, and neither stud nor flange threads are protected from exposure to water. In practice this has been found to be adequate for studs complying with Regulatory Guide 1.65 Regulatory Position 1 & 2, as exposure to applied loads and operating and servicing environments has not required the replacement of any BWR studs (which were in compliance as stated above) or flange threads. No corrosion protection for studs is proposed.

For details, refer to Section 5.4.

A.1.67 REGULATORY GUIDE 1.67 (October 1973), INSTALLATION OF OVERPRESSURE PROTECTION DEVICES

The guidance provided by this Regulatory Guide has been applied in the installation of the Fermi 2 overpressure protection devices.

A.1.68 REGULATORY GUIDE 1.68 (August 1978, Revision 2), INITIAL TEST PROGRAMS FOR WATER-COOLED REACTOR POWER PLANTS

Compliance with Revision 2 to Regulatory Guide 1.68 is required of applicants for operating licenses docketed after August 15, 1978. Since the docket date for Fermi 2 significantly precedes this effective date, Revision 2 to the Regulatory Guide was not implemented.

The preoperational and initial startup test program were in compliance with those portions of Regulatory Guide 1.68, Revision 0, applicable to BWRs and to Fermi 2 systems, except as noted below:

a. Position D.2.o (Appendix A)

No test of rod pattern exchange was planned. This test has been eliminated from the normal GE prescribed test program and equivalent testing is incorporated in the core performance test

b. Position D.2.r (Appendix A)

No two-pump reactor recirculation pump trip at 100 percent power will be performed. With recent improvement in analytical methods, the two-pump trip at 100 percent power is no longer considered to be a significant fuel thermal transient. The two-pump trip would subject the plant to a large power loss and potential scram. The planned one-pump trip testing will provide adequate plant instability response testing.

Revisions 1 and 2 of Regulatory Guide 1.68 do not affect Edison's position with regard to the Fermi 2 initial test program.

For further details refer to Chapter 14.

A.1.68.1 <u>REGULATORY GUIDE 1.68.1 (January 1977, Revision 1), PREOPERATIONAL AND INITIAL STARTUP TESTING OF FEEDWATER AND CONDENSATE SYSTEMS FOR BOILING WATER REACTOR POWER PLANTS</u>

The Fermi 2 Preoperational and Startup Phase Testing Program for the condensate and feedwater systems meets the intent of Regulatory Guide 1.68.1, Revision 1.

For details refer to Subsections 14.1.3 and 14.1.4.

A.1.68.2 <u>REGULATORY GUIDE 1.68.2 (July 1978, Revision 1), INITIAL STARTUP TEST PROGRAM TO DEMONSTRATE REMOTE SHUTDOWN CAPABILITY FOR WATER-COOLED NUCLEAR POWER PLANTS</u>

Fermi 2 is in compliance with Regulatory Guide 1.68.2. Preoperational testing to demonstrate the remote-shutdown capabiliity of Fermi 2 was conducted in accordance with the requirements of this guide.

For details, refer to Subsection 14.1.4.8.26.

A.1.69 <u>REGULATORY GUIDE 1.69 (December 1973), CONCRETE RADIATION SHIELDS FOR NUCLEAR POWER PLANTS</u>

Regulatory Guide 1.69 cites ANSI N101.6-1972, "Concrete Radiation Shields," as applicable to nuclear power plant shielding. The Fermi 2 plant design meets the intent of this guide.

For details refer to Section 12.1.

A.1.70 REGULATORY GUIDE 1.70 (November 1978, Revision 3), STANDARD FORMAT AND CONTENT OF SAFETY ANALYSIS REPORTS FOR NUCLEAR POWER PLANTS

The Fermi 2 UFSAR is in the format of Revision 1 to this guide, which was the current revision at the time of submittal of the original FSAR. Chapter 15 is in the format of Revision 2.

A.1.71 REGULATORY GUIDE 1.71 (December 1973), WELDER QUALIFICATION FOR AREAS OF LIMITED ACCESSIBILITY

Edison's welding program at Fermi 2 requires qualification of welders as described in this regulatory guide. This requirement applies to both Edison and contractor welders working at Fermi 2. Welds are evaluated individually to determine if testing for compliance with this guide is required.

A.1.72 REGULATORY GUIDE 1.72 (July 1978, Revision 2), SPRAY POND PIPING MADE FROM FIBERGLASS-REINFORCED THERMOSETTING RESIN

This regulatory guide is not applicable to Fermi 2 design and QA requirements. The Fermi 2 plant does not use fiberglass-reinforced thermosetting plastic materials in the construction of ultimate heat sink piping.

A.1.73 REGULATORY GUIDE 1.73 (January 1974) QUALIFICATION TESTS OF ELECTRIC VALVE OPERATORS INSTALLED INSIDE THE CONTAINMENT OF NUCLEAR POWER PLANTS

Regulatory Guide 1.73 pertains to qualification and testing of Class 1 electric valve operators for service within the containment of light-water-cooled nuclear power plants. Based on Section III, "Design Control," of Appendix B to 10 CFR 50, "Quality Assurance Criteria for Nuclear Power Plants and Fuel Reprocessing Plants," this guide requires qualification testing of a prototype unit under conservative design conditions. To guide such testing, the commission has adopted IEEE Standard 382-1972, "IEEE Trial-Use Guide for Type Test of Class 1 Electric Valve Operators for Nuclear Power Generating Stations," as acceptable methods for testing. Review of Fermi 2 electric valve operators considering the criteria of IEEE 382-1972 shows that the valve operators are in compliance with the requirements stated in Position 1 of the guide. Valve operators within containment are provided with NEMA Class H insulation. The insulation as well as the operators are seismic, radiation, and temperature qualified to withstand containment normal operating conditions and the DBA conditions. The test sequence given in IEEE 382-1972 is more conservative than actual operating conditions. Therefore, in compliance with Position 2, Section 4.5.2 of the standard was applied in the test-analysis of the operators. These tests included periodic actuating conditions at 340°F steam atmosphere and radiation testing of 2.0 x 10^8 rads. These conditions simulate the most severe DBA and are thus as conservative as Position 3 of this guide. An exception is valve E11-F608, which has non-Class H insulation. However, this valve is not required to operate during or after an accident to mitigate the consequences of the accident.

A.1.74 REGULATORY GUIDE 1.74 (February 1974), QUALITY ASSURANCE TERMS AND DEFINITIONS

In order to ensure that Fermi 2 has been designed and built in accordance with the commitments made in (1) the Final Safety Analysis Report, (2) a planned and systematic program of Quality Assurance Criteria for Nuclear Power Plants and Fuel Reprocessing Plants, and (3) 10 CFR 50, a documented lexicon of terms and definitions, which describes and characterizes the operating functions of plant structures, systems, and components, which is universal and conforming to common industrial usage, must be devised. To comply with the intent of the recommendations of Regulatory Guide 1.74 and 10 CFR 50, ANSI N45.2.10 was adopted by Fermi 2. This standard of word usage was applied to project contracts, letters of intent, work orders, purchase orders or proposals, and legal authorizations. The recently updated document ANSI N45.2.10-1973 recommended by this guide and the Fermi 2 adopted ANSI N45.2.10 differ insignificantly. Fermi 2 word usage thus conforms generally with QA definitions contained in ANSI N45.2.10. Any changes in usage at the late date within the project would have been detrimental to the continuity of project documentation and personnel communications. Therefore, the changes in the updated revision of ANSI N45.2.10 were not incorporated into Fermi 2 project documents.

A.1.75 REGULATORY GUIDE 1.75 (September 1978, Revision 2), PHYSICAL INDEPENDENCE OF ELECTRIC SYSTEMS

The Fermi 2 plant is not in full compliance with Regulatory Guide 1.75. This guide was issued after the design criteria of Fermi 2 were formulated. Revision 1 of this guide requires application of IEEE Standard 384-1974, "IEEE Trial Use Standard Criteria for Separation of Class 1E Equipment and Circuits." This standard classifies associated circuits as non-Class 1E circuits which share power supplies, enclosures, or raceways with Class 1E circuits or are not separated by distance or barriers from Class 1E components. The Fermi 2 plant does not classify by unique identification or color coding associated circuits.

IEEE Standard 384 also requires a use of isolation devices that do not influence Class 1E equipment during a LOCA. Thus these devices cannot interrupt normal device functions solely by fault current.

In general, the associated circuits must be analyzed to demonstrate no degradation of Class 1E circuit functions. Although identification of associated circuits per se has not been performed, a complete study of Class 1E circuits and their interaction with all other circuits has proved that sufficient isolation and physical separation exist in Fermi 2 design to ensure safe operation.

The comparison of the Fermi 2 design and the regulatory position of Regulatory Guide 1.75, Revision 1, is found in Subsection 3.12.4.

A.1.76 REGULATORY GUIDE 1.76 (April 1974), DESIGN BASIS TORNADO FOR NUCLEAR POWER PLANTS

Under GDC 2, "Design Bases for Protection Against Natural Phenomena," of Appendix A to 10 CFR 50, it is required that structures, systems, and components be able to withstand the effects of natural phenomena. In particular, Regulatory Guide 1.76 cites tornado effects as a concern for design and defines maximum wind conditions. In compliance with Position 1 of this guide, the Fermi 2 plant has been analyzed with conditions defined in a design-basis tornado. The Fermi 2 design-basis tornado is a tornado having a rotational wind velocity of 300 mph, a translational wind velocity of 60 mph and a resultant external pressure drop of 3 psi at the rate of 1 psi/sec.

The Fermi 2 design-basis tornado is virtually identical with the tornado defined in Table 1 of Regulatory Guide 1.76. As described in Subsection 3.3.2.1, the rotational and translational wind velocities given in the guide are slightly different (290 mph/70 mph, respectively); however, the total maximum velocity is the same. Although the rate of pressure drop given in the guide is faster (2 psi/sec) the magnitude of the pressure drop is the same.

Even though the Fermi 2 design-basis tornado was established several years before the issuance of Regulatory Guide 1.76, values were used in the analysis that compare very favorably with the recommendations issued in the guide.

The design of the 4160-V RHR cable vaults and the manholes and ductbanks between these cable vaults and the Reactor/Auxiliary building cable vaults is based on criteria established in Regulatory Guide 1.76, Revision 1 (March 2007) and applicable sections of NUREG-0800, Standard Review Plan 3.5.3 Revision 3 (March 2007).

The Design Basis Tornado wind characteristics are in accordance with Regulatory Guide 1.76 Revision 1 (March 2007) are as follows:

a. A maximum wind velocity of 230 mph

b. A maximum rotational wind velocity of 184 mph

c. A translational wind velocity of 46 mph

d. An external pressure drop of 1.2 psi at the rate of 0.5 psi/sec

For details refer to Subsection 3.3.2.1.

A.1.77 <u>REGULATORY GUIDE 1.77 (May 1974), ASSUMPTIONS USED FOR EVALUATING A CONTROL ROD EJECTION ACCIDENT FOR PRESSURIZED WATER REACTORS</u>

This guide is not applicable to Fermi 2, which is a BWR.

A.1.78 <u>REGULATORY GUIDE 1.78 (Revision 1), ASSUMPTIONS FOR EVALUATING THE HABITABILITY OF A NUCLEAR POWER PLANT CONTROL ROOM DURING A POSTULATED HAZARDOUS CHEMICAL RELEASE</u>

The release of hazardous chemicals presents a potential loss of control room habitability. Criterion 4, "Environmental and Missile Basis," and Criterion 19, "Control Room," of 10 CFR 50 govern the safe operation of a nuclear power plant under normal and abnormal conditions of toxic chemical releases.

Of the toxic chemicals listed in Regulatory Guide 1.78, the following have been identified as present within a 5-mile radius of the plant:

Chemical	Quantity	Location	Distance From Control Center (ft)
Liquid nitrogen	6000 gal	West wall of Reactor building	170

In general, Fermi 2 is in compliance with Regulatory Guide 1.78, Revision 1. However, there are shipments of hazardous chemicals by rail and road routes within a 5-mile radius of the plant. The closest transportation line lies about 3.5 miles from the plant. As discussed in Section 6.4.3.4, at this distance, a release of a hazardous chemical is not considered a threat to Fermi 2 control room habitability.

A.1.79 REGULATORY GUIDE 1.79 (September 1975, Revision 1), PREOPERATIONAL TESTING OF EMERGENCY CORE COOLING SYSTEMS FOR PRESSURIZED WATER REACTORS

This guide is not applicable to Fermi 2, which is a BWR.

A.1.80 REGULATORY GUIDE 1.80 (June 1974), PREOPERATIONAL TESTING OF INSTRUMENT AIR SYSTEMS

Preoperational testing of the control air system was in accordance with this guide.

A.1.81 REGULATORY GUIDE 1.81 (January 1975, Revision 1), SHARED EMERGENCY AND SHUTDOWN ELECTRIC SYSTEMS FOR MULTI-UNIT NUCLEAR POWER PLANTS

This guide is not applicable to Fermi 2 because the current design incorporates only a single nuclear generating unit.

A.1.82 REGULATORY GUIDE 1.82 (May, 1996, Revision 2), WATER SOURCES FOR LONG TERM RECIRCULATION COOLING FOLLOWING A LOSS-OF-COOLANT ACCIDENT

Consistent with Section D, the Detroit Edison response to NRC Bulletin 96-03 committed to replace the original RHR and CS suction strainers with new, larger passive strainers designed to meet the sizing criteria of Revision 2 of this regulatory guide. The new strainers, which were designed and installed in RF06, are of the GE optimized stacked-disk [OSD] design. Whereas the original design sizing was predicated on the deterministic assumption of 50% plugging, the new OSD strainers were designed under the commitment to satisfy the mechanistic design methodology described in Revision 2 of the Regulatory Guide. In their closure of the Fermi response to Bulletin 96-03, the NRC expressed their understanding that the design of the Fermi OSD strainers was performed in accordance with the method provided in NEDO-32686, BWROG Utility Resolution Guidance. The NRC SER that approved the URGs did not accept its proposed analytical methodology for calculating debris head loss and instead stipulated that the calculation of debris head loss were based on vendor supplied analytical correlations developed from tested performance. This requirement is satisfied by utilizing the debris head loss methodology in the NRC-approved GE Licensing

Topical Report NEDO-32721P-A, except as modified to correct elements of the method affected by errors identified in GE Safety Communication 08-02.

A.1.83 REGULATORY GUIDE 1.83 (July 1975, Revision 1), INSERVICE INSPECTION OF PRESSURIZED WATER REACTOR STEAM GENERATOR TUBES

This guide is not applicable to Fermi 2, which is a BWR.

A.1.84 REGULATORY GUIDE 1.84 (September 1983, Revision 21), DESIGN AND FABRICATION CODE CASE ACCEPTABILITY--ASME SECTION III, DIVISION 1

The Fermi 2 plant is in compliance with Regulatory Guide 1.84.

To ensure integrity of the RCPB commensurate with its important safety function, Fermi 2 has applied the code cases of the ASME Boiler and Pressure Vessel Code Section III, to design, fabrication, erection, and testing of Class 1 components within the limitations set forth in 10 CFR 50, Section 50.55(a).

For specific identification of the code cases used, refer to Table 5.2-3.

A.1.85 REGULATORY GUIDE 1.85 (September 1983, Revision 21), MATERIALS CODE CASE ACCEPTABILITY--ASME SECTION III, DIVISION 1

To ensure integrity of the RCPB commensurate with its important safety function, Fermi 2 has applied the code cases of the ASME Boiler and Pressure Vessel Code Section III, to design, fabrication, erection, and testing of Class 1 components within the limitations set forth in 10 CFR 50.55(a) and Regulatory Guide 1.85. Thus the Fermi 2 RCPB is in compliance with the positions of this guide.

For specific identification of the code cases used, refer to Table 5.2-3.

A.1.86 REGULATORY GUIDE 1.86 (June 1974), TERMINATION OF OPERATING LICENSES FOR NUCLEAR REACTORS

This guide is not presently applicable to Fermi 2. At the time of decommissioning and dismantlement of the Fermi 2 plant, Edison intends to follow procedures in compliance with this guide.

A.1.87 REGULATORY GUIDE 1.87 (June 1975, Revision 1), GUIDANCE FOR CONSTRUCTION OF CLASS 1 COMPONENTS IN ELEVATED TEMPERATURE REACTORS (SUPPLEMENT TO ASME SECTION III CODE CASES 1592, 1593, 1594, 1595, and 1596)

This guide is not applicable to the Fermi 2 BWR.

A.1.88 REGULATORY GUIDE 1.88 (October 1976, Revision 2), COLLECTION, STORAGE, AND MAINTENANCE OF NUCLEAR POWER PLANT QUALITY ASSURANCE RECORDS

The guidelines presented in Regulatory Guide 1.88 (Revision 2) apply to nuclear power plants that were issued a construction permit after December 1975. Fermi 2 received its construction permit in September 1972 and is therefore exempt from these guidelines.

The NRC regulatory staff has accepted ANSI Standard N45.2.9-1974, "Requirement for the Collection, Storage, and Maintenance of Quality Assurance Records for Nuclear Power Plants," as an approved method of complying with the Commission's regulations in regard to QA records.

The QA Record System for the initial design and construction phase was based on the requirements in Criterion XVII of 10 CFR 50, Appendix B. To attempt to retrofit the QA records program to conform to all aspects of the ANSI Standard would not have been feasible, and changing the QA record system as it applied to the remaining design and construction work would have been extremely disruptive.

During the operational phase of Fermi 2, the records management operation will be conducted in two stages. From the time the record is generated until it is transmitted to Information Systems for permanent storage, the record will be maintained in an interim storage cabinet with at least 1-hr fire rating. Subsequent storage by Information Systems will comply with Regulatory Guide 1.88. The interim storage in a 1-hr cabinet will not exceed 1 year.

A.1.89 REGULATORY GUIDE 1.89 (June 1984, Revision 1), ENVIRONMENTAL QUALIFICATION OF CERTAIN ELECTRIC EQUIPMENT IMPORTANT TO SAFETY FOR NUCLEAR POWER PLANTS

The guidelines presented in Regulatory Guide 1.89, Revision 1, apply to nuclear power plants which were not previously required, by the NRC, to qualify equipment in accordance with NUREG-0588, "Interim Staff Position on Environmental Qualification of Safety Related Electrical Equipment."

Fermi 2 was required to provide environmental qualification to NUREG-0588 per NRC memorandum and Order CLI-80-21 (see Subsection 3.11.5 for compliance). Therefore, the requirements of Regulatory Guide 1.89, Revision 1, are not applicable to Fermi 2 except for replacement equipment (Section C.6 of Regulatory Guide 1.89, Revision 1).

With regard to replacement equipment, the requirement is to upgrade all replacement equipment, installed subsequent to February 22, 1983, to the provisions of 10 CFR 50.49 unless there are "sound reasons to the contrary." However, the requirements of 10 CFR 50.49 (see Section 3.11), regarding replacement equipment, are such that holders of operating licenses are not required to requalify electrical equipment important to safety in accordance with 10 CFR 50.49 if the NRC had previously required qualification of that equipment in accordance with NUREG-0588.

Since the Fermi 2 Environmental Qualification Program was established based on the requirements of NUREG-0588, the requirements for replacement equipment specified in

NUREG-0588 and NRC Generic Letter 82-09 provide the guidelines to be used for Fermi 2. Certain information contained in Regulatory Guide 1.89, Revision 1, will be used in addition to the above guidelines when further clarifications are required. An exception to these requirements has been taken in that a specific program for addressing equipment upgrade for components being procured was not implemented until April 1985 and that equipment already procured and/or in stock prior to April 1985 was not reevaluated to these equipment upgrade requirements.

The specific replacement equipment requirements applicable to Fermi 2 are as follows:

a. Equipment qualified to NUREG-0588, Category I, requirements is considered qualified to the highest standards required by 10 CFR 50.49. Replacements for this category of equipment are not required to be upgraded

b. Equipment qualified to NUREG-0588, Category II, requirements shall be upgraded to NUREG-0588, Category I, when replacement equipment is procured unless "sound reasons to the contrary," as specified in Generic Letter 82-09 and/or Regulatory Guide 1.89, Revision 1, are established and documented.

A.1.90 REGULATORY GUIDE 1.90 (August 1977, Revision 1), INSERVICE INSPECTION OF PRESTRESSED CONCRETE CONTAINMENT STRUCTURES WITH GROUTED TENDONS

This regulatory guide is not applicable to Fermi 2, which does not use a concrete containment.

A.1.91 REGULATORY GUIDE 1.91 (February 1978, Revision 1), EVALUATION OF EXPLOSIONS POSTULATED TO OCCUR ON TRANSPORTATION ROUTES NEAR NUCLEAR POWER PLANTS

This guide applies to nuclear power plants for which construction permit applications were docketed on or after March 14, 1975. Fermi 2 was docketed in 1969 and is exempt from the guidelines of Regulatory Guide 1.91. However, Fermi 2 has completed review of this guide.

Fermi 2 is located in design-basis tornado region I. This is based on a calculated maximum wind speed of 360 mph and a dynamic wind pressure of 3 psi (see Subsection 3.3.2.1). A survey of transportation routes within 10 miles of Fermi 2 has been made. The results are documented in Subsections 2.2.1 and 2.2.2. As stated in Subsection 2.2.3.3, no conceivable event--including explosions associated with offsite airways, shipping channels, highways, railroads, and pipelines in the area--is expected to influence normal operation of the plant. All transportation routes, "distances of closest approach," are in excess of 4 miles or 21,000 ft from Fermi 2. Figure 2 of Regulatory Guide 1.91 indicates that an explosion in excess of 5000 tons of equivalent TNT would be necessary to affect plant operations. No further consideration of explosion possibilities on transportation routes is warranted. Fermi 2 is thus in compliance with Regulatory Guide 1.91.

A.1.92 REGULATORY GUIDE 1.92 (February 1976, Revision 1), COMBINING MODAL RESPONSES AND SPATIAL COMPONENTS IN SEISMIC RESPONSE ANALYSIS

The guidelines presented in Regulatory Guide 1.92 apply to nuclear power plants for which construction permit applications were docketed after February 1976. The application for Fermi 2 was docketed in 1969 and because of this, Fermi 2 is exempt from the guidelines of Regulatory Guide 1.92. However, Edison has completed review and analysis of the Fermi 2 design with respect to compliance with Regulatory Guide 1.92, Revision 1. Design calculations incorporated in the Fermi 2 vibration-response analysis use spatial component and vibration mode combination by taking the square root of the sum of the squares (SRSS) with due considerations to closely spaced modes in modal combinations as required by Regulatory Guide 1.92, Revision 1. The details of this method are described in Subsection 3.7.3.4. The mathematical analysis in which the resultant modes were evaluated is described in Subsection 3.7.2.1.2.3. It is concluded, therefore, that the Fermi 2 design conforms to the requirements of Regulatory Guide 1.92, Revision 1.

A.1.93 REGULATORY GUIDE 1.93 (December 1974), AVAILABILITY OF ELECTRIC POWER SOURCES

As required by GDC 17, "Electric Power Systems," of Appendix A to 10 CFR 50, two physically independent offsite power and transmission networks along with redundant onsite ac power sources and redundant onsite dc power supplies must be included in the design of each nuclear unit. Limiting conditions for operation (LCO) during the use of emergency electrical power supplies are given in Regulatory Guide 1.93 in accordance with 10 CFR 50, "Licensing of Production and Utilization Facilities," Section 50.36(c)(2).

Regulatory Guide 1.93 is used by the Regulatory Staff in evaluating all construction permit applications for which the issue date of the SER is July 1, 1974, or after. Hence Fermi 2 is not required to comply with this guide, and such compliance is not envisaged. The Fermi 2 project review reveals that the only possible way to fully comply with this guide and still meet the original design intent would be to add a third onsite source (a fifth EDG) that could be used in either division. The plant design and construction had progressed to the point where this change was no longer feasible.

The results of the review that led to these conclusions are summarized below.

The intent of the regulatory positions as stated in Regulatory Guide 1.93 is to implement the safest operating mode whenever the available electric power sources are less than LCO. In the case of Fermi 2, the LCO consists of two offsite sources and two onsite ac power sources. The offsite sources are (1) a 4.16-kV service line stepped down from a 345-kV transmission source by S.S. transformer 65 and (2) a 4.16-kV service line from S.S. transformer 64 stepped down from a 13.2-kV source from the 120-kV transmission bus via switchyard transformer 1. (Refer to Figure 8.3-1.) The two onsite ac sources consist of the four EDGs, two per division. The onsite dc sources consist of dual 130/260-V battery systems, one per division. In the terms of Regulatory Guide 1.93, there are two offsite and two onsite ac sources and two dc sources for LCO.

The regulatory guide's positions describe five levels of degradation of emergency power sources. These levels, the Regulatory Guide compliance position, and the Fermi 2 project position are described on the following pages.

Level of Degradation	Regulatory Guide 1.93 Position	Fermi 2 Project Position
1. The available ac power sources are one less than LCO	Power operation may continue for 72 hr based on system conditions and reserves. If source is restored during this time, unrestricted operation may continue	a. Loss of one offsite source: Fermi 2 would be shut down b. Loss of one onsite source: Fermi 2 must take exception to the Regulatory position. If EDG damage were severe, it could be months before Fermi 2 could return to power under the limits imposed by this regulatory guide. The Fermi 2 design was based on continuous power generating as long as the remaining standby source is verified regularly.
2. The available offsite ac power sources are two less that the LCO	Power operation may continue for 24 hr, pending possibility of restoring circuits.	With loss of both offsite sources, Fermi 2 must shut down.
3. The available offsite and onsite ac power sources are each one less than the LCO	Power operation may continue for 12 hr with limitation based on one source being restored during that time. If either source is restored, operation may continue for 72 hr in accordance with Position 1.	a. Loss of offsite ac power source: Fermi 2 must be shut down. b. Loss of onsite ac power source: if the offsite source is restored, Fermi 2 should be able to return to power based on verification of the remaining onsite source (see Position 1)

Level of Degradation	Regulatory Guide 1.93 Position	Fermi 2 Project Position
4. The available onsite ac power sources are two less than the LCO	Power operation should not exceed 2 hr. If one source is restored within 2 hr, operation may continue for 72hr.	If both onsite sources are lost, Fermi 2 would be shut down. However, if one source were returned, Fermi 2 would continue to operate, as long as that source was verified regularly.
5. The available onsite dc supplies are one less than LCO	Power operation may continue for a period not to exceed 2 hr. If dc power is restored unrestricted, operation may be resumed.	Fermi 2 would comply with this position. The possibility of this occurring considering the Fermi 2 dc system design is extremely remote.

A.1.94 REGULATORY GUIDE 1.94 (April 1976, Revision 1), QUALITY ASSURANCE REQUIREMENTS FOR INSTALLATION, INSPECTION, AND TESTING OF STRUCTURAL CONCRETE AND STRUCTURAL STEEL DURING THE CONSTRUCTION PHASE OF NUCLEAR POWER PLANTS

The implementation of Regulatory Guide 1.94 applies to nuclear power plants submitting applications for construction permits on or after October 15, 1976. The application for Fermi 2 was docketed in 1969. The necessary tests, inspections, records, and data for compliance were not a strict part of Fermi 2 construction procedures. For this reason, records are not in strict compliance with ANSI N45.2.5-1974. Various methods of construction, testing, recording, and material testing have been used during the fabrication of plant structures. As a result, documentation that ensures high quality in materials and workmanship has been retained by the Project's Quality Assurance Group. An outline of these activities as pursued by Fermi 2 is presented in Section 17.1.

A.1.95 REGULATORY GUIDE 1.95 (January 1977, Revision 1), PROTECTION OF NUCLEAR POWER PLANT CONTROL ROOM OPERATORS AGAINST AN ACCIDENTAL CHLORINE RELEASE

Superseded by License Amendment 147

A.1.96 REGULATORY GUIDE 1.96 (June 1976, Revision 1), DESIGN OF MAIN STEAM ISOLATION VALVE LEAKAGE CONTROL SYSTEMS FOR BOILING WATER REACTOR NUCLEAR POWER PLANTS

Superseded by License Amendment 160.

A.1.97 REGULATORY GUIDE 1.97 (December 1980, Revision 2), INSTRUMENTATION FOR LIGHT-WATER-COOLED NUCLEAR POWER

PLANTS TO ASSESS PLANT AND ENVIRONS CONDITIONS DURING AND FOLLOWING AN ACCIDENT

As a result of the post-TMI concerns delineated in NUREG-0737, the postaccident monitoring instrumentation provided for Fermi 2 has been extensively modified.

New channels of instrumentation have been added as described in NUREG-0737, Items II.B.3, II.D.3, II.F.1.1, II.F.1.2, and II.F.1.3. A number of existing instrument channels have been modified to meet new functional requirements specified in NUREG-0737, Items II.F.1.1, II.F.1.4, II.F.1.5, and II.D.3.3.

The subject of instrumentation for the determination of inadequate core cooling was actively pursued by the BWR Owners Group, which developed an industry position on the application of Regulatory Guide 1.97, Revision 2. Edison actively participated in the BWR Owners Group that developed an industry response to more adequately address the subject of postaccident instrumentation for BWR designs. As a consequence of the fairly comprehensive additions and modifications to the Fermi 2 postaccident monitoring system required by NUREG-0737, the modified system is in conformance with Regulatory Guide 1.97 or Edison has provided adequate justification to support an alternative means of meeting the intent of Regulatory Guide 1.97. Edison has submitted reports of compliance with Regulatory Guide 1.97 in References 1 and 2. (Also see Subsection 7.5.1.4.)

Additional references are also provided, which include SER from the NRC, Inspection Report, additional clarification and commitment letters.

A.1.98 REGULATORY GUIDE 1.98 (March 1976), ASSUMPTIONS USED FOR EVALUATING THE POTENTIAL RADIOLOGICAL CONSEQUENCES OF A RADIOACTIVE OFFGAS SYSTEM FAILURE IN A BOILING WATER REACTOR

The analysis of the radiological consequences of a radioactive offgas system failure is presented in Section 15.11.

The analysis of the radiological consequences of the release from continued operation of the steam-jet air ejector after a line break downstream of the steam-jet air ejector is presented in Subsection 15.7.1. The analyses presented in Subsection 15.7.1 follow the Regulatory Guide 1.98 assumptions. (The Regulatory Guide considers only one [lumped] accident, which combines the two events discussed above.)

A few of the assumptions related to the inventories available for release and released from the offgas system differ somewhat from the corresponding assumptions in Regulatory Guide 1.98.

A.1.99 REGULATORY GUIDE 1.99 (May, 1988 Revision 2), RADIATION EMBRITTLEMENT OF REACTOR VESSEL MATERIALS

The Fermi 2 procedures for predicting the effects of neutron radiation on reactor vessel material comply with the requirements of Regulatory Guide 1.99, Revision 2.

For details, refer to Subsection 5.2.4.

A.1.100 REGULATORY GUIDE 1.100 (August 1977, Revision 1), SEISMIC QUALIFICATION OF ELECTRIC EQUIPMENT FOR NUCLEAR POWER PLANTS

The Fermi 2 design is not in conformance with the requirements of Regulatory Guide 1.100, Revision 1. This guide requires the design to conform with the requirements and recommendations specified by IEEE Standard 344-1975 for conducting seismic qualification of Class 1E equipment.

According to the acceptance criteria of SRP 3.10, since the Fermi 2 construction permit application and the preliminary safety analysis report (PSAR) were docketed before October 27, 1972, the seismic qualification of Category I instrumentation, electrical equipment, and supports should meet the requirements of IEEE Standard 344-1971.

As described in Section 3.10 of the UFSAR, the Fermi 2 design complies with the requirements of IEEE Std. 344-1971.

A.1.102 REGULATORY GUIDE 1.102 (September 1976, Revision 1), FLOOD PROTECTION FOR NUCLEAR POWER PLANTS

The Fermi 2 flood protection provisions are in compliance with Regulatory Guide 1.102, Revision 1. (Refer to NUREG-0314, Sections 2.4 and 3.4.)

A.1.103 REGULATORY GUIDE 1.103, (October 1976), POST-TENSIONED PRESTRESSING SYSTEMS FOR CONCRETE REACTOR VESSELS AND CONTAINMENTS

This guide is not applicable to the Fermi 2 plant design.

A.1.105 REGULATORY GUIDE 1.105 (November 1976, Revision 1), INSTRUMENT SETPOINTS

The implementation of Regulatory Guide 1.105, Revision 1, applies to nuclear power plants with construction permit applications docketed after December 15, 1976. The Fermi 2 construction permit application was docketed in April 1969, but Edison has established an acceptable degree of compliance with Regulatory Guide 1.105, Revision 1.

The instrumentation supplied for Fermi 2 complies fully with Regulatory Positions C.1 through C.5 of Regulatory Guide 1.105, Revision 1. The testability option is being implemented on Fermi 2 to ensure this degree of compliance. The documentation required by Regulatory Position C.6 of Regulatory Guide 1.105, Revision 1, has been generated for a specific number of safety system setpoints as part of the BWR generic instrument setpoint methodology response to the NRC staff position on this guide (NRC letter to Edison dated June 14, 1983).

A.1.106 REGULATORY GUIDE 1.106 (March 1977, Revision 1), THERMAL OVERLOAD PROTECTION FOR ELECTRIC MOTORS ON MOTOR-OPERATED VALVES

Two regulatory position options are delineated in Regulatory Guide 1.106, Revision 1. Regulatory Position C.1 is recommended, but Regulatory Position C.2 is allowed as an acceptable degree of compliance.

In complying with Regulatory Position C.2, Fermi 2 established motor-operated valve thermal overload device trip setpoints by considering the following:

a. Variations in ambient temperature at the installed locations of the overloads and the valve motors

b. Variations in motor heating data and the overload's trip characteristics

c. Setpoint drift verification through periodic testing.

A.1.107 REGULATORY GUIDE 1.107 (February 1977, Revision 1), QUALIFICATIONS FOR CEMENT GROUTING FOR PRESTRESSING TENDONS IN CONTAINMENT STRUCTURES

This guide is not applicable to Fermi 2, which is a BWR with a Mark I containment.

