The recommended lengths for various values of δ and r are listed in Table 3.9-41. Also, a graph of r versus δ for various values of ℓ is given in Figure 3.9-24. In this analysis, nozzle movements are checked in three orthogonal directions.

The problem of pipe expansion can be handled in a similar manner, except that the movement, δ, is imposed by the expansion of a section of pipe.

As an example, the length of low-carbon steel (SA-106 grade B or equivalent) pipe required to accommodate the expansion of the length, ℓ', at 300°F is

$$\ell = 1.232\sqrt{\ell' r_o} \qquad (3.9\text{-}27)$$

where

ℓ' = expanding length of pipe, ft

ℓ = required offset, ft

r_o = outside radius of pipe, in.

Similar equations for both austenitic and ferritic steel at various design temperatures were developed. Values for different lengths and radii at several design temperatures for both austenitic and ferritic steels are listed in Table 3.9-42.

Where nozzle movement and pipe expansion can occur simultaneously, the sum of the lengths required for each is used as the total length of perpendicular pipe required.

3.9.3 Components Not Covered by the ASME Code

3.9.3.1 General

Safety-related mechanical components not covered by the ASME B&PV Code are identified in Table 3.9-43. The design codes for each principal component are identified and qualification methods for such equipment are summarized herein. This subsection specifically addresses (1) the details of the mechanical design and analytical procedures for the design of the fuel; (2) the methods and procedures used to determine the operability of the control rod drives and control rod insertability under LOCA and seismic loadings; and (3) mechanical and structural loading criteria for motors, the RCIC turbine, and active instrumentation designed to manufacturer's standards and design calculations.

3.9.3.2 Fuel Mechanical Design and Analytical Procedures

The fuel bundle performance history is specified by the cycle specific design reference fuel cycle as defined in Subsection 4.2.l. Performance of individual fuel rods is then determined from the fuel bundle performance history coupled with the exposure-dependent design, local and axial power, and exposure peaking factors. The most limiting fuel rods within the peak performance fuel bundle, with respect to power and exposure combination, are then analyzed to determine thermal and mechanical performance characteristics.

The performance of all fuel rods satisfies the requirements identified in Subsection 4.2.1. Satisfaction of these requirements for all fuel rods is demonstrated by analysis of the performance of the most limiting fuel rods, with respect to power and exposure level identified in the design reference fuel cycle.

Thermal design analyses performed include, but are not limited to, the determination of cladding (Zircaloy-2) and fuel (UO_2) temperatures, cladding and fuel thermal expansion, fuel irradiation swelling, and fuel fission gas generation and release as a function of time. Using these thermal analysis results, the mechanical design analyses are then performed to determine the most limiting cladding stress and/or strain due to such loadings as

a. Internal fuel rod pressure from gaseous fission product release to the fuel rod plenum plus initial fill gas

b. Differential fuel-cladding expansions

c. External coolant pressure

d. Flow-induced rod vibrations.

Finally, the limiting combinations of cladding stress in the categories summarized in Subsection 4.2.1 are identified and compared to the cladding design stress limits. All stresses are below the defined limits.

3.9.3.3 Control Rod Drive Operability and Control Rod Insertability Under LOCA and Seismic Loadings

In the event of a significant seismic disturbance and/or LOCA, only the rapid insertion mode (scram) is essential. Descriptions of the CRD and the CRD system operation during scram are presented in Subsection 4.5.2.2.

The hydraulic nature of the CRDs and their location relative to the reactor vessel provide scram operability that is insensitive to LOCA and seismic loadings. In addition, insertability of the control rods during seismic events is ensured by the generous control-rod-to-channel and control-rod-to-guide tube clearances. However, LOCA produces larger than normal pressure differentials across the reactor vessel internals, tending to reduce these clearances. These pressure differentials are considered in determining the insertability of the control rods.

The highest pressure differentials across the RPV internals occur as a result of a postulated steam line break. To ensure adequate control-rod-to-guide tube clearance, the guide tube must be capable of resisting the external to internal pressure difference without collapse. In addition, any increase of friction force due to channel bulging is shown to be small compared to the total force available to insert the control rods. The above are addressed in Subsections 4.2.2 and 4.2.3. The adequacy of the design margins of the control rod guides to prevent control tube collapse in the event of a main steam line break or recirculation line break (LOCA) was noted as a concern by the AEC in its Safety Evaluation Report on the Fermi 2 Construction Permit (Reference 11). The concern was identified as Post-Construction Permit Open Item No. 9. The Edison position on this open item was submitted to the AEC in May 1973 (Reference 12). The position was based on information supplied by GE and concluded that design margins of the control rod guide tubes were adequate and that no collapse under normal or abnormal conditions was expected. The AEC, after reviewing Reference 12, requested additional information in the form of five specific questions (Reference 13). Edison responded to these five questions on February 14, 1974 (Reference 14), and received AEC provisional approval to start construction by AEC letter dated June 25, 1974 (R. DeYoung to H. Tauber).

3.9.3.4 Mechanical and Structural Loading Criteria for Equipment Not Covered by ASME Code

For nonpressure-retaining equipment important to safety (i.e., motors, the RCIC turbine, and active instrumentation), the following criteria apply.

3.9.3.4.1 Reactor Core Isolation Cooling Turbine

The turbine mechanical and structural loading criteria are given in Table 3.9-35.

3.9.3.4.2 Motors, Motor Control Centers, Switchgear, and Diesel Generators

These components are designed to meet the support and structures criteria (Subsection 3.9.2.2.4.1) and provision for anchor bolts (Subsection 3.9.2.2.4.2) for the following.

Operating Conditions	Loads
Normal	Normal operating + dead weight
Upset	Normal operating + dead weight + OBE
Emergency and Faulted	Normal operating + dead weight + SSE

3.9.3.4.3 Air-Handling Equipment (Safety Related)

The following air-handling systems require equipment satisfying the requirements of this section:

a. Standby gas treatment train
   1. Exhaust fans
   2. Carbon dioxide tanks
   3. Decay heat removal fans
   4. Room cooling units.

b. Emergency equipment area cooling units
   1. ECCS pump room cooling units
   2. Switchgear room cooling units
   3. Emergency equipment cooling water (EECW) pump area cooling units
   4. Thermal recombiner area cooling units.

c. Control center air conditioning system (CCACS)
   1. Multizone unit
   2. Return air fans
   3. Chillers
   4. Chilled water pumps
   5. Equipment room cooling units
   6. Emergency makeup air filter
   7. Emergency recirculation air filter
   8. Emergency recirculation air filter fans.

The above equipment includes fans, housings, ducts, coils, dampers, drives, motors, and plenums (coils are ASME Section III items except for control center equipment room cooling units, and cooling coil in multizone unit). All associated safety-related components and accessories have been designed to Category I requirements.

These components have provisions for installation to meet support and structure criteria of Subsection 3.9.2.2.4.1 and provision for anchor bolts per Subsection 3.9.2.2.4.2. These components are located in Category I buildings and are supplied with electrical power sources and utility services (control air, water, and drains) of Category I classifications. In addition, the buildings provide flood, tornado, wind, missile, and dynamic effects of ruptured piping protection to the air-handling equipment.

3.9.4 Operability Assurance Program

3.9.4.1 General

Active mechanical equipment classified as Category I is designed to perform its function during the life of the plant under postulated plant conditions. Equipment with faulted-condition functional requirements includes active pumps and valves in fluid systems, such as the RHR system, core spray system, and the HPCI and RCIC systems. Operability has been ensured by a series of comprehensive preoperational tests.

Certain Category I valves and pumps were procured before Branch Technical Position MEB position papers concerning operability assurance (References 15 through 18) were available. The codes that were used in the procurement of these components are given in Tables 3.2-2 and 3.2-3. Table 3.9-44 provides a comparison of the Fermi 2 operability assurance program criteria to those provided in NRC Standard Review Plan 3.9.3.

3.9.4.2 ASME Code Class Valves

Safety-related active valves perform their mechanical motion in times of an accident. Assurance is therefore required that these valves will operate during a seismic event. Qualification tests accompanied by analyses have been conducted for all active valves in the GE scope-of-supply.

All other safety-related code Class 1, 2, and 3 active valves equipped with motor operators have been operationally qualified by a combination of test and analysis. Prototype tests have been performed for motor operators situated inside the primary containment and the steam tunnel and subjected to faulted environmental conditions associated with a LOCA. These tests are essentially consistent with the guidelines of IEEE-382, l972. The specific conditions are as follows.

Conditions	Test Results
Seismic operational capability	Up to 5.0g (two planes)
Radiation environment	2 x 10^8 rad
Pressure-temperature environment	IEEE-382, BWR profile
Humidity	100 percent steam atmosphere

Motor-operated active valves located outside the primary containment are equipped with identical motor operators, except that motor insulation is Class B NEMA rated for 130°C service and 100 percent humidity. The operability of the motor valve assembly is ensured by analytical methods.

Each valve type and size has been analyzed, as described in sections 3.9.1 and 3.9.2, to ensure that design loads do not render the valve inoperative. In addition, the below-described preservice and inservice testing is conducted.

The safety-related valves are subject to a series of stringent tests prior to service and during the plant life. Prior to installation, the following tests are performed: shell hydrostatic test to code requirements, backseat and main seat leakage tests, disk hydrostatic test, functional tests to verify that the valve will open and close within the specified time limits when subjected to the design differential pressure, and operability qualification of valve actuators.

Cold hydro-qualification tests, hot functional qualification tests, and periodic inservice operation are performed in situ to verify and ensure the functional ability of the valve. These tests and appropriate maintenance ensure operability of the valve for the design life of the plant.

Valves that are safety related, but can be classified as not having an overhanging structure, such as check valves and safety/ relief valves, are considered separately.

Because of the particularly simple characteristics of the check valves, they are qualified by a combination of the following tests and analysis:

a. Stress analysis including the seismic loads where applicable
b. In-shop hydrostatic test
c. In-shop seat leakage test
d. Periodic in-situ valve exercising and inspection, as applicable, to ensure the functional capability of the valve.

Safety/relief valves are also subjected to tests and analyses similar to check valves. These consist of stress analyses including the seismic loads, in-shop hydrostatic seat leakage, and performance tests. In addition to these tests, periodic in-situ valve inspection, as applicable and periodic valve removal, refurbishment, performance testing, and reinstallation are performed to ensure the functional capability of the valve (Technical Specifications).

During a seismic event, it is anticipated that the seismic accelerations imposed upon the valve may cause it to open momentarily and discharge under system conditions which otherwise would not result in valve opening.

Using the methods described, all the safety-related valves in the systems are qualified for operability during a seismic event. These analytical methods conservatively simulate the seismic event and ensure that the active valves will perform their safety-related function when necessary.

3.9.4.3 ASME Code Class Pumps

No active pumps are located inside the primary containment. Those active pumps located in the secondary containment and subject to adverse environmental conditions as a result of high- energy and moderate-energy pipe breaks outside the primary containment are discussed in Section 3.6.

All active pumps are qualified for operability by first being subjected to extensive tests, both prior to installation in the plant and after installation in the plant. The in-shop tests include the following:

a. Hydrostatic tests of pressure-retaining parts to 1.25 times the design pressure times the ratio of material allowable stress at the test temperature to the allowable stress value at the design temperature

b. Seal leakage tests

c. Performance tests, while the pump is operated with flow, to determine total developed head, minimum and maximum head, net positive suction head (NPSH) requirements, and other pump/motor parameters.

After the pump is installed in the plant, it undergoes the cold hydro-tests, functional tests, and the required periodic inservice inspection and operational tests. These tests demonstrate reliability of the pump for the design life of the plant.

In addition to these tests, the safety-related active pumps have been analyzed for operability during a seismic condition by ensuring that the pump will not be damaged during the seismic event, and the pump will continue operating despite the seismic loads. Performing these analyses, with the conservative loads stated and with the restrictive stress limits discussed in Subsection 3.9.2 as allowables, will ensure that critical parts of the pump will not be damaged during the seismic condition. Therefore, the reliability of the pump for postseismic-condition operation will not be impaired by the seismic event.

The pump/motor rotor combination is designed to rotate at a constant speed under all conditions. Because of the high rotary inertia in the operating pump rotor, and the nature of the random short duration loading characteristics of the seismic event, the seismic loading will cause only a slight increase in the torque necessary to drive the pump at the constant design speed.

Furthermore, a generic analysis was performed for motor-driven, vertically mounted RHR and core spray pump motor assemblies to determine shaft and rotor deflections associated with the SSE forces, and to assess the operability of rotating equipment during a seismic event. The results show negligible effect for perpendicular and axial rotor loads equivalent to l.5g static acceleration, which is significantly higher than the resonance equipment response peak of the applicable Fermi 2 floor response spectrum.

The HPCI pump is also analyzed, but because of its rigidity, the analysis of deflections is limited to alignment with the driver.

The functional ability of active pumps after a seismic condition is ensured, since only normal operating loads and steady-state nozzle loads exist. Since it is demonstrated that the pumps would not be damaged during the faulted condition, the postseismic-condition operating loads will be no worse than the normal plant operating limits. This is ensured by requiring that the imposed nozzle loads (steady-state loads) for normal conditions and postseismic conditions are limited by the magnitudes of the normal condition nozzle loads.

NOTES:

a. System Code Class

Notations for principal construction codes are

III-1, 2, 3 - ASME Boiler and Pressure Code Section III, Class 1, 2, or 3

B31.7-1 - ANSI Nuclear Power Piping Code Class I

B31.1.0 - ANSI B31.1.0 Standard Code for Pressure Piping, Power Piping.

b. Levels of Testing - The designations in this table refer to the following specific paragraphs:

Type A: Visual Monitoring – The vibration surveys conducted will visually monitor deflections of selected points. Acceptable vibratory response of the overall system will be verified also. The vibration testing will be performed during:

A.1 – Preoperational test phase

A.2 – Startup test phase

Type B: Thermal Expansion

X – Observation or recording of the thermal expansion movements of key points on the piping will be made during startup test phase. Testing will be conducted during both heatup and cooldown phases of system operation.

c. That portion of EECWS piping between the outboard isolation valves and components inside primary containment is ASME Section III, Class 2.

Type C: Vibration Measurement - Acceptable overall vibratory response of the system will be verified. The vibration surveys conducted will entail the following:

TABLE 3.9-1 VIBRATION AND DYNAMIC EFFECTS TEST PROGRAM SYSTEMS TEST LEVEL MATRIX

C.1 – Steady-state vibration measurement, using mechanical devices, of maximum deflection at selected points during the startup test phase

C.2 – Measurement, using mechanical devices and remote recording devices, of vibration and deflection at selected main steam SRV discharge line

C.3 – Measurement of the piping system vibration and structural deflection, and piping system transient pressure levels and forces at selected points on the piping system, will be conducted during startup test phase transient tests

C.4 – Measurement of the piping system transient vibration and structural deflection and piping system transient pressure levels and forces at selected points on the piping system will be conducted during an inadvertent turbine trip after the startup test program is completed.

Type D: Rotating Equipment Vibration Testing

X – Baseline vibration data will be obtained for the rotating equipment associated with this piping. See Subsection 3.9.1.1.2 for an inclusive list of the rotating equipment that will be tested.

Top of shield wall	64	92.82	194.09	64.30	110.67

NOTES:

(a) Refer to Figure 3.9-3 for node number.

(b) Combine pressure and jet load from 12” recirculation line break.

TABLE 3.9-7 RPV INTERNALS ANALYSIS SUMMARY

	Stress (ksi)	
	Calculated	Allowable
Core support weld	11.414	20.28
Shroud buckling	4.82	12.497
Top guide	12.30	20.28
Jet pump	53.38	60.84
Head spray nozzle[b]	18.73	63.0
Core ΔP line	42.82	50.70
Fuel assembly (acceleration)	1.04g	3.12g[a]

[a] This is the design-basis acceleration rather than the allowable limit.

[b] Head spray piping is no longer attached to the reactor pressure vessel. Calculated stress value in this table is conservative.

TABLE 3.9-8 RPV EQUIPMENT ANALYSIS SUMMARY

Component		Stress (ksi) Calculated[a]	Allowable
RPV support (ring girder)	tension	94.0	125.0
	shear	18.01	33.4
RPV stabilizer	bending	21.16	36.0
	shear	6.3	21.5
CRD housing		13.15	20.0
Control rod guide tube		5.7	25.4

[a] The stress reported here is the highest of the dynamic load evaluation or the original design basis.

TABLE 3.9-9 RPV SUPPORT EQUIPMENT ANALYSIS SUMMARY

	Design	Calculated	Allowable
Shroud support (primary local plus bending)	16.2 ksi	53.9 ksi	55.9 ksi
Vessel skirt	23.6 ksi	14.5 ksi	a
Vessel stabilizer bracket	45.6 ksi	<45.6 ksi[b]	63.45 ksi

[a] Not calculated because the original design load produces a stress that is lower than the emergency allowable (28.7 ksi).

[b] Actual stress was not calculated because the calculated new load is lower than the original design load.

TABLE 3.9-10 RESULTS FOR REACTOR PRESSURE VESSEL AND INTERNALS

Shroud Support Gusseted Plate and Cylinder[a,b]

Criteria	Loading	Primary Stress Type	Allowable Stress (psi)	Calculated Stress (psi)
ASME B&PV Code Sec. III Primary Stress Limit for SB-168:				
For design condition: S_m = 23,300 psi 1.5 S_m = 35,000 psi	Design mechanical loads ≥ following: Normal and upset condition load 1. Dead weight 2. Design earthquake (operating-basis earthquake) 3. Design pressure differential	General membrane $P_L + P_B$	23,300 35,000	2900 23,500
For emergency condition: 1.2 S_m= 28,000 psi	Emergency-condition loads 1. Dead weight 2. Maximum credible earthquake (design-basis earthquake) 3. Normal pressure differential	General membrane $P_L + P_B$	28,000 42,100	4300 33,900
For faulted condition:[c]	Faulted-condition loads 1. Dead weight 2. Maximum credible earthquake 3. Pressure drop across core support plate due to LOCA blowdown	General membrane	c	4800[b] 39,600[b]

TABLE 3.9-10 RESULTS FOR REACTOR PRESSURE VESSEL AND INTERNALS

Vessel Support Skirt

Criteria	Loading	Primary Stress Type	Allowable Stress (psi)	Calculated Stress (psi)
ASME B&PVC Code Sec. III Primary Stress Limit for SA-516 Grade 70:				
For design condition: S_m = 19,150 psi	Design mechanical loads ≥ following: Normal- and upset-condition loads 1. Dead weight 2. Design earthquake (operating-basis earthquake)	General membrane	19,150	12,500
For emergency condition: S_y = 30,750 psi	Emergency-condition loads 1. Dead weight 2. Maximum credible earth- quake (design-basis earthquake)	General membrane	30,750	20,900
For faulted condition[c]	Faulted condition loads 1. Dead weight 2. Maximum credible earthquake 3. Jet reaction forces	General membrane	c	23,700[c]

TABLE 3.9-10 RESULTS FOR REACTOR PRESSURE VESSEL AND INTERNALS

Stabilizer Bracket-Adjacent Shell

Criteria	Loading	Primary Stress Type	Allowable Stress (psi)	Calculated Stress (psi)
ASME B&PV Code Sec. III Primary Local Membrane Plus Primary Bending Limit for SA-533 Grade B, Class I:				
For design condition: S_m = 26,700 1.5 x 26,700 = 40,050	Normal and upset condition load	General membrane Local membrane plus bending	26,700 40,050	26,500 28,400
	1. Design earthquake (operating-basis earthquake) 2. Design pressure			
For emergency condition: S_y = 42,600 1.5 S_y = 64,000	Emergency condition load	General membrane Local membrane plus bending	42,600 64,000	28,600 46,000
	1. Maximum credible earthquake (design earthquake) 2. Design pressure			
For faulted condition[c]:	Faulted-condition load	Local membrane plus bending	c c	26,500[c] 24,600[c]
	1. Maximum credible earthquake (design-basis earthquake) 2. Jet reaction forces 3. Design pressure			

[a] Gusseted support plate segments are sufficiently stiff that stability (buckling) would not be a predicted failure mode with increasing overturning (seismic) moment.

[b] Symbols are as defined in the ASME B&PV Code.

[c] Since the calculated stress for the faulted condition is less than the allowable stress for the emergency condition, and the allowable stress for the faulted condition is greater than the allowable stress for the emergency condition, the faulted allowable was not calculated.

TABLE 3.9-11 ACCELERATION (g) FOR FUEL ASSEMBLY

Node*	PR	JR	SSE	$(PR^2 + SSE^2 + JR^2)^{1/2}$	Design Basis
1 (top)	0.39	0.46	0.44	0.75	1.30
3	0.33	0.38	0.50	0.71	1.90
4	0.23	0.32	0.70	0.80	2.70
5	0.37	0.21	0.78	0.89	3.12
6	0.22	0.37	0.67	0.80	2.54
7	0.42	0.57	0.58	0.92	1.68
8	0.42	0.86	0.46	1.06	1.08

* See Figure 3.9-3.

TABLE 3.9-12 FUEL ASSEMBLY (INCLUDING CHANNEL)[a]

Acceptance Criteria	Loading	Primary Load Type	Calculated Peak Acceleration	Evaluation Basis Acceleration
Acceleration envelope	Horizontal direction	Horizontal acceleration profile	1.5 g	b
	1. Peak pressure 2. Safe-shutdown earthquake 3. Annulus pressurization			
	Vertical direction	Vertical accelerations	1.4 g	b
	1. Peak pressure 2. Safe-shutdown earthquake 3. Annulus pressurization			

[a] From an assessment comparing bounding limits (net holddown forces) to those for other BWR-4 plants already analyzed, a screening calculation was performed for Fermi 2. According to this analysis, Fermi 2 would experience virtually no fuel movement.

[b] Evaluation-basis accelerations and evaluations are contained in NPDE-21175-3-P.

TABLE 3.9-13 REACTOR PRESSURE VESSEL SUPPORT EQUIPMENT

Criteria	Loading	Location	Allowable Stress (psi)	Calculated Stress (psi)
RPV stabilizer Primary stress limit				
AISC specification for the construction, fabrication, and erection of structural steel for buildings	Upset condition 1. Spring preload 2. Operating-basis earthquake	Rod	90,000	f_{b+t} = 82,000[a]
		Bracket	22,000 14,000	f_b = 9200 f_v = 2730
For normal and upset conditions AISC allowable stresses, but without the usual increase for earthquake loads				
For emergency conditions 1.5 x AISC allowable stresses	Emergency condition 1. Spring preload 2. Design-basis earthquake	Bracket	33,000 21,000	f_b = 18,400 f_v = 5460
For faulted conditions Material yield strength	Faulted condition 1. Spring preload 2. Design-basis earthquake 3. Jet reaction load	Bracket	36,000 21,500	f_b = 21,160 f_v = 6300
RPV support (ring girder) Primary stress limit				
AISC specification for the design, fabrication, and erection of structural steel for buildings	Normal and upset condition 1. Dead loads 2. Operating-basis earthquake 3. Loads due to scram	Top flange	22,000	f_b = 10,000
		Bottom flange	22,000	f_b = 10,000
		Vessel to girder bolts	54,000 20,000	f_t = 35,200 f_v = 4450
For normal and upset conditions AISC allowable stresses, but without the usual increase for earthquake loads				
For emergency conditions 1.5 x AISC allowable stresses	Emergency condition 1. Dead loads 2. Design-basis earthquake 3. Loads due to scram	Top flange	33,000	f_b = 22,000
		Bottom flange	33,000	f_b = 20,000
		Vessel to girder bolts	81,000 30,000	f_t = 70,400 f_v = 8900
For faulted conditions 1.67 x AISC allowable stresses for structural steel members. Yield strength bolts (vessel to ring girder)	Faulted condition 1. Dead loads 2. Design-basis earthquake 3. Jet reaction load	Top flange	36,800	f_b = 28,000
		Bottom flange	36,800	f_b = 23,400
		Vessel to girder bolts	125,000 33,400	f_t = 94,000 f_v = 18,010

TABLE 3.9-13 REACTOR PRESSURE VESSEL SUPPORT EQUIPMENT

Criteria	Loading	Location	Allowable Stress (psi)	Calculated Stress (psi)
CRD housing support Primary stress limit				
AISC specification for the design, fabrication, and erection of structural steel for buildings	Faulted condition loads	Beams (top cord)	33,000 33,000	f_a = 12,200 f_b = 16,500
	1. Dead weight	Beams (bottom cord)	33,000 33,000	f_a = 10,300 f_b = 11,700
	2. Impact force from failure of a CRD housing	Grid structure	41,500 27,500	f_b = 40,700 f_v = 12,500
For normal and upset conditions $f_a = 0.60\ f_y$ (tension) $f_b = 0.60\ f_y$ (bending) $f_v = 0.40\ f_y$ (shear) For faulted conditions f_a limit = 1.5 f_a (tension) f_b limit = 1.5 f_b (bending) f_v limit = 1.5 f_v (shear) f_y = Material yield strength	(Dead weights and earthquake loads are very small as compared to jet force)			

[a] The ratio max. stress/stress limit is highest for upset loading conditions.

TABLE 3.9-14 REACTOR PRESSURE VESSEL INTERNALS AND ASSOCIATED EQUIPMENT

Criteria	Loading	Primary Stress Type	Allowable Stress (psi)	Calculated Stress (psi)
Top guide - highest stressed beam				
Primary stress limit - The allowable primary membrane stress plus bending stress is based on ASME B&PV Code Sec. III for type 304 stainless steel plate				
For normal and upset condition Stress Intensity SA = 1.5 S_m = 1.5 x 16,900 psi = 25,350 psi	Normal and upset - condition loads 1. Operating-basis earthquake 2. Weight of structure	General membrane plus bending	25,350	12,820
For emergency condition: S_{limit} = 1.5 S_A = 1.5 x 25,350 = 38,025 psi	Emergency condition loads 1. Design-basis earthquake 2. Weight of structure	General membrane plus bending	38,025	12,220
For faulted condition: S_{limit} = 2 S_A = 2 x 25,350 = 50,700 psi	Faulted-condition loads (same as emergency condition)	General membrane plus bending	50,700	20,250
Top guide beam end connections				
Primary stress limit - ASME B&PV Code Sec. III, defines material stress limit for type 304 stainless steel				
For normal and upset condition Stress Intensity S_A = 0.6 S_m = 0.6 x 16,900 psi = 10,140 psi	Normal and upset-condition loads 1. Operating-basis earthquake 2. Weight of structure	Pure shear	10,140	4,500
For emergency condition: S_{limit} = 1.5 S_A = 1.5 x 10,140 psi = 15,210 psi	Emergency-condition loads 1. Design-basis earthquake 2. Weight of structure	Pure shear	15,210	4,400
For faulted condition: S_{limit} = 2 S_A = 2 x 10,140 psi = 20,280 psi	Faulted-condition loads (same as emergency condition)	Pure shear	20,280	12,300

TABLE 3.9-14 REACTOR PRESSURE VESSEL INTERNALS AND ASSOCIATED EQUIPMENT

Criteria	Loading	Primary Stress Type	Allowable Stress (psi)	Calculated Stress (psi)
Top guide aligners				
Primary stress limit - The allowable primary membrane stress plus bending stress is based on ASME B&PV Code Sec. III for type 304 stainless steel plate				
For normal and upset condition Stress Intensity $S_A = 1.5\ S_m = 1.5 \times 16{,}900$ psi = 25,350 psi	Normal and upset-condition loads 1. Operating-basis earthquake 2. Weight of structure	General membrane plus bending	25,350	0[a]
For emergency condition: $S_{limit} = 1.5\ S_A = 1.5 \times 25{,}350 = 38{,}025$	Emergency-condition loads 1. Design-basis earthquake 2. Weight of structure	General membrane plus bending	38,025	0[a]
For faulted condition: $S_{limit} = 2\ S_A = 2 \times 25{,}350 = 50{,}700$ psi	Faulted-condition loads (same as emergency condition)	General membrane plus bending	50,700	0[a]
Core support			Allowable ΔP	Calculated ΔP
	Normal and upset-condition loads 1. Normal operation pressure drop 2. Operating-basis earthquake		27	18.9
For allowable stresses see top guide, longest beam, above	Emergency condition loads 1. Normal operation pressure drop 2. Design-basis earthquake		40.5	20.6

TABLE 3.9-14 REACTOR PRESSURE VESSEL INTERNALS AND ASSOCIATED EQUIPMENT

Criteria	Loading	Primary Stress Type	Allowable Stress (psi)	Calculated Stress (psi)
	Faulted-condition loads 1. Pressure drop after recirculation line rupture 2. Design-basis earthquake		54	27.7
Core support aligners				
Primary stress limit - ASME B&PV Code Sec. III, defines material stress limit for type 304 stainless steel	Normal and upset-condition loads 1. Operating-basis earthquake 2. Normal operation pressure drop	Pure Shear	10,155	0[b]
For allowable shear stresses, see top guide beam end connections, above	Emergency condition load 1. Design-basis earthquake 2. Normal operation pressure drop	Pure shear	15,232	0[b]
	Faulted condition load 1. Design-basis earthquake 2. Steam line rupture	Pure Shear	20,310	0[b]
Control rod drive housing				
Primary stress limit - The allowable primary membrane stress is based on ASME B&PV Code Sec. III, for Class I vessels, for type 304 stainless steel	Normal and upset-condition loads 1. Design pressure 2. Stuck rod scram loads 3. Operating-basis earthquake with housing lateral support installed	Maximum membrane stress intensity occurs at the tube-to-tube weld near the center of the housing for normal, upset and emergency conditions	16,660	13,150
For normal and upset condition S_m = 16,600 psi at 575°F				

TABLE 3.9-14 REACTOR PRESSURE VESSEL INTERNALS AND ASSOCIATED EQUIPMENT

Criteria	Loading	Primary Stress Type	Allowable Stress (psi)	Calculated Stress (psi)
For emergency conditions: S_{limit} = 1.2 S_m = 1.2 x 16,660 = 20,000 psi	Emergency condition loads 1. Design pressure 2. Stuck rod scram loads 3. Design-basis earthquake, with support installed		20,000	13,150
Control rod drive Primary stress limit - The allowable primary membrane stress plus bending stress is based on ASME B&PV Code	Normal and upset condition loads. Maximum hydraulic pressure from the control rod drive supply pump[c]	Maximum stress intensity occurs at a point on the Y-Y axis of the indicator tube	25,860	20,790
For normal and upset condition S_A = 1.5 S_m = 1.5 x 17,238 = 25,860 psi				
Control rod guide tube Primary stress limit- The allowable primary membrane stress plus bending stress is based on ASME B&PV Code Sec. III for type 304 stainless steel tubing				
For normal and upset conditions S_m = 16,925 psi				
For faulted condition: S_{limit} = 1.5 S_m = 1.5 x 16,295 = 25,400 psi	Faulted condition loads 1. Dead weight 2. Pressure drop across guide tube due to failure of steam line	The maximum bending stress under faulted loading conditions occurs at the center of the guide tube	25,400	5,701
In-core housing Primary stress limit- The allowable primary membrane stress is based on ASME B&PV Code Sec. III for Class 1 vessels for type 304 stainless steel				
For normal and upset conditions: S_m = 16,660 psi at 575°F				

TABLE 3.9-14 REACTOR PRESSURE VESSEL INTERNALS AND ASSOCIATED EQUIPMENT

Criteria	Loading	Primary Stress Type	Allowable Stress (psi)	Calculated Stress (psi)
For emergency condition: S_{limit} = 1.2 S_m = 1.2 x 16,600 = 20,000 psi	Emergency condition loads 1. Design pressure 2. Design-basis earthquake	Maximum membrane stress intensity occurs at the outer surface of the vessel penetration	20,000	15,290

[a] Thirty-two wedges that will resist the horizontal seismic top guide shear load are installed in the annulus between the top guide and shroud. Therefore there is no load on the top guide aligners

[b] The friction force between core support and core support flange due to the preload of the studs is greater than the shear load induced by the specified earthquake.

[c] Accident conditions do not increase this loading. Earthquake loads are negligible.

TABLE 3.9-15 INITIAL FUEL LOAD 100 MIL FUEL CHANNELS

Criteria	Loading	Primary Stress Type	Moment Limit Accounting for Pressure Loads (in.-lb)	Maximum Moment (in.-lb)
Fuel channels				
Primary stress limit – Design stress intensity S_m for zircaloy determined according to methods recommended by ASME B&PV Code Sec. III. Allowable moment determined by calculating limit moment, then applying SFmin for applicable loading conditions	Normal and upset condition load 1. Operating-basis earthquake 2. Normal pressure load	Membrane and bending	35,000	9550
(S = 9,000 psi; 1.5 S_m = 13,500 psi) (1.5 S_m = Allowable Stress)	Faulted condition load 1. Design-basis earthquake 2. Loss-of-coolant accident pressure	Membrane and bending	68,000	15,850

TABLE 3.9-17 MAIN STEAM ISOLATION VALVES

Criteria	Method of Analysis	Allowable Stress (psi), Minimum Thickness (in.), or Minimum Area (in.^{2})	Calculated Stress (psi), Actual Thickness (in.) or Minimum Area (in.^{2})
Design of Pressure-Retaining Parts	All references are made to ASME Code for Pumps and Valves for Nuclear Power, dated November 1968. Reference the same code for explanation of the symbols used.		
Body Minimum Wall Thickness	Reference Article 452.1b(2), Nonstandard Pressure - Rated Valve, Table NB 451.4 For design condition of 1,250 psig and 575°F The primary service rating = 655 lb, based on a core diameter of 23 in. t_m= 1.925 in. (including a corrosion allowance of 0.12 in.)	1.925 in.	1.9375 in.
Body Shape Rules	Reference Article 452.2, Body Shape Rules		
Radius of Crotch	Reference Article 452.2a(1), Radius of Crotch Criterion: $r_2 > 0.3$ tm; $r_2 = 1.0$ in., $t_m = 1.925$ in., 0.3 x 1.925 = 0.578 <1.0; criterion satisfied	0.578 in.	1.0 in.
Out-of-Roundness	Reference Article 452.2e. Since no ovality was built into the valve body, the requirements of this article are satisfied.	Not applicable	Not applicable
Flat Wall Limitation	Reference Article 452.2g, Flat Wall Limitation. Since no flat sections were built into the valve body design, the requirements of this article are satisfied.	Not applicable	Not applicable
Primary Crotch Stress Due to Internal Pressure	Reference Article 452.3 Criterion: $P_m = \left(\frac{A_f}{A_m} + 0.5\right) P_s < S_m$ where $A_f = 504$ in.^{2}, $A_m = 58$ in.^{2}, $P_s = 1.375$ psig, $P_m = 12{,}650$ psi, $S_m = 19{,}400$ psi; since $S_m > P_m$, criterion satisfied	19,400 psi	12,650 psi
Valve Body Secondary Stress	Reference Article 452.4		
Primary Plus Secondary Stress Due to Internal Pressure	Reference Article 452.4a $Q_p = C_p \left(\frac{r_i}{t_e} + 0.5\right) P_s C_a$ where $C_p = 3$, $r_i = 11.625$ in., $P_s = 1{,}375$ psi, $t_e = 2.75$ in. for wye-type valve, $C_a = 1.33 \rightarrow Q_p = 25{,}965$ psi		
Secondary Stress Due to Pipe Reaction	Reference Article 452.4b, Figures 452.4b(3), 452.4b(4), 452.4b(5)		
Direct or Axial Load Effect	$P_{ed} = \frac{F_d S}{G_d}$, where S = 30,750 psi, $F_d = 30$ in.^{2}, $G_d = 183$ in.$^2 \rightarrow P_{ed} = 5{,}040$ psi	19,400 psi	5,040 psi
Bending Load Effect	$P_{eb} = C_b \frac{F_b S}{G_b}$ where S = 30,750 psi, $F_b = 340$ in.^{3}, i.d. = 23.25 in., $r_i = 11.625$ in., $t_e = 2.75$ in., $\bar{r} = 13.90$ in. as $\frac{t_e}{\bar{r}} = 0.197 > 0.19 \rightarrow C_b = 1$ $G_b = \frac{I}{r_i + t_e}$ where I = 15,028 in.^{4}, $r_i = 11.625$ in., $t_e = 2.75$ in. $\rightarrow G_b = 1{,}052$ in.$^3 \rightarrow P_{eb} = 9{,}940$ psi	19,400 psi	9,940 psi
Torsion Load Effect	Reference Article 452.4b $P_{et} = 2\,\frac{F_b S}{G_t}$ where $F_b = 340$ in.^{3}, S = 30,750 psi, $G_t = 2{,}162$ in.^{3}, $P_{et} = 9{,}670$ psi	19,400 psi	9,670 psi

TABLE 3.9-17 MAIN STEAM ISOLATION VALVES

Criteria	Method of Analysis	Allowable Stress (psi), Minimum Thickness (in.), or Minimum Area (in.^{2})	Calculated Stress (psi), Actual Thickness (in.) or Minimum Area (in.^{2})
Thermal Secondary Stress at Crotch Region	Reference Article 452.4C, Figures 452.4C(4), 452.4C(3), 452.4C(5) $Q_T = Q_{T_1} + Q_{T_2}$ where $T_{e_1} = 3$ in., $Q_{T_1} = 1{,}100$ psi, $Q_{T_2} = C_6C_2\Delta T_2$ where $C_2 = 0.21$, $C_6 = 220$, and $\Delta T_2 = 5.6$ $Q_{T_2} = 260$ psi, $Q_T = 1{,}360$ psi Criterion: $S_N = Q_p + P_e = 2\ Q_{T_2} \leq 3\ S_m$ where $Q_p = 25{,}965$, $P_e = 9{,}940$, $Q_T = 1{,}360$ as $38{,}625 \leq 58{,}200$, criterion satisfied	58,200 psi	38,625 psi
Normal Duty Valve Fatigue Requirements	Reference Article 452.5, Figure 452.5(a) Criterion $N_a \geq 2{,}000$ cycles. $S_{p_1} = \frac{2}{3}\ Q_p + \frac{P_{eb}}{2} + Q_{T_2} + 1.3Q_{T_1}, Q_{T_1} = 1{,}100$ psi $S_{P_2} = 0.4Q_p + \frac{K}{2}\ (P_{eb} + 2Q_{T_2})$ where $Q_p = 25{,}965$, $P_{eb} = 9{,}940$, $Q_{T_1} = 1{,}160$, $Q_{T_2} = 260$ psi, $K = 2 \rightarrow S_{p_1} = 23{,}970$ psi, $S_{P_2} = 20{,}845$ psi, S_a equal to the larger of S_{p_1} and $S_{P_2} \rightarrow S_a = 23{,}970$ psi $\rightarrow N_a = 55{,}000 \pm 2{,}000$, criterion satisfied	2,000 cycles	55,000 cycles
Cyclic Loading Requirements at Valve Crotch	Reference Article 454 Thermal Transients Not Excluded by Code Criterion: $\sum \frac{N_{ri}}{N_i} < 1$ Calculate the fatigue usage factor (I_t) as follows: $S_n\ \mathrm{Max} = Q_p + P_{eb} + C_6(C_3 + C_4)\Delta T_f\ \mathrm{max}$ $S_n \mathrm{max} = 105{,}810$ psi for $\Delta T_{fi} = 90$, $N_{ri} = 120$, $N_i = 2{,}700$ $\frac{N_{ri}}{N_i} = 0.044$ $\Delta T_{fi} = 122$, $N_{ri} = 10$, $N_i = 1{,}600$ $\frac{N_{ri}}{N_i} = 0.006$ $\Delta T_{fi} = 342$, $N_{ri} = 8$, $N_i = 42$ $\frac{N_{ri}}{N_i} = 0.19$ as $I_t = \sum \frac{N_{ri}}{N_i} = 0.240 < 1$, criterion satisfied	1	0.240[a]
Disk Design Calculation	From Roark's Formulas for Stress and Strain, third addition Disk design conditions, $P_s = 1{,}250$ psi at 575°F, $S_m = 17{,}800$ psi at 600°F Case No. 13: $S_t = \frac{3W}{4mt^2\,(a^2 - b^2)}\ [a^4\ (3m + 1) + b^4\ (m - 1) - 4_m a^2b^2 - 4\ (m + 1)a^2b^2\ \left(\ln\left(\frac{a}{b}\right)\right)]$ where W = 1,250 psi, m = 10/3, $t = 5.625$ in., a = 10.75 in., b = 1.75 in., $S_{t_{13}} = 10{,}354$ psi Case No. 14: $S = \frac{3\ W}{2\pi mt^2}\left[\frac{2a^2\,(m+1)}{a^2 - b^2}\ \ln\left(\frac{a}{b}\right) + (m - 1)\right]$ where $W = 59{,}044\ lb_f$, t = 5.625 in., m = 10/3 a = 10.75 in., b = 1.75 in., $S_{t_{14}} = 4{,}943$ psi Total stress = $S_{t_{13}} + S_{t_{14}} = 15{,}297$ psi, allowable stress = 17,800 psi	17,800 psi	15,297 psi

TABLE 3.9-17 MAIN STEAM ISOLATION VALVES

Criteria	Method of Analysis	Allowable Stress (psi), Minimum Thickness (in.), or Minimum Area (in.^{2})	Calculated Stress (psi), Actual Thickness (in.) or Minimum Area (in.^{2})
	Case No. 21: $S_r = \frac{3W}{4t^2}\left[\frac{4a^4(m+1)\ln\left(\frac{a}{b}\right)a^4(m+3)+b^4(m-1)+4a^2b^2}{a^2(m+1)+b^2(m-1)}\right]$ where W = 1,250 psi, m = 10/3, t = 3.125 in., a = 10.75 in., b = 7.25 in. → $S_{r_{21}}$ = 5760 psi		
	Case No. 22: $Sr = \frac{3W}{2^h t^2}\left[\frac{2a^2(m+1)\ln\left(\frac{a}{b}\right)+a^2(m-1)-b^2(m-1)}{a^2(m+1)+b^2(m-1)}\right]$ where W = 1,250 psi, m = 10/3, t = 3.125 in., a = 10.75 in., b = 7.25 in. → $S_{r_{22}}$ = 10,740 psi Total stress = $S_{r_{21}}$+ $S_{r_{22}}$ = 16,500 psi, allowable stress = 17,800 psi	17,800 psi	16,500 psi
Tensile Stress at Thread Relief Valve Stem	Valve open $S_A = \frac{F}{A_t}$ where F = 31,586 lb, A_t = 1.956 in.^{2}, S_{max} = 16,148 psi Valve closed F = 46,342 lb, S_{max} = 23,692 psi	30,600 psi	23,692 psi
Bonnet Design Calculations Including Seismic Accelerations for SSE	Paragraph UG – 34c(2) of ASME Code Section VIII		
Minimum Thickness	$P_{fd} = P + P_{eg}$, $P_{eg} = \frac{16M}{\pi G^3} + \frac{4F}{\pi G^2}$ where M = 335,253 in.-lb, F = 46,342 lb, G = 24.75 in., P_{eg} = 204 psi, P_{fd} = 1,459 psi $t = d\sqrt{\frac{CP_{fd}}{S} + \frac{(1.78W)(hg)}{Sd^3}}$ where C = 0.3, P_{fd} =1,459 psi, S = 17,800 psi, hg = 2.625 in., W = 910,144 lb, d = 24.75 in. → t = 4.975 in., t = 4.975 + 0.120 = 5.095 in. (corrosion allowance is 0.120 in.)	5.095 in.	5.344 in.
Reinforcement	Reference Paragraph I-704.41(c) of USAS B31-7 To account for the opening for stem in the bonnet Required reinforcement d x t x 0.5 = (d_3t_3 + d_4t_4)/2 d_3 = 1.875, t_4 = 2.223, t_3 = 2.875, d_4 = 3 Reinforcement = 6.030 in.^{2} required 6.6126 in.^{2} available	6.030 in.^{2}	6.6126 in.^{2}
Bonnet Studs Design Calculation	Reference Article E-1000 Bolt used 20 pieces of 2.652 in.^{2}/bolts Total bolt area = 53.04 in^2		
Normal Operation	1. Pressure stress at operating condition $S_1 = \frac{W_{m1}}{A_b} =$ 17,160 psi where W_{m1}= 910,144 lb A_b = 53.04 in.^{2}	27,700 psi	17,160 psi
	2. Gasket load at ambient condition with no internal pressure $S_2 = \frac{W_{m2}}{A_b} =$ 2,019 psi where W_{m2}= 107,065 lb_f A_b = 53.04 in.^{2} Maximum tensile stress = 17,160 psi Thermal stress is assumed negligible because the coefficients of thermal expansion of bonnet place and stud are the same.	35,000 psi	2,019 psi
Longitudinal Hub Stress	$S_H = \frac{fM_o}{Lg_1{}^2 B} + \frac{PB}{4g_o}$ = 21,773 psi < 1.5 S_{fo} = 26,700 psi	26,700 psi	21,773 psi