A.1.108 REGULATORY GUIDE 1.108 (August 1977, Revision 1), PERIODIC TESTING OF DIESEL GENERATOR UNITS USED AS ONSITE ELECTRIC POWER SYSTEMS AT NUCLEAR POWER PLANTS

The Fermi 2 EDG design and preoperational and periodic testing meet the intent of this Regulatory Guide except where the Technical Specifications surveillance requirements differ. Exceptions are taken to the following regulatory positions:

C.1.b(3) When performing testing of the EDGs in other than the fast (10-sec) start mode, the governor and exciter circuits must be bypassed. Automatic transfer to emergency operation therefore cannot occur without manual action by the testing operator slow starting is allowed in the Technical Specifications to minimize mechanical stress and wear in the diesel engines

C.2.a The testing frequency for diesel generator units is controlled by the Technical Specification Surveillance Frequency Control Program and is not tied to regulatory position C.2.a requirements

C.2.a(3) The 24-hr full-load-carrying test is performed at 2500 to 2600 kW for 22 hr and 2800 to 2900 kW for 2 hr, rather than at the continuous load and 2-hr rating of this regulatory position. The kilowatt load for this test is established in the Technical Specifications

C.2.a(5) The hot-restart test is performed with the loss of offsite power loads only, as established in the Technical Specifications. A demonstration is not performed with design accident loading sequence

C.2.a(8) This test is not performed since position C.1.b(3) is not met

C.2.c(1) The testing frequency for diesel generator units is controlled by the Technical Specification Surveillance Frequency Control Program and is not tied to regulatory position C.2.c requirements

C.2.c(2) The periodic testing load-carrying demonstration is at 2500 to 2600 kW in accordance with the Technical Specifications, rather than at the continuous rating recommended in this position. Also, the Technical Specifications require that the rapid loading (2500 to 2600 kW in less than or equal to 150 sec) only need be demonstrated per the Technical Specification Surveillance Frequency control Program, in conjunction with the 10-sec start test. The testing frequency for diesel generator units is controlled by the Technical Specification Surveillance Frequency Control Program and is not tied to regulatory position C.2.c requirements

C.2.d Test interval of the EDGs is determined in accordance with Technical Specifications and the Corrective Action Program. The testing frequency for diesel generator units is controlled by the Technical Specification Surveillance Frequency Control Program and is not tied to regulatory position C.2.d requirements

C.3.b Reporting requirements were deleted when Technical Specification Amendment 107 was implemented.

A.1.109 REGULATORY GUIDE 1.109 (October 1977, Revision 1), CALCULATION OF ANNUAL DOSES TO MAN FROM ROUTINE RELEASES OF REACTOR EFFLUENTS FOR THE PURPOSE OF EVALUATING COMPLIANCE WITH 10 CFR PART 50 APPENDIX I

Fermi 2 is in conformance with the requirements of this regulatory guide. For details refer to Subsection 11.2.9 and Appendix 11A.

A.1.110 REGULATORY GUIDE 1.110 (March 1976), COST-BENEFIT ANALYSIS FOR RADWASTE SYSTEMS FOR LIGHT-WATER-COOLED NUCLEAR POWER PLANTS

Fermi 2 is in conformance with the requirements of Regulatory Guide 1.110 (refer to NUREG-0389, Cost-Benefit Analysis Requirements of Appendix I to 10 CFR Part 50; Their Application to Certain Nuclear Power Plants Docketed Before January 2, 1971; January, 1978).

A.1.111 REGULATORY GUIDE 1.111 (July 1977, Revision 1), METHODS FOR ESTIMATING ATMOSPHERIC TRANSPORT AND DISPERSION OF GASEOUS EFFLUENTS IN ROUTINE RELEASES FROM LIGHT-WATER-COOLED REACTORS

Fermi 2 is in conformance with the requirements of this regulatory guide. For details refer to Subsection 2.3.5 and Appendix 11A.

A.1.112 REGULATORY GUIDE 1.112 (April 1976), CALCULATION OF RELEASES OF RADIOACTIVE MATERIALS IN GASEOUS AND LIQUID EFFLUENTS FROM LIGHT-WATER-COOLED POWER REACTORS

Fermi 2 is in conformance with the requirements of this regulatory guide. For details refer to Appendix 11A.

A.1.113 REGULATORY GUIDE 1.113 (April 1977, Revision 1), ESTIMATING AQUATIC DISPERSION OF EFFLUENTS FROM ACCIDENTAL AND ROUTINE REACTOR RELEASES FOR THE PURPOSE OF IMPLEMENTING APPENDIX I

Fermi 2 is in conformance with the requirements of this regulatory guide. For details refer to Appendix 11A.

A.1.114 REGULATORY GUIDE 1.114 (November 1976, Revision 1), GUIDANCE ON BEING OPERATOR AT THE CONTROLS OF A NUCLEAR POWER PLANT

Fermi 2 is in conformance with the requirements of this regulatory guide.

A.1.115 REGULATORY GUIDE 1.115 (July 1977, Revision 1), PROTECTION AGAINST LOW-TRAJECTORY TURBINE MISSILES

Fermi 2 is in conformance with the intent of Regulatory Guide 1.115, Revision 1. The Fermi 2 barrier designs for low-trajectory missile protection were evaluated by use of the Modified Petry Formula. For details on missile protection, refer to Section 3.5.

A.1.116 REGULATORY GUIDE 1.116 (June 1976), QUALITY ASSURANCE REQUIREMENTS FOR INSTALLATION, INSPECTION, AND TESTING OF MECHANICAL EQUIPMENT AND SYSTEMS

The NRC regulatory staff has recognized ANSI Standard N45.2.8-1975, "Supplementary Quality Assurance Requirements for Installation, Inspection, and Testing of Mechanical Equipment and Systems for the Construction Phase of Nuclear Power Plants," as an acceptable method of complying with the Commission's regulations in regard to such equipment and systems. Regulatory Guide 1.116, which endorses ANSI N45.2.8 with certain minor exceptions and clarifications, was issued in June 1976. Since the Fermi 2 QA Program for the design and construction phase was established several years before the issuance of ANSI N45.2.8 or Regulatory Guide 1.116, it was based on the requirements of Appendix B to 10 CFR 50. The QA Program included all the elements necessary for NRC approval at that time, and has been followed for all installation, inspection, and testing of mechanical systems so far accomplished. It was not practical to modify the QA Program to include all aspects of the program set forth in ANSI N45.2.8 for the remaining installation, inspection, and testing of mechanical systems as this would have had a disruptive effect on both cost and schedule.

Regulatory Guide 1.116 also states that the requirements of ANSI N45.2.8 are considered to be applicable during the operations phase. Consequently, the requirements of Regulatory

Guide 1.116 will be followed for those applicable operational phase activities that are comparable to activities occurring during the construction phase.

A.1.117 REGULATORY GUIDE 1.117 (April 1978, Revision 1), TORNADO DESIGN CLASSIFICATION

The Fermi 2 construction permit was issued prior to May 30, 1978. Therefore, Regulatory Guide 1.117 does not apply.

A.1.118 REGULATORY GUIDE 1.118 (June 1978, Revision 2), PERIODIC TESTING OF ELECTRIC POWER AND PROTECTION SYSTEMS

Regulatory Guide 1.118 is required only for construction permit applicants under review. Therefore, Fermi 2 is not required to comply. Fermi 2 complies with the intent of Regulatory Guide 1.118 Rev 2 and IEEE 338-1977 to test power (electrical) system in a formal manner. This test requirement was not contained in IEEE 338-1971; Fermi 2 complies with IEEE 338-1971 for all remaining protection system testing. Power system surveillance test procedures have been developed. Reactor protection system test commitments are found in Subsection 7.2.1.1.3.8.

A.1.120 REGULATORY GUIDE 1.120 (November 1977, Revision 1), FIRE PROTECTION GUIDELINES FOR NUCLEAR POWER PLANTS

Regulatory Guide 1.120, Revision 1, was reissued for an extended comment period of 1 year. During this comment period, the existing BTP APCSB 9.5-1, Appendix A, was still the determining guide for fire protection (in accordance with NRC letter dated November 7, 1977, from the Office of Standards Development).

Fermi 2 fire protection follows the intent of BTP APCSB 9.5-1, Appendix A, Construction Permit Received Prior to July 1, 1976. BTP APCSB 9.5-1, Appendix A, is the controlling document for Fermi 2 fire protection. Appendix 9A describes the positions of compliance to the BTP.

A.1.121 REGULATORY GUIDE 1.121 (August 1976), BASES FOR PLUGGING DEGRADED PWR STEAM GENERATOR TUBES

Regulatory Guide 1.121 is not applicable to Fermi 2.

A.1.122 REGULATORY GUIDE 1.122 (February 1978, Revision 1), DEVELOPMENT OF FLOOR DESIGN RESPONSE SPECTRA FOR SEISMIC DESIGN OF FLOOR-SUPPORTED EQUIPMENT OR COMPONENTS

Regulatory Guide 1.122 is required only for construction permit applicants under review. Thus, the Fermi 2 plant is not required to comply.

A.1.123 REGULATORY GUIDE 1.123 (July 1977, Revision 1), QUALITY ASSURANCE REQUIREMENTS FOR CONTROL OF PROCUREMENT OF ITEMS AND SERVICES FOR NUCLEAR POWER PLANTS

The NRC regulatory staff has accepted ANSI Standard N45.2.131976, "Quality Assurance Requirements for Control of Procurement of Items and Services for Nuclear Power Plants," as an acceptable method of complying with the Commission's regulations in regard to control of procurement. The initial issue of Regulatory Guide 1.123 applied to construction permit and operating license applications docketed after June 15, 1977, and Revision 1 is applicable to those docketed after August 1, 1977. The Fermi 2 QA Program for the design and construction phase was established several years before the issuance of either ANSI N45.2.13 or Regulatory Guide 1.123, and is based on the requirements of Appendix B to 10 CFR 50. At the stage of the procurement effort when Regulatory Guide 1.123 was issued, it was not feasible to make any retroactive changes in the system of Procurement Control. The Fermi 2 QA Program already included the basic elements set forth in ANSI Standard N45.2.13. Consequently, a change to the system for control of procurement which could affect only the small fraction of the procurement effort still to be done was impractical as any possible benefits would be far outweighed by the cost and schedule impact.

During the operational phase of Fermi 2, the procurement control program will be conducted in compliance with Regulatory Guide 1.123, with the following exception: With respect to ANSI N45.2.13, Section 3.2, "Control of the Procurement Documents," Subsection 3.2.3, "Quality Assurance Program Requirements," DTE takes the following exception:

When purchasing commercial grade calibration or testing services from a laboratory holding accreditation by an Accreditation Body (AB) which is a signatory to the International Laboratory Accreditation Cooperation (ILAC) Mutual Recognition Arrangement (MRA), commercial grade surveys need not be performed provided each of the conditions in the following list are met. The ILAC accreditation process cannot be used as part of the commercial grade dedication process of Nondestructive Examination (NDE) or Nondestructive Testing (NDT) services in lieu of performing a commercial grade survey.

1. A documented review of the supplier's accreditation is performed and includes a verification of the following:

    a) The calibration or test laboratory holds accreditation by an accrediting body recognized by the ILAC MRA. The accreditation encompasses ISO/IEC-17025:2017, "General Requirements for the Competence of Testing and Calibration Laboratories."

    b) For procurement of calibration services, the published scope of accreditation for the calibration laboratory covers the needed measurement parameters, ranges, and uncertainties.

    c) For procurement of testing services, the published scope of accreditation for the test laboratory covers the needed testing services including test methodology and tolerances/uncertainties.

    d) The laboratory has achieved accreditation based on an on-site accreditation assessment by the selected AB within the past 48 months. The laboratory's accreditation cannot be based on two consecutive remote accreditation assessments.

2. The purchase documents require that:

    a) The service must be provided in accordance with their accredited ISO/IEC-17025:2017 program and scope of accreditation.

    b) As found calibration data must be reported in the certificate of calibration when calibrated items are found to be out of tolerance (for calibration services only).

    c) The equipment/standards used to perform the calibration must be identified in the certificate of calibration (for calibration services only).

    d) Subcontracting of these accredited services is prohibited.

    e) The customer must be notified of any condition that adversely impacts the laboratory's ability to maintain the scope of accreditation.

    f) Performance of the services listed on this order is contingent on the laboratory's accreditation having been achieved through an on-site accreditation assessment by the AB within the past 48 months.

    g) Additional technical and quality requirements, as necessary, based upon a review of the procured scope of services, which may include, but are not necessarily limited to, tolerances, accuracies, ranges, and industry standards.

3. It is validated, at receipt inspection, that the laboratory's documentation certifies that:

    a) The contracted calibration or test service has been performed in accordance with their ISO/IEC-17025:2017 program, and has been performed within their scope of accreditation.

    b) The purchase order's requirements are met.

A.1.124 REGULATORY GUIDE 1.124 (January 1978, Revision 1), SERVICE LIMITS AND LOADING COMBINATIONS FOR CLASS 1 LINEAR-TYPE COMPONENT SUPPORTS

The Fermi 2 construction permit was issued prior to January 10, 1978. Therefore, Regulatory Guide 1.124 does not apply.

A.1.125 REGULATORY GUIDE 1.125 (October 1978, Revision 1), PHYSICAL MODELS FOR DESIGN AND OPERATION OF HYDRAULIC STRUCTURES AND SYSTEMS FOR NUCLEAR POWER PLANTS

Regulatory Guide 1.125 does not apply to Fermi 2 as the construction permit was docketed prior to November 1977.

A.1.126 REGULATORY GUIDE 1.126 (March 1978, Revision 1), AN ACCEPTABLE MODEL AND RELATED STATISTICAL METHODS FOR THE ANALYSIS OF FUEL DENSIFICATION

General Electric Fuel Design Analysis and Manufacturing Procedures as applied to the design and production of the Fermi 2 fuel are in full compliance with Regulatory Guide 1.126.

A.1.127 REGULATORY GUIDE 1.127 (March 1978, Revision 1), INSPECTION OF WATER CONTROL STRUCTURES ASSOCIATED WITH NUCLEAR POWER PLANTS

This guide does not apply to any Fermi 2 structure. As part of the normal maintenance program, the shore barrier will be resurveyed by Edison on an annual basis and after storms in which the crest elevation of incident waves at the shoreline exceeds the top of the shore barrier. (See Subsection 3.4.4.5.) The inspection of the RHR complex reservoir is included in the normal maintenance program.

A.1.128 REGULATORY GUIDE 1.128 (October 1978, Revision 1), INSTALLATION DESIGN AND INSTALLATION OF LARGE LEAD STORAGE BATTERIES FOR NUCLEAR POWER PLANTS

Regulatory Guide 1.128 is required only for construction permit applicants under review. Thus, Fermi 2 is not required to comply.

A.1.129 REGULATORY GUIDE 1.129 (February 1978, Revision 1), MAINTENANCE, TESTING, AND REPLACEMENT OF LARGE LEAD STORAGE BATTERIES FOR NUCLEAR POWER PLANTS

Regulatory Guide 1.129 invokes the use of IEEE Standard 450-1975. Fermi 2 will maintain its present commitment to IEEE 450-1972 and the BWR Standard Technical Specifications with regard to the 130/260-V dc system. See response to Regulatory Guide 1.32 (Subsection A.1.32) for specific compliance.

A.1.130 REGULATORY GUIDE 1.130 (October 1978), SERVICE LIMITS AND LOADING COMBINATIONS FOR CLASS 1 PLATE-AND-SHELL-TYPE COMPONENT SUPPORTS

Regulatory Guide 1.130 applies to construction permit applications docketed after April 1, 1978. It is not applicable to Fermi 2. The Fermi 2 construction permit was docketed April, 1969.

A.1.131 REGULATORY GUIDE 1.131 (August 1977), QUALIFICATION TESTS OF ELECTRIC CABLES, FIELD SPLICES, AND CONNECTIONS FOR LIGHT-WATER-COOLED NUCLEAR POWER PLANTS

Regulatory Guide 1.131 is applicable only for construction permit applications docketed after May 1, 1978; therefore, application of Regulatory Guide 1.131 is not required for Fermi 2. See Subsection 8.3.1.4.2 for cable qualification.

A.1.132 REGULATORY GUIDE 1.132 (March 1979, Revision 1), SITE INVESTIGATIONS FOR FOUNDATIONS OF NUCLEAR POWER PLANTS

Fermi 2 is in compliance with Regulatory Guide 1.132, Revision 0.

Regulatory Guide 1.132, Revision 1, was issued to evaluate investigations submitted in connection with construction permit applications docketed after March 30, 1979. The guide is also applicable for those facilities where the construction permit was issued prior to March 30, 1979, but major changes in plant layout or design took place after this date.

The Fermi 2 construction permit was issued prior to March 30, 1979, and therefore Regulatory Guide 1.132, Revision 1, is not applicable. However, Fermi 2 generally conforms to the requirements presented in the regulatory guide.

The specific item where the Revision 1 guideline differs from the Fermi 2 compliance is as follows:

"Safety-Related Pipelines"--The regulatory guide requires borings at 100-ft intervals, geological sections along the pipelines, and mapping of the excavation, if founded in bedrock. In addition, if the pipeline is soil supported, sophisticated sampling techniques are required. Although sophisticated sampling techniques were not used, the site investigations were performed in accordance with the state of the art at the time.

In conclusion, Fermi 2 site investigations meet the intent, and in most cases the letter, of Regulatory Guide 1.132, Revision 1.

A.1.133 REGULATORY GUIDE 1.133 (May 1981, Revision 1), LOOSE- PART DETECTION PROGRAM FOR THE PRIMARY SYSTEM OF LIGHT-WATER-COOLED REACTORS

Fermi 2 original design was in compliance with the requirements of Regulatory Guide 1.133, Revision 1.

However, the Regulatory Guide is no longer applicable to Fermi as the compliance to the requirements of RG 1.133 is not required per GE Licensing Topical Report NEDC-32975, which has been reviewed and accepted by the NRC SE dated January 25, 2001.

A.1.134 REGULATORY GUIDE 1.134 (September 2014, Revision 4), MEDICAL EVALUATION OF NUCLEAR POWER PLANT PERSONNEL REQUIRING OPERATOR LICENSES

Fermi 2 is in conformance with the requirements of Regulatory Guide 1.134.

A.1.135 REGULATORY GUIDE 1.135 (September 1977), NORMAL WATER LEVEL AND DISCHARGE AT NUCLEAR POWER PLANTS

Under Section D, Implementation of Regulatory Guide 1.135, the NRC states, ". . . the method described herein will be used in the evaluation of submittals for construction permit applications docketed after May 1, 1978. . .." As the construction permit application for Fermi 2 was docketed in 1969, Regulatory Guide 1.135 is not applicable to Fermi 2.

A.1.136 REGULATORY GUIDE 1.136 (October 1978, Revision 1), MATERIAL FOR CONCRETE CONTAINMENTS

Fermi 2 has a steel primary containment; therefore Regulatory Guide 1.136 does not apply.

A.1.137 REGULATORY GUIDE 1.137 (October 1979, Revision 1) FUEL OIL SYSTEMS FOR STANDBY DIESEL GENERATORS

The fuel oil system was designed and installed prior to the issuance of this regulatory guide. However, the Fermi 2 diesel fuel oil system conforms to the basic arrangement, testing, and other requirements of Regulatory Guide 1.137. There are differences in design detail, but overall the intent of the guide is met.

Specific requirements for fuel-oil testing are contained in the Fermi 2 Technical Specifications, and include provisions for testing of delivered fuel oil prior to storage in the tanks and for periodic sampling thereafter. The Technical Specifications requirements satisfy the intent of Regulatory Guide 1.137, Position C.2.

A.1.138 REGULATORY GUIDE 1.138 (April 1978), LABORATORY INVESTIGATIONS OF SOILS FOR ENGINEERING ANALYSIS AND DESIGN OF NUCLEAR POWER PLANTS

The Fermi 2 construction permit was issued prior to December 1, 1978. Therefore, Regulatory Guide 1.138 does not apply.

A.1.139 REGULATORY GUIDE 1.139 (May 1978), GUIDANCE FOR RESIDUAL HEAT REMOVAL

The Fermi 2 plant is in compliance with Regulatory Guide 1.139.

A.1.140 REGULATORY GUIDE 1.140 (October 1979, Revision 1), DESIGN, TESTING, AND MAINTENANCE CRITERIA FOR NORMAL VENTILATION EXHAUST SYSTEM AIR FILTRATION AND ADSORPTION UNITS OF LIGHT-WATER-COOLED NUCLEAR POWER PLANTS

Various discharge filter systems have been provided for Fermi 2 to control the discharge of radioactive material during normal and operational occurrences. The filter and/or radiation monitors are provided for compliance with GDC 60 and 61 of Appendix A, and Appendix I to 10 CFR 50. The filters were purchased in accordance with standards applicable at the time, such as ORNL-NSIC-65.

Fermi 2 is in compliance with the intent of Revision 1 of this regulatory guide. These filters were designed and constructed prior to the issuance of Regulatory Guide 1.140 and ANSI Standards N510 and N509. However, the design and construction of radwaste building ventilation exhaust hood and building exhaust filters do meet the basic intent and performance criteria in these guidelines.

A.1.141 REGULATORY GUIDE 1.141 (October 1979, Revision 1), CONTAINMENT ISOLATION PROVISIONS FOR FLUID SYSTEMS

The Fermi 2 isolation system has been reviewed for compliance with NUREG-0737, Item II.E.4.2. The requirements in NUREG-0737 encompass, expand, and supersede Regulatory Guide 1.141, Revision 1, and the present design of the containment isolation system for Fermi 2, in general, conforms to the requirements of NUREG-0737.

A.1.142 REGULATORY GUIDE 1.142 (April 1978), SAFETY-RELATED CONCRETE STRUCTURES FOR NUCLEAR POWER PLANTS (OTHER THAN REACTOR VESSELS AND CONTAINMENTS)

The Fermi 2 construction permit was issued prior to December 15, 1978. Therefore, Regulatory Guide 1.142 does not apply.

In 2009 a second set of Category I 4160-V ductbanks, manholes and above ground cable vaults were designed and constructed. These Category I structures are in compliance with Regulatory Guide 1.142, Revision 2, with the following exception:

Regulatory Guide 1.142, Rev. 2 cites the use of ACI 349-97, “Code Requirements for Nuclear Safety Related Concrete Structures” along with the 15 Regulatory Positions on the use of ACI 349-97. Fermi used a later ACI Code, 349-01, while still complying with all the applicable 15 Positions of the Reg. Guide for the second set of Category I 4160-V ductbanks, manholes and above ground cable vaults. The requirements in the later ACI code is consistent with ACI 349-97.

Position 15 of Regulatory Guide 1.142, Rev. 2 states that Section 11.6 of ACI 318-99 “…” should be used in lieu of 11.6 of ACI 318-97” … “for evaluating members subject to torsion or combination of shear and torsion”. ACI 349-01 incorporated recent revisions of ACI 318; which includes ACI 318-99 Section 11.6 changes and therefore, is consistent and complies with Position 15.

A.1.143 REGULATORY GUIDE 1.143 (October 1979, Revision 1), DESIGN GUIDANCE FOR RADIOACTIVE WASTE MANAGEMENT SYSTEMS, STRUCTURES, AND COMPONENTS INSTALLED IN LIGHT-WATER-COOLED NUCLEAR POWER PLANTS

Fermi 2 is in compliance with Regulatory Guide 1.143, Revision 1, with the following exceptions:

a. Fermi 2 uses nonconsumable inserts (backing rings) in butt-welded pipes of 2.5 in., or larger, diameter. Edison had previously stated its position on the adequacy of this feature in connection with conformance to Regulatory Guide 1.143, Revision 0

b. Regulatory Guide 1.143, Revision 1, requires that concrete be designed in accordance with ACI 318-77, instead of ACI 349-76 as required by Regulatory Guide 1.143, Revision 0. The Fermi 2 turbine house/ radwaste building was designed in accordance with ACI 318-63 and/or ACI 318-71. Since ACI 318-77 is an updated version of ACI 318-71, without any significant changes to the strength requirements of a structural frame, it is Edison's opinion that the turbine house/radwaste building structure does comply with the requirements of Regulatory Guide 1.143, Revision 1, in this regard. Edison had previously stated the adequacy of the concrete standards associated with radwaste structures in connection with conformance to Regulatory Guide 1.143, Revision 0

c. Regulatory Guide 1.143, Revision 1, calls for hydrotesting of the offgas system and holding pressure for 30 minutes, with no leakage indicated. Fermi 2 piping was tested in full compliance with ASME Section III, ND6000, 1971 winter Addendum, which calls for a 10-minute hold. Edison's justification for a 10-minute hydrotest hold pressure is as follows:

    1. The Fermi 2 offgas piping is already built to more stringent requirements than called for in this regulatory guide

    2. The Fermi 2 offgas system normally operates under a vacuum

    3. The ASME 10-minute requirement is sufficient to detect any defects in the piping system.

    The adequacy of the offgas system test had been previously stated by Edison in connection with the conformance of Fermi 2 to Regulatory Guide 1.143, Revision 0

    A study (Reclassification of the offgas system) was performed, which concluded the Fermi 2 offgas system may be reclassified as non-ASME Code Section III. The code governing the piping and valves is ANSI B31.1.0.

    Modifications made to the offgas piping system subsequent to the code reclassification will be in compliance with ANSI B31.1.0, which is consistent with Regulatory Guide 1.143.

d. Regulatory Guide 1.143, Revision 1, calls for certain portions (primarily charcoal adsorber tank supports) of the offgas system to be designed to specified seismic design criteria. The design of the Fermi 2 offgas system does not conform to the specified seismic design criteria

e. Overflow of the condensate storage or condensate return tank is contained within the containment wall around both tanks. Lost condensate is pumped to the valve pit sumps and then pumped to radwaste. Direct access to Lake Erie by water seeping into the ground is prevented by the clay fill seal beneath the shore barrier. Initial movement of any seepage would be downward to mix and dilute with the ground water from the dolomite aquifer

f. Regulatory Guide 1.143, Revision 1, specifies QA practices appropriate for radwaste systems. The QA practices that were applied consist of measures established to control design activities, the procurement and receiving inspection of pressure boundary items and instrumentation, and the inspection of the installation of pressure boundary items and instrumentation

g. Regulatory Guide 1.143, Revision 1, Section 4.3, states that "process lines should not be less than 3/4-in. (nominal). "The Fermi 2 system contains three process lines (waste slurries and evaporator concentrates) to the extruder which are 1/2-in. Schedule 80 pipe. These pipes have a wall thickness which is actually greater than 3/4-in. Schedule 40 piping. The 1/2-in. piping was needed in these lines to provide and maintain an adequate transport velocity. The lines were specifically designed for slurry service, and feature butt-welded construction, 5-D bends (no elbow fittings), and automatic flushing.

A.1.144 REGULATORY GUIDE 1.144 (September 1980, Revision 1) AUDITING OF QUALITY ASSURANCE PROGRAMS FOR NUCLEAR POWER PLANTS

DTE is in conformance with the requirements and recommendations of this regulatory guide, with the following exceptions:

(1) That a grace period of 25 percent is applied to the completion of annually required documented supplier evaluations and the completion of triennial audits as required by section C.3.b.(2). The total combined time interval for any three consecutive audit intervals should not exceed 3.25 times the specified audit interval.

When procuring commercial grade calibration or testing services from a laboratory holding accreditation by an Accreditation Body (AB) which is a signatory to the International Laboratory Accreditation Cooperation (ILAC) Mutual Recognition Arrangement (MRA), the accreditation process and accrediting body may be credited with carrying out a portion of the purchaser’s duties of verifying acceptability and effective implementation of the calibration or testing service laboratory’s quality assurance program.

In lieu of performing commercial grade survey or accepting a commercial grade survey performed by another licensee, a documented review of the laboratory’s accreditation is performed which includes a verification of each of the conditions in the following list. The ILAC accreditation process cannot be used as part of the commercial grade dedication process of Nondestructive Examination (NDE) or Nondestructive Testing (NDT) services in lieu of performing a commercial grade survey.

1. The calibration or test laboratory holds accreditation by an accrediting body recognized by the ILAC MRA. The accreditation encompasses ISO/IEC-17025:2017, “General Requirements for the Competence of Testing and Calibration Laboratories.”
2. For procurement of calibration services, the published scope of accreditation for the calibration laboratory covers the needed measurement parameters, ranges, and uncertainties.
3. For procurement of testing services, the published scope of accreditation for the test laboratory covers the needed testing services including test methodology and tolerances/uncertainties.

4. The laboratory has achieved accreditation based on an on-site accreditation assessment by the selected AB within the past 48 months. The laboratory's accreditation cannot be based on two consecutive remote accreditation assessments.

(2) DTE will review the information described in the second paragraph of section C.3.b(2) as it becomes available through its ongoing receipt inspection, operating experience and supplier evaluation programs, in lieu of performing a specific evaluation on an annual basis. The results of the reviews are promptly considered for effect on a supplier's continued qualification and adjustments made as necessary (including corrective actions, adjustments of supplier audit plans, and input to third party auditing entities as warranted). In addition, the results are reviewed periodically to determine if, as a whole, they constitute a significant condition adverse to quality requiring additional action.

QA programs of others, that is suppliers, may be audited and evaluated by another nuclear utility provided an agreement has been established to include DTE's scope of supply and for reviews of programs and their changes, DTE's QA requirements.

A.1.145 REGULATORY GUIDE 1.145 (August 1979), ATMOSPHERIC DISPERSION MODELS FOR POTENTIAL ACCIDENT CONSEQUENCE ASSESSMENTS AT NUCLEAR POWER PLANTS

This analysis uses offsite χ/Q determinations based on this regulatory guide.

A.1.146 REGULATORY GUIDE 1.146 (August 1980), QUALIFICATION OF QUALITY ASSURANCE PROGRAM AUDIT PERSONNEL FOR NUCLEAR POWER PLANTS

The established design and construction QA program, which predates the development of ANSI N45.2.23, was not committed to comply with Regulatory Guide 1.146. However, the adopted practices for the training and qualification of auditor personnel met the requirements of the ANSI standard.

The operations QA program complies with the requirements of Regulatory Guide 1.146, except as follows:

(1) Regardless of the methods used for demonstrating proficiency, the prospective lead auditor shall have participated on at least one Nuclear Quality Assurance Audit within the year preceeding the individual's effective date of qualification. Upon successful demonstration of the ability to effectively implement the audit process and effectively lead audits, and having met the other requirements of section 2.3 of ANSI N.45.2.23-1978, the individual may be certified as being qualified to lead audits.

(2) For sections 3.2 and 5.3 of ANSI N45.2.23-1978, a grace period of 90 days is applied to complete the annual assessment of each lead auditor's qualification.

A.1.147 REGULATORY GUIDE 1.147 (latest edition), INSERVICE INSPECTION CODE CASE ACCEPTABILITY--ASME SECTION XI, DIVISION 1

Fermi 2 is in conformance with the requirements of this regulatory guide. Code cases that apply and have been adopted for use are identified in the inservice inspection program.

A.1.148 REGULATORY GUIDE 1.148 (March 1981), FUNCTIONAL SPECIFICATION FOR ACTIVE VALVE ASSEMBLIES IN SYSTEMS IMPORTANT TO SAFETY IN NUCLEAR POWER PLANTS

The Fermi 2 construction permit and licenses to manufacture were issued prior to July 1, 1981. Therefore, Regulatory Guide 1.148 does not apply. However, the intent of this guide will be met for the new equipment ordered for Fermi 2 after July 1, 1981.

A.1.152 REGULATORY GUIDE 1.152 (NOVEMBER 1985), CRITERIA FOR PROGRAMMABLE DIGITAL COMPUTER SYSTEM SOFTWARE IN SAFETY-RELATED SYSTEMS OF NUCLEAR POWER PLANTS

The Fermi 2 procedures conform to the requirements for designing, verifying, and implementing software and validating computer systems as specified in ANSI/IEEE-ANS-7-4.3.2-1982, "Application Criteria for Programmable Digital Computer Systems in Safety Systems of Nuclear Power Generating Stations." In addition, Fermi 2 conforms with IEEE Standard 7-4.3.2-1993, "IEEE Standard Criteria for Digital Computers in Safety Systems of Nuclear Power Generating Stations." The 1993 version provides clarifications and detailed descriptive guidelines without changing the basic technical criteria in the 1982 version.

A.1.155 REGULATORY GUIDE 1.55 (AUGUST 1988), STATION BLACKOUT

The Fermi 2 plant is in compliance with Regulatory Guide 1.155. The compliance of the Fermi 2 plant to the regulatory Guide 1.155 was determined using the NUMARC 87-00 "Guidelines and Technical Bases for NUMARC Initiatives Addressing Station Blackout at Light Water Reactors". The following is a summary of some of the important conclusions from this determination:

a. A minimum emergency diesel generator (EDG) reliability target of .95 per demand for each EDG has been selected and a reliability program is in place to monitor and maintain this reliability level.

b. The Fermi 2 plant minimum acceptable station blackout coping capability was determined to be 4 hours. The Fermi 2 specific plant evaluation determined it is capable of withstanding and recovering from a station blackout event of 4 hour duration.

c. Fermi 2 has an Alternate AC (AAC) power supply available on site that can be started from the Fermi 2 control center and switched to the plant onsite ac power system in less than one (1) hour. The AAC is the 18 MW Combustion Turbine Generator (CTG) 11-1 located near the plant's 120 KV switchyard. The AAC power system is inspected and tested periodically to demonstrate operability and reliability. An alternate to CTG 11-1 is CTG 11-2, 11-3, or 11-4 which can be started with the standby diesel generator.

d. Procedures and training have been established for operator actions necessary to cope with a station blackout event.

e. Quality assurance activities have been implemented as applicable for the non-safety systems and equipment required to support responses to a station blackout event. Further discussion of Station Blackout is provided in Section 8.4, "Station Blackout (SBO)."

A.1.160 REGULATORY GUIDE 1.160 (JANUARY 1995), MONITORING THE EFFECTIVENESS OF MAINTENANCE AT NUCLEAR POWER PLANTS

The Fermi 2 plant is in compliance with Regulatory Guide 1.160. Regulatory Guide 1.160 endorses the use of NUMARC 93-01 as acceptable guidance for implementing the Maintenance Rule (10 CFR 50.65). Regulatory Guide 1.160 states that methods other than those expressed in NUMARC 93-01 may be used to implement the Maintenance Rule. However, the NRC will determine the acceptability of other methods on a case by case basis.

Fermi 2 has utilized NUMARC 93-01 as the base document for implementing the Maintenance Rule. However, after appropriate justification, exceptions were taken. Most of these exceptions were improvements to NUMARC 93-01 guidance.

A.1.163 REGULATORY GUIDE 1.163 (SEPTEMBER 1995), PERFORMANCE-BASED CONTAINMENT LEAK-TEST PROGRAM

By License Amendment 108, the Fermi 2 Plant has implemented the approach as described in Regulatory Guide 1.163 "Performance Based Containment Leak Test Program." This program allows the testing periodicity to be extended from the present two year limit for Type B and C tests up to 120 months for Type B test and up to 60 months for Type C tests. Also, the periodicity for Type A test has been extended from 3 every 10 years to once per 10 years. Regulatory Guide 1.163 approves Nuclear Energy Institute (NEI) 94-01, Revision 0, which provides methods acceptable to the NRC staff for complying with provisions of Option B in Appendix J to 10 CFR 50, subject to four exceptions listed in Regulatory Guide 1.163. By License Amendment No. 153, a one-time extension of the Type A test interval to 15 years was implemented. By License Amendment 205, the program was revised for the permanent extension of the Type A test interval to once every 15 years and extension of the Type C test interval up to 75 months. The program is in accordance with NEI 94-01 Revision 3-A, dated July 2012, and the limitations and conditions specified in NEI 94-01 Revision 2-A, dated October 2008.