TABLE 3.9-17 MAIN STEAM ISOLATION VALVES

Criteria	Method of Analysis	Allowable Stress (psi), Minimum Thickness (in.), or Minimum Area (in.^{2})	Calculated Stress (psi), Actual Thickness (in.) or Minimum Area (in.^{2})
Radial Stress	Reference UA-51 (1), Equation (7) of Section VIII of ASME B&PV Code, 1971 Edition $S_R = \frac{(1.33t_e + 1)M_o}{Lt^2B}$ = 12,288 psi < 1.5 S_{fo} = 26,700 psi	26,700 psi	12,288 psi
Tangential	$S_T = \left(\frac{YM_o}{t^2B}\right) - ZS_R$ = 7,117 psi < 1.5 S_{fo} = 26,700 psi where Y = 4.5, t = 4.125 in., Z = 2.4, B = 21.75 in.	26,700 psi	7,117 psi
Body Flange Design Calculations	Reference Paragraph I-704.5.1 of USAS B31-7 Total flange moment under operating conditions $M_o = M_D + M_G + M_T$ $M_D = H_D h_D$, $H_D = 0.785\ B^2P$, $h_D = R + 0.5g$, where B = 21.75 in., P = 1,459 psi → H_D = 542,080 lb_f h_D = 2.813 in., M_D = 1,524,871 in.-lb $M_G = H_G h_G$, $H_G = W_{m1} - H$, $h_G = \frac{C-G}{2}$ where W is the higher of W_{m1} and W_{m2} W_{m1} = 910,144 lb W_{m2} = 107,065 lb H_G = 208,210 lb, h_G = 2.625 in. → M_G = 546,531 in.-lb $M_T = H_T h_T$ H_T = 159,854 lb, h_T = 3.375 in., M_T = 539,507 in.-lb M_o = 2,610,929 in.-lb Total flange moment under gasket seating condition $M_o = W\frac{(C-G)}{2}$, $W = \frac{(A_m + A_b)S_a}{2}$ where C = 30 in., A_b = 53.04 in.^{2}, G = 24.75 in., A_m = 32.857 in.^{2}, S_a = 35,000 psi at 100°F → W = 1,503,193 lb → M_o = 3,010,718 in.-lb Where w = design pressure, 1250 psi m = inverse of Poisson ratio, 3.3333 t = disk thickness, 5.875 in. a = outside radius of poppet, 10.75 in. b = inside radius of pilot hole, 1.75 in. St = Maximum stress at inner edge, 9,489 psi For a plate with a hole in the center, outer edge supported and uniformly loaded along the inner edge $St = \frac{3W}{2\pi mt^2}\left[\frac{2a^2(m+1)}{a^2 - b^2}\ln\left(\frac{a}{b}\right) + (m-1)\right]$ where W = operator, spring and internal pressure acting on pilot poppet, 59,044 < B S_t = Maximum stress at inner edge, 4531 psi Total stress = $St_1 + St_2$ = 14,020 as 17,800 > 14,020 criterion satisfied	17,800	14,020
	3. Disk Flexibility Roark's Formula for stress and strain, third edition, case 21 Max. Stress $\sigma_1 = \frac{3W}{4t^2}\left[\frac{4a^4(m+1)\ln\left(\frac{a}{b}\right) - a^4(m+3) + b^4(m-1) + 4a^2b^2}{a^2(m+1) + b^2(m-1)}\right]$ Deflection $\Delta_1 = \frac{3W(m^2-1)}{16m^2{E_t}^3}\left[\begin{matrix} a^6(7m+3) + b^6(m-1) - a^4b^2(m+7) - a^2b^4(7m-5) \\ -4a^2b^2[a^2(5m-1) + b^2(m+1)]\ln\frac{a}{b} \\ \frac{-16a^4b^2(m+1)(\ln\frac{a}{b})^2}{a^2(m+1)+b^2(m-1)} \end{matrix}\right]$ where E = modulus of elasticity, 25.7 x 10^6 psi at 600°F		

TABLE 3.9-17 MAIN STEAM ISOLATION VALVES

Criteria	Method of Analysis	Allowable Stress (psi), Minimum Thickness (in.), or Minimum Area (in.^{2})	Calculated Stress (psi), Actual Thickness (in.) or Minimum Area (in.^{2})
	σ_1 = 5760 psi		
	Δ_1 = 0.00035 in.		
	Roark's Formulas for Stress and Strain, third edition, Case 22		
	$\sigma_2 = \frac{3W_2}{2\pi t^2}\left[\frac{2a^2(m+1)\ln\left(\frac{a}{b}\right)+a^2(m-1)-b^2(m-1)}{a^2(m+1)+b^2(m-1)}\right]$		
	$\Delta_2 = \frac{3W_2}{4\pi m^2Et^3}\left[a^4(3m+1)-b^4(m-1)-2a^2b^2(m+1)\frac{-8ma^2b^2\ln\left(\frac{a}{b}\right)-4a^2b^2(m+1)\left(\ln\left(\frac{a}{b}\right)\right)^2}{a^2(m+1)+b^2(m-1)}\right]$		
	where W_2 = Operator, spring, and internal pressure acting on main disc, 252,755 lb		
	σ_2 = 10,740 psi		
	Δ_2 = 0.00086 in.		
	Total stress $\sigma_2 = \sigma_1 + \sigma_2$ = 16,500 psi		
	Total deflect $\Delta_t = \Delta_1 + \Delta_2$ = 0.0012 in.		
	as 17,800 > 16,500	17,800	16,500

For the above calculation:

W_1 = total applied load, 59,044 lb for St
W_2 = total applied load, 252,755 for St_2

w = design pressure, 1250 psi
a = large disc radius, 10.75 in.
b = smaller disc radius, 7.25 in.
t = larger disk thickness, 3.125 in
m = inverse of Poisson Ratio, 3.3333
E = Young's Modulus, 25.7 x 10^6 psi at 600 °F

TABLE 3.9-17 MAIN STEAM ISOLATION VALVES

Criteria	Method of Analysis	Allowable Stress (psi) of Minimum Thickness Required	Calculated Stress, Actual Thickness
Stem Analysis	1. Valve open Tension at undercut at back seat $S = \frac{W}{A} = 15{,}230$ psi Criterion satisfied	30,600	15,230
	Where W = total open force, 31,586 lb A = cross sectional area, 2.074 in.^{2}		
	Tension at undercut at thread $S = \frac{W}{A} = 16{,}148$ psi Criterion satisfied	30,600	16,148
	Where W = total open force, 31,586 lb A = cross sectional area, 1.956 in.^{2}		
	Tension at thread at root area $S = \frac{W}{A} = 15{,}953$ psi Criterion satisfied	30,600	15,953
	Where W = total opening load, 31,586 lb A = cross sectional area, 1.98 in.^{2}		
	Stress at thread $S = \frac{W}{A} = 5561$ psi Criterion satisfied	18,360	5,561
	Where W = total opening load, 31,586 lb A = cross sectional area, 5.74 in.^{2}		
	2. Valve closed Compression at undercut at back seat $S = \frac{W}{A} = 22{,}344$ psi Criterion satisfied	30,600	22,344
	Where W = total closed load, 46,345 lb A = cross sectional area, 2.074 in.^{2}		
	Compression at undercut at thread $S = \frac{W}{A} = 23{,}692$ psi Criterion satisfied	30,600	23,682
	Where W = total closed load, 46,342 lb A = cross sectional area, 1.956 in.^{2}		
	Compression at thread root area $S = \frac{W}{A} = 23{,}405$ psi Criterion satisfied	30,600	23,405
	Where W = total closed load, 46,342 lb A = cross sectional area, 1.98 in.^{2}		
	Shear at thread $S = \frac{W}{A} = 8{,}141$ psi Criterion satisfied	18,360	8,141
	Where W = total closed load, 46,342 lb A = root area of thread, 4.75 in.^{2}		

TABLE 3.9-17 MAIN STEAM ISOLATION VALVES

Criteria	Method of Analysis	Allowable Stress (psi) of Minimum Thickness Required	Calculated Stress, Actual Thickness
Cyclic Rating	Based on Article 454 1. Instantaneous fluid temperature $\Delta T_{fo} = \frac{3Sm-Qp-Peb}{C_6(C_3-C_4)} > 150\ °F$ Where C_3 = 0.625 from Figure 454.3b C_4 = 0.0105 from Figures 454.3a and 454.4c(4) C_6 = 220 from Figure 454.3 T_{fo} = 158 °F > 150 °F Criterion satisfied 2. Fatigue stress intensity resulting in step change at 300 °F Salt = 84,140 psi N_{300} = 900 cycles at 500 °F Salt = 155,540 psi N_{500} = 170 cycles at 158 °F Salt = 40,540 psi N_{158} = 8000 cycles applied the above to Figure 454.2, these points are above the thermal cyclic rating curve and therefore qualified for cyclic rating per article 454.3. 3. Thermal cyclic index (article 454.2) $It = \sum \frac{Nri}{Ni} < 1$ Where It = cyclic rating index Nri = Required number of fluid step changes at ΔTi Ni = Permissible number of fluid step changes at ΔTi It = 0.240 < 1 Criterion satisfied		
Special Requirement with Pipe Rupture	Based on Article 452.4b Secondary stresses due to pipe reaction, crotch secondary effect due to bending load; and crotch secondary effect due to pipe torsion. Reference item 4, part 2, except in this case the stress from connecting pipe is raised to 41,000 psi Ped = 6,722psi Peb = 13,251 psi Pet = 12,896 psi These are all below 1.5 Sm = 29,100 Criterion satisfied	24,100	13,251
	Valve Body Secondary Stresses Also Sn = Q_p + Pe + $2Q_T$ Sn= 41,936 psi < 3 Sm (= 58,200) Criterion satisfied	58,200	41,936
	So even at the high pipe connection load the crotch area maximum stress is still within code allowance		

[a] See FP FERM 310 (Ref. 19) for maximum Cumulative Usage Factor values using event number of cycles based on Fermi 2 operating history.

TABLE 3.9-18 STRUCTURAL AND MECHANICAL LOADING CRITERIA

Reactor Recirculation Gate Valve, 28-In. Discharge

Component Loads Design	Design Procedure	Required Design Value	Actual Design Value
Body and Bonnet			
Loads: Design pressure, design temp., pipe reaction, thermal effects			
Pressure rating, psi	Used Tables 451.4 & 451.5 of NPVC	P_r = 799 psi	P_r = 799 psi
Minimum wall thickness, in.	Used Table 452.1 of NPVC, dm = 22	$t_m \geq 2.205$ in.	$t_m = 2.205$ min.
Primary membrane stress, psi	Used Paragraph 452.3 of NPVC	$P_m \leq S_{m(500°F)} = 19{,}600$ psi	$P_m = 9512$ psi
Secondary stress due to pipe reaction	Used Paragraph 452.4b of NPVC (S = 16,600 psi)	P_e = greatest value of P_{ed} P_{eb} and $P_{et} \leq 1.5\ S_{m(500°F)}$ 1.5 (19,600) = 29,400 psi	$P_{ed} = 5502$ psi $P_{eb} = 12{,}550$ psi $P_{et} = 12{,}080$ psi $P_e = P_{eb} = 12{,}550$ psi
Primary plus secondary stress due to internal pressure	Used Paragraph 452.4a of NPVC	$S_n \leq 3\ S_{m(500°F)} = 58{,}800$ psi	$Q_p = 24{,}255$ psi
Thermal secondary stress	Used Paragraph 452.4c of NPVC	$S_n \leq 3\ S_{m(500°F)} = 58{,}800$ psi	$Q_T = 6560$ psi
Sum of primary plus secondary stress	Used Paragraph 452.4 of NPVC	$S_n \leq 3\ S_{m(500°F)} = 58{,}800$ psi	$S_n = Q_p + P_e + 2Q_T$ $S_n = 49{,}925$psi
Fatigue requirements	Used Paragraph 452.4 of NPVC	$N_a \geq 2000$ cycles	$N_a = 3.0 \times 10^5$ cycles
Cyclic rating	Used Paragraph 454 of NPVC	$I_t \leq 1$	$I_t = 0.006$ (normal duty)[a]

TABLE 3.9-18 STRUCTURAL AND MECHANICAL LOADING CRITERIA

Reactor Recirculation Gate Valve, 28-In. Discharge

Component Loads Design	Design Procedure	Required Design Value	Actual Design Value
Body and Bonnet Bolting			
Loads: Design pressure & temp., gasket loads, stem operational load, seismic load (design-basis earthquake)	USAS B31.7 Paragraph 1-704.5.1 Used ASME Section VIII, 1968 Paragraph UA-47 to UA-51 as required by Paragraph 453.1 of NPVC		
Bolt area	USAS B31.7 Paragraph 1-704.5.1 Used ASME Section VIII, 1968 Paragraph UA-47 to 51 as required by Paragraph 453.1 of NPVC	$A_b \geq 42.46$ in.^{2}	$A_b = 55.86$ in.^{2}
Body flange stresses	USAS B31.7 Paragraph 1-704.5.1 Used ASME Section VIII, 1968 Paragraph UA-47 to UA-51 as required by Paragraph 453.1 of NPVC	$S_b \leq 27{,}975$ psi	$S_b = 21{,}628$ psi
Operating condition	USAS B31.7 Paragraph 1-704.5.1 Used ASME Section VIII, 1968 Paragraph UA-47 to UA-51 as required by Paragraph 453.1 of NPVC	$S_H \leq 1.5\ S_{m(575°F)} = 28{,}837$ psi $S_R \leq 1.5\ S_{m(575°F)} = 28{,}837$ psi $S_T \leq 1.5\ S_{m(575°F)} = 28{,}837$ psi	$S_H = 25{,}970$ psi $S_R = 7909$ psi $S_T = 7909$ psi
Gasket seating condition	USAS B31.7 Paragraph 1-704.5.1 Used ASME Section VIII, 1968 Paragraph UA-47 to UA-51 as required by Paragraph 453.1 of NPVC	$S_H \leq 1.5\ S_{m(150°F)} = 30{,}000$ psi $S_R \leq 1.5\ S_{m(150°F)} = 30{,}000$ psi $S_T \leq 1.5\ S_{m(150°F)} = 30{,}000$ psi	$S_H = 29{,}225$ psi $S_R = 11{,}727$ psi $S_T = 11{,}918$ psi

TABLE 3.9-18 STRUCTURAL AND MECHANICAL LOADING CRITERIA

Reactor Recirculation Gate Valve, 28-In. Discharge

Component Loads Design	Design Procedure	Required Design Value	Actual Design Value
Bonnet flange			
Operating condition	Calculate bonnet flange thickness according to rules of ASME Section VIII, Art. UA-6, Fig. UA-6c	$S_{max} \leq 1.5\ S_{m(575°F)}$ = 19,600 psi	S = 5863 psi
Stresses in Stem Loads: Operator thrust and torque			
Stem thrust stress	Calculate stress due to operator thrust in critical cross section	S_T , C ≤ S_m = 44,100 psi	S_T , C = 28,512 psi
Stem torque stress	Calculate shear stress due to operator torque in critical cross section	$S_S \leq 0.8\ S_m$ = 35,280 psi	S_S = 23,011 psi
Disk Analysis			
Loads: Maximum differential pressure			
Maximum stress in the disk	Calculate maximum according to Table10 of Roark's "Formula for Stress and Strain"	$S_{max} \leq 1.5\ S_{m(575°F)}$ = 28,500 psi	Max. stress = 22,885 psi
Yoke and Yoke Connections			
Maximum stress in yoke	Calculate stresses in the yoke to acceptable structural analysis methods	$S_{max} \leq S_m$ = 19,400 psi	Max. stress = 8488 psi
Yoke - bonnet bolt stress	Calculate stresses in the yoke bolts	$S_{max} \leq S_m$ = 28,800 psi	Max. stress = 7940 psi

TABLE 3.9-18 STRUCTURAL AND MECHANICAL LOADING CRITERIA

Reactor Recirculation Gate Valve, 28-In. Discharge

Component Loads Design	Design Procedure	Required Design Value	Actual Design Value
Body and Bonnet			
Loads: Design pressure, design temp., pipe reaction, thermal effects			
Pressure rating, psi	Used Tables 451.4 & 451.5 of NPVC	P_r = 655 psi	P_r = 655 psi
Minimum wall thickness, in.	Used Table 452.1 of NPVC, dm = 22	$t_m \geq 1.70$ in.	$t_m = 1.70$ min.
Primary membrane stress, psi	Used Paragraph 452.3 of NPVC	$P_m \leq S_{m(500°F)} = 19,600$	$P_m = 8797$ psi
Secondary stress due to pipe reaction	Used Paragraph 452.4b of NPVC (S = 23,700 psi)	P_e = greatest value of P_{ed} P_{eb} and $P_{et} \leq 1.5$ $S_{m(500°F)}$ 1.5 (19,600) = 29,400 psi	P_{ed} = 5253 psi P_{eb} = 11,917 psi P_{et} = 11,573 psi $P_e = P_{eb}$ = 11,917 psi
Primary plus secondary stress due to internal pressure	Used Paragraph 452.4a of NPVC	$S_n \leq 3\ S_{m(500°F)}$ = 58,800 psi	Q_p = 20,580 psi
Thermal secondary stress	Used Paragraph 452.4c of NPVC	$S_n \leq 3\ S_{m(500°F)}$ = 58,800 psi	Q_T = 5815 psi
Sum of primary plus secondary stress	Used Paragraph 452.4 of NPVC	$S_n \leq 3\ S_{m(500°F)}$ = 58,800 psi	$S_n = Q_p + P_e + 2Q_T$ S_n = 44,127 psi
Fatigue requirements	Used Paragraph 452.4 of NPVC	$N_a \geq 2000$ cycles	$N_a > 10^6$ cycles
Cyclic rating	Used Paragraph 454 of NPVC	$I_t \leq 1$	I_t = 0.131 (normal duty)[a]

TABLE 3.9-18 STRUCTURAL AND MECHANICAL LOADING CRITERIA

Reactor Recirculation Gate Valve, 28-In. Discharge

Component Loads Design	Design Procedure	Required Design Value	Actual Design Value
Body and Bonnet Bolting Loads: Design pressure and temp., gasket loads, stem operational load, seismic load (design-basis earthquake)	USAS B31.7 Paragraph 1-704.5.1 Used ASME Section VIII, 1968 Paragraph UA-47 to UA-51 as required by Paragraph 453.1 of NPVC		
Bolt area	USAS B31.7 Paragraph 1-704.5.1 Used ASME Section VIII, 1968 Paragraph UA-47 to UA-51 as required by Paragraph 453.1 of NPVC	$A_b \geq 36.8$ in.^{2} $S_b \leq 27{,}975$ psi	$A_b = 55.86$ in.^{2} $S_b = 17{,}326$ psi
Body flange stresses	USAS B31.7 Paragraph 1-704.5.1 Used ASME Section VIII, 1968 Paragraph UA-47 to UA-51 as required by Paragraph 453.1 of NPVC		
Operating condition	Same as above	$S_H \leq 1.5\ S_{m(575°F)} = 28{,}837$ psi $S_R \leq 1.5\ S_{m(575°F)} = 28{,}837$ psi $S_T \leq 1.5\ S_{m(575°F)} = 28{,}837$ psi	$S_H = 20{,}891$ psi $S_R = 6336$ psi $S_T = 6336$ psi
Gasket seating condition	USAS B31.7 Paragraph 1-704.5.1 Used ASME Section VIII, 1968 Paragraph UA-47 to UA-51 as required by Paragraph 453.1 of NPVC	$S_H \leq 1.5\ S_{m(150°F)} = 30{,}000$ psi $S_R \leq 1.5\ S_{m(150°F)} = 30{,}000$ psi $S_T \leq 1.5\ S_{m(150°F)} = 30{,}000$ psi	$S_H = 27{,}887$ psi $S_R = 11{,}366$ psi $S_T = 11{,}647$ psi
Bonnet flange	Same as above		

TABLE 3.9-18 STRUCTURAL AND MECHANICAL LOADING CRITERIA

Reactor Recirculation Gate Valve, 28-In. Discharge

Component Loads Design	Design Procedure	Required Design Value	Actual Design Value
Operating condition	Calculate bonnet flange thickness according to rules of ASME Section VIII, Art. UA-6, Fig. UA-6(c)	$S_{max} \leq S_{m(575°F)}$ = 19,600 psi	S = 5960 psi
Stresses in Stem			
Loads: Operator thrust and torque			
Stem thrust stress	Calculate stress due to operator thrust in critical cross section	S_T, C ≤ S_m = 44,100 psi	S_T, C = 24,343 psi
Stem torque stress	Calculate shear stress due to operator torque in critical cross section	$S_S \leq 0.8\ S_m$ = 35,280 psi	S_S = 19,185 psi
Disk Analysis			
Loads: Maximum differential pressure			
Maximum stress in the disk	Calculate maximum according to Table10 of Roark's "Formula for Stress and Strain"	$S_{max} \leq 1.5\ S_{m(575°F)}$ = 28,500 psi	Max. stress = 19,432 psi
Yoke and Yoke Connections			
Maximum stress in yoke	Calculate stresses in the yoke to acceptable structural analysis methods	$S_{max} \leq S_m$ = 19,400 psi	Max. stress = 5552 psi
Yoke - bonnet bolt stress	Calculate stresses in the yoke bolts	$S_{max} \leq S_m$ = 28,800 psi	Max. stress = 4008 psi

[a] See FP FERM 310 (Ref. 19) for maximum Cumulative Usage Factor values using event number of cycles based on Fermi 2 operating history.

TABLE 3.9-19 MAIN STEAM SAFETY/RELIEF VALVES (PILOT OPERATED), FERMI 2
(ASME Code, Section III, 1968, Including Addenda through Summer 1970)

Topic	Method of Analysis	Target Rock 7567F Analysis	Allowable Value	Calculated
1. BODY INLET AND OUTLET FLANGE STRESSES Note, Topics 1 and 2: Design Pressures: P_d = 1375 psig (inlet) P_b = 625 psig (outlet) These are the equivalent maximum anticipated pressures under all operating conditions. Analyses include applied moments of M = 400,000 in.-lb (inlet) and M = 300,000 in.-lb (outlet) Actual tested capability (including accelerations and moments) is as described in Topic 11. The analyses also include consideration of seismic, operational, and flow reaction forces. Allowable vs. tested capabilities are provided in Topic 12.	$S_H = \frac{fMo}{Lg_1{}^2B} + \frac{PB}{4g_o} < 1.5\ Sm$ $S_R = \frac{(\frac{4te}{3}+1)Mo}{Lt^2B} < 1.5\ Sm$ $S_T = \frac{YM_o}{t^2B} - Z\,S_R < 1.5\ Sm$ where S_H = Longitudinal "hub" wall stress, psi. S_R = Radial "flange" stress, psi. S_T = Tangential "flange" stress, psi.	P_D(Target Rock) = P (codes) Body Material: A105 Gr. II Sm = 19,400 psi (500°F, equivalent inlet and outlet temperature)	1.5 Sm = 29,100 psi	Inlet: S_H = 1.2 Sm = 0.77(allowable) S_R = 0.52 Sm = 0.35 (allowable) S_T = 1.2 Sm = 0.76(allowable) Outlet: S_H = 0.36 Sm = 0.24(allowable) S_R = 0.5 Sm = 0.33 (allowable) S_T = 1.36 Sm = 0.91(allowable)
2. INLET AND OUTLET STUD AREA REQUIREMENTS	Total cross-sectional area shall exceed the greater of: $Am_1 = \frac{Wm_1}{Sb}$, or $Am_2 = \frac{Wm_2}{Sa}$ where Am_1 = total required bolt (stud) area for operating conditions Am_2 = total required bolt (stud) area for gasket seating	$\left.\begin{matrix} Am_1 = \frac{Wm_1}{Sb} \\ Am_2 = \frac{Wm_2}{Sa} \end{matrix}\right\}$ # Bolting Material: SA193 GR#B7 # Where Am (required minimum) is the greater of Am_1 and Am_2; and A_b (actual bolt area) must exceed Am.	Inlet: ($Am_1 > Am_2$) = 8.02 in.^{2} Outlet: Am = 4.73	Inlet: A_b (actual area) = 1.72 Am (required min.) Outlet: A_b = 2.04 Am
3. BODY WALL THICKNESS	1. Valve Wall Thickness Criterion: $t_{min} = t_A$ where t_{min} = minimum calculated thickness requirement, including corrosion allowance. t_A = Actual wall thickness. (Note: This t_{min} is t_m per notation of the codes.)	Section at inlet: $t_{RQD} < t_{ACT}$ Section at middle of body $t_{RQD} < t_{ACT_C}$	 t_{RQD} = 0.67 in. Actual thickness greater than t_m at the section under consideration.	t_{ACT} = 1.67 (t_{RQD}) t_{ACT_C} = 1.28 (t_{RQD})

TABLE 3.9-19 MAIN STEAM SAFETY/RELIEF VALVES (PILOT OPERATED), FERMI 2
(ASME Code, Section III, 1968, Including Addenda through Summer 1970)

Topic	Method of Analysis	Target Rock 7567F Analysis	Allowable Value	Calculated
	2. Cyclic Rating:	$It = \sum \frac{Nri}{Ni}$ (i = 1, 2 & 3)	It (max) = 1.0	It = 0.33[a] = 0.33 (allowable)
	Thermal $It = \sum \frac{Nri}{Ni}$	$N_a \geq$ 2,000 cycles, as based on $S_A = S_{P_2}$ ($>S_{P_1}$), where S_A (Target Rock) = Sa (codes)	Na ≥ 2,000 cycles	Na (based on S_{P_2}) = 1.8 x 10^5 cycles: ∴ satisfies criteria
	Fatigue Na ≥ 2,000 cycles, as based on Sa, where Sa is defined as the larger of $S_{P_1} = \left(\frac{2}{3}\right) Q_P + \frac{P_{eb}}{2} + Q_{T_2} + 1.3Q_{T_1}$ or $S_{P_2} = 0.4Q_P + \frac{K}{2}(P_{eb} + 2Q_{T_3})$ where S_{P_1} = Fatigue stress intensity at inside surface of crotch, psi. S_{P_2} = Fatigue stress intensity at outside surface of crotch, psi.	{(Uses same notation as codes)}		
4. BONNET FLANGE STRESS (BODY SIDE)	$S_{H_1} = \frac{PB_1}{4g_1} \mp \frac{6M_H}{\pi B_1 g_1^2}$ (longitude hub stress adjacent to flange) $S_{H_2} = \left(\frac{Q}{\pi B_1 t} + P\right)(Z + Y) + \frac{Et\theta_B}{B_1} + \frac{0.075PB_1}{g_1} \pm \frac{1.8M_H}{\pi B_1 g_1^2}$ (circumferential stress in hub adjacent to flange) $S_R = \frac{6(M_P + M_S)}{t^2(\pi C - nD)}$ (@ Bolt circle) $S_R = \left(\frac{Q}{\pi B_1 t} + P\right) \pm \frac{6M_S}{\pi B_1 t^2}$ (adjacent to hub) $ST = \left(\frac{Q}{\pi B_1 t} + P\right) Z \pm \left(\frac{Et\theta_B}{B_1} + \frac{1.8M_S}{\pi B_1 t^2}\right)$	$S_H < 1.5\ S_m$ $S_R < 1.5\ S_m$ $S_T < 1.5\ S_m$ P_{FD} (Target Rock) = P (codes) Material: A105 Gr. II. S_m = 19,400 psi (@500°F)	1.5 Sm = 29,100 psi	S_H = 0.82 Sm = 0.55 (allowable) S_R = 0.5 Sm = 0.33 (allowable) S_T = 0.27 Sm = 0.18 (allowable)

TABLE 3.9-19 MAIN STEAM SAFETY/RELIEF VALVES (PILOT OPERATED), FERMI 2
(ASME Code, Section III, 1968, Including Addenda through Summer 1970)

Topic	Method of Analysis	Target Rock 7567F Analysis	Allowable Value	Calculated
5. BONNET FLANGE STRESS (BONNET SIDE)	Using Roark's formula for stress and strain, Table X, 4th. Edition, superposition of case 2 and 3	$S_R < 1.5$ Sm $S_T < 1.5$ Sm	1.5 Sm = 29,100 psi	$S_R = S_T = 1.27$ = 0.85 (available)
	$S_R = S_T = \frac{-3W}{2\pi mt^2}\left[m + (m+1)\log\frac{a}{ro} - (m-1)\frac{r_o^2}{4a^2}\right]$ $S_R = S_T = \frac{-3W}{2\pi mt^2}\left[\frac{1}{2}(m-1) + (m+1)\log\frac{a}{r_o} - (m-1)\frac{r_o^2}{2a^2}\right]$	Material: A105 Gr II Sm = 19,400 (@500°F)		
6. BONNET STUD AREA REQUIREMENTS	Total cross-sectional area shall exceed: $Am_1 = \frac{Wm_1}{Sb}$ where Am_1 = total required bolt (stud) area	$Am_1 = \frac{Wm_1}{Sb}$ Bolting Material: SA 193 Gr B7	$Am_1 = 9.839$	Am (actual) = 1,044 (required minimum)
7. BONNET WALL THICKNESS	Using Roark's formula for stress and strain, Table XIII, case 35, considering the circumferential stress, S_2 (the governing stress), and setting equal to Sm. $S_2 = P\frac{b^2+a^2}{b^2-a^2}$ where P = design pressure a = inside diameter b = outside diameter	$t_m < t_a$	tm = 0.119 in.	ta = 3.75 t_m
8. PILOT VALVE HOUSING FLANGE	$S_H = \frac{fM_o}{Lg_1^2B}$ $S_R = \frac{(\frac{4te}{3}+1)M_o}{Lt^2B}$ $S_T = \frac{YM_o}{t^2B} - Z\,S_R$ where S_H = Longitudinal "hub" wall stress, psi S_R = Radial "flange" stress, psi S_T = Tangential "flange" stress, psi	$S_H < 1.5$ Sm $S_R < 1.5$ Sm $S_T < 1.5$ Sm Material A105 Gr II Sm = 19,400 psi (@500°F)	1.5 Sm = 29,100 psi	S_H = 0.54 Sm = 0.36 (allowable) S_R = 0.36 Sm = 0.24 (allowable) S_T = 0.30 Sm = 0.20 (allowable)

TABLE 3.9-19 MAIN STEAM SAFETY/RELIEF VALVES (PILOT OPERATED), FERMI 2
(ASME Code, Section III, 1968, Including Addenda through Summer 1970)

Topic	Method of Analysis	Target Rock 7567F Analysis	Allowable Value	Calculated
9. PILOT VALVE BODY FLANGE STRESS	Using Roark's formulas for stress and strain, 4th. edition, Table X case 2	$S_R = S_T < Sm$ Material: A105 Gr II Sm = 19,400 psi (@500°F)	Sm = 19,400 psi	$S_R = S_T$ =0.34 (available)

$$S_R = S_T = \frac{-3W}{2\pi m t^2}\left[m + (m+1)\log\frac{a}{r_o} - (m-1)\frac{{r_o}^2}{4a^2}\right]$$

where

W = applied load

m = reciprocal of Poisson's ratio

a = radius of flange

r_o = radius of applied load

Topic	Method of Analysis	Target Rock 7567F Analysis	Allowable Value	Calculated
10. MAIN DISC STRESS	Using Roark's formulas for stress and strain, 4th edition, page 250	$S_{max} < Sm$ Material: SA182 Sm = 13,600 psi (@ 500°F)	Sm = 13,600 psi	S_{max} = 0.68 (allowable)

$$S_{max} = \frac{\beta W a^2}{{t_o}^2}$$

where

β = 1.63

W = applied load

a = radius of disc

t_o = thickness at center

11. SEISMIC CAPABILITY: Stress analysis uses $F_{vertical}$ = (mass of valve) x (2.0g) and $F_{horizontal}$ = (mass of valve) x (3.0g), with concurrent 400,000 in.-lb and 300,000 in.-lb applied at the inlet and outlet, respectively. Valve operability has been verified by test, with applied moments of 800,000 in.-lb and 600,000 in.-lb at the inlet and outlet, respectively, and at actual acceleration levels of $a_{vertical}$ = 6g and $a_{horizontal}$ = 8g. Tests were per IEEE-344 (1975).

12. VALVE LOADS: For a comparison of calculated loadings and seismic capability see Tables 3.9-24 and 3.9-25.

[a] See FP FERM 310 (Ref. 19) for maximum Cumulative Usage Factor values using event number of cycles based on Fermi 2 operating history.

TABLE 3.9-20 RECIRCULATION PUMPS

Criteria	Method of Analysis	Analytical Results	Allowable Stress or Actual Thickness
1. Casing Minimum Wall Thickness Loads:	$t = \frac{PR}{SE-0.6P} + C$	t = 2.72 in.	$S_{allow.}$ = 15,114 psi $t_{act.}$ = 2.750 in.
	where		
Normal and Upset Condition	t = min. req'd. thickness, in.		
Design pressure and temperature	P = design pressure, psig R = max. internal radius, in. S = allowable working stress, psi E = joint efficiency C = corrosion allowance, in.		
Primary membrane stress limit:			
Allowable working stress per ASME Sec. III, Class C			
2. Casing Cover Minimum Thickness Loads:	$S_S = \frac{F}{A}$ F = force A = area at shear point	S_S = 3440 psi	$S_{alow.}$ = 8775 psi $t_{act.}$ = 3.5 in.
Normal and Upset Condition	$S_b = \frac{Kqa^2}{h^2}$		
Design pressure and temperature			
Primary Bending and Shear		S_b = 6050 psi	$S_{allow.}$ = 15,114 psi
Stress limit:	q = pressure load		$t_{act.}$ = 7in.
1.5 S_m per ASME Code for pumps and valves for Nuclear Power Class I	a = radius of O.D. b = radius of I.D. h = plate thickness		
3. Cover and Seal Flange Bolt Loads:	Bolting loads, areas, and stresses shall be calculated in accordance with "Rules for Bolted Flange Connections"	Cover Flange Bolts	

TABLE 3.9-20 RECIRCULATION PUMPS

Criteria	Method of Analysis	Analytical Results	Allowable Stress or Actual Thickness
		$S_{act.} = 18,178$ psi	$S_{allow.} = 20,000$ psi

6. Seal Chamber Minimum Wall Thickness Loads	$t = \frac{PR}{SE-0.6P} + C$	t = 0.753 in.	$S_{allow.}$ = 15,114 psi $t_{act.}$ = 1.375 in.
Normal and Upset Condition Design pressure and temperature Piping reactions during normal operation	where t = min. required thickness, in. P = design pressure, psig R = max. internal radius, in. S = allowable working stress, psi E = joint efficiency C = corrosion allowance, in.		
Combined Stress Limit: 1.5 S_m per ASME Code for pumps and valves for Nuclear Power Class I			
7. Mounting Bracket Combined Stress Loads: Flooded weight SSE horizontal seismic force = 1.76 g	Bracket vertical loads shall be determined by summing the equipment and fluid weights and vertical seismic forces. Bracket horizontal loads shall be determined by applying the specified seismic force at mass center of pumping motor assembly (flooded)	Combined stress (shear plus tensile) Lug no.1 S_C = 6505 psi Lug no.2 S_C = 7976 psi Lug no.3 S_C = 10,762 psi	S_m = 15,150 psi S_y = 30,000 psi
SSE vertical seismic force = 0.67g			
Combined Stress Limit			
Yield stress	Horizontal and vertical loads shall be applied simultaneously to determine tensile, shear, and bending stresses in the brackets. Tensile, shear, and bending stresses shall be combined to determine max. combined stresses		

TABLE 3.9-20 RECIRCULATION PUMPS

Criteria	Method of Analysis	Analytical Results	Allowable Stress or Actual Thickness
8. Stresses Due to Seismic Loads Loads: Operation pressure and temperature SSE horizontal seismic force = 1.76g SSE vertical seismic force = 0.67g Combined Stress Limit: Yield stress	The flooded pump-motor assembly shall be analyzed as a free body supported by constant support hangers from the pump brackets. Horizontal and vertical seismic forces shall be applied at mass center of assembly and equilibrium reactions shall be determined for the motor and pump brackets. Loads, shear, and moment diagrams shall be constructed using live loads, dead loads, and calculated snubber reactions. Combined bending, tension shear stresses shall be determined for each major component of the assembly including motor support barrel, bolting and pump casing. The maximum combined tensile stress in the cover bolting shall be calculated using tensile stresses determined from loading diagram plus tensile stress from operating pressure	Motor Bolt Tensile Stresses $S_{act.}$= 10,703 psi Pump Cover Bolt Tensile Stress $S_{act.}$= 20,611 psi Motor Support Barrel Combined $S_{act.}$= 1606 psi	$S_{allow.}$ = 30,800 psi $S_{allow.}$ = 32,000 psi $S_{allow.}$ = 22,400 psi

TABLE 3.9-28 STANDBY LIQUID CONTROL PUMP

	Criteria	Method of Analysis	Allowable Stress or Minimum Thickness Required (psi)	Calculation (psi)
1.	Closure Bolting Loads: Normal and Upset	Bolting loads and stresses calculated per "Rules for Bolted Flange Connections" ASME Section VIII, App. II	Stuffing box bolts 25,000	18,150
	Design pressure and temperature.		Cylinder head bolts 25,000	19,600
	Design gasket load			
	Bolting Stress Limit			
	Allowable working stress per ASME Section VIII			
2.	Wall Thickness	Pressure Area Method. Maximum stress point on fluid cylinder	16,500	9000
	Loads: Normal and Upset			
	Design pressure and temperature			
	Stress limit			
	ASME Section VIII			
3.	Motor Mount Bolts Loads: Emergency	Seismic forces acting on motor bolts subject to tension and shear	Tension 16,500 Shear 10,000	860 1220
	Design-basis earthquake			
	Stress Limit			
	0.9 yield tension and twice allowable shear ASME VIII			
4.	Nozzle Loads	For the maximum moment due to pipe reaction, the maximum force shall not exceed the allowable	Force in lb, moment in ft-lb	

TABLE 3.9-28 STANDBY LIQUID CONTROL PUMP

Criteria	Method of Analysis	Allowable Stress or Minimum Thickness Required (psi)	Calculation (psi)
Loads: Normal Plus Upset			
Design pressure and temperature, dead weight, thermal expansion and operating-basis earthquake	Total nozzle stress with this criterion does not exceed stress limits. Mount bolts do not exceed stress limits	Suction[a]	
		F = 730	F = 90
		M = 450	M = 75
		Discharge	
		F = 350	F = 220
		M = 108	M = 63
Loads: Emergency		Suction[a]	
Design pressure and temperature, dead weight, thermal expansion and design-basis earthquake		F = 875	F = 105
		M = 540	M = 80
		Discharge	
		F = 420	F = 284
		M = 130	M = 83
Stress Limit			
ASME Section VIII for normal and upset, 1.5 of allowable stress for emergency. Mount bolts 0.9 yield for tension and twice allowable shear for emergency	--	--	--

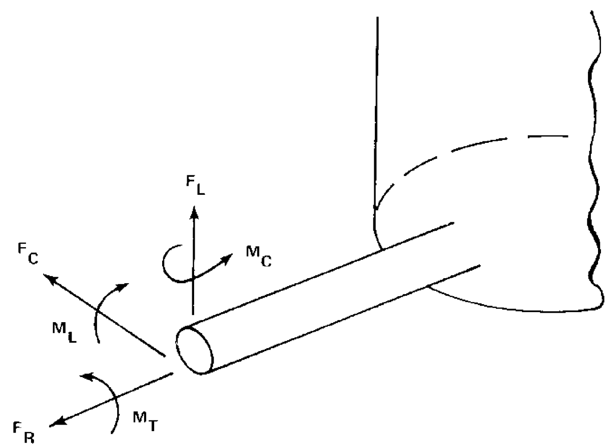
[a] Nozzle loads are the maximum allowable resultant loads applied simultaneously.

TABLE 3.9-29 STANDBY LIQUID CONTROL TANK

Criteria	Method of Analysis	Allowable Stress or Minimum Thickness Required (psi)	Calculation (psi)
1. Shell Thickness	Minimum thickness	0.015 in.	3/16 in. (actual)
Loads: Normal and upset	$t = \frac{2.6D(H-1)G}{SE}$ in.		
Design pressure and temperature	D = Nom. I.D.		
	H = Tank height		
Stress Limit	G = Specif. gravity		
Allowable working stress per ASME Section VIII	S = Allowable stress		
	E = Joint efficiency		
	Not less than 3/16 in.		
2. Shell Stress	Loads will not produce excessive tensile or compressive (buckling) stresses	Tensile	
Loads: Emergency		18,750	9716
Design-basis earthquake nozzle load		Compressive	
		18,750	2895
Stress Limit			
ASME Section VIII Compression 1/3 yield			

TABLE 3.9-29 STANDBY LIQUID CONTROL TANK

Criteria	Method of Analysis	Allowable Stress or Minimum Thickness Required (psi)	Calculation (psi)
3. Application of forces and moments by attaching pipe on outlet nozzle under combined maximum thermal expansion dead weight and design-basis earthquake loading reaction plus load due to internal pressure shall not produce an equivalent bending and torsional stress in the nozzles or shell in excess of the allowable stress as defined by the ASME B&PV Code Section III	Stresses will not be excessive if piping loads do not exceed the allowables	F_C = 235 lb F_L = 235 lb F_R = 105 lb M_C = 366 in.-lb M_L = 366 in.-lb M_T = 1050 in.-lb	F_C = 10 lb F_L = 50 lb F_R = 40 lb M_C = 160 in.-lb M_L = 1000 in.-lb[a] M_T = 75 in.-lb



[a] Equipment was requalified for the higher nozzle loadings.

TABLE 3.9-30 RESIDUAL HEAT REMOVAL PUMP

	Criteria	Method of Analysis	Allowable Stress psi	Calculation psi
1.	Closure Bolting Loads: Normal and Upset Design pressure and temperature Design gasket load Seismic acceleration, nozzle forces and/or moments, static mass forces Bolting Stress Limit Allowable working stress per ASME Section VIII	Bolting loads and stresses calculated per "Rules for Bolted Flange Connections" ASME Section VIII, App. II	Maximum allowable stress 20,000	Maximum calculated 16,370
2.	Wall Thickness Loads: Normal and Upset Design pressure and temperature Stress Limit ASME Section VIII	Per rules of Part UG Section VIII	Maximum allowable stress main pump 17,500	Maximum calculated 14,960

TABLE 3.9-30 RESIDUAL HEAT REMOVAL PUMP

	Criteria	Method of Analysis	Allowable Nozzle Forces and Moments, Force in lb, Moment in ft – lb	Calculated Nozzle Forces and Moments
3.	Nozzle Loads Loads: Normal Plus Upset Design pressure and temperature Dead weight, force and/or moment, and operating-basis earthquake Loads: Emergency Design pressure and temperature Dead weight, force and/or moment, and design-basis earthquake Stress Limit ASME Section VIII primary local membrane stress 1.5 of allowable stress for normal and upset, 1.8 of allowable stress for emergency	For the maximum stresses due to the maximum loads	The following expression relates the allowable combination of forces and moments  $\left\lvert\frac{F_i}{F_0}\right\rvert + \left\lvert\frac{M_i}{M_0}\right\rvert \leq 1$ where Fi = Largest of the three actual external orthogonal forces (Fx, Fy, and Fz) that may be imposed by the pipe Mi = Largest of the three actual external orthogonal moments (Mx, My, and Mz) permitted from the pipe when they are combined simultaneously for any condition Fo = Allowable value of Fi when all moments are zero Mo = Allowable value of Mi when all forces are zero The values of Fo and Mo are given below Normal Plus Upset: Suction: Fo = 10,440 Mo = 49,190 Discharge: Fo = 7030 Mo = 26,410 Emergency:	Force in lb, moment in ft–lb Emergency Loads[a]: Suction (pump D):

TABLE 3.9-30 RESIDUAL HEAT REMOVAL PUMP

Criteria	Method of Analysis	Allowable Nozzle Forces and Moments, Force in lb, Moment in ft – lb		Calculated Nozzle Forces and Moments
		Suction:	Fo = 12,520 Mo = 59,030	F_R = 25,000 M_R =82,800
		Discharge:	Fo = 8430 Mo = 31,700	Discharge (Pump B): F_R = 23,200 M_R = 56,000

[a] Equipment was requalified for higher nozzle loadings.

TABLE 3.9-31 RESIDUAL HEAT REMOVAL HEAT EXCHANGER

	Criteria	Method of Analysis	Allowable Stress or Minimum Thickness Required (psi)	Actual (psi)
1.	Closure Bolting Loads: Normal and Upset Design pressure and temperature Design gasket load	Bolting loads and stresses are calculated per "Rules for Bolted Flange Connections" ASME Section VIII, App. II		
	Bolting Stress Limit Allowable working stress per ASME Section VIII	Shell-channel bolted joint	25,000	24,675
2.	Wall Thickness Loads: Normal and Upset Design pressure and temperature Stress Limit	Shell side ASME Section III C, TEMA Class C Tube side ASME Section VIII and TEMA Class C		
	ASME Section VIII	a. Shell	0.830 in.	1.125 in.
		b. Shell cover	0.805 in.	1.00 in.
		c. Channel ring	0.832 in.	1.00 in.
		d. Tubes	0.044 in.	0.049/0.053
		e. Channel cover	6.627 in.	6.625 in.
		f. Tube sheet	6.697 in.	6.750 in.
3.	Nozzle Loads Design Pressure and Temperature	The maximum moments due to pipe reaction and the maximum forces shall not exceed the allowable limits	(See below)	(See below and next page)
	Dead weight, thermal expansion design-basis earthquake	Primary stress less than 1.5 ASME Section VIII allowable

TABLE 3.9-33 HIGH-PRESSURE COOLANT INJECTION TURBINE

	Criteria	Method of Analysis	Allowable Stress or Minimum Thickness Required (psi)	Calculation (psi)
1.	Closure Bolting Loads: Normal and Upset Design pressure and temperature Design gasket load Bolting Stress Limit Allowable working stress per ASME Section VIII	Bolting loads and stresses calculated per "Rules for Bolted Flange Connections" ASME Section VIII, App. II	Maximum allowable stress 20,000	Maximum calculated 18,290
2.	Casing Wall Thickness Loads: Normal and Upset Design pressure and temperature Stress Limit ASME Section VIII	Per rules of Part UG Section VIII	Maximum allowable stress 17,500	Maximum calculated 7200
3.	Nozzle Loads	For the resultant moment due to pipe reaction, the resultant force shall not exceed the allowable Detailed design analysis has demonstrated the acceptability of these values	Force in lb, moment in ft - lb	
	Loads: Normal Design pressure and temperature Dead weight and thermal expansion		Inlet F = (7570 – M)/3	F_R = 1320 M_R = 3370
			Exhaust F = (9930 – M)/3	F_R = 1090 M_R = 3560
	Loads: Normal plus Upset Design pressure and temperature		Inlet F = (16,000 – M)/4	F_R = 1970 M_R = 4690
	Dead weight, thermal expansion, and operating-basis earthquake		Exhaust F = (20,000 – M)/0.8	F_R = 2280 M_R = 9770
	Loads: Emergency Design pressure and temperature		Inlet F = (16,000 – M)/4	F_R = 1970 M_R = 4690
	Dead weight, thermal expansion, and design-basis earthquake		Exhaust F = (20,000 – M)/0.8	F_R = 2590 M_R = 11,600

TABLE 3.9-33 HIGH-PRESSURE COOLANT INJECTION TURBINE

Criteria	Method of Analysis	Allowable Stress or Minimum Thickness Required (psi)	Calculation (psi)
Stress limits Specified by vendor for normal, ASME Section VIII for upset, increased 20 percent for emergency			
4. Turbine Mounting Bolts (turbine to baseplate) Loads: Normal and Upset Operating-basis earthquake Nozzle loads for OBE, dead weight and thermal expansion Loads: Emergency Design-basis earthquake Nozzle loads for design-basis earthquake, dead weight, and thermal expansion Stress limits ASME Section VIII allowable for normal and upset. For emergency 0.9 yield and twice allowable shear	Vertical and horizontal forces on mounting bolts calculated as the sum of seismic accelerations on the turbine and the pipe reaction forces and moments on the nozzles	Tensile and shear stress for bolting materials as specified in ASME Section VIII	By meeting the nozzle load criteria of 3 above, the detailed seismic analysis indicates the mounting bolts satisfy the allowable stress requirements

TABLE 3.9-34 HIGH-PRESSURE COOLANT INJECTION PUMP

	Criteria	Method of Analysis	Allowable Stress Thickness Required (psi)	Calculation (psi)
1.	Closure Bolting	Bolting loads and stresses calculated per "Rules for Bolted Flange Connections" ASME Section VIII, App. II	Main	Maximum calculated
	Loads: Normal and Upset		Maximum allowable stress 20,000	19,950
	Design pressure and temperature		Booster 20,000	17,400
	Design gasket load			
	Bolting Stress Limit			
	Allowable working stress per ASME Section VIII			
2.	Casing Wall Thickness	Per rules of Part UG Section VIII nozzle stress maximum case stress	Maximum allowable stress	Maximum calculated
	Loads: Normal and Upset		main pump 14,000 booster pump 14,000	12,050 3650
	Design pressure and temperature			
	Stress Limit			
	ASME Section VIII			
3.	Nozzle Loads	For the maximum resultant moment due to pipe reaction, the maximum resultant force shall not exceed the allowable	Force in lb, moment in ft-lb	
	Loads: Normal Plus Upset			
	Design pressure and temperature	Total nozzle stress with this criterion does not exceed stress limits	Suction F = 33,000 – 0.79M	F_R = 6370 M_R = 22,240
	Dead weight, thermal expansion, and operating-basis earthquake		Discharge F = 32,000 – 1.54M	F_R = 4730 M_R = 15,630

TABLE 3.9-34 HIGH-PRESSURE COOLANT INJECTION PUMP

Criteria	Method of Analysis	Allowable Stress Thickness Required (psi)	Calculation (psi)
Loads: Emergency			
Design pressure and temperature Dead weight, thermal expansion, and design-basis earthquake		Suction F = 43,000 – 0.74M	F_R = 10,690 M_R = 28,890
		Discharge F = 47,000 – 1.23M	F_R = 7020 M_R = 24,220
Stress Limit			
ASME Section VIII for normal and upset, 1.5 of allowable stress for emergency			

TABLE 3.9-35 REACTOR CORE ISOLATION COOLING TURBINE

	Criteria	Method of Analysis	Allowable Stress or Minimum Thickness Required (psi)	Calculation (psi)
1.	Closure Bolting Loads: Normal and Upset Design pressure and temperature Design gasket load Bolting Stress Limit Allowable working stress per ASME Section VIII	Bolting loads and stresses calculated per "Rules for Bolted Flange Connections" ASME Section VIII, App. II	Maximum allowable stress 20,000	Maximum calculated 6400
2.	Casing Wall Thickness Loads: Normal and Upset Design pressure and temperature Stress Limit ASME Section VIII	Per rules of Part UG Section VIII	Maximum allowable stress 17,500	Maximum calculated 12,700
3.	Nozzle Loads	For the resultant moment due to pipe reaction, the resultant force shall not exceed the allowable	Force in lb, moment in ft-lb	
	Loads: Normal Design pressure and temperature Dead weight and thermal expansion	Detailed design analysis has demonstrated the acceptability of these values	Inlet $F = (2,620 - M)/3$	$F_R = 50$ $M_R = 250$
			Exhaust $F = (6,000 - M)/3$	$F_R = 790$ $M_R = 2550$
	Loads: Normal plus Upset Design pressure and temperature		Inlet $F = (7,000 - M)/4.7$	$F_R = 620$ $M_R = 530$
	Dead weight, thermal expansion, and operating-basis earthquake		Exhaust $F = 3(10,000 - M)$ but not to exceed 10,000 lb	$F_R = 1710$ $M_R = 5350$

3.10 SEISMIC DESIGN OF CATEGORY I INSTRUMENTATION AND ELECTRICAL EQUIPMENT

3.10.1 Seismic Design Criteria

3.10.1.1 Introduction

All Category I instrumentation and electrical equipment is designed to resist and withstand the effects of the two postulated Fermi 2 earthquakes, the safe-shutdown earthquake (SSE) and the operating-basis earthquake (OBE).

Category I instrumentation and electrical equipment is designed to withstand the effects of the SSE as defined in Section 3.7 without functional impairment. A list of major Category I instrumentation and electrical equipment is included in Table 3.2-1.

From the basic input ground motion data described in Sections 2.5 and 3.7, a series of response spectra at various floor elevations in both the vertical and horizontal directions was developed. After the dynamic analysis of the building was completed, the maximum seismic loadings derived from the appropriate spectra were included in the purchase specifications of Category I systems and equipment.

All vendors are required to qualify their equipment for both the SSE and the OBE using the response curves applicable to the particular building location of their equipment.

Suppliers of Category I equipment such as batteries, racks, local process-connected instrument panels, and control consoles are required to submit test data, operating experience, and/or calculations to substantiate that their components and systems would not suffer loss of function during and/or (as required) after seismic loadings as a result of the SSE. Before the equipment was accepted by Edison, proof of compliance with the accepted seismic qualifications procedures was provided to the Fermi 2 project for approval.

Since the construction permit application for Fermi 2 was docketed before October 27, 1972, the seismic qualification of Category I instrumentation, electrical equipment, and supports is required to meet the requirements of IEEE 344-1971 (Reference 1). The NRC staff conducted a review (Seismic Qualification Review Team (SQRT) audit to ensure that such components have an adequate margin to perform their intended design functions during the seismic event. During the review period, 1981 through 1984, Edison provided the SQRT with information regarding the seismic qualification of specific pieces of installed equipment and confirmed that all safety-related equipment identified to be installed at the time of fuel load was seismically qualified. Fermi 2 has a seismic qualification program to address design changes related to Category I equipment.

Category I components purchased after the issuance of IEEE 344-1975 (Reference 2) are specified to be qualified to the requirements of that standard.

As stated in Subsection 3.7.1.2, all structures, systems, and components required for cold shutdown were reaffirmed to be acceptable with respect to the Fermi 2 site-specific earthquake excitation.

Nuclear steam supply system (NSSS) items were qualified to acceleration levels that were selected to envelop potential facility excitation predictions at the time of initiation of the

Fermi 2 design. Although these acceleration levels do not envelop all facility accelerations at the time of fuel load, detailed evaluations of NSSS items have revealed significant excess aseismic design capabilities rendering the equipment quite satisfactory for Fermi 2 use. In addition, all NSSS item site-specific earthquake acceptability affirmations have been documented as satisfactory.

3.10.1.2 Reactor Protection System and Engineered Safety Feature Circuits

The Category I instrumentation and electrical equipment associated with the reactor protection system (RPS), engineered safety feature (ESF) circuits, nuclear safety systems circuits, and the emergency power system include instruments, sensory equipment, control equipment, power supplies, diesel generators, drywell penetrations, batteries, underground ducts, motor control centers (MCCs), switchgear, cable trays and conduits, consoles, local instrumentation panels, and anchorage systems. These systems maintain functional operability during and following any pre- or postaccident SSE excitation at the equipment location.

The design of the building and the electrical equipment support structures has used the applicable floor response spectra shown in Section 3.7 in determining the response spectra at the equipment locations in the RPS, nuclear safety features, and in the ESF circuits.

The seismic criterion used in the design and subsequent qualification of all Class 1E instrumentation and electrical equipment supplied by GE was as follows:

> The Class IE equipment shall be capable of performing all safety related functions during normal plant operation, during anticipated transients, during design-basis accidents, and during postaccident operation while being subjected to, and after the cessation of the accelerations resulting from, the SSE at the point of attachment of the equipment to the building or supporting structure.

The specific criteria for each of the many Class 1E systems are covered in Chapter 7. The criteria for each of the devices used in the many Class 1E systems depend on the use in a given system; for example, a relay in one system may have as its safety function to deenergize and open its contacts within a certain time, while in another system it must energize and close its contacts. Since GE supplies many devices for many applications, the approach taken was to test the device in all modes that might be used. In this way, the capability of protective action initiation and the proper operation of safety-feature circuits are ensured.

Non-GE Category I equipment will also maintain functional operability during and/or (as required) after the SSE, as dictated by the response spectra for the equipment location. Proof of this is shown by the vendor seismic qualification and confirmatory review of each item.

If a seismic disturbance occurs after a major accident, the emergency core cooling will not be interrupted. The control circuits, switchgear, and diesel-generator design are such that the system will not be shut down once it is initiated, except by operator-initiated signal or by some other protective device signal.

3.10.1.3 Extent of Compliance With IEEE 344-l97l

3.10.1.3.1 General Electric-Supplied Equipment

The compliance of GE-supplied Class 1E equipment with IEEE 344-1971 (Reference 1) can be summarized as follows:

a. Scope - Compliance not applicable

b. Definition - Compliance not applicable

c. Procedures - General Electric-supplied Class 1E equipment meets the requirement that the seismic qualification should demonstrate the capability to perform the required function during and after the SSE. In addition, those items necessary for shutdown after loss of offsite power were reaffirmed to be acceptable for the site-specific earthquake situation. Both analysis and testing were used, but most equipment was tested. Analysis was used to determine the adequacy of mechanical strength (mounting bolts, etc.) after operating capability was confirmed by testing

   1. Analysis - General Electric-supplied Class 1E equipment with primarily mechanical safety functions (pressure boundary devices, etc.) was analyzed, since the passive nature of its critical safety role usually made testing impractical. Analytical methods sanctioned by IEEE 344-l97l were used in such cases

   2. Testing - General Electric-supplied Class 1E equipment having primarily active electrical safety functions was tested in compliance with Section 3.2 of IEEE 344-1971.

d. Documentation - The documentation is that which verifies that the seismic qualification of GE-supplied Class 1E equipment is in accordance with the requirements of Section 4 of IEEE 344-1971.

3.10.1.3.2 Non-General Electric-Supplied Equipment

The qualification and documentation procedures used for non-GE-supplied Category I equipment and systems are specified in Subsection 3.10.1.3.3, which encompasses and amplifies the requirements of IEEE 344-1971.

3.10.1.3.3 Criteria for Seismic Qualification of Category I Equipment (Non-General Electric-Supplied)

The criteria for qualification of Category I instrumentation and electrical equipment (non-GE-supplied) are established in this subsection. The IEEE Guide for Seismic Qualification of Class I Electric Equipment for Nuclear Power Generating Stations is a basic part of these criteria except as specified and amended below. Paragraph numbers in parentheses conform to the paragraph numbers in IEEE 344-1971. Equipment purchased after 1971 conforms to this or later versions of this standard.

3.10.1.3.3.1 Scope (1)

All Category I instrumentation and electrical systems and equipment (assemblies and devices) supplied for this plant must withstand the postulated seismic occurrence specified herein. The equipment vendor is responsible for ensuring that the equipment and systems operate safely under the postulated seismic conditions, and he must verify that the equipment will meet the stated functional requirements for continued operation without any malfunction or loss of function during and/or (as required) after the specified events.

3.10.1.3.3.2 Category I Equipment (2.1)

Class I, as defined in Paragraph 2.1 of IEEE 344-1971, is synonymous with Category I equipment.

3.10.1.3.3.3 Safe-Shutdown Earthquake (2.2)

For Fermi 2, the design-basis earthquake, as defined in Paragraph 2.2 of IEEE 344-1971, is synonymous with SSE.

3.10.1.3.3.4 Malfunction (2.8 - Additional Definition)

Equipment malfunction or functional impairment is the failure of equipment to operate in the same manner in which it would have operated in the absence of a seismic disturbance. For protective systems, malfunction is the loss of capability to initiate a protective action, or the initiation of a spurious protective action.

3.10.1.3.3.5 Procedures (3)

When the malfunction of Category I equipment is considered, testing is the method recommended to verify the functional requirements. Table 3.10-1 summarizes seismic qualification testing of typical non-GE-supplied equipment.

3.10.1.3.3.6 Analysis (3.1)

The number of masses should be sufficient to define the dynamic behavior of the equipment. The mathematical model should be shown even for a single degree of freedom.

3.10.1.3.3.7 (Additional 3.1.6)

The analysis shall include the combined effect of gravity loads, and other loads included in the specification, combined with the appropriate seismic loads. The seismic stresses may be computed independently for the vertical and horizontal directions. The horizontal excitation may be based on an envelope encompassing the maximum acceleration levels of the N-S and E-W components of the horizontal spectra given in the Edison electrical equipment specifications. The vertical and horizontal responses are considered to act simultaneously in combining the stresses.

The normal operating primary stresses, combined with the SSE stresses, are not to exceed the minimum guaranteed American Society for Testing and Materials (ASTM) yield strength at the appropriate temperature. Combinations of primary, local, and self-limiting secondary stresses may exceed yield stress levels to the extent permitted by the appropriate codes as long as malfunction is prevented. Where biaxial or triaxial loads are involved, the principal stresses shall be calculated and kept within the allowable material stress levels.

3.10.1.3.3.8 Testing (3.2.2.4.2)

The test shall be conducted over a minimum frequency range of 1 to 33 Hz.

3.10.1.3.3.9 Test Data (4.3)

If proof of performance is obtained by testing, the test data shall contain the following information:

a. Equipment identification

b. Equipment specification

c. Test facility

    1. Location

    2. Test equipment.

d. Test method

e. Test data

f. Data analysis and evaluation (including the floor acceleration versus frequency spectra for the surface upon which the equipment was mounted when tested)

i. Calibration history of test equipment.

3.10.1.3.3.10 Certification of Compliance (4.4)

All test data submitted by the vendor to satisfy the requirements of this specification are witnessed and reviewed to determine that the data adequately demonstrate that the equipment satisfies the intent of these specifications.

3.10.2 Seismic Analyses, Testing Procedures, and Restraint Measures

3.10.2.1 Amplification of Floor Inputs by Supports

Response spectra for floors and walls where Category I equipment is located were supplied to the vendors. If the vendor chose to test or analyze a certain device or component not directly supported on the floor for which the spectra are applicable, account was taken of possible amplification through the support structure.

3.10.2.2 Cable Tray and Cable Support System

The cable trays and cable tray support system were verified to withstand forces caused by dead-load, live-load, and seismic conditions.

The following combinations of dead load, live load, and earthquake load were investigated and checked to determine the most severe condition:

a. Dead load of various components with allowable stresses according to American Iron and Steel Institute (AISI) Specifications

   The dead load on cable trays consists of cables plus tray. In the case of hangers, it includes the dead weight of hangers also. Originally, the cable tray loading within the relay room, cable spreading room, and directly below the relay room floor was 50 lb/ft^2. All other cable trays were designed to a dead load of 40 lb/ft^2. An on-going program was later established to monitor the actual weight of cables in the trays and to account for fire wrap, conduit and air drop loads. Cable tray design load is adjusted to reflect these actual loads

b. Dead load plus a concentrated live load of 200 lb at the mid-span to AISC allowable stresses for reactor, aux building and RHR complex. The concentrated live load is 250 lb for the drywell cable trays

c. Dead load plus seismic load.

The cable trays and the support system were modeled as a multidegree-of-freedom system with the mass of the cables plus tray lumped at the levels at which they are supported. Figure 3.10-1 shows typical models for a three-layer hanger with one, two, and three diagonal members for horizontal excitation.

For vertical excitation, the fundamental period of vibration was computed by using a simplified model of continuous beam with hinged ends. This approximation was found to be consistent with the numerous models studied for this purpose.

The response spectra obtained from the analysis of the building were used in determining the response of the cable tray support.

The horizontal and vertical seismic excitations were assumed to be acting simultaneously along the principal axis of the cable tray system. The seismic response was computed by taking the sum of the individual responses.

It was observed that contribution due to nonfundamental modes was negligible, and hence the effect of closely spaced modes was negligible also.

The design was based on the l968 edition of the "Specifications For the Design of Cold-Formed Steel Structural Members."

For the trays in the drywell, a concentrated live load of 250 lb was specified. As stated in Subsections 3.7.3.17.2 and 8.3.1.4.3, in the design specification for cable trays, dead-weight loading did not include the weight of fire wrapping material or any other attachments, such as top hat cover, which were subsequently added. Accordingly, hanger modifications were made where necessary, and the structural adequacy of the cable trays was verified.

3.10.2.3 Battery Racks, Battery Chargers, Instrument Racks, and Control Consoles

Response spectra for floors and walls where Category I equipment is located have been supplied to the vendor. The vendors were required to submit test data, operating experience, and/or calculations to verify that battery racks, battery chargers, instrument racks, and control consoles would not suffer any loss of function during or after the SSE. For equipment in the GE scope of supply, procedures are in accordance with GE Topical Report NEDO-10678 (Reference 3). For non-GE-supplied equipment, testing procedures are in accordance with IEEE 344-1971, as modified in Subsection 3.10.1.3.3, with the exception of the equipment purchased prior to the issuance of IEEE 344-1971. Equipment purchased prior to the issuance of IEEE 344-1971 is designed to withstand the SSE postulated by the response spectra for its location during and/or (as required) after such an event.

3.10.3 Seismic Analysis and Testing Procedures for General Electric-Supplied Equipment

3.10.3.1 Seismic Analysis

Very few of the GE-supplied Class 1E devices were completely qualified by analysis alone. A sample of such an analysis is shown in Appendix B of NEDO-10678 (Reference 3). Besides being used for passive mechanical devices, analysis was used in combination with testing for larger assemblies containing Class 1E devices. For instance, a test might have been run to determine whether there were natural frequencies in the equipment within the critical seismic frequency range (see Paragraph 3.2.2.3.1 of IEEE 344-1971). If the equipment was determined to be free of natural frequencies, then it was assumed to be rigid, and a static analysis was performed as shown in Appendix C of NEDO-10678 (see Paragraph 3.2.3.4 of IEEE Standard 344-1971. If it had natural frequencies in the critical frequency range, then calculations of transmissibility and responses to varying input accelerations were made to determine whether Class 1E devices mounted in the assembly would operate without malfunctioning.

3.10.3.2 Testing Procedures

Since the Class 1E equipment supplied by GE was and is used in many systems on many different plants under widely varying seismic requirements, the seismic qualification tests were performed using an expected worst-case envelope of 1.5g horizontal and 0.5g vertical at all frequencies from 5 to 33 Hz. (The actual qualification range was 0.25 to 33 Hz, but, since test facility capability usually limited the lower frequency test to 5 Hz, a combination of test and analysis was used to ensure that there were no untested resonances. A sample analysis is shown in Appendix B of NEDO-10678.) In general, Class 1E equipment was tested by the procedures described below.

3.10.3.2.1 Devices

The test procedure for devices required that the device be mounted on the table of the vibration machine in a manner similar to that in which it was to be installed. The device was tested in the operating states in which it was to be used while performing its Class 1E functions, and these states were monitored before, during, and after the test to ensure proper function and absence of spurious function. In the case of a relay, both energized and deenergized states and normally open and normally closed contact configurations were tested if the relay is used in those configurations in its Class 1E functions.

The seismic excitation was a single-frequency "continuous" test in which the applied vibration was a sinusoidal table motion at a fixed peak acceleration and a discrete frequency at any given time. Each frequency and acceleration combination was maintained for about 30 sec, except when a resonance search was made (see IEEE Paragraph 3.2.2.4.1 of Standard 344-1971). The vibratory excitation was applied in three orthogonal axes individually, with the axes chosen as those coincident with the most probable mounting configuration.

The first step was to search for resonances in each device. This was done since resonances cause amplification of the input vibration and are the most likely cause of malfunction. The resonance search was usually run at low acceleration levels (0.2g) to avoid destroying the test sample in case a severe resonance was encountered. The resonance search was run at frequencies from 5 to 33 Hz in accordance with IEEE 344-1971 in no less than 7 minutes; if the device was large enough, the vibrations were monitored by accelerometers placed at critical locations from which resonances were determined by comparing the acceleration level with that at the table of the vibration machine. Usually, the devices were either too small for an accelerometer, had their critical parts in an inaccessible location, or had critical parts that would be adversely affected by the mounting of an accelerometer. In these cases, the resonances were detected by visual (strobe light) or audible observation, or performance.

After the frequency scan and resonance determination, the devices were tested to determine their malfunction limit. This test was a necessary adjunct to the assembly test. The malfunction limit test was run at each resonant frequency as determined by the frequency scan. In this test, the acceleration level was gradually increased until either the device malfunctioned or the limit of the vibration machine was reached. If no resonances were detected (as was usually the case), the device was considered to be rigid (all parts move in unison) and the malfunction limit was therefore independent of frequency. To achieve maximum acceleration from the vibration machine, rigid devices were malfunction tested at the upper test frequency (33 Hz) since this procedure allowed the maximum acceleration to be obtained from deflection-limited machines.

Typical results of tests on the devices used in Class 1E applications are given in Table 3.2 of NEDO-10678 and include the malfunction limit and resonant frequencies for each device tested.

The above procedures were required of purchased devices as well as those made by GE. Vendor test results were reviewed, and if the results were unacceptable, the tests were repeated either by GE or the vendor. If the vendor tests were adequate, the device was considered to be qualified to the limits of the test.

3.10.3.2.2 Assemblies

Assemblies (e.g., control panels) containing devices whose seismic malfunction limits had been established were tested by mounting the assembly on the table of a vibration machine, in the manner it was to be mounted when in use, and vibration-testing it by running a low-level resonance search. Like the devices, the assemblies were tested in the three orthogonal axes. The resonance search was run in the same manner as described for devices. If resonances were present, the transmissibility between the input and the location of each Class 1E device was determined by measuring the accelerations at each device location and calculating the magnification between it and the input. Once known, the transmissibilities could be used analytically to determine the response at any Class 1E device location for any given input. (It was assumed that the transmissibilities were linear functions of acceleration even though they actually decrease as acceleration is increased. This assumption is therefore a conservative one.) If the input accelerations to the device were determined to be below its malfunction limit, the assembly was assumed to be qualified. If no resonances existed, the assembly was considered to be a rigid body with a transmissibility equal to 1, so that a device mounted on it would be limited directly by the assembly input acceleration.

Since control panels and racks constitute the majority of Class 1E electrical assemblies supplied by GE, seismic qualification testing of these will be discussed in more detail. There are four generic types, as shown in Table 3.10-2. One or more of each type was tested by the procedures described above.

Figures 3-1 through 3-4 of NEDO-10678 illustrate the panel types referenced in Table 3.10-2 and show typical accelerometer locations. Table 3.10-3 lists typical seismically tested panels supplied by GE.

The full-acceleration level tests described above disclosed that most of the panel types had more than adequate mechanical strength and that a given panel design acceptability was simply a function of its amplification factor and the malfunction levels of the devices mounted on it. Subsequent panels were, therefore, tested at lower acceleration levels and the transmissibilities to the various devices measured as described above. By dividing the devices' malfunction levels by the panel transmissibility between the device and the panel input, the panel seismic qualification level could be determined. Several high-level tests have been run on selected generic panel designs to ensure the conservatism in using the transmissibility analysis described.

3.10.3.2.3 Purchased Equipment

The seismic qualification of equipment supplied to GE by others was required to follow the same procedures as used by GE. The qualification data were supplied to and reviewed by GE for conformance with the required procedures.

UPDATED FINAL SAFETY ANALYSIS REPORT

FIGURE 3.10-1

TYPICAL MASS MODEL

3.11 ENVIRONMENTAL DESIGN OF MECHANICAL AND ELECTRICAL EQUIPMENT

3.11.1 Equipment Identification

Mechanical, electrical, and instrumentation portions of the engineered safety feature (ESF) systems, nuclear safety features, and reactor protection system (RPS) are designed to operate properly for the period required over a range of environmental conditions. The environmental conditions range from those of normal operation to those resulting from postulated accidents. The environmental design criteria established in Subsections 3.11.1 through 3.11.4 form the basis for the original Fermi 2 design. This information was derived from the parameters established by GE as part of their original design criteria. After performing their required functions, the systems can withstand these environmental conditions without functional impairment of the system involved, or other plant systems.

Table 3.11-1 lists the safety equipment and components inside the primary containment, which are designed to operate or be in a fail-safe condition during and following any accident up to the design-basis accidents (DBAs). Design environmental conditions and the associated duration of these conditions are also identified. The design environmental conditions envelop the maximum temperatures, pressures, humidity, and durations for the equipment over a wide variety of accident conditions up to a DBA, but the conditions will not necessarily occur coincidentally. Table 3.11-2 explains the significance of the design temperatures, pressures, and durations.

Safety-related equipment and components outside the primary containment that are designed to operate or fail into a safe condition during and following any accident, including the DBAs, are listed in Table 3.11-3. Design environmental conditions and associated durations of conditions are also given in this table. The design environmental and duration envelopes provided were used as guidelines for the selection of equipment and components used outside the primary containment. These conditions do not occur coincidentally during postulated accident conditions nor for all specific zone locations within the general areas listed.

Portions of the ESF systems, nuclear safety features, and RPS are located in a controlled environment which is considered an integral part of the ESF system, nuclear safety feature, or RPS. These areas and the controlled parameters are given in Table 3.11-4.

Fan-coil cooling units using water from the emergency equipment cooling water (EECW) system are used to control the environment to within the limits specified. These units are described in Section 9.4. Redundancy of units and equipment precludes the loss of the controlled environment as discussed in Subsection 3.11.4.

The RPS and ESF equipment is capable of functioning for the required design duration and, subsequently, remains in a fail-safe condition when subjected to the local environmental conditions (e.g., close proximity to the break) if the equipment is

a. Required to detect a steam line accident condition

b. Required to perform a steam line isolation function

c. Required to perform a water line isolation function and could be subjected to the environment, such as electrical cable or valve operator

d. Required for safety system operation, and is located so a steam line break in some other system exposes the safety system equipment to the local accident environment

e. Required to track the postaccident environment condition, such as pressure, temperature, hydrogen, oxygen, and radiation monitors.

Isolation valves and associated equipment required to perform the isolation function, per Items b. and c. above, will perform their required accident mitigation function in the local steam environment, and subsequently remain in a safe (closed) condition. Isolation valves inside the primary containment have been type- tested and have satisfied IEEE 382-1972.

Both equipment required for postaccident surveillance and ESF and RPS equipment, exposed to the local steam environment and required to be functional for the entire duration of the accident (items d. and e. above), will remain functional for a 100-day postaccident environment.

For equipment specified in Items a. through e. above, rotating machinery components such as pumps, motors, or operators in a safety system (i.e., emergency core cooling system [ECCS], reactor core isolation cooling [RCIC]) with a leak, are designed to function in the local environment caused by the leak.

3.11.2 Qualification Tests and Analysis

3.11.2.1 Environmental Criteria and Design Bases

The environmental conditions expected to exist during routine plant operations, both inside and outside the primary containment, are given in Table 3.11-5. Also included in Table 3.11-5 is the accident-basis radiation environment along with the DBA type. The accident-basis environmental conditions are defined as those which deviate from the routine plant operations environmental conditions given in Table 3.11-5. The accident-basis environment is specified as an envelope, which is not based upon one specific DBA, but on all postulated accidents relevant to an envelope. The worst-case environment was derived from Reference 1. The accident-basis environmental envelope is outlined in Table 3.11-2 for inside the primary containment. The ESF systems and RPS have been designed to remain operational or fail into a safe condition when subjected to the temperatures listed in Tables 3.11-2 and 3.11-5, unless such equipment is physically separated from the accident-basis environment.

The worst-case design environment for mechanical and Class 1E electrical equipment outside the primary containment is dependent on the location within the plant. Each location has been analyzed for different types of postulated accidents to define the maximum values of temperature, pressure, relative humidity, and radiation environment values. These values, which may differ between locations, are specified as the accident environment.

The radiation-accident-basis design environment has been calculated using conservative fission product inventories. The worst-case radiation-accident design environment is that resulting from the LOCA as derived from the AEC publication TID-14844, March 23, 1962.

In calculating doses on equipment and materials, fission products assumed to be in the recirculated water were 50 percent of the core halogen inventory and 1 percent of the core solid fission product inventory.

In calculating the range of radiation monitors and radiation doses to equipment in the containment atmosphere, fission products assumed to be in the primary containment atmosphere were 25 percent of the core halogen inventory, 1 percent of the core solid fission product inventory, and 100 percent of the noble gases.

With the implementation of the plant Hydrogen Water Chemistry program, normal radiation levels in those sections of the plant subject to main-steam environments will increase. Such increases have been taken into account in the overall environmental design of equipment and in the plant Environmental Qualification Program.

3.11.2.2 Qualification Tests

All Class 1E equipment and components were evaluated with respect to IEEE 323-1971. Since many of these items are used in several systems and in different plant locations, they were tested or analyzed for the worst-case situation. Wherever possible, the tests were performed to determine the malfunction limits for the critical parameters of the instruments for different applications. On the other hand, where the environmental conditions were known to have no effect on the equipment (i.e., reactor building pressure transients and radiation on solid-state electronic equipment), the tests were not performed. Class 1E equipment and components purchased after November 15, 1974, were evaluated with respect to IEEE 323-1974 (see also Subsection 3.11.5).

The Class 1E equipment supplied by GE was qualified by testing and was first described by equipment specifications that included or enveloped the intended application environment. Type tests were performed on pilot units to show conformance to the requirements of the equipment specifications. The test results were documented in a qualification test report.

In general, the Class 1E equipment supplied by GE was qualified by type tests; however, where the equipment's primary safety function is nonelectrical, such as forming a portion of a pressure boundary, calculations of the type contained in an ASME Boiler and Pressure Vessel (B&PV) Code stress analysis were used to establish qualification.

The four drywell cooler fans, which can also serve for post-LOCA atmosphere mixing, are the only continuous duty Class 1E motors inside the drywell. These motors have been tested beyond the requirements of IEEE 334-1971. Testing for these motors has included short-term transient testing at pressures up to 85 psig and temperatures up to 340°F in a saturated steam environment, and long-term testing at reduced pressure (20 psig) and temperature (250°F). Motor insulation has also been tested for radiation damage resistance.

General Electric-supplied mechanical equipment has either been qualification tested or analyzed for temperature effects to ensure that the material properties are not degraded by the environment of temperature, pressure, humidity, and radiation. Qualification testing has been done either by tests on that particular piece of mechanical equipment or on similar mechanical equipment.

The standby gas treatment system (SGTS) is designed to operate in the accident environment. Normal operation has a negligible effect on the SGTS, as indicated in Table 3.11-4. Periodic testing ensures operability of the system. Other non-GE-supplied equipment such as the control center heating, ventilation and air conditioning (HVAC) system, is located in areas not affected by the accident. The control center HVAC operation, including operation under accident conditions, is described in Subsection 9.4.1.

3.11.3 Qualification Test Results

Test results for GE-supplied Class 1E electric equipment are covered by GE Topical Report NEDO-10698, previously referenced, and in particular, Table 3.1 of that report.

The drywell cooler fans use two classes of insulation, "RN" for two-speed fans and "RH" for the single-speed fans. A motor with "RN" insulation has been tested in a saturated steam environment as indicated and has been shown to be suitable for the duty required. The tests show that the motors can withstand a temperature of at least 340°F for 3 hr, and a temperature of 320°F for an additional 4 hr, and at least 250°F indefinitely. A dosage of 10^9 rad of gamma radiation during the life of the motor can also be tolerated. Insulation breakdown occurs faster as conditions become more severe. Thermal endurance tests of 100 hr at 213°C indicate that the insulation will survive an insulation temperature (not ambient) of 105°C for 40 years.

3.11.4 Loss of Ventilation

3.11.4.1 Control Center

a. The control center is served by the control center air conditioning system (CCACS) as described in Subsection 9.4.1. The CCACS and the directly associated systems are designed to perform their intended functions during LOCA conditions, with the simultaneous occurrences of the safe-shutdown earthquake (SSE) as defined in Section 3.7, and the loss of all offsite power as described in Subsections 8.2.2.2 and 9.4.1.3. The CCACS is designed to provide fresh, filtered, and tempered ventilating air and/or air conditioning to all spaces within the control center. Space temperature inside the control center is maintained at a nominal temperature of 75°F [except for the mechanical equipment room (MER) and SGTS room which are discussed in Subsection 9.4.1.1], and the relative humidity is maintained at 50 percent on a year-round basis to ensure personnel comfort and satisfy safety-related control and electrical equipment requirements

   The reliability of the CCACS is achieved by providing two redundant air conditioning systems. The two systems separately supply air to the control center and, except for the common passive ductwork, are physically separated to preclude simultaneous loss of safety function that might occur as a consequence of a single accident. The return fans are used either to recirculate conditioned air or to discharge it to the outdoors. The supply fans in the multizone units provide the motive power to circulate the air to the various rooms. The two separate chilled water loops, each containing a liquid chiller and a pump, provide chilled water to the multizone units through two physically separated circuits

b. In the event of a failure of any major equipment component of the CCACS, the 100 percent standby system is available to preclude any adverse effect on the main control room and relay room environs. The standby air conditioning system is started manually from the main control room

c. The probability of losing both the 100 percent-capacity air conditioning systems, consisting of multizone units and liquid chillers at the same time, is remote. Only one multizone unit, liquid chiller, and chilled water pump is required for either the normal air conditioning or 100 percent recirculation modes. However, the CCACS is capable of providing fresh air from 100 percent outside air, which under certain outside temperature conditions (winter temperatures), could provide adequate cooling. The outside air can be supplied by either of the two 100 percent multizone units, and on occasions in conjunction with the two 100 percent return air fans, can recirculate the conditioned air in the rooms without outside air

d. The performance of the CCACS is verified while the system is in operation. The system ductwork and its components are subjected to leak and noise tests during manufacture and erection. Chillers, pumps, and piping systems are subjected to hydrostatic test during their manufacture and erection as well as being subjected to a manufacturing performance test

   Filters and filter housings are subjected to manufacturers' performance and production tests before installation as well as DOP and the appropriate tracer gas tests after installation. In addition, the complete air conditioning, heating, cooling, and ventilation systems are subjected to preoperational testing to demonstrate capability of maintaining the control center at 75°F and 50 percent relative humidity [except for the mechanical equipment room (MER) and SGTS room which are discussed in Subsection 9.4.1.1]

e. In the extremely unlikely event that the control center must be vacated, a remote shutdown panel located on the second floor of the auxiliary building provides remote control of the reactor systems needed to carry out the shutdown function. This panel is described in Section 7.5.

3.11.4.2 Engineered Safety Feature Switchgear Rooms

Two separate rooms are provided to house the Class IE electrical equipment. The Class 1E equipment provided in each ESF switchgear room is 100 percent redundant and satisfies IEEE-279-1971 and IEEE-308-1971 design criteria. The ESF switchgear heat-removal system is described in Subsection 9.4.2.

Each ESF switchgear room is provided with two 50 percent-capacity fan-coil units. Cooling water is supplied by the reactor building closed-cooling water/EECW (RBCCW/EECW) systems. These units are used to limit room temperature to less than 120°F, which is less than the maximum temperature for which equipment operation has been evaluated. Since the switchgear rooms are redundant, the two 50 percent heat-removal units in each room satisfy the single-failure criteria.

In the event of failure of a switchgear heat-removal unit, the ESF systems' function can be performed by the redundant equipment in the other essential switchgear room, and safe shutdown of the reactor is achievable.

3.11.4.3 Reactor/Auxiliary Building Safety-Related Ventilation Systems

During normal operation, the reactor/auxiliary building ventilation system provides ventilation for safety-related equipment in these buildings except for areas served by the CCACS. However, in the event the reactor building is isolated because of an abnormal condition, fan-coil cooling units provide the cooling for safety-related equipment. One unit of 100 percent capacity is furnished for each of the following:

a. Each division of residual heat removal (RHR) pumps
b. Each division of core spray pumps. The Division I unit also cools the RCIC pump
c. The high-pressure coolant injection (HPCI) pump room
d. Each division of the SGTS filter unit room
e. Each division of EECW pumps
f. Deleted

In addition, two units, each of 50 percent capacity, are furnished for each division switchgear room.

The fan-cooling units are physically separated and are located in Category I structures. Because of the separation, redundancy, and number of fan-coil cooling units supplied, it is extremely unlikely that cooling to both divisions of the same safety-related equipment would be lost.

The redundant battery rooms are ventilated by exhaust fans (one of two 100 percent capacity fans per room) which are required to operate during a DBA. Thus again, complete loss of battery room ventilation is unlikely. The fan-coil cooling units and exhaust fans are discussed further in Subsection 9.4.2.

3.11.4.4 Residual Heat Removal Complex Safety-Related Ventilation Systems

As described in Subsection 9.4.7, the RHR complex is composed of two identical divisions with the safety-related equipment in one division l00 percent redundant to that in the other division. Each division has two diesel generator rooms, two diesel-oil-storage rooms, two switchgear rooms, and a pump room.

To maintain conditions below the limits specified in Table 3.11-4, each diesel generator room, switchgear room, and pump room is ventilated with two 50 percent-capacity supply air fans. The intake air for the switchgear and pump rooms is filtered by medium-efficiency filters. These ventilation systems are of Category I design and are powered from the same ESF bus supplying equipment in the room being cooled. They are not required unless the equipment served is required, and are designed to start when the associated diesel generator starts, or a preset high room temperature is reached. Because a separate ventilation system is provided for each of the above rooms, the loss of a ventilation system does not affect safe shutdown of the plant. Each diesel-fuel-oil-storage room ventilation system purges air from a diesel generator room, a CO_2 storage room, and a ventilation equipment room to the outside. Each system is of Category I design and powered from the ESF bus corresponding to the diesel generator served. This system is designed to run continuously for all modes of operation. Again, as a system is supplied for each set of redundant rooms, loss of a system does not affect safe shutdown of the plant. With the redundancy and independence of ventilation systems described above, it is obvious that the probability of losing ventilation in both divisions of safety-related equipment is extremely small.

3.11.5 Environmental Qualification of Safety-Related Electrical Equipment Related To 10 CFR 50.49

All electrical equipment important to safety and exposed to a harsh environment has been reviewed to ensure that equipment required to perform necessary safety functions is capable of maintaining functional operability under all service conditions, including postulated accident conditions. This review was based on the criteria delineated for Category II plants as defined by NUREG-0588, "Interim Staff Position on Environmental Qualification of Safety Related Electrical Equipment," and 10 CFR 50.49. Details of the Fermi 2 harsh environment qualification program are found in Reference 2. This document is maintained and updated periodically.

Environmental envelopes were developed specifically for this harsh-environment review, using NUREG-0588 as the source document for developing the environmental profiles. Areas inside and outside the containment containing equipment important to safety were divided into environmental zones, which included the drywell, all rooms and areas in the reactor building, the auxiliary building, and the RHR complex. The temperatures, pressures, humidities, and radiation levels were determined for each of these zones. The environments defined include the most limiting environments for the most severe postulated accident events in all applicable areas, as well as the environments expected during normal operation for the life of the plant.

The information established in Subsections 3.11.1 through 3.11.4 forms the basis for the original Fermi 2 EQ program. This information was derived from GE as part of their original design criteria. All environmental qualification activities performed for Fermi 2 related to 10 CFR 50.49 will incorporate the information contained in Reference 2.

TABLE 3.11-1 ACCIDENT ENVIRONMENT - INSIDE PRIMARY CONTAINMENT

Component	Duration[a]	Temperature	Pressure[b]	Relative Humidity
6 Main steam isolation valves, including operator and cable; main steam drain isolation valves, including operator and cable; standby liquid control injection check valve	3 hr	340°F	-2 to 35 psig	100%
	6 hr	340°F	-2 to 35 psig	100%
	1 day	250°F	-2 to 25 psig	100%
	100 days	200°F	-2 to 20 psig	100%
7 Drywell cooling system	45 Sec	340°F	-2 to 56 psig	100%
	3 hr	340°F	-2 to 35 psig	100%
	6hr	320°F	-2 to 35 psig	100%
	1 day	250°F	0 to 25 psig	100%
	100 days	200°F	0 to 20 psig	100%

[a] Durations shown are termination times measured from the initiation of the postulated accident; (i.e., Condition 1, the 3-hr duration, is the period from 45 sec through 3 hr, the 1-day duration is the period from 6 hr through 1 day (24 hr).

[b] The equipment inside the primary containment will be subjected to 56 psig and 135°F for a maximum of 3 days during periodic leak testing.

[c] 56 psig is 90 percent of maximum containment internal pressure of 62 psig, as allowed by ASME B&PV Code Section III, Article 13, Paragraph N-1312, Sub-Paragraph (2).

[d] For the recirculation valves to perform their safety function they must close following a recirculation line break, so that the core flooding can be carried out in the required time. For this safety requirement the environmental conditions will not exceed 310°F at 56 psig for ½ hr. The specified conditions in (4) above are to enable a normal vessel shutdown cooling procedure during a steam leak.