A.1.181 REGULATORY GUIDE 1.181 (SEPTEMBER 1999), CONTENT OF THE UPDATED FINAL SAFETY ANALYSIS REPORT IN ACCORDANCE WITH 10 CFR 50.71 (e)

Fermi 2 complies with the general intent of this regulatory guide. Regulatory Guide 1.181 endorses the use of NEI 98-03, "Guidelines for Updating Final Safety Analysis Reports," dated June 1999 as an acceptable method for complying with the provisions of 10 CFR 50.71(e).

A.1.183 REGULATORY GUIDE 1.183 (JULY 2000) ALTERNATIVE RADIOLOGICAL SOURCE TERMS FOR EVALUATING DESIGN BASIS ACCIDENTS AT NUCLEAR POWER REACTORS

The analyses of the control rod drop accident, as discussed in Section 15.4.9, loss of coolant accidents, in general, as discussed in Section 15.6.5, and fuel-handling accidents involving fuel that meets the burnup specification associated with Table 3, Footnote 11 of this regulatory guide, as discussed in Subsection 15.7.4, conform with the regulatory position of this guide.

Analyses of the radiological consequences associated with other Fermi 2 design basis accidents do not conform to the assumptions and methodologies of this regulatory guide.

A.1.196 REGULATORY GUIDE 1.196 (May 2003) CONTROL ROOM HABITABILITY AT LIGHT-WATER NUCLEAR POWER REACTORS

Fermi 2 complies with the guidance set forth in this regulatory guide with the following exceptions:

Positions 2.1 and 2.2: The identification of the licensing bases for CRH and determination of whether CRH is consistent with the licensing bases were completed in the response to Generic Letter 2003-01, “Control Room Habitability.”

The levels of compliance to other Regulatory Guides referenced in Regulatory Guide 1.196 are discussed in applicable sections of UFSAR Appendix A.

A.1.197 REGULATORY GUIDE 1.197 (May 2003) DEMONSTRATING CONTROL ROOM ENVELOPE INTEGRITY AT NUCLEAR POWER REACTORS

Fermi 2 complies with the guidance set forth in this regulatory guide with the following exceptions:

Component Testing described in section C.1.2 and Alternate Test Methods in section C.1.3 are not performed at Fermi 2.

A.4 DIVISION 4 APPLICABLE REGULATORY GUIDES

A.4.1 REGULATORY GUIDE 4.1 (April 1975, Revision 1), PROGRAMS FOR MONITORING RADIOACTIVITY IN THE ENVIRONS OF NUCLEAR POWER PLANTS

Fermi 2's Radiological Environmental Monitoring Program complies with the regulatory guidance of Revision 1 of the NRC Radiological Assessment Branch's Position on the radiological portion of Regulatory Guide 4.8's environmental monitoring program, dated November, 1979.

A.4.2 REGULATORY GUIDE 4.2 (July 1976, Revision 2), PREPARATION OF ENVIRONMENTAL REPORTS FOR NUCLEAR POWER STATIONS

Edison filed an Environmental Report and proposed Technical Specifications - Operating License Stage in April, 1975; Supplement 4 was filed in February 1978. The format of the Environmental Report (OL) does not conform to Revision 2; however, the information contained within the report and its supplements conforms to the requirements of Regulatory Guide 4.2 as it applies to the application for an operating license.

A.4.4 REGULATORY GUIDE 4.4 (May 1974), REPORTING PROCEDURE FOR MATHEMATICAL MODELS SELECTED TO PREDICT HEATED EFFLUENT DISPERSION IN NATURAL WATER BODIES

Fermi 2 conforms to the requirements of this guide. The mathematical models used to analyze the thermal plume from the Fermi 2 discharge into Lake Erie are in accordance with the reporting format as set forth in Regulatory Guide 4.4.

For details refer to Sections 5.1 and 6.1 of the Environmental Report.

A.4.6 REGULATORY GUIDE 4.6 (May 1974), MEASUREMENTS OF RADIONUCLIDES IN THE ENVIRONMENT--STRONTIUM-89 AND STRONTIUM-90 ANALYSIS

Compliance with the intent of Regulatory Guide 4.6 is a component of the Fermi 2 Operational Environmental Radiological Monitoring Program criteria specifications.

A.4.8 REGULATORY GUIDE 4.8 (December 1975), ENVIRONMENTAL TECHNICAL SPECIFICATIONS FOR NUCLEAR POWER PLANTS

Fermi 2's Radiological Environmental Monitoring Program complies with the regulatory guidance of Revision 1 of the NRC Radiological Assessment Branch's Position on the radiological portion of Regulatory Guide 4.8's environmental monitoring program, dated November 1979.

A.4.10 REGULATORY GUIDE 4.10 (June 1976, Revision 1), IRREVERSIBLE AND IRRETRIEVABLE COMMITMENTS OF MATERIAL RESOURCES

The Fermi 2 ER(OL) does not conform to Regulatory Guide 4.10.

A.4.11 REGULATORY GUIDE 4.11 (August 1977, Revision 1), TERRESTRIAL ENVIRONMENTAL STUDIES FOR NUCLEAR POWER STATIONS

The Fermi 2 baseline studies and construction monitoring do not conform to Regulatory Guide 4.11, as they were in effect prior to issuance of the guide. The preoperational and operational programs conform to the intent of Regulatory Guide 4.11 as it applies to the site.

A.4.13 REGULATORY GUIDE 4.13 (July 1977, Revision 1, Issued for Comment), PERFORMANCE, TESTING, AND PROCEDURAL SPECIFICATIONS FOR THERMOLUMINESCENCE DOSIMETRY: ENVIRONMENTAL APPLICATIONS

Compliance with the intent of Regulatory Guide 4.13 is a component of the Fermi 2 Operational Environmental Radiological Monitoring Program criteria specifications.

A.4.15 REGULATORY GUIDE 4.15 (December 1977), QUALITY ASSURANCE FOR RADIOLOGICAL MONITORING PROGRAMS (NORMAL OPERATIONS)--EFFLUENT STREAMS AND THE ENVIRONMENT

Compliance with the intent of Regulatory Guide 4.15 is a component of the Fermi 2 Operational Environmental Radiological Monitoring Program criteria specifications.

A.4.16 REGULATORY GUIDE 4.16 (March 1978), MEASURING, EVALUATING, AND REPORTING RADIOACTIVITY IN RELEASES OF RADIOACTIVE MATERIALS IN LIQUID AND AIRBORNE EFFLUENTS FROM NUCLEAR FUEL PROCESSING AND FABRICATION PLANTS

Regulatory Guide 4.16 is not applicable to electric power production facilities.

A.5 DIVISION 5 APPLICABLE REGULATORY GUIDES

A.5.7 REGULATORY GUIDE 5.7 (May 1980, Revision 1), ENTRY/EXIT CONTROL FOR PROTECTED AREAS, VITAL AREAS, AND MATERIAL ACCESS AREAS

Not applicable.

A.5.12 REGULATORY GUIDE 5.12 (November 1973), GENERAL USE OF LOCKS IN THE PROTECTION AND CONTROL OF FACILITIES AND SPECIAL NUCLEAR MATERIALS

The use of locks at Fermi 2 conforms to the general intent of Regulatory Guide 5.12; however, there are some variations from the criteria contained within the guide. The use of locks at Fermi 2 is described in the Fermi 2 Physical Security Plan.

A.5.15 REGULATORY GUIDE 5.15 (January 1974), SECURITY SEALS FOR THE PROTECTION AND CONTROL OF SPECIAL NUCLEAR MATERIAL

Edison will conform to the requirements of this guide when use of locks and seals is necessary in the Fermi 2 plant.

A.5.17 REGULATORY GUIDE 5.17 (January 1974), TRUCK IDENTIFICATION MARKINGS

This guide does not apply to Edison. When special nuclear material is shipped from Fermi 2 it will be shipped in contractor vehicles to which this guide will apply.

This Regulatory Guide has been withdrawn.

A.5.20 REGULATORY GUIDE 5.20 (January 1974), TRAINING, EQUIPPING, AND QUALIFYING OF GUARDS AND WATCHMEN

Appendix B to 10 CFR 73 was promulgated subsequent to the issuance of this regulatory guide and covers the same subject. Edison will comply with 10 CFR 73, Appendix B.

A.5.29 REGULATORY GUIDE 5.29 (June 1975, Revision 1), NUCLEAR MATERIAL CONTROL SYSTEMS FOR NUCLEAR POWER PLANTS

Edison will provide the control necessary to insure that special nuclear material is properly accounted for in accordance with the applicable sections of 10 CFR 74 and not specifically ANSI N15.8.

A.5.32 REGULATORY GUIDE 5.32 (May 1975, Revision 1), COMMUNICATION WITH TRANSPORT VEHICLES

The requirements of Regulatory Guide 5.32 do not apply to Fermi 2. Regulatory Guide 5.32 references certain paragraphs of 10 CFR 73, specifically 73.1(b)(2), which exempt conformance to this guide.

A.5.43 REGULATORY GUIDE 5.43 (January 1975), PLANT SECURITY FORCE DUTIES

The Fermi 2 Physical Security Plan is not designed to conform specifically to Regulatory Guide 5.43.

The Fermi 2 Physical Security Plan, including security force duties, conforms to 10 CFR 73, Section 73.55, "Requirements for Physical Protection of Licensed Activities in Nuclear Power Reactors Against Industrial Sabotage. NEI 03-12, Revision 1, was used to develop the plan.

For additional information refer to Section 13.7.

This Regulatory Guide has since been withdrawn (as of April 2020).

A.5.44 REGULATORY GUIDE 5.44 (October 1997, Revision 3), PERIMETER INTRUSION ALARM SYSTEMS

The design of the perimeter intrusion detection system at Fermi 2 conforms to the general intent of the suggestions contained in Regulatory Guide 5.44; however, there are some variations from the suggested criteria contained within the guide.

The perimeter intrusion detection system is described in the Fermi 2 Physical Security Plan and Safeguards Contingency Plan. The Physical Security Plan describes what type of sensors were installed, where they were installed, and how the system effectiveness will be evaluated.

For additional information refer to Section 13.7.

A.5.57 REGULATORY GUIDE 5.57 (June 1980, Revision 1), SHIPPING AND RECEIVING CONTROL OF STRATEGIC SPECIAL NUCLEAR MATERIAL

Edison will conform to the requirements of this guide when shipping spent nuclear fuel as required by 10 CFR 73.1(b)(5).

A.5.71 REGULATORY GUIDE 5.71 (January 2010, Revision 0), CYBER SECURITY PROGRAMS FOR NUCLEAR FACILITIES

The Fermi 2 Cyber Security Program and Cyber Security Plan are not designed to conform specifically to Regulatory Guide 5.71. The Fermi 2 Cyber Security Plan was approved by the NRC License Amendment 185. The Fermi 2 Cyber Security Program, including the Cyber Security Plan, conforms to 10 CFR 73, Section 73.54, “Protection of digital computer and communication systems and networks”. NEI 08-09, Revision 6, “Cyber Security Program for Nuclear Power Reactors” was used to develop the Cyber Security Plan.

A.8 DIVISION 8 APPLICABLE REGULATORY GUIDES

A.8.1 REGULATORY GUIDE 8.1 (February 1973), RADIATION SYMBOL

Fermi 2 is in conformance with the requirements of this regulatory guide. For details refer to Subsection 12.1.1.3.

A.8.2 REGULATORY GUIDE 8.2 (February 1973), GUIDE FOR ADMINISTRATIVE PRACTICES IN RADIATION MONITORING

Fermi 2 is in conformance with the requirements of this regulatory guide. For details refer to Chapters 11, 12, and 13.

A.8.3 REGULATORY GUIDE 8.3 (February 1973), FILM BADGE PERFORMANCE CRITERIA

This Regulatory Guide has since been withdrawn (as of January 1998).

A.8.4 REGULATORY GUIDE 8.4 (June 2011, Revision 1), DIRECT READING AND INDIRECT READING POCKET DOSIMETERS

Edison is in conformance with the requirements of this regulatory guide.

A.8.5 REGULATORY GUIDE 8.5 (February 1973), IMMEDIATE EVACUATION SIGNAL

Fermi 2 complies with the intent of this guide. The two systems described below accomplish the objectives of the guide.

Area radiation monitors (ARMs) are provided for the entire plant and include "criticality" monitors for the fuel storage pool and new-fuel vault areas. These two monitors each have a local audible alarm and other features such as control room annunciation and recorder input, fast response time, and seal-in alarm circuitry. Subsection 12.1.4 describes the ARM system in more detail.

Beyond these dedicated ARM channels is the emergency alarm system, which provides a signal to ensure personnel evacuation. The emergency alarm system is described in Subsection 9.5.2 and is discussed in the Radiological Emergency Response Preparedness Plan.

Both the ARM and the emergency alarm systems are subject to initial and periodic tests performed as part of the preoperational test and surveillance programs.

A.8.6 REGULATORY GUIDE 8.6 (May 1973), STANDARD TEST PROCEDURE FOR GEIGER-MUELLER COUNTERS

Fermi 2 is in conformance with the requirements of this regulatory guide.

A.8.7 REGULATORY GUIDE 8.7 (May 1973), OCCUPATIONAL RADIATION EXPOSURE RECORDS SYSTEMS

Fermi 2 is in conformance with the requirements of this regulatory guide. For details refer to Subsection 12.3.4.3.

A.8.8 REGULATORY GUIDE 8.8 (June 1978, Revision 3), INFORMATION RELEVANT TO ENSURING THAT OCCUPATIONAL RADIATION EXPOSURES AT NUCLEAR POWER STATIONS WILL BE AS LOW AS IS REASONABLY ACHIEVABLE

Fermi 2 is in conformance with the requirements of this regulatory guide. For details refer to Subsection 12.3.1.

A.8.9 REGULATORY GUIDE 8.9 (September 1973), ACCEPTABLE CONCEPTS, MODELS, EQUATIONS, AND ASSUMPTIONS FOR A BIOASSAY PROGRAM

Fermi 2 is in compliance with the requirements of this regulatory guide. For details refer to Subsection 12.3.1.

A.8.10 REGULATORY GUIDE 8.10 (September 1975, Revision 1), OPERATING PHILOSOPHY FOR MAINTAINING OCCUPATIONAL RADIATION EXPOSURES AS LOW AS IS REASONABLY ACHIEVABLE

Fermi 2 is in compliance with the requirements of this regulatory guide. For details refer to Subsection 12.3.1.

A.8.12 REGULATORY GUIDE 8.12 (December 1974), CRITICALITY ALARM SYSTEMS

This regulatory guide is based on a combination of 10 CFR 70, Section 70.24, "Criticality Accident requirements," ANS N16.1-1969, "Criticality Accident Alarm System," with Section 70.24 taking precedence. Fermi 2 complies with the regulatory positions as follows:

a. Criticality Monitoring on the Refuel Floor

   The refuel floor is located on the fifth floor of the reactor building. Monitoring for an inadver-tent criticality event on the refuel floor is provided by two redundant detectors (D21-N115 and D21-N117). These detectors are high sensitivity gamma ray detectors (GM tubes) and are located on the east wall approximately 9 ft to 12 ft in the air. The alarm trip setting on these detectors is in the proscribed range of 5-20 mR/hr, which is adequate to detect the minimum accident of concern as described in 10 CFR 70.24 and ANSI/ANS 8.3-1986. The alarm circuitry of these detectors is arranged in a fail safe mode such that any malfunction of the detectors or a loss of power results in an alarm condition. Additionally, the detectors have a meter pegging circuit which precludes a downscale low reading (foldover) during saturation of the GM tube due to high intensity radiation fields. Periodic performance tests are conducted to confirm instrument response to radiation and the operability of the alarm signal generator. The aforementioned design meets the criterion of GDC 63, "Monitoring Fuel and Waste Storage." Moreover, Fermi 2 personnel are instructed to evacuate areas in which radiation or criticality alarms are activated. Evacuation of plant areas is periodically tested by the conduct of emergency response drills.

b. Handling and Transporting New Fuel in the Yard and Reactor Building During Transit to the Refuel Floor

   A criticality safe analysis has been performed for safe storage and transport of GE BWR nuclear fuel shipping containers during new fuel receipt for Fermi 2. The analysis provides assurance that an inadvertent criticality is highly improbable during onsite storage, handling and transportation of new fuel within shipping containers. This meets the criterion of GDC 62, "Prevention of Criticality in Fuel Storage and Handling." The safety analysis is the bases for Fermi 2's exemption from the requirements of 10 CFR 70.24, as granted by the Nuclear Regulatory Commission as identified by reference numbers 9 and 10 herein. The exemption requires criticality monitoring in areas where new fuel is handled outside the inner metal shipping containers. In contrast, the exemption allows administrative controls, such as the use of geometrically safe configurations as bound by the aforesaid safety analysis for areas in which the new fuel remains in the inner metal shipping containers.

c. Criticality Monitoring for the New Fuel Storage Vault

Due to lack of detector redundancy, Fermi 2 does not strictly comply to 10 CFR 70.24 with regard to storage of new fuel in the new fuel storage vault. Accordingly, the fuel pool is used for storage of new fuel rather than the new fuel storage vault. New fuel vault personnel entries require monitoring as governed by plant procedures. The single detector (D21-N116) in the new fuel storage vault is adequate to detect the minimum accident of concern as described in 10 CFR 70.24. This fail safe monitor is located below the 1.5 ft thick concrete floor of the concrete floor of the vault with an alarm trip setting of greater or equal to 5 mR/hr and less than or equal to 20 mR/hr. Calculations indicate this monitor is adequate for the representative critical dose data for a design basis criticality accident. Periodic tests are performed to confirm instrument response to radiation. In addition, a field test of each alarm signal generator is made periodically. During these tests, clarity of the alarm above area background noise will be ascertained.

d. Criticality Monitoring for Calibration Sources and Incore Instrumentation Not in Use

Additionally, the aforementioned NRC exemption states that the quantity of other forms of special nuclear material that is stored onsite in any given location at Fermi 2 (e.g., calibration sources and incore instrumentation that is not in use) is small enough to preclude achieving a critical mass, thus not requiring criticality monitoring.

A.8.13 REGULATORY GUIDE 8.13 (November 1975, Revision 1), INSTRUCTION CONCERNING PRENATAL RADIATION EXPOSURE

Fermi 2 is in conformance with the requirements of this regulatory guide.

A.8.14 REGULATORY GUIDE 8.14 (August 1977, Revision 1), PERSONNEL NEUTRON DOSIMETERS

Fermi 2 is in conformance with the requirements of this regulatory guide. For details refer to Subsection 12.3.4.

A.8.15 REGULATORY GUIDE 8.15 (October 1976), ACCEPTABLE PROGRAMS FOR RESPIRATORY PROTECTION

Fermi 2 is in conformance with the requirements of this regulatory guide. For details refer to Subsection 12.3.2.2.2.

A.8.26 REGULATORY GUIDE 8.26 (September 1980), APPLICATIONS OF BIOASSAY FOR FISSION AND ACTIVATION PRODUCTS

The Fermi 2 bioassay program is in conformance with the requirements of this regulatory guide. For details refer to Subsection 12.3.4.2.

B. AGING MANAGEMENT PROGRAMS AND ACTIVITIES

The Fermi 2 license renewal application (Reference B.3-1) and information in subsequent related correspondence provided sufficient basis for the NRC to make the findings required by 10 CFR 54.29 (Reference B.3-2). As required by 10 CFR 54.21(d), this UFSAR supplement contains a summary description of the programs and activities for managing the effects of aging (Section B.1) and a description of the evaluation of time-limited aging analyses for the period of extended operation (Section B.2). The period of extended operation is the 20 years after the expiration date of the original operating license for Fermi 2.

B.1 AGING MANAGEMENT PROGRAMS

The integrated plant assessment for license renewal identified aging management programs necessary to provide reasonable assurance that components within the scope of license renewal will continue to perform their intended functions consistent with the current licensing basis (CLB) for the period of extended operation. This section describes the aging management programs and activities required during the period of extended operation.

Aging management programs will be implemented prior to entering the period of extended operation. For programs requiring enhancements, the programs are described as including the features that will be in place when the enhancements are fully implemented. Each description lists the enhancements required for the program as it existed when the license renewal application was submitted.

Conditions adverse to quality, such as failures, malfunctions, deficiencies, deviations, defective material and equipment and nonconformances, are promptly identified and corrected. In the case of significant conditions adverse to quality, measures are implemented to ensure that the cause of the condition is determined and that corrective action is taken to preclude recurrence. In addition, the identification and cause of the significant condition adverse to quality and the corrective action implemented is documented and reported to appropriate levels of management. The corrective action controls of the Fermi 2 Quality Assurance Program (10 CFR Part 50, Appendix B) are applicable to all aging management programs and activities required during the period of extended operation.

Corrective actions for systems, structures and components are accomplished per the existing Fermi 2 Corrective Action Program and Fermi 2 procedures. The site Corrective Action Program and procedure control program apply to license renewal aging management activities for both safety-related and nonsafety-related structures and components.

The confirmation process is part of the Corrective Action Program and includes the following:

- Reviews to assure that proposed actions are adequate for conditions adverse to quality.
- Tracking and reporting of open corrective actions.
- Review of corrective action effectiveness for significant conditions adverse to quality.

If the confirmation process leads to a corrective action requiring inspection or testing, the corrective action will be documented in accordance with the Corrective Action Program. The Corrective Action Program constitutes the confirmation process for the Fermi 2 aging management programs and activities.

Fermi 2 quality assurance (QA) procedures, review and approval processes, and administrative controls are implemented in accordance with the requirements of 10 CFR 50, Appendix B. The Fermi 2 QA Program applies to safety-related structures and components. The phrase "Administrative Controls" refers to the adherence to the policies, directives, and procedures and includes the formal review and approval process that procedures and manuals undergo as they are issued and subsequently revised. The Fermi 2 QA Program aspects related to procedure controls and administrative controls (document control requirements for procedures and manuals) and retention of records apply to Fermi 2 aging management activities associated with license renewal for both safety-related and nonsafety-related structures, systems, and components.

The Operating Experience program (OEP) at Fermi 2 and the Corrective Action Program help to assure continued effectiveness of aging management programs through evaluations of operating experience. The OEP implements the requirements of NRC NUREG-0737, *Clarification of TMI Action Plan Requirements*, Section l.C.5, and evaluates site and industry operating experience for impact on Fermi 2. The Corrective Action Program implements the requirements of 10 CFR 50, Appendix B, Criterion XVI and is used to evaluate and effect appropriate actions in response to operating experience relevant to Fermi 2 that indicates a condition adverse to quality or a nonconformance.

Revisions to NUREG-1801, *Generic Aging Lessons Learned (GALL) Report*, and other NRC guidance documents on aging management are considered sources of operating experience.

The operating experience program interfaces with and relies on active participation in the Institute of Nuclear Power Operations' operating experience program, as endorsed by the NRC.

In accordance with procedure, incoming operating experience items are screened to identify items that may involve age-related degradation or impact to aging management programs (AMPs), including programs being developed. Items so identified are further evaluated, and AMPs are either enhanced or new AMPs are developed, as appropriate, when it is determined through these evaluations that the effects of aging may not be adequately managed.

Plant-specific operating experience associated with aging management and age-related degradation is reported to the industry in accordance with guidelines established in the operating experience program.

DTE will make the following changes to the process for operating experience review (OER).

- Procedures will be revised to add an aging type code to Corrective Action Program documents that describe either plant conditions related to aging or industry operating experience related to aging.
- Procedures will be revised to provide for training of personnel responsible for submitting, screening, assigning, evaluating, or otherwise processing plant-specific and industry operating experience concerning age-related degradation and aging

management, as well as for personnel responsible for implementing AMPs, based on the complexity of the job performance requirements and assigned responsibilities.

- Procedures will be revised to specify that evaluations of operating experience concerning age-related degradation will include consideration of the affected systems, structures or components, the environments, materials, aging effects, aging mechanisms, and aging management programs.

DTE currently performs periodic self-assessments on many aging management programs. DTE will enhance the Fermi 2 self-assessment process to provide for periodic evaluation of the effectiveness of each aging management program described in the UFSAR supplement. For new aging management programs, the first evaluation will be performed within five years of implementing the program.

B.1.1 ABOVEGROUND METALLIC TANKS PROGRAM

The Aboveground Metallic Tanks Program is a new program that will manage loss of material and cracking for outdoor tanks within the scope of license renewal that are sited on soil or concrete. Preventive measures to mitigate corrosion and cracking were applied during construction, such as using the appropriate materials, protective coatings, and elevation as specified in design and installation specifications. For the insulated aluminum condensate storage tank (CST), the program will monitor the condition of a representative sample of the tank external surface for signs of loss of material, using visual inspections and surface examinations. Internal and external portions of the CST will be inspected in accordance with Table 4a, "Tank Inspection Recommendations," identified in LR-ISG-2012-02. There are no indoor tanks included in this program.

This program will also manage the bottom surface of the CST, which is on a concrete ring foundations and sand. The program will require ultrasonic testing (UT) of the tank bottoms to assess the thickness against the thickness specified in the design specification. UT of the tank bottoms will be performed whenever the tank is drained or at intervals not less than those recommended in Table 4a during the period of extended operation. Caulking or sealant at the concrete/tank interfaces is not credited in the installation and design specifications.

Within the ten years prior to the period of extended operation and every ten years thereafter, a volumetric examination of a minimum 25% of the CST tank bottom interface with the concrete ring foundation will be performed to manage loss of material. The volumetric inspection will be on a 2” grid or less, depending on the technology utilized.

This program will be implemented prior to the period of extended operation, with initial inspections within the ten years prior to the period of extended operation. The combustion turbine generator (CTG) fuel oil tank is in-scope for this program but inspections are not required since the tank was replaced in 2019.

B.1.2 BOLTING INTEGRITY PROGRAM

The Bolting Integrity Program manages loss of preload, cracking, and loss of material for closure bolting for safety-related and nonsafety-related pressure-retaining components using preventive and inspection activities. This program does not include the reactor head closure studs or structural bolting. Preventive measures include material selection (e.g., use of materials with an actual yield strength of less than 150 kilo-pounds per square inch [ksi]), lubricant selection (e.g., restricting the use of molybdenum disulfide), applying the appropriate preload (torque), and checking for uniformity of gasket compression where appropriate to preclude loss of preload, loss of material, and cracking. This program supplements the inspection activities required by ASME Section XI for ASME Class 1, 2, and 3 bolting. For ASME Class 1, 2, and 3 bolting and non-ASME Code class bolts, periodic system walkdowns and inspection (at least once per refueling cycle) ensure identification of indications of loss of preload (leakage), cracking, and loss of material before leakage becomes excessive. Identified leaking bolted connections will be monitored at an increased frequency in accordance with the corrective action process. Applicable industry standards and guidance documents, including NUREG-1339, EPRI NP-5769, and EPRI TR-104213, are used to delineate the program.

The Bolting Integrity Program will be enhanced as follows.

- Revise Bolting Integrity Program procedures to perform opportunistic inspections for Control Center HVAC system safety-related pressure-retaining bolting in a lube oil external environment, including the bolting threads to ensure that loss of material in crevice locations that are not readily visible can be detected.
- Revise Bolting Integrity Program procedures to perform opportunistic inspections for CTG system nonsafety-related pressure-retaining bolting in a lube oil external environment.
- Revise Bolting Integrity Program procedures to ensure consideration of actual yield strength when procuring high-strength bolting material. If procured, closure bolting with actual yield strength greater than or equal to 150 ksi is monitored for cracking.
- Revise Bolting Integrity Program procedures to state that bolting for safety-related pressure-retaining components is inspected for leakage, loss of material, cracking, and loss of preload/loss of prestress. Closure bolting with actual yield strength greater than or equal to 150 ksi is monitored for cracking.
- Revise Bolting Integrity Program procedures to (1) implement applicable recommendations for pressure boundary bolting in NUREG-1339, EPRI NP-5769, and EPRI TR-104213; (2) state both ASME Code class bolted connections and non-ASME Code class bolted connections are inspected at least once per refueling cycle; and (3) include volumetric examination per ASME Code Section XI, Table IWB-2500-1, Examination Category B-G-1, for closure bolting with actual yield strength greater than or equal to 150 ksi regardless of code classification.
- Revise Bolting Integrity Program procedures to inspect RHRSW, EESW, and EDGSW systems' pump and valve bolting submerged in the RHRSW reservoir at least once every refueling outage and to opportunistically inspect bolting threads during maintenance activities.
- Revise Bolting Integrity Program procedures to include the additional guidance and recommendations of EPRI NP-5769 for replacement of ASME pressure-

retaining bolts and the guidance provided in EPRI TR-104213 for the replacement of other pressure-retaining bolts.

- Revise Bolting Integrity Program procedures to stipulate that administrative controls are in accordance with the Fermi 2 10 CFR 50 Appendix B Quality Assurance Program.

Enhancements will be implemented prior to the period of extended operation.

B.1.3 BORAFLEX MONITORING PROGRAM

The Boraflex Monitoring Program is an existing program to manage the Boraflex material affixed to the spent fuel storage racks. This program is currently required by Technical Specification 5.5.13 and includes activities implemented in response to NRC GL 96-04 to assure that the required five percent sub-criticality margin is maintained. The Boraflex currently in the spent fuel racks will not be credited for neutron absorption during the period of extended operation and therefore this aging management program will not be relied upon during the period of extended operation. All of the neutron-absorbing material to be credited during the period of extended operation will be managed by the Neutron-Absorbing Material Monitoring Program in Section B.1.27.

B.1.4 BURIED AND UNDERGROUND PIPING PROGRAM

The Buried and Underground Piping Program is a new program that will manage the effects of aging on the external surfaces of buried and underground piping components within the scope of license renewal. The program will manage aging effects of loss of material and cracking for the external surfaces of buried and underground piping fabricated of aluminum, carbon steel, gray cast iron, and stainless steel through preventive and mitigative measures (e.g., coatings, backfill quality, and cathodic protection) and periodic inspection activities during opportunistic or directed excavations. There are no underground or buried tanks for which aging effects would be managed by the Buried and Underground Piping Program. Fermi 2 utilizes a cathodic protection system. Fermi 2 has performed preliminary laboratory soil composition analyses on samples removed from the site to evaluate the potential corrosivity of the soil for use in life cycle management.

Inspections are conducted by qualified individuals. Where the coatings, backfill or the condition of exposed piping does not meet acceptance criteria such that the depth or extent of degradation of the base metal could have resulted in a loss of pressure boundary function when the loss of material rate is extrapolated to the end of the period of extended operation, an increase in the sample size is conducted. Soil testing will be conducted once in each ten-year period starting ten years prior to the period of extended operation, if a reduction in the number of inspections recommended in Table XI.M41-2 of NUREG-1801, is taken based on a lack of soil corrosivity.

When using the 100 mV, -750 mV or -650 polarization criteria as an alternative to the -850 mV criterion, for steel piping, electric resistance probes (ERPs) will be installed in select locations as determined by a Cathodic Protection Specialist. The ERPs will be made of the most anodic metal in the system to ensure adequate protection of the most anodic system metal. Concurrent with the ERPs, permanent reference cells and reference metal will be installed. Installation of the permanent reference cells at pipe depth and near the piping of interest will allow for an accurate measurement of pipe-to-soil potential, minimizing the influence of mixed metals. Where used, the electrical resistance probes will be uncoated and placed in the immediate vicinity of the buried piping it is representing. For each installation application, two probes will be installed; one connected to the cathodic protection system and one left unprotected. The test probe left unprotected (not connected to the pipe) will be free of the mixed metals influence.

This program will be implemented prior to the period of extended operation.

B.1.5 BWR CRD RETURN LINE NOZZLE PROGRAM

The BWR Control Rod Drive (CRD) Return Line Nozzle Program manages cracking of the CRD return line nozzle using preventive, mitigative, and inservice inspection activities, in accordance with Fermi 2 commitments to implement the recommendations in NUREG-0619 and ASME Code Section XI, Subsection IWB, Table IWB 2500-1. Examinations that can detect the presence of cracking are performed to assure detection of cracks before the loss of intended function of the CRD return line nozzle. Cracking found during inservice inspection is evaluated in accordance with ASME Code Section XI requirements. The CRD return line nozzle was capped during construction prior to plant operation.

The BWR CRD Return Line Nozzle Program will be enhanced as follows.

- Revise BWR CRD Return Line Nozzle Program procedures as necessary to ensure that ultrasonic test (UT) examinations will be used to detect applicable aging effects.

Enhancements will be implemented prior to the period of extended operation.

B.1.6 BWR FEEDWATER NOZZLE PROGRAM

The BWR Feedwater Nozzle Program manages cracking of the BWR feedwater nozzles using inspection activities to monitor the effects of cracking due to cyclic loading.

This program augments the examinations specified in the ASME Code, Section XI, with the recommendation and schedule of General Electric NE-523-A71-0594, Revision 1, and NUREG-0619 to perform periodic testing of critical regions of the BWR feedwater nozzles. The feedwater nozzles were never clad and include the improved sparger design. Cracking is evaluated and dispositioned in accordance with the ASME Code.

B.1.7 BWR PENETRATIONS PROGRAM

The BWR Penetrations Program manages cracking due to cyclic loading or stress corrosion cracking (SCC) and intergranular SCC (IGSCC) of BWR instrument penetrations, control rod drive (CRD) housing and incore housing (ICH) penetrations, and standby liquid control (SLC) nozzles/core ΔP nozzles.

Leakage inspections (VT-2) and ultrasonic inspections are scheduled and performed, flaws are evaluated, scope is expanded as required, and acceptance criteria are provided in accordance with the guidelines of the ASME Code Section XI and NRC-approved BWRVIP-49-A, BWRVIP-47-A, and BWRVIP-27-A.

B.1.8 BWR STRESS CORROSION CRACKING PROGRAM

The BWR Stress Corrosion Cracking Program manages intergranular stress corrosion cracking (IGSCC) in stainless steel or nickel alloy reactor coolant pressure boundary piping and piping welds 4 inches or larger in nominal diameter containing reactor coolant at a temperature above 93°C (200°F) during power operation, regardless of code classification.

Scheduled volumetric examinations provide timely detection of IGSCC and leakage of coolant in accordance with the methods, inspection guidelines, and flaw evaluation criteria delineated in the ASME Code; NUREG-0313, Rev. 2; NRC GL 88-01 and its Supplement 1; NRC-approved BWRVIP-75-A; and other requirements specified per 10 CFR 50.55a with NRC-approved alternatives. Ten percent of the feedwater and condensate systems Category D welds are inspected each refueling outage unless 100% of the welds have already been inspected in the Inservice Inspection Interval.

The program includes preventive measures such as induction heating stress improvement, solution annealing, and mechanical stress improvement process to minimize stress corrosion cracking.