[e] Some of the equipment identified in Items 5, 6, and 7 is also required to operate at the beginning of the event. This equipment is therefore also shown in Items 2 through 4 above.

TABLE 3.11-2 DESIGN-BASIS ACCIDENT ENVIRONMENTAL ENVELOPE

Temperatures	
340°F	Upper boundary on maximum superheat temperature for a steam leak with the RPV at 400-500 psig, containment at 35 psig.
320°F	Maximum superheat temperature during shutdown cooling line flush after reactor has been depressurized to 150 psia.
250°F	Maximum long-term temperature in the containment during the first day following a postulated DBA.
200°F	Extended long-term temperature in the containment following a postulated DBA.
Pressures	
-2 psig	Assumed negative design pressure of the primary containment.
56 psig	Positive design pressure of the primary containment, coinciding with the 281°F design temperature.
35 psig	Containment pressure corresponding to all the noncondensables initially in the drywell being transferred to wetwell.
25 psig	Upper boundary on extended long-term pressure at one day and shorter following a postulated DBA.
20 psig	Upper boundary on extended long-term pressure at longer than one day following a postulated DBA.
62 psig	Assumed peak containment pressure.
Durations	
45 sec	Conservative time duration to cover positive design pressure.
1 hr	Time duration during which valves that must isolate automatically on low RPV level or high drywell pressure must be operable.
3 hr	Time duration to depressurize the RPV at a rate not exceeding 100°F/hr, down to 150 psia.
4.5 hr	Time at which shutdown cooling system flush is complete. Normal shutdown cooling necessitates closure of recirculation line valves.
6 hr	Time duration to complete RPV depressurization to approximate containment pressure. This time includes RPV depressurization to 150 psia not exceeding a rate 100°F/hr, flushing of system, and depressurization to approximate containment pressure.
100 days	Maximum postulated accident duration.

TABLE 3.11-3 DESIGN-BASIS ENVIRONMENT - OUTSIDE PRIMARY CONTAINMENT[a]

NOTE: COMPONENTS ARE DESIGNED TO BE OPERABLE UNDER THE FOLLOWING CONDITIONS:

Component	Duration	Temperature[b]	Relative Pressure	Humidity
1. HPCI pump, turbine, control, instrumentation and electrical equipment; RCIC pump, turbine, controls, instrumentation, and electrical equipment (other than in steam tunnel).	1 hr[c,g]	148°F[c]	7 in. H_2O gage[c]	100%[c]
2. RHR system isolation valves, including operators and cable; RHR pumps, heat exchanger, controls instrumentation and electrical equipment; core spray systems isolation valves, including operator and cable; core spray pumps, controls, instrumentation, and electrical equipment.	6 months[d] 1 hr	148°F[d,e] 148°F[d,e]	Zero in. H_2O gage 7 in. H_2O gage	90% 100%

NOTE: VALVES ARE DESIGNED NOT TO BE OPERABLE BUT MUST NOT FAIL OPEN UNDER THE FOLLOWING CONDITIONS:

Component	Duration	Temperature[b]	Relative Pressure	Humidity
3. HPCI system isolation valves, including operator and cable; RCIC system isolation valves, including operator and cable; main steam isolation valves in steam tunnel, including operators; feedwater isolation valves, including operator and cable; reactor water cleanup isolation valves, including operator and cable	13 sec[f] 1 hr	228°F 220°F	5.1 psig[f] 2.0 psig	100%[f] 100%

---

[a] Design condition where operation is required. Note that these are design conditions and the actual conditions to which this equipment is environmentally qualified under the Fermi 2 EQ Program are documented in EQ0-EF2-018.

[b] Temperatures given do not take into account any temperature rise caused by direct steam impingement.

[c] 148°F, 100 percent R.H., and 7 in. static pressure may occur concurrently for the 1 hr as given, but R.H. and static pressure will decay after this period.

[d] Temperature based on RHR equipment operating. RHR pump basement and sub-basement quadrants: 153°F peak.

[e] Motors rated for continuous operation in an ambient temperature of 104°F will operate in a higher ambient temperature with decreased life expectancy. Space cooling may be required to limit the ambient to an acceptable level.

[f] Steam tunnel transient conditions due to main steam line rupture.

[g] These time frames are retained for historical purposes. HPCI is environmentally qualified to support a 3-hr mission time.

TABLE 3.11-4 ENVIRONMENTAL DESIGN OF AREAS CONTAINING SAFETY-RELATED EQUIPMENT AND COMPONENTS – OUTSIDE CONTAINMENT[b]

Location	Temperature	Relative Humidity
1. Control center[a]	75 °F	60% max.
2. ESF switchgear room	< 120°F max.	90% max.
3. Core spray, RCIC, RHR, HPCI emergency equipment rooms	148 °F max.[c]	90% max.
4. Standby gas treatment system room	104 °F max.	90% max.
5. Thermal recombiner area[d]	104 °F max.	90% max.
6. Emergency equipment cooling water pump room	104 °F max.	90% max.
7. Diesel Generator rooms (RHR complex)	65 °F min. 122 °F max.	-
8. Switchgear room (RHR complex)	65 °F min. 104 °F max.	-
9. Pump room (RHR complex)	104 °F max.	100% max.
10. Diesel-generator fuel-oil-storage room, and CO_2 storage room (RHR complex)	65 °F min. 125 °F max.	
11. Ventilation equipment rooms (RHR complex)	65 °F min. 104 °F max.	

Note a-Temperature for mechanical equipment room (MER) is 95°F.

Note b-These are design conditions and the actual conditions to which the equipment in this area is environmentally qualified under the Fermi 2 EQ Program are documented in EQ0-EF2-018.

Note c-RHR pump basement and sub-basement quadrants: equipment qualified to 153°F peak temperature.

Note d-The thermal recombiner units are retired in place, de-energized, and isolated from primary containment with redundant locked-closed isolation valves. The associated area coolers are retained and credited as a heat sink for post-accident environmental conditions.

TABLE 3.11-5 DESIGN ENVIRONMENTAL CONDITIONS (PLANT OPERATIONAL) [l,m]

---

[a] Gamma dose rate — Rads/hr
Neutron Flux — Neutrons/cm^2/sec

[b] Gamma dose — Rads
Neutron fluence — Neutrons/cm^2 (NVT)
Normal conditions — Integrated over 40years – 100% load factor @ rated power

[c] Gamma dose — Rads
Neutron fluence — Neutrons/cm^2 (NVT)
Accident conditions — Integrated over 6 months

[d] LOCA analysis was based upon the assumption that 100% of the noble gases, 50% of the halogens, and 1% of the solid fission products were released from the core.

[e] Primary containment atmosphere during normal operation may be inerted with nitrogen.

[f] Components located in the turbine building or radwaste building required to operate under normal conditions, if any, should be designed for equivalent conditions as shown for reactor building.

[g] The same minimum temperature (100°F), shall apply at the inside base of the shield wall. Air velocity over vessel insulation and exposed vessel parts shall be approximately 6 ft./sec.

[h] During the loss of offsite power, and emergencies, except during DBA, temperature of area underneath the RPV will be maintained at 185°F or lower for up to 30 minutes.

[i] Whenever the residual heat removal and core spray motor and emergency core cooling systems are running, during test periods, area space coolers may be required to maintain the ambient temperature listed.

[j] The maximum temperature and humidity will occur simultaneously in these spaces less than 1% of the time.

[k] The drywell volumetric average temperature may increase over 135°F and up to 145°F.

[l] These are design conditions and the actual conditions to which the equipment in this area is environmentally qualified under the Fermi 2 EQ Program are documented in EQ0-EF2-018.

[m] The environmental conditions documented in this table were established by GE as part of the original Fermi 2 design criteria as documented in GE specification 22A3019 (Reference 5).

3.12 SEPARATION CRITERIA FOR SAFETY-RELATED MECHANICAL AND ELECTRICAL EQUIPMENT

3.12.1 Introduction

This section defines separation criteria for safety-related mechanical and electrical equipment. Safety-related equipment to which the criteria apply is that equipment necessary to mitigate the effects of abnormal operational transients or accidents. The objective of the criteria is to delineate the separation requirements necessary to achieve true independence of safety-related functions compatible with the redundant equipment provided.

The sections to follow individually address mechanical and electrical equipment separation. The specific systems and equipment to which the criteria apply are listed, followed by the corresponding criteria.

3.12.2 Mechanical Systems and Equipment

3.12.2.1 Affected Systems and Equipment

The mechanical systems and related equipment (i.e., piping, valves, pumps, and heat exchangers) affected by the criteria of Subsection 3.12.2.2.1 are

a. Emergency core cooling system (ECCS)

   1. Low pressure coolant injection (LPCI) system
   2. Core spray system
   3. High pressure coolant injection (HPCI) system
   4. Automatic depressurization system (ADS).

b. Reactor core isolation cooling (RCIC) system

c. Deleted

d. Standby gas treatment system (SGTS)

e. Emergency equipment cooling water (EECW) system

f. Control center air conditioning system (CCACS)

g. Fan-coil unit ventilation systems

   1. ECCS equipment pump rooms
   2. SGTS filter unit rooms
   3. EECW pump area
   4. Hydrogen recombiner area
   5. Engineered safety feature (ESF) switchgear rooms
   6. CCACS equipment room

7. Residual heat removal (RHR) complex equipment rooms.

h. Nuclear pressure relief system

i. Main steam isolation valves (MSIVs)

j. Containment cooling mode of RHR system

k. Emergency equipment service water (EESW) system

l. Standby liquid control system (SLCS)

m. RHR service water system

n. Emergency diesel generator (EDG) and oil systems

o. Control air system.

3.12.2.2 Criteria

3.12.2.2.1 General

Separation of the affected mechanical systems and equipment is accomplished in such a manner that the substance and intent of 10 CFR 50 are fulfilled.

Consideration is given to the redundant and diverse requirements of the affected systems.

Consideration is given to the type, size, and orientation of possible breaks of the reactor coolant pressure boundary (RCPB) specified in Section 3.6.

The protection afforded by the ECCS network satisfies the single failure criterion. A single failure means an occurrence that results in the loss of capability of a component to perform its intended safety functions. Multiple failures resulting from a single occurrence are considered part of the single failure. Fluid systems are considered to be designed against an assumed single failure, if a single failure of any active component (assuming passive components function properly) does not result in a loss of capability of the system to perform its safety function.

The affected mechanical systems and equipment, along with their associated structures, are appropriately separated so that, by virtue of separation or other adequate provisions, systems important to safety are adequately protected against:

a. The LOCA dynamic effects outlined in Section 3.6

b. Missiles as defined in Section 3.5

c. Fires capable of damaging redundant mechanical safety equipment.

The need for and the adequacy of separation are determined in conjunction with the criteria specified in Sections 3.5 and 3.6.

3.12.2.2.2 System Separation

Piping for a redundant safety system is run independently of its counterpart. Supports, restraints, and mechanical components of redundant piping of the same system are not shared in common, unless it can be shown that such sharing does not significantly impair their ability to perform their safety functions.

Containment penetrations are separated so that damage to or failure of one branch of a system will not render its redundant counterpart(s) inoperable.

3.12.2.2.3 Physical Separation

Mechanical equipment and piping, including control system conduit and tubing for the ECCS, are separated so that no single credible event, such as a LOCA, is capable of disabling sufficient equipment to prevent reactor shutdown, removal of decay heat from the core, or isolation of the containment to the extent that an offsite dose in excess of 10 CFR 50.67 or 10 CFR 100 requirements results.

The ADS is separated from the HPCI system such that no portion of the HPCI influent line or HPCI steam supply line is located within jet impingement damage distance or pipe movement damage distance of any component considered essential to the operation of the ADS.

Provisions are made to ensure that no single failure could incapacitate both the HPCI and RCIC.

The RHR service water system, EESW system, and EDGs, all located in the RHR complex, are split into two divisions separated by a common wall that also serves as a missile barrier (see Section 3.5). The divisions are identical and each division is capable of performing the intended system safety function independent of the other division. The equipment of each system is housed in a Category I structure that also provides protection against natural phenomena such as tornadoes and floods. Piping between the RHR complex and the reactor/auxiliary building is provided for each division and is separated so that no single event is capable of damaging the piping in both divisions.

The CCACS likewise consists of two redundant, full-capacity systems, separated such that no single failure can incapacitate both divisions.

Independent fan-coil units are provided for each redundant piece of equipment and are separated in the same manner and provide the same protection as the equipment they serve.

3.12.3 Electrical Systems and Equipment

3.12.3.1 Affected Systems

The systems with electrical portions that might be affected by the criteria of Subsection 3.12.3.2.1 are those listed in Subsection 3.12.2.1 plus the reactor protection system (RPS) and other systems required for safe shutdown of the reactor. Affected equipment included in these systems are instrument channels, trip systems, trip actuators, standby power sources, average power range monitors (APRMs), and intermediate range monitors (IRMs).

3.12.3.2 Criteria

These systems have been fabricated in accordance with the intent of Institute of Electrical and Electronics Engineers (IEEE) 279-1971 and IEEE 308-1971 as applicable. Explicit criteria are given in Subsection 3.12.3.2.1.

3.12.3.2.1 General

As a consequence of the design of these systems and components and the separation provided, the single-failure criterion defined in accordance with Paragraph 4.2 of IEEE 279-1971 is satisfied. In addition, several potentially adverse effects are considered in the determination of the degree of separation. These are:

a. Electrical fires in wireways that could cause failure of unprotected insulation on other cables in the same wireway

b. Gross failure of electrical equipment in any single compartment of an instrument or control panel

c. Mechanical damage of equipment in a single location, the area of which is limited by the damaging potential of surrounding equipment

d. Damage caused by earthquakes of the safe-shutdown earthquake (SSE) magnitude

e. Single events that could disable an automatic protective function, i.e., reactor scram, containment isolation, or core cooling. Also, single failures that could incapacitate both the HPCI and RCIC systems, with initiation of the ADS and ECCS resulting during an abnormal operational transient.

Equipment associated with the RPS, safe shutdown systems (systems required for safe shutdown), and ESF systems are identified so that two facts are physically apparent to operating and maintenance personnel: first, that the equipment is part of the RPS, safe shutdown systems, or the ESF system engineered equipment; and second, the grouping (or division) of enforced segregation with which the equipment is associated, is identified. Identification and divisions conform to the following:

a. Panels and racks associated with the RPS, safe-shutdown systems, and ESF systems are labeled with marker plates that are conspicuously different in color from those for other panels or racks. The marker plates include identification of the proper division (I or II, for example). The equipment identification number and applicable segregation code, both numerical and color code, are applied to each piece of safety-related equipment

b. Junction and/or pull boxes enclosing wiring for the RPS, safe-shutdown systems, and ESF systems have identification similar to and compatible with the panel and racks considered above

c. Cables external to cabinets and/or panels for the RPS, safe shutdown systems, and ESF systems have color-coded jackets to distinguish them in color from other cables and to identify their separation division, as applicable. The color coding system is used throughout the plant for identification. For instance, Division I cable is orange, Division II cable is blue, and balance- of-plant (BOP) cable is black. The exceptions to cable color loading are described in Section 8.3.1.5.1. Reactor protection system cables are colored black since they are routed through their own exclusive, totally enclosed raceway system, as described in Subsection 3.12.3.2.2. The raceways are clearly identified with RPS channel numbers

d. Raceways that carry RPS wiring are identified at entrance points of each room they pass through (and exit points unless the room is small enough to facilitate convenient following of cable), and at intervals along the raceways, by markers indicating their separation division. The raceways have alpha-numeric fire resistant painted identification with color coding as described in Item c. above

e. Redundant sensory equipment is identified by suffix letters in accordance with Tables 3.12-1 and 3.12-2 for the RPS and Table 3.12-3 for the ESF systems. These tables also show the allocation of sensors to separated divisions. Allocations for safe shutdown systems sensors are given in Table 3.12-1 for the deenergize-to-operate type and in Table 3.12-3 for the energize-to-operate type.

3.12.3.2.2 System Separation

The following apply specifically to the RPS; however, the wiring guidelines also apply to the safe shutdown systems:

a. Wiring for the RPS, including the neutron monitoring system (NMS), outside the control system cabinets is run in enclosed raceway, with each of the four channels monitoring each variable being physically separated. Under-vessel neutron monitoring cables are exempted from this wireway requirement because of space limitations and the need for flexibility of IRM cables. The IRM and source range monitor (SRM) cables may be combined in the same wireway; however, the four- divisional separation is maintained.

b. Wiring to duplicate sensors on a common process tap is run in separate wireways to separate destinations

c. Wiring for sensors of more than one variable in the same trip channel can be, and is, run in the same wireway

d. Wires from both RPS trip system trip actuators to a single group of scram solenoids may be run in a single wireway. However, a single wireway does not contain wires to more than one group of scram solenoids. Wiring for two solenoids on the same control rod may be run in the same wireway

e. Cables through the containment penetrations are so grouped that failure of all cabling in a single penetration cannot prevent a scram. Conduits inside the dry-well are grouped so that failure of any one conduit will not result in disabling any APRM channel

f. Power supplies to systems that deenergize to operate require only that separation which is deemed prudent to give continuity of operation. Therefore, even though the load circuits go to separated panels, the protection system flywheel motor-generator sets and load circuit breakers are not required to comply with the separation criteria of this subsection for safety reasons

g. Even though the load circuits go to separated panels, the RPS wiring is run and/or protected in such a manner that no common source of potentially damaging energy (e.g., electrical fire in non-RPS wireways) could reasonably result in loss of ability to scram when required

h. The RPS has four independent input instrument channels for each measured variable. The four separate wireways for the four sensors for a specific variable are, in some cases, combined into two groupings or divisions for routing purposes by combining Divisions IA and IB as shown in Table 3.12-1 and Figure 3.12-1. However, under permitted bypass conditions, there is no case in which the total disabling of equipment within a single division is capable of preventing a required scram action.

3.12.3.2.3 Physical Separation

Electrical equipment and wiring for the ESF systems are segregated into separate divisions that are designated I and II, so that no single credible event is capable of disabling sufficient equipment to prevent reactor shutdown, removal of decay heat from the core, or isolation of the primary containment in the event of an accident. Separation requirements apply to control power and motive power for all systems concerned. In addition, the RCIC and HPCI systems are treated as functionally redundant counterparts and are divisionally separated, the RCIC system being in Division I, the HPCI system in Division II.

Arrangement and/or protective barriers are such that no locally generated force or missile can destroy both redundant safe shutdown and ESF system functions. In addition, because of treatment as functionally redundant systems, the same is true for the HPCI and RCIC systems. In the absence of confirming analysis to support less stringent requirements, the following rules apply:

a. In rooms or compartments having heavy rotating machinery, such as the main turbine generator, or the reactor feedwater pumps; or in rooms containing high-pressure feedwater piping or high-pressure steam lines such as those between the reactor and the turbine, at least one cable is run in metal (rigid or flexible) conduit if cables of different divisions are located in the room or compartment

b. Switchgear associated with redundant safety systems that are located in a potential mechanical damage zone such as that discussed above have a minimum horizontal separation of 20 ft or are separated by a protective wall equivalent to a 6-in.-thick reinforced-concrete wall

c. In any compartment containing an operating crane such as the turbine building, main floor, and the region above the reactor pressure vessel (RPV), there is a minimum horizontal separation of 20 ft or a 6-in.-thick reinforced-concrete wall between trays containing cables of the two divisions

d. Each RPS motor-generator set is housed in its own reinforced-concrete room with 12-in.-thick walls. The only path a missile such as a flywheel could take (to leave the room) would be through the door, but the position of the flywheel with respect to the door opening eliminates that possibility. Therefore, redundant safety-related systems cannot be failed due to such an event. The damage would be limited to the associated equipment located inside the room where the flywheel failure occurred. In addition, the RPS system cabling in this location will be contained in conduit

e. In the battery rooms, the only equipment is the batteries themselves and the only cabling is the main dc power cables to the main distribution cabinets located outside the battery rooms. The main power cables in the battery room, in addition to being fire retardant, are contained in conduit.

Arrangement of wiring and cabling ensures that fire will not propagate from one division to another. Cables have been tested and certified to be fire retardant (i.e., cable burning will stop when flame is removed). In addition, cables have been tested and certified to remain operating for 5 minutes during a fire. In addition, arrangement of wiring cabling of the HPCI and RCIC systems ensures that both systems are not disabled by a single failure. In the absence of confirming analysis to support less stringent requirements, the general guidelines used to determine the allocation of electrical wiring between segregated divisions of the safe shutdown and ESF systems are

a. Separation is such that no single failure can prevent operation of an ESF function (e.g., core cooling). Redundant (even dissimilar) systems are, in some cases, needed to perform the required function to satisfy the single-failure criteria. Table 3.12-4 illustrates the separation of subsystems of the nuclear safety and ESF systems valves. Figures 3.12-2 through 3.12-4 illustrate the ESF equipment separation into divisions and the allowable interconnections through isolating devices. Interconnecting wireways are assigned to the same division as the power for the contained circuits, and separation between divisions is maintained except at the immediate area of entrance to the cabinet of the other division, where steel barriers are provided

b. The inboard isolation system valve wiring between the control panel and the valve proper is separated from the outboard isolation valve wiring. (Figure 3.12-3 illustrates this requirement.) The manual controls for the isolation valves may be treated as an exception to this inboard division, if deemed necessary from an operational point of view, provided that no single failure can prevent the required automatic operation of at least one of an inboard/outboard pair of isolation valves

c. Routing of cables for RPS safe shutdown and ESF systems power through rooms or spaces where there is potential for accumulation of large quantities (gallons) of oil or other combustible fluids through leakage or rupture of lube oil or cooling systems is avoided. Where such routing is practically unavoidable, only one division of these cables is allowed in any such space

d. In any room or compartment in which the only source of fire is of an electrical nature, cable trays have a minimum horizontal separation of 3 ft, if no physical barrier exists between trays. If a horizontal separation of 3 ft is unattainable, a fire-resistant barrier is provided, extending at least 1 ft above (or to the ceiling) and 1 ft below (or to the floor) line of sight between the two trays. These trays are of the open-bottom type (ladder type) for power/control cable and solid-bottom-covered type for instrumentation

e. For subject cable trays, there is a minimum vertical separation of 5 ft between horizontal trays stacked one above the other; however, vertical stacking of trays is avoided wherever possible. In cases where trays must be run stacked one above the other, and where the trays meet the 5-ft vertical separation requirement, the lower tray has a solid-metal cover. Where the 5-ft separation can not be met, the upper tray also has a solid-metal bottom and a fire-resistant barrier is placed between the redundant trays

f. In the case of crossover of one tray over another (or over a panel), there is a minimum vertical separation of 18 in. (tray bottom to tray bottom), with the bottom tray covered with a metal cover, and the top tray provided with a metal bottom for a distance of 5 ft on each side of the tray crossover point

g. Any openings in floors for vertical runs of cables are sealed with fire-resistant material

h. There are two sets of Category I ductbanks between the RHR complex and the Reactor/Auxiliary building, with a Division I and Division II ductbank in each set. In each case, the buried cable ducts between the RHR complex and the Reactor/Auxiliary building provide adequate cable separation to maintain independence of redundant circuits.

   The first set of ductbanks was installed during plant construction. The buried cable runs between the RHR complex and reactor/auxiliary building are housed in reinforced- concrete ducts below grade and are physically separated by a distance of at least 20 ft. The separation is 30 ft at the point the cable ducts leave the reactor/ auxiliary building. The ducts make a sweeping bend with a minimum separation of 20 ft. The ducts then run parallel with a separation of 24 ft. This separation increases until the ducts enter (still below grade) the RHR complex. 4160-V essential power circuits are not routed within these ductbanks.

   The second set of ductbanks and associated manholes is installed above the maximum ground water elevation of 576.0 ft with ducts sloped to the manholes, such that circuits contained are not subject to continuous wetting. These are also cast-in-place, rectangular reinforced concrete ductbanks, but are located with the ductbank top approximately six inches below the surface and manhole covers at grade level. The Division I and Division II 4160-V ductbanks are separated by approximately 25 feet at the Auxiliary building entrance. The separation narrows to approximately 10’-6” at the closest point as they make a sweeping turn and widens to approximately 20 feet at the entrance to manholes 16946A and 16947A. The ductbank separation again narrows to approximately 7’-8” at a top elevation of approximately 580’-6” (three feet below grade) and runs underneath the ISFSI Transfer Pad to manholes 16946B and 16947B. The ductbanks exit manholes 16946B and 16947B with a separation of approximately 15 feet that increases to a separation of greater than 20 feet after approximately 30 feet from the manholes. The separation increases to approximately 115 feet during the run from manholes 16946B and 16947B to manholes 16946C and 16947C, located near the RHR building. Ductbank separation for the ductbank run between manholes 16946C and 16947C and the RHR Building cable vaults is greater than 80 feet. 4160-V essential power circuits are routed within these ductbanks.

The Division II 4160-V ductbank crosses above the original Division I ductbank at two locations:

1. Approximately 15 feet south of the Auxiliary building, with the Division I ductbank at a top elevation approximately 8'-9" below grade and a vertical separation between the ductbanks of approximately five feet, with an additional twenty inches of reinforced concrete separating the closest conduits in each ductbank.

2. Approximately forty feet north-west of manhole 16947B, with the Division I ductbank approximately five feet below grade and a vertical separation between the ductbanks of approximately eighteen inches, also with an additional twenty inches of concrete between the closest conduits in each ductbank.

The 4160-V RHR cable vaults and the manholes and ductbanks between these cable vaults and the Reactor/Auxiliary building cable vaults are designed as tornado missile barriers per the requirements of Regulatory Guide 1.76 Revision 1. Because of the tornado missile barrier design, the redundant cables will not be subject to a common mode failure from a tornado missile and, due to the separation provided, a redundant division cable will not cause a failure in the surviving divisional cable. (See Section 3.5 for a discussion of tornado missile protection.)

The minimum horizontal and vertical separation and/or barrier in the cable spreading room is

a. Where cables of different separation divisions approach the same or adjacent control panels with spacing less than the 3-ft minimum, at least one cable is run in metal (rigid or flexible) conduit to a point where 3 ft of separation exists

b. A minimum horizontal separation of 3 ft is provided between trays containing cables of different separation divisions if no physical barrier exists between trays. If a horizontal separation of less than 3 ft is not attainable, a fire-resistant barrier is provided extending at least 1 ft above (or to the ceiling) and 1 ft below (or to the floor) line-of-sight distance between the two trays. These trays may be of the open-bottom type (ladder type) or solid-metal-bottom type

c. Vertical stacking of trays carrying cables of different divisions is avoided wherever possible. There is a minimum vertical separation of 5 ft between horizontal trays running parallel one above the other. In situations where 5 ft of separation cannot be maintained, the top trays have solid metal bottoms and the bottom trays have solid covers with a fire-resistant barrier provided between the trays

d. In the case of crossing of a tray of one separation division over a tray of the other division, there is a minimum vertical separation of 18 in. (tray bottom to tray bottom), and the bottom tray is covered with a metal cover and the top tray is provided with a metal bottom for a distance of 5 ft on each side of the intersection (identical to Item f. above).

No single control panel (or local panel or instrument rack) includes wiring essential to the protective function of two systems that are backups for each other, except as allowed by the applicable paragraphs below:

a. If two panels containing circuits of different separation divisions are less than 3 ft apart, there is a steel barrier between the two panels. Panel ends closed by steel end plates are considered acceptable barriers, provided that terminal boards and wireways are spaced a minimum of 1 in. from the end plate

b. Floor-to-top of panel fireproof barriers are provided between adjacent panels of different divisions

c. Penetrations of separation barriers within a subdivided panel where they occur are sealed so that an electrical fire could not reasonably propagate from one section to the other and destroy the protective function

d. For operational reasons, the mode switch, scram discharge volume (SDV) high-water-level-trip bypass switch, scram reset switch, and manual scram switch (all manual switches) are located on one panel. In this case, each device is mounted in a can with a sufficient number of barrier devices to maintain adequate separation. Also, conduit is provided from the cans to the logic cabinets

e. A specific set of separation criteria must be met by the internal wiring of individual operating panels, logic cabinets, or instrument racks that contain components (control devices and wiring) of both ESF divisions. Generally, the criteria specify the use of separate terminal boards and spacing of terminal boards and wiring to preclude the possibility of fire propagation from one division of wiring to another. Separation of control devices is accomplished by physical location or a suitable metallic barrier. Whenever possible, the redundant control devices are located on opposite sides of the barrier formed by the end enclosures of adjacent panels to effect the desired separation and immunity to fire damage. Alternatively, separation of a pair of redundant control devices that must be located in close proximity is achieved by totally enclosing the wiring to one of the devices within a fire-resistant material. In a few specific cases the criterion for separation within the metallic enclosure (cabinet or panel) is relaxed. This relaxation of the criterion is allowable since an analysis for the particular system shows that the complete failure of the equipment within the enclosure will not compromise the system's redundant counterpart or the redundant power supply (refer to the single-failure analysis in GE Report NEDO-10139, Compliance of Protection Systems to Industry Criteria: General Electric BWR Nuclear Steam Supply System)

f. Logic wiring associated with the plant annunciator and sequential recorders in some instances runs between divisional areas of a subdivided panel. An example would be the electrical connection of relay isolated contacts in each section of the RPS to provide an alarm function for the plant annunciator system. Interposing relays or equivalent isolation means are incorporated to effect the required degree of electrical separation. If practical design constraints tend to compromise the ability to provide the desired degree of separation, the design is analyzed to establish the existence of single-failure design adequacy

g. In response to an NRC concern where BOP cables tied electrically into Division II cables, Edison reviewed about 550 schematics where 1E and non-1E circuits interfaced electrically without the intrinsic separation provided by isolation devices as described in Regulatory Guide 1.75. As a result of this review, several cases where 1E and non-1E circuits interface electrically were identified, and the cases were categorized into representative samples for the purpose of analysis and documentation. The analysis of the representative samples of 1E and non-1E circuits showed that the ability of the 1E system to perform its assigned function was not impaired by the postulated electrical faults on the non-1E circuits that are associated with them, or the circuits were revised to provide additional protection or isolation. These analyses are maintained as a controlled design calculation. Future design changes must meet these conditions or additional analyses will be performed to the same criteria as established in these initial cases.

h. Single-fuse isolation between 1E and non-1E loads is acceptable if the following conditions are met:

    1. The fuse must be safety related and thus meet commensurate quality and qualification standards

    2. The fuse must be mounted in a safety-related enclosure

    3. It must be shown that the single-failure criterion is satisfactorily met assuming an accident and the single failure in the safety-related fuse; i.e., if an accident occurs and an assumed fault occurs in the non-1E load, it must be demonstrated that given a single failure of the safety-related fuse under the worst fault in the non-1E load and assuming all the potential cascading consequences of that fault/ failure, adequate safe shutdown may still be achieved by alternative safety-related means.

3.12.4 Comparison With Regulatory Guide 1.75

Fermi 2 design criteria were developed and electrical systems designed prior to issuance of Revision 1 of Regulatory Guide 1.75 in January 1975. The Fermi 2 design has, however, been reviewed, and the following differences have been identified:

a. Section 3 of IEEE Standard 384-1974 classifies associated circuits as non-Class 1E circuits that share power supplies, enclosures, or raceways with Class 1E circuits or are not physically separated from Class 1E circuits by acceptable separation distances or barriers. The Fermi 2 circuits are divided into three categories: Division I, Division II, and BOP. Divisional separation of redundant safety equipment is maintained throughout. However, no attempt is made to uniquely identify BOP cables that would fall into the "associated" category.

Fermi 2 separation criterion does state that, once a BOP cable comes in contact with a divisional tray, it cannot cross over to the other divisions. This is maintained by a computerized cable-routing program that does not allow a cable to be routed to the other division

The degradation of Class 1E circuits is avoided by the following design features:

1. The insulating materials and cable ratings are the same for BOP cables as Class 1E cables, the only exception being the fiber-optic cables. These cables are non-conducting cables, carrying light pulses, i.e., carry no fault energy and therefore cannot create shorts between circuits. The cable insulation is non-flame propagating, and certified to IEEE-383-1974, Paragraph 2.5.

2. The cable insulation is selected and tested not to propagate fire, thus eliminating the danger of a cable propagating a failure from one tray to another.

b. Balance-of-plant loads that are fed from Class 1E buses use breakers as a separation device. These breakers are fully qualified Class 1E devices. The cabling from the breakers to the load and to the control panel is BOP cabling. The breakers have full fault protection, but they are not opened on a LOCA signal. The incidence of reported false LOCA signals, notably due to high drywell pressure, indicates that this would cause unnecessary degradations in plant operational flexibility. As an added precaution, the large loads handled by 4160-V breakers have the external control circuit operated by a BOP battery, while the internal breaker control, including fault clearance, is operated by Class 1E battery power. The interfacing devices are Class 1E relays located in the switchgear (see Figure 3.12-5). The 480-V breakers feeding BOP loads from Class 1E buses are controlled entirely from the Class 1E battery. Since these are nonessential loads, the control cables between the switchgear and control room are treated as BOP cables. Control fuses in the switchgear protect the Class 1E battery. The Class 1E 480 volt distribution panel on each EDG, which feed BOP loads, is protected by 1E fuses located in the Class 1E MCC feeding the distribution panels. These Class 1E fuses provide isolation of the BOP load, assuming a failure of the distribution panels Class 1E overcurrent protective devices on faults on the non-1E circuit. The consequences of the loss of the Class 1E distribution panel have shown that EDG operability is not impacted.

c. Section 5.1.2 of IEEE 384 states that exposed Class 1E raceways be marked at intervals not to exceed 15 ft. Edison Specification 3071-128, standard EE, calls for markings "at point of entry into a room. . .." In addition, a standard note on all Fermi 2 cable tray identification drawings states that "tray numbers should occur at close intervals to enable any section to be readily and accurately identified"

d. Section 5.6.3 of IEEE 384 calls for Class 1E wire bundles or cables internal to control boards to be distinctly identified

These boards have already been manufactured, and no such marking has been provided. Division I and Division II circuits have been carefully isolated. Where a Division I circuit enters a Division II panel, it is run in metallic conduit, and the Division I device is canned. The same applies to Division II circuits entering a Division I panel. There is, however, no attempt to separate the BOP wiring or devices from the Class 1E wiring. The materials of the wiring are the same, which ensures that the reliability of the safety functions is not degraded.

TABLE 3.12-1 REACTOR PROTECTION SYSTEM AND DEENERGIZE-TO-OPERATE SENSOR SUFFIX LETTERS AND DIVISION ALLOCATION (INCLUDING PRIMARY CONTAINMENT ISOLATION CONTROL SYSTEM)

Total Sensors	Division IA Trip Logic A1	Division IB Trip Logic B1	Division IIA Trip Logic A2	Division IIB Trip Logic B2
4	A	B	C	D

3.13 COMPUTER PROGRAMS FOR STRUCTURAL ANALYSIS AND DESIGN

The computer programs referred to in Sections 3.7 and 3.8 are described herein. All programs have been verified, within the stated assumptions and limitations, for the correctness of the theory used and the validity of the results obtained for a wide variety of typical problems. Results have been checked against known solutions or solutions obtained from other programs using a different analytical approach. Furthermore, whenever applicable, internal checks, such as equilibrium and orthogonality checks, are printed out for each problem. Subsection 3.13.1 describes the computer programs used by Sargent & Lundy (S&L). Subsection 3.13.2 describes the computer programs used by Chicago Bridge & Iron (CBI). Subsection 3.13.4 describes the computer programs used by Stone & Webster, Michigan (S&W). Major computer programs used by others are described in Subsection 3.13.3.

3.13.1 Computer Programs Used by Sargent & Lundy

Subsections 3.13.1.1 through 3.13.1.32 describe computer programs used by S&L. The building structures to which each were applied are shown parenthetically following each program title.

3.13.1.1 AFEM - Axisymmetric Finite Element Method (Reactor/Auxiliary Building)

The Axisymmetric Finite Element Method (AFEM) is used for analysis of axisymmetric thick shells of revolution subjected to axisymmetric loads. The analysis is done using the finite element method with axisymmetric solid triangular elements. The analysis may be done for nodal loads, normal and shear pressures, and thermal loadings. For force or displacement-type boundary conditions, oblique or skewed restraints may be used.

The program output includes the displacements of each node, and the direct stresses, shear stresses, and principal stresses with their associated directions for each element. Boundary stresses are obtained through an extrapolation procedure, and the section stress resultants are obtained using a numerical integration procedure.

The Axisymmetric Finite Element Method is a modified version of the finite element program AMG032, developed by Rohm & Haas Company for the Redstone Arsenal Research Division, Huntsville, Alabama. It was obtained and modified by S&L in 1971. It is currently maintained on a UNIVAC 1106 operating under EXEC 8.

Three of the problems used to validate AFEM are presented here. Results obtained from AFEM are compared with hand calculations.

3.13.1.1.1 Problem 1

Problem 1 concerns the analysis of a uniformly loaded circular plate as shown in Figure 3.13-1. The solution from AFEM is compared to an evaluation of equations given by Timoshenko and Goodier in Reference 1.

Two computer runs using different grid sizes were used. As shown in Figures 3.13-2 through 3.13-5, the theoretical and computer solutions compare favorably.

3.13.1.1.2 Problem 2

Figure 3.13-6 shows the geometry for problem 2. A thick cylinder is loaded with its own weight and the body force is kept constant with the depth. For this problem the expressions for stresses are

$$\sigma_Z = \int_Z^h k\, d_Z = -kh\left[1-\left(\frac{Z}{h}\right)\right] \tag{3.13-1}$$

and

$$\sigma_r = \sigma_\theta = \tau_{r\theta} = \tau_{rZ} = 0 \tag{3.13-2}$$

K = material density = 200 lb/in.^{3}

As shown in Figure 3.13-7, the results from AFEM are within 5 percent of the theoretical solution.

3.13.1.1.3 Problem 3

The third problem is a temperature distribution problem. The thick cylinder in Figure 3.l3-8 is subjected to a steady-state temperature gradient. The inside temperature of the cylinder is 10°F higher than the outside temperature. A steady state is assumed in this long cylinder with a concentric hole. If T_i is the temperature on the inner surface of the cylinder and the outer surface temperature is zero, the temperature T at any distance r from the center is represented by the expression

$$T = \frac{T_i}{\log\left({}^{b}/_{a}\right)}\log\frac{b}{r} \tag{3.13-3}$$

The expressions for stresses are given in Reference 1. Properties for this problem are

a. Radius of the cylinder a = 5 in.

b. Radius of the hole b = 1 in.

c. Modulus of elasticity E = 10^6 psi

d. Poisson's ratio $\upsilon = 0.2$

e. Thermal coefficient α = 1/3000 in./in./°F

f. Inside temperature Ti = 10°F

As shown in Figures 3.13-9 and 3.13-10, the results compare favorably.

3.13.1.2 DSASS - Dynamic Seismic Analysis of Shear Structures (Reactor/Auxiliary Building)

Dynamic Seismic Analysis of Shear Structures (DSASS) is used for dynamic analysis of structures that could be modeled as slabs interconnected with springs. The masses are lumped at the slab levels and the springs offer resistance to relative displacements at their ends. The program considers the combined effects of translational, torsional, and rocking motion. The program uses either the response spectrum or time-history method of analysis. In the case of time-history analysis, the decoupled differential equations of motion are numerically integrated using Newmark's β-method (Reference 2). The program output includes modal responses, probable maximum time history of structural response, and response spectrum at any slab.

The DSASS program was developed by S&L in 1967. Version V is currently maintained on a UNIVAC 1106 operating under EXEC 8. This version has been used successfully since 1971.

To demonstrate the validity of the program, a three-story shear frame is analyzed and compared to a solution obtained by Biggs. The structure is represented by the closed-coupled system shown in Figure 3.13-11. The masses and stiffness values used are also given in the figure.

For the analysis, the following response spectrum was used:

Frequency (Hz)	Displacement (in.)
1.00	3.30
2.18	1.40
3.18	0.66

Table 3.13-1 represents a comparison of results obtained from DSASS and by Biggs. As demonstrated in this comparison, results obtained from DSASS are accurate.

3.13.1.3 DYNAS - Dynamic Analysis of Structures (Reactor/ Auxiliary Building and Residual Heat Removal Complex)

Dynamic Analysis of Structures (DYNAS) is designed for performing dynamic analysis of structures that can be idealized as three- dimensional space frames or rigid slabs connected by translational or torsional springs. The program considers the combined effects of translational, torsional, and rocking motions on the structure. The program uses either the response spectrum or time-history method of analysis, depending on the type of forcing function available. Both methods use the normal mode approach. In the case of time-history analysis, the decoupled differential equations of motion are numerically integrated using Newmark's β-method (Reference 2).

The program can be used for analyzing structures with parts having different associated dampings. The option is also available to analyze a large structural system using the modal synthesis technique. The system is divided into subsystems whose modal characteristics are computed separately, and then synthesized to obtain the response of the complete system. The base motion can be applied simultaneously in two orthogonal directions. Response spectra can be generated at specified slabs or joints. The program output includes modal responses, probable maximum responses, time history of structural response, and response spectrum at specified joints.

The DYNAS program, developed by S&L in 1970, is currently maintained on a UNIVAC 1106 operating under EXEC 8. Two examples of the problems used for validating the program are presented herein.

3.13.1.3.1 Problem 1

In the first problem, a three-story shear building is analyzed and compared to a solution obtained by Biggs (Reference 3). The structure is represented by the closed-coupled system shown in Figure 3.13-11, as are masses and stiffness values used. For the analysis, the following response spectrum was used:

Frequency (Hz)	Displacement (in.)
1.00	3.30
2.18	1.40
3.18	0.66

The results obtained by Biggs and from DYNAS are compared in Table 3.13-1.

3.13.1.3.2 Problem 2

In the second example, results of DYNAS are compared to those obtained by Wilson et al. (Reference 4) using the SAP IV program. At the fixed end of a cantilever beam (Figure 3.13-12), an acceleration is applied (Figure 3.13-13). The natural periods calculated by both SAP IV and DYNAS are shown in Table 3.13-2.

A comparison of the bending moment at the fixed end of the cantilever beam is shown in Figure 3.13-14. As demonstrated in both examples, DYNAS performs an accurate analysis.

3.13.1.4 DYNAX - Dynamic Analysis of Axisymmetric Structures (Reactor/Auxiliary Building and Residual Heat Removal Complex)

Dynamic Analysis of Axisymmetric Structures (DYNAX) is a finite element program for performing both static and dynamic analyses of axisymmetric structures. Its formulation is based on a small displacement theory.

Three types of finite elements are available: quadrilateral, triangular, and shell. The geometry of the structure can be general as long as it is axisymmetric. Both the isotropic and orthotropic elastic material properties can be modeled. Discrete and distributed springs are available for modeling elastic foundations.

For static analysis, input loads can be structure weight, nodal forces, nodal displacements, distributed loads, or temperatures. Loads can be axisymmetric or nonaxisymmetric. For the solids of revolution, the program outputs nodal displacements and element and nodal point stresses in the global system (radial, circumferential, and axial). In the case of shells of revolution, the output consists of nodal displacements, and element and nodal point shell forces in a shell coordinate system (meridional, circumferential, and normal).

For dynamic analysis, three methods are available: direct integration, modal superposition, and response spectrum. In the case of dynamic analysis by direct integration or modal superposition, a forcing function can be input as

a. Nodal force components versus time for any number of nodes

b. Vertical or horizontal ground acceleration versus time.

For nonaxisymmetric loads, the equivalent Fourier expansion is used. In the case of dynamic analysis by response spectrum method, spectral velocity versus natural frequency for up to four damping constants is input. The output of dynamic analysis is in terms of nodal displacements, element stresses, and resultant forces and moments at specified time steps. When the modal superposition method is used, and in the case of earthquake response analysis, the requested numbers of frequencies and mode shapes are computed and printed together with the cumulative response of all the specified modes, as computed by the root sum square method and the absolute sum method.

DYNAX was developed under the acronym ASHAD by S. Ghosh and E. L. Wilson of the University of California, Berkeley, in 1969 (Reference 5). It was acquired by S&L in 1972 and is operating under EXEC 8 on a UNIVAC 1106.

To validate the major analytical capabilities of DYNAX, documented results from six problems are compared with DYNAX results. As shown in these six problems, DYNAX is capable of producing accurate results for both static and dynamic analyses of shells.

3.13.1.4.1 Problem l

The first problem is taken from S. Timoshenko, Theory of Plates and Shells (Reference 6). A clamped shallow spherical shell (Figure 3.13-15) is analyzed for displacements and stresses produced by a uniform pressure applied on its outside surface. DYNAX and Timoshenko's solutions are compared in Figures 3.13-16 and 3.13-17.

3.13.1.4.2 Problem 2

The second problem, taken from Theory of Elasticity by Timoshenko and Goodier (Reference 1) is a plane strain analysis of a thickwalled cylinder subjected to external pressure. The finite element idealization and the loading system used for this case are shown in Figure 3.13-18. Results of the DYNAX analysis are compared with the exact solution in Figure 3.13-19. The agreement for both stresses and displacements is excellent.

3.13.1.4.3 Problem 3

The third problem was presented in an article by Budiansky and Radkowski in an August 1963 issue of the AIAA Journal (Reference 7). The structure (Figure 3.13-20), is a short, wide cylinder with a moderate thickness-to-radius ratio. The applied loads and the output stresses are pure uncoupled harmonics. For this finite element analysis, the cylinder is divided into 50 elements of equal size. This problem checks the harmonic deflections, element stresses, and forces. Figure 3.13-21, Sheets 1 and 2, compares DYNAX results with the results given in the article.

3.13.1.4.4 Problem 4

The fourth problem is taken from an article by Reismann and Padlog (Reference 8). A ring (line) load of magnitude P (500 lb) is suddenly applied to the center of a freely supported cylindrical shell. The dimensions of the shell and the time history of load are shown in Figure 3.13-22. Because of symmetry, only one-half of the cylinder is modeled, using 80 elements of equal size. The time history of radial deflection and meridional moments from DYNAX and from Reismann and Padlog are compared in Figures 3.13-23 and 3.13-24 respectively.

3.13.1.4.5 Problem 5

For the fifth problem, the method of mode superposition is used to solve a shallow spherical cap with clamped support under the action of suddenly applied, uniformly distributed load. The dimensions of the shell and the load time history are shown in Figure 3.13-25. The first 12 modes were considered to formulate the uncoupled equations of motion. Each of these equations was solved by the step-by-step integration method using a time step of 0.1×10^{-4} sec. The results are compared with those obtained by S. Klein (Reference 9); see Figures 3.13-26 and 3.13-27.

3.13.1.4.6 Problem 6

The sixth problem is a hyperbolic cooling tower (Figure 3.13-28). The tower is analyzed for horizontal earthquake motion. A response spectrum for 2 percent damping (Figure 3.13-29) was used for this analysis. The root mean square values of the meridional force are compared with those obtained by Abel et al. (Reference 10) in Figure 3.13-30.

3.13.1.5 EASE - Elastic Analysis for Structural Engineering (Reactor/Auxiliary Building)

The Elastic Analysis for Structural Engineering (EASE) was developed by Engineering Analysis Corporation, Redondo Beach, California. The program is maintained by Control Data Corporation and is in the public domain. It performs static analysis of two- and three-dimensional trusses and frames, plane elastic bodies, and plate-and-shell structures. The finite element approach is used with the standard linear or beam elements, the plane stress triangular element, and a triangular plate bending element.

The program accepts temperature loads, as well as pressure, gravity, or concentrated loads. A plot feature of the input is available.

The program output includes joint displacements, beam forces, and triangular element stresses and moments.

3.13.1.6 INDIA - Interaction Diagram for Reinforced Concrete Members (Reactor/Auxiliary Building and Residual Heat Removal Complex)

INDIA (Load-Moment Interaction Diagram) is a program used to compute the coordinates and to plot the bending moment-axial load interaction diagram for a rectangular, reinforced-concrete section. The program will plot interaction curves for ultimate strength, yield strength, and working stress methods. Both compression and tension axial loads are considered, as well as positive and negative moments for appropriate cross sections.

The procedures used for the working stress and yield stress methods are taken from American Concrete Institute (ACI) 3l8 Code. Equations used for the ultimate stress method are taken from a University of Illinois civil engineering study. INDIA was originally developed at S&L on the IBM 1130 in 1971. It was converted to a UNIVAC 1106, where it has been successfully operating under EXEC 8 since 1972.

To demonstrate the validity of the program, a sample problem, shown in Table 3.13-3 and Figure 3.13-31, was executed. Calculations were made by hand, and all results were found to be consistent with the theoretical approach.

3.13.1.7 KALSHEL - Kalnins' Shell of Revolution (Reactor/Auxiliary Building)

Kalnins' Shell of Revolution (KALSHEL) is a computer program used to analyze thin axisymmetric shells of revolution for arbitrary load conditions. The solution is obtained by transforming the H. Reissner-Neisser equations to eight first-order ordinary differential equations. An Adams method of numerical integration is used as a basis for the solution of transformed equations. Since the program is based on classical shell theory, it has the same limitations.

The shell wall may vary in thickness along the meridian. It consists of up to four layers of different isotropic or orthotropic materials. Branch shells may be connected to the main shell. Surface loads and line loads in the radial, tangential, or meridional directions, meridional moments, and temperature distributions may be considered in the analysis. The temperature distributions are assumed to vary linearly across the thickness. All loads may be asymmetric.

The program output includes shell displacements in the radial, tangential, and meridional directions, meridional rotations, meridional moment, hoop moment, meridional force, hoop force, transverse-shear force, and twist-shear force. In addition, outer fiber stresses calculated from the stress resultants may be obtained.

The program was originally developed by A. Kalnins of Lehigh University (Reference ll). It was acquired by S&L in l969. This version was modified by S&L to sum displacements and stress resultants of the individual Fourier harmonics along meridians at specified angles. The program is currently maintained on the S&L UNIVAC 1106 operating under EXEC 8.

A number of test cases were run to check the program options and validity of solution. One of the practical problems included here is the analysis of conical shell subjected to eccentric line load. The shell is made of two parts, cylindrical and conical, and both are of reinforced concrete with different thicknesses as shown in Figure 3.13-32. The problem has been analyzed by this program and also by the public domain program SABOR III.

Results from the two programs are compared in Figures 3.13-33 through 3.13-36. Figures 3.13-33 and 3.13-34 show a comparison of shell forces along a meridian at 0° (symmetric with respect to the load). Figures 3.13-35 and 3.13-36 show a comparison of shell forces around the circumference at an elevation where the load is applied. As shown in these figures, the results compare favorably.

3.13.1.8 MASS IV - Matrix Analysis of Seismic Stresses (Reactor/Auxiliary Building)

Matrix Analysis of Seismic Stresses (MASS) IV is used for performing seismic analysis of plane and space trusses and frames and plane grids. Either the response spectrum method or the time-history method can be used, depending on the forcing function available. Both methods use the normal mode approach. In the case of time-history analysis, the decoupled differential equations of motion are integrated numerically using Newmark's β-method (Reference 2). Included in the program are input options allowing for member releases, input stiffness between two nodes, and rigid members. The program output includes

a. Stiffness
b. Mass and mass-stiffness triple product matrices
c. Modal periods
d. Eigenvectors and participation factors
e. Modal displacements
f. Member and joint forces
g. Probable and absolute maxima of displacements and forces.

The MASS program was developed by S&L in 1968. Version IV is currently maintained on a UNIVAC 1106 operating under EXEC 8. It has been used successfully since 1971. Two problems for validating the program are presented.

3.13.1.8.1 Problem 1

In the first problem, a three-story shear building is analyzed and compared to a solution obtained by Biggs (Reference 3). The structure is represented by the closed-coupled system shown in Figure 3.13-11. The masses and stiffness values used are also shown. For the analysis, the following response spectrum was used:

Frequency (Hz)	Displacement (in.)
1.00	3.30
2.18	1.40
3.18	0.66

The results obtained by Biggs and from MASS IV are compared in Table 3.13-1.

3.13.1.8.2 Problem 2

In the second problem, results of MASS IV are compared to those obtained by Wilson (Reference 4) using the SAP IV program. At the fixed end of a cantilever beam, an acceleration is applied (Figure 3.13-37). The natural periods calculated by both SAP IV and MASS IV are shown in Table 3.13-2. A comparison of the bending moment at the fixed end of the cantilever beam is shown in Figure 3.13-38. As demonstrated in both examples, MASS IV performs an accurate analysis.

3.13.1.9 PLFEM II - Plate Finite Element Method (Reactor/Auxiliary Building)

Plate Finite Element Method (PLFEM II) is used to analyze plane elastic bodies, plates, and shell structures by the stiffness matrix method. The program uses two finite elements, rectangular and triangular.

Elastic spring supports or an elastic foundation may be considered in the analysis. Orthotropic materials may also be considered in conjunction with the rectangular element. Pressure loads, concentrated forces, nodal displacements, and temperature loads may be considered in the analysis. All loading cases may be factored or combined in any manner.

The program output includes deflections and rotations of all joints and membrane stresses (normal, shearing, and principal) at the center of each element; the resultant moments (x, y, twisting, and principal); and shears and reaction forces. An equilibrium check is made to determine the accuracy of the results.

PLFEM II, developed on a UNIVAC 1108 in 1966, is maintained by S&L. Since May 1972, it has been operating successfully on the S&L UNIVAC 1106 under EXEC 8.

Three sample problems are presented to demonstrate the validity of PLFEM. Plots of the computer results obtained are compared with theoretical results and results obtained by other methods.

3.13.1.9.1 Problem 1

The first problem is an analysis of a rectangular tank filled with water, which was presented by Y. K. Cheung and J. D. Davies in an article in May 1967 (Reference 12). The finite element used was presented by Zienkiewicz and Cheung in the Proceedings of the Institute of Civil Engineers in August 1964 (Reference 13). Experimental results obtained agreed exactly with the finite element results except at a few isolated points where very small differences were noted. The PLFEM grid and loading for the tank problem are shown in Figure 3.13-39. The grid used is the same size as that used by Cheung and Davies. Moments in three regions of the tank are plotted along with the PLFEM results in Figures 3.13-40 through 3.13-42.

3.13.1.9.2 Problem 2

In the second analysis, a rectangular plate with a circular hole in its center is subjected to a uniform plane stress. The grid used in the PLFEM analysis is shown in Figure 3.13-43. Because of double symmetry, only one-quarter of the plate is analyzed. Results obtained from the PLFEM analysis are plotted in Figure 3.13-44 against the exact values as given by Timoshenko and Goodier in Reference 1.

3.13.1.9.3 Problem 3

In the third problem, a square plate having a rectangular hole in its center is analyzed for the effect of a temperature gradient through the plate. The grid used in the PLFEM analysis is shown in Figure 3.13-45. Only one-quarter of the plate is analyzed because of double symmetry. Moment values obtained by PLFEM are plotted for two regions of the plate in

Figure 3.13-46. For comparison, values of the moments obtained by an analysis based on the Hrennekoff framework analogy are also shown.

3.13.1.10 SLSAP - Sargent & Lundy Structural Analysis Program (Reactor/Auxiliary Building and Residual Heat Removal Complex)

The S&L Structural Analysis Program (SLSAP) was developed by E. Wilson of the University of California at Berkeley. It is maintained by S&L. The program uses the stiffness matrix method to analyze two- and three-dimensional frames, trusses, and grids; three-dimensional elastic solids; and axially symmetric solids, plates, and shells, for arbitrary static loads. Dynamic analyses for frequencies and mode shapes, spectral analysis, and numerical integration analyses are also possible.

The program allows materials with arbitrary elastic constants, combined loadings, rigid members, elastic supports, and a combination of different element types.

Included in the program output are displacement and rotations of all joints, nodes, forces, or stresses in members or elements; frequencies and mode shapes; and dynamic response in terms of displacements and forces.

The original version of SLSAP dates back to 1968. S&L currently maintains the SLSAP IV version. The program can successfully operate on either a UNIVAC 1106 or a CDC 6600 computer. It is primarily used for static analysis. Results from the program have been compared with several other static and dynamic computer programs and classical solutions. Two examples of these validation problems are presented.

3.13.1.10.1 Problem 1

The first problem is a cantilever beam under both uniform and concentrated load (the beam was modeled for SLSAP using 10 equal-length beam elements). It has a cross-sectional area of 1 x 2 in., length 10 in., and a Young's modulus of 30 x 10^3 ksi. A uniform load q = 2 kips/in. and a concentrated load of 10 kips at one end of the beam are applied. The results from the program are compared to analytical results obtained by Timoshenko and Gere. Figure 3.13-47 shows excellent agreement for the bending moment obtained in both solutions.

3.13.1.10.2 Problem 2

In the second problem, a simply supported square plate under uniform loading is analyzed. A 10-in.-square by 1-in.-thick square plate with Poisson's ratio = 0.3 and Young's modulus = 30 x 10^3 ksi, was loaded with 1-ksi pressure. The results obtained were compared to those presented by S. Timoshenko and S. Woinowsky-Krieger. The bending moments M_{xx} and M_{yy} for both the x and y symmetry lines obtained in the two solutions are shown in Figure 3.13-48. The maximum bending moment that occurs at the center of the plate differs by only 1.05 percent.

3.13.1.11 SOR III - Shell of Revolution (Reactor/Auxiliary Building)

The Shell of Revolution (SOR III) was developed by Knolls Atomic Power Laboratory for the AEC. It is maintained by S&L. This program analyzes thin shells of revolution subjected to axisymmetric loading by numerically integrating the governing differential equations, using a generalized Adams-Moulton method.

Arbitrary distribution of normal, tangential, and moment surface loadings, as well as edge forces and deflections, may be considered in the axisymmetric loadings. Input of boundary conditions allows the consideration of elastic support conditions. The effect of temperature variations along the meridian or across the thickness also is considered.

The program output includes shell displacements, outer fiber stresses and strains, and stress resultants. Version III was acquired by S&L in 1969 and is currently maintained on S&L's UNIVAC 1106 computer. The S&L version has been modified to punch data for plotting.

Results from this program have been frequently compared with other available solutions and other computer programs to test the validity of the program. One of these comparisons is the analysis of a circular, flat, reinforced-concrete plate. The details of the problem and the boundary conditions are shown in Figure 3.13-49. Results of the SOR III analysis were compared with the finite element program, SABOR III. Figure 3.13-50 shows the bending moment in the meridional and hoop directions. Figure 3.13-51 shows the comparison of radial shear. As shown in these figures, results compare favorably.

3.13.1.12 SSANA - Spring-Slab Analysis (Reactor/Auxiliary Building and Residual Heat Removal Complex)

Spring-Slab Analysis (SSANA) was written to facilitate the reduction of a reinforced-concrete shear building and the equipment in the building to a system of rigid slabs interconnected by weightless linear springs. The program calculates the centroid, total weight, and the weight moment of inertia about the vertical and two horizontal centroidal axes of each slab. The program also calculates the spring stiffness of concrete walls and its distance from the mass centroid.

Spring constants of shear walls are computed based on the following equation:

$$K = \frac{1}{DT}$$

where

DT = DF + DS

DF = Flexural deflection/unit load

DS = Shear deflection/unit load

SSANA was written and is maintained by S&L. It currently operates on a UNIVAC 1106 operating under EXEC 8.

Hand calculations were used to validate the program. As an example of this validation, stiffness and rotary mass were calculated for elements of the structure shown in Figure 3.13-

52. A comparison of results from SSANA and hand calculations shown in Tables 3.13-4 and 3.13-5 demonstrates the accuracy of the program.

3.13.1.13 STRESS-II - Structural Engineering Systems Solver (Reactor/Auxiliary Building)

The Structural Engineering Systems Solver (STRESS-II) was developed by the Massachusetts Institute of Technology. It is maintained by the University Computing Company and is in the public domain. The program uses the stiffness matrix method to analyze plane and space trusses and frames, and plane grids.

The structure can be analyzed for arbitrary joint loads, member loads, temperature changes, and joint displacements. A plotting feature is available with the program. The output includes joint displacements, equilibrium checks and reactions, and member forces.

The version currently used by S&L was adapted to the UNIVAC 1100 Series computer by the Chi Corporation, Cleveland, Ohio, which has maintained it since 1972.

3.13.1.14 STRUDL II - Structural Design Language (Reactor/ Auxiliary Building and Residual Heat Removal Complex)

The Structural Design Language (STRUDL II) was developed by the Massachusetts Institute of Technology. It is maintained by McDonnell Douglas Automation Company. Linear, static, or dynamic analyses may be performed for finite element representations of structures using stiffness matrix methods. Nonlinear static problems and stability problems also may be treated.

The program is capable of analyzing plane trusses and frames, grids and elastic bodies, space trusses and frames, or three- dimensional elastic solids subjected to arbitrary loads, temperature changes, or specified displacements. Either earthquake accelerations or time-history force may be used. In addition to analysis, the program is capable of doing structural steel design according to the American Iron and Steel Institute (AISI) Code, and reinforced or prestressed concrete design according to the ACI Code.

The program output depends on the type of finite element used and the analysis that was performed. Included in the output are displacements and member forces and moments, or element stresses and moments. Eigenvalues, eigenvectors, and time-history response or nodal response may be obtained for dynamic analyses. Member sizes may be obtained if the design portion is used.

This program has been in the public domain since 1968. Two versions are currently being used: one is maintained by the McDonnell Douglas Automation Company on IBM 370 Series hardware, and one is maintained by UNIVAC on the 1100 Series hardware.

3.13.1.15 TEMCO III - Reinforced Concrete Sections Under Eccentric Loads and Thermal Gradients (Reactor/ Auxiliary Building and Residual Heat Removal Complex)

TEMCO analyzes reinforced-concrete sections subject to separate or combined action of eccentric loads and thermal gradients. The effect of temperature is induced in the section by reactions created by the curvature restraint.

The analysis may be done assuming either a cracked or an uncracked section. Material properties can be assumed to be either linear or nonlinear. The program is capable of handling rectangular as well as nonrectangular sections. The program input consists of section dimensions, areas and location of each layer of reinforcing steel, loads, load combinations, and material properties.

The curvature and axial strain corresponding to the given eccentric loads (axial load and bending moment) are determined by an iterative procedure. Thermal gradient is applied on the section by inducing reactions created by the curvature restraint, i.e., there is no curvature change due to a thermal gradient on the section. The axial expansion is assumed to be free after thermal gradient is applied. An iterative procedure is again used for finding the final strain distribution in which equilibrium of internal and external loads is satisfied.

The program output consists of the echo of input, combined loads, final location of neutral axis, final stresses in steel and concrete, and final internal forces. Similar intermediate results (before thermal gradient is applied) can also be output if desired. The program has applications to a wide variety of reinforced-concrete beams and columns, slabs, and containment structures subject to various combinations of external loads and thermal gradients. The program was developed and is maintained by S&L. Since February 1972, the program has been extensively used at S&L on UNIVAC 1106 hardware operating under EXEC 8.

To demonstrate the validity of TEMCO, program results are compared with hand-calculated results. Three example problems are considered. The section and material properties for each problem are given in Table 3.13-6, along with the applied external forces and thermal gradients.

The first problem considered involves a section with two layers of steel under the action of a compressive force applied at the centerline of the section, a bending moment, and a thermal gradient. A cracked analysis of the section is required, assuming nonlinear material properties.

The second problem considered involves a section with two layers of steel under the action of a tensile force applied at the centerline of the section, a bending moment, and a thermal gradient. A cracked analysis of the section is required, assuming nonlinear material properties.

The third problem considered involves a section with two layers of steel under the action of a tensile force applied at the centerline of the section, a bending moment, and a thermal gradient. A cracked analysis of the section is required, assuming linear material properties. The hand-calculated solution was obtained according to the following outlined procedure:

a. Assume the location of neutral axis and the stress distribution to be the same as those given by the program under the given mechanical loading

b. Compute the strain distribution under the given mechanical loading

c. Compute the stress resultants by integration and using the proper stress-strain relationships

d. Check for equilibrium with external mechanical loads

e. If equilibrium is satisfied, compute the curvature imposed on the section by the given thermal gradient

f. Compute the final curvature by subtracting the thermal curvature from the mechanical curvature

g. Compute the new axial strain so that equilibrium is satisfied, keeping the curvature constant

h. Compute the final stress resultants by integration, using the proper stress-strain relationships

i. Compute the thermal moment

j. Check for equilibrium and compare program results with hand-calculated results.

Results obtained using this procedure, together with those computed by TEMCO, are presented in Table 3.13-7. It is concluded that results given by the program agree very well with results obtained by hand calculations, and that equilibrium between internal and external forces is satisfied for all three problems.

3.13.1.16 CAPAN - Cable Pan Analysis (Reactor/Auxiliary Building and Residual Heat Removal Complex)

Cable Pan Analysis (CAPAN) is a computer program used in the analysis of continuous cable pan systems. Section properties of cable pans and allowable stresses for bending about both axes for both seismic and nonseismic conditions are computed. Given a pair of response spectra for any slab, allowable pan support spacing can also be computed.

Peak accelerations (both horizontal and vertical) are used in computing the moments due to seismic loads. The allowable spacing is computed for dead load, dead load plus live load, and dead load plus earthquake. The minimum value is chosen as allowable pan spacing.

CAPAN was developed by S&L in 1972. It is currently maintained on a UNIVAC 1106 operating under EXEC 8.

As an example of validation, the support spacing of a pan 12 in. wide, 4 in. deep, and 14 gage thick was analyzed. CAPAN results and those from hand calculations were compared. As shown in Table 3.13-8, the results are in good agreement.

3.13.1.17 MVI - Matrix Analysis for Seismic Stresses Input Generator (Reactor/Auxiliary Building and Residual Heat Removal Complex)

Mass V Input Generator (MVI) is a computer program that generates data on cable pan hangers. These data are stored on magnetic tape and later used as input to S&L program MASS V (Matrix Analysis for Seismic Stresses) to perform seismic analysis. It is written in Fortran V language and represents the first step of Method l in the design of cable pan hanger systems that support Category I cables.

For a given width and height of hanger, number of levels, and member properties, MVI generates frame geometry and other necessary data in a format acceptable to the MASS V program. Each hanger is loaded with unit mass per level, and subjected to unit horizontal acceleration. Since this is an input-generation program for MASS V, the program is validated by checking generated input for MASS V.

3.13.1.18 ELHAN - Elastic Hanger Analysis (Reactor/Auxiliary Building and Residual Heat Removal Complex)

Elastic Hanger Analysis (ELHAN) is a postprocessor program used in the design of hangers to support Category I cables. It represents Step 3 in the design of Type l cable pan hangers. The hangers described in the program MVI are designed by using ELHAN. The various functions performed by ELHAN are as follows.

a. Reads variations of dead load and horizontal and vertical response spectra for all slabs. The response spectra should be obtained from the project seismic report. For horizontal excitation, the response spectra used is the envelope of maximum response due to north/ south and east/west

b. Reads results of MASS V program from tape as described in Step 2

c. Forces and deflections obtained as above are modified to represent actual load on the hangers and actual floor acceleration (results are stored for unit load and unit acceleration)

d. Computes forces induced due to dead load and vertical excitation

e. Combines and checks stresses.

The program has an option to design vertical members with or without compression criteria. If compression criteria are used, the members with (KL/r) ratios greater than 200 are omitted from the tabulation. The program also has an option to print the data stored on the tape for checking purposes. The program was checked against hand calculations. In all cases the program correctly selected all failing members.

3.13.1.19 RIGHAN - Rigid Hanger Analysis (Reactor/Auxiliary Building and Residual Heat Removal Complex)

Rigid Hanger Analysis (RIGHAN) is a program used for the analysis and design of laterally supported cable pan hangers. Input to the program consists of variations of dead load and hanger widths, member properties, and a set of horizontal and vertical response spectra for each slab. The program is used to compute stresses due to the combined dead load and horizontal and vertical excitations.

Rigid Hanger Analysis was developed by S&L in 1972. It is currently maintained on a UNIVAC 1106 operating under EXEC 8.

A typical hanger used for validation is shown in Figure 3.13-53. Results of the program were compared with hand calculations. As shown in Table 3.13-9, RIGHAN correctly analyzes and designs rigid hangers.

3.13.1.20 MASS V - Matrix Analysis for Seismic Stresses (Reactor/Auxiliary Building and Residual Heat Removal Complex)

Matrix Analysis for Seismic Stresses (MASS V) is used to perform seismic analysis of plane and space trusses and frames and plane grids. Either the response spectrum method or the time-history method can be used, depending on the forcing function available. Both methods use the normal mode approach. In the case of time-history analysis, the decoupled differential equations of motion are integrated numerically using Newmark's β-method (Reference 2).

Included in the program are input options allowing for member releases, input stiffness between two nodes, and rigid members. The program output includes

a. Stiffness

b. Mass and mass-stiffness triple product matrices

c. Modal periods

d. Eigenvectors and participation factors

e. Modal displacements

f. Member and joint forces

g. Probable and absolute maxima of displacements and forces.

The MASS program was developed by S&L in 1968. Version V is currently maintained on a UNIVAC 1106 operating under EXEC 8. It has been used successfully since 1972. Two examples of the problems for validating the program are presented.

3.13.1.20.1 Problem 1

In the first example, a three-story shear building is analyzed and compared to a solution obtained by Biggs (Reference 3). The structure is represented by the closed-coupled system shown in Figure 3.13-11. The masses and stiffness values used are also given in Figure 3.13-11. For the analysis, the following response spectrum was used:

Frequency (Hz)	Displacement (in.)
1.00	3.30
2.18	1.40
3.18	0.66

The results obtained by Biggs and from MASS V are compared in Table 3.13-1.

3.13.1.20.2 Problem 2

In the second example, results of MASS V are compared to those obtained by Wilson et al. (Reference 14) using the SAP IV program.

At the fixed end of a cantilever beam (Figure 3.13-12), an acceleration is applied (Figure 3.13-13). The natural periods calculated by both SAP IV and MASS V are shown in Table 3.13-2. A comparison of the bending moment at the fixed end of the cantilever beam is shown in Figure 3.13-54. As demonstrated in both examples, MASS V performs an accurate analysis.

3.13.1.21 PCAUC - Portland Cement Association, Ultimate Strength Design of Reinforced Concrete Columns (Residual Heat Removal Complex)

Portland Cement Association, Ultimate Strength Design of Reinforced Concrete Columns (PCAUC) is used to design or to investigate reinforced-concrete columns using the ultimate strength theory in accordance with ACI 318-71 Code. The program is capable of designing or investigating tied columns subjected to an axial load combined with uniaxial or biaxial bending moments. The program input consists of the dimensions of sections, material properties, reinforcement requirements, and loading data. The slenderness effect is not included in the present program.

Output from the design part of the program includes the steel reinforcement arrangement, ultimate capacity for all loading cases, and interaction control points data. Output from the investigation part of the program includes either biaxial or uniaxial interaction data. Sargent & Lundy has modified the original PCA program to follow the 1971 ACI building code and to provide more design options and greater capacity.

PCAUC is a modified version of the program "Ultimate Strength Design of Concrete Columns," developed by the Portland Cement Association. The program was obtained by S&L in 1972 and modified. It is currently maintained on the UNIVAC 1106 operating under EXEC 8.

To validate PCAUC, documented results from several problems were compared with PCAUC results. Three of these problems are presented herein.

3.13.1.21.1 Problem 1

The first problem is taken from Wang and Salmon, Reinforced Concrete Design (Reference 15). The reinforcement for a 17 x 17-in. square tied column is designed for compression control loads. The loads include a deadload axial load of 214 kips and bending moment of 47 ft-kips, and a liveload axial load of 132 kips and a bending moment of 23 ft-kips. The reinforcement is designed according to the ACI Code with $f_c' = 3000$ lb/in.^{2} and $f_y = 40{,}000$ lb/in.^{2}

The solution as given in Reference 15 is identical to the solution obtained from PCAUC, shown in Figure 3.13-55. It should be noted that the ultimate capacity provided by PCAUC has been reduced by a factor of 0.7.

3.13.1.21.2 Problem 2

The second problem is also taken from Reference 15. The reinforcement for a tied column 14 in. wide and 20 in. deep is designed for tension control loads with a deadload axial load of 43 kips and bending moment of 96 ft-kips, and a liveload axial load of 32 kips and bending moment of 85 ft-kips. The reinforcement is designed according to ACI Code using symmetrical reinforcement with respect to its width, and with $f_c' = 4500$ lb/in.^{2} and $f_y = 50{,}000$ lb/in.^{2}. The solution given in Reference l5 is identical to the solution obtained from PCAUC, shown in Figure 3.13-56.

3.13.1.21.3 Problem 3

The third problem is taken from Notes on ACI 318-71 Building Code Requirements With Design Applications, by the Portland Cement Association (Reference 16). A square tied column 28 in. x 28 in. is designed for biaxial bending loads for the following service loads.

Service Load	Dead Load	Live Load
Axial	550 kips	300 kips
M_x	320 ft-kips	200 ft-kips
M_y	160 ft-kips	100 ft-kips

The bending is designed according to the ACI Code with $f_c' = 5{,}000$ lb/in^2 and $f_y = 60{,}000$ lb/in.^{2}.

The selected reinforcement obtained from PCAUC, shown in Figure 3.13-57, is identical to that from Reference 16. It should also be noted that the interaction control points obtained by both show good agreement.

3.13.1.22 STAND - Structural Analysis and Design (Reactor/ Auxiliary Building)

Structural Analysis and Design (STAND) is an integrated system programmed to perform analysis and design of structural steel members according to the 1969 AISC Specification. It consists of the following subsystems:

a. Beam edit
b. Rolled beam design
c. Composite beam design
d. Plate girder design
e. Column edit
f. Column design
g. Column baseplate design.

The program input consists of member geometry and basic loadings. The design is performed for specified combinations of basic loadings and overstress factors. For floor framing systems, the program is capable of automatically transferring reactions from tributary beams to supporting members. There are many design control parameters available, such as minimum and maximum depth limitations, shape of the rolled section, location of the lateral support of the compression flange, material grade of yield stress, deflection limitations, flange cutoff criterion, and location of stiffeners.

For columns, the program can be used to account for axial loading as well as uniaxial or biaxial bending. For column baseplate design, only axial load and column combinations are considered.

The program output includes the complete final design and provides the designer with sufficient intermediate information to enable him to evaluate the results. For rolled and composite beam designs, complete details of shop-welded and field-bolted end connections are contained in the output. Supplementary information for economic evaluation of the design is also provided.

STAND was developed and is maintained by S&L. Since May 1972, the program has been extensively used at S&L on UNIVAC 1106 hardware operating under EXEC 8. Some of the principal applications include the design of steel floor framing using various types of horizontal structural elements, and the design of columns or beam columns.

To validate STAND, results from the program were compared with results from example design problems in the Manual of Steel Construction (Reference 17). Four problems are given herein.

3.13.1.22.1 Problem 1

The first problem is a rolled beam design problem (Example 1, pp. 2-4, 5). A beam of 36 ksi steel is designed for a 125 kip-ft angling moment, assuming its compression flange is braced at 6.0-ft intervals. The results, listed in Table 3.13-10, show that STAND selects a more efficient section.

3.13.1.22.2 Problem 2

The second problem is a composite beam design problem (Example 1, pp. 2-143, 144). A non-coverplated composite interior floor beam is designed. Limits of 1.5 in. for deadload deflection and 1.2 in. for liveload deflection are imposed. The results, shown in Table 3.13-11, are nearly identical.

3.13.1.22.3 Problem 3

The third problem is a column design problem with three examples, (Examples 1, 2, and 5, pp. 3-4, 5, 9). The first is the design of a W12 column of 36-ksi steel that will support a concentric load of 670 kips. The effective length with respect to its minor axis is 16 ft, and to its major axis, 31 ft.

The second is the design of an 11-ft-long W12 interior bay column of 36-ksi steel that will support a concentric load of 540 kips. The column, rigidly framed at the top by 30-ft-long, W30 x 116 girders connected to each flange, is braced normal to its web at the top and the base.

The third is the design of a Wl4 column of 36-ksi steel for a tier building, 18-ft story height, that will support a 600-kip gravity load and a 190-kip-ft maximum wind moment, assuming K = l relative to both axes and bending is about the major axis.

The results from all three checks are identical to those in the AISC Manual, and are shown in Table 3.13-12.

3.13.1.22.4 Problem 4

The fourth problem is a plate girder design problem (Example 1, p. 2-108). A welded plate girder is designed to support a uniform load of 3 kips/ft and two concentrated loads of 70 kips as shown in Figure 3.13-58. The compression flange of the girder is laterally supported only at points of concentrated load. The close results are shown in Table 3.13-13.

3.13.1.23 PLGIRD - Plate Girder Design (Reactor/Auxiliary Building)

Plate Girder Design (PLGIRD) is used to design welded plate girders according to specified loadings and geometries. The design criteria are in accordance with the AISC Specification for the Design of Structural Steel for Buildings, 1969. The program can automatically account for variations in steel stress according to the material thickness for seven types of structural steel. The program also takes into account the variation of the weight of the girder along the span due to flange cutoffs. Input to the program consists of the specified minimum or maximum web depth, maximum flange width, maximum plate thickness, and vertical loadings.

PLGIRD was developed by S&L in 1967. It is currently maintained on a UNIVAC 1106 operating under EXEC 8.

To validate PLGIRD, results from the program were compared with results from example design problems in the Manual of Steel Construction (Reference 17). One of these problems is given.

A welded plate girder (Example 1, p. 2-108) is designed to support a uniform load of 3 kips/ft and two concentrated loads of 70 kips, as shown in Figure 3.13-58. The compression flange of the girder is laterally supported only at points of concentrated load. The close results are shown in Table 3.13-13.

3.13.1.24 MESHG (Reactor/Auxiliary Building and Residual Heat Removal Complex)

The program MESHG is written for the UNIVAC 1106/130k machine. It is used as a preprocessor for finite element programs that are currently available. Its main function is to check the geometry of the input by plotting the mesh. Options are available allowing the user to scale the plot, number elements and/or nodes, draw different isometric views of three-dimensional data, rotate axes for two-dimensional data, and plot a vector field. This program is repeatedly verified by inspection of each plotted mesh.

3.13.1.25 COGO (Reactor/Auxiliary Building and Residual Heat Removal Complex)

COGO is a problem-oriented computer language and programming system for solving geometric problems in civil engineering on a digital computer. Each problem is solved by writing a "COGO program," consisting of a series of commands that describe the operations to be performed in order to effect a solution. Data needed to perform each operation are included as part of the command. COGO was developed at the Massachusetts Institute of Technology, and is in the public domain.

3.13.1.26 PIPSYS (Reactor/Auxiliary Building and Residual Heat Removal Complex)

Integrated Piping Analysis System (PIPSYS) is used to analyze piping systems of power plants for static and dynamic loadings, and to compute the combined stresses. The following analyses are performed:

a. Static - analysis of thermal, displacement, distributed, and concentrated weight loadings on piping systems

b. Dynamic - analysis of piping system response to seismic and fluid transient loads

c. Stress combination - computation of the combined stresses in the piping components in accordance with the ASME Boiler and Pressure Vessel (B&PV) Code Section III (Reference 18).

The static, dynamic, and stress combination analyses can be performed independently or in sequence. Results of the static and dynamic analyses can be stored on magnetic tape for use at a later date to perform the stress combination analysis. The piping configuration can be plotted on a Calcomp plotter.

The input consists of the piping system geometry, material properties, and static and dynamic loadings. Various options exist to control the length of the output. The default option generally prints only the summary of input data and final results.

PIPSYS was developed by S&L in 1972. It is currently maintained on a UNIVAC 1106 operating under EXEC 8. To demonstrate the validity of the PIPSYS program, three problems are presented.

3.13.1.26.1 Problem 1

To illustrate the validity of the static portion of PIPSYS, the problem shown in Figure 3.13-59 was analyzed and the results compared to those given in Reference 19. Table 3.13-14 shows the comparison of member end moments. As shown, the results from PIPSYS and Reference 19 are in good agreement.

3.13.1.26.2 Problem 2

To illustrate the validity of the stress combination analysis portion of PIPSYS, the problem outlined in Reference 20 was reanalyzed on the PIPSYS program. The layout of the piping system is shown in Figure 201 of Reference 21. The stress analysis is performed at location 19. The summary of load sets and descriptions is presented in Table 3.13-15. The results of the stress analysis are presented in Tables 3.13-16 and 3.13-17. The notations and equation numbers correspond to the ASME B&PV Code (Reference 18). The PIPSYS results are in very close agreement with those presented in Reference 20.

3.13.1.26.3 Problem 3

To illustrate the validity of the dynamic analysis portion of PIPSYS, a problem was analyzed and the results obtained from PIPSYS were compared with those from two public domain computer programs. These are DYNAL (Reference 22) and NASTRAN (References 23 and 24).

Figure 3.13-60 shows a schematic representation of the piping system analyzed. The system is modeled with simple beam elements with a total of 136 degrees of freedom. Figure 3.13-61 shows the time-dependent blowdown forces at the relief valve locations. Results of PIPSYS are compared with DYNAL and NASTRAN in Table 3.13-18 and in Figure 3.13-62. The results from all three programs are in quite close agreement.

3.13.1.27 NOHEAT

Sargent & Lundy's NOHEAT computer program is used to determine the code quantities $(\Delta T_1)_I$, $(\Delta T_2)_I$, and $(\alpha ATA\text{-}\alpha BTB)_I$, resulting from fast fluid temperature changes. It can be used for piping products and dissimilar metal joints.

Each fitting is modeled using an axisymmetric solid finite element mesh, with a time-dependent forced-convection heat flow boundary condition forced on the inside surface of the pipe. The meshes are internally generated using user-supplied dimensions. The forced-convection boundary conditions are determined using the design thermal transient definitions associated with Envelope Load Set. The following procedure is then used to determine the time-dependent (ΔT_1), (ΔT_2), and $(\alpha ATA\text{-}\alpha BTB)$ quantities:

a. The time-dependent temperature distribution on the fitting is determined by direct time integration of the finite element heat conduction equations

b. Integrations of the temperature distribution at every instant in time are then performed using the code definitions in NB-3653 to determine the quantities (ΔT_1), (ΔT_2), $(\alpha ATA\text{-}\alpha BTB)$.

3.13.1.28 AXTRAN

Sargent & Lundy's AXTRAN computer program is used to determine the code quantity $(\alpha ATA\text{-}\alpha BTB)_I$ resulting from axial temperature distribution along stagnant lines.

The program models the piping as an infinitely long cooling fin. Heat loss from the fin is governed by insulation characteristics that are obtained from the insulation vendor. Input to the program consists of a temperature-versus-time description of the thermal transient to be forced on the model, and a physical description of the model. Output from the program consists of a time history of the temperature distribution along the pipe and a time history of the code nominal stress $Eab(\alpha ATA\text{-}\alpha BTB)_I$.

3.13.1.29 SEISHANG

3.13.1.29.1 SEISHANG (Version 3) (Reactor/Auxiliary Building and Residual Heat Removal Complex)

SEISHANG (Seismic Analysis of Hangers) is used for the analysis and design of electrical cable and heating, ventilation and air conditioning (HVAC) duct support systems. The program computes the allowable spans for cable trays and selects the proper member sections for various types of supports. The input load functions can be in the form of dead load, live load, or dynamic response spectra.

Program input consists of geometric data, material properties, member properties, and external loadings. Program output consists of allowable spans, member sizes, and mechanical response.

SEISHANG was developed at S&L in 1976. It is currently maintained on UNIVAC 1100 Series hardware under EXEC 8.

To demonstrate the validity of the program, two problems are presented.

3.13.1.29.1.1 Problem 1

A typical cable tray, shown in Figure 3.13-63, is analyzed and compared to the solution obtained by hand calculation. The results obtained from SEISHANG and by hand calculation are compared in Table 3.13-19. The results show good agreement.

3.13.1.29.1.2 Problem 2

Two typical HVAC supports, shown in Figures 3.13-64 and 3.13-65, are analyzed and compared to the solution obtained from the DYNAS (09.7.090-9.0) computer program, Reference 25. The results obtained from SEISHANG and from DYNAS are compared in Tables 3.13-20 and 3.13-21. The HVAC support shown in Figure 3.13-64 is also analyzed by the PIPSYS (09.5.065-3.4) computer program, Reference 26. The results obtained from SEISHANG and from PIPSYS are compared in Table 3.13-22. The results show good agreement.

3.13.1.29.2 SEISHANG (Version 4)

SEISHANG (Seismic Analysis of Hangers) is used for the analysis and design of electrical cable and HVAC duct support systems. The program computes the allowable spans for cable trays and selects the proper member sections for various types of supports. The input load functions can be in the form of dead load, live load, or dynamic response spectra.

Program input consists of geometric data, material properties, member properties, and external loadings. Program output consists of allowable spans, member sizes, and mechanical response.

SEISHANG was developed at S&L in 1976. It is currently maintained on UNIVAC 1100 Series hardware under EXEC 8.

To demonstrate the validity of the program, two problems are presented.

3.13.1.29.2.1 Problem 1

A typical cable tray, shown in Figure 3.13-63, is analyzed and compared to the solution obtained by hand calculation. The results obtained from SEISHANG and by hand calculation are compared in Table 3.13-19. The results show good agreement.

3.13.1.29.2.2 Problem 2

A typical cable tray support, shown in Figure 3.13-66, is analyzed and compared to the solution obtained from the PIPSYS (09.5.065-6.1) computer program, Reference 27. The analysis results obtained from SEISHANG and from PIPSYS are compared in Table 3.13-23. For member stress calculation, the results obtained from SEISHANG and from hand calculations are compared in Table 3.13-24. The results show good agreement.

3.13.1.30 SUPS (Reactor/Auxiliary Building and Residual Heat Removal Complex)

The SUPS program includes the PFRAME, CONNECTIONS, CINCH, and APLAN modules discussed below.

3.13.1.30.1 PFRAME

PFRAME (Interactive Plane Frame Analysis) is an interactive program that analyzes two-dimensional frames for static loads, using the stiffness approach. Joint movements are allowed only three degrees of freedom. Members are considered as prismatic beam elements. Loads are defined as global joint forces or member end forces.

Input consists of joint coordinates, fixities, member incidence, material/section properties, and joint/member forces. All input is free format and prompted by the program.

Output consists of joint displacements, rotations, support reactions, member end forces, and moments.

PFRAME is a module of the SUPS package and was developed at S&L in 1982. It is maintained on UNIVAC 1100 Series hardware operating under EXEC 8.

The program's validity is demonstrated by two problems. The first is a continuous beam problem shown in Figure 3.13-67. Table 3.13-25 compares PFRAME's results with the solution shown in Beer and Johnston, Reference 28. The second problem is the frame shown in Figure 3.13-68. Table 3.13-26 compares PFRAME's results with the solution shown in Gere and Weaver, Reference 29. The tables show good comparison.

3.13.1.30.2 CONNECTIONS

CONNECTIONS (Connections Investigation Program) aids in checking the adequacy of connections. The program checks the design of sliding- and friction-type Framed Beam Connections.

Design procedures used are given in Structural Design Standard E7 (Reference 30) and conform to the requirements of the AISC Manual of Steel Construction, 1978 Edition (Reference 31). Criteria for reassessing connections on nuclear projects are discussed in Reference 32. The program is interactive with self-documenting input, and prints out a summary of results. References 33 and 34 are applicable for general information.

The program is a module of the SUPS package and was developed at S&L in 1982. It is currently maintained on UNIVAC 1100 Series hardware operating under EXEC 8.

Two problems have been selected to validate the program for each type of connection except for Connection Detail No. 7.7.5 for which three problems are used. Results obtained from the program were compared with hand-calculation results; the results are identical.

The following examples were selected to validate the program for bolted/bolted sliding-type connections (Detail No. 7.7.1 of Reference 30).

3.13.1.30.2.1 Problem 1

Example 1a - Uncoped Connection (L2 = E3)

General criteria with operating-basis earthquake (OBE) load case. W10x39 beam (A36) and two 7 x 4 x 3/8 x 6 angles (A36) with 7/8-in.-diameter bolts (A325) (two bolts with pitch equal to 3 in. on instanding leg, four bolts in two rows with pitch equal to 3 in. on outstanding leg). The connection is subjected to a vertical load (R_y = 3.83K), a lateral load (R_x = 1.98K), and a torsional moment (M_z = 4.02K-in.).

The dimensions for connection angles are as follows:

L1	=	6.0 in.	E2	=	7.0 in.
L3	=	0.0 in.	E3	=	3.0 in.
OL	=	4.0 in.	E1	=	1.5 in.
			S	=	0.375 in.

On the outstanding angle, the gage is equal to 5.5 in. and the surface condition is Type A.

Results obtained by hand calculation and program analysis are compared in Table 3.13-27.

Example 1b - Coped Connection

All the parameters are the same as in Example 1a, except the coped distances on the top flange are L2 = 5.5 in. and L3 = 1.25 in. Results obtained by hand calculation and program analysis are compared in Table 3.13-28.