B.1.9 BWR VESSEL ID ATTACHMENT WELDS PROGRAM

The BWR Vessel ID [inside diameter] Attachment Welds Program manages cracking in structural welds for BWR reactor vessel internal integral attachments using inspections, scheduling, acceptance criteria, and flaw evaluation in conformance with the requirements of ASME Section XI and guidelines of BWRVIP-48-A. The program includes welds between the vessel wall and vessel ID brackets that attach components to the vessel. The internal attachment weld can be a simple weld or a weld build-up pad on the vessel.

B.1.10 BWR VESSEL INTERNALS PROGRAM

The BWR Vessel Internals Program manages cracking, loss of material due to wear, and reduction of fracture toughness for BWR vessel internal components using inspection and flaw evaluation. The program provides (1) determination of the susceptibility of cast austenitic stainless steel components, (2) accounting for the synergistic effect of thermal aging and neutron irradiation, and (3) implementation of a supplemental examination program, as necessary.

Applicable industry standards and NRC-approved BWRVIP documents provide the basis for scheduling inspections to provide timely detection of aging effects, appropriate NDE inspection techniques, acceptance criteria, flaw evaluation, and repair/replacement, as needed. At Fermi 2, management of the reactor vessel internals is implemented in accordance with ASME Section XI and BWRVIP-94, "BWR Vessel and Internals Project, Program Implementation Guide".

The crack growth rate evaluations and fracture toughness values specified in BWRVIP-14-A, BWRVIP-99-A, and BWRVIP-100-A are used for cracked core shroud welds exposed to the neutron fluence values specified in these BWRVIP reports.

This program also addresses aging degradation of CASS and X-750 alloy. Fermi 2 did not use precipitation-hardened (PH) martensitic stainless steel (e.g., 15-5 and 17-4 PH steel) materials and martensitic stainless steel (e.g., 403, 410, 431 steel) in BWR vessel internal components.

The BWR Vessel Internals Program will be enhanced as follows.

- The susceptibility to neutron or thermal embrittlement for reactor vessel internal components composed of CASS and X-750 alloy will be evaluated.
- BWR Vessel Internals Program procedures will be revised as follows. Portions of the susceptible components determined to be limiting from the standpoint of thermal aging susceptibility, neutron fluence, and cracking susceptibility (i.e., applied stress, operating temperature, and environmental conditions) will be inspected, using an inspection technique capable of detecting the critical flaw size with adequate margin. The critical flaw size will be determined based on the service loading condition and service-degraded material properties. The initial inspection will be performed either prior to or within five years after entering the period of extended operation. If cracking is detected after the initial inspection, the frequency of re-inspection will be justified based on fracture toughness properties appropriate for the condition of the component. The sample size for the initial inspection of susceptible components will be 100 percent of the accessible component population, excluding components that may be in compression during normal operations.
- BWR Vessel Internals Program procedures will be revised as follows. In accordance with an applicant action item for BWRVIP-25 safety evaluation: (a) install core plate wedges prior to the period of extended operation, or (b) complete a plant-specific analysis that justifies no inspections are required, or (c) complete a plant-specific analysis to determine acceptance criteria for continued inspection of core plate hold-down bolts in accordance with BWRVIP-25.

  For Option (b), the analysis will address loss of preload due to stress relaxation in the core plate rim hold-down bolts and quantify the loss of preload/stress relaxation that will occur in these bolts during the period of extended operation. The analysis will be submitted to the NRC two years prior to the period of extended operation. Additionally, the UFSAR will be revised to address the analysis if it is determined to meet the criteria for a TLAA at least two years prior to the period of extended operation.

  For Option (c), the analysis will address loss of preload due to stress relaxation in the core plate rim hold-down bolts and quantify the loss of preload/stress relaxation that will occur in these bolts during the period of extended operation. The analysis, inspection plan with acceptance criteria, and justification for the inspection plan will be submitted to the NRC two years prior to the period of extended operation. Additionally, the UFSAR will be revised to address the analysis if it is determined to meet the criteria for a TLAA at least two years prior to the period of extended operation.
- Revise BWR Vessel Internals Program procedures such that the flaw evaluation methodology for the top guide grid beam will address the following three items if they have not been resolved generically during the NRC review and approval process of BWRVIP-183:

(1) Detected flaws evaluated using the methodology in BWRVIP-183 Section 4 will be demonstrated to be sufficiently far from geometric discontinuities (i.e. notches or slots) such that the stress condition in the vicinity of the flaw is consistent with that for a single edge-crack plate. Appropriately applied K values which account for the effects of geometric discontinuities will be used and justified in the flaw evaluation.

(2) The flaw evaluation methodology in BWRVIP-183 Section 4 will be used to justify continued operation on a cycle-by-cycle basis. Use of the flaw evaluation methodology to justify operation for more than once cycle will require NRC approval and would be based on plant-specific operating experience including crack length measurements of detected top guide grid beam flaws to benchmark the accuracy of the flaw evaluation methodology.

(3) When applying the flaw evaluation methodology in BWRVIP-183 Section 4, a severed beam evaluation consistent with BWRVIP-183 Section 5 will also be performed. The severed beam analysis will demonstrate that even if a beam was completely severed beam, it would not be expected to interfere with the ability of the control rod drive system to insert control rods.

- Revise BWR Vessel Internals Program procedures to perform opportunistic inspections of the differential pressure and standby liquid control line inside the reactor vessel when the line becomes accessible.

Enhancements will be implemented prior to the period of extended operation.

B.1.11 COMPRESSED AIR MONITORING PROGRAM

The Compressed Air Monitoring Program manages loss of material in compressed air systems by periodically monitoring air samples for moisture and contaminants and by opportunistically inspecting internal surfaces within compressed air systems. Air quality is maintained in accordance with limits established by considering manufacturer recommendations, as well as recommendations in EPRI NP-7079 and TR 108147, ASME OM-S/G-1998 (Part 17), ANSI standard ISA-S7.0.01-1996, and ISA-S7.3. Inspection frequency, acceptance criteria, and design and operating reviews are performed in accordance with NRC GL 88-14. The program was developed using applicable industry standards and documents such as ISA-S7.3, Quality Standard for Instrument Air, for guidance on preventive measures, inspection of components, and testing and monitoring air quality.

Periodic internal visual inspections of critical components (compressors, dryers, after-coolers, filters, etc.) are performed to detect signs of corrosion. Air quality is monitored and trended to determine if alert levels or limits are being approached or exceeded. Dew point testing and trending is performed quarterly. Particulates, dew points, hydrocarbon content, and corrosive contaminants are monitored.

The Compressed Air Monitoring Program will be enhanced as follows.

- Revise Compressed Air Monitoring Program procedures to include periodic and opportunistic inspections of accessible internal surfaces of piping, compressors, dryers, aftercoolers, and filters. In addition, include in the Compressed Air Monitoring Program procedures the applicable provisions recommended in EPRI NP

7079, EPRI TR-108147, and ASME OM-S/G-1998, Part 17 for air system contaminants, inspection frequency, inspection methods, and acceptance criteria for components subject to aging management review that are exposed to compressed air in the emergency diesel generator (EDG) starting air system and control air system.

Enhancements will be implemented prior to the period of extended operation.

B.1.12 CONTAINMENT INSERVICE INSPECTION – IWE PROGRAM

The Containment Inservice Inspection (CII) – IWE Program implements the requirements of 10 CFR 50.55a. The regulations in 10 CFR 50.55a impose the inservice inspection (ISI) requirements of the ASME Boiler and Pressure Vessel (B&PV) Code, Section XI, Subsection IWE, for steel containments (Class MC). The Fermi 2 containment design does not include a concrete containment subject to ASME Section XI, Subsection IWL requirements, and therefore the requirements of Class CC are not applicable. There are no tendons associated with Fermi 2's steel containment vessel. The Fermi 2 primary containment is a General Electric Mark I pressure suppression containment and consists of a drywell, a torus (or suppression chamber), and a vent system connecting the drywell and the torus. The scope of the CII-IWE Program includes the steel containment vessel and its integral attachments, containment equipment hatches and airlock and moisture barriers, and pressure-retaining bolting. Visual inspections monitor loss of material of the steel containment vessel surface areas, including welds and base metal and containment vessel integral attachments, metal shell, personnel and equipment access hatches, and pressure-retaining bolting. The CII-IWE Program specifies acceptance criteria, corrective actions, augmented inspections as required and provisions for expansion of the inspection scope when identified degradation exceeds the acceptance criteria. Appendix J, Type A and Type B testing is performed in lieu of surface examinations of dissimilar metal welds of penetration sleeves, penetration bellows, and torus vent line bellows as allowed as an alternative in NUREG-1801, Section XI.S1. The code of record for the examination of the Fermi 2 containment, Class MC components, and related requirements is in accordance with ASME Code Section XI, Subsections IWE, 2001 Edition with the 2003 Addenda, as mandated and modified by 10 CFR 50.55a.

The CII-IWE Program will be enhanced as follows:

- Revise plant procedures to require inspection of the sand cushion drain lines to monitor the internal conditions of the drain lines (e.g. for moisture, sand, blockage) and ensure there is no evidence of blockage at least once prior to the period of extended operation and once every 10 years during the period of extended operation.
- Revise plant procedures to specify the preventive actions delineated in NUREG-1339 and in EPRI NP-5769, NP-5067, and TR-104213 that emphasize proper selection of bolting material, installation torque or tension, and the use of lubricants and sealants for high strength bolting.
- Revise plant procedures to include the preventive actions for storage of ASTM A325 and A490 bolting from Section 2 of Research Council for Structural Connections publication, "Specification for Structural Joints Using ASTM A325 or A490 Bolts."
- Revise plant procedures to determine drywell shell thickness in the sand cushion areas before the period of extended operation and once in each ten year interval

during the period of extended operation. From the results (including prior results), develop a corrosion rate to demonstrate that the drywell shell will have sufficient wall thickness to perform its intended function through the period of extended operation.

- Revise plant procedures to require corrective actions should moisture be detected or suspected in the inaccessible area on the exterior of the drywell shell, including:
  - Identify surfaces requiring augmented inspections for the period of extended operation in accordance with Subsection IWE-1240, as identified in Table IWE-2500-1, Examination Category E-C.
  - Use examination methods that are in accordance with Subsection IWE-2500.
  - Demonstrate through use of augmented inspections performed in accordance with Subsection IWE that corrosion is not occurring or that corrosion is progressing so slowly that the degradation will not jeopardize the intended function of the drywell shell through the period of extended operation.

Enhancements will be implemented prior to the period of extended operation.

B.1.13 CONTAINMENT LEAK RATE PROGRAM

The Containment Leak Rate Program consists of tests performed in accordance with the regulations and guidance provided in 10 CFR Part 50, Appendix J, "Primary Reactor Containment Leakage Testing for Water-Cooled Power Reactors," Option B; Regulatory Guide 1.163, "Performance-Based Containment Leak-Testing Program"; NEI 94-01, "Industry Guideline for Implementing Performance-Based Options of 10 CFR Part 50, Appendix J"; and ANSI/ANS 56.8, "Containment System Leakage Testing Requirements." The Containment Leak Rate Program does not prevent degradation but provides measures for detection of pressure boundary degradation in various systems penetrating containment. Corrective actions are taken if leakage rates exceed acceptance criteria. The program also provides for detection of age-related degradation in material properties of gaskets, O-rings, and packing materials for the containment pressure boundary access points.

Three types of tests are performed under Option B. Type A tests are performed to determine the overall primary containment integrated leakage rate at the loss of coolant accident peak containment pressure. Performance of the integrated leakage rate test per 10 CFR Part 50, Appendix J, Option B, demonstrates the leak-tightness and structural integrity of the containment. Type B and Type C containment local leak rate tests (LLRT), as defined in 10 CFR 50, Appendix J, are intended to detect local leaks and to measure leakage across each pressure-containing or leakage-limiting boundary of containment penetrations. Containment leakage rate tests are performed at frequencies that comply with the requirements of 10 CFR Part 50, Appendix J, Option B.

B.1.14 DIESEL FUEL MONITORING PROGRAM

The Diesel Fuel Monitoring Program manages loss of material in piping, tanks, and other components exposed to an environment of diesel fuel oil by verifying the quality of the fuel oil source. This is accomplished by limiting the quantities of contaminants in diesel fuel oil. Parameters monitored include water, sediment, total particulate, biodiesel concentration, and levels of microbiological activity. Sampling is performed before the fuel oil is allowed to enter the fuel oil storage tanks. The program also requires periodic multi-level sampling of fuel oil storage tanks, where possible. Where multi-level sampling cannot be performed, a representative sample is taken from the lowest part of the tank. If biological activity is identified, biocides are added to prevent biological activity.

Effectiveness of the program is periodically verified by inspecting low flow areas where contaminants may collect, such as in the bottom of tanks. The tanks are periodically sampled, drained, cleaned, and internally inspected for signs of moisture, contaminants and corrosion. Internal tank inspections will be performed at least once during the ten-year period prior to the period of extended operation, and at least once every ten years during the period of extended operation. Where degradation is observed, a wall thickness determination will be made, and the extent of the condition is determined as a part of the Corrective Action Program. Applicable industry standards and guidance documents are used to establish inspection frequency, if not specified by the Fermi 2 Technical Specifications Surveillance Frequency Control Program.

The One-Time Inspection Program describes inspections planned to verify that the Diesel Fuel Monitoring Program has been effective at managing aging effects.

The Diesel Fuel Monitoring Program will be enhanced as follows.

- Revise Diesel Fuel Monitoring Program procedures to monitor and trend water and sediment, particulates, and levels of microbiological organisms in the EDG fuel oil storage tanks, EDG fuel oil day tanks, diesel fire pump fuel oil tank, and combustion turbine generator (CTG) fuel oil tank quarterly. In addition, revise program procedures to state that biocides or corrosion inhibitors may be added as a preventive measure or are added if periodic testing indicates biological activity or evidence of corrosion, respectively.
- Revise the Diesel Fuel Monitoring Program procedures to include a ten-year periodic cleaning and internal visual inspection of the EDG fuel oil storage tanks, EDG fuel oil day tanks, and diesel fire pump fuel oil tank with the following instructions. The cleanings and internal inspections will be performed at least once during the ten-year period prior to the period of extended operation and at succeeding ten-year intervals. If visual inspection is not possible, perform a volumetric inspection. If evidence of degradation is observed during visual inspection, perform a volumetric examination of the affected area. The CTG fuel oil tank is in-scope for this program but inspections are not required since the tank was replaced in 2019.

  The schedule for the Preventive Maintenance (PM) event to perform diesel fire pump fuel oil tank draining, flushing, and inspection will continue at its frequency at the time of the enhancement implementation, until a PM evaluation of results from fuel oil samples and tank inspections indicates that the system will be capable of continuing to perform its function during the period of extended operation with a lower frequency, not less than once per ten-year interval for cleaning and internal visual inspection consistent with NUREG-1801.

Enhancements will be implemented prior to the period of extended operation.

B.1.15 ENVIRONMENTAL QUALIFICATION (EQ) OF ELECTRIC COMPONENTS PROGRAM

The Environmental Qualification (EQ) of Electric Components Program implements the requirements of 10 CFR 50.49. As required by 10 CFR 50.49, EQ components are refurbished, replaced, or their qualification is extended prior to reaching the aging limits established in the evaluation. The Fermi 2 EQ Program manages component thermal, radiation, and cyclical aging through the use of aging evaluations based on 10 CFR 50.49(f) qualification methods. Reanalysis addresses attributes of analytical methods, data collection and reduction methods, underlying assumptions, acceptance criteria, corrective actions if acceptance criteria are not met, and the period of time prior to the end of qualified life when the reanalysis will be completed.

In accordance with 10 CFR 54.21(c)(1)(iii), implementation of the EQ Program provides reasonable assurance that the effects of aging will be managed such that applicable components will continue to perform their intended functions consistent with the current licensing basis through the period of extended operation.

B.1.16 EXTERNAL SURFACES MONITORING PROGRAM

The External Surfaces Monitoring Program manages aging effects of components fabricated from metallic, elastomeric, and polymeric materials through periodic visual inspection of external surfaces during system inspections and walkdowns for evidence of leakage, loss of material (including loss of material due to wear), cracking, fouling, and change in material properties. When appropriate for the component and material, physical manipulation, such as touching, pressing, flexing, and bending, is used to augment visual inspections to confirm the absence of hardening and loss of strength in non-metallic materials. The External Surfaces Monitoring Program is also credited for situations where the material and environment combinations are the same for the internal and external surfaces such that the external surfaces are representative of the internal surfaces.

Inspections are performed at a frequency of at least once per refueling cycle by personnel qualified through plant-specific programs. Deficiencies are documented and evaluated under the Corrective Action Program. Surfaces that are not readily visible during plant operations and refueling outages are inspected when they are made accessible and at such intervals that would ensure the components' intended functions are maintained. Inspections of insulated components where the insulation is required to reduce heat transfer will be performed to ensure insulation degradation due to moisture intrusion has not occurred.

Where visual inspection for leakage may not effectively detect cracking in gas-filled stainless steel and aluminum components exposed to outdoor air, alternate detection methods (e.g. performance monitoring or use of a soap solution with the component pressurized) will be employed.

Periodic representative surface condition inspections of the in-scope mechanical indoor components under insulation (with process fluid temperature below the dew point) and outdoor components under insulation will be performed.

For polymeric materials, the visual inspection will include 100 percent of the accessible components. The sample size of polymeric components that receive physical manipulation is at least 10 percent of the available surface area.

Acceptance criteria are defined to ensure that the need for corrective action is identified before a loss of intended function. For stainless steel, a clean shiny surface is expected. For flexible polymers, a uniform surface texture (no cracks) and no change in material properties (e.g., hardness, flexibility, physical dimensions, color unchanged from when the material was new) are expected. For rigid polymers, no surface changes affecting performance, such as erosion, cracking, crazing, checking, and chalking, are acceptable. For insulation, no discoloration, staining, or surface irregularities from moisture intrusion is expected.

The External Surfaces Monitoring Program will be enhanced as follows.

- Revise External Surfaces Monitoring Program procedures to clarify that periodic inspections will be performed of systems in scope and subject to aging management review for license renewal in accordance with 10 CFR 54.4 (a)(1) and (a)(3). Inspections shall include areas surrounding the subject systems to identify hazards to those systems. Inspections of nearby systems that could impact the subject systems will include SSCs that are in scope and subject to aging management review for license renewal in accordance with 10 CFR 54.4(a)(2).
- Revise External Surfaces Monitoring Program procedures to inspect 100 percent of accessible components at least once per refueling cycle and to ensure required walkdowns include instructions to inspect for the following related to metallic components:
  - Corrosion (loss of material).
  - Leakage from or onto external surfaces (loss of material).
  - Worn, flaking, or oxide-coated surfaces (loss of material).
  - Corrosion stains on thermal insulation (loss of material).
  - Protective coating degradation (cracking, flaking, and blistering).
  - Leakage for detection of cracks on the external surfaces of stainless steel components exposed to an air environment containing halides (cracking).
- Revise External Surfaces Monitoring Program procedures to include instructions for monitoring aging effects for flexible polymeric components through physical manipulations of the material, with a sample size for manipulation of at least ten percent of the available surface area. Inspect accessible surfaces for the following:
  - Surface cracking, crazing, scuffing, dimensional changes (e.g., ballooning and necking).
  - Discoloration.
  - Exposure of internal reinforcement for reinforced elastomers.
  - Hardening as evidence by loss of suppleness during manipulation where the component and material are appropriate to manipulation.

- Shrinkage, loss of strength.

- Revise External Surfaces Monitoring Program procedures to specify the following for insulated components:
  - Periodic representative inspections will be conducted during each 10-year period.
  - For a representative sample of insulated indoor components exposed to condensation (because the component is operated below the dew point) and insulated outdoor components, insulation will be removed for visual inspection of the component surface. Inspections include a minimum of 20 percent of the in-scope piping length for each material type (e.g., steel, stainless steel, copper alloy, aluminum), or for components with a configuration which does not conform to a 1-foot axial length determination (e.g., valve, accumulator), 20 percent of the surface area. Alternatively, insulation will be removed and a minimum of 25 inspections performed that can be a combination of 1 foot axial length sections and individual components for each material type.
  - Inspection locations are based on the likelihood of corrosion under insulation (CUI). For example, CUI is more likely for components experiencing alternate wetting and drying in environments where trace contaminants could be present and for components that operate for long periods of time below the dew point. Subsequent inspections will consist of an examination of the exterior surface of the insulation for indications of damage to the jacketing or protective outer layer of the insulation, if the following conditions are verified in the initial inspection:
    - No loss of material due to general, pitting or crevice corrosion, beyond that which could have been present during initial construction, and
    - No evidence of cracking.

    If the external visual inspections of the insulation reveal damage to the exterior surface of the insulation or there is evidence of water intrusion through the insulation (e.g. water seepage through insulation seams/joints), periodic inspections under the insulation will continue as described above.
  - Removal of tightly adhering insulation that is impermeable to moisture is not required unless there is evidence of damage to the moisture barrier. If the moisture barrier is intact, the likelihood of CUI is low for tightly adhering insulation. Tightly adhering insulation is considered to be a separate population from the remainder of insulation installed on in-scope components. The entire population of in-scope accessible piping component surfaces that have tightly adhering insulation will be visually inspected for damage to the moisture barrier with the same frequency as for other types of insulation inspections. These inspections will not be credited towards the inspection quantities for other types of insulation.

- Revise External Surfaces Monitoring Program procedures to include acceptance criteria for the parameters observed.
  - Metals should not have any indications of relevant degradation.

- Flexible polymers should have a uniform surface texture and color with no cracks and no dimension change, no abnormal surface conditions with respect to hardness, flexibility, physical dimensions, and color.
- Rigid polymers should have no erosion, cracking, crazing, or chalking.
- For insulation, no discoloration, staining, or surface irregularities from moisture intrusion.

- Revise External Surfaces Monitoring Program procedures to stipulate that administrative controls are in accordance with the Fermi 2 10 CFR 50 Appendix B Quality Assurance Program.
- Revise External Surfaces Monitoring Program procedures to include instructions for detection of cracking of gas-filled stainless steel and aluminum components exposed to outdoor air.
- Revise External Surfaces Monitoring Program procedures to:

  a) Visually inspect jacketed and non-jacketed insulation required to reduce heat transfer at a frequency consistent with NUREG-1801 Section XI.M36, as modified by LR-ISG-2012-02, to ensure that insulation degradation due to moisture intrusion has not occurred.

  b) Ensure procedures include instructions to inspect for signs of water intrusion. Inspect accessible surfaces for the following signs of water intrusion: discoloration, staining, or surface irregularities.

Enhancements will be implemented prior to the period of extended operation.

B.1.17 FATIGUE MONITORING PROGRAM

The Fatigue Monitoring Program ensures that fatigue usage remains within allowable limits for components identified to have a TLAA by (a) tracking the number of critical thermal and pressure transients for selected components, (b) verifying that the severity of monitored transients are bounded by the design transient definitions for which they are classified, (c) assessing the impact of the reactor coolant environment on a set of sample critical components including those from NUREG/CR-6260 and those components identified to be more limiting than the components specified in NUREG/CR-6260, and (d) addressing applicable fatigue exemptions. Tracking the number of critical thermal and pressure transients for the selected components ensures a code design usage factor of less than or equal to 1, including environmental effects where applicable. The environmental effects on fatigue for the identified critical components will be evaluated.

The program monitors the number of occurrences for the plant transients that cause significant fatigue usage. The program also provides for updates of fatigue usage calculations on an as-needed basis if an allowable cycle limit is approached or in a case where a transient definition has been changed, unanticipated new thermal events are discovered, or the geometry of components has been modified.

As an alternative to monitoring occurrences of transients, NUREG-1801, Section X.M1, Fatigue Monitoring, also allows more detailed monitoring of local pressure and thermal conditions to be performed to allow the actual fatigue usage for the specified critical locations to be calculated. Therefore the program will include Stress-Based Fatigue (SBF) monitoring. SBF monitoring computes stress history for a given component from transient pressure and temperature data collected from plant instruments, and the corresponding stress history at the critical location in the component. The stress history is analyzed to identify stress cycles and then a cumulative usage factor is computed. The recommendations of NRC Regulatory Issue Summary (RIS) 2008-30 will be applied for any use of SBF. Use of SBF monitoring will appropriately account for environmental effects on fatigue usage.

The Fatigue Monitoring Program will be enhanced as follows.

- Revise Fatigue Monitoring Program procedures to monitor and track critical thermal and pressure transients for components that have been identified to have a fatigue TLAA.
- Develop environmentally assisted fatigue (EAF) usage calculations that consider the effects of the reactor water environment for a set of sample reactor coolant system components. This sample set will include the locations identified in NUREG/CR-6260 and additional plant-specific component locations in the reactor coolant pressure boundary if they are found more limiting than those considered in NUREG/CR-6260. Environmental correction factors will be determined using formulae consistent with those recommended in NUREG-1801, X.M1.
- Revise Fatigue Monitoring Program procedures to provide updates of the fatigue usage calculations on an as-needed basis if an allowable cycle limit is approached, or in a case where a transient definition has been changed, unanticipated new thermal events are discovered, or the geometry of components has been modified. For components with assumed minimal cycle counts, ensure that exemption assumptions are not exceeded.
- After the EAF calculations are completed, revise the Fatigue Monitoring Program procedures to state that the program counting of the cycle limits maintains the cumulative fatigue usage below the design limit through the period of extended operation, with consideration of the reactor water environmental fatigue effects. Revise Fatigue Monitoring Program procedures to allow for use of cycle-based fatigue (CBF) or stress-based fatigue (SBF) monitoring methods (including environmental effects) if a component's CUF value is projected to exceed 1.0 after EAF calculations are completed.
- Revise Fatigue Monitoring Program procedures so that the scope of the program includes monitoring the operating hours for the main steam bypass operation at the 30%-45% valve open position and perform trending to ensure that the operating time for the main steam bypass operation remains below the design limit during the period of extended operation.
- Revise Fatigue Monitoring Program procedures to provide for corrective actions to prevent the operating time for the main steam bypass from exceeding the analysis during the period of extended operation. Acceptable corrective actions include repair of the component, replacement of the component, or a more rigorous analysis of the

component to demonstrate that the service life will not be exceeded during the period of extended operation.

The second enhancement for EAF usage calculations will be implemented at least two years prior to entering the period of extended operation. All other enhancements will be implemented prior to the period of extended operation.

B.1.18 FIRE PROTECTION PROGRAM

The Fire Protection Program manages the following through periodic visual inspection of components and structures with a fire barrier intended function.

- Carbon steel components (loss of material).
- Concrete components (cracking and loss of material).
- Masonry walls (cracking and loss of material).
- Fire resistant materials (loss of material, change in material properties, cracking/delamination, and separation).
- Elastomer components (increased hardness, shrinkage, and loss of strength).

The program includes visual inspections of not less than ten percent of each type of penetration seal at a frequency described in the Technical Requirements Manual (TRM). These inspections examine any sign of degradation, such as cracking, seal separation from walls and components, separation of layers of material, rupture and puncture of seals that are directly caused by increased hardness, and shrinkage of seal material due to loss of material. If any signs of degradation are detected within the sample, the scope of the inspection is expanded to include additional seals.

Visual inspections of the fire barrier walls, ceilings, and floors in structures within the scope of license renewal are performed at a frequency described in the TRM. Inspections of fire barriers include inspections of coatings and wraps. Visual inspection of the fire barrier walls, ceilings, and floors and other fire barrier materials to detect any sign of degradation, such as cracking and loss of material caused by freeze-thaw, chemical attack, and reaction with aggregates, are performed to ensure their intended fire protection functions are maintained.

Periodic visual inspections and functional tests are utilized to manage the aging effects of fire doors. Visual inspections of fire door surfaces and functional testing of fire door closing mechanisms and latches are performed at a frequency described in the TRM.

The Fire Protection Program performs visual periodic inspections and functional tests of the CO2 and Halon systems in accordance with the TRM. These actions verify that the systems actuate correctly and that system integrity is maintained by inspecting for conditions of corrosion that could lead to a loss of material.

The Fire Protection Program will be enhanced as follows.

- Revise Fire Protection Program procedures to perform visual inspections to manage loss of material of the Halon and CO2 fire suppression system.
- Revise Fire Protection Program procedures to require visual inspections of in-scope (a) fire wrap and fire stop materials for loss of material, change in material properties,

cracking/delamination, separation, increased hardness, shrinkage, and loss of strength; (b) carbon steel penetration sleeves for loss of material; (c) steel framing, roof decking, and floor decking for loss of material; (d) concrete fire barriers including manways, manhole covers, handholes, and roof slabs for loss of material and cracking; and (e) railroad bay airlock doors for loss of material. Inspections are performed at a frequency in accordance with the NRC-approved fire protection program or at least once every refueling cycle.

Enhancements will be implemented prior to the period of extended operation.

B.1.19 FIRE WATER SYSTEM PROGRAM

The Fire Water System Program manages loss of material due to general, pitting, and crevice corrosion, microbiologically influenced corrosion, or fouling, and flow blockage due to fouling for in-scope long-lived passive water-based fire suppression system components using periodic flow testing and visual inspections. When visual inspections are used to detect loss of material, the inspection technique is capable of detecting surface irregularities that could indicate wall loss due to corrosion, corrosion product deposition, and flow blockage due to fouling.

Testing or replacement of sprinkler heads that have been in service for 50 years is performed in accordance with the 2011 Edition of NFPA 25. Portions of the water-based fire water system that a) are normally dry, but periodically subject to flow (e.g., dry-pipe or downstream of deluge valve in a deluge system) and b) cannot be drained or allow water to collect are subject to augmented testing beyond that specified in NFPA 25. These augmented inspections include a) periodic full flow tests at the design pressure and flow rate, or internal inspections, and b) volumetric wall thickness evaluations. Applicable industry standards and guidance documents are also used to delineate the program (e.g., insurance loss control manual and INPO operating experience issuances).

Water system pressure is continuously monitored such that loss of pressure is detected and corrective action initiated.

Program acceptance criteria include (a) the water based fire protection system can maintain required pressure, (b) no unacceptable signs of degradation or fouling are observed during nonintrusive or visual inspections, and (c) in the event surface irregularities are identified, testing is performed to ensure minimum design pipe wall thickness is maintained. The Fire Water System Program will be enhanced as follows.

- Revise Fire Water System Program procedures to ensure sprinkler heads are tested or replaced in accordance with NFPA 25 (2011 Edition), Section 5.3.1.
- Revise Fire Water System Program procedures to perform an inspection of wet fire water system piping condition at least once every five years by opening a flushing connection at the end of one main and by removing a sprinkler toward the end of one branch line for the purpose of inspecting the interior for evidence of loss of material and the presence of foreign organic or inorganic material that could result in flow obstructions or blockage of a sprinkler head. Where multiple wet-pipe systems are in a building, every other system shall be inspected in a five year period. Then, in the next five year period, the remaining systems in that building shall be inspected. Refer

to NFPA 25 (2011 Edition) Sections 14.2.1 and 14.2.2) The inspection method used shall be capable of detecting surface irregularities that could indicate wall loss due to corrosion, corrosion product deposition, and flow blockage due to fouling. Ensure procedures require a follow-up volumetric wall thickness evaluation where irregularities are detected.

- Revise Fire Water System Program procedures to ensure a) sprinkler heads are tested or replaced in accordance with NFPA 25 (2011 Edition) Section 5.3.1 and b) the fire protection engineer approves the sprinkler testing laboratory.
- Revise Fire Water System Program procedures to a) specify that in accordance with NFPA Section 13.2.5.2 when there is a 10 percent reduction in full flow pressure when compared to the original acceptance test or previously performed tests, the cause of the reduction shall be identified and corrected as necessary and b) note the time to return to static pressure after performing a main drain test.
- Revise Fire Water System Program procedures to notify the fire protection engineer of test results and deficiencies identified or detected during testing.
- Revise Fire Water System Program procedures to ensure piping is cleaned and sprinklers are replaced if obstructions are identified during internal inspections. Sprinklers loaded with dust may be cleaned using air rather than replaced.
- Revise Fire Water System Program procedures to perform an internal inspection of wet fire water system piping conditions at least once every five years by opening a flushing connection at the end of one main and by removing a sprinkler toward the end of the branch line for the purpose of inspecting the interior for evidence of loss of material and the presence of foreign organic and inorganic material that could result in flow obstructions or blockage of sprinkler heads. Where multiple wet-pipe systems are in a building, every other system shall be inspected in a five year period. Then, in the next five year period, the remaining systems in that building shall be inspected.
- Revise Fire Water System Program procedures to perform at least once every five years either an internal inspection of the dry components downstream of the deluge valves for the hydrogen seal oil unit by removing a sprinkler toward the end of one branch line and inspecting for evidence of loss of material and the presence of foreign organic and inorganic material that could result in flow obstructions or blockage of sprinklers,

  <u>or</u>

  Revise Fire Water System Program procedures to perform at least once every five years an air or smoke test to verify there is no flow obstruction or blockage of sprinklers.
- Revise Fire Water System Program procedures to perform an inspection of the water distribution piping associated with charcoal filters for loss of material and foreign organic or inorganic material when the charcoal beds are replaced.

- Revise Fire Water System Program procedures to perform an obstruction investigation whenever any of the criteria listed in NFPA Section 14.2.1.3 or 14.3.1 are met.
- Perform a fire water system walkdown of the piping and components that are designed to be dry (e.g., downstream of deluge valves or manual isolations of dry fire water piping), but are periodically wetted, to determine if any piping sections are collecting water and are subject to both of the following augmented inspections:
  - In each five year interval, beginning five years prior to the period of extended operation, either a) conduct a flow test or flush sufficient to detect potential flow blockage, or b) conduct a visual inspection of 100 percent of the internal surface of piping segments that cannot be drained or piping segments that allow water to collect.
  - In each five year interval of the period of extended operation, inspect 20 percent of the length of piping segments that cannot be drained or piping segments that allow water to collect using volumetric techniques to measure wall thickness. Measurement points will be obtained so that each potential degraded condition can be identified (e.g., general corrosion, MIC). The 20 percent of piping that will be inspected in each five year interval will be in different locations than previously inspected piping.
- Revise Fire Water System Program procedures to include acceptance criteria that any indication of fouling is evaluated.
- Revise Fire Water System Program procedures to specify that if the presence of sufficient foreign organic or inorganic material to obstruct pipe or sprinklers is detected during pipe inspections, the material is removed and the source and extent of condition determined, corrected, and the condition entered into the Corrective Action Program.
- Revise Fire Water System Program procedures to replace sprinklers associated with representative tested sprinkler, if the representative test sprinkler fails to meet the test requirements.
- Revise Fire Water System Program procedures to replace any sprinkler that shows signs of corrosion.
- If the decreasing trend in fire water system flow tests is not resolved through the Corrective Action Program prior to the period of extended operation, revise Fire Water System Program procedures to continue performing annual fire water system flow tests during the period of extended operation until such a time as trend data from fire water system flow tests indicates that the system will be capable of performing its intended function throughout the period of extended operation and therefore TRM frequency may be resumed.
- Revise Fire Water System Program procedures to include formal documentation of the CCHVAC makeup and recirculation fire water supply drain down inspection for indications of flow blockage.