3.13.1.30.2.2 Problem 2

The following examples were selected to validate the program for bolted/welded sliding type connection with side plates (Detail No. 7.7.2 of Reference 30).

Example 2a - Uncoped Connection General Criteria

W8x35 member and plate with two bolts, 7/8-in.-diameter and an allowable tension of 44 (ksi). The connection is subjected to a vertical load of 8.0 (K), a lateral load of 2.27 (K), and a torsional moment of 3.05 (K-in.). The material type for the member is A36 steel and for the plate is A588 steel. The dimensions for the connection plate are distance L1 = 5.50 in. and thickness Tp = 0.375 in.

Slot and pitch sizes are 0.25 in. and 3.0 in. respectively. Distances E1 and E3 are 0.5 in. and 2.75 in. respectively. Use a full penetration weld and consider general criteria with OBE load case.

Results obtained by hand calculation and program analysis are compared in Table 3.13-29.

Example 2b - (Coped Connection)

Same as Example 2a, but the member is coped. Distances L2 and L3 are 5.5 in. and 1.25 in. respectively.

Results obtained by hand calculation and program analysis are compared in Table 3.13-30.

3.13.1.30.2.3 Problem 3

The following examples were selected to validate the program for framed shop-welded/field-bolted-type connections (Detail No. 7.2.9 of Reference 30).

Example 3a - Uncoped Connection (L2=E3)

General criteria with OBE load case. W8x24 beam (A36) and two 4 x 3-1/2 x 3/8 x 5.5 angles (A36) with 7/8-in.-diameter bolts (A325) (fillet weld on instanding leg, weld size equal to 5/16 in., four bolts in two rows with pitch equal to 3.0 in. on outstanding leg). The connection is subjected to a vertical load (R_y = 1.98K), a lateral load (R_x = 0.44K), and an axial load (R_z = 1.38K).

The dimensions for the connection angle are as follows:

E3	=	1.25 in.	L1	=	5.5 in.
E	=	3.5 in.	L3	=	0.0 in.
B	=	0.0 in	OL	=	4.0 in.

On the outstanding angle, the gage is equal to 5.25 in., and the surface condition is Type A.

Results obtained by hand calculation and program analysis are compared in Table 3.13-31.

Example 3b - Coped Connection

All the parameters are the same as in Example 3a, except the coped distances on the top flange are L2 = 5.5 in. and L3 = 1.25 in. Results obtained by hand calculation and program analysis are compared in Table 3.13-32.

3.13.1.30.2.4 Problem 4

The following examples were selected to validate field-welded/ shop-welded friction-type connections (Detail No. 7.2.11 of Reference 30).

Example 4a - Uncoped Connection

General criteria with OBE load case. W10x39 beam (A36) and two 4 x 3-1/2 x 3/8 x 5.5 angles (A36) with 5/16-in. fillet weld (E70) on both instanding and outstanding legs. The connection is subjected to a vertical load (R_y = 2.60K), a lateral load (R_x = 1.50K), an axial load (R_z = 1.50K), and a torsional moment (M_z = 5.0 kip-in.).

The dimensions for the connection angle are as follows:

L1	=	5.5 in.	E3	=	1.25 in.
L3	=	0.0 in	E1	=	4.0 in.
E2	=	3.5 in.	B	=	0.0 in.

Results obtained by hand calculation and program analysis are compared in Table 3.13-33.

Example 4b - Coped Connection

All the parameters are the same as in Example 4a, except that the beam is coped on top with distance L2 = 5.5 in. and L3 = 1.25 in. Results obtained by hand calculation and program analysis are compared in Table 3.13-34.

3.13.1.30.3 CINCH

CINCH (Anchor Plate Assembly Analysis) is an interactive prompting program that analyzes individual expansion anchored plates with a single attachment and concrete expansion anchors. Design procedures are given in Structural Design Standard E11 (Reference 35). The program with its assumptions and limitations is consistent with this standard. The program is self-documenting and prints out a summary of results.

The program is a module of the SUPS package and was developed at S&L in 1984. It is currently maintained on UNIVAC 1100 Series hardware operating under EXEC 8.

The program was validated by comparing the program results to detailed hand calculations. Two problems used for this comparison are shown in the following. The CINCH results are compared with hand calculations in Tables 3.13-35 and 3.13-36.

3.13.1.30.3.1 Problem 1 (Initial Design)

Concrete thickness = 18 in.

Attachment size:

X-dimension = 8 in.

Y-dimension = 8 in.

The center of the attachment area is at the center of the plate. The C.G. of the attachment is at the center of the attachment area.

Default material properties are used.

Loading

SSE Case			OBE Case		
M_x	=	10,000 in-lb	M_x	=	8,400 in-lb
M_y	=	12,000 in-lb	M_y	=	10,000 in-lb
M_z	=	5,000 in-lb	M_z	=	4,200 in-lb
F_x	=	800 lb	F_x	=	670 lb
F_y	=	2,000 lb	F_y	=	1,670 lb
F_z	=	11,000 lb	F_z	=	9,200 lb

3.13.1.30.3.2 Problem 2 (As-Built Reassessment)

18 in. x 18 in. x 1 in. plate with 8-3/4-in.-diameter anchors in reinforced concrete.

Attachment size:

X-dimension = 10 in.

Y-dimension = 10 in.

The center of the attachment area is at X = 8.5 in. Y = 9.5 in. The C. G. of the attachment is offset from the center of the attachment area by X offset = -0.5 in., Y offset = 0.5 in.

OBE Load Case

M_x	=	25 kip-in.	F_x	=	5 kips
M_y	=	37 kip-in.	F_y	=	13 kips
M_z	=	20 kip-in.	F_z	=	15 kips

Loads are not reversible.

An edge of concrete is defined parallel to the x-axis at 3 in. above the top of the plate.

Concrete thickness = 18 in.

3.13.1.30.4 APLAN

APLAN (Attachment Plate Analysis) is a finite element program that can analyze rectangular attachment plates mounted on reinforced-concrete or concrete masonry by means of expansion anchors, headed welding studs, or wire embedments.

APLAN communicates with the user through a simple command- oriented language. It uses free-format input that consists of one or more key words interspersed with its arguments. This command language is used to define plate geometry, anchor location, and loading configurations, and to perform finite element analysis. The material properties for standard expansion anchored and embedded plates, as defined by Standard SDS E11 (Reference 35), have default values in the program, but the user can change these.

Efficient finite elements permit the analysis to be performed interactively. These finite elements are used to perform decoupled bending and plane stress analysis of the attachment plate. The bending analysis includes the partial contact of the plate with the concrete wall, which can result in prying and amplification of anchor tension forces. Plane-stress analysis is performed to determine the shear reactions on the anchors.

The output is printed at the terminal. This program has the capability to print out all the finite element solutions for every element and node of the plate. Because the comprehensive information requires enormous printout time, the program is defaulted to echo out all user input data, equilibrium check, all anchor reactions, and maximum element stress location. The user has the option to request the full output.

The program is a module of the SUPS package and was developed at S&L in 1985. It is currently maintained on UNIVAC 1100 Series hardware operating under EXEC 8.

The program was validated by comparing the program results to those generated by the ADINA program (Reference 36). Three problems were used for this comparison.

3.13.1.30.4.1 Problem 1

17 in. x 19 in. x 3/4 in. plate, shown in (a) of Figure 3.13-69.

8-3/4-in.-diameter concrete expansion anchors.

Concentrated load applied at x = 5 in., y = 13 in.

Loads:	F_z	=	2.50 kips
	M_x	=	50.20 kip-in.
	M_y	=	40.0 kip-in.

Comparison of results showed:

Anchor Number	APLAN Reaction	ADINA Reaction
1	0.19	0.19
2	0.04	0.05
3	0.00	0.00
4	1.34	1.35
5	0.00	0.00
6	3.19	3.20
7	1.35	1.36
8	0.48	0.48

3.13.1.30.4.2 Problem 2

15 in. x 15 in. x 1 in. plate.

Four studs 7/8-in.-diameter, 8 in. long at 1 1/2-in. edge distance.

Concentrated load applied at x = 9 in., y = 9 in.

Loads:	F_z	=	4.00 kips
	M_x	=	40 kip-in.
	M_y	=	50 kip-in.

Comparison of results showed:

Stud Number	APLAN Reaction	ADINA Reaction
1	1.17	1.23
2	0.01	-0.0003
3	4.51	4.49
4	2.93	3.0

3.13.1.30.4.3 Problem 3

12 in. x 22 in. x 1/2 in. plate, shown in (b) of Figure 3.13-69.

Twenty-one deformed wire anchors 0.302-in.-diameter, 1 ft-7 in. long.

Loads: F_z = 24 kips

Comparison of results showed the APLAN stress as 17.13 ksi, and the ADINA stress as 17.49 ksi.

3.13.1.31 ADINA (Reactor/Auxiliary Building)

ADINA (Automatic Dynamic Incremental Nonlinear Analysis) is a computer program for the static and dynamic displacement and stress analysis of solids, structures, and fluid-structure systems. The program can be used to perform linear and nonlinear analyses. The structural systems can be composed of combinations of different finite elements. The program presently contains the following element types:

a. Three-dimensional truss element

b. Two-dimensional plane stress or plane strain element

c. Three-dimensional plane stress element

d. Two-dimensional axisymmetric shell or solid element

e. Three-dimensional solid or thick shell elements

f. Three-dimensional two-node beam element

g. Curved beam element

h. Three-node thin plate/shell element

i. Thin shell element

j. Two- and three-dimensional fluid elements.

The nonlinearities may be due to large displacements and non-linear material behavior. The material descriptions presently available are:

For the Truss Elements

a. Linear elastic

b. Nonlinear elastic

c. Thermo-elastic

d. Elastoplastic (isotropic or kinematic hardening)

e. Thermo-elastic-plastic and creep (isotropic or kinematic hardening).

For the Two-Dimensional Elements

a. Isotropic linear elastic

b. Orthotropic linear elastic

c. Isotropic thermo-elastic

d. Curve description model

e. Concrete model

f. Elastic-plastic materials, von Mises (isotropic or kinematic hardening) and Drucker-Prager yield conditions

g. Thermo-elastic-plastic-creep, von Mises condition (isotropic or kinematic hardening)

h. Mooney-Rivlin material.

<u>For the Three-Dimensional Elements</u>

a. Isotropic linear elastic

b. Orthotropic linear elastic

c. Isotropic thermo-elastic

d. Curve description model

e. Concrete model

f. Elastic-plastic materials, von Mises (isotropic or kinematic hardening) and Drucker-Prager yield conditions

g. Thermo-elastic-plastic-creep, von Mises isotropic or kinematic hardening yield condition.

<u>For the Two-Node Beam Element</u>

a. Linear elastic

b. Elastic-plastic, von Mises yield condition.

<u>For Curved Beam Element</u>

a. Linear elastic

b. Elastic-plastic, von Mises yield condition (isotropic or kinematic hardening).

<u>For Three-Node Plate/Shell Element</u>

a. Linear elastic

b. Elastic-plastic, Ilyushin yield condition isotropic hardening.

<u>For the Shell Element</u>

a. Linear elastic

b. Elastic-plastic, von Mises yield condition (isotropic hardening).

The ADINA program is an out-of-core solver, so very large finite element systems can be considered. Also, all structure matrices are stored such that only nonzero elements are processed, resulting in maximum system capacity and solution efficiency.

In dynamic analysis, the frequencies of the system can be calculated, and the system response can be evaluated using mode superposition or implicit direct-time integration (the Newmark method or the Wilson method), or explicit direct-time integration (the central difference method).

In nonlinear analysis, the finite-element system response is evaluated using an incremental solution of the equations of equilibrium. The incremental equilibrium schemes that can be used are an accelerated modified Newton iteration or the BFGS method. Substructuring can be used to increase the solution efficiency.

ADINA was developed by Klaus-Jurgen Bathe (Reference 37) at the Massachusetts Institute of Technology. It is currently maintained by S&L on the UNIVAC 1100 Series hardware operating under EXEC 8. To demonstrate the validity of the major analytical capabilities of ADINA, the test problems are taken from the ADINA User's Manual and are compared with solutions of the S&L version.

3.13.1.31.1 Problem 1

Frequency Analysis of a Tower Cable

The cable stretched between a ground anchor point and tower attach point, shown in Figure 3.13-70, was analyzed for frequencies of vibration. The cable was modeled using 12 truss elements of linear elastic material, as shown in Figure 3.13-70. The cable had an initial tension of 7520 lb. Insulators weighing 510 lb each were located at nodes 2, 4, and 6, and a cluster of six insulators totaling 3060 lb was located at node 8. Nodes 3, 5, 7, and 9 through 12 are intermediate nodes located along the cable without insulators. The total vertical load acting on the cable nodes was 5677.83 lb, which includes the insulator weights and the cable self-weight.

For the frequency analysis, a lumped-mass matrix of the cable has been assumed to which the masses of insulators have been added. The periods of vibration of the cable about the static equilibrium configuration are given in Table 3.13-37.

3.13.1.31.2 Problem 2

Large Displacement Analysis of an Elastic Simply Supported Plate

The simply supported square plate subjected to a uniformly distributed pressure shown in Figure 3.13-71 was analyzed for its large deflection response. One single 16-node shell element was used to model one-quarter of the plate.

Figure 3.13-71 shows the displacement response predicted in the finite element analysis. The computed displacement response compares very closely to the solutions given by Levy (Reference 38). The effect of using different assumptions on the plate edge in-plane displacements was modeled using the constraint equation option in ADINA.

3.13.1.31.3 Problem 3

Thermo-Elastic Static Analysis of a Cantilever Beam

The cantilever beam shown in Figure 3.13-72 was subjected to a linearly varying temperature gradient in the Z-direction. No mechanical loads were applied. The beam was modeled using three 16-node, three-dimensional elements. Since displacements and strains are small, the analysis was carried out for material non-linearities only, and by using appropriate displacement boundary conditions, only the portion of the beam above the neutral surface was included in the finite element model.

Figure 3.13-73 shows the displacement response of the cantilever neutral surface. Excellent agreement with the solution by Boley and Weiner was obtained (Reference 39).

3.13.1.31.4 Problem 4

Static Analysis of a Reinforced-Concrete Beam

The simply supported reinforced-concrete beam subjected to two symmetric concentrated loads, as shown in Figure 3.13-74, was analyzed using ten 6-node, concrete plane-stress elements and 10 steel truss elements. The material properties of the concrete were idealized using the concrete model with the parameters given in Figure 3.13-74. Materially nonlinear-only response was assumed, i.e., large-displacement effects were neglected.

Figure 3.13-75 gives the calculated transverse displacements at the midspan of the beam, for A_{st} = 2.00 in.^{2} for nonlinear static response. The loading scheme used is also shown in this figure. Other results on analysis for A_{st} = 0.62 in.^{2} are compared with the response predicted by Suidan and Schnobrich (Reference 40), who assumed a linear stress-strain relationship for the concrete with the constant Young's modulus equal to E_0 of this analysis, and who modeled the steel reinforcement as a smeared stiffness added to the concrete.

3.13.1.31.5 Problem 5

Analysis of a Beam Subjected to a Traveling Load

The simply supported beam in Figure 3.13-76 was analyzed for its dynamic response. The beam was subjected to a constant-magnitude force traveling across its span at a constant velocity. In the analysis, 20 beam elements were used to model the structure, and small displacements and elastic material conditions were assumed. To model the traveling load, the time function and arrival time option were used in ADINA.

Figure 3.13-76 shows the midspan lateral deflection during the period the load is acting on the beam. The analysis results using ADINA are also compared with one-mode analytical solution given by Biggs (Reference 3).

3.13.1.32 FRAME (Reactor/Auxiliary Building and Residual Heat Removal Complex)

FRAME (Integrated Frame Analysis System) analyzes frames for static and dynamic loadings, performs load combinations, and checks stresses against allowable stresses.

The following analyses are performed:

a. Static: Analysis of distributed and concentrated weight loadings and reaction loadings on frames

b. Dynamic: Analysis of frame response to seismic loads using pseudo-static methods.

The static and dynamic analyses can be performed independently or in sequence.

The input consists of the frame geometry, material properties, and static and dynamic loadings. Various options exist to control the length of the output. The default option generally prints only the summary of input data and final results.

The load combinations are done per user specification. Three methods of combination are used: (1) combination by addition considering signs; (2) combination by addition of absolute values; and (3) combination by square-root-of-the-sum-of-the-squares (SRSS). Loads designated as WT (self-weight of the members and additional lumped weights) are combined considering the signs. Loads designated as RO (reaction loads) or SE (seismic) are combined by either summation of absolute values or by SRSS, as specified by the user. To account for the sign reversal inherent in the RO and SE loads, these loads are combined with the absolute value of the result of the WT-type load combination to give the "worst case" final loads. Two values of the load combination are also obtained for the axial load: the combined WT load with the sign is combined with the combined RO and SE terms with both plus and minus signs. These two values are used in determining the tension and compression stresses.

The stress-checking provisions follow those of the 1978 AISC Specification (Reference 41), and Structural Design Standard E-37 for Mechanical Component Auxiliary Support Steel Framing (Reference 42). AISI Specifications (Reference 43) are used to check the stress levels in Unistrut members (Reference 44).

Allowable stresses calculated using the above-referenced documents are multiplied by an overstress factor (input by the user). However, these stresses are limited to "SLIM*FY", where 'SLIM', defined as stress limiting factor, is calculated as follows:

a. For axial stresses (direct or bending)

$$\text{SLIM} = \frac{1}{\text{Minimum Factor of Safety}} \leq 1.0$$

b. For shear stress

$$\text{SLIM} = \frac{1}{\sqrt{3}\,(\text{Minimum Factor of Safety})} \leq 0.57$$

Minimum factor of safety is input by the user. Overstress factor is 1.0 for normal load combinations.

Presently the program can check member design for Unistrut wide flange, structural tube sections, and single angle members.

FRAME was developed at S&L in 1983. It is currently maintained on UNIVAC 1100 Series hardware operating under EXEC 8.

To demonstrate the validity of the analysis performed by the FRAME program, the following two examples are presented.

To illustrate the validity of the static portion of FRAME, the problem shown in Figure 3.13-77 was analyzed and the results compared to those given in Reference 45. Table 3.13-38 shows comparison of member end forces; the results are in good agreement. To illustrate the validity of the dynamic analysis portion of FRAME, which uses a pseudo-dynamic method of analysis in which the system is analyzed for a static loading equivalent to the mass times the specific acceleration applied at all mass points, the problem shown in Figure 3.13-78 was analyzed. A static selfweight-loading analysis was performed for each of the three global directions. The results for each direction loading were multiplied by the corresponding direction g level to obtain the individual direction-excitation results. The final result is taken as the SRSS of the three direction-excitation results. The results for the program and independent calculations are compared in Table 3.13-39; the results agree.

To demonstrate the validity of the load combinations performed by the FRAME program, the following example is presented. The frame shown in Figure 3.13-77 was analyzed for three loadings: self- weight, WT1; reaction loading as shown in Figure 3.13-77, R01; and seismic OBE, SE1. Two load combinations were generated: WT plus absolute sum of reaction load and seismic; and WT plus SRSS of reaction load and seismic. The individual analysis results at select locations are given in Table 3.13-40. Also shown in Table 3.13-40 is the comparison of the load combination results from FRAME and hand calculations; the results agree.

To demonstrate the validity of the member design portion, the following examples (one for each shape of member) have been selected.

3.13.1.32.1 Problem 1 - Tube Section

A 6 x 4 x 3/8 tube section under the loading shown in Figure 3.13-79 was used to validate the design check for tube sections. Additional data are given in Table 3.13-41. FRAME output is compared with hand calculations in Table 3.13-41; they are in close agreement.

3.13.1.32.2 Problem 2 - Wide Flange Section

A W12x40 section under the loading shown in Figure 3.13-80 was used to validate the design check for wide-flange sections. Additional data are given in Table 3.13-42. FRAME output is compared with hand calculations in Table 3.13-41; they are in close agreement.

3.13.1.32.3 Problem 3 - Unistrut Section

A P1000 Unistrut section under the loading shown in Figure 3.13-81 was used to validate the design check for Unistrut sections. Additional data are given in Table 3.13-42. FRAME output is compared with hand calculations in Table 3.13-41; they are in close agreement.

3.13.1.32.4 Problem 4 - Single Angle Section

A 3 x 2 x 3/8 angle section under loading shown in Figure 3.13-82 was used to validate the design check for single-angle sections. Additional data are given in Table 3.13-42. FRAME output is compared with hand calculations in Table 3.13-41; they are in close agreement.

To demonstrate the validity of the connection module, five problems were selected. The problem data given are in Table 3.13-43. These problems were validated by comparing the FRAME results to the results obtained from hand calculations. A comparison of results is given in Table 3.13-44.

3.13.2 Computer Programs Used by Chicago Bridge & Iron

Subsections 3.13.2.1 through 3.13.2.9 provide a description of the CBI computer programs used for general analysis and design work. Computer program information beyond that included herein, or in the Stress Report and Calculations, is proprietary. However, test problems and verifications are on file and available at CBI.

The description of programs used by CBI includes a discussion on the design of the drywell and torus. There have been extensive modifications to the torus subsequent to its original installation. The details of modifications to the torus are presented in the Fermi 2 Plant Unique Analysis report. See References 46 through 51.

3.13.2.1 Program 405

This is a program used for the analysis of a ring with a constant moment of inertia and modulus of elasticity. The loads are in the ring. The mathematics are based upon the Hardy-Cross column analysis for rings as referenced in Theory of Modern Steel Structures, Vol. II, by Grinter, page 259. The loads can be moments, tangential, or radial to the ring. The printouts are coefficients at incremental distances around the ring. The printout titles for the output are as follows:

X	=	Angle and degrees as measured from a reference axis
V	=	A radial shear with force units acting in a radial direction through the ring
T	=	An axial thrust in the ring with units of force
M/R	=	A coefficient with units of force which when multiplied by the radius to the centroid will equal a moment
EI/RR	=	A coefficient which when multiplied by the radius^2 will equal the rotation of the ring at the point
REI/RRR	=	A coefficient which when multiplied by the radius^3 equals the radial deflection of the point
CEI/RRR	=	A coefficient which when multiplied by the radius^3 will equal the tangential deflection of the point.

3.13.2.2 Program 601

This program is based on the mathematics of Program 405. In addition, the coefficients have been multiplied by the proper radius. This means that the thrust and moment only have to be divided by the area and section modulus, respectively, to find the stresses at the point.

3.13.2.3 Program 655

This program is based on the theory and equations presented in NASA-TN 1219. In the program the influence of the loads on any ring is not evaluated beyond the adjacent rings. Basically, the only difference between this program and the previous ring programs is that the shear in the ring with loads is transferred into the shell between the rings.

3.13.2.4 Program 7 - 81N - Kalnins' Shell Program

This program was developed by Aerturs Kalnins at Yale University, based on a method of analysis published in Reference 11. The program is used for shell stresses at discontinuities, with the exception of nozzles.

3.13.2.5 Program 772

This is a program for checking nozzle reinforcing. It is designed essentially for containment vessels, and adheres to area replacement criteria specified by ASME Sections III and VIII. The program does no design work, merely checking the adequacy of preselected reinforcing plate dimensions and weld sizes.

3.13.2.6 Program 6 - 20 Cookbook Nozzles

This program computes the local stresses in cylindrical and spherical shells due to a load or a combination of loads acting on a nozzle that penetrates the shell. The solution for local shell stresses is made using the dimensionless parameters (input) from the graphs in the Welding Research Council Bulletin No. 107. When reinforcing is present, these parameters are found using the procedures of Bijlaard, as outlined in Welding Research Council Bulletins 49 and 50.

If a solution for unit loads is desired, the card for loads is left blank. The program assigns unit loads of 1000 lb to the radial load and the shears, and 100 in.-lb to the moments.

Tests are performed in the cylinder and sphere subroutines to see if either an insert or pad plate or no reinforcing is present. Depending on the results of these tests, a particular set of denominators is computed for use in the stress calculations in the stress subroutine. When reinforcing is present, the program checks the stress at the edge of the reinforcing. The thicknesses used in the computation of stresses are described in the following subsection.

3.13.2.7 Program 860 - Rigid Attachment to Spherical Shell

3.13.2.7.1 General

This program computes shell stresses around a rigid attachment to a spherical shell due to any combination of loading, radial, shear, or moment. The program uses the nomenclature, the curves for coefficients, and the mathematics of the Welding Research Council Bulletin No. 107. Given the basic geometry of the attachment, the program will compute the parameters as required from Figures SR-2 and SR-3 and the shell stresses around the attachment.

If the load card is blank, the program assigns unit loads of 1000 lb to P and U1, and 100 in.-lb to M1. There is one printout for each of the unit loads.

If the width of reinforcing is less than 1.65 times the square root of the spherical radius, times either the thickness of the insert or an equivalent thickness for pads, the stresses are also checked at the edge of the reinforcing. All induced moments at the nozzle-to-shell junction and the induced moment M_x at the edge of reinforcing, are increased by 20 percent to satisfy the requirements of Welding Research Council Bulletins 49 and 50 (References 52 and 53) by Bijlaard. If the width of reinforcing is greater than 1.65 times the square root of the spherical radius, times either the insert thickness or equivalent thickness, only the stresses at the nozzle-to-shell junction are computed. None of the induced moments are increased. The thickness used in the solution of stresses about a reinforced nozzle is determined as follows.

3.13.2.7.2 Reinforced Nozzle Parameters For Bijlaard Analysis

At Nozzle-to-Shell Junction

a. T = Thickness of insert or equivalent thickness for pad-type reinforcing. T equivalent = 1/2 $\{(TS + TP)^3 + (TP)^3 + (TS)^3\}^{1/3}$ where TP is the thickness of the pad and TS is the shell thickness without reinforcing. The quantity under the cube root is the average of the moment of inertia of the total thickness of the shell plus pad and the sum of the individual moments of inertia of the shell and the pad

b. All parameters are found using T. The stresses are computed using T. The programs compute the membrane stress using the total thickness of the pad plus shell. However, the parameters contain the equivalent thickness which is divided out to obtain N_x, N_y, or N first

Example: $\frac{N_X T}{P} \quad \frac{P}{T(TS+TP)}$

c. If the width of reinforcing, W, is less than C RT, where R is the mean radius of the shell, T is the thickness defined in item 1, and C is normally assumed to equal 1.65, the reinforcing is assumed to act as a rigid plug and the induced moments M_x and M_y for spheres or M_x and M for cylinders are increased by 20 percent because of effects of reinforcing (References 52 and 53). If W is greater than $C\sqrt{RT}$, the reinforcing is assumed to act as a shell plate with no increase in induced moments.

At Edge of Reinforcing

a. TS = Thickness of shell without reinforcing

T = Thickness of insert or equivalent thickness for pad-type reinforcing. See Item b. above.

b. Parameters for induced moment M_x are found using T. All other parameters are found using TS. The shell stresses are computed using TS. The programs divide out the only equivalent thickness in the parameters containing M_x only

Example: $\frac{M_X RT}{M_1} \quad \frac{6M_1}{(TS)^2 RT}$

c. Increase the parameters containing the induced moment M_x by 20 percent.

3.13.2.8 Program 7-78, Drywell Primary Membrane Stress Analysis

The drywell shell is analyzed for stresses due to the customer- specified loading combinations. Primary membrane stresses are computed for each of the loading combinations, and the resulting stresses are compared to the ASME Code allowables. In addition, the compressive stresses are compared to an allowable buckling stress, and a buckling ratio is computed.

The drywell primary membrane stresses are found using the general equations for an axisymmetrically loaded shell of revolution. The derivation of the general equations can be found in Chapter 14 of Theory of Plates and Shells by Timoshenko (Reference 6). The equations are as follows:

General Equation No. 1: $\frac{N_\phi}{R_\phi} + \frac{N_\theta}{R_\theta} = P$

General Equation No. 2: $2\pi r_o N_\phi \sin\phi + Z = 0$

where

N_ϕ	=	meridional membrane stress resultant
N_θ	=	circumferential membrane stress resultant
R_ϕ	=	radius of curvature in meridional plane
R_θ	=	radius of curvature in circumferential plane
P	=	pressure
ϕ	=	angle between pole of revolution and point
Z	=	resultant of total load on shell
r_o	=	$R_\theta \sin\phi$

It should be noted that the stress resultants at structural discontinuities, such as the cylinder-to-knuckle and knuckle-to- sphere, are the maximum stress resultants. The stress resultants are found using the appropriate equations for the smaller thickness at the point of discontinuity.

Pressure

Top Head - The top head is designed for stresses due to internal and external pressure. The thickness required for internal pressure is found using the formulas in Paragraph UA-4(c) of Section VIII of the ASME Code, while the allowable external pressure is found according to the requirements of Paragraph UG-33 of Section VIII of the ASME Code. This design is in accordance with Code Case 1392.

The top head is also designed for stresses due to a jet load. The stresses resulting from this jet load are computed using Case 20 on page 304 of Reference 54.

Cone - The top cone, if one exists, is designed according to the requirements of Paragraph UA-5 of Section VIII of the ASME Code. This analysis is in compliance with Code Case 1392.

Knuckle - The knuckle pressure stress resultants are analyzed in this section, using the "pressure area method" as outlined in Reference 55.

Cylinder - The cylinder is designed for both internal and external pressure, in accordance with Code Case 1392. The design for internal pressure is made using the equations for thickness of UG-27(c) of Section VIII of the ASME Code.

The external pressure design is made using the method described in Paragraph UG-28 of Section VIII of the ASME Code. The curves in Figure UCS-38.2, which are referred to in Paragraph UG-28, are defined by the following equation:

$$\text{Allowable External Pressure} = \frac{2.6\,E\,[T/D]^{2.5}}{4\left[L/D - 0.45\left[T/D^{0.5}\right]\right]}$$

where

E = modulus of elasticity of steel

T = thickness of cylinder

D = diameter of cylinder

L = length of cylinder including one-third the vertical height of the knuckle and the lesser of one-third of the length of the cone to its apex or length to the flange

Sphere - The sphere is analyzed for both internal and external pressure. The stress resultants due to internal pressure are found using the general equations reduced to the following form:

$$N_\phi = N_\theta = \frac{PR}{2}$$

where

R = radius of sphere

The sphere is also checked for buckling stresses when subjected to external pressure. A discussion of this buckling analysis is found in the discussion of allowables for compressive stress resultants. The buckling stress resultant due to external pressure is considered in conjunction with the stress resultants due to dead loads and the effects of seismic loading on these dead loads.

Vertical Loads

The vertical loads include, but are not limited to, the weight of the penetrations, compressible material, shell steel, jet deflectors, refueling water, and spray headers. Also included with the vertical loads is the effect of vertical earthquake acting on the above loads. The stress resultants for these loads are found using the general equations reduced to the following forms for the various shapes.

Cylinder

General Equation No. 2 $\quad N_\phi = \frac{\text{Vertical Load}}{\text{Circumference}} = \frac{\text{Load}}{2\pi R_\theta}$

General Equation No. 1 $\quad N_\theta = 0$

where

P = 0

R_ϕ = ∞

R_θ = circumferential radius

Knuckle

General Equation No. 2 $N_\phi = \frac{\text{Load}}{\text{Circumference} * \sin\phi}$

$= \frac{\text{Load}}{2\pi L_1 (\sin\phi)^2}$

General Equation No. 1 $N_\theta = N_\phi \frac{L_1}{-R_2}$

where (refer to [a] in Figure 3.13-83)

P = 0 for all loads except shell weight and compressible material

R_2 = knuckle radius (negative number)

L_1 = distance from pole to point as measured on the normal

Special consideration is given to the weight of the shell and compressible material. N_ϕ is computed using General Equation No. 2 above. However, the density of the shell is considered to act as a pressure in the radial direction in finding N_θ. Therefore, the General Equation No. 1 for N_θ due to shell weight or compressible material is as follows:

General Equation No. 1 $N_\theta = -\rho + L_1 \cos\phi + N_\phi \frac{L_1}{R_2}$

where

P = $-\rho t \cos\phi$

ρ = density of steel or compressible material

t = thickness of shell

L_1 = distance from pole to point as measured on normal

R_2 = knuckle radius (negative number)

Sphere

General Equation No. 2 $N_\phi = \frac{\text{Weight}}{2\pi R(\sin\phi)^2}$

General Equation No. 1 $N_\theta = -N_\phi$

where

P = 0 for all loads except shell weight and compressible material

R = radius of sphere

The weight of the shell and the weight of the compressible material is again treated as a pressure in the radial direction for finding the stress resultant N_θ.

General Equation No. 1 $N_\theta = -\rho t R \cos\phi - N_\phi$

where

R = radius of sphere

P = $-\rho t \cos\phi$

ρ = density of steel or compressible material

t = thickness of shell

Horizontal Earthquake

The effect of the horizontal earthquake is to produce a shear load acting on the shell at the elevation of the load. This shear is found by multiplying the load by the horizontal earthquake factor for the elevation of the load. This factor is taken from curves for horizontal earthquake given in the customer specifications. From statics the shear load can be considered to produce a moment at a lower elevation. This moment tends to rotate the drywell shell about the plane under consideration.

In the earthquake analysis, the drywell is analyzed as a free- standing, cantilevered column. However, the drywell can be supported by the surrounding building at the stabilizer elevation. This support is separated from the stabilizer of the drywell by a l0 mil-gap. Thus, during the incidence of an earthquake, the vessel may generate a shear in the opposite direction of the shear of the applied loads. This shear is the reaction at the stabilizer elevation, which is treated in the same manner as the other shear loads. The reaction is found using a combination of Castigliano's First Theorem and the unit load method using the following equations:

$$\Delta = \frac{1}{E}\int \frac{M}{I}\frac{\delta M}{\delta P}\,dx + \frac{1}{G}\int \frac{V}{A}\frac{\delta V}{\delta P}\,dx$$

ΔImposed = ΔHorizontal Earthquake Acting on Vessel + ΔUnit Load x Reaction

The stress resultants due to moment are computed using the general equations. These equations have been reduced as follows for the three general shapes in the drywell.

Cylinder

General Equation No. 2 $$N_\phi = \frac{\text{Moment}}{\text{Section Modulus}} = \frac{\text{Moment}}{\pi R^2}$$

General Equation No. 1 $$N_\theta = 0$$

where

P = 0

R_ϕ = ∞

R_θ = radius of curvature in circumferential plane

Knuckle (refer to [b] in Figure 3.13-83)

General Equation No. 2 $$N_\phi = \frac{\text{Moment}}{\text{Section Modulus}* \sin\phi}$$

$$N_\phi = \frac{\text{Moment}}{\pi(L_1 \sin\phi^2 * \sin\phi)}$$

General Equation No. 1 $$N_\theta = -N_\phi \frac{L_1}{R_2}$$

where

$P = 0$

$L_1 =$ distance from pole to point as measured on the normal

$R_2 =$ knuckle radius (negative number)

Sphere

General Equation No. 2

$$N_\phi = \frac{\text{Moment}}{\text{Section Modulus} \times \sin\phi^*}$$

$$N_\phi = \frac{\text{Moment}}{(R\sin\phi)^2 \times \sin\phi}$$

General Equation No. 1 $\quad N_\theta = -N_\phi$

where

$P = 0$

$R =$ radius of sphere

* sin ϕ used to transfer stress resultant into plane of shell.

Drywell Flooded

In the flooding of the drywell, the stress analysis is made for stresses both in the meridional and circumferential directions (Figure 3.13-84). In the meridional direction, floodwater weight adds to the other gravity loads and causes an increase in the compressive stress. These other loads are the weight of the shell steel, the weight of the compressible material (if applicable), the weight of the penetrations, dead loads, and live loads. In the consideration of the meridional stress, the buckling of the shell is the limiting factor. In the circumferential direction, the hydrostatic pressure due to the floodwater increases the total circumferential stresses. The stresses in each direction are analyzed both with and without seismic effect.

Meridional Stress - In the analysis of the meridional stresses, there are two conditions considered critical, and therefore an analysis is made for each.

One condition exists when the floodwater reaches its maximum elevation as specified by the customer. This condition is considered critical because it obviously involves the largest amount of floodwater in the drywell shell, and also because it involves the greatest hydrostatic pressure that the drywell shell will experience under the flooding condition.

The second condition occurs instantaneously as the drywell is filled and the water reaches the critical point P (see Figure 3.13-85). This point P is considered critical for two reasons:

a. With reference to Figure 3.13-85, it can be seen that the maximum water weight that the shell will carry will exist when the water level is at point P or higher. No matter how high the water floods above point P, only the overhanging water (bounded by the shell, point P, and embedment) can be carried by the shell. The remaining water is carried by the internal concrete through the shell into the foundation

b. With reference to Figure 3.13-86, it can be seen that there is an unbalanced hydrostatic pressure acting on the drywell shell between point P and the vertical cylindrical shell. This unbalanced pressure is a buoyant force that is calculated based on Volume (B) with respect to Archimedes' principle. This buoyant force acts upward and thereby reduces the buckling stress.

Considering the above two reasons, it can be seen that the worst loading condition, that is, the maximum water load at embedment, and the minimum bouyant force (equal to 0) will both be attained with the water level at point P.

While the additional weight of the floodwater will increase the buckling stress, the water pressure inside the vessel will permit increasing the critical buckling stress. A calculation for this increase is made, and the result is added to the normal shell allowable buckling stress to give the critical buckling stress.

By combining the compressive meridional stress due to the floodwater with those stresses due to the normal loads, and then dividing this total into the increased critical buckling stress, a factor of safety is calculated.

Circumferential Stress - In the analysis of the circumferential stresses, the general membrane equation from Page 39 of Reference 56 is used:

$$N_\theta = PR - N_\phi$$

where

P	=	hydrostatic pressure due to floodwater
R	=	drywell sphere radius
N_ϕ	=	meridional stress resultants

Allowables

Tensile - The stress that results from the combination of loading for each condition of loading is compared to the allowable general membrane stress intensity. This is in accordance with the requirements of Section III of the ASME Code for Class B vessels.

Compressive - The compressive stress resultants are compared to allowables obtained according to the paragraphs titled "Biaxial Compression-Equal Unit Forces" and "Biaxial Compression-Unequal Unit Forces" of the Welding Research Council Bulletin No. 69. The allowables used are found by assuming that the sphere reacts as a cylinder with a radius equal to the radius of the sphere. There are three cases of loading considered. The allowables for these three cases are

a. Uniaxial compressive stress resultant

$$N_{ALL} = 1.8 * 10^6 \frac{t^2}{R}$$

b. Biaxial equal compressive stress resultants

$$N_{ALL} = 0.9 * 10^6 \frac{t^2}{R}$$

c. Biaxial unequal compressive stress resultants. This case is treated as the summation of a uniaxial condition with the biaxial condition with equal stress resultants (see [c] of Figure 3.13-83)

$$\frac{N_\theta - N_\phi}{1.8*10^6 \frac{t^2}{R}} + \frac{N_\phi}{0.9*10^6 \frac{t^2}{R}} \leq 1$$

3.13.2.9 Program 7-71

As stated in Subsection 3.13.2, the description of programs used by CBI includes a discussion on the design of the drywell and torus. There have been extensive modifications to the torus subsequent to its original installation. The details of modifications to the torus are presented in the Fermi 2 Plant Unique Analysis report. See References 47 through 52.

3.13.2.9.1 Torus Columns and Column "Stubs" Design

The inner and outer columns and the inner and outer column "stubs" that connect the columns to the torus ring are designed by the computer program using the approach illustrated in Figure 3.13-87.

The column "stubs" are welded to the columns by full fusion welds.

Coefficient of friction for lubrite = 0.1

Friction Force = 0.1P (resisted by column knee braces)

Shear due to horizontal seismic force taken by the torus seismic ties.

The inner and outer columns and column "stubs" (which are usually built-up sections) may have different cross-sectional properties but these must qualify as "compact" sections in accordance with AISC specifications.

The inner and outer columns may have different lengths.

The total length of the columns is taken as the distance from the top surface of the column baseplates (PT.C) to the point where the vertical centerline of the corresponding column "stub" intersects the outer surface of the torus ring (PT.D).

To determine the value of the "effective slenderness ratio" under axial compression only, the values of "K" adopted are K = 1.20 for buckling in radial direction and K = 0.65 for buckling in tangential direction (refer to Section 1.8 of AISC Commentary).

The total axial load and bending moment is taken to be the same for the outer column and outer column "stub," and for the inner column and inner column "stub."

The inner column and column "stub" have been designed for an axial load consisting of the dead load of torus and contents, vertical seismic load, and vertical component of inner brace load which is transferred to the column by the torus ring.

The outer column and column "stub" have been designed for an axial load consisting of dead load of torus and contents, vertical seismic load, vertical component of outer knee brace load, and the overturning effect of horizontal seismic force which is conservatively assumed to be applied directly to the outer columns.

The principal factor causing bending moment is the differential temperature expansion 'Δ' between the column "stub" attachment and the attachment of the knee bracing to the torus shell (Figure 3.13-88).

The differential movement of these two points as a result of pressure-induced stresses has been neglected as these are very small compared to the temperature-induced differential movement of these two points.

The column baseplates rest on a lubrite pad, and are free to slide and compensate for the overall expansion of the torus without causing any bending to be induced in the columns and column "stubs."

The bending moment in the columns and column "stubs" is produced by the differential movement of the column stub attachment to the torus ring radially outward with respect to the column base.

This bending moment is given by

$$M = \frac{6EI\Delta}{L^2}$$ (Refer to AISC, P. 2-127, Case 23)

Here it is assumed that the knee brace transmits the radial movement of the brace attachment to the column baseplates which slide on the lubrite pads; after which the columns are assumed to be fixed at the column bases and the corresponding column "stub" attachments then undergo the differential expansion radially outward with respect to the torus without any rotation at the junction with the torus ring.

The program computes the actual axial and bending stresses for the inner and outer columns and column "stubs" which are shown on the computer printout. Allowable stresses are also calculated per Sections 1.5.1.3 and 1.5.1.4 of the AISC Specification which are also shown on printout. These actual stresses are compared to the corresponding allowable stresses using the ratios per Section 1.6.1 of the AISC Specifications.

In addition, the program also checks the outer and inner column "stub" attachment welds to the torus ring.

<u>Column Baseplate (refer to [a] of Figure 3.13-89.)</u>

The column baseplate is designed for the column axial load per page 3-75 of the AISC Specifications. The program assumes 3000 psi concrete for calculations.

Allowable concrete bearing F_P = 0.25x3000 x F

F = Factor for increasing allowable stress during flooded condition

Required area = $\text{Col Load}/F_P$

Actual Bearing F_{PA} = $\text{Col Load}/\text{Furnished Area}$

Allow bending F_B = (0.75) (yield F)

Required plate thickness = $\sqrt{\frac{3F_{PA}X^2}{F_B}}$

X = Larger of M or N

Column Knee Braces (see [b] of Figure 3.13-89.)

The column knee braces consist of two angles back to back and are designed to take the friction force due to the column base sliding on the lubrite pad with a coefficient of friction equal to (0.1).

The allowable compressive stress is calculated per Section 1.5.1.3 of the AISC Code and is shown on the printout. The maximum distance (L_s) between spacers is calculated per Section 1.18.2.4 and is shown on the printout.

3.13.2.9.2 Torus Support Ring

The stresses in the torus support ring are analyzed by a computer program using the approach as outlined in the following discussion:

The ring is subjected to the following loadings:

a. Column stub reactions

b. Column deflections

c. Column knee brace reactions

d. Header dead load

e. Downcomer jet thrust

f. Internal pressure.

The reaction loads are broken into components so that the three basic loadings (other than internal pressure) are radial, tangential, and bending moment. The magnitude of the loads applied to the ring and their point of application (angular location) are shown on the printout and are specified as radial, tangential, or moment with respective signs. The loads are applied as shown in Figure 3.13-90.

The sign conventions for the ring loads are as follows:

a. Radial = positive when acting inward

b. Tangential = positive when acting clockwise

c. Moment = positive when acting clockwise.

The column stub reactions and moments are broken into two parts and assumed to act 10° apart as shown in Figure 3.13-90. The header dead load and the downcomer jet loads are assumed as radial loads due to their very small angle with the centerline.

The ring loads, as shown on the printout, may be checked by referring to the following:

a.	Column stub axial load	Printout from column stub design section
b.	Column stub bending moment	Printout from column stub attachment weld
c.	Brace axial load	Printout from brace design
d.	Header dead load	See sheet
e.	Downcomer jet load	See customer specifications

For the stress analysis of the ring, the suppression chamber has been assumed as a ring-stiffened cylinder with fixed ends made up of four similar bays. The ring loads as discussed above are placed on the second ring and bending, thrust, and pressure stresses on this ring are calculated by computer program No. 655 based on theory derived in NASA Technical Note No. 1219. Stresses from the internal pressure are calculated by the "pressure area method" from Reference 55.