Enhancements will be implemented prior to the period of extended operation.

B.1.20 FLOW-ACCELERATED CORROSION PROGRAM

The Flow-Accelerated Corrosion (FAC) Program manages loss of material due to wall thinning caused by FAC for carbon steel piping and components through (a) performing an analysis to determine systems susceptible to FAC, (b) conducting appropriate analysis to predict wall thinning, (c) performing wall thickness measurements based on wall thinning predictions and operating experience, and (d) evaluating measurement results to determine the remaining service life and the need for replacement or repair of components.

The program also manages wall thinning due to various erosion mechanisms in treated water and steam systems for all materials that may be identified through industry or plant-specific operating experience.

The program relies on implementation of guidelines published by EPRI in NSAC-202L, Rev. 3, and internal and external operating experience. The program uses a predictive code for portions of susceptible systems with design and operating conditions that are amenable to computer modeling. When field measurements identify that the predictive code is not conservative, the model is recalibrated. The model is also adjusted as a result of any power uprates.

A representative sample of components is selected based on the most susceptible locations for wall thickness measurements at a frequency in accordance with NSAC-202L Rev. 3 guidelines to ensure that FAC degradation is identified and mitigated before the component integrity is challenged. Inspections are performed using ultrasonic or other approved testing techniques capable of detecting wall thickness. Measurement results are used to confirm predictions and to plan long-term corrective action. In the event measurements of wall thinning exceed predictions, the extent of the wall thinning is determined as a part of the Corrective Action Program. Components predicted to reach the minimum allowed wall thickness before the next scheduled outage are isolated, repaired, replaced, or reevaluated under the Corrective Action Program.

The FAC Program will be enhanced as follows.

- Revise procedures to indicate that the FAC Program also manages loss of material due to erosion mechanisms of cavitation, flashing, liquid droplet impingement, and solid particle erosion for any material in treated water or steam environments. Include in program procedures a susceptibility review based on internal operating experience; external operating experience; EPRI TR-1011231, Recommendations for Controlling Cavitation, Flashing, Liquid Droplet Impingement, and Solid Particle Erosion in Nuclear Power Plant Piping; and NUREG/CR-6031, Cavitation Guide for Control Valves. Piping subject to erosive conditions is not excluded from inspections, even if it has been replaced with FAC-resistant material. Periodic wall thickness measurements of such piping should continue until the effectiveness of corrective actions is assured.

- Revise FAC Program procedures to specify that downstream components are monitored for wall thinning when susceptible upstream components are replaced with FAC-resistant materials.

Enhancements will be implemented prior to the period of extended operation.

B.1.21 INSERVICE INSPECTION PROGRAM

The Inservice Inspection (ISI) Program manages loss of material, cracking, and reduction in fracture toughness for ASME Class 1, 2, and 3 pressure-retaining components, including welds, pump casings, valve bodies, integral attachments, and pressure-retaining bolting, using volumetric, surface, and/or visual examination and leakage testing as specified in ASME Code Section XI, 2001 Edition with 2003 Addenda. The examinations, scheduling, acceptance criteria, flaw evaluation, and re-examinations are in accordance with the requirements identified in ASME Section XI with NRC-approved alternatives.

Additional limitations, modifications, and augmentations approved under the provisions of 10 CFR 50.55a with NRC-approved alternatives are included as a part of this program. Every ten years this program is updated to the latest ASME Section XI code edition and addendum approved by the NRC per 10 CFR 50.55a. Repair and replacement activities for these components are covered in Subsection IWA of the ASME code edition of record.

B.1.22 INSERVICE INSPECTION – IWF PROGRAM

The Inservice Inspection (ISI) – IWF Program performs periodic visual examinations of ASME Class 1, 2, 3 and MC piping and component supports to determine general mechanical and structural condition or degradation of component supports such as verification of clearances, settings, physical displacements, loose or missing parts, debris, corrosion, wear, erosion, or the loss of integrity at welded or bolted connections. The ISI-IWF Program is implemented through plant procedures which provide administrative controls, including corrective actions, for the conduct of activities that are necessary to fulfill the requirements of ASME Section XI, as mandated by 10 CFR 50.55a. The monitoring methods are effective in detecting the applicable aging effects, and the frequency of monitoring is adequate to prevent significant degradation.

The ISI-IWF Program will be enhanced as follows.

- Revise plant procedures to specify the preventive actions delineated in NUREG-1339 and EPRI NP-5769, NP-5067, and TR-104213 that emphasize proper selection of bolting material, installation torque or tension, and the use of lubricants and sealants for high-strength bolting.
- Revise plant procedures to require structural bolting replacement and maintenance activities to include appropriate preload and proper tightening (torque or tension) as recommended in EPRI documents, American Society for Testing of Materials (ASTM) standards, American Institute of Steel Construction (AISC) Specifications, as applicable.
- Revise plant procedures to include the preventive actions for storage of ASTM A325 and A490 bolting from Section 2 of Research Council for Structural Connections publication, "Specification for Structural Joints Using ASTM A325 or A490 Bolts."
- Revise plant procedures to include the preventive action of using bolting material that has an actual measured yield strength less than 150 ksi, except in the case of like-for-like replacement of existing bolting material in the reactor pressure vessel skirt to ring girder bolted joint.

- Revise plant procedures to specify that detection of aging effects will include monitoring anchor bolts for loss of material, loose or missing nuts or bolts, and cracking of concrete around the anchor bolts.
- Revise plant procedures to identify the following unacceptable conditions:
  - Debris, dirt, or excessive wear that could prevent or restrict sliding of the sliding surfaces as intended in the design basis of the support.
  - Cracked or sheared bolts, including high-strength bolts, and anchors.
- Revise plant procedures to include assessment of the impact on the inspection sample, in terms of sample size and representativeness, if components that are part of the sample population are re-worked.

Enhancements will be implemented prior to the period of extended operation.

B.1.23 INSPECTION OF OVERHEAD HEAVY LOAD AND LIGHT LOAD (RELATED TO REFUELING) HANDLING SYSTEMS PROGRAM

The Inspection of Overhead Heavy Load and Light Load (Related to Refueling) Handling Systems (OVHLL) Program performs periodic visual examinations and preventive maintenance to manage loss of material due to corrosion, loose bolting or rivets, and crane rail wear of cranes and hoists, based on industry standards and guidance documents. The program evaluates the effectiveness of the maintenance monitoring program and the effects of past and future usage on the structural reliability of cranes and hoists. The program includes structural components, including structural bolting, that make up the bridge, the trolley, lifting devices, and rails in the rail system and includes cranes and hoists that meet the provisions of 10 CFR 54.4(a)(1) and (a)(2) as well as NUREG-0612, "Control of Heavy Loads at Nuclear Power Plants." The activities rely on visual examinations and functional testing to ensure that cranes and hoists are capable of sustaining their rated loads, thus ensuring their intended function is maintained during the period of extended operation.

The Inspection of OVHLL Program will be enhanced as follows.

- Revise plant procedures to specify the monitoring of rails in the rail system for loss of material due to wear; monitor structural components of the bridge, trolley and hoists for deformation, cracking, and loss of material due to corrosion; and monitor structural connections/bolting for loose or missing bolts, nuts, pins or rivets and any other conditions indicative of loss of bolting integrity.
- Revise plant procedures to specify inspection frequency requirements will be in accordance with ASME B30.2 or other appropriate standard in the ASME B30 series.
- Revise plant procedures to require that significant loss of material due to wear of rails in the rail system and any sign of loss of bolting integrity will be evaluated in accordance with ASME B30.2 or other appropriate standard in the ASME B30 series.
- Revise plant procedures to specify that maintenance and repair activities will utilize the guidance provided in ASME B30.2 or other appropriate standard in the ASME B30 series.

Enhancements will be implemented prior to the period of extended operation.

B.1.24 INTERNAL SURFACES IN MISCELLANEOUS PIPING AND DUCTING COMPONENTS PROGRAM

The Internal Surfaces in Miscellaneous Piping and Ducting Components Program is a new program that will manage fouling, cracking, loss of material, and change in material properties using representative sampling and opportunistic visual inspections of the internal surfaces of piping and components in environments other than open-cycle cooling water, closed treated water, and fire water. Program periodic surveillances or maintenance activities will be conducted when the surfaces are accessible for visual inspection.

Where practical, the inspections will focus on the bounding or lead components most susceptible to aging because of time in service and severity of operating conditions. At a minimum, in each ten-year period during the period of extended operation, a representative sample of 20 percent of the population (defined as components having the same combination of material, environment, and aging effect) or a maximum of 25 components per population will be inspected. Opportunistic inspections will continue in each period despite meeting the sampling limit.

For metallic components, visual inspection of surface conditions will be used to detect evidence of loss of material and fouling. For non-metallic components, visual inspections and physical manipulation or pressurization will be used to detect evidence of surface discontinuities such as cracking and change in material properties. Visual examinations of elastomeric components will be accompanied by physical manipulation such that changes in material properties are readily observable. The sample size for physical manipulation will be at least ten percent of accessible surface area, including visually identified suspect areas.

Specific acceptance criteria will be as follows:

- Stainless steel: clean surfaces, shiny, no abnormal surface condition.
- Metals: no abnormal surface condition.
- Elastomerics: no change in material properties.
- Rigid polymers: no surface changes affecting performance such as erosion and cracking.

Conditions that do not meet the acceptance criteria will be entered into the Corrective Action Program for evaluation. Any indications of relevant degradation will be evaluated using design standards, procedural requirements, current licensing basis, and industry codes or standards.

This program will be implemented prior to the period of extended operation.

B.1.25 MASONRY WALL PROGRAM

The Masonry Wall Program is based on guidance provided in I.E. Bulletin 80-11, "Masonry Wall Design," and Information Notice (IN) 87-67, "Lessons Learned from Regional Inspections of Licensee Actions in Response to I.E. Bulletin 80-11." The scope of the Masonry Wall Program includes masonry walls within the scope of license renewal as delineated in 10 CFR 54.4. The program manages loss of material and cracking of masonry walls so that the evaluation basis established for each masonry wall within the scope of license renewal remains valid through the period of extended operation. The program will be implemented as part of the Structures Monitoring Program (Section B.1.42).

The program includes visual inspections of masonry walls identified as performing intended functions in accordance with 10 CFR 54.4. Included components are masonry walls required by 10 CFR 50.48, radiation shielding masonry walls, and masonry walls with the potential to affect safety-related components. Structural steel components, steel edge supports, and steel bracing of masonry walls are managed by the Structures Monitoring Program (Section B.1.42).

Enhancements to this program are included in the enhancements to the Structures Monitoring Program (Section B.1.42).

B.1.26 METAL ENCLOSED BUS INSPECTION PROGRAM

The Metal Enclosed Bus Inspection Program is a new condition monitoring program that provides for the inspection of the internal and external portions of metal enclosed bus (MEB) to identify age-related degradation of the bus and bus connections, the bus enclosure assemblies, the bus insulation and the bus insulators. This program will inspect the MEB between combustion turbine generator (CTG) transformer CTG 11 and peaker bus 1-2B located in the 120-kV switchyard, and between CTG11-1 generator and CTG11-1 output breaker A2 in the peaker yard, including the MEB connections to the generator and breaker A2. The MEB associated with CTG 11-1 is utilized as the alternate AC source for a station blackout (SBO) event and to support response by the Dedicated Shutdown Panel to an Appendix R fire.

The program calls for the visual inspection of MEB internal surface (bus enclosure assemblies) to detect age-related degradation, including cracks, corrosion, foreign debris, excessive dust buildup, and evidence of moisture intrusion. MEB insulating material is visually inspected for signs of reduced insulation resistance due to thermal/thermoxidative degradation of organics/thermoplastics, radiation-induced oxidation, moisture/debris intrusion, or ohmic heating, as indicated by embrittlement, cracking, chipping, melting, swelling, discoloration, or surface contamination, which may indicate overheating or aging degradation. The internal bus insulating supports or insulators will be inspected for structural integrity and signs of cracks. MEB external surfaces are visually inspected for loss of material due to general, pitting, and crevice corrosion. Accessible elastomers (e.g., gaskets, boots, and sealants) are inspected for degradation, including surface cracking, crazing, scuffing, and changes in dimensions (e.g., "ballooning" and "necking"), shrinkage, discoloration, hardening, and loss of strength. A sample of accessible bolted connections will be inspected for increased resistance of connection by using thermography or by measuring connection resistance using a micro-ohmmeter. Torque checking will not be used as an alternative test method. Twenty percent of the population with a maximum sample of 25 will constitute a representative sample size. Otherwise, a technical justification of the methodology and sample size used for selecting components should be included as part of the program's site documentation. These inspections are performed at least once every ten years.

As an alternative to thermography or measuring connection resistance of accessible bolted connections covered with heat shrink tape, sleeving, insulating boots, etc., visual inspection of insulation material may be used to detect surface anomalies, such as embrittlement, cracking, chipping, melting, discoloration, swelling, or surface contamination. When this alternative visual inspection is used to check bolted connections, the first inspection is completed prior to the period of extended operation and every five years thereafter.

This program will be used instead of the Structures Monitoring Program (Section B.1.42) for external surfaces of the bus enclosure assemblies.

This program will be implemented prior to the period of extended operation. This new program will be implemented consistent with the corresponding program described in NUREG-1801, Section XI.E4, Metal-Enclosed Bus.

B.1.27 NEUTRON-ABSORBING MATERIAL MONITORING PROGRAM

The Neutron-Absorbing Material Monitoring Program provides reasonable assurance that degradation of the neutron-absorbing materials (e.g. Boral) used in spent fuel pools that could compromise the criticality analysis will be detected. The program relies on periodic inspection, testing, and other monitoring activities to assure that the required five percent sub-criticality margin is maintained during the period of extended operation. The program monitors loss of material and changes in dimension, such as blisters, pits, and bulges that could result in a loss of neutron-absorbing capability. The parameters monitored include physical measurements and geometric changes in test coupons. The frequency of testing will be based on the condition of the neutron-absorbing material, justified with plant-specific and industry operating experience, prior to the period of extended operation, at a minimum of once every ten years in the period of extended operation. The approach to relating measurement results of the coupons to the spent fuel neutron-absorber materials considers the spent fuel loading strategy. In the event that a loss of neutron-absorbing capacity is anticipated based on coupon testing, additional testing will be performed to ensure the sub-criticality requirements are met.

The Neutron-Absorbing Material Monitoring Program will be enhanced as follows.

- Prior to the period of extended operation, revise Neutron-Absorbing Material Monitoring Program procedures to establish an inspection frequency, justified with plant-specific operating experience, of at least once every ten years, based on the condition of the neutron-absorbing material.
- Revise Neutron-Absorbing Material Monitoring Program procedures to perform trending of coupon testing results to determine the rate of degradation. Ensure the predicted boron-10 areal density will be sufficient to maintain the subcritical conditions required by technical specifications until the next coupon test.

Enhancements will be implemented prior to the period of extended operation.

B.1.28 NON-EQ CABLE CONNECTIONS PROGRAM

The Non-EQ Cable Connections Program is a new one-time inspection program that consists of a representative sample of electrical connections within the scope of license renewal, which is inspected or tested at least once prior to the period of extended operation to confirm that there are no aging effects requiring management during that period. Cable connections included in this program are those connections susceptible to age-related degradation resulting in increased resistance of connection due to thermal cycling, ohmic heating, electrical transients, vibration, chemical contamination, corrosion, or oxidation that are not subject to the environmental qualification requirements of 10 CFR 50.49. Inspection methods may include thermography, contact resistance testing, or other appropriate testing methods without removing the connection insulation, such as heat shrink tape, sleeving, insulating boots, etc.. Torque checking will not be used as an alternative test method. The one-time inspection provides additional confirmation to support industry operating experience that shows that electrical connections have not experienced a high degree of failures and that existing installation and maintenance practices are effective.

The factors considered for sample selection will be application (medium and low voltage, defined as < 35 kV), circuit loading (high loading), connection type (crimped, bolted, and tap box), and location (high temperature, high humidity, vibration, etc.). The representative sample size will be based on 20 percent of the connection population with a maximum sample of 25. The technical basis for the sample selections will be documented. If an unacceptable condition or situation is identified in the selected sample, the corrective action program will be used to evaluate the condition and determine appropriate corrective action.

The inspections will be performed prior to the period of extended operation.

B.1.29 NON-EQ INACCESSIBLE POWER CABLES (400 V TO 13.8 KV) PROGRAM

The Non-EQ Inaccessible Power Cables (400 V to 13.8 kV) Program is a new condition monitoring program that will manage the aging effect of reduced insulation resistance on inaccessible power (400 V to 13.8 kV) cables that have a license renewal intended function. The program calls for inaccessible or underground (e.g., in conduit, duct bank, or direct buried) power (greater than or equal to 400 volts) cables exposed to significant moisture, to be tested at least once every six years to provide an indication of the condition of the conductor insulation, with the first tests occurring before the period of extended operation. The specific type of test to be used should be a proven, commercially available test capable of detecting reduced insulation resistance of the cable's insulation system due to wetting or submergence. The applicant can assess the condition of the cable insulation with reasonable confidence using one or more of the following techniques: dielectric loss (dissipation factor/power factor), AC voltage withstand, partial discharge, step voltage, time domain reflectometry, insulation resistance and polarization index, line resonance analysis, or other testing that is state-of-the-art at the time the tests are performed. One or more tests are used to determine the condition of the cables so they will continue to meet their intended function during the period of extended operation.

The program will include periodic inspections for water accumulation in manholes within the scope of this program. The inspection frequency for water collection is established and performed based on plant-specific operating experience with cable wetting or submergence in manholes (i.e., the inspection is performed periodically based on water accumulation over time and event-driven occurrences such as heavy rain or flooding). The periodic inspection should occur at least annually. The inspection should include direct observation that cables are not wetted or submerged, that cables/splices and cable support structures are intact, and dewatering/drainage systems (i.e., sump pumps) and associated alarms operate properly. In addition, operation of dewatering devices should be inspected and operation verified prior to any known or predicted heavy rain or flooding.

This program will be implemented prior to the period of extended operation.

B.1.30 NON-EQ INSTRUMENTATION CIRCUITS TEST REVIEW PROGRAM

The Non-EQ Instrumentation Circuits Test Review Program is a new performance monitoring program that will manage the aging effects of applicable cables in the following systems or sub-systems.

- Neutron monitoring
  - Intermediate range channels (IRMs)
  - Average power range monitors (includes local power range monitors [LPRM] detector strings)
- Process radiation monitoring
  - Control center emergency air inlet radiation monitors
  - Fuel pool ventilation exhaust radiation monitors
  - Main steam line radiation monitors

The Non-EQ Instrumentation Circuits Test Review Program calls for the review of calibration results or findings of surveillance tests on electrical cables and connections used in circuits with sensitive, high-voltage, low-level current signals, such as radiation monitoring and nuclear instrumentation, to provide an indication of the existence of aging effects based on acceptance criteria related to instrumentation circuit performance. By reviewing the results obtained during normal calibration or surveillance, an applicant may detect severe aging degradation prior to the loss of the cable and connection intended function. The review of calibration results or findings of surveillance tests is performed at least once every ten years. In cases where cables are not included as part of calibration or surveillance program testing circuit, a proven cable test (such as insulation resistance tests, time domain reflectometry tests, or other testing judged to be effective in determining cable system insulation condition as justified in the application) is performed. The test frequency is based on engineering evaluation and is at least once every ten years.

For sensitive instrumentation circuit cables that are disconnected during instrument calibrations, testing using a proven method for detecting deterioration for the insulation system (such as insulation resistance tests or time domain reflectometry) will occur at least once every ten years, with the first test occurring before the period of extended operation. Applicable industry standards and guidance documents will be used to delineate the program.

The program will be implemented prior to the period of extended operation.

B.1.31 NON-EQ INSULATED CABLES AND CONNECTIONS PROGRAM

The Non-EQ Insulated Cables and Connections Program is a new condition monitoring program that provides reasonable assurance the intended functions of insulated cables and connections exposed to adverse localized environments caused by heat, radiation[1], moisture, and chemical contamination (i.e. bird droppings) can be maintained consistent with the current licensing basis through the period of extended operation.

The program consists of accessible insulated electrical cables and connections installed in adverse localized environments to be visually inspected at least once every ten years for cable jacket and connection insulation surface anomalies, such as embrittlement, discoloration, cracking, melting, swelling, or surface contamination, that could indicate incipient conductor insulation aging degradation from temperature, radiation, or moisture.

An adverse localized environment is a condition in a limited plant area that is significantly more severe than the plant design environment for the cable or connection insulation materials.

This program will be implemented prior to the period of extended operation with the first inspection prior to the period of extended operation.

B.1.32 OIL ANALYSIS PROGRAM

The Oil Analysis Program ensures that loss of material and fouling are not occurring by maintaining the quality of the lubricating oil. The program ensures that contaminants (primarily water and particulates) are within acceptable limits. Testing activities include sampling and analysis of lubricating oil for detrimental contaminants. Testing results indicating the presence of water in oil samples initiate corrective action that may include evaluating for in-leakage.

The One-Time Inspection Program utilizes inspections or non-destructive evaluations of representative samples to verify that the Oil Analysis Program has been effective at managing the aging effects.

The Oil Analysis Program will be enhanced as follows.

- Revise Oil Analysis Program procedures to identify components within the scope of the program.
- Revise Oil Analysis Program procedures to provide a formalized analysis technique for particulate counting.
- Revise Oil Analysis Program procedures to include the sampling and testing recommendations of equipment manufacturers or industry standards.

Enhancements will be implemented prior to the period of extended operation.

B.1.33 ONE-TIME INSPECTION PROGRAM

The One-Time Inspection Program is a new program that will consist of a one-time inspection of selected components to accomplish the following:

---

[1] Reduced insulation resistance from an environment of radiation and air (oxygen) includes radiolysis, photolysis of organics, or radiation induced oxidation. Photolysis is limited to UV sensitive materials.

- Verify the effectiveness of an aging management program that is designed to prevent or minimize aging to the extent that it will not cause the loss of intended function during the period of extended operation. The aging effects evaluated are loss of material, cracking, and fouling.
- Confirm the insignificance of an aging effect for situations in which additional confirmation is appropriate using inspections that verify degradation is not occurring.
- Trigger additional actions that ensure the intended functions of affected components are maintained during the period of extended operation.

The sample size will be 20 percent of the components in each material-environment-aging effect group up to a maximum of 25 components. Identification of inspection locations will be based on the potential for the aging effect to occur. Examination techniques will use established NDE methods with a demonstrated history of effectiveness in detecting the aging effect of concern, including visual, ultrasonic, and surface techniques. Acceptance criteria will be based on applicable ASME or other appropriate standards, design basis information, or vendor-specified requirements and recommendations. Any indication or relevant condition of degradation detected is evaluated. The need for follow-up examinations will be evaluated based on inspection results.

The One-Time Inspection Program will not be used for structures or components with known age-related degradation mechanisms or if the environment in the period of extended operation is not expected to be equivalent to that in the prior 40 years. In these cases, a periodic plant specific inspection will be performed.

The following table identifies potential inspection methods for specific aging effects.

Parameters Monitored and Inspection Methods for Specific Aging Effects			
Aging Effect	Aging Mechanism	Parameters Monitored	Inspection Methods
Loss of material	Crevice corrosion	Surface condition Wall thickness	Visual (VT-1 or equivalent) and/or volumetric (UT)
Loss of material	Galvanic corrosion	Surface condition Wall thickness	Visual (VT-3 or equivalent) and/or volumetric (UT)
Loss of material	General corrosion	Surface condition Wall thickness	Visual (VT-3 or equivalent) and/or volumetric (UT)

Parameters Monitored and Inspection Methods for Specific Aging Effects			
Aging Effect	Aging Mechanism	Parameters Monitored	Inspection Methods
Loss of material	Microbiologically induced corrosion (MIC)	Surface condition Wall thickness	Visual (VT-3 or equivalent) and/or volumetric (UT)
Loss of material	Pitting corrosion	Surface condition Wall thickness	Visual (VT-1 or equivalent) and/or volumetric (UT)
Loss of material	Erosion	Surface condition Wall thickness	Visual (VT-1 or equivalent) and/or volumetric (UT)
Reduction of heat transfer	Fouling	Surface condition	Visual (VT-3 or equivalent)
Cracking	SCC or cyclic loading	Surface condition	Enhanced visual (EVT-1 or equivalent) or surface examination (magnetic particle, liquid penetrant) or volumetric (radiographic testing or UT)

The program will include activities to verify effectiveness of aging management programs and activities to confirm the insignificance of aging effects as described below.

Diesel Fuel Monitoring Program (Section B.1.14)	One-time inspection activity will verify the effectiveness of the Diesel Fuel Monitoring Program by confirming that unacceptable loss of material is not occurring.
Oil Analysis Program (Section B.1.32)	One-time inspection activity will verify the effectiveness of the Oil Analysis Program by confirming that unacceptable loss of material and fouling is not occurring.

Water Chemistry Control – BWR Program (Section B.1.43)	One-time inspection activity will verify the effectiveness of the Water Chemistry Control – BWR Program by confirming that unacceptable cracking, loss of material, and fouling is not occurring.
Stainless steel reactor vessel flange leak off piping and valve body	One-time inspection activity will confirm that cracking is not occurring or is occurring so slowly that the aging effect will not affect the component intended function during the period of extended operation.
A representative sample of internal and external surfaces of core spray piping passing through the waterline region of the suppression pool	One-time inspection activity will confirm that loss of material is not occurring or is occurring so slowly that the aging effect will not affect the component intended function during the period of extended operation.
A representative sample of internal and external surfaces of residual heat removal (RHR) piping passing through the waterline region of the suppression pool	One-time inspection activity will confirm that loss of material is not occurring or is occurring so slowly that the aging effect will not affect the component intended function during the period of extended operation.
A representative sample of internal and external surfaces of high pressure coolant injection (HPCI) turbine exhaust piping passing through the waterline region of the suppression pool and HPCI turbine exhaust drain piping to the suppression pool	One-time inspection activity will confirm that loss of material is not occurring or is occurring so slowly that the aging effect will not affect the component intended function during the period of extended operation.
A representative sample of internal and external surfaces of nuclear pressure relief piping passing through the waterline region of the suppression pool	One-time inspection activity will confirm that loss of material is not occurring or is occurring so slowly that the aging effect will not affect the component intended function during the period of extended operation.
A representative sample of internal and external surfaces of reactor core isolation cooling (RCIC) piping	One-time inspection activity will confirm that loss of material is not occurring or is occurring so slowly that the aging effect will not affect the component intended function during the period of extended operation.

passing through the waterline region of the suppression pool	
A representative sample of internal surfaces of the normally dry suppression chamber spray piping that is periodically wetted by RHR system testing	One-time inspection activity will confirm that loss of material is not occurring or is occurring so slowly that the aging effect will not affect the component intended function during the period of extended operation.
A sample of 25 one-foot long locations of the mechanical draft cooling towers galvanized spray piping will be inspected	One-time inspection activity will confirm that loss of material is not occurring or is occurring so slowly that the aging effect will not affect the component intended function during the period of extended operation.

Inspections will be performed within the ten years prior to the period of extended operation.

B.1.34 ONE-TIME INSPECTION – SMALL-BORE PIPING PROGRAM

The One-Time Inspection – Small-Bore Piping Program is a new program that will augment ASME Code, Section XI (2001 Edition with 2003 Addenda) requirements and be applicable to small-bore ASME Code Class 1 piping and components with a nominal pipe size diameter less than four inches (NPS 4) and greater than or equal to one inch (NPS 1) in systems that have not experienced cracking of ASME Code Class 1 small-bore piping. Fermi 2 has not experienced cracking of ASME Code Class 1 small-bore piping less than NPS 4 and greater than or equal to NPS 1 due to stress corrosion, cyclical (including thermal, mechanical, and vibration fatigue) loading, or thermal stratification and thermal turbulence. The program can also be used for systems that have experienced cracking but have implemented design changes to effectively mitigate cracking.

This program will provide a one-time volumetric or (socket welds only) opportunistic destructive inspection of ASME Class 1 piping butt weld locations and socket weld locations that are susceptible to cracking. Volumetric examinations will be performed using a demonstrated technique that is capable of detecting the aging effect of cracking in the volume of interest. In the event the opportunity arises to perform a destructive examination of an ASME Class 1 small-bore socket weld that meets the susceptibility criteria, then the program will take credit for two volumetric examinations. The program will include pipes, fittings, branch connections, and full and partial penetration welds.

This program will include a sampling approach. Sample selection will be based on susceptibility to stress corrosion, cyclic loading (including thermal, mechanical, and vibration fatigue), thermal stratification and thermal turbulence, and failure history. Since Fermi 2 will not have more than 30 years of operation at the time of submitting the license renewal application, the inspections include ten percent of the weld population or a maximum of 25 welds of each weld type (e.g., full penetration and socket weld).

The program will include measures to verify that degradation is not occurring, thereby either confirming that there is no need to manage aging-related degradation or validating the effectiveness of any existing program for the period of extended operation. If evidence of cracking is revealed by this one-time inspection, it will be entered into the Corrective Action Program to determine extent of condition, and a follow-up periodic inspection will be managed by a plant-specific program. Flaws or indications are evaluated in accordance with the ASME Code.

The inspection will be performed within the six-year period prior to the period of extended operation.

B.1.35 PERIODIC SURVEILLANCE AND PREVENTIVE MAINTENANCE PROGRAM

There is no corresponding NUREG-1801 program.

The Periodic Surveillance and Preventive Maintenance Program manages aging effects not managed by other aging management programs, including loss of material, fouling, loss of material due to wear, and loss of sealing. Any indication or relevant condition of degradation detected is evaluated. Inspections occur at least once every five years during the period of extended operation.

The Periodic Surveillance and Preventive Maintenance Program also manages loss of material in carbon steel components exposed to raw water due to the recurring internal corrosion aging mechanism collectively referred to as multiple corrosion mechanisms (MCM). MCM was identified as a recurring internal corrosion aging mechanism (RICAM) in an operating experience review conducted by DTE in accordance with LR-ISG-2012-02 Section A.

The Fermi 2 aging management review credits the following inspection activities.

- Visually inspect and manually flex the rubber gasket/seal for reactor building spent fuel storage pool gates to verify no loss of sealing.
- Inspect suppression chamber spray nozzles for flow blockage using an air test or by removal and inspection of the nozzles for blockage.
- Determine wall thickness of selected service water system piping components to manage loss of material due to recurring internal corrosion by multiple corrosion mechanisms.
- Perform advanced eddy current testing on a representative sample of emergency diesel generator (EDG) system air coolant, lube oil, and jacket water heat exchanger tubes to manage loss of material due to wear and potential stress corrosion induced circumferential cracking.
- Determine wall thickness of selected EDG system piping components to manage loss of material due to recurring internal corrosion by multiple corrosion mechanisms.
- Use visual or other NDE techniques to inspect internal surfaces to manage fouling of the fire water system heat exchanger tubes exposed to raw water.

- Visually inspect a representative sample of the dry piping downstream of the manual isolation valve for the cable spreading room wet pipe system for flow blockage. The first inspection will be within the five years prior to the period of extended operation.
- Visually inspect a representative sample of combustion turbine generator (CTG) system lube oil heat exchanger tubes to manage loss of material due to wear.
- Visually inspect a representative sample of CTG system atomizing air precooler heat exchanger tubes to manage fouling and loss of material due to wear.
- Visually inspect and clean CTG system atomizing air booster compressor suction filter to manage fouling.
- Visually inspect and clean CTG system compressor extraction air filter to manage fouling.
- Use visual or other NDE techniques to inspect a sample of the containment atmospheric control system recombiner components' internal surfaces to manage loss of material. The area sampled may be outside the recombiner housing.
- Perform thermography on a sample of non-jacketed insulation having an intended function of “insulation” to assess its insulating ability. A sample will consist of at least 20 percent of the available population of non-jacketed insulation where the insulated piping has a heat load and is not located in a high radiation area. The first thermography will be during the five years prior to the period of extended operation.
- Nonsafety-related systems, structures, and components affecting safety-related systems, structures, and components.
  - Determine wall thickness of selected RHR Service Water system (E11) piping components to manage loss of material due to recurring internal corrosion by multiple corrosion mechanisms.
  - Perform visual or ultrasonic inspection of a representative sample of the internal surface of fuel pool cooling and cleanup system (G41) abandoned piping to manage loss of material.
  - Visually inspect the internal surface of a representative sample of condensate system (N20) piping, pump casing, tanks, and valve bodies to manage loss of material.
  - Visually inspect the internal surface of a representative sample of heater drains system (N22) piping, thermowells, and valve bodies to manage loss of material.
  - Visually inspect the internal surface of a representative sample of main turbine generator and auxiliaries system (N30) piping, tanks, and valve bodies to manage loss of material.
  - Visually inspect the internal surface of a representative sample of condenser and auxiliaries system (N61) piping and valve bodies to manage loss of material.
  - Visually inspect the internal surface of a representative sample of process sampling system (P33) chiller and cooler housing to manage loss of material.

- Determine wall thickness of selected general service water system (P41) piping components to manage loss of material due to recurring internal corrosion by multiple corrosion mechanisms.
- Determine wall thickness of selected emergency equipment service water system (P45) piping components to manage loss of material due to recurring internal corrosion by multiple corrosion mechanisms.
- Visually inspect the internal surface of a representative sample of drips, drains and vents system (P95) piping and valve bodies to manage loss of material.
- Determine wall thickness of selected EDG system (R30) piping components to manage loss of material due to recurring internal corrosion by multiple corrosion mechanisms.
- Visually inspect the internal surface of a representative sample of reactor/ auxiliary building HVAC system (T41) piping, strainer housing, tubing, and valve bodies to manage loss of material.
- Visually inspect the internal surface of a representative sample of containment atmospheric control system (T48) piping and valve bodies to manage loss of material.

The Periodic Surveillance and Preventive Maintenance Program will be enhanced as follows.

- Revise the Periodic Surveillance and Preventive Maintenance Program procedures as necessary to incorporate the identified activities.
- Revise Periodic Surveillance and Preventive Maintenance Program procedures to require periodic determination of wall thickness for selected piping components.
- Revise Periodic Surveillance and Preventive Maintenance Program procedures to require wall thickness measurements using UT or other suitable techniques at selected locations be periodically performed to identify loss of material due to MCM in system piping components. The selected locations are based on pipe configuration, flow conditions and operating history to represent a cross-section of potential MCM sites. The selected locations are periodically reviewed to validate their relevance and usefulness, and are modified accordingly. Prior to the period of extended operation, select a method (or methods) from available technologies for inspecting internal surfaces of buried piping that provides suitable indication of piping wall thickness for a representative set of buried piping locations.
- Revise Periodic Surveillance and Preventive Maintenance Program procedures to compare wall thickness measurements to nominal wall thickness or previous measurements to determine rates of corrosion degradation. Compare wall thickness measurements to code minimum wall thickness plus margin for corrosion during the refueling cycle (T_{marg}) to determine acceptability of the component for continued use. Perform subsequent wall thickness measurements as needed for each selected location based on the rate of corrosion and expected time to reach T_{marg}. Perform a minimum of five MCM degradation inspections per year until the rate of MCM corrosion occurrences no longer meets the criteria for recurring internal corrosion.

- Revise the Periodic Surveillance and Preventive Maintenance Program procedures to state that the acceptance criterion is no indication of relevant degradation and to incorporate the following:
  - Examples of acceptance criteria for metallic components
    - No excessive corrosion (loss of material).
    - No leakage from or onto internal surfaces (loss of material).
    - No excessive wear (loss of material).
    - No flow blockage due to fouling.
    - No loss of piping component structural integrity.
  - Examples of acceptance criteria for elastomeric components
    - Flexible polymers should have a uniform surface texture and color with no cracks and no dimension change, no abnormal surface conditions with respect to hardness, flexibility, physical dimensions, and color.

Enhancements will be implemented prior to the period of extended operation.

B.1.36 PROTECTIVE COATING MONITORING AND MAINTENANCE PROGRAM

The Protective Coating Monitoring and Maintenance Program monitors and maintains Service Level I coatings applied to carbon steel and concrete surfaces inside containment (e.g., steel containment vessel shell, structural steel, supports, penetrations, and concrete walls and floors). The program addresses accessible coated surfaces inside containment. The Fermi 2 program will be enhanced to meet the technical basis of ASTM D5163-08. With these enhancements, the program provides an effective method to assess coating condition through visual inspections by identifying degraded or damaged coatings and providing a means for repair of identified problem areas.

Service Level I protective coatings are not credited to manage the effects of aging. Proper monitoring and maintenance of protective coatings inside containment ensures operability of post-accident safety systems that rely on water recycled through the containment. The proper monitoring and maintenance of Service Level I coatings ensures there is no coating degradation that would impact safety functions, for example, by clogging emergency core cooling systems suction strainers and possibly causing unacceptable head loss in the system.

The Protective Coating Monitoring and Maintenance Program will be enhanced as follows.

- Revise plant procedures to include in the program Service Level I coating applied to steel and concrete surfaces of the steel containment vessel (e.g., steel containment vessel shell, structural steel, supports, penetrations, and concrete walls and floors).
- Revise plant procedures to include information and instructions for monitoring Service Level I coating systems to be used for the inspection of coatings in accordance with guidelines identified in ASTM D5163-08.
- Revise plant procedures to specify the parameters monitored or inspected in accordance with subparagraph 10.2 of ASTM D5163-08.

- Revise plant procedures to establish the inspection frequency in accordance with paragraph 6 of ASTM D5163-08.
- Revise plant procedures to develop an inspection plan and specify inspection methods to be used as identified in accordance with subparagraph 10.1 of ASTM D5163-08.
- Revise plant procedures to specify that the nuclear coating specialist qualification recommendations and duties be as defined in ASTM D7108. As a minimum, qualification of inspection personnel (protective coating surveillance personnel) who perform these inspections shall be as specified in ASTM D4537.
- Revise plant procedures to specify a protective coatings program owner (inspection coordinator and inspection results evaluator) or equivalent to nuclear coating specialist defined in ASTM D5163-08 is responsible for the overall plant coatings program and has general duties and responsibilities similar to those defined for a nuclear coating specialist in Section 5 of ASTM D7108-05.
- Revise plant procedures to specify that detection of aging effects will include visual inspections of coatings near sumps or screens associated with the emergency core cooling system (ECCS).
- Revise plant procedures to specify instruments and equipment needed for inspection in accordance with subparagraph 10.5 of ASTM D5163-08.
- Revise plant procedures to specify that upon the completion of a planned refuel outage, a coatings outage summary report will be prepared of the coating work performed in Service Level I areas during the outage. The summary report prioritizes repair areas as areas that must be repaired during the same outage or postponed to future outages, keeping the coatings under surveillance during the interim period.
- Revise plant procedures to specify that the last two performance monitoring reports pertaining to the coating systems will be reviewed prior to the inspection or monitoring process.
- Revise plant procedures to describe the characterization, documentation, and testing of defective or deficient coating surface in accordance with subparagraphs 10.2.1 through 10.2.6, 10.3, and 10.4 of ASTM D5163-08.
- Revise plant procedures to specify that the coatings outage summary report will be evaluated and approved by the protective coatings program owner.

Enhancements will be implemented prior to the period of extended operation.

B.1.37 REACTOR HEAD CLOSURE STUDS PROGRAM

The Reactor Head Closure Studs Program manages cracking due to stress corrosion cracking (SCC) or intergranular stress corrosion cracking (IGSCC) and loss of material due to wear or corrosion for reactor head closure stud bolting (studs, washers, nuts, bushings, and threads in flange) using inservice inspection (ASME Section XI 2001 Edition 2003 Addendum Table IWB-2500-1) and preventive measures to mitigate cracking. The program follows examination and inspection requirements to detect and size cracks and detect loss of material.

Acceptance criteria and evaluation of indications are in accordance with ASME Section XI and other requirements specified per 10 CFR 50.55a with NRC-approved alternatives.

Preventive actions include avoiding the use of metal-plated stud bolting, use of an acceptable surface treatment, use of stable lubricants, and use of bolting materials with low susceptibility to stress corrosion cracking. The program uses visual, surface, and volumetric examinations as required by ASME Section XI. The program also relies on recommendations to address reactor head closure studs degradation listed in NUREG-1339 and NRC Regulatory Guide (RG) 1.65.

The reactor vessel studs, nuts, closure washers, and threaded bushings at Fermi 2 are fabricated from SA-540 Grade B23 and B24 carbon steel. RG 1.65, October 1973, identifies that SA-540 Grades B23 and B24, when tempered to a maximum tensile strength of 170 ksi, are relatively immune to SCC. Nevertheless, since the actual yield strength is not known, the aging management review conservatively identified the stud material as susceptible to cracking.

The Reactor Head Closure Studs Program will be enhanced as follows.

- Revise Reactor Head Closure Studs Program procedures to ensure that replacement studs are fabricated from bolting material with actual measured yield strength less than 150 kilo-pounds per square inch.
- Revise Reactor Head Closure Studs Program procedures to include a statement that excludes the use of molybdenum disulfide (MoS^2) on the reactor vessel closure studs and also refers to recommendations in RG 1.65, Rev. 1.

Enhancements will be implemented prior to the period of extended operation.

B.1.38 REACTOR VESSEL SURVEILLANCE PROGRAM

The Reactor Vessel Surveillance Program manages reduction of fracture toughness of reactor vessel beltline materials due to neutron irradiation embrittlement and monitors reactor vessel long-term operating conditions that could affect neutron irradiation embrittlement of the reactor vessel using material data and dosimetry. The program includes all reactor vessel beltline materials as defined by 10 CFR 50 Appendix G, Section II.F, and complies with 10 CFR 50, Appendix H for vessel material surveillance.

The objective of the reactor vessel material surveillance program is to provide sufficient material data and dosimetry to (a) monitor irradiation embrittlement at the end of the period of extended operation and (b) determine the need for operating restrictions on the inlet temperature, neutron spectrum, and neutron flux.

The original Fermi 2 reactor vessel surveillance program was designed to monitor reactor vessel beltline materials by testing surveillance capsules withdrawn from the Fermi 2 reactor vessel.

The Fermi 2 reactor vessel surveillance program has been integrated into the Boiling Water Reactor Vessel and Internals Project (BWRVIP) Integrated Surveillance Program (ISP). The surveillance sample materials remaining in the Fermi 2 reactor pressure vessel (RPV) are maintained as spares for possible future use. The BWRVIP ISP replaces individual plant reactor pressure vessel surveillance capsule programs with representative weld and base materials data from host reactors. Throughout the term of the ISP, the BWRVIP monitors the progress, coordinates future actions such as withdrawal and testing of future capsules and reporting of surveillance capsule test results, and identifies additional program needs. The BWRVIP will identify and implement changes to the program as the need arises. When specific changes are identified to the ISP testing matrix, withdrawal schedule, or testing and reporting of individual capsule results, these modifications will be submitted to the NRC in a timely manner so that appropriate arrangements can be made for implementation.

The integrated surveillance program for the extended period of operation (ISP(E)), based on BWRVIP document BWRVIP-86, Revision 1, has been approved for use by the NRC. BWRVIP 135 provides reactor pressure vessel surveillance data and other technical material information for the plants participating in the ISP and is revised periodically as additional surveillance data is obtained.

B.1.39 RG 1.127, INSPECTION OF WATER-CONTROL STRUCTURES ASSOCIATED WITH NUCLEAR POWER PLANTS PROGRAM

Fermi 2 is not committed to the requirements of NRC Regulatory Guide (RG) 1.127, "Inspection of Water-Control Structures Associated with Nuclear Power Plants." However, the program at Fermi 2 was developed based on guidance provided in the NRC RG 1.127, Revision 1, and provides an inservice inspection and surveillance program for the Fermi 2 shore barrier and raw water-control structures associated with emergency cooling water systems or flood protection. The scope of the Fermi 2 program includes water-control structures within the scope of license renewal as delineated in 10 CFR 54.4. The program performs periodic visual examinations to monitor the condition of water-control structures and structural components, including structural steel and structural bolting associated with water-control structures, and miscellaneous steel associated with these structures. The program addresses age-related deterioration, degradation due to extreme environmental conditions, and the effects of natural phenomena that may affect water-control structures so that the consequences of age-related deterioration and degradation can be prevented or mitigated prior to loss of intended function. The program will be implemented as part of the Structures Monitoring Program (Section B.1.42).

Enhancements to this program are included in the enhancements to the Structures Monitoring Program (Section B.1.42).

B.1.40 SELECTIVE LEACHING PROGRAM

The Selective Leaching Program is a new program that will demonstrate the absence of selective leaching in a selected sample of components (i.e., 20 percent of the population with maximum of 25 components) fabricated from gray cast iron and copper alloys (except for inhibited brass) that contain greater than 15 percent zinc or greater than 8 percent aluminum exposed to raw water, treated water, waste water, or soil. A sample population is defined as components with the same material and environment combination. Where practical, the sample population will focus on bounding or leading components most susceptible to aging due to time in service, severity of operating condition, and lowest design margin. The program will include a one-time visual inspection of selected components coupled with hardness measurement or other mechanical examination techniques such as destructive testing, scraping or chipping to determine whether loss of material is occurring due to selective leaching that may affect the ability of a component to perform its intended function during the period of extended operation.

Follow-up of unacceptable inspection findings will include an evaluation using the Corrective Action Program and possible expansion of the inspection sample size and location.

This inspection will be performed within five years prior to the period of extended operation.

B.1.41 SERVICE WATER INTEGRITY PROGRAM

The Service Water Integrity Program manages loss of material and fouling for safety-related service water system components fabricated from carbon steel, copper alloys, and stainless steel exposed to service water systems as described in the Fermi 2 response to NRC GL 89-13. The program includes (a) surveillance and control techniques to manage effects of biofouling, corrosion, various erosion mechanisms, and silting; (b) tests to verify heat transfer capability of heat exchangers important to safety; (c) routine inspections and maintenance. System walkdowns are performed.

The Service Water Integrity Program will be enhanced as follows.

- Revise Service Water Integrity Program procedures to include inspection to determine if loss of material due to erosion is occurring in the system.
- Revise Service Water Integrity Program procedures to stipulate that administrative controls are in accordance with the Fermi 2 10 CFR 50 Appendix B Quality Assurance Program.

Enhancements will be implemented prior to the period of extended operation.

B.1.42 STRUCTURES MONITORING PROGRAM

The Structures Monitoring Program provides for aging management of structures and structural components, including structural bolting, within the scope of license renewal. The program was developed based on guidance in Regulatory Guide (RG) 1.160, Revision 2, "Monitoring the Effectiveness of Maintenance at Nuclear Power Plants," and NUMARC 93-01, Revision 2, "Industry Guidelines for Monitoring the Effectiveness of Maintenance at

Nuclear Power Plants," to satisfy the requirement of 10 CFR 50.65, "Requirements for Monitoring the Effectiveness of Maintenance at Nuclear Power Plants." The scope of the Structures Monitoring Program includes structures within the scope of license renewal as delineated in 10 CFR 54.4. The program performs periodic visual examinations to monitor the condition of structures and structural components, including components such as concrete and steel components, structural bolting, component supports, concrete masonry blocks, and other structures such as earthen structures. Inspections are performed at a frequency to ensure there is no loss of intended function between inspections. The program will be enhanced to perform inspections at least once every five years, with provisions for more frequent inspections, to ensure there is no loss of intended function between inspections. The scope of the program also includes the condition monitoring of masonry walls and water-control structures as described in the Masonry Wall Program and in the NRC RG 1.127, "Inspection of Water-Control Structures Associated with Nuclear Power Plants," aging management.

The Structures Monitoring Program is augmented by plant procedures to ensure that the selection of bolting material, installation torque or tension, and the use of lubricants and sealants are appropriate for the intended purpose. These procedures will be enhanced to include the guidance of NUREG-1339 and EPRI TR-104213, NP-5067, and NP-5769 to ensure proper specification of bolting material, lubricant, and installation torque.

The Structures Monitoring Program will be enhanced as follows.

- Revise plant procedures to add the following structures to the program.
  - Condensate storage tank and condensate return tank foundations and retaining barrier
  - CTG-11-1 fuel oil storage tank foundation
  - Independent spent fuel storage installation (ISFSI) rail transfer pad
  - Manholes, handholes and duct banks
  - Shore barrier
  - Transformer and switchyard support structures and foundations
- Revise plant procedures to specify that the following in-scope structures are included in the RG 1.127, Inspection of Water-Control Structures Associated with Nuclear Power Plants Program:
  - General service water pump house
  - Residual heat removal complex
  - Shore barrier
- Revise plant procedures to ensure that masonry walls located in in-scope structures are in the scope of the Masonry Wall Program.
- Revise plant procedures to include a list of structural components and commodities within the scope of license renewal to be monitored in the program.

- Revise plant procedures to include periodic sampling and chemical analysis of ground water.
- Revise plant procedures to include the following preventive actions:
  - Preventive actions delineated in NUREG-1339 and EPRI NP-5769, NP-5067, and TR-104213 that emphasize the proper selection of bolting material, installation torque or tension, and the use of lubricants and sealants for high-strength bolting.
  - Preventive actions for storage of ASTM A325 and A490 bolting from Section 2 of Research Council for Structural Connections publication, "Specification for Structural Joints Using ASTM A325 or A490 Bolts."
- Revise plant procedures to include the following parameters to be monitored or inspected:
  - For concrete structures, base inspections on quantitative requirements of industry codes (i.e., ACI 349.3R-02), standards and guidelines (i.e., ASCE 11) and consideration of industry and plant-specific operating experience.
  - For concrete structures and components, include loss of material, loss of bond, increase in porosity and permeability, loss of strength, and reduction in concrete anchor capacity due to local concrete degradation.
  - For chemical analysis of ground water, monitor pH, chlorides, and sulfates.
  - Monitor gaps between the structural steel supports and masonry walls that could potentially affect wall qualification.
- Revise plant procedures to include the following components to be monitored for the associated parameters:
  - Structural bolting and anchors/fasteners (nuts and bolts) for loss of material, loose or missing nuts and/or bolts, and cracking of concrete around the anchor bolts.
  - Elastomeric vibration isolators and structural sealants for cracking, loss of material, loss of sealing, and change in material properties (e.g., hardening).
- Revise plant procedures to provide technical guidance for torque value requirements for specified bolting material subject to plant operating environments.
- Revise plant procedures to include the following for detection of aging effects:
  - Personnel (Inspection Engineer and Program Administrator or Responsible Engineer) involved with the inspection and evaluation of structures and structural components, including masonry walls and water-control structures, meet the qualifications guidance identified in ACI 349.3R-02.
  - Visual inspection of elastomeric material should be supplemented by feel or touch to detect hardening if performance of the intended function of the elastomeric material is suspect. Include instructions to augment the visual examination of elastomeric material with physical manipulation of at least ten percent of available surface area.
  - Structures will be inspected at least once every five years.

- Submerged structures will be inspected at least once every five years.
- If normally inaccessible areas become accessible due to plant activities, an inspection of these areas shall be conducted. Additionally, inspections will be performed of inaccessible areas in environments where observed conditions in accessible areas indicate that significant degradation may be occurring in the inaccessible areas.
- Sampling and chemical analysis of ground water at least once every five years. The Structures Monitoring Program owner will review the results and evaluate any anomalies and perform trending of the results.
- Masonry walls will be inspected at least once every five years, with provisions for more frequent inspections in areas where significant aging effects (i.e., missing blocks, cracking, etc.) is observed to ensure there is no loss of intended function between inspections.
- Inspection of water-control structures should be conducted under the direction of qualified personnel experienced in the investigation, design, construction, and operation of these types of facilities.
- Inspections of water-control structures on an interval not to exceed five years.
- Perform special inspections of water-control structures immediately (within 30 days) following the occurrence of significant natural phenomena, such as large floods, earthquakes, hurricanes, tornadoes, and intense local rainfalls.

• Revise plant procedures to prescribe quantitative acceptance criteria based on the quantitative acceptance criteria of ACI 349.3R-02and information provided in industry codes, standards, and guidelines including ACI 318, ANSI/ASCE 11, and relevant AISC specifications. Industry and plant-specific operating experience will also be considered in the development of the acceptance criteria.

• Revise plant procedures to include acceptance criteria for masonry wall inspections that ensure observed aging effects (cracking, loss of material or gaps between the structural steel supports and masonry walls) do not invalidate the wall's evaluation basis or impact its intended function.

• Revise Structures Monitoring Program procedures to include testing and evaluation of water/mineral deposits where in-leakage is observed in concrete elements. Testing and evaluation will determine whether leaching of calcium hydroxide and carbonation are occurring that could impact the intended function(s) of the concrete structure.

• The following testing and evaluation will be performed prior to the period of extended operation to confirm that previously identified conditions are not the result of leaching of calcium hydroxide and carbonation that could impact the intended function(s) of the concrete structure.

  - Available water/mineral deposit samples will be tested for mineral and iron content to assess the effect of the water in-leakage on the reinforced concrete elements involved.

  - The results of the testing and Structures Monitoring Program inspections will be used to determine corrective actions per the Corrective Action Program. Possible corrective actions include, but are not limited to, more frequent inspections, sampling and analysis of the in-leakage water for mineral and iron content, testing core bore samples, and evaluation of the affected area using evaluation and acceptance criteria of ACI 349.3R-02.

Enhancements will be implemented prior to the period of extended operation.

B.1.43 WATER CHEMISTRY CONTROL – BWR PROGRAM

The Water Chemistry Control – BWR Program manages loss of material, cracking, and fouling in components exposed to a treated water environment through periodic monitoring and control of water chemistry. The Water Chemistry Control – BWR Program monitors and controls water chemistry parameters such as pH, chloride, conductivity, and sulfate. EPRI BWR Water Chemistry Guidelines is used to provide guidance.

The One-Time Inspection Program utilizes inspections or non-destructive evaluations of representative samples to verify that the Water Chemistry Control – BWR Program has been effective at managing aging effects. The representative sample includes low flow and stagnant areas.

B.1.44 WATER CHEMISTRY CONTROL – CLOSED TREATED WATER SYSTEMS PROGRAM

The Water Chemistry Control – Closed Treated Water Systems Program manages loss of material, cracking, and fouling in components exposed to a closed treated water environment, through monitoring and control of water chemistry, including the use of corrosion inhibitors, chemical testing, and visual inspections of internal surface condition. The EPRI Closed Cooling Water Chemistry Guideline, industry guidance, and vendor recommendations are used to delineate the program.

The Water Chemistry Control – Closed Treated Water Systems Program will be enhanced as follows.

- Revise the Water Chemistry Control – Closed Treated Water Systems Program procedures to include the following systems.
  - Process sampling system sample cooler loops
  - CCHVAC chill water system
- Revise the Water Chemistry Control – Closed Treated Water Systems Program procedures to provide chemical treatment including a corrosion inhibitor for the following systems in accordance with industry guidelines and vendor recommendations.
  - Process sampling system sample cooler loops
  - CCHVAC chill water system

- Revise Water Chemistry Control – Closed Treated Water Systems Program procedures to specify water chemistry parameters monitored and the acceptable range of values for these parameters in accordance with EPRI Closed Cooling Water Chemistry Guideline, industry guidance, or vendor recommendations.
- Revise Water Chemistry Control – Closed Treated Water Systems Program procedures to inspect accessible components whenever a closed treated water system boundary is opened. Ensure that a representative sample of piping and components is inspected at a frequency of at least once every ten years. These inspections will be conducted in accordance with applicable ASME Code requirements, industry standards, or other plant-specific inspection guidance by qualified personnel using procedures that are capable of detecting corrosion, fouling, or cracking.

  If visual examination identifies adverse conditions, then additional examinations, including ultrasonic testing, are conducted. Components inspected will be those with the highest likelihood of corrosion, fouling, or cracking. A representative sample is 20 percent of the population (defined as components having the same material, environment, and aging effect combination) with a maximum of 25 components.

  Perform treated water sampling and analysis of the closed treated water systems per industry standards and in no case greater than quarterly unless justified with an additional analysis. The process sampling system sample cooler loops will be sampled and tested annually.

Enhancements will be implemented prior to the period of extended operation.

B.1.45 COATING INTEGRITY PROGRAM

The Coating Integrity Program is a new program that will include periodic visual inspections of coatings/linings applied to the internal surfaces of in-scope piping, piping components, heat exchangers, and tanks where loss of coating or lining integrity could prevent accomplishment of a license renewal intended function. Some internally coated components are not managed by the Coating Integrity Program since they are not safety related, leakage through their pressure boundary would not impact a nearby safety-related component and if the coating comes loose, it would not cause a flow blockage that would impact another component's safety related function or function to support a regulated event. For coatings/linings in the program that do not meet the acceptance criteria, physical testing is performed where possible (i.e., sufficient room to conduct testing) in conjunction with visual inspection. Hand tool cleaning and power tool cleaning will be controlled by site procedures that incorporate standards established by the Society of Protective Coatings (SSPC). Specifically, the standards include SSPC-SP 2 Hand Tool Cleaning, SSPC-SP 3 Power Tool Cleaning, and SSPC-SP 11 Power Tool Cleaning to Bare Metal. Further, where applicable, standards for water-jet cleaning will also be incorporated. These would include SSPC-SP WJ-1, 2, 3, and 4. Although there is not an SSPC standard for tap testing, guidance for tap testing is provided in the EPRI Comprehensive Coatings Training Course and other equivalent training. This guidance will also be incorporated into site procedures. The training and qualification of individuals involved in inspections of non-cementitious coatings/linings are in accordance with ASTM standards endorsed in RG 1.54. In addition, the EPRI Comprehensive Coatings Training Course or other equivalent training will be incorporated into site training and qualification requirements for a Coating Specialist. For cementitious coatings, training and qualifications are based on an appropriate combination of education and experience related to inspecting concrete surfaces. Service Level 1 coatings are managed by the Protective Coating Monitoring and Maintenance Program (Section B.1.36).

Baseline coating/lining inspections will occur in the 10-year period prior to the period of extended operation. Subsequent inspections are based on an evaluation of the effect of a coating/lining failure on in-scope component intended functions, potential problems identified during prior inspections, and service life history, but should not exceed the inspection intervals in Table 4a "Inspection Intervals for Internal Coatings/Linings for Tanks, Piping, Piping Components, and Heat Exchangers" identified in LR-ISG-2013-01.

B.2 EVALUATION OF TIME-LIMITED AGING ANALYSES

In accordance with 10 CFR 54.21(c), an application for a renewed license requires an evaluation of time-limited aging analyses for the period of extended operation. The following time-limited aging analyses have been identified and evaluated to meet this requirement.

B.2.1 REACTOR VESSEL NEUTRON EMBRITTLEMENT

The reactor vessel neutron embrittlement time-limited aging analyses, including consideration for measurement uncertainty recapture/thermal power optimization (MUR/TPO) (Refs. DTE Electric Company to NRC, "License Amendment Request for Measurement Un, NRC to DTE Electric, "Fermi 2—Issuance of Amendment re: Measurement Uncertainty Re), either have been projected to the end of the period of extended operation in accordance with 10 CFR 54.21(c)(1)(ii) or will be managed for the period of extended operation in accordance with 10 CFR 54.24(c)(1)(iii) as summarized below.

Based on the plant operating history, a projected value of 52 EFPY is used to evaluate reactor vessel neutron embrittlement time-limited aging analyses (TLAAs).

B.2.1.1 REACTOR VESSEL FLUENCE

Fluence is calculated based on a time-limited assumption defined by the operating term. Therefore, analyses that evaluate reactor vessel neutron embrittlement based on calculated fluence are time-limited aging analyses.

The reactor vessel fluence has been calculated to include higher power level beginning with cycle 17, when the reactor power increased due to the MUR/TPO uprate. The peak neutron fluence projected for 52 EFPY is 1.03E+18 n/cm^2 at the vessel inner surface. The high energy (> 1 MeV) neutron fluence for the welds and shells of the reactor pressure vessel (RPV) beltline region was determined using the General Electric-Hitachi (GEH) method for neutron flux calculation documented in report NEDC-32983P-A. The method adheres to the guidance prescribed in Regulatory Guide (RG) 1.190.

The neutron fluence calculation results are inputs into fracture toughness analyses. The effects of aging due to neutron irradiation are considered in the neutron embrittlement

TLAAs for the reactor vessel (e.g., upper-shelf energy analysis and P-T limits analysis). The neutron fluence analysis has been projected to the end of the period of extended operation in accordance with 10 CFR 54.21(c)(1)(ii).

B.2.1.2 ADJUSTED REFERENCE TEMPERATURE

A key parameter that characterizes the fracture toughness of a material is the reference nil-ductility transition temperature (RT_{NDT}). The effects of neutron radiation on RT_{NDT} are reflected in the reference temperature change (ΔRT_{NDT}). The adjusted reference temperature (ART) is calculated by adding ΔRT_{NDT} to initial RT_{NDT} with an appropriate margin for uncertainties (ΔRT_{NDT} + RT_{NDT} + margin) as defined by RG 1.99 Revision 2.

The method used for the evaluation of the 52 EFPY ART is the same method used by GEH for the MUR/TPO ART evaluation. The ART values for all beltline materials are calculated using fluence values determined with an NRC-approved method that complies with RG 1.190. All projected values are well below the 200°F suggested in Section C.3 of RG 1.99 as an acceptable nominal value of ART for the end of life. The TLAA for ART has been projected to the end of the period of extended operation in accordance with 10 CFR 54.21(c)(1)(ii). Formal revisions of affected analyses are completed as part of the established process for generation of updated P-T operating limits.

B.2.1.3 PRESSURE-TEMPERATURE LIMITS

Appendix G of 10 CFR 50 requires that the reactor vessel remain within established pressure-temperature (P-T) limits during boltup, hydro-test, pressure tests, normal operation, and anticipated operational occurrences. These limits are calculated using materials and fluence data, including data obtained through the Reactor Vessel Surveillance Program (Section B.1.38).

The P-T limit curves will continue to be updated, as required by Appendix G of 10 CFR Part 50, assuring that limits remain valid through the period of extended operation.

The time-limited aging analyses for reactor vessel pressure-temperature limits will be managed for the period of extended operation in accordance with 10 CFR 54.21(c)(1)(iii).

B.2.1.4 UPPER SHELF ENERGY

Upper-shelf energy (USE) is evaluated for beltline materials. Fracture toughness criteria in 10 CFR 50 Appendix G require that beltline materials maintain USE no less than 50 ft-lb during operation of the reactor. The 52 EFPY USE values for the beltline materials were determined using methods consistent with RG 1.99. The determination used the peak ¼T fluence. The re-sults of the evaluation demonstrate that all beltline material remains above 50 ft-lb throughout the period of extended operation.

The time-limited aging analysis for upper shelf energy has been projected to the end of the period of extended operation in accordance with 10 CFR 54.21(c)(1)(ii).

B.2.1.5 REACTOR VESSEL CIRCUMFERENTIAL WELD INSPECTION RELIEF

The reactor pressure vessel (RPV) circumferential weld parameters at 52 EFPY will remain within the NRC's (64 EFPY) bounding parameters from the BWRVIP-05 SER. The fact that the values projected to the end of the period of extended operation are less than the 64 EFPY value provided by the NRC leads to the conclusion that the RPV conditional failure probability is less than the conditional failure probability of the NRC analysis. As such, the conditional probability of failure for circumferential welds remains below that determined during the NRC's final safety evaluation of BWRVIP-05.

The reactor vessel circumferential weld inspection relief for the period of extended operation will be submitted to the NRC in accordance with 10 CFR 50.55(a). The effects of aging associated with the time-limited aging analysis for reactor vessel circumferential weld inspection relief will be managed in accordance with 10 CFR 54.21(c)(1)(iii).

B.2.1.6 REACTOR VESSEL AXIAL WELD FAILURE PROBABILITY

The NRC SER for BWRVIP-74-A evaluated the failure frequency of axially oriented welds in BWR reactor vessels. Applicants for license renewal must evaluate axially oriented RPV welds to show that their failure frequency remains below the value calculated in the BWRVIP-74 SER. The SER states that an acceptable way to do this is to show that the mean RT_{NDT} of the limiting axial beltline weld at the end of the period of extended operation is less than the values specified in the SER.

The projected 52 EFPY Fermi 2 mean ART is less than the bounding value shown in the NRC SER for BWRVIP-74. The reactor vessel axial weld TLAA has been projected to the end of the period of extended operation in accordance with 10 CFR 54.21(c)(1)(ii).

B.2.1.7 REACTOR PRESSURE VESSEL CORE REFLOOD THERMAL SHOCK ANALYSIS

General Electric Report NEDO-10029 is referenced in UFSAR Section A.1.2 and Table 1.6-1. NEDO-10029 addressed the concern for brittle fracture of the reactor pressure vessel due to reflood following a postulated loss of coolant accident (LOCA). The thermal shock analysis documented in NEDO-10029 assumed a design basis recirculation line break LOCA followed by a low pressure coolant injection, accounting for the full effects of neutron embrittlement at the end of 40 years. Because this analysis bounded only 40 years of operation, reflood thermal shock of the reactor pressure vessel has been identified as a TLAA for Fermi 2 requiring evaluation for the period of extended operation.

A later analysis of the BWR vessels was developed in 1979 (Ranganath, S., "Fracture Mechanics Evaluation of a Boiling Water Reactor Vessel Following a Postulated Loss of Coolant Accident," Fifth International Conference on Structural Mechanics in Reactor Technology, Berlin, Germany, August 1979 (Accession No. 9110110105 in Public Legacy Library)). The Ranganath analysis has been used to evaluate the TLAA through the period of extended operation. The Ranganath analysis which was performed for a 6-inch thick BWR-6 pressure vessel is bounding for the Fermi 2 vessel. The thickness of the lower shell for the Fermi 2 vessel is 7.125 inches; the thickness of the lower-intermediate shell is 6.125 inches.

The Ranganath analysis is bounding for Fermi 2 because (1) the pressure stress (higher for a thinner vessel) is near zero in a thermal shock event and therefore can be neglected, and (2) the difference in temperature and thermal stresses at the ¼T location between a 6-inch thick vessel and a 6.125-inch or 7.125-inch thick vessel (as demonstrated in Figures 3 and 4 of Ranganath) is small. The fluence level and ART values used are specific to Fermi 2, as projected for 52 EFPY. The analysis shows that when the peak stress intensity occurs at approximately 300 seconds after the LOCA, the temperature of the vessel wall at 1.5 inches deep is approximately 400°F.

The maximum ART value calculated for the Fermi 2 RPV beltline material is 102°F. Using the equation for fracture toughness K_{IC} presented in Appendix A of ASME Section XI and the maximum ART value, the material reaches upper shelf at approximately 206°F, which is well below the approximately 400°F temperature predicted for the thermal shock event at the time of peak stress intensity. Therefore, the revised evaluation, using the Ranganath analysis, has projected the TLAA through the period of extended operation. The reactor pressure vessel core reflood thermal shock TLAA has been projected to the end of the period of extended operation in accordance with 10 CFR 54.21(c)(1)(ii).

B.2.2 METAL FATIGUE

B.2.2.1 CLASS 1 METAL FATIGUE ANALYSES

Fatigue evaluations were performed in the design of the Fermi 2 Class 1 components. Class 1 fatigue evaluations are contained in analyses and stress reports, and because they are based on a number of transient cycles assumed for a 40-year operating term, these evaluations are considered time-limited aging analyses.

The Fatigue Monitoring Program (Section B.1.17) tracks transient cycles and requires corrective actions, if the numbers of cycles approach analyzed values. It provides for use of cycle-based fatigue or stress-based fatigue monitoring methods if a component's cumulative usage factor based on cycle counting is projected to exceed 1.0 after the environmentally assisted fatigue (EAF) calculations are complete. The Fatigue Monitoring Program will manage the effects of aging due to fatigue in accordance with 10 CFR 54.21(c)(1)(iii).

The following provides additional information for specific Class 1 components.

Reactor Pressure Vessel

As described in UFSAR Section 5.4.6.3.1 and shown in UFSAR Figure 5.4-1, the RPV is a vertical, cylindrical pressure vessel with hemispherical heads of welded construction. Fatigue evaluations for the reactor vessel were performed as part of the vessel design.

Fermi 2 monitors transient cycles using the Fatigue Monitoring Program (Section B.1.17) and assures that action is taken if the actual cycles approach their analyzed numbers. As such, the Fatigue Monitoring Program will manage the effects of aging due to fatigue on the reactor vessel in accordance with 10 CFR 54.21(c)(1)(iii).

Reactor Pressure Vessel Feedwater Nozzle

As described in UFSAR Section 5.2.1.20, Fermi 2 installed a feedwater sparger and thermal sleeve prior to plant operation to eliminate thermal fatigue concerns on the feedwater nozzle.

The vessel was manufactured with unclad feedwater nozzles, so no cladding removal was necessary. The inner thermal sleeve is the feed pipe for the sparger and is sealed against the safe-end with a piston ring. The inner thermal sleeve is welded to the sparger forged tee. As described in UFSAR Section 5.2.1.20, the Fermi 2 feedwater sparger and thermal sleeve design conforms to NUREG-0619.