The computer prints out the component stresses (bending, thrust, and pressure) in addition to the total stresses on the inner and outer flanges of the ring.

3.13.3 Computer Programs Used by Others

Computer programs used by S&L, CBI, and S&W, Michigan, are described in Subsections 3.13.1, 3.13.2, and 3.13.4, respectively. Other significant computer programs used by these and other support organizations (including Edison) are described in this section. A number of computer programs were used by NUTECH Engineers, Inc., in the plant-unique analysis required by the NRC (NUREG-0661, Safety Evaluation Report, Mark I Containment Long-Term Program). The major computer programs used in these analyses are described in the Fermi 2 Plant Unique Analysis reports (References 46 through 51), which were submitted in response to NUREG-0661 requirements.

3.13.3.1 ADLPIPE - Arthur D. Little, Inc.

There are three types of documentation for ADLPIPE. The first is the multitude of hand checks made during the development and change of the program. The second is by the many user groups who have their own method of evaluation and documentation, both analytical and experimental. These groups have contributed immeasurably to the current state of ADLPIPE reliability. The third type is the documentation and internal checks that Arthur D. Little, Inc., has generated.

This third type of documentation and internal checks is in four forms:

a. Fifty-two common errors are checked for and automatically reported
b. All internal program data may be printed during problem solution
c. Sample problems (benchmarks) are compared to other solutions
d. Mathematical techniques used are described.

3.13.3.1.1 Input Check

Automatic message for 52 different types of input error. See Input Preparation Manual.

3.13.3.1.2 Intermediate Data

a. Force vectors are printed prior to inversion of the stiffness matrix
b. Deflection vector is printed after stiffness matrix inversion
c. Member data are printed out after input is read
d. Contracted stiffness matrix is printed prior to inversion

e. Eigenvectors of dynamical matrix are printed after eigenvalue routine

f. Eigenvalues of dynamical matrix are printed after eigenvalue routine

g. Dynamical matrix is printed after formation from stiffness matrix

h. Flexibility matrix is printed after inversion of stiffness matrix

i. Reduced stiffness matrix and mass vector are printed after reduction of stiffness matrix to order of dynamical matrix

j. Contents of logic unit 14, flags, properties, stress coefficients, and moments for each member

k. Modal effective mass for dynamic model/solution evaluation.

3.13.3.1.3 Typical Benchmark Calculations

This section defines and references eight benchmark calculations typical of the verification that has been done with ADLPIPE. The solution to each problem from other sources is compared to the ADLPIPE solution.

3.13.3.1.4 Analytical Description Technique

See Reference 21 and 57 through 60.

3.13.3.2 PASS Teledyne Materials Research

3.13.3.2.1 Introduction

The PASS computer program is a postprocessor to the ADLPIPE computer program which provides an elastic analysis of redundant piping systems subjected to thermal, static, and dynamic loads. The program accepts, as input, the ADLPIPE Math Model describing the piping geometry, and the internal forces, moments, and deflections resulting from the flexibility analysis for various load conditions (dead weight, hydrotest, thermal, seismic inertia, and attachment displacements).

The PASS program also functions as a report generator for the hanger selection summary reports. The summary defines the support system and summarizes in a tabular report style format:

a. Nozzle and anchor loads

b. Hanger and restraint loads

c. A stress summary of selected data points in accordance with the rules of NC-3652 for sustained loads - Equation (8); occasional loads - Equation (9); thermal expansion -Equation (10); and Equation (11) for Class 1 and Class 2 components

d. A stress summary in accordance with the rules of NB-3652 for the primary stress-intensity limit - Equation (9), for Class 1 components only.

3.13.3.2.2 Purpose

The purpose of this program is to determine the adequacy of the piping support system for a given ADLPIPE Math Model by evaluating stresses for sustained loads, occasional loads, and thermal expansion in accordance with the design and analysis philosophy of subsections

NB-3652 and NC-3652 in Section III of the ASME B&PV Code. The program also provides load summaries for anchors and restraints, and reports the maximum loads for each load condition and the required net design load.

3.13.3.2.2.1 Method of Solution

The PASS program is designed to read the ADLPIPE Math Model and determine all network point restraints from the restraint cards. Those points restrained in the six degrees of freedom are considered anchors; other restraint points are defined by a restraint code in the respective X, Y, and Z direction on the network point identification cards of the ADLPIPE Math Model. The program then prints out the ADLPIPE Math Model and a restraint summary table of all network point restraints indicating the direction and type of restraint. The outside diameter and thickness for each member, and bend radii for all elbows, are then determined and a table of member geometries printed. Points to be analyzed are subsequently read by the program, which must include all restraint points in the same sequence as they appear in the ADLPIPE Math Model.

The internal forces, moments, and deflections for each load condition are then read by the program and stored for those data points defined on the network point restraint cards and for those points undergoing stress evaluation. As the data for each load condition are read, the program performs a check on the deflection data such that if a card is missing for a point, the forces will be read as deflections causing a diagnostic to be printed for that load condition. If the data check encounters deflections greater than 20 in., the program finishes reading the input data and then terminates the job. The analyst must then correct his data and resubmit the job.

Once the input data have been read in for all load conditions, the net design loads are determined for each anchor point in the following manner.

a. The deadweight loads and hydrotest loads are retrieved for the point of interest

b. The loads for all thermal conditions are scanned and the maximum positive (+) and maximum negative (-) loads for each direction determined

c. The resultants of the deadweight loads, plus maximum positive thermal and maximum negative thermal, are evaluated and the magnitudes compared to the hydrotest loads, if applicable. The greater of the dead-weight plus-thermal or the hydrotest is used in the computation of the net design load

d. The maximum static load, dead-weight-plus-thermal or hydrotest, is summed up with the maximum seismic load (SSE) plus end effects (SSE, inertial plus building movements). Note: See Revision E changes to above (Subsection 3.13.3.2.2.2).

The same procedure is followed for evaluating the net design load on restraints with the exception of springs and snubbers. Only deadweight and hydrotest loads are considered for a spring and only seismic loads for a snubber.

Thermal and seismic displacements are then determined for all restraint points. The thermal displacements are defined by a maximum and minimum range, while the seismic displacements are to be considered plus (+) and minus (-), since for a normal mode analysis the resultant internal forces and moments are computed from the square root of the sum of the squares of the modal forces and moments.

a. Option 1

$$(F_i)^2 = (F_i)_X^2 + (F_i)_Z^2 + |F_i|_Y$$

$$(M_i)^2 = (M_i)_X^2 + (M_i)_Z^2 + |M_i|_Y$$

$$(\delta_i)^2 = (\delta_i)_X^2 + (\delta_i)_Z^2 + |\delta_i|_Y$$

b. Option 2

$$(F_i)^2 = (F_i)_X^2 + (F_i)_Y^2 + (F_i)_Z^2$$

$$(M_i)^2 = (M_i)_X^2 + (M_i)_Y^2 + (M_i)_Z^2$$

$$(\delta_i)^2 = (\delta_i)_X^2 + (\delta_i)_Y^2 + (\delta_i)_Z^2$$

where

i	=	x, y, z
x, y, z	=	response directions
X, Y, Z	=	shock directions

The program then evaluates stresses for Class 2 specified data points in accordance with the rules of NC-3652.

a. Sustained loads (NC-3652.1)

$$\frac{PD_o}{4t} + 0.75i\left(\frac{M_A}{Z}\right) \leq 1.0\ S_h \qquad (8)$$

b. Occasional loads (NC-3652.2)

$$\frac{P_{max}D_o}{4t} + 0.75i\frac{(M_A + M_B)}{Z} \leq 1.2\ S_h \qquad (9)$$

c. Thermal expansion (NC-3652.3)

$$i\left(\frac{M_c}{Z}\right) \leq S_A \qquad (10)$$

$$\frac{PD_o}{4t} + 0.75i\left(\frac{M_A}{Z}\right) + i\frac{M_c}{Z} \leq (S_h + S_A) \qquad (11)$$

The primary stress-intensity limit Equation (9) of NB-3652 is evaluated for design conditions of all Class 1 data points specified in the node list for stress analysis.

$$B_1\left(\frac{PD_o}{2t}\right) + B_2\left(\frac{D_o}{2I}\right)M_i \leq 1.5\ S_m \qquad (9)$$

For a complete definition of the preceding equations, refer to subsections NB-3652 and NC-3652 of Section III in the ASME B&PV Code. The program currently evaluates Equations (9), (10), and (11) of NC-3652 with and without moments due to secondary end effects (building or equipment movements). The moments produced by such displacements from seismic inertia effects are included with earthquake moments in the evaluation of Equation (9) in NC-3652.1 and Equation (9) in NB-3652.

The stress intensification factor, i, of NC-3652 is determined by the program in accordance with Figure NC-3672.9(a)-1 for Class 2 components, and stress indices B_1 and B_2 of NB-3652 are determined in accordance with Table NB-3683.2-1 for Class 1 components. If the stress intensification factor, i, or stress indices B_1 and B_2 are provided with the stress input data, these factors will override standard values computed by the program. In addition to printing stress summary tables for all specified stress points, the program determines critical points as those points with the greatest stress to allowable ratio for Eqauations (8) and (9) of NC-3652 (Class 2) and Equation (9) of NB-3652 (Class 1).

3.13.3.2.2.2 Revision E - Design Loads

The PASS program has been updated by Revision E to reflect the following method of computing design loads for nozzle/anchor reactions and hanger/restraint reactions:

Maximum Design Load (+):

DL1 = + SEISMIC (DBE) + E.E. (DBE)

DL2 = + SEISMIC (DBE) + E.E. (DBE) + DYNAMIC (+) + DEAD WEIGHT

DL3 = + SEISMIC (DBE) + E.E. (DBE) + DYNAMIC (+) + THERMAL (+)
+ DEAD WEIGHT

DL4 = MAX.(+) OF (DEAD WEIGHT OR HYDRO) (+) DESIGN LOAD

= MAX. (+) OF DL1, DL2, DL3, DL4

Minimum Design Load (-):

DL1 = - SEISMIC (DBE) - E.E. (DBE)

DL2 = - SEISMIC (DBE) - E.E. (DBE) + DYNAMIC (-) + DEAD WEIGHT

DL3 = - SEISMIC (DBE) - E.E. (DBE) + DYNAMIC (-) + THERMAL (-)
+ DEAD WEIGHT

DL4 = MAX. (-) OF (DEAD WEIGHT OR HYDRO) (-) DESIGN LOAD

= MAX. (-) OF DL1, DL2, DL3, DL4

3.13.3.2.3 PASS Verification

This section contains the solution comparisons between PASS and independent hand calculations for a sample problem. The comparisons of (1) anchor and nozzle reactions, (2) hanger/restraint reactions and displacement tolerances, and (3) the Class 2 stress evaluation are presented in Tables 3.13-45 through 3.13-48. The results show very close, if not exact, agreement. The tabulated PASS values, except hanger/restraint reactions in Table 3.13-46, apply to both D and E Revisions of PASS. The hanger/restraint reactions shown in Table 3.13-46 were taken from the Revision E version of the program.

The Revision D version of PASS can overcompute hanger/restraint reactions where there are seismic end effects (seismic anchor movements) load cases. For the seismic end effects case, the Revision D version computes the hanger/restraint reactions by taking the absolute sum of resulting pipe loads on either side of these supports, which is conservative, whereas the Revision E version uses the more correct algebraic sum.

3.13.3.9 CVPT Report

Refer to Subsection 3.6.3.1.6.

3.13.3.10 TMRSAP

TMRSAP, a computer program owned by Teledyne Engineering Services (TES), is assigned to perform an elastic analysis of complex piping systems subjected to thermal, static, and dynamic loads.

The piping systems are modeled using either of two element types, namely, boundary element or pipe element (tangent and bend). These elements may be used in a static or dynamic analysis. The pipe element is represented by a straight segment (tangent) or a circularly curved segment (bend); both elements require a uniform section and uniform material properties. Elements can be directed arbitrarily in space. The member stiffness matrices account for bending, torsion, axial, and shear deformations. In addition, the effect of internal pressure on the stiffness of curved pipe elements is considered.

The loads contributed by the pipe elements include gravity in the global directions and loads due to thermal distortions and deformations induced by internal pressure. Forces and moments acting at the member ends and at the center of each bend are calculated in coordinate systems aligned with the member's cross section.

The input consists of the piping system geometry, material properties, and static and dynamic loadings.

Various benchmark problem solutions have been used to verify and qualify the TMRSAP program. The solutions of benchmark problems have been compared with closed-form solutions available in the literature or with solutions obtained using other similar codes.

3.13.3.11 TMRPASS

The TMRPASS computer program determines the adequacy of the piping support system for a given TMRSAP structural model by evaluating stresses for sustained loads, occasional loads, and thermal expansion in accordance with the design and analysis philosophy of Subarticles NB-3652 and NC-3652 in Section III of the ASME B&PV Code. The program also provides design load summaries for anchors and restraints, and reports the maximum loads for each load condition and the required net design load.

The program requires as input the TMRSAP structural model describing the piping geometry, as well as the internal forces, moments, and deflections resulting from the flexibility analyses for various load conditions (dead weight, hydrotest, thermal, seismic inertia, and attachment displacements).

The verification and qualification of TMRPASS were performed by comparing TMRPASS output with the results of hand calculations for a typical piping system.

3.13.3.12 ANSYS

ANSYS, engineering analysis system, is a general-purpose computer program with capabilities for transient heat-transfer analyses; static elastic, plastic, creep, dynamic, and dynamic plastic analyses; large deflection and stability analyses; and one- dimensional fluid-flow analyses. The output from the transient heat-transfer analyses is in the form required to do thermal stress analyses at selected time points in the transient with the same analyses models. The program was formulated and developed by Swanson Analysis Systems, Inc.

3.13.3.13 STAAD-III/STAAD.Pro

STAAD-III is a general-purpose structural analysis program marketed by United Information Systems of Kansas City. It performs a static structural analysis of framed structures using the stiffness method of solution. A natural frequency calculation of a structure can be performed by the program as a user option. Internal structure forces, moments, and stresses and nodal displacements and rotations can be output from the analysis portion of the program.

STAAD-III has a postprocessor that performs an evaluation in accordance with the AISC Specification for Structural Steel. It also performs an evaluation of welded connections.

STAAD.Pro is a comprehensive and integrated finite element analysis and design program capable of analyzing structures exposed to static loading, a dynamic response, wind, earthquake, and moving loads. Its analytical capabilities include linear static, response spectra, time history, cable, imperfection, pushover and non-linear analyses. The program is developed by Bentley Systems, Inc. and is an updated version of the STAAD-III program which they obtained when they acquired Research Engineers International.

3.13.3.14 DYNAFLEX

DYNAFLEX is a computer program used to analyze piping systems for static and dynamic loads and to compute the combined stresses. The following analyses are performed:

a. Static - analysis of distributed and concentrated weight, displacement, and thermal loadings on piping systems

b. Dynamic - analysis of piping system response to seismic loads using the uniform response spectrum method

c. Stress combination - computation of the combined stresses in piping components in accordance with the ASME Code Section III, Subarticle NC-3650, or with the ANSI B31.1 Code for Power Piping.

DYNAFLEX is a proprietary program owned, maintained, and supported by Intercomp, Inc., Houston, Texas, and marketed by United Information Systems of Kansas City.

Test problems verifying the accuracy of the results obtained from DYNAFLEX have been run, comparing results with other piping analysis programs such as ADLPIPE and PIPESD. In addition, program updates are verified using a standard series of problems and also specific problems designed to verify the specific updates made to the program.

3.13.3.15 BASEPLT

The program BASEPLT is a preprocessor to the STARDYNE computer code developed for the specific purpose of analyzing flexible baseplates. The BASEPLT preprocessor generates the input runstream, including control cards, for a STARDYNE/SPRING nonlinear solution of a baseplate analysis. The program is marketed and supported by Control Data Corporation, Minneapolis, Minnesota, and available in the public domain.

3.13.3.16 PISYS/ANSI7

These computer programs are used by GE for piping stress analyses and were written by and meet the Quality Assurance Standards of GE. The programs have been approved for production use by a special committee after independent review and verification. All changes to these programs require verification and approval by this committee. The computer program master files are stored in the GE Energy Division archive tapes.

PISYS performs static and dynamic analyses of piping systems. The analysis modules of PISYS were taken directly from the SAP4G program. The ANSI7 program calculates stresses (and cumulative usage factors) for Class 1, 2, and 3 piping components in accordance with Article NB-3600 and Subarticle NC-3652 of ASME Code Section III. This program also calculates combined loads on piping equipment in accordance with the equipment load combinations given in the Piping Design Specification and compares them with the allowable loads.

3.13.3.17 Holtec Computer Programs

All computer programs utilized by Holtec International to perform the analyses documented in this safety analysis report are benchmarked and verified in accordance with Holtec International's Quality Assurance procedures. The significant programs employed are listed and described below.

3.13.3.17.1 DYNARACK

DYNARACK performs dynamic simulations on systems and structures. It is used to simulate rack structure response to seismic excitation.

3.13.3.17.2 ONEPOOL

ONEPOOL is used to predict SFP bulk temperatures. All discharge scenarios and heat exchanger performances can be modeled.

3.13.3.17.3 FLUENT

FLUENT is a computational fluid dynamics code used to determine fluid motion in the SFP.

3.13.3.17.4 THERPOOL

THERPOOL is utilized to evaluate local pool water and fuel cladding temperatures.

3.13.3.17.5 NITAWL

Part of Oak Ridge National Laboratory's SCALE system of computer codes. It collects cross sections from the 238 group master library for specified materials and compiles them into the proper format for input to KENO-5a. It also calculates the shielded resonance cross sections for U-238.

3.13.3.17.6 KENO-5a

KENO-5a calculates the k-effective of spent fuel storage racks in three dimensions.

3.13.3.17.7 MCNP-4A and MCNP-05P†

MCNP is used to evaluate criticality and shielding problems with a high degree of accuracy.

†Original HOLTEC criticality analyses performed using MCNP-4A were subsequently updated using GNF version of MCNP-05.

3.13.3.17.8 CASMO-4

CASMO-4 is used for spatial and burnup calculations.

3.13.3.17.9 ANSYS

ANSYS is used in conjunction with the dynamics simulation code DYNARACK in spent fuel pool structure evaluations. ANSYS has also been used to evaluate seismic class I Reactor Building 1st and 5th floor stresses in response to seismic excitation with ISFSI loads, as well as for analysis of ISFSI component internal structure and support stresses. Also refer to section 3.13.3.12.

3.13.3.18 AutoPIPE

AutoPIPE is a computer aided engineering (CAE) program for calculation of piping stresses, flange analysis, pipe support design, and equipment nozzle loading analysis under static and dynamic loading conditions. In addition to piping codes, AutoPIPE incorporates ASME, British Standard, API, NEMA, ANSI, ASCE, AISC, UBC, and WRC guidelines and design limits to provide comprehensive analysis of the entire system.

AutoPIPE provides unique capabilities for process, power, oil and gas, nuclear, underground, offshore floating, production, storage, and offloading (FPSO) platform and subsea pipeline areas with international piping codes. Advanced AutoPIPE capabilities include built-in wave loading, buried pipeline analysis, jacketed piping, dynamic loadings, orthotropic fiberglass reinforced plastic (FRP/GRP), and high-density polyethylene (HDPE) plastic piping analysis. It also includes thermal stratification or bowing, thermal transient, pipe/structure interaction, fluid transient with closure time and relief valve utilities, advanced load sequencing, non-linear support gaps and friction and jacketed piping. Local stress calculation to WRC 107, WRC 297, PD 5500, KHK, API 650 is available using AutoPIPE Nozzle.

AutoPIPE quality assurance program has been subjected to numerous nuclear and Nuclear Procurement Issues Committee (NUPIC) audits to 10 CFR 50 App. B, ISO9001, CSA N286.7-99, ASME NQA-1, and ANSI N45.2 standards. AutoPIPE Nuclear provides design of critical safety pipework to ASME Class 1, 2, or 3.

3.13.3.19 GT STRUDL

GT STRUDL is a large-scale general purpose structural analysis computer program. The matrix displacement method of analysis based upon finite element idealization is used throughout the program. GT STRUDL has the ability to perform static and dynamic analysis for framed structures and three-dimensional solid structures.

GT STRUDL is used in the analysis and design of nuclear and nonnuclear linear type pipe supports and seismic Category I duct supports.

3.13.4 Computer Programs Used by Stone & Webster, Michigan, Incorporated

Subsections 3.13.4.1 through 3.13.4.4 describe four computer programs used by S&W. They were applied to piping and support design only.

3.13.4.1 NUPIPE - Elastic Piping Analysis with NB, NC 3600 Solutions

NUPIPE is a program for thermal, deadweight, and seismic analysis done in accordance with Subarticle NB3600, NC3600, or ND3600 of Reference 62. It considers stress intensities as specified in Equations 9 through 14 given in the above-mentioned Subarticle NB3600, and also determines the usage factors for points undergoing analysis of normal, upset, emergency, and faulted conditions. This program accepts the complete geometric and physical description of the piping system, provides a complete error and coordinate check for the inputs, and computes internal forces and moments, support and equipment reactions, and displacements and stress values for a variety of loading cases including weight, thermal expansion, applied forces, applied displacements, and earthquakes.

The NUPIPE program has been verified with ADLPIPE (Reference 63) for thermal, weight, and response spectrum seismic analysis. The results from both the programs are presented in Tables 3.13-49 through 3.13-55. The model used for this comparison is presented in Figure 3.13-91.

The comparison is made also with ASME Benchmark Solution (see Reference 64, Problem 5) for force time-history dynamic response. The model used for this comparison is shown in Figure 3.13-92. The results for comparisons are presented in form of plots in Figure 3.13-92. The natural frequencies are given in Table 3.13-56.

The Class 1 piping stress conforms with the hand calculations. The model used is shown in Figure 3.13-93. The results are tabulated in Tables 3.13-57 and 3.13-58.

3.13.4.2 HTLOAD - Heat Loads

3.13.4.2.1 General Description

HTLOAD is a computer program that performs a finite difference method analysis of piping system response to thermal transients of its contained fluid. The output gives overall thermal growth, linear and nonlinear temperature distribution through the pipe wall, gross discontinuity information (T_A-T_B), and Equations 10 and 11 results of Article NB3600 of ASME Section III.

HTLOAD can analyze piping, with or without a thermal sleeve, that is subject to changes in fluid temperature, velocity, and/or state. The properties of subcooled or saturated water and superheated or saturated steam are taken from the ASME steam tables (Reference 65). The pressure range is from 0.45 psia to 6210 psia.

This computer program also performs thermal analysis for pipes with different insulating conditions, ranging from noninsulated to perfectly insulated. It has stored properties for insulation such as unibestos, asbestos, reflective aluminum, reflective stainless, and calcium silicate. Provision is further made for hand input properties of other insulation types.

Also stored in the program are the piping material properties of carbon steel, austenitic stainless, low-chrome steel, high-chrome steel, and nickel-chrome iron for the temperature range of 32°F to 1600°F.

Program input includes piping material insulation information, time lapse for initial to final fluid temperature, calculation time limit, fluid velocities, initial and final temperature and pressure, and pipe and thermal sleeve dimensions.

HTLOAD requires that each thermal transient be input as a step change, a ramp change, or as a twelve-point arbitrary function.

Output results are used in the calculation of piping stress in accordance with Article NB3600 of ASME Section III. HTLOAD also performs the primary, plus secondary, stress intensity range check (Equation 10) and the peak stress intensity range calculation (Equation 11) from Article NB3600.

3.13.4.2.2 Program Verification

The sample problem selected for solution by HTLOAD consists of a 2-in. Schedule 160, stainless steel pipe with one end connected to a 1/2-in.-thick socket-welded fitting. Saturated water flowing within the piping system changes temperature from 400°F to 500°F in a period of 10 sec. Velocity of fluid is 7560 ft/hr. Input properties are listed in Tables 3.13-59 and 3.13-60.

Reynolds number and heat-transfer coefficients are compared with hand calculations (Reference 66) and are given in Table 3.13-61.

Comparison between HTLOAD and Brock and McNeill's charts (Reference 67) for ΔT_1 and ΔT_2 is given in Table 3.13-62. Table 3.13-63 represents the comparison between TRHEAT (Reference 68) and HTLOAD for ΔT_1, ΔT_2, and T_A-T_B.

3.13.4.3 PITRUST

PITRUST is a program to calculate local stresses in the pipe caused by cylindrical welded attachments under external loadings. This program uses the Bijlaard method, as published in Reference 69, to calculate local stresses in the pipe wall caused by cylindrical welded attachments under external loadings, including pressure, dead load, and combinations of maximum seismic reactions.

Program PITRUST has been verified by comparing its solution of a test problem to the solution of the same problem by an independently written piping local stress program, CYLNOZ, in the public domain. The CYLNOZ piping local stress program was written by Franklin Institute (Philadelphia, Pennsylvania) and is used presently by engineering companies. The test problem is of a 72.375-in. O.D. x 0.375-in.-thick run pipe, reacting under an external loading condition of 1000 lb force (normal and shear) and 1000 in.-lb bending and torsional moments transmitted by a 16-in.-O.D. nozzle. A comparison of results is tabulated in Table 3.13-64. Program PITRUST has been verified also by comparing its solution of the test problem to the experimental results obtained in Reference 70. A comparison of these results is tabulated in Table 3.13-65.

3.13.4.4 PILUG

PILUG is a program to calculate local stresses in the pipe wall caused by rectangular welded attachments under external loadings. This program uses the Bijlaard method, as described in

Reference 69, to calculate local stresses in pipe walls caused by rectangular welded attachments under external loadings, including pressure, dead load, and combinations of maximum seismic reactions.

Program PILUG has been verified by comparing its solution of a test problem to results obtained by hand calculations using the formulations specified in Reference 69. A comparison of results is tabulated in Table 3.13-66.

TABLE 3.13-1 COMPARISON OF DSASS V, DYNAS, MASS IV, AND MASS V RESULTS WITH BIGGS

Mode Number	Biggs	DSASS V, DYNAS MASS IV, MASS V
Structural Frequency (Hz)		
1	1.00	1.00
2	2.18	2.18
3	3.18	3.18
Probable Maximum Story Displacement (in.)		
1	1.50	1.51
2	3.22	3.20
3	4.86	4.68
Absolute Maximum Story Shear (kip)		
1	3020	3010
2	2080	2068
3	1345	1353
Probable Maximum Story Shear (kip)		
1	2250	2262
2	1740	1757
3	895	902

TABLE 3.13-2 NATURAL PERIODS FOR THE EIGHT LOWEST FLEXURAL MODES

	Periods in Seconds	
Mode Number	SAP IV	DYNAS, MASS IV, MASS V
1	525.79	525.69
2	85.368	85.369
3	30.965	30.964
4	16.059	16.060
5	9.9006	9.9010
6	6.8276	6.8279
7	5.1865	5.1866
8	4.3777	4.3778

TABLE 3.13-3 INDIA SAMPLE PROGRAM

INTERACTION DIAGRAM AXIAL LOAD VS. BENDING MOMENT REFERRED TO THE PLASTIC CENTROID OF THE SECTION.

LIST OF SYMBOLS

B	= WIDTH OF SECTION, IN.
T	= HEIGHT OF SECTION, IN.
D	= DEPTH OF TENSILE STEEL, IN.
AS	= AREA OF TENSILE STEEL, SQ IN.
DC	= DEPTH OF COMPRESSION STEEL, IN.
ASC	= AREA OF COMPRESSION STEEL, SQ IN.
ES	= MODULUS OF ELASTICITY OF REINFORCING STEEL, KSI
SSY	= YIELD STRESS OF REINFORCING STEEL, KSI
SSU	= ULTIMATE STRESS OF REINFORCING STEEL, KSI
PRESTR	= INITIAL PRESTRAIN OF REINFORCING STEEL
ULTSTR	= ULTIMATE STRAIN OF REINFORCING STEEL
CUS	= 28 DAY STRENGTH OF CONCRETE CYLINDER, KSI
EPSZ	= CONCRETE STRAIN FOR MAXIMUM STRESS
EPSU	= CONCRETE STRAIN AT CRUSHING
NSTESS	= NUMBER OF POINTS IN INTERACTION DIAGRAM
EPEL	= MAXIMUM TOP STRAIN FOR WHICH ID IS COMPUTED

CHAPTER 4: REACTOR

This chapter was prepared using the latest approved version of the licensing topical report "General Electric Standard Application for Reactor Fuel" (GESTAR II) NEDE-24011-P-A including the "United States Supplement," NEDE-24011-P-A-US (Reference 1). Applicable sections of this report are referenced as noted in Sections 4.1 through 4.4. Reference is made to standardized information contained in the topical report, consistent with the NRC overall standardization philosophy. Additional cycle-specific reload information is in the cycle-specific supplemental reload licensing report.

4.1 REACTOR SUMMARY DESCRIPTION

The reactor assembly consists of the reactor pressure vessel (RPV) and its internal components, including the core, shroud, steam separator and dryer assemblies, and jet pumps. Also included in the reactor assembly are the control rods, control rod drive (CRD) housings, and the CRDs. The RPV cutaway, Figure 4.1-1, shows the arrangement of reactor assembly components. A summary of the important design and performance characteristics is given in Section 1.3. Loading conditions for reactor assembly components are specified in Table 3.9-14. Summary tables of the pertinent reactor data are presented at the end of Sections 4.2, 4.3, and 4.4.

4.1.1 Reactor Pressure Vessel

The RPV design and description are covered in Section 5.4.

4.1.2 Reactor Internal Components

The major reactor internal components are the core (fuel, channels, control rods, and instrumentation), the core support structure (including the core shroud, shroud head separators, top guide, and core support plate), the steam dryer assembly, and the jet pumps. Except for the zirconium alloys in the reactor core, these reactor internals are stainless steel or other corrosion- resistant alloys. All major internal components of the RPV can be removed except the jet pump diffusers, the core shroud, the core spray spargers, and the jet pump inlet piping. The removal of the steam dryers, shroud head separators, fuel assemblies, incore assemblies, control rods, and control rod guide tubes can be accomplished on a routine basis.

4.1.2.1 Reactor Core

4.1.2.1.1 General

The design of the Fermi 2 BWR core and fuel is based on the proper combination of many design variables and operating experience. These factors contribute to the achievement of high reliability.

A number of important features of the BWR core design are summarized in the following:

a. The BWR core mechanical design is based on conservative application of stress limits, operating experience, and experimental test results. The pressure levels (approximately 1000 psia) result in moderate cladding temperatures and stress levels.

b. The low coolant saturation temperature, high heat transfer coefficients, and neutral water chemistry of the BWR are significant, advantageous factors in minimizing zircaloy temperature and associated temperature-dependent corrosion and hydride buildup. The relatively uniform fuel cladding temperatures throughout the core minimize migration of the hydrides to cold cladding zones and reduce thermal stresses.

c. The basic thermal and mechanical criteria applied in the design have been proven by irradiation of statistically significant quantities of fuel. The design heat fluxes and linear heat generation rates are similar to values proven in fuel assembly irradiation.

d. The design power distribution used in sizing the core represents a worst-expected state of operation.

e. The GE thermal analysis basis, GETAB, is applied to ensure that more than 99.9 percent of the fuel rods in the core are expected to avoid boiling transition for the most severe abnormal operational transient described in Chapter 15 and the cycle-specific supplemental reload licensing report. The possibility of boiling transition occurring during normal reactor operation is insignificant.

f. Because of the large negative moderator density coefficient of reactivity, the BWR has a number of inherent advantages. These are the use of recirculation coolant flow for load following, the inherent self-flattening of the radial power distribution, the ease of control, the spatial xenon stability, and the ability to override xenon in order to follow load.

Boiling water reactors do not have instability problems due to xenon. This has been demonstrated by special tests which have been conducted on operating BWRs in an attempt to force the reactor into xenon instability, and by calculations. No xenon instabilities have ever been observed in the test results. All of these indicators have proven that xenon transients are highly damped in a BWR due to the large negative power coefficient of reactivity (Reference 1).

Important features of the reactor core arrangement are as follows:

a. The bottom-entry cruciform control rods consist of: (1) boron carbide (B_4C) in stainless steel tubes or (2) boron carbide (B_4C) in stainless steel tubes and hafnium metal. Duralife 140 control rods are surrounded by a stainless steel sheath. Marathon C, Ultra-MD, and Ultra-HD control rods have absorber tubes that are edge welded to form the cruciform shape.

b. The fixed in-core ion chambers provide continuous-power-range neutron flux monitoring. A probe tube in each in-core assembly provides for a traversing ion chamber for calibration and axial detail. Source range monitors (SRM) and intermediate range monitors (IRM) are located in-core and are axially retractable. The in-core location of the startup and IRM instruments provides coverage of the large reactor core and provides an acceptable signal-to-noise ratio and neutron-to-gamma ratio. All in-core instrument leads enter from the bottom and the instruments are in service during refueling. In-core instrumentation is further discussed in Chapter 7.

c. As shown by experience obtained at Dresden 1 and other plants, the operator, utilizing the in-core flux monitor system, can maintain the desired power distribution within a large core by proper control rod scheduling.

d. The zirconium alloy reusable channels provide a fixed flow path for the boiling coolant, serve as a guiding surface for the control rods, and protect the fuel during handling operations.

e. The mechanical reactivity control permits criticality checks during refueling. The core is designed to be subcritical at any time in its operating history with any one control rod fully withdrawn.

f. The selected control rod pitch represents a practical value of individual control rod reactivity worth and allows ample clearance below the RPV between CRD mechanisms for ease of maintenance and removal.

4.1.2.1.2 Core Configuration

The reactor core is arranged as an upright circular cylinder containing a large number of fuel cells and is located within the RPV. The coolant flows upward through the core. The core arrangement (plan view) and the lattice configuration are shown in Figure 4.1-2.

4.1.2.1.3 Fuel Assembly Description

As can be seen from Figure 4.1-2, the BWR core is essentially composed of only two components: fuel assemblies and control rods. The fuel assembly and control rod mechanical designs (See Subsection 4.5.2.2) are basically the same as those used in Dresden 1 and in all subsequent GE BWRs. A description of the fuel assembly including fuel rods, water rods, other fuel assembly components, and channels is given in Section 4.2. A brief description of the fuel rods and bundle is given below.

4.1.2.1.3.1 Fuel Rod

A fuel rod consists of uranium oxide (UO_2) pellets and a zircaloy cladding tube. Barrier fuel bundles consist of fuel rods with a thin, high purity zirconium liner, i.e. barrier, mechanically bonded to the cladding tube. A fuel rod is made by stacking pellets into a zircaloy cladding tube that is evacuated, backfilled with helium, and sealed by welding zircaloy end plugs in each end of the tube.

The BWR fuel rod is designed as a pressure vessel. The ASME Boiler and Pressure Vessel (B&PV) Code, Section III, is used as a guide in the mechanical design and stress analysis of the fuel rod.

The rod is designed to withstand the applied loads, both external and internal. The fuel pellet is sized to provide sufficient clearance within the fuel tube to accommodate axial and radial differential expansion between fuel and cladding. Overall fuel rod design is conservative in its accommodation of the mechanisms affecting fuel in a BWR environment. Fuel rod design bases are discussed in more detail in Subsection 4.2.1.

4.1.2.1.3.2 Fuel Bundle

Each fuel bundle contains fuel rods and water rods that are spaced and supported in a square array by spacers and a lower and upper tie plate. The fuel bundle has two important design features:

a. The bundle design places minimum external forces on a fuel rod; each fuel rod is free to expand in the axial direction.

b. The unique structural design permits the removal and replacement, if required, of individual fuel rods.

Before fuel is inserted into the reactor, a zirconium alloy fuel channel is placed around the fuel bundle, forming a fuel assembly.

The fuel assemblies of which the core is comprised are designed to meet all the criteria for core performance and to provide ease of handling. Selected fuel rods in each assembly differ from the others in uranium enrichment. This arrangement produces more uniform power production across the fuel assembly.

4.1.2.1.4 Assembly Support and Control Rod Location

A few peripheral fuel assemblies (24) and their individual fuel support pieces are supported by the core support plate. Otherwise, individual fuel assemblies in the core rest on fuel support pieces mounted on top of the control rod guide tubes. Each guide tube, with its fuel support piece, bears the weight of four assemblies and is supported by a control rod drive penetration nozzle in the bottom head of the RPV. The core support plate provides lateral support and guidance at the top of each control rod guide tube. For a discussion of fuel channel wear from flow-induced instrument tube vibrations caused by flow through the bypass holes in the core support plate, see Subsection 4.5.1.2.3.

The top guide, mounted inside the core shroud, provides lateral support and guidance for each fuel assembly. The reactivity of the core is controlled by cruciform control rods containing boron carbide or a combination of boron carbide and hafnium metal and by the associated mechanical hydraulic drive system. The control rods occupy alternate spaces between fuel assemblies. Each independent CRD enters the core from the bottom and can accurately position its associated control rod during normal operation and yet exert approximately 10 times the force of gravity to insert the control rod during the scram mode of operation. Bottom entry allows optimum power shaping in the core, ease of refueling, and convenient CRD maintenance.

4.1.2.2 Shroud

The shroud is a cylindrical, stainless steel structure that surrounds the core and provides a barrier to separate the upward flow through the core from the downward flow in the annulus. The shroud also provides a floodable volume in the unlikely event of an incident that tends to drain the RPV. A flange at the top of the shroud cylinder mates with a flange on the shroud head to form the core discharge plenum. The shroud support is welded to the RPV wall and is designed to support and locate the jet pumps and core support structure. The 20 jet pump discharge diffusers penetrate the shroud support below the core elevation to introduce the coolant to the lower inlet plenum.

Mounted inside the shroud in the space between the top of the core and the flange at the top of the shroud are the two core spray spargers with spray nozzles for injection of cooling water. The core spray spargers and nozzles do not interfere with the installation or removal of fuel from the core. A pipe for the injection of neutron absorber (sodium pentaborate) solution is mounted below the core to ensure mixing with the cooling water rising through the core.

4.1.2.3 Shroud Head and Separators

The shroud head and separators consist of a flange and dome onto which is welded an array of standpipes (225), with a steam separator located at the top of each standpipe. The shroud head mounts on the flange at the top of the shroud top cylinder and forms the cover (shroud head) of the core discharge plenum region. The joint between the shroud head and shroud top cylinder does not require a gasket or other replacement sealing techniques. The fixed axial flow-type steam separators have no moving parts and are made of stainless steel.

In each separator, the steam/water mixture rising from the standpipe impinges on vanes that give the mixture a spin to establish a vortex wherein the centrifugal forces separate the steam from the water. Steam leaves the separator at the top and passes into the wet steam plenum below the dryer. The separated water exits from the lower end of the separator and enters the pool that surrounds the standpipes to enter the downcomer annulus. An internal steam separator schematic is shown in Figure 4.1-3.

For ease of removal, the shroud head and separators are bolted to the top cylinder by long shroud head bolts that extend above the separators for easy access during refueling. The shroud head and separators are guided into position on the shroud and flange with guide rods and locating pins. The objective of the longbolt design is to provide direct access to the bolts during reactor refueling operations with minimum-depth underwater tool manipulation during the removal and installation of the assemblies.

4.1.2.4 Steam Dryer Assembly

The steam dryer assembly is mounted in the RPV above the shroud head and separators and forms the top and sides of the wet steam plenum. Vertical guide rods on the inside of the RPV provide alignment for the dryer assembly during installation. The dryer assembly is supported by pads extending from the RPV wall and is locked into position during operation by the RPV top head. Steam from the separators flows upward into the dryer assembly. The steam leaving the top of the dryer assembly flows into four RPV steam outlet nozzles that are located alongside the steam dryer assembly. Moisture is removed by the dryer vanes and flows first through a system of troughs and pipes to the pool surrounding the separators and then into the downcomer annulus between the shroud and RPV wall. A schematic of a typical steam dryer panel is shown in Figure 4.1-4.

4.1.3 Reactivity Control Systems

4.1.3.1 Operation

The control rods perform dual functions of power distribution shaping and reactivity control. Power distribution in the core is controlled during operation of the reactor by manipulation of selected patterns of rods. The rods, which enter from the bottom of the near-cylindrical reactor core, are positioned in a manner such as to counterbalance steam voids in the top of the core and effect significant power flattening.

The reactivity control function requires that all rods be available for both reactor scram and reactivity regulation. Because of this, the control elements are mechanically designed to withstand the dynamic forces resulting from a scram. They are connected to bottom-mounted, hydraulically actuated drive mechanisms that allow either axial positioning for reactivity regulation or rapid scram insertion. The design of the rod-to-drive connection permits each blade to be attached or detached from its CRD without disturbing the remainder of the control system. The bottom-mounted CRDs permit the entire control system to be left intact and operable for tests with the RPV open. See also Subsection 4.5.2.2.2.4.

4.1.3.2 Description of Rods

The cruciform-shaped control rods consist of (1) boron carbide (B_4C) in stainless steel tubes or (2) boron carbide (B_4C) in stainless steel tubes and hafnium metal. Duralife 140 control rods are surrounded by a stainless steel sheath. Marathon C, Ultra-MD, and Ultra-HD control rods have absorber tubes that are edge welded to form the cruciform shape. Hafnium metal (another neutron absorber) is used in the Duralife 140, Marathon C, and Ultra-HD control rod designs to extend service life. Refer to Subsection 4.5.2.1.2 for a description of the control rods.

Control rods are cooled by the core bypass flow that is made up of leakage through various flow paths of the fuel support and lower core plate structure.

4.1.3.3 Supplementary Reactivity Control

The control requirements of the initial core are considerably in excess of the equilibrium core requirements because all the fuel is fresh. The initial core control requirements are met by use of the combined effects of the movable control rods and a supplementary burnable poison. The supplementary burnable poison is gadolinia (Gd_2O_3) mixed with UO_2 in several fuel rods in each fuel bundle.

4.1.4 Analysis Techniques

4.1.4.1 Reactor Internal Components

Computer codes used for the analysis of the internal components are listed below:

a. MASS (Mechanical Analysis of Space Structure)

b. SNAP and MULTISHELL

c. GASP

d. NOHEAT

e. FINITE

f. SAMIS (Structural Analysis and Matrix Interpretive System)

g. GEMOP (General Matrix Manipulation Program)

h. SHELL 5 and SHELL 9

i. HEATER

j. FAP-71 (Fatigue Analysis Program)

k. DYSEA (Dynamic and Seismic Analysis).

Detailed descriptions of these programs are given in the subsections that follow.

4.1.4.1.1 MASS (Mechanical Analysis of Space Structure)

4.1.4.1.1.1 Program Description

The program, proprietary of GE, is an outgrowth of the plate and panel analysis program originally developed by L. Beitch in the early 1960s. The program is based on the principle of the finite element method. Governing matrix equations are formed in terms of joint displacements using a "stiffness-influence-coefficient" concept originally proposed by L. Beitch (Reference 1a). The program offers curved beam, plate, and shell elements. It can handle mechanical and thermal loads in a static analysis and predict natural frequencies and mode shapes in a dynamic analysis.

4.1.4.1.1.2 Program Version

The Nuclear Energy Division of GE is using a past revision of MASS. This revision is identified as revision "0" in the computer production library.

4.1.4.1.1.3 History of Use

Since its development in the early 1960s, the program has been successfully applied to a wide variety of jet-engine structural problems, many of which involve extremely complex geometries. The use of the program in the GE Nuclear Energy Division also started shortly after its development.

4.1.4.1.1.4 Extent of Application

In addition to the GE Jet Engine Division, the Nuclear Energy Division, and the Missile and Space Division, the Appliance Division and the Turbine Division have also applied the program to a wide range of engineering problems. The Nuclear Energy Division used it mainly for piping and reactor internals analysis.

4.1.4.1.2 SNAP (MULTISHELL)

4.1.4.1.2.1 Program Description

The SNAP program, which is also called MULTISHELL, is a code that determines the loads, deformations, and stresses of axisymmetric shells of revolution (cylinders, cones, disks, toroids, and rings) for axisymmetric thermal boundary and surface load conditions. Thin shell theory is inherent in the solution of E. Reissner's differential equations for each shell's influence coefficients. Surface loading capability includes pressure, average temperature, and linear through-wall gradients; the latter two may be linearly varied over the shell meridian. The theoretical limitations of this program are the same as those of classical theory.