As a part of the NUREG-0619 review, a plant-specific feedwater nozzle fracture mechanics assessment was completed. The projected number of startup/shutdowns plus scrams is less than the total cycles utilized in this analysis. Therefore, the analysis remains valid for the period of extended operation in accordance with 10 CFR 54.21(c)(1)(i).

The analysis of the feedwater nozzle includes fatigue from potential rapid cycling behind the thermal sleeves. The feedwater nozzle has fatigue usage contribution from rapid cycling that is part of the total fatigue usage for that location. The usage is calculated based on time and feedwater temperature in order to include the rapid cycling effect.

The effects of fatigue on the feedwater nozzles will be managed for the period of extended operation in accordance with 10 CFR 54.21(c)(1)(iii).

Reactor Pressure Vessel Internals

A reactor vessel general assembly drawing is shown in UFSAR Figure 4.5-1, and a cutaway drawing is shown in UFSAR Figure 5.4-1. The Fermi 2 reactor pressure vessel internals are not ASME code pressure boundary components. ASME analyses were completed for some RVI locations. Fermi 2 will monitor transient cycles using the Fatigue Monitoring Program (Section B.1.17) and assure that action is taken before the numbers of accrued cycles exceed their analyzed numbers. As such, the Fatigue Monitoring Program will manage the effects of aging due to fatigue on the reactor vessel internals in accordance with 10 CFR 54.21(c)(1)(iii).

Reactor Recirculation Pumps

As identified in UFSAR Table 3.2-1, the reactor recirculation pumps were designed to the NPVC 1 (NPVC-1, 2, 3 Draft ASME Code for Pumps and Valves for Nuclear Power, Class I, II, III). As identified in Note z of UFSAR Table 3.2-1 and UFSAR Table 3.2-4 Note j, the reactor recirculation pumps were upgraded to the 4th generation design, and the modified components were designed and manufactured to ASME III, 1989. Representative analyses of recirculation pumps are summarized in UFSAR Table 3.9-20.

The Fatigue Monitoring Program (Section B.1.17) will manage the effects of aging due to fatigue on the reactor recirculation pumps in accordance with 10 CFR 54.21(c)(1)(iii).

Class 1 Piping

UFSAR Table 3.2-1 provides a summary of the safety classes for the principal structures, systems, and components of the plant. Components of the reactor coolant pressure boundary whose failure could cause a loss of reactor coolant at a rate in excess of the normal makeup system capability are Class 1 components. Detailed fatigue analyses were generated to analyze multiple locations on each system within the Class 1 boundary.

The Fatigue Monitoring Program (Section B.1.17) will monitor the numbers of cycles incurred to assure that action is taken if the numbers approach the values analyzed. As such, the Fatigue Monitoring Program will manage the effects of aging due to fatigue on the Class 1 piping in accordance with 10 CFR 54.21(c)(1)(iii).

B.2.2.2 NON-CLASS 1 METAL FATIGUE ANALYSES

UFSAR Table 3.2-1 provides a summary of the safety classes for the principal structures, systems, and components of the plant. As identified in UFSAR Table 3.2-1, the non-Class 1 piping within the scope of license renewal is built to ASME III or ANSI B31.1.

The design of ASME III Code Class 2 and 3 or ANSI B31.1 piping systems incorporates a stress range reduction factor for piping design with respect to thermal stresses. In general, a stress range reduction factor of 1.0 in the stress analyses applies for up to 7000 thermal cycles. Fermi 2 evaluated the validity of this assumption for 60 years of plant operation. The results of this evaluation indicate that the 7000 thermal cycle assumption will not be exceeded for 60 years of operation. Therefore, the non-Class 1 piping stress calculations are valid for the period of extended operation in accordance with 10 CFR 54.21(c)(1)(i).

Non-Class 1 components other than piping require fatigue analyses if they were built to a section of the code such as ASME Section III, NC-3200 or ASME Section VIII, Division 2. A review of the non-Class 1 components identified non-Class 1 fatigue analysis applicable to expansion joints. Fatigue analyses were identified for expansion joints that assumed a bounding number of cycles. These expansion joint fatigue analyses are treated as time-limited aging analyses. Evaluation of these expansion joint analyses determined the number of analyzed cycles was adequate for 60 years of operation. Therefore, these non-Class 1 expansion joint TLAAs are valid for the period of extended operation in accordance with 10 CFR 54.21(c)(1)(i).

B.2.2.3 EFFECTS OF REACTOR WATER ENVIRONMENT ON FATIGUE LIFE

NUREG/CR-6260 addresses the application of environmental correction factors to fatigue analyses (cumulative usage factors [CUFs]) and identifies locations of interest for consideration of environmental effects. NUREG/CR-6260 identified the following component locations to be the most sensitive to environmental effects for General Electric plants.

(1) Reactor vessel shell and lower head

(2) Reactor vessel feedwater nozzle

(3) Reactor recirculation piping (including inlet and outlet nozzles)

(4) Core spray line reactor vessel nozzles and associated Class 1 piping

(5) Residual heat removal nozzles and associated Class 1 piping

(6) Feedwater line Class 1 piping

Environmentally assisted fatigue (EAF) screening was performed for these NUREG/CR-6260 locations and the remaining ASME Class 1 reactor pressure vessel and piping locations for which fatigue had been assessed that are (1) wetted (in contact with liquid reactor coolant) and (2) form part of the reactor coolant pressure boundary. The components with the highest calculated CUF in each system were evaluated for the effects of EAF. The screening evaluation used guidance in NUREG/CR-6909, as allowed by NUREG-1801, Revision 2. The fatigue curves in NUREG/CR-6909 were applied for all materials. The methodology discussed in EPRI 1024995, "Environmentally Assisted Fatigue Screening: Process and Technical Basis for Identifying EAF Limiting Locations" was used as guidance to determine which locations are bounding. These locations are referred to as Sentinel locations. The Sentinel locations are monitored to manage the effects of aging including EAF in the period of extended operation. This screening has determined there are locations that, when accounting for environmental effects, have projected usage factors greater than 1.0. Additional action will be needed, e.g. more detailed analysis or stress-based or cycle-based fatigue monitoring, as part of the Fatigue Monitoring Program (Section B.1.17) for these locations.

Fermi 2 will manage the effects of fatigue, including environmentally assisted fatigue, under the Fatigue Monitoring Program (Section B.1.17) for the period of extended operation in accordance with 10 CFR 54.21(c)(1)(iii).

B.2.3 ENVIRONMENTAL QUALIFICATION OF ELECTRICAL COMPONENTS

All operating plants must meet the requirements of 10 CFR 50.49, which defines the scope of electrical components to be included in a program for qualifying electric equipment important to safety (EQ program) and also sets forth requirements for an EQ program. Qualification is established for the environmental and service conditions expected for normal plant operation and also those conditions postulated for plant accidents. A record of qualification for in-scope components must be prepared and maintained in auditable form. Equipment qualification evaluations for EQ components that result in a qualification of at least 40 years, but less than 60 years, are considered TLAAs for license renewal.

The Fermi 2 Environmental Qualification (EQ) of Electric Components Program (EQ Program) (Section B.1.15) manages component thermal, radiation, and cyclical aging, as applicable, through the use of aging evaluations based on 10 CFR 50.49(f) qualification methods. As required by 10 CFR 50.49, EQ components not qualified for the current license term are to be refurbished, replaced, or have their qualification extended prior to reaching the limitations established in the evaluation. The Fermi 2 EQ Program ensures that EQ components are maintained in accordance with their qualification bases.

The Fermi 2 EQ Program is an existing program established to meet Fermi 2 commitments for 10 CFR 50.49. The program is consistent with NUREG-1801, Section X.E1, "Environmental Qualification (EQ) of Electric Components." The Fermi 2 EQ Program will manage the effects of aging on the intended function(s) of EQ components that are the subject of EQ TLAAs for the period of extended operation in accordance with 10 CFR 54.21(c)(1)(iii).

B.2.4 FATIGUE OF PRIMARY CONTAINMENT, ATTACHED PIPING, AND COMPONENTS

As described in UFSAR Section 3.8, the primary containment (a Mark I containment) is a leak-tight steel-plate containment vessel consisting of a light-bulb-shaped drywell and a torus-shaped suppression chamber. The Fermi 2 analysis is documented in the Plant Unique Analysis Report (PUAR) for Fermi 2. Fermi 2 will manage the aging effects due to fatigue using the Fatigue Monitoring Program (Section B.1.17) in accordance with 10 CFR 54.21(c)(1)(iii).

The vent line bellows were qualified for bellows expansion from the drywell and torus temperature increase following an accident or from earthquakes. The bellows remain qualified for the period of extended operation in accordance with 10 CFR 54.21(c)(1)(i).

Fermi 2 has a refueling bellows attached to the vessel near the reactor vessel flange and a drywell seal bellows outside of the drywell shell. These bellows remain qualified for the period of extended operation in accordance with 10 CFR 54.21(c)(1)(i).

Fermi 2 has penetration bellows at the traversing incore probe (TIP) penetrations. The fatigue analysis determined the bellows were qualified for many more cycles than they are expected to experience. Therefore, the bellows remain valid for the period of extended operation in accordance with 10 CFR 54.21(c)(1)(i).

As described in UFSAR Section 3.8.2.1.3.1, sleeved penetration assemblies with bellows consist of the process pipe, guard pipe, penetration sleeve bellows, and flued head. For Class 1 piping, the design of the flued head meets ASME III Class 1 requirements, which specify a fatigue analysis that determines the cumulative usage factor for the flued head. Fermi 2 will manage the aging effects due to fatigue of these penetrations using the Fatigue Monitoring Program (Section B.1.17) in accordance with 10 CFR 54.21(c)(1)(iii).

The sleeved penetration assembly bellows were determined to be capable of handling the movement from many more cycles than are projected. The sleeved penetration assembly bellows analyses remain valid for the period of extended operation in accordance with 10 CFR 54.21(c)(1)(i).

B.2.5 OTHER PLANT-SPECIFIC TLAAs

B.2.5.1 EROSION OF THE MAIN STEAM LINE FLOW RESTRICTORS

UFSAR Section 5.5.4.4 states that the main steam flow restrictors are fabricated from stainless steel and that only very slow erosion will occur with time. The section later postulates that even with an erosion rate of 0.004 inches per year, the increase in choked flow after 40 years would be no more than 5 percent. Analysis of the erosion rate is evaluated as a TLAA.

DTE Electric evaluated the erosion-corrosion rate for the main steam flow restrictors. This evaluation considered the specific material of the Fermi 2 flow restrictors and determined the expected erosion-corrosion rate when operating at the velocities that would be present following an extended power uprate, which is a greater velocity than anticipated following the MUR/TPO uprate. The evaluation determined that the expected erosion-corrosion rate would be much less than the conservative erosion rate provided in the UFSAR. Assuming the expected erosion-corrosion rate for 60 years of operation, the increase in restrictor-choked flow rate will remain no more than five percent as specified in UFSAR Section 5.5.4.4.

This analysis has been projected through the period of extended operation in accordance with 10 CFR 54.21(c)(1)(ii).

B.2.5.2 DETERMINATION OF HIGH-ENERGY LINE BREAK LOCATIONS

UFSAR Sections 3.6.1 and 3.6.2 state that the method used to determine the intermediate locations of pipe breaks in high-energy lines includes an evaluation based on CUFs being less than 0.1 if other stress criteria are also met.

Design criteria for piping between the primary containment and outboard isolation valves provide for maximum stresses considering all normal and upset conditions as calculated by the equations in the ASME Boiler & Pressure Vessel Code Section III Paragraph NB-3653. As identified in UFSAR Section 3.6.2.1.2.2, pipe breaks were not postulated in the high energy piping between the containment penetration and outboard isolation valves since the piping was conservatively designed and restrained. The calculated CUFs for containment penetration piping were also limited to values less than 0.1 if equation 10 of NB-3653 exceeds 2.4 S_m.

The CUFs, as calculated in the design fatigue analyses, are based on the design transients assumed for the original 40-year life of the plant; therefore, the CUF analyses used in the selection of postulated high-energy line break locations are considered TLAAs.

The Fatigue Monitoring Program (Section B.1.17) identifies when the transients affecting high-energy piping are approaching their analyzed numbers of cycles.

DTE Electric will manage the effects of aging associated with the fatigue analyses used in the selection of postulated high-energy line break locations using the Fatigue Monitoring Program in accordance with 10 CFR 54.21(c)(1)(iii).

B.2.5.3 JET PUMP AUXILIARY SPRING WEDGE ASSEMBLY

Auxiliary spring wedges have been installed on jet pumps 1, 2 and 15 at Fermi 2 to maintain continuous three point contact for the inlet mixer to the restrainer bracket. A calculation evaluates relaxation of the spring preload for the jet pump auxiliary spring wedge assemblies. The evaluation considers a neutron fluence of 1.2E+20 n/cm^2 (E > 1 MeV) for a 40-year design life. The relaxation of the spring preload in the spring wedge assembly is a TLAA.

To disposition the TLAA, a fluence analysis was performed to determine the fluence values at the three currently installed wedges on the jet pumps and at the bounding location for possible future installation of wedge assemblies through the period of extended operation. The analysis determined that wedge 1 is the limiting case with the projected neutron fluence for wedge 1 slightly exceeding the design fluence prior to the end of the period of extended operation. An evaluation of the slightly higher fluence for wedge 1 determined that it has no impact on the most limiting stresses that were reported in the original stress report. The slightly higher fluence for wedge 1 has no adverse impact on the structural integrity and functional performance.

The results of the analysis demonstrated that the available preload at the end of period of extended operation is considerably greater than the required preload. Additionally, the auxiliary spring wedge assembly is designed to function independent of the spring preload, i.e. the spring wedge function works at any preload. There will be contact between the belly band, auxiliary spring wedge assembly and the restrainer bracket.

This TLAA has been projected to the end of the period of extended operation in accordance with 10 CFR 54.21(c)(1)(ii).

B.2.5.4 JET PUMP SLIP JOINT REPAIR CLAMPS

The jet pump slip joint repair clamp is connected to the diffuser and the mixer. The clamp is installed with a preload that may be relaxed due to neutron fluence. The analysis that evaluated relaxation of the slip joint repair clamp is a TLAA.

To evaluate the TLAA, a fluence analysis including the increased fluence due to the MUR/TPO was performed to determine the fluence at the installed positions on the jet pumps including 52 EFPY. It was determined the neutron irradiation does not impact the amount of expected relaxation. The original relaxation value remains valid for 52 EFPY of operation and the stress report results remain applicable for the period of extended operation.

This TLAA has been projected to the end of the period of extended operation in accordance with 10 CFR 54.21(c)(1)(ii).

B.2.5.5 FLAW EVALUATIONS FOR THE REACTOR VESSEL

During refueling outage 9 (RF9) in 2003, new ASME Section XI, Appendix VIII qualified ultrasonic examination procedures were used for the first time on reactor pressure vessel welds. These new techniques employed greatly improved flaw detection and sizing methods and detected several reactor vessel flaws. A reexamination in RF12 used the phased array technique and identified flaws at two additional locations.

A fracture mechanics evaluation was performed to determine the acceptability of the reactor vessel flaw indications. The analysis evaluated the bounding flaw location for consideration of the pressure-temperature analysis. The analysis determined the indications are acceptable for 52 EFPY with consideration of the effects of MUR/TPO.

This TLAA has been projected to the end of the period of extended operation in accordance with 10 CFR 54.21(c)(1)(ii).

B.2.5.6 MAIN STEAM BYPASS LINES CUMULATIVE OPERATING TIME

A flaw evaluation concluded that the bypass lines are acceptable for safe operation when operated within the 100 day constraint. The cumulative time the main steam bypass lines are operated with the bypass valves between 30 and 45 percent open will be reported annually. A cumulative value of 100 days is not to be exceeded without prior NRC notification.

Fermi 2 will manage the main steam bypass valves' cumulative usage time using the Fatigue Monitoring Program (Section B.1.17) in accordance with 10 CFR 54.21(c)(1)(iii).

B.2.5.7 CRANE (HEAVY LOAD) CYCLES

UFSAR Section 9.1.4.2.2 states that the reactor building overhead crane meets the structural guidelines of Crane Manufacturers Association of America (CMAA) Specification No. 70. CMAA-70 identifies an allowable stress range based on joint category and service class. The definition of service class considers the load class and the load cycles expected on the crane.

The lowest range of cycles in CMAA-70 is 20,000 to 100,000 for Class A cranes; therefore, the analysis associated with the CMAA-70 lift cycle limit is considered a TLAA.

It is estimated that the number of lifts for the reactor building overhead crane will remain below the 100,000 cycles established in CMAA-70 for a Class A service hoist.

Therefore, the evaluation of lift cycles for the reactor building crane remains valid for the period of extended operation consistent with 10 CFR 54.21(c)(1)(i).

B.2.5.8 CORE SUPPORT PLATE HOLD-DOWN BOLT STRESS RELAXATION

The core support plate is fastened to the core support structure using 34 stainless steel bolting connections. The core plate hold-down bolts are subject to stress relaxation due to thermal and irradiation effects. The BWRVIP determined that all core support bolts will maintain some preload for 40 years of service in BWRVIP-25. Revision 1-A to BWRVIP-25 contains Appendix I, which provides a technical basis justifying no examinations to be performed on core plate bolts provided certain loading and fluence criteria are bounded by plant-specific values.

Plant-specific analysis considering the limiting plant-specific design basis vertical load combinations and fluence projections were used to demonstrate that the Fermi 2 core plate bolts are bounded by the analysis in BWRVIP-25, Revision 1-A, for the period of extended operation. The peak core plate bolt fluence value of 1.06E+20 n/cm^2 at 52 EFPY was used to bound the entire length of the bolt. The use of BWRVIP-25 Revision 1-A to resolve licensee commitments regarding BWRVIP-25 examinations was accepted by the staff by NRC SER (Reference 5), and use of BWRVIP-25 Revision 1-A at Fermi was accepted by NRC SER (Reference 6).

This TLAA has been projected to the end of the period of extended operation in accordance with 10 CFR 54.21(c)(1)(ii).

1	DTE will make the following changes to the process for operating experience review. a. Procedures will be revised to add an aging type code to corrective action program documents that describe either plant conditions related to aging or industry operating experience related to aging. b. Procedures will be revised to provide for training of personnel responsible for submitting, screening, assigning, evaluating, or otherwise processing plant-specific and industry operating experience concerning age-related degradation and aging management, as well as for personnel responsible for implementing AMPs, based on the complexity of the job performance requirements and assigned responsibilities. c. Procedures will be revised to specify that evaluations of operating experience concerning age-related degradation will include consideration of the affected systems, structures or components, the environments, materials, aging effects, aging mechanisms, and aging management programs.	A.1	Completed	LRA DTE letter NRC-15-0009 dated 1/15/15 DTE letter NRC-16-0045 dated 7/6/16
2	DTE currently performs periodic self-assessments on many aging management programs. DTE will enhance the Fermi 2 self-assessment process to provide for periodic evaluation of the effectiveness of each aging management program described in the updated final safety analysis report (UFSAR) supplement. For new aging management programs, the first evaluation will be performed within 5 years of implementing the program.	A.1	Within 5 years of implementing the program for new programs.	LRA
3	Implement the new Aboveground Metallic Tanks Program that will manage loss of material and cracking for outdoor tanks within the scope of license renewal that are sited on soil or concrete. Condensate storage tank (CST) internal inspections will be conducted in accordance with Table 4a of LR-ISG-2012-02. This program will also manage the bottom surfaces of the CST. Within the 10 years prior to the period of extended operation and every 10 years thereafter, a volumetric examination of a minimum 25 percent of the CST tank bottom interface with the concrete ring foundation will be performed to manage loss of material. The	A.1.1	Prior to September 20, 2024, or the end of the last refueling outage prior to March 20, 2025, whichever is later. 			taken) will be performed within the 10 years prior to March 20, 2025.	
7	Enhance the BWR Vessel Internals Program as follows: a. The susceptibility to neutron or thermal embrittlement for reactor vessel internal components composed of cast austenitic stainless steel (CASS) and X-750 alloy will be evaluated. b. BWR Vessel Internals Program procedures will be revised as follows. Portions of the susceptible components determined to be limiting from the standpoint of thermal aging susceptibility, neutron fluence, and cracking susceptibility (i.e., applied stress, operating temperature, and environmental conditions) will be inspected, using an inspection technique capable of detecting the critical flaw size with adequate margin. The critical flaw size will be determined based on the service loading condition and service-degraded material properties. The initial inspection will be performed either prior to or within 5 years after entering the period of extended operation. If cracking is detected after the initial inspection, the frequency of re-inspection will be justified based on fracture toughness properties appropriate for the condition of the component. The sample size for the initial inspection of susceptible components will be 100 percent of the accessible component population, excluding components that may be in compression during normal operations. c. BWR Vessel Internals Program procedures will be revised as follows. In accordance with an applicant action item for BWRVIP-25 safety evaluation: (a) install core plate wedges prior to the period of extended operation, or (b) complete a plant-specific analysis that justifies no inspections are required, or (c) complete a plant-specific analysis to determine acceptance criteria for continued inspection of core plate hold-down bolts in accordance with BWRVIP-25.	A.1.10	Perform initial inspection either prior to March 20, 2025, or before March 20, 2030. Submit analysis and inspection plan to the NRC prior to March 20, 2023. Remaining activities: Prior to September 20, 2024, or the end of the last refueling outage prior to March 20, 2025, whichever is later.	LRA DTE letter NRC-15-0010 dated 2/5/15 DTE letter NRC-15-0044 dated 4/27/15 DTE letter NRC-15-0062 dated 6/9/15 DTE letter NRC-15-0083 dated 8/20/15

TABLE B-1 Fermi 2 License Renewal Commitments

Item Number	Commitment	FSAR Supplement Section/LRA Section	Enhancement or Implementation Schedule	Source
	For Option (b), the analysis will address loss of preload due to stress relaxation in the core plate rim hold-down bolts and quantify the loss of preload/stress relaxation that will occur in these bolts during the period of extended operation. The analysis will be submitted to the NRC 2 years prior to the period of extended operation. Additionally, the UFSAR will be revised to address the analysis if it is determined to meet the criteria for a time-limited aging analysis (TLAA) at least 2 years prior to the period of extended operation. For Option (c), the analysis will address loss of preload due to stress relaxation in the core plate rim hold-down bolts and quantify the loss of preload/stress relaxation that will occur in these bolts during the period of extended operation. The analysis, inspection plan with acceptance criteria, and justification for the inspection plan will be submitted to the NRC 2 years prior to the period of extended operation. Additionally, the UFSAR will be revised to address the analysis if it is determined to meet the criteria for a TLAA at least 2 years prior to the period of extended operation. d. Revise BWR Vessel Internals Program procedures such that the flaw evaluation methodology for the top guide grid beam will address the following three items if they have not been resolved generically during the NRC review and approval process of BWRVIP-183: (1) Detected flaws evaluated using the methodology in BWRVIP-183 Section 4 will be demonstrated to be sufficiently far from geometric discontinuities (i.e., notches or slots) such that the stress condition in the vicinity of the flaw is consistent with that for a single edgecrack plate. Appropriately applied K values which account for the effects of geometric discontinuities will be used and justified in the flaw evaluation. (2) The flaw evaluation methodology in BWRVIP-183 Section 4 will be used to justify continued operation on a			

TABLE B-1 Fermi 2 License Renewal Commitments

Item Number	Commitment	FSAR Supplement Section/LRA Section	Enhancement or Implementation Schedule	Source
	cycle-by-cycle basis. Use of the flaw evaluation methodology to justify operation for more than once cycle will require NRC approval and would be based on plant-specific operating experience including crack length measurements of detected top guide grid beam flaws to benchmark the accuracy of the flaw evaluation methodology. (3) When applying the flaw evaluation methodology in BWRVIP-183 Section 4, a severed beam evaluation consistent with BWRVIP-183 Section 5 will also be performed. The severed beam analysis will demonstrate that even if a beam was a completely severed beam, it would not be expected to interfere with the ability of the control rod drive system to insert control rods. e. Revise BWR Vessel Internals Program procedures to perform opportunistic inspections of the differential pressure and standby liquid control line inside the reactor vessel when the line becomes accessible.			
8	Enhance the Compressed Air Monitoring Program as follows: a. DELETED b. Revise Compressed Air Monitoring Program procedures to include periodic and opportunistic inspections of accessible internal surfaces of piping, compressors, dryers, aftercoolers, and filters. In addition, include in the Compressed Air Monitoring Program procedures the applicable provisions recommended in EPRI NP-7079, EPRI TR- 108147, and ASME OM-S/G-1998, Part 17 for air system contaminants, inspection frequency, inspection methods, and acceptance criteria for components subject to aging management review that are exposed to compressed air and components in the EDG starting air system and control air system.	A.1.11	Completed	LRA
9	Enhance the Containment Inservice Inspection (CII)-IWE Program as follows: a. Revise plant procedures to require inspection of the sand	A.1.12	Prior to	LRA DTE letter

TABLE B-1 Fermi 2 License Renewal Commitments

Item Number	Commitment	FSAR Supplement Section/LRA Section	Enhancement or Implementation Schedule	Source
	cushion drain lines to monitor the internal conditions of the drain lines (e.g., for moisture, sand, blockage) and ensure there is no evidence of blockage at least once prior to the period of extended operation and once every 10 years during the period of extended operation. b. Revise plant procedures to specify the preventive actions delineated in NUREG-1339 and in EPRI NP-5769, NP-5067, and TR-104213 that emphasize proper selection of bolting material, installation torque or tension, and the use of lubricants and sealants for high strength bolting. c. Revise plant procedures to include the preventive actions for storage of American Society for Testing and Materials (ASTM) A325 and A490 bolting from Section 2 of Research Council for Structural Connections publication, "Specification for Structural Joints Using ASTM A325 or A490 Bolts." d. [Deleted] e. [Deleted] f. Revise plant procedures to determine drywell shell thickness in the sand cushion areas before the period of extended operation and once in each 10-year interval during the period of extended operation. From the results (including prior results), develop a corrosion rate to demonstrate that the drywell shell will have sufficient wall thickness to perform its intended function through the period of extended operation. g. Revise plant procedures to require corrective actions should moisture be detected or suspected in the inaccessible area on the exterior of the drywell shell, including: • Identify surfaces requiring augmented inspections for the period of extended operation in accordance with Subsection IWE-1240, as identified in Table IWE-2500-1, Examination Category E-C. • Use examination methods that are in accordance with Subsection IWE-2500.		September 20, 2024, or the end of the last refueling outage prior to March 20, 2025, whichever is later.	NRC-15-0004 dated 1/15/15

TABLE B-1 Fermi 2 License Renewal Commitments

Item Number	Commitment	FSAR Supplement Section/LRA Section	Enhancement or Implementation Schedule	Source
	• Demonstrate through use of augmented inspections performed in accordance with Subsection IWE that corrosion is not occurring or that corrosion is progressing so slowly that the degradation will not jeopardize the intended function of the drywell shell through the period of extended operation.			
10	Enhance Diesel Fuel Monitoring Program as follows: a. Revise Diesel Fuel Monitoring Program procedures to monitor and trend water and sediment, particulates, and levels of microbiological organisms in the EDG fuel oil storage tanks, EDG fuel oil day tanks, diesel fire pump fuel oil tank, and CTG fuel oil tank quarterly. In addition, revise program procedures to state that biocides or corrosion inhibitors may be added as a preventive measure or are added if periodic testing indicates biological activity or evidence of corrosion, respectively. b. Revise the Diesel Fuel Monitoring Program procedures to include a 10-year periodic cleaning and internal visual inspection of the EDG fuel oil storage tanks, EDG fuel oil day tanks and diesel fire pump fuel oil tank with the following instructions. The cleanings and internal inspections will be performed at least once during the 10-year period prior to the period of extended operation and at succeeding 10-year intervals. If visual inspection is not possible, perform a volumetric inspection. If evidence of degradation is observed during visual inspection, perform a volumetric examination of the affected area. The schedule for the Preventive Maintenance (PM) event to perform diesel fire pump fuel oil tank draining, flushing, and inspection will continue at its frequency at the time of the enhancement implementation, until a PM evaluation of results from fuel oil samples and tank inspections indicates that the system will be capable of continuing to perform its	A.1.14	Prior to September 20, 2024, or the end of the last refueling outage prior to March 20, 2025, whichever is later.	LRA DTE letter NRC-15-0056 dated 5/19/15

TABLE B-1 Fermi 2 License Renewal Commitments

Item Number	Commitment	FSAR Supplement Section/LRA Section	Enhancement or Implementation Schedule	Source
	function during the period of extended operation with a lower frequency, not less than once per 10-year interval for cleaning and internal visual inspection consistent with NUREG-1801.			
11	Enhance External Surfaces Monitoring Program as follows: a. Revise External Surfaces Monitoring Program procedures to clarify that periodic inspections will be performed of systems in scope and subject to aging management review for license renewal in accordance with 10 CFR 54.4 (a)(1) and (a)(3). Inspections shall include areas surrounding the subject systems to identify hazards to those systems. Inspections of nearby systems that could impact the subject systems will include structures, systems, and components (SSCs) that are in scope and subject to aging management review for license renewal in accordance with 10 CFR 54.4(a)(2). b. Revise External Surfaces Monitoring Program procedures to inspect 100 percent of accessible components at least once per refueling cycle and to ensure required walk downs include instructions to inspect for the following related to metallic components: • Corrosion (loss of material). • Leakage from or onto external surfaces (loss of material). • Worn, flaking, or oxide-coated surfaces (loss of material). • Corrosion stains on thermal insulation (loss of material). • Protective coating degradation (cracking, flaking, and blistering). • Leakage for detection of cracks on the external surfaces of stainless steel components exposed to an air environment containing halides (cracking). c. Revise External Surfaces Monitoring Program procedures to include instructions for monitoring aging effects for flexible polymeric components through physical manipulations of the material, with a sample size for manipulation of at least 10 percent of the available surface area. Inspect accessible surfaces for the following:	A.1.16	Completed	LRA DTE letter NRC-14-0051 dated 7/30/14 DTE letter NRC-15-0007 dated 1/28/15 DTE letter NRC-15-0032 dated 4/17/15 DTE letter NRC-15-0067 dated 6/18/15

TABLE B-1 Fermi 2 License Renewal Commitments

Item Number	Commitment	FSAR Supplement Section/LRA Section	Enhancement or Implementation Schedule	Source
	• Surface cracking, crazing, scuffing, dimensional changes (e.g., ballooning and necking). • Discoloration. • Exposure of internal reinforcement for reinforced elastomers. • Hardening as evidence by loss of suppleness during manipulation where the component and material are appropriate to manipulation. • Shrinkage, loss of strength. d. Revise External Surfaces Monitoring Program procedures to specify the following for insulated components: • Periodic representative inspections will be conducted during each 10-year period. • For a representative sample of insulated indoor components exposed to condensation (because the component is operated below the dew point) and insulated outdoor components, insulation will be removed for visual inspection of the component surface. Inspections include a minimum of 20 percent of the in-scope piping length for each material type (e.g., steel, stainless steel, copper alloy, aluminum), or for components with a configuration which does not conform to a 1-foot axial length determination (e.g., valve, accumulator), 20 percent of the surface area. Alternatively, insulation will be removed and a minimum of 25 inspections performed that can be a combination of 1-foot axial length sections and individual components for each material type. • Inspection locations are based on the likelihood of corrosion under insulation (CUI). For example, CUI is more likely for components experiencing alternate wetting and drying in environments where trace contaminants could be present and for components that operate for long periods of time below the dew point.			

TABLE B-1 Fermi 2 License Renewal Commitments

Item Number	Commitment	FSAR Supplement Section/LRA Section	Enhancement or Implementation Schedule	Source
	Subsequent inspections will consist of an examination of the exterior surface of the insulation for indications of damage to the jacketing or protective outer layer of the insulation, if the following conditions are verified in the initial inspection: o No loss of material due to general, pitting or crevice corrosion, beyond that which could have been present during initial construction, and o No evidence of cracking. If the external visual inspections of the insulation reveal damage to the exterior surface of the insulation or there is evidence of water intrusion through the insulation (e.g., water seepage through insulation seams/joints), periodic inspections under the insulation will continue as described above. • Removal of tightly adhering insulation that is impermeable to moisture is not required unless there is evidence of damage to the moisture barrier. If the moisture barrier is intact, the likelihood of CUI is low for tightly adhering insulation. Tightly adhering insulation is considered to be a separate population from the remainder of insulation installed on in-scope components. The entire population of in-scope accessible piping component surfaces that have tightly adhering insulation will be visually inspected for damage to the moisture barrier with the same frequency as for other types of insulation inspections. These inspections will not be credited towards the inspection quantities for other types of insulation. e. Revise External Surfaces Monitoring Program procedures to include acceptance criteria for the parameters observed. • Metals should not have any indications of relevant degradation.			

TABLE B-1 Fermi 2 License Renewal Commitments

Item Number	Commitment	FSAR Supplement Section/LRA Section	Enhancement or Implementation Schedule	Source
	• Flexible polymers should have a uniform surface texture and color with no cracks and no dimension change, no abnormal surface conditions with respect to hardness, flexibility, physical dimensions, and color. • Rigid polymers should have no erosion, cracking, crazing or chalking. • For insulation, no discoloration, staining, or surface irregularities from moisture intrusion. f. Revise External Surfaces Monitoring Program procedures to stipulate that administrative controls are in accordance with the Fermi 2 10 CFR Part 50 Appendix B Quality Assurance Program. g. Revise External Surfaces Monitoring Program procedures to include instructions for detection of cracking of gas-filled stainless steel and aluminum components exposed to outdoor air. h. Revise External Surfaces Monitoring Program procedures to: (a) Visually inspect jacketed and nonjacketed insulation required to reduce heat transfer at a frequency consistent with NUREG-1801 Section XI.M36, as modified by LR-ISG-2012-02, to ensure that insulation degradation due to moisture intrusion has not occurred. (b) Ensure procedures include instructions to inspect for signs of water intrusion. Inspect accessible surfaces for the following signs of water intrusion: discoloration, staining, or surface irregularities.			
12	Enhance the Fatigue Monitoring Program as follows: a. Revise Fatigue Monitoring Program procedures to monitor and track critical thermal and pressure transients for components that have been identified to have a fatigue TLAA. b. Develop environmentally assisted fatigue (EAF) usage calculations that consider the effects of the reactor water environment for a set of sample reactor coolant system components. This sample set will include the locations	A.1.17	Part (b): At least 2 years prior to March 20, 2025. Remainder: Prior to September 20, 2024.	LRA DTE letter NRC-15-0005 dated 1/20/15 DTE letter

TABLE B-1 Fermi 2 License Renewal Commitments

Item Number	Commitment	FSAR Supplement Section/LRA Section	Enhancement or Implementation Schedule	Source
	identified in NUREG/CR-6260 and additional plant-specific component locations in the reactor coolant pressure boundary if they are found to be more limiting than those considered in NUREG/CR-6260. Environmental correction factors will be determined using formulae consistent with those recommended in NUREG-1801, X.M1. c. Revise Fatigue Monitoring Program procedures to provide updates of the fatigue usage calculations on an as-needed basis if an allowable cycle limit is approached, or in a case where a transient definition has been changed, unanticipated new thermal events are discovered, or the geometry of components has been modified. For components with assumed minimal cycle counts, ensure that exemption assumptions are not exceeded. d. After the EAF calculations are completed, revise the Fatigue Monitoring Program procedures to state that the program counting of the cycle limits maintains the cumulative fatigue usage below the design limit through the period of extended operation, with consideration of the reactor water environmental fatigue effects. Revise Fatigue Monitoring Program procedures to allow for use of cycle-based fatigue (CBF) or stress-based fatigue (SBF) monitoring methods (including environmental effects) if a component's cumulative usage factor (CUF) value is projected to exceed 1.0 after EAF calculations are completed. e. Revise Fatigue Monitoring Program procedures so that the scope of the program includes monitoring the operating hours for the main steam bypass operation at the 30%-45% valve open position and perform trending to ensure that the operating time for the main steam bypass operation remains below the design limit during the period of extended operation. f. Revise Fatigue Monitoring Program procedures to provide			NRC-15-0011 dated 2/12/15

TABLE B-1 Fermi 2 License Renewal Commitments

Item Number	Commitment	FSAR Supplement Section/LRA Section	Enhancement or Implementation Schedule	Source
	for corrective actions to prevent the operating time for the main steam bypass from exceeding the analysis during the period of extended operation. Acceptable corrective actions include repair of the component, replacement of the component, or a more rigorous analysis of the component to demonstrate that the service life will not be exceeded during the period of extended operation.			
13	Enhance the Fire Protection Program as follows: a. Revise Fire Protection Program procedures to perform visual inspections to manage loss of material of the Halon and CO2 fire suppression system. b. Revise Fire Protection Program procedures to require visual inspections of in-scope: • Fire wrap and fire stop materials for loss of material, change in material properties, cracking/delamination, separation, increased hardness, shrinkage, and loss of strength. • Carbon steel penetration sleeves for loss of material. • Steel framing, roof decking, and floor decking for loss of material. • Concrete fire barriers including manways, manhole covers, handholes, and roof slabs for loss of material and cracking. • Railroad bay airlock doors for loss of material. Inspections are performed at a frequency in accordance with the NRC-approved fire protection program or at least once every refueling cycle.	A.1.18	Prior to September 20, 2024.	LRA DTE letter NRC-15-0009 dated 1/15/15
14	Enhance the Fire Water System Program as follows: a. Revise Fire Water System Program procedures to ensure sprinkler heads are tested or replaced in accordance with National Fire Protection Association (NFPA) 25 (2001 Edition), Section 5.3.1. b. Revise Fire Water System Program procedures to perform an	A.1.19	Prior to September 20, 2024, or the end of the last refueling outage prior to March 20, 2025, whichever is later, with	LRA DTE letter NRC-14-0051 dated 7/30/14

TABLE B-1 Fermi 2 License Renewal Commitments

Item Number	Commitment	FSAR Supplement Section/LRA Section	Enhancement or Implementation Schedule	Source
	inspection of wet fire water system piping condition at least once every 5 years by opening a flushing connection at the end of one main and by removing a sprinkler toward the end of one branch line for the purpose of inspecting the interior for evidence of loss of material and the presence of foreign organic or inorganic material that could result in flow obstructions or blockage of a sprinkler head. Where multiple wet-pipe systems are in a building, every other system shall be inspected in a 5-year period. Then, in the next 5-year period, the remaining systems in that building shall be inspected. (Refer to NFPA 25 (2011 Edition), Sections 14.2.1 and 14.2.2.) The inspection method used shall be capable of detecting surface irregularities that could indicate wall loss due to corrosion, corrosion product deposition, and flow blockage due to fouling. Ensure procedures require a followup volumetric wall thickness evaluation where irregularities are detected. c. Revise Fire Water System Program procedures to: (a) ensure sprinkler heads are tested or replaced in accordance with NFPA 25 (2011 Edition) Section 5.3.1 and (b) the fire protection engineer approves the sprinkler testing laboratory. d. Revise Fire Water System Program procedures to: (a) specify that in accordance with NFPA 13.2.5.2 when there is a 10 percent reduction in full flow pressure when compared to the original acceptance test or previously performed tests, the cause of the reduction shall be identified and corrected as necessary; and (b) note the time to return to static pressure after performing a main drain test. e. Revise Fire Water System Program procedures to notify the fire protection engineer of test results and deficiencies identified or detected during testing.		the exception that the activities described in this commitment for piping segments designed to be dry but determined to be collecting water shall be conducted within 5 years prior to March 20, 2025.	DTE letter NRC-15-0002 dated 1/15/15 DTE letter NRC-15-0031 dated 4/10/15

TABLE B-1 Fermi 2 License Renewal Commitments

Item Number	Commitment	FSAR Supplement Section/LRA Section	Enhancement or Implementation Schedule	Source
	f. Revise Fire Water System Program procedures to ensure piping is cleaned and sprinklers are replaced if obstructions are identified during internal inspections. Sprinklers loaded with dust may be cleaned using air rather than replaced. g. Revise Fire Water System Program procedures to perform an internal inspection of wet fire water system piping conditions at least once every 5 years by opening a flushing connection at the end of one main and by removing a sprinkler toward the end of the branch line for the purpose of inspecting the interior for evidence of loss of material and the presence of foreign organic and inorganic material that could result in flow obstructions or blockage of sprinkler heads. Where multiple wet-pipe systems are in a building, every other system shall be inspected in a 5-year period. Then, in the next 5-year period, the remaining systems in that building shall be inspected. h. [Deleted] i. Revise Fire Water System Program procedures to perform at least once every 5 years either an internal inspection of the dry components downstream of the deluge valves for the hydrogen seal oil unit by removing a sprinkler toward the end of one branch line and inspecting for evidence of loss of material and the presence of foreign organic and inorganic material that could result in flow obstructions or blockage of sprinklers, or Revise Fire Water System Program procedures to perform at least once every 5 years an air or smoke test to verify there is no flow obstruction or blockage of sprinklers. j. Revise Fire Water System Program procedures to perform an inspection of the water distribution piping associated with charcoal filters for loss of material and foreign organic or inorganic material when the charcoal beds are replaced. k. Revise Fire Water System Program procedures to perform an			

TABLE B-1 Fermi 2 License Renewal Commitments

Item Number	Commitment	FSAR Supplement Section/LRA Section	Enhancement or Implementation Schedule	Source
	obstruction investigation whenever any of the criteria listed in NFPA Section 14.2.1.3 or 14.3.1 are met. l. Perform a fire water system walkdown of the piping and components that are designed to be dry (e.g., downstream of deluge valves or manual isolations of dry fire water piping), but are periodically wetted, to determine if any piping sections are collecting water and are subject to both of the following augmented inspections: • In each 5-year interval, beginning 5 years prior to the period of extended operation, either (a) conduct a flow test or flush sufficient to detect potential flow blockage, or (b) conduct a visual inspection of 100 percent of the internal surface of piping segments that cannot be drained or piping segments that allow water to collect. • In each 5-year interval of the period of extended operation, inspect 20 percent of the length of piping segments that cannot be drained or piping segments that allow water to collect using volumetric techniques to measure wall thickness. Measurement points will be obtained so that each potential degraded condition can be identified (e.g., general corrosion, microbiologically induced corrosion (MIC)). The 20 percent of piping that will be inspected in each 5-year interval will be in different locations than previously inspected piping. m. Revise Fire Water System Program procedures to include acceptance criteria that any indication of fouling is evaluated. n. Revise Fire Water System Program procedures to specify that if the presence of sufficient foreign organic or inorganic material to obstruct pipe or sprinklers is detected during pipe inspections, the material is removed and the source and extent of condition determined, corrected, and the condition entered into the corrective action program. o. Revise Fire Water System Program procedures to replace			

TABLE B-1 Fermi 2 License Renewal Commitments

Item Number	Commitment	FSAR Supplement Section/LRA Section	Enhancement or Implementation Schedule	Source
	sprinklers associated with representative tested sprinkler, if the representative test sprinkler fails to meet the test requirements. p. Revise Fire Water System Program procedures to replace any sprinkler that shows signs of corrosion. q. If the decreasing trend in fire water system flow tests is not resolved through the corrective action program prior to the period of extended operation, revise Fire Water System Program procedures to continue performing annual fire water system flow tests during the period of extended operation until such a time as trend data from fire water system flow tests indicates that the system will be capable of performing its intended function throughout the period of extended operation and, therefore, Technical Requirements Manual (TRM) frequency may be resumed. r. Revise Fire Water System Program procedures to include formal documentation of the Control Center Heating, Ventilation, and Air Conditioning (CCHVAC) makeup and recirculation fire water supply drain down inspection for indications of flow blockage.			
15	Enhance the Flow-Accelerated Corrosion Program as follows: a. Revise procedures to indicate that the Flow-Accelerated Corrosion Program also manages loss of material due to erosion mechanisms of cavitation, flashing, liquid droplet impingement, and solid particle erosion for any material in treated water or steam environments. Include in program procedures a susceptibility review based on internal operating experience, external operating experience, EPRI TR-1011231, and NUREG/CR-6031. Piping subject to erosive conditions is not excluded from inspections, even if it has been replaced with flow-accelerated corrosion-resistant material. Periodic wall thickness measurements of such piping should continue until the effectiveness of corrective actions is assured. b. Revise Flow-Accelerated Corrosion Program procedures to	A.1.20	Completed	LRA

TABLE B-1 Fermi 2 License Renewal Commitments

Item Number	Commitment	FSAR Supplement Section/LRA Section	Enhancement or Implementation Schedule	Source
	specify that downstream components are monitored closely for wall thinning when susceptible upstream components are replaced with resistant materials.			
16	Enhance the Inservice Inspection (ISI)-IWF Program as follows: a. Revise plant procedures to specify the preventive actions delineated in NUREG-1339 and EPRI NP-5769, NP-5067, and TR-104213 that emphasize proper selection of bolting material, installation torque or tension, and the use of lubricants and sealants for high-strength bolting. b. Revise plant procedures to require structural bolting replacement and maintenance activities to include appropriate preload and proper tightening (torque or tension) as recommended in EPRI documents, ASTM standards, American Institute of Steel Construction (AISC) Specifications, as applicable. c. Revise plant procedures to include the preventive actions for storage of ASTM A325 and A490 bolting from Section 2 of Research Council for Structural Connections publication, "Specification for Structural Joints Using ASTM A325 or A490 Bolts." d. Revise plant procedures to specify that detection of aging effects will include monitoring anchor bolts for loss of material, loose or missing nuts or bolts, and cracking of concrete around the anchor bolts. e. Revise plant procedures to identify the following unacceptable conditions: • Debris, dirt, or excessive wear that could prevent or restrict sliding of the sliding surfaces as intended in the design basis of the support. • Cracked or sheared bolts, including high-strength bolts, and anchors. f. Revise plant procedures to include the preventive action of using bolting material that has an actual measured yield strength less than 150 ksi, except in the case of like-for-like	A.1.22	Completed	LRA DTE letter NRC-15-0032 dated 4/17/15 DTE letter NRC-15-0044 dated 4/27/15

TABLE B-1 Fermi 2 License Renewal Commitments

Item Number	Commitment	FSAR Supplement Section/LRA Section	Enhancement or Implementation Schedule	Source
	replacement of existing bolting material in the reactor pressure vessel skirt to ring girder bolted joint. g. Revise plant procedures to include assessment of the impact on the inspection sample, in terms of sample size and representativeness, if components that are part of the sample population are re-worked.			
17	Enhance the Inspection of Overhead Heavy Load and Light Load (Related to Refueling) Handling Systems (OVHLL) Program as follows: a. Revise plant procedures to specify the monitoring of rails in the rail system for loss of material due to wear; monitor structural components of the bridge, trolley and hoists for deformation, cracking, and loss of material due to corrosion; and monitor structural connections/bolting for loose or missing bolts, nuts, pins, or rivets, and any other conditions indicative of loss of bolting integrity. b. Revise plant procedures to specify inspection frequency requirements will be in accordance with ASME B30.2 or other appropriate standard in the ASME B30 series. c. Revise plant procedures to require that significant loss of material due to wear of rails in the rail system and any sign of loss of bolting integrity will be evaluated in accordance with ASME B30.2 or other appropriate standard in the ASME B30 series. d. Revise plant procedures to specify that maintenance and repair activities will use the guidance provided in ASME B30.2 or other appropriate standard in the ASME B30 series.	A.1.23	Completed	LRA
18	Implement the new Internal Surfaces in Miscellaneous Piping and Ducting Components Program to manage fouling, cracking, loss of material, and change in material properties using representative sampling and opportunistic visual inspections of the internal surfaces of piping and components in environments other than open-cycle cooling water, closed treated water, and fire water. Program periodic surveillances or maintenance activities will be conducted when the surfaces are accessible for visual inspection.	A.1.24	Prior to September 20, 2024.	LRA

TABLE B-1 Fermi 2 License Renewal Commitments

Item Number	Commitment	FSAR Supplement Section/LRA Section	Enhancement or Implementation Schedule	Source
19	Implement the new Metal Enclosed Bus Inspection Program to provide for the inspection of the internal and external portions of metal enclosed bus to identify age-related degradation of the bus and bus connections, the bus enclosure assemblies, the bus insulation and the bus insulators.	A.1.26	Completed	LRA
20	Enhance Neutron-Absorbing Material Monitoring Program as follows: a. Prior to the period of extended operation, revise Neutron-Absorbing Material Monitoring Program procedures to establish an inspection frequency, justified with plant-specific operating experience, of at least once every 10 years, based on the condition of the neutron-absorbing material. b. Revise Neutron-Absorbing Material Monitoring Program procedures to perform trending of coupon testing results to determine the rate of degradation. Ensure the predicted boron-10 areal density will be sufficient to maintain the subcritical conditions required by technical specifications until the next coupon test.	A.1.27	Prior to September 20, 2024.	LRA
21	Implement the new Non-EQ Cable Connections Program, a one-time inspection program that consists of a representative sample of electrical connections within the scope of license renewal, which is inspected or tested at least once prior to the period of extended operation to confirm that there are no aging effects requiring management during that period. Cable connections included in this program are those connections susceptible to age-related degradation resulting in in-creased resistance of connection due to thermal cycling, ohmic heating, electrical transients, vibration, chemical contamination, corrosion, or oxidation that are not subject to the environmental qualification requirements of 10 CFR 50.49.	A.1.28	Completed	LRA
22	Implement the new Non-EQ Inaccessible Power Cables (400 V to 13.8 kV) Program, a condition monitoring program that will manage the aging effect of reduced insulation resistance on inaccessible power (400 V to 13.8 kV) cables that have a license renewal intended function. The program calls for inaccessible or underground (e.g., in conduit, duct bank, or direct buried) power (greater than or equal to 400 V) cables exposed to significant moisture, to be tested at least once every 6 years to provide an indication of the condition of the conductor insulation, with	A.1.29	Prior to September 20, 2024, or the end of the last refueling outage prior to March 20, 2025, whichever is later.	LRA

TABLE B-1 Fermi 2 License Renewal Commitments

Item Number	Commitment	FSAR Supplement Section/LRA Section	Enhancement or Implementation Schedule	Source
	the first tests occurring before the period of extended operation. The program will include periodic inspections for water accumulation in manholes within the scope of this program.			
23	Implement the new Non-EQ Instrumentation Circuits Test Review Program, a performance monitoring program that will manage the aging effects of applicable cables in the following systems or sub-systems. • Neutron monitoring - Intermediate range channels (IRM) - Average power range monitors (includes local power range monitors [LPRM] detector strings) • Process radiation monitoring - Control center emergency air inlet radiation monitors - Fuel pool ventilation exhaust radiation monitors - Main steam line radiation monitors The Non-EQ Instrumentation Circuits Test Review Program calls for the review of calibration results or findings of surveillance tests on electrical cables and connections used in circuits with sensitive, high-voltage, low-level current signals, such as radiation monitoring and nuclear instrumentation, to provide an indication of the existence of aging effects based on acceptance criteria related to instrumentation circuit performance. The review of calibration results or findings of surveillance tests is performed at least once every 10 years. In cases where cables are not included as part of calibration or surveillance program testing circuit, a proven cable test (such as insulation resistance tests, time domain reflectometry tests, or other testing judged to be effective in determining cable system insulation condition as justified in the application) is performed. The test frequency is based on engineering evaluation and is at least once every 10 years.	A.1.30	Prior to September 20, 2024, or the end of the last refueling outage prior to March 20, 2025, whichever is later.	LRA
24	Implement the new Non-EQ Insulated Cables and Connections Program, a condition monitoring program that provides reasonable assurance that the intended functions of insulated cables and connections exposed to adverse localized environments caused by heat, radiation, moisture, and chemical contamination (i.e., bird droppings) can be maintained consistent with the current licensing basis through the period of extended operation. The program consists of accessible insulated electrical cables	A.1.31	Prior to September 20, 2024, or the end of the last refueling outage prior to March 20, 2025, whichever is later.	LRA DTE letter NRC-15-0056 dated 5/19/15

TABLE B-1 Fermi 2 License Renewal Commitments

Item Number	Commitment	FSAR Supplement Section/LRA Section	Enhancement or Implementation Schedule	Source
	and connections installed in adverse localized environments to be visually inspected at least once every 10 years.			
25	Enhance the Oil Analysis Program as follows: a. Revise Oil Analysis Program procedures to identify components within the scope of the program. b. Revise Oil Analysis Program procedures to provide a formalized analysis technique for particulate counting. c. Revise Oil Analysis Program procedures to include the sampling and testing requirements of equipment manufacturers or industry standards.	A.1.32	Prior to September 20, 2024.	LRA
26	Implement the new One-Time Inspection Program that will consist of a one-time inspection of selected components to accomplish the following: • Verify the effectiveness of an aging management program that is designed to prevent or minimize aging to the extent that it will not cause the loss of intended function during the period of extended operation. The aging effects evaluated are loss of material, cracking, and fouling. • Confirm the insignificance of an aging effect for situations in which additional confirmation is appropriate using inspections that verify degradation is not occurring. • Trigger additional actions that ensure the intended functions of affected components are maintained during the period of extended operation.	A.1.33	Inspections will be performed within the 10 years prior to March 20, 2025.	LRA
27	Implement the new One-Time Inspection – Small-Bore Piping Program that will augment ASME Code, Section XI (2001 Edition with 2003 Addenda) requirements and be applicable to small-bore ASME Code Class 1 piping and components with a nominal pipe size diameter less than 4 inches (NPS 4) and greater than or equal to 1 inch (NPS 1) in systems that have not experienced cracking of ASME Code Class 1 small-bore piping.	A.1.34	The inspection will be performed within the 6-year period prior to March 20, 2025.	LRA
28	Enhance the Periodic Surveillance and Preventive Maintenance Program as follows:	A.1.35	Prior to	LRA

TABLE B-1 Fermi 2 License Renewal Commitments

Item Number	Commitment	FSAR Supplement Section/LRA Section	Enhancement or Implementation Schedule	Source
	a. Revise the Periodic Surveillance and Preventive Maintenance Program procedures as necessary to incorporate the identified activities in LRA Section A.1.35. b. Revise the Periodic Surveillance and Preventive Maintenance Program procedures to state that acceptance criterion is no indication of relevant degradation and to incorporate the following: • Examples of acceptance criteria for metallic components - No excessive corrosion (loss of material) - No leakage from or onto internal surfaces (loss of material) - No excessive wear (loss of material) - No flow blockage due to fouling - No loss of piping component structural integrity • Examples of acceptance criteria for elastomeric components - Flexible polymers should have a uniform surface texture and color with no cracks and no dimension change, no abnormal surface conditions with respect to hardness, flexibility, physical dimensions, and color. c. Revise Periodic Surveillance and Preventive Maintenance Program procedures to require periodic determination of wall thickness for selected piping components. d. Revise Periodic Surveillance and Preventive Maintenance Program procedures to require wall thickness measurements using ultrasonic testing (UT) or other suitable techniques at selected locations to be periodically performed to identify loss of material due to multiple corrosion mechanisms (MCM) in system piping components. The selected locations are based on pipe configuration, flow conditions, and operating history to represent a cross-section of potential MCM sites. The selected locations are periodically reviewed to validate their relevance and usefulness, and are modified accordingly. Prior		September 20, 2024. Initial inspection of cable spreading room dry piping will be performed within the 5 years prior to March 20, 2025.	DTE letter NRC-14-0051 dated 7/30/14 DTE letter NRC-15-0002 dated 1/15/15

TABLE B-1 Fermi 2 License Renewal Commitments

Item Number	Commitment	FSAR Supplement Section/LRA Section	Enhancement or Implementation Schedule	Source
	to the period of extended operation, select a method (or methods) from available technologies for inspecting internal surfaces of buried piping that provide(s) suitable indication of piping wall thickness for a representative set of buried piping locations. e. Revise Periodic Surveillance and Preventive Maintenance Program procedures to compare wall thickness measurements to nominal wall thickness or previous measurements to determine rates of corrosion degradation. Compare wall thickness measurements to code minimum wall thickness plus margin for corrosion during the refueling cycle (Tmarg) to determine acceptability of the component for continued use. Perform subsequent wall thickness measurements as needed for each selected location based on the rate of corrosion and expected time to reach Tmarg. Perform a minimum of five MCM degradation inspections per year until the rate of MCM corrosion occurrences no longer meets the criteria for recurring internal corrosion.			
29	Enhance the Protective Coating Monitoring and Maintenance Program as follows: a. Revise plant procedures to include in the program Service Level I coating applied to steel and concrete surfaces of the steel containment vessel (e.g., steel containment vessel shell, structural steel, supports, penetrations, and concrete walls and floors). b. Revise plant procedures to include information and instructions for monitoring Service Level I coating systems to be used for the inspection of coatings in accordance with guidelines identified in ASTM D5163-08. c. Revise plant procedures to specify the parameters monitored or inspected in accordance with subparagraph 10.2 of ASTM D5163-08. d. Revise plant procedures to establish the inspection frequency in accordance with paragraph 6 of ASTM D5163-08.	A.1.36	Prior to September 20, 2024	LRA

TABLE B-1 Fermi 2 License Renewal Commitments

Item Number	Commitment	FSAR Supplement Section/LRA Section	Enhancement or Implementation Schedule	Source
	e. Revise plant procedures to develop an inspection plan and specify inspection methods to be used as identified in accordance with subparagraph 10.1 of ASTM D5163-08. f. Revise plant procedures to specify that the nuclear coating specialist qualification recommendations and duties be as defined in ASTM D7108. As a minimum, qualification of inspection personnel (protective coating surveillance personnel) who perform these inspections shall be as specified in ASTM D4537. g. Revise plant procedures to specify a protective coatings program owner (inspection coordinator and inspection results evaluator) or equivalent to nuclear coating specialist defined in ASTM D5163-08, is responsible for the overall plant coatings program and has general duties and responsibilities similar to those defined for a nuclear coating specialist in Section 5 of ASTM D7108-05. h. Revise plant procedures to specify that detection of aging effects will include visual inspections of coatings near sumps or screens associated with the ECCS. i. Revise plant procedures to specify instruments and equipment needed for inspection in accordance with subparagraph 10.5 of ASTM D5163- 08. j. Revise plant procedures to specify that upon the completion of a planned refuel outage, a coatings outage summary report will be prepared of the coating work performed in Service Level I areas during the outage. The summary report prioritizes repair areas as areas that must be repaired during the same outage or postponed to future outages, keeping the coatings under surveillance during the interim period. k. Revise plant procedures to specify that the last two performance monitoring reports pertaining to the coating systems will be reviewed prior to the inspection or monitoring process.			

TABLE B-1 Fermi 2 License Renewal Commitments

Item Number	Commitment	FSAR Supplement Section/LRA Section	Enhancement or Implementation Schedule	Source
	l. Revise plant procedures to describe the characterization, documentation, and testing of defective or deficient coating surface in accordance with subparagraphs 10.2.1 through 10.2.6, 10.3, and10.4 of ASTM D5163-08. m. Revise plant procedures to specify that the coatings outage summary report will be evaluated and approved by the protective coatings program owner.			
30	Enhance the Reactor Head Closure Studs Program as follows: a. Revise Reactor Head Closure Studs Program procedures to ensure that replacement studs are fabricated from bolting material with actual measured yield strength of less than 150 kilopounds per square inch (ksi). b. Revise Reactor Head Closure Studs Program procedures to include a statement that excludes the use of molybdenum disulfide (MoS_2) on the reactor vessel closure studs and also refers to recommendations in Regulatory Guide 1.65, Rev. 1.	A.1.37	Completed	LRA
31	[Deleted]			LRA DTE letter NRC-15-0020 dated 3/5/15
32	Implement the new Selective Leaching Program that will demonstrate the absence of selective leaching in a selected sample of components (i.e., 20 percent of the population with maximum of 25 components) fabricated from gray cast iron and copper alloys (except for inhibited brass) that contain greater than 15 percent zinc or greater than 8 percent aluminum exposed to raw water, treated water, waste water, or soil.	A.1.40	Inspection will be performed within 5 years prior to March 20, 2025.	LRA
33	Enhance the Service Water Integrity Program as follows: a. Revise Service Water Integrity Program procedures to include inspection to determine if loss of material due to erosion is occurring in the system. b. Revise Service Water Integrity Program procedures to stipulate that administrative controls are in accordance	A.1.41	Completed	LRA

TABLE B-1 Fermi 2 License Renewal Commitments

Item Number	Commitment	FSAR Supplement Section/LRA Section	Enhancement or Implementation Schedule	Source
	with the Fermi 2 10 CFR Part 50 Appendix B Quality Assurance Program.			
34	Enhance the Structures Monitoring Program as follows: a. Revise plant procedures to add the following structures to the program. • CST and condensate return tank foundations and retaining barrier • CTG-11-1 fuel oil storage tank foundation • Independent spent fuel storage installation (ISFSI) rail transfer pad • Manholes, handholes, and duct banks • Shore barrier • Transformer and switchyard support structures and foundations b. Revise plant procedures to specify that the following in-scope structures are included in the RG 1.127, Inspection of Water-Control Structures Associated with Nuclear Power Plants Program (Section A.1.39): • General service water pump house • Residual heat removal complex • Shore barrier c. Revise plant procedures to ensure that masonry walls located in in-scope structures are in the scope of the Masonry Wall Program (Section A.1.25). d. Revise plant procedures to include a list of structural components and commodities within the scope of license renewal to be monitored in the program. e. Revise plant procedures to include periodic sampling and chemical analysis of groundwater. f. Revise plant procedures to include the following preventive actions: • Preventive actions delineated in NUREG-1339 and EPRI NP-5769, NP-5067, and TR-104213 that emphasize the proper selection of bolting material, installation torque or tension, and the use of lubricants and sealants for high-strength bolting.	A.1.42	Prior to September 20, 2024. Testing and evaluation for possible leaching in previously identified conditions will commence in 2015.	LRA DTE letter NRC-14-0070 dated 10/24/14 DTE letter NRC-14-0082 dated 12/26/14 DTE letter NRC-15-0008 dated 1/26/15 DTE letter NRC-15-0030 dated 3/19/15

TABLE B-1 Fermi 2 License Renewal Commitments

Item Number	Commitment	FSAR Supplement Section/LRA Section	Enhancement or Implementation Schedule	Source
	• Preventive actions for storage of ASTM A325 and A490 bolting from Section 2 of Research Council for Structural Connections publication, "Specification for Structural Joints Using ASTM A325 or A490 Bolts." g. Revise plant procedures to include the following parameters to be monitored or inspected: • For concrete structures, base inspections on quantitative requirements of industry codes (i.e., American Concrete Institute (ACI) 349.3R-02), standards and guidelines (i.e., American Society of Civil Engineers (ASCE) 11) and consideration of industry and plant-specific operating experience. • For concrete structures and components, include loss of material, loss of bond, increase in porosity and permeability, loss of strength, and reduction in concrete anchor capacity due to local concrete degradation. • For chemical analysis of groundwater, monitor pH, chlorides, and sulfates. • Monitor gaps between the structural steel supports and masonry walls that could potentially affect wall qualification. h. Revise plant procedures to include the following components to be monitored for the associated parameters: • Structural bolting and anchors/fasteners (nuts and bolts) for loss of material, loose or missing nuts and/or bolts, and cracking of concrete around the anchor bolts. • Elastomeric vibration isolators and structural sealants for cracking, loss of material, loss of sealing, and change in material properties (e.g., hardening). i. Revise plant procedures to provide technical guidance for torque value requirements for specified bolting material subject to plant operating environments. j. Revise plant procedures to include the following for detection of aging effects:			

TABLE B-1 Fermi 2 License Renewal Commitments

Item Number	Commitment	FSAR Supplement Section/LRA Section	Enhancement or Implementation Schedule	Source
	• Personnel (Inspection Engineer and Program Administrator or Responsible Engineer) involved with the inspection and evaluation of structures and structural components, including masonry walls and water-control structures, meet the qualifications guidance identified in ACI 349.3R-02. • Visual inspection of elastomeric material should be supplemented by feel or touch to detect hardening if performance of the intended function of the elastomeric material is suspect. Include instructions to augment the visual examination of elastomeric material with physical manipulation of at least 10 percent of available surface area. • Structures will be inspected at least once every 5 years. • Submerged structures will be inspected at least once every 5 years. • If normally inaccessible areas become accessible due to plant activities, an inspection of these areas shall be conducted. Additionally, inspections will be performed of inaccessible areas in environments where observed conditions in accessible areas indicate that significant degradation may be occurring in the inaccessible areas. • Sampling and chemical analysis of groundwater at least once every 5 years. The Structures Monitoring Program owner will review the results and evaluate any anomalies and perform trending of the results. • Masonry walls will be inspected at least once every 5 years, with provisions for more frequent inspections in areas where significant aging effects (e.g., missing blocks, cracking) is observed to ensure there is no loss of intended function between inspections. • Inspection of water-control structures should be conducted under the direction of qualified			

TABLE B-1 Fermi 2 License Renewal Commitments

Item Number	Commitment	FSAR Supplement Section/LRA Section	Enhancement or Implementation Schedule	Source
	personnel experienced in the investigation, design, construction, and operation of these types of facilities. • Inspections of water-control structures on an interval not to exceed 5 years. • Perform special inspections of water-control structures immediately (within 30 days) following the occurrence of significant natural phenomena, such as large floods, earthquakes, hurricanes, tornadoes, and intense local rainfalls. k. Revise plant procedures to prescribe quantitative acceptance criteria based on the quantitative acceptance criteria of ACI 349.3R-02 and information provided in industry codes, standards, and guidelines including ACI 318, American National Standards Institute (ANSI)/ASCE 11, and relevant AISC specifications. Industry and plant-specific operating experience will also be considered in the development of the acceptance criteria. l. Revise plant procedures to include acceptance criteria for masonry wall inspections that ensure observed aging effects (cracking, loss of material or gaps between the structural steel supports and masonry walls) do not invalidate the wall's evaluation basis or impact its intended function. m. Revise Structures Monitoring Program procedures to include testing and evaluation of water/mineral deposits where in-leakage is observed in concrete elements. Testing and evaluation will determine whether leaching of calcium hydroxide and carbonation are occurring that could impact the intended function(s) of the concrete structure. n. The following testing and evaluation will be performed prior to the period of extended operation to confirm that previously identified conditions are not the result of leaching of calcium hydroxide and carbonation that could impact the intended function(s) of the concrete structure.			

TABLE B-1 Fermi 2 License Renewal Commitments

Item Number	Commitment	FSAR Supplement Section/LRA Section	Enhancement or Implementation Schedule	Source
	• Available water/mineral deposit samples will be tested for mineral and iron content to assess the effect of the water in-leakage on the reinforced concrete elements involved. • The results of the testing and Structures Monitoring Program inspections will be used to determine corrective actions per the corrective action program. Possible corrective actions include, but are not limited to, more frequent inspections, sampling and analysis of the in-leakage water for mineral and iron content, testing core bore samples, and evaluation of the affected area using evaluation and acceptance criteria of ACI 349.3R-02.			
35	Enhance the Water Chemistry Control – Closed Treated Water Systems Program as follows: a. Revise the Water Chemistry Control – Closed Treated Water Systems Program procedures to include the following systems. • Process sampling system sample cooler loops • CCHVAC chill water system b. Revise the Water Chemistry Control – Closed Treated Water Systems Program procedures to provide chemical treatment, including a corrosion inhibitor for the following systems in accordance with industry guidelines and vendor recommendations. • Process sampling system sample cooler loops • CCHVAC chill water system c. Revise Water Chemistry Control – Closed Treated Water Systems Program procedures to specify water chemistry parameters monitored and the acceptable range of values for these parameters in accordance with EPRI Closed Cooling Water Chemistry Guideline, industry guidance, or vendor recommendations. d. Revise Water Chemistry Control – Closed Treated Water	A.1.44	Prior to September 20, 2024.	LRA DTE letter NRC-15-0030 dated 3/19/15

TABLE B-1 Fermi 2 License Renewal Commitments

Item Number	Commitment	FSAR Supplement Section/LRA Section	Enhancement or Implementation Schedule	Source
	Systems Program procedures to inspect accessible components whenever a closed treated water system boundary is opened. Ensure that a representative sample of piping and components is inspected at a frequency of at least once every 10 years. These inspections will be conducted in accordance with applicable ASME Code requirements, industry standards, or other plant-specific inspection guidance by qualified personnel using procedures that are capable of detecting corrosion, fouling, or cracking. If visual examination identifies adverse conditions, then additional examinations, including UT, are conducted. Components inspected will be those with the highest likelihood of corrosion, fouling, or cracking. A representative sample is 20 percent of the population (defined as components having the same material, environment, and aging effect combination) with a maximum of 25 components. Perform treated water sampling and analysis of the closed treated water systems per industry standards and in no case greater than quarterly unless justified with an additional analysis. The process sampling system sample cooler loops will be sampled and tested annually.			
36	Implement the Coating Integrity Program as described in LRA Section B.1.45.	A.1.45	Prior to September 20, 2024, or the end of the last refueling outage prior to March 20, 2025, whichever is later. Initial inspections will be performed within the 10 years prior to March 20, 2025.	DTE letter NRC-15-0021 dated 2/5/15
37	Enhance the BWR CRD Return Line Nozzle Program as follows:	A.1.5	Completed	DTE letter NRC-15-0056 dated 5/19/15

TABLE B-1 Fermi 2 License Renewal Commitments

Item Number	Commitment	FSAR Supplement Section/LRA Section	Enhancement or Implementation Schedule	Source
	a. Revise BWR CRD Return Line Nozzle Program procedures as necessary to ensure that UT examinations will be used to detect applicable aging effects.