4.1.4.1.2.2 Program Version

The current version maintained by the GE Jet Engine Division at Evandale, Ohio.

4.1.4.1.2.3 History of Use

The initial version of the Shell Analysis Program was completed by the Jet Engine Division in l96l. Since then, a considerable amount of modification and addition has been made to accommodate its broadening area of application. Its application in the Nuclear Energy Division had a history of over 10 years when used for the Fermi 2 analysis.

4.1.4.1.2.4 Extent of Application

The program has been used to analyze jet engine, space vehicle, and nuclear reactor components. Because of its efficiency and economy, in addition to reliability, it has been one of the main shell analysis programs in GE's Nuclear Energy Division.

4.1.4.1.2.5 Test Problems

The program has been used to analyze the pressure vessel specified in Article I-7 of ASME Section III. The program results are compared with those from other shell programs under three loadings: internal pressure, axial temperature gradient, and linear radial temperature gradient. It was found that the thin-shell theory programs (OMP, SOR, and MULTISHELL) were within 4 percent of thin-shell theoretical results for the pressure loading and within 1 percent of each other for the other two loadings. The thick-shell theory program (SEAL-SHELL-2) was within 7 percent of theory for the pressure loading and within 9 percent of the thin-shell codes on the other two loadings. Detailed results are presented in Figures 4.l-5 through 4.1-13.

4.1.4.1.3 GASP

4.1.4.1.3.1 Program Description

GASP is a finite element program for the stress analysis of axisymmetric or plane two-dimensional geometries. The element representations can be either quadrilateral or triangular. Axisymmetric or plane structural loads can be input at nodal points. Displacements, temperatures, pressure loads, and axial inertia can be accommodated. Effective plastic stress and strain distributions can be calculated using a bilinear stress-strain relationship by means of an iterative convergence procedure.

4.1.4.1.3.2 Program Version and Computer

The GE version, originally obtained from the developer, Professor E. L. Wilson, operates on the Honeywell 6000 computer.

4.1.4.1.3.3 History of Use

The program was developed by E. L. Wilson in l965 (Reference 2). The present version in GE's Nuclear Energy Division has been in operation since l967.

4.1.4.1.3.4 Extent of Application

The application of GASP in the GE Nuclear Energy Division is mainly for elastic analysis of axisymmetric and plane structures under thermal and pressure loads. The GE version has been extensively tested and used by engineers in the company.

4.1.4.1.3.5 Test Problems

The ASME computer-program-verification problem l9 (Reference 3) was solved using the triangular elements of GASP and ANSYS (Figure 4.1-14). The results of both solutions are very close to each other and they agree with a closed-form solution given in Reference 3 (Figure 4.1-15).

4.1.4.1.4 NOHEAT

4.1.4.1.4.1 Program Description

The NOHEAT program (Reference 4) is a two-dimensional and axisymmetric transient nonlinear temperature analysis program. An unconditionally stable numerical integration scheme is combined with iteration procedure to compute temperature distribution within the body subjected to arbitrary time- and temperature-dependent boundary conditions.

This program utilizes the finite element method. Included in the analysis are the three basic forms of heat transfer, conduction, radiation, and convection, as well as internal heat generation. In addition, cooling pipe boundary conditions are also treated. The output includes temperature of all the nodal points for the time instants required by the user. The program can handle multitransient temperature input.

4.1.4.1.4.2 Program Version

The current version of the program is an improvement of the program NOHEAT originally developed by I. Farhoomand and Professor E. L. Wilson of the University of California at Berkeley.

4.1.4.1.4.3 History of Use

The program was developed in l97l and installed in the Honeywell computer by one of its original developers, I. Farhoomand, in 1972. A number of heat transfer problems related to the reactor pedestal have been satisfactorily solved using the program.

4.1.4.1.4.4 Extent of Application

The program using finite element formulation is compatible with the finite element stress-analysis computer program GASP. Such compatibility simplified the connection of the two analyses and minimized human error.

4.1.4.1.4.5 Test Problems

Problem 1

Problem 1 involves one-dimensional temperature response of a plate with insulated back face after sudden change in external front surface temperature.

The prescribed heat-input boundary condition is useful in problems of aerodynamics, nuclear reactor power plants, and similar problems. The temperature response of a plate caused by a sudden change in external front surface temperature has been solved by direct integration technique (Reference 5). Figure 4.1-16 shows the response in a nondimensional form. The following variables are used in the description of the figure:

a. T_o = Initial temperature of figure

b. T_e = Boundary temperature

c. α = Thermal diffusivity of body material = $k/\rho c$

d. k = Conductance

e. ρ = Density

f. c = Specific heat

g. t = Time

h. L = Plate thickness

i. T = Temperature of the body at time t.

A linear finite element analysis was conducted using T = 0, T_e = 100, k = 0.0006, ρ = 0.3, c = 0.1, L = 100. The finite element mesh is shown in Figure 4.1-17. The result of the finite element analysis (dark circles in Figure 4.1-16) indicates excellent agreement with the result of the analytical solution.

Problem 2

Problem 2 involves temperature response of the front face of a plate with insulated back face after sudden exposure to constant-temperature radiation.

This example demonstrates the accuracy of the finite element as compared with an analytical solution of a radiation heat transfer problem. Consider a plate of thickness L, with finite conductivity k, specific heat c, and density ρ. The back face of the plate is insulated and the front face is subjected to a constant radiation heat flow with sink temperature, T_s = 0°R. The time variation of the temperature of the front surface was computed in a nondimensional form by the application of an approximate analytical technique (Reference 5). Figure 4.1-18 presents the temperature response for a particular value of parameter M. The variables used to construct Figure 4.l-18 are

a. σ = 17.3×10^{-10} Btu/hr ft^4/°R

b. F_e = Shape factor for plate surface

c. F_A = Shape factor for sink

d. T_o = Initial temperature of plate (°R)

e. T_e = Surface temperature of plate (°R).

Several finite element analyses with the same time increment but different numbers of iterations within each cycle were conducted. The finite element mesh layout is shown in Figure 4.1-19. In the analyses F_A = F_e = 1., T_o = 500, M = l, α = k/c = 0.02 and T_x = 0°R.

Comparison of the finite element solutions with the analytical solution indicates that the incremental approach without iteration does not converge to the "true" solution. However, if one iteration is made in each time increment, the finite element result becomes nearly identical to the analytical result.

4.1.4.1.5 FINITE

4.1.4.1.5.1 Program Description

FINITE is a general-purpose finite element computer program for elastic stress analyses of two-dimensional structural problems including plane stress, plane strain, and axisymmetric structures. It has provision for thermal, mechanical, and body force loads. The materials of the structure may be homogeneous or nonhomogeneous and isotropic or orthotropic. The development of the FINITE program is based on the GASP program, described in Subsection 4.1.4.1.3.

4.1.4.1.5.2 Program Version

The present version of the program at the GE Nuclear Energy Division was obtained from the developer, J. E. McConoclee of the GE Gas Turbine Department in 1969 (Reference 6).

4.1.4.1.5.3 History of Use

Since its completion in 1969, the program has been widely used in the GE Gas Turbine and Jet Engine Divisions for the analysis of turbine components.

4.1.4.1.5.4 Extent of Application

The program is used at GE's Nuclear Energy Division in the analysis of axisymmetric or nearly axisymmetric BWR internals.

4.1.4.1.5.5 Test Problems

Two simple examples are described herein with a comparison of the stresses calculated by FINITE with theoretical solutions.

The two cases considered are

a. A tube with internal pressure

b. A spinning disk of elliptical cross section.

The analytical models for these cases are shown in Figures 4.1-20 and 4.1-21, and comparisons of the calculated stresses with theoretical solutions are shown in Figures 4.1-22 and 4.1-23.

Figure 4.1-22 shows a comparison of the radial and tangential stresses at the midlength of the tube with those calculated using the Lamé solution.

Figure 4.1-23 shows a comparison of the radial and tangential stresses calculated by FINITE using the plane stress (with variable thickness) option with those obtained using the analysis of Goldberg and Sadowsky (Reference 7). This problem could have been done more exactly using the axisymmetric option which would have given the variation of the stresses through the thickness of the disk. However, the purpose in this case was explicitly to check out the use of the variable thickness plane stress case and a comparison of these results with an exact solution. Another purpose of this case was to check out the use of the skew boundary condition.

4.1.4.1.6 SAMIS (Structural Analysis and Matrix Interpretive System)

4.1.4.1.6.1 Program Description

The SAMIS program (References 8 through 10) is well designed to solve problems involving matrix algebra with particular emphasis on structural applications. The user has control over the flow of the calculations through the use of "pseudo instructions." Execution of the program is performed in two phases: the generation phase and the manipulative phase. Input data defining the idealization of a structure is read and stiffness, stress, and load coefficient matrices are generated for elements available to the user. The program has two fundamental and widely used finite elements incorporated. A triangular flat plate element, called a facet, is available for idealization of plate and shell structures, and a straight beam element is available for idealization of frames and trusses and plate/shell structure stiffener representation.

The element formulation and analyses are based on the finite element matrix displacement method. The triangular plate and beam elements are capable of resisting stretching, shearing, bending, and twisting stresses. In the second phase of execution, the generated or input matrices are manipulated according to the rules of matrix algebra as directed by the user.

The program is written in modular form, making it easy to add new modules without major reprogramming of subroutines. This facilitates adding to the structural element library other elements to extend idealization capability. Those structural problems consisting of elements that cannot be adequately idealized by triangular plate or beam elements may have their stiffness coefficients submitted directly as input matrices.

4.1.4.1.6.2 Program Version

The SAMIS version was obtained from the developer, Philco Corporation, Western Development Laboratory, via the Space Division. A considerable amount of modification was made on the input and output of the original version to suit the analysis need of this division of GE. Both spectrum and time-history analyses can be performed using the GE Nuclear Energy Division version.

4.1.4.1.6.3 History of Use

The SAMIS program was developed by the Philco Corporation, Western Development Laboratories, under contract to and in association with the Jet Propulsion Laboratory in 1966. The program was first used by GE in 1967 and in the Nuclear Energy Division of GE in 1970.

4.1.4.1.6.4 Extent of Application

The current GE version of SAMIS has been extensively used since 1970 in the analysis of reactor components' response to seismic loadings. Results of test problems were found to agree closely with theoretical results of the same problem.

4.1.4.1.6.5 Test Problem

The clamped square plate frequency study considers a square plate having all four of its edges clamped. Figure 4.1-24 shows a quarter panel of the plate.

The particular plate dimensions and material properties used in the analysis were as follows:

a. $a = 10$ in.

b. $t = 0.05$ in.

c. $E = 30 \times 10^6$ lb/in.^{2}

d. $\nu = 0.03$

e. $\rho = 7.26 \times 10^{-4}$ lb-sec^2/in.^{4}.

For all grids used in the study, the triangular elements in any one grid were all uniform size except as noted.

A total of four grid models were analyzed for the clamped plate, each based on selected value of a/c = a/d or c = d for the square plate models. Each case will be referred to by number. In the table below are listed four cases and the grid size function for each case.

Case No.	a/c, a/d
1	4
2	5
3	6
4	7

For each case, three sets of modes were computed: symmetric modes, antisymmetric modes, and mixed modes (symmetric about X and antisymmetric about Y). The fourth set of modes was not required since the plate is square and the remaining mixed mode set (symmetric about Y and antisymmetric about X) would only be duplicate frequencies of the first mixed mode set.

Table 4.1-1 is a list of computed frequencies for the clamped square plate models. The first six frequencies are listed for each case along with the percent variation from the theoretical frequencies. The table shows, as would be expected, successive improvement in computed frequencies as the grid is refined. The results for Case Number 4 show rather good agreement for all six frequency values, the largest difference being in the third and sixth frequency values which differ from the exact frequency by 12.6 percent and 13.3 percent, respectively. A number of other models could be analyzed using larger grid size functions; however, it is doubtful that the improvement in accuracy would be as marked as in the initial four models for the six frequencies.

4.1.4.1.7 GEMOP (General Matrix Manipulation Program)

4.1.4.1.7.1 Program Description

GEMOP is a general matrix manipulation program capable of performing the majority of standard matrix operations. There presently are 41 operation commands in the program. A maximum of nine full 60 by 60 matrices and six 60-element vectors may be stored in core at any one time. Also available for search and storage are up to a maximum of three tapes. This latest version of the program includes subroutines for calculating earthquake, or other forcing functions, and response of a lumped-mass structure, either by time-history or spectral response methods. The most used features are in the eigenvalue, eigenvector subroutine and response subroutine. The response is calculated for a system subjected to any piecewise linear forcing function.

4.1.4.1.7.2 Program Version

The current version of the program being used in GE was obtained from the originator, the Knolls Atomic Power Laboratory, in June 1969. It was converted from Control Data Corporation to GE computers.

4.1.4.1.7.3 History of Use

The program was originally written in the GE Knolls Atomic Power Laboratory for the solution of vibration problems.

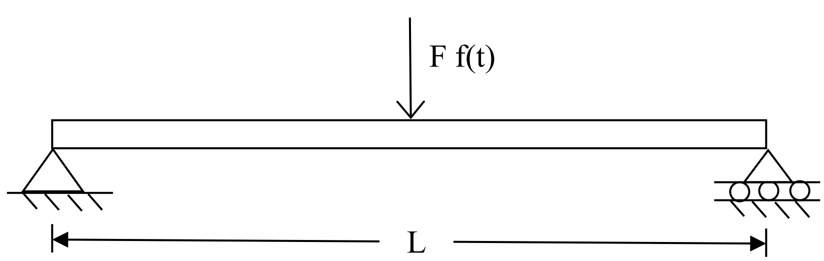
4.1.4.1.7.4 Extent of Application

Since its installation in the Nuclear Energy Division in 1969, the general matrix manipulation program has been constantly used to solve seismic problems involving small lumped-mass systems of less than 80 degrees of freedom. Because of its limitation on problem size, the program is being replaced by SAMIS.

4.1.4.1.7.5 Test Problems

To evaluate its capability, the computer program has been used to solve the following sample problem. The satisfactory agreement between the lumped-mass numerical solution and the continuous system theoretical solution indicates the reliability of the general matrix manipulation program.

Consider a simply supported beam with a suddenly applied load at its center as the problem.



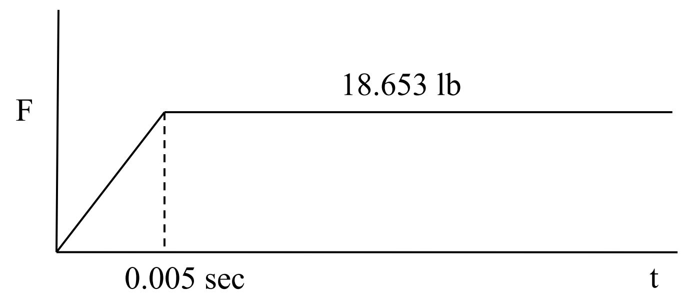
L = l00 in.

E = 30 x 10^6 psi

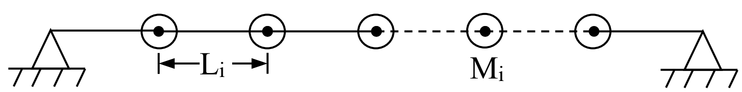
I = 2.5907 $in.^4$

A = 9.8696 $in.^2$

$\rho = 0.3 \text{ lb/in.}^3$



For this problem the beam is modeled as a five-lump mass system, or



all lengths are equal

$L_i \quad = \quad L/6$

all masses are equal

$$M_i = \frac{M}{5} = \frac{AL\rho}{5g} \qquad (4.1\text{-}1)$$

A comparison of the calculated natural frequencies of the lumped-mass system compared with the continuous system shows very good agreement.

Beam Natural Frequencies

Mode	GEMOP Lumped-Mass Frequency (Hz)	Continuous System Frequency (Hz)	GEMOP Error (percent)
1	5.00	5.00	0.0
2	19.98	20.00	0.1
3	44.66	45.00	0.8
4	77.33	80.00	3.3
5	110.59	125.00	11.5

The maximum displacement response of the beam is calculated considering zero damping and a cutoff frequency of 45 Hz. With this cutoff frequency, the calculated response included the effect of Modes 1, 2, and 3. The calculated maximum response for this second case was 0.997 in., compared with the theoretical value of 1.00 in. This indicates an error of only 0.32 percent.

4.1.4.1.8 SHELL 5 and SHELL 9

4.1.4.1.8.1 Program Description

SHELL 5 and SHELL 9 are two finite-shell element programs used to analyze smoothly curved thin-shell structures with any distribution of elastic material properties, boundary constraints, and mechanical thermal and displacement loading conditions. The basic element is triangular. Its membrane displacement fields are linear polynomial functions and its bending displacement field is a cubic polynomial function (Reference 11). Five degrees of freedom (three displacements and two bending rotations) are obtained at each nodal point. SHELL 9 is an improvement of SHELL 5. It includes a more accurate shell element with nine degrees of freedom at each node. Output displacements and stresses are in a local (tangent) surface coordinate system.

Due to the approximation of element membrane displacements by linear functions, the in-plane rotation about the surface normal is neglected. Therefore, the only rotations considered are those caused by bending of the shell cross section. Application of the method is not recommended for shell intersection (or discontinuous surface) problems where in-plane rotation can be significant.

4.1.4.1.8.2 Program Version

A copy of the source deck of SHELL 5 is maintained in the GE Nuclear Energy Division. SHELL 9 is a proprietary computer program of Gulf Atomic Incorporated.

4.1.4.1.8.3 History of Use

SHELL 5 and SHELL 9 are programs developed by Gulf General Atomic Incorporated (Reference 12) in 1969. The programs have been in production status at Gulf General Atomic and other major computer operating systems since 1970.

4.1.4.1.8.4 Extent of Application

SHELL 5 has been used at GE to analyze the reactor shroud support and torus.

4.1.4.1.8.5 Test Problems

Two examples showing comparisons of solutions obtained by the present method with a solution based on a simpler model, an exact solution, and experimental data are presented in Figures 4.1-25 through 4.1-29. Figure 4.1-26 shows the radial displacement for the line-loaded cylinder shown in Figure 4.1-25 compared with the exact solution (Reference 13) and a solution obtained for the element model of Reference 11 with linear membrane and cubic bending displacement approximations. Symmetry permitted the analysis of one slice. In order to show the dependence of the solution on the mesh density, the circumferential angle of the slice was varied, which is equivalent to varying the number of elements. It should be pointed out that this comparison does not constitute a complete study, and other examples may show different convergence behavior. The differences between the two models shown by this example warrant further study.

Figure 4.1-27 shows the finite element idealization of a nozzle-to-cylinder intersection problem that is under experimental investigation at the Oak Ridge National Laboratory.

Because of symmetry about the longitudinal plane, only half of the structure is analyzed for internal pressure. The idealization consisted of 640 modal points and 1168 elements. Comparisons of the analysis with the experimental data in the vicinity of the right-angle intersection for the longitudinal plane are shown in Figures 4.1-28 and 4.1-29. Figure 4.1-28 shows the axial and circumferential outside surface stresses for the cylinder. Figure 4.1-29 shows the axial and circumferential outside surface stresses for the nozzle. The analytical results compare favorably with the distribution and magnitude of experimental stresses (obtained from strain gage results).

4.1.4.1.9 HEATER

4.1.4.1.9.1 Program Description

HEATER is a computer program (Reference 14) used in the hydraulic design of feedwater spargers and their associated delivery heads and piping. The program utilizes test data obtained by GE using full-scale mockups of a feedwater sparger combined with a series of models that represent the complex mixing processes obtained in the upper plenum, downcomer, and lower plenum. Mass and energy balances throughout the nuclear steam supply system (NSSS) are modeled in detail.

4.1.4.1.9.2 Program Version

This program was developed at GE's Nuclear Energy Division.

4.1.4.1.9.3 History of Use

The program was developed by various individuals beginning in 1970. The present version of the program has been in operation since January 1972.

4.1.4.1.9.4 Extent of Application

The program is used in the hydraulic design of the feedwater spargers for each BWR plant in the evaluation of design modifications and the evaluation of unusual operational conditions.

4.1.4.1.9.5 Test Problems

Various critical parts of the program have been verified by hand calculation. The program has also been used to predict test results.

4.1.4.1.10 FAP-71 (Fatigue Analysis Program)

4.1.4.1.10.1 Program Description

The FAP-71 computer code, or Fatigue Analysis Program, is a stress-analysis tool used as an aid in performing ASME B&PV Code Section III structural design calculations. Specifically, FAP-71 is used in determining the primary plus secondary stress range and number of allowable fatigue cycles at points of interest. For structural locations at which the $3S_m$ (P+Q) ASME Code limit is exceeded, the program can perform either (or both) of two elastic-plastic fatigue life evaluations: (a) the method reported in ASME Paper 68-PVP-3; and (b) the present method documented in Paragraph NB-3228.3 of the 1971 Edition of the ASME B&PV Section III Code.

The program can accommodate up to 25 transient stress states of as many as 20 structural locations.

4.1.4.1.10.2 Program Version

The present version of FAP-71 was completed by L. Young of GE's Nuclear Energy Division in 1971 (Reference 15).

4.1.4.1.10.3 History of Use

Since its completion in 1971, the program has been applied to several design analyses of GE BWR vessels.

4.1.4.1.10.4 Extent of Application

The program is used in conjunction with several shell analysis programs in determining the fatigue life of BWR mechanical components subject to thermal transients.

4.1.4.1.10.5 Test Problems

The program has been verified using hand calculations.

4.1.4.1.11 DYSEA

4.1.4.1.11.1 Program Description

The DYSEA (Dynamic and Seismic Analysis) program is a GE proprietary program developed specifically for seismic and dynamic analyses of the reactor building coupled to the RPV and internals. It calculates the dynamic response of linear structural systems by either temporal modal superposition or response spectrum method. Fluid-structure interaction effect in the RPV is taken into account by way of hydrodynamic mass.

The DYSEA program was based on the SAP IV program with added capability to handle the hydrodynamic mass effect. Structural stiffness and mass matrices similar to SAP IV are formulated. Solution is obtained in time domain by calculating the dynamic response mode by mode. Time integration is performed by using Newmark's β-method. Response spectrum solution is also available as an option.

4.1.4.1.11.2 Program Version

The DYSEA version was developed at GE by modifying the SAP IV program. Capability was added to handle the hydrodynamic mass effect due to fluid-structure interaction in the reactor. It can handle three-dimensional dynamic problems with beams, trusses, and springs. Both acceleration time-histories and response spectra may be used as input.

4.1.4.1.11.3 History of Use

The DYSEA program was developed in the summer of 1976. It has been adopted as a standard production program since 1977 and has been used extensively in all dynamic and seismic analyses of the reactor building coupled to the RPV and internals.

4.1.4.1.11.4 Extent of Application

The current version of DYSEA has been used in all dynamic and seismic analyses since its development. Results from test problems were found to be in close agreement with those obtained from either verified programs or analytic solutions.

4.1.4.1.11.5 Test Problems

Problem 1

The first test problem involves finding the eigenvalues and eigenvectors from the following characteristic equation:

$$(\omega^2[M] - [K])\,\{\chi\} = 0$$

where ω is the circular frequency and χ is the eigenvector. The stiffness and the mass matrices are represented by [K] and [M], respectively, and are given by

$$[M] = \begin{bmatrix} 1-\frac{4}{\pi^2} & \frac{4}{\pi^2} & -\frac{4}{9\pi^2} \\ & 1-\frac{4}{9\pi^2} & \frac{4}{\pi^2} \\ Symmetric & & 1-\frac{4}{25\pi^2} \end{bmatrix}$$

$$[K] = \begin{bmatrix} 1+\frac{4}{\pi^2} & 3 & \frac{5}{9} \\ & 1+\frac{9\pi^2}{4} & 15 \\ Symmetric & & 1+\frac{25\pi^2}{4} \end{bmatrix}$$

The analytic solutions and the solutions from DYSEA are

Eigenvalues ω_i

i	DYSEA Solution	Analytic Solution
1	5.7835	5.7837
2	30.4889	30.4878
3	75.0493	75.0751

Eigenvector χ

DYSEA Solution	Analytic Solution
$\begin{bmatrix} 1.000 & 1.000 & 1.000 \\ -0.0319 & -1.5536 & -1.2105 \\ -0.0072 & -0.066 & 2.0271 \end{bmatrix}$	$\begin{bmatrix} 1.000 & 1.000 & 1.000 \\ -0.0319 & -1.554 & -1.211 \\ -0.0072 & 0.0666 & 2.027 \end{bmatrix}$

Problem 2

The second test problem compares the dynamic responses of the reactor building coupled to the RPV and internals when subjected to earthquake ground motion.

The mathematical model of the reactor building coupled to the RPV and internals is given in Figure 4.1-30. The input in the form of ground spectra is applied at the basemat level. Response spectrum analysis was used in the analysis.

Natural frequencies of the system and the maximum responses at key locations have been calculated by both DYSEA and SAMIS. Comparisons of results are given in Tables 4.1-2 and 4.1-3. The results calculated by DYSEA agree closely with those obtained by SAMIS.

4.1.4.2 Fuel Rod Thermal Analysis

Fuel thermal design analysis techniques are described in Subsection 4.2.3.

4.1.4.3 Reactor Systems Dynamics

The analysis techniques and computer codes used in reactor systems dynamics are described in Reference 16.

4.1.4.4 Nuclear Analysis

The analysis techniques and nuclear data used to determine the neutronic characteristics of the assembly and the core are generally similar to those used in the industry for light-water reactors. The methods are described fully in Subsection 4.3.3.

4.1.4.5 Neutron Fluence Calculations

The neutron fluence calculational technique is described in Subsection 4.3.2.8.

4.1.4.6 Thermal-Hydraulic Calculations

The thermal-hydraulic calculational techniques are described in Subsection 4.4.4.5.

LUMPED MASS MODEL

4.2 FUEL SYSTEM DESIGN

Fermi 2 is a BWR 4 with a 251 in. pressure vessel and 764 fuel assemblies loaded on a C lattice. The subsection numbers in Section 4.2 generally correspond to the subsection numbers of Appendix A of GESTAR II (Reference 1). Any additional information or differences are given for the applicable subsection.

4.2.1 Design Bases

Information in fuel system design bases is provided in Reference 1, Subsection A.4.2.1.

4.2.2 Description and Design Drawings

Information on fuel system design bases is provided in Reference 1, Subsection A.4.2.2, except for the reactivity control assembly description, which is described below.

4.2.2.1 Reactivity Control Assembly

4.2.2.1.1 Control Rods

The control rods perform the dual function of power shaping and reactivity control (See Figures 4.5-8 through 4.5-10). Power distribution in the core is controlled during operation of the reactor by manipulating selected patterns of control rods. Control rod displacement tends to counterbalance steam void effects at the top of the core and results in significant power flattening. See Subsection 4.5.2.1.2 for a description of the control rods.

4.2.3 Design Evaluations

Information on fuel system evaluation for compliance with the design bases is provided in Reference 1, Subsection A.4.2.3.

4.2.4 Testing, Inspection and Surveillance Plans

Information on testing, inspection and surveillance is provided in Reference 1, Subsection A.4.2.4. Fuel assembly surveillance plans are further described below.

Fermi 2 has a pre-established Fuel Reliability Action Plan for detection, analysis, reporting and taking corrective action whenever fuel failures occur. Detection is based primarily on sampling radioactivity in the off-gas system. At the end of a fuel cycle, fuel inspection and reconstitution using proven vendor techniques will be performed as needed to provide a basis for accomplishing the discharge of all failed fuel rods in accordance with a zero-defect goal. A zero-defect goal implies that no detected failed fuel rods will be re-inserted into the core after a refueling outage.

Proven inspection techniques used include the following:

a. Leak-detection tests such as sipping

b. Visual inspection with various aids such as binoculars, borescope, periscope, and/or underwater TV with a photographic record of observations

c. Nondestructive testing of selected fuel rods by ultrasonic test and/or eddy current test techniques

d. Dimensional measurements of selected fuel rods.

Such inspections may also be performed on fuel where there is no indication of fuel failure to obtain additional data on fuel performance. This fuel may either be from discharged bundles or from bundles scheduled for re-irradiation.

Unexpected conditions or abnormalities that may arise, such as distortions, cladding perforation, or surface disturbances, will be analyzed. Resolution of specific technical questions indicated by site examinations may require examination of selected fuel rods in radioactive material laboratory facilities.

Fermi 2 participated in a vendor's lead fuel test assembly program to obtain fuel performance data for an improved fuel design. This program took place with the insertion of full-length lead bundles during the second refueling outage. Performance inspection of this program is complete and only four lead fuel test assemblies were used. They are currently discharged. Additional lead fuel test programs may be instituted as the need requires.

4.3 NUCLEAR DESIGN

Most of the information in Section 4.3 is provided in the licensing topical report GESTAR II (Reference 1). The design bases and licensing requirements are independent of enrichment.

4.3.1 Design Bases

The design bases are those that are required for the plant to operate, meeting all safety requirements. Safety design bases fall into two categories: (1) the reactivity basis, which prevents an uncontrolled positive reactivity excursion, and (2) the overpower basis, which prevent the core from operating beyond the fuel integrity limits.

4.3.1.1 Reactivity Basis

The nuclear design shall meet the following basis: The core shall be capable of being made subcritical at any time or at any core condition with the highest worth control rod fully withdrawn.

4.3.1.2 Overpower Bases

The Technical Specification limits on minimum critical power ratio (MCPR), maximum linear heat generation rate (MLHGR), and the maximum average planar linear heat generation rate (MAPLHGR) are determined such that the fuel will not exceed required licensing limits during abnormal operational occurrences or accidents.

4.3.2 Description

The BWR core design consists of a light-water moderated reactor, fueled with slightly enriched uranium-dioxide. The use of water as a moderator produces a neutron energy spectrum in which fissions are caused principally by thermal neutrons. At normal operating conditions, the moderator boils, producing a spatially variable distribution of steam voids in the core. The BWR design provides a system for which reactivity is reduced by an increase in the steam void content in the moderator. This void feedback effect is one of the inherent safety features of the BWR system. Any system input which increases reactor power, either in a local or gross sense, produces additional steam voids which reduce reactivity and thereby reduce the power.

4.3.2.1 Nuclear Design Description

The initial fuel loading is composed of three distinct bundle types, each with a unique rod-by-rod enrichment distribution. The bottom and top of each fuel rod in two of these bundle types consists of 6 inches of natural uranium. The third bundle type contains only natural uranium fuel rods. The three unique bundle types are distributed in the initial core based on the principle of minimizing radial power peaking and maximizing core reactivity for the end-of-cycle state. This same strategy is carried into the reload core. A diagram of the cycle-specific reference pattern loading is shown in the cycle-specific supplemental reload licensing report.

The peripheral core zone of the initial core is composed of bundles containing only natural uranium fuel rods. The interior of the core is divided into two zones: an inner zone which comprises about 50 percent of the core area, and an outer zone, a ring, which comprises about 35 percent of the core area. The outer zone consists entirely of the high enrichment bundles. The inner zone is an array of high and medium enrichment bundles arranged in a checkerboard fashion.

Beginning with Cycle 2, the core is loaded with a Control Cell Core (CCC) configuration. The CCC uses a strategy in which control rod movement to offset reactivity changes during power operation is limited to a fixed group of control rods. Each of these rods and its four surrounding fuel bundles comprise a control cell. Low-reactivity bundles are placed in control cells so that control rod motion occurs adjacent to low power fuel. The control cells are located in octant symmetric positions in the core and are separated from each other by a four-bundle cell. All other control rods are normally completely withdrawn from the core while at power.

The reference loading pattern is the basis for all fuel licensing. It is designed with the intent that it will represent, as closely as possible, the actual core loading pattern; however, there will be occurrences where the number and/or types of bundles in the reference design and the actual core loading do not agree exactly.

Any differences between the reference loading pattern and the actual loading pattern are evaluated as described in Reference 1, Section 3.4.

4.3.2.2 Power Distribution

The core power distribution is a function of fuel bundle design, core loading, control rod pattern, core exposure distributions and core coolant flow rate. The thermal performance parameters, MAPLHGR, MLHGR, and MCPR, defined in Table 4.3-1, limit unacceptable core power distributions.

4.3.2.2.1 Power Distribution Calculations

Core power distributions are calculated based on the reference loading pattern shown in the cycle-specific Supplemental Reload Licensing Report. These calculations confirm that the limits established by the thermal performance parameters are not violated. Appropriate design allowances are included at the design stage to ensure that these limits are met. A full range of calculated power distributions along with the resultant exposure shapes and corresponding control rod patterns are also shown in Reference 2.

4.3.2.2.2 Power Distribution Measurements

The techniques for measurement of the power distribution within the reactor core, together with instrumentation correlations and operating limits, are discussed in Reference 3.

4.3.2.2.3 Power Distribution Accuracy

The accuracy of the calculated power distributions is discussed in References 4 and 5.

4.3.2.2.4 Power Distribution Anomalies

Stringent inspection procedures are utilized to ensure the correct arrangement of the core following fuel loading. A fuel loading error (a mislocated or a misoriented fuel bundle in the core) would be a very improbable event, but calculations have been performed to determine the effects of such events on CPR. The inherent design characteristics of the BWR are well suited to limit gross power tilting. The stabilizing nature of the large moderator void coefficient effectively reduces the effect of perturbations on the power distribution. In addition, the in-core instrumentation system, together with the on-line computer, provides the operator with prompt information on the power distribution so that he can readily use control rods or other means to limit the undesirable effects of power tilting. Because of these design characteristics, it is not necessary to allocate a specific margin in the peaking factor to account for power tilt. If, for some reason, the power distribution could not be maintained within normal limits using control rods and flow, then the total core power would have to be reduced.

4.3.2.3 Reactivity Coefficients

Reactivity coefficients, the differential changes in reactivity produced by differential changes in core conditions, are useful in calculating stability and evaluating the response of the core to external disturbances. The base initial condition of the system and the postulated initiating event determine which of the several defined coefficients are significant in evaluating the response of the reactor. The coefficients of interest, relative to BWR systems, are discussed here individually.

There are two primary reactivity coefficients that characterize the dynamic behavior of BWRs; these are the Doppler reactivity coefficient and the moderator void reactivity coefficient. Also associated with the BWR is a power reactivity coefficient and a temperature coefficient. The power coefficient is a combination of the Doppler and void reactivity coefficients in the power operating range, and the temperature coefficient is merely a combination of the Doppler and moderator temperature coefficients. Power and temperature coefficients are not specifically calculated for reload cores. The Doppler and void coefficients are unique for each core, however their values are not typically reported to the customer by the fuel vendor.

4.3.2.3.1 Doppler Reactivity Coefficient

The Doppler coefficient is of prime importance in reactor safety. The Doppler coefficient is a measure of the reactivity change associated with an increase in the absorption of resonance-energy neutrons caused by a change in the temperature of the material in question. The Doppler reactivity coefficient provides instantaneous negative reactivity feedback to any rise in fuel temperature, on either a gross or local basis. The magnitude of the Doppler coefficient is inherent in the fuel design and does not vary significantly among BWR designs. For most structural and moderator materials, resonance absorption is not significant, but in U-238 and Pu-240 an increase in temperature produces a comparatively large increase in the effective absorption cross-section. The resulting parasitic absorption of neutrons causes a significant loss in reactivity. In BWR fuel, in which approximately 96 percent of the uranium in UO_2 is U-238, the Doppler coefficient provides an immediate negative reactivity response that opposes increased fuel fission rate changes.

Although the reactivity change caused by the Doppler Effect is small compared to other power-related reactivity changes during normal operation, it becomes very important during postulated rapid power excursions in which large fuel temperature changes occur. The most severe power excursions are those associated with rod drop accidents. A local Doppler feedback associated with a 3000°F to 5000°F temperature rise is available for terminating the initial excursion. The Doppler coefficient is determined using the theory and methods described in Reference 6.

4.3.2.3.2 Moderator Void Coefficient

The moderator void coefficient should be large enough to prevent power oscillation due to spatial xenon changes yet small enough that pressurization transients do not unduly limit plant operation. In addition, the void coefficient in a BWR has the ability to flatten the radial power distribution and to provide ease of reactor control due to the void feedback mechanism. The overall void coefficient is always negative over the complete operating range since the BWR design is undermoderated.

A detailed discussion of the methods used to calculate void reactivity coefficients, their accuracy and their application to plant transient analyses is presented in Reference 6.

4.3.2.4 Control Requirements

The General Electric BWR control rod system is designed to provide adequate control of the maximum excess reactivity anticipated during the plant operation. The shutdown capability is evaluated at various temperatures and exposures in a xenon-free core.

4.3.2.4.1 Shutdown Reactivity

The core must be capable of being made subcritical, with margin, in the most reactive condition throughout the operating cycle with the most reactive control rod fully withdrawn and all other rods fully inserted. The shutdown margin is determined by using the BWR simulator code (Section 3.3 of Reference 1) to calculate the core multiplication at selected exposure points with the strongest rod fully withdrawn. The shutdown margin is calculated based on the carryover of the minimum expected exposure at the end of the previous cycle. The core is assumed to be at various temperatures and exposures in a xenon-free condition in order to ensure that the calculated values are conservative. Further discussion of the uncertainty of these calculations is given in References 7 and 8.

As exposure accumulates and burnable poison depletes in the lower exposure fuel bundles, an increase in core reactivity may occur. The nature of this increase depends on specifics of fuel loading and control state.

The cold k_{eff} is calculated with the strongest control rod out at various exposures through the cycle. A value R is defined as the difference between the strongest rod out k_{eff} at beginning of cycle (BOC) and the maximum calculated strongest rod out k_{eff} at any exposure point. The strongest rod out k_{eff} at any exposure point in the cycle is equal to or less than:

$$k_{eff} = k_{eff}\,(\text{Strongest rod withdrawn})_{BOC} + R$$

where

R is always greater than or equal to 0.

The cycle-specific calculated values of k_{eff} with the strongest rod withdrawn at BOC and R are reported in cycle-specific supplemental reload licensing report. For completeness, the uncontrolled k_{eff} and fully controlled k_{eff} values are also reported.

4.3.2.4.2 Reactivity Variations

The excess reactivity designed into the core is controlled by the control rod system supplemented by gadolinia-uranium fuel rods. Control rods are used during the cycle partly to compensate for burnup and partly to control the power distribution.

4.3.2.4.3 Standby Liquid Control System

The Standby Liquid Control System (SLCS) is designed to provide the capability of bringing the reactor, at any time in a cycle, from a full power and minimum control rod inventory (which is defined to be at the peak of the xenon transient) to a subcritical condition with the reactor in the most reactive xenon-free state. The requirements of this system are dependent primarily on the reactor power level and on the reactivity effects of voids and temperature between full power and cold, xenon-free condition. The cycle-specific shutdown capability of the SLCS is given in cycle-specific supplemental reload licensing report.

4.3.2.5 Control Rod Patterns and Reactivity Worths

Control rod patterns are chosen to achieve an exposure distribution approaching the target end-of-cycle exposure shape and a power distribution meeting the thermal limits. Control rod patterns will be altered as necessary to meet these criteria.

4.3.2.6 Criticality of Reactor During Refueling

The core is subcritical at all times.

4.3.2.7 Stability

4.3.2.7.1 Xenon Transients

Boiling water reactors do not have instability problems due to xenon. This has been demonstrated by (1) never having observed xenon instabilities in operating BWRs, (2) special tests which have been conducted on operating BWRs in an attempt to force the reactor into xenon instability, and (3) calculations. All of these indicators have proven that xenon transients are highly damped in a BWR due to the large negative power coefficient (Reference 9).

4.3.2.7.2 Thermal Hydraulic Stability

Information on thermal hydraulic stability is provided in Reference 1, Subsection A.4.3.2.7.2, and is also covered in Subsection 4.4.4.6. Cycle-specific thermal hydraulic stability is covered in cycle-specific supplemental reload licensing report.

4.3.2.8 Vessel Irradiations

4.3.2.8.1 Historical Information

Neutron vessel fluence calculations used for determining the lead factor (the ratio of the surveillance capsule flux to the peak vessel inside surface flux) were carried out using a two-dimensional, discrete ordinate, Sn transport code with general anisotropic scattering. This code was a widely used discrete ordinates code which solved a wide variety of radiation transport problems. Slab, cylinder, and spherical geometries are allowed with various boundary conditions. The fluence calculations incorporate, as an initial starting point, a distributed fission neutron source distribution prepared from core physics data. Anisotropic scattering is considered for all regions. The cross sections are represented by third order Legendre polynomial expansions.

4.3.2.8.2 Measurement Uncertainty Recapture/Thermal Power Optimization Uprate, 24-Month Cycle, and GNF3 New Fuel Introduction Analysis

An RPV fluence evaluation was performed by GE in support of a planned Fermi 2 shift to GNF3 fuel and 24-month operating cycles. Detailed flux calculations were performed for pre-MUR/TPO cycles at the Licensed Thermal Power (LTP) levels corresponding to the respective cycles and for an MUR/TPO core that is representative of future cycles at the target power level of 3486 MWt. The NRC approved GE fluence methodology was used for these flux calculations. In addition, fluence distributions at 52 Effective-Full-Power-Years (EFPY) were evaluated based on calculated LTP and anticipated MUR/TPO flux distributions, in conjunction with the cycle-dependent energy generation data.

The peak fluence for the RPV inner surface used for developing the P-T curves was 9.92×10^{17} n/cm^2. The peak fluence for the girth weld location was calculated based on its elevation between the lower and lower intermediate shell plates, and is also provided in Reference 12. This fluence value was applied to this girth weld and all plates and welds in the lower shell.

The N16 water level instrumentation (WLI) nozzle(s), which are within the beltline region, were also considered in this evaluation. Fluence was determined for the specific location of these nozzles. The peak fluence for the WLI nozzles used for determination of the P-T curves was 3.59×10^{17} n/cm^2.

The fluence determined for the WLI nozzles is based upon operation at 3293 MWt for 3.4 EFPY, 3430 MWt for 16.38 EFPY, and 3486 MWt for 32.22 EFPY.

All vessel components have been evaluated considering MUR/TPO. The basis for all fluence values is contained in Reference 12.

The current NRC approved GE methodology for neutron flux calculations is documented in Reference 13. GE's methodology adheres to the guidance contained in Regulatory Guide 1.190 for neutron flux evaluation.

4.3.3 Analytical Methods

Information on the analytical methods is provided in Section 3.3 of Reference 1, and in Reference 13.

4.3.4 Changes

Information on changes relative to the design is provided in Reference 1, Subsection A.4.3.4.

4.3 NUCLEAR DESIGN

Most of the information in Section 4.3 is provided in the licensing topical report GESTAR II (Reference 1). The design bases and licensing requirements are independent of enrichment.

4.3.1 Design Bases

The design bases are those that are required for the plant to operate, meeting all safety requirements. Safety design bases fall into two categories: (1) the reactivity basis, which prevents an uncontrolled positive reactivity excursion, and (2) the overpower basis, which prevent the core from operating beyond the fuel integrity limits.

4.3.1.1 Reactivity Basis

The nuclear design shall meet the following basis: The core shall be capable of being made subcritical at any time or at any core condition with the highest worth control rod fully withdrawn.

4.3.1.2 Overpower Bases

The Technical Specification limits on minimum critical power ratio (MCPR), maximum linear heat generation rate (MLHGR), and the maximum average planar linear heat generation rate (MAPLHGR) are determined such that the fuel will not exceed required licensing limits during abnormal operational occurrences or accidents.

4.3.2 Description

The BWR core design consists of a light-water moderated reactor, fueled with slightly enriched uranium-dioxide. The use of water as a moderator produces a neutron energy spectrum in which fissions are caused principally by thermal neutrons. At normal operating conditions, the moderator boils, producing a spatially variable distribution of steam voids in the core. The BWR design provides a system for which reactivity is reduced by an increase in the steam void content in the moderator. This void feedback effect is one of the inherent safety features of the BWR system. Any system input which increases reactor power, either in a local or gross sense, produces additional steam voids which reduce reactivity and thereby reduce the power.

4.3.2.1 Nuclear Design Description

The initial fuel loading is composed of three distinct bundle types, each with a unique rod-by-rod enrichment distribution. The bottom and top of each fuel rod in two of these bundle types consists of 6 inches of natural uranium. The third bundle type contains only natural uranium fuel rods. The three unique bundle types are distributed in the initial core based on the principle of minimizing radial power peaking and maximizing core reactivity for the end-of-cycle state. This same strategy is carried into the reload core. A diagram of the cycle-specific reference pattern loading is shown in the cycle-specific supplemental reload licensing report.

TABLE 4.3-1 DEFINITION OF FUEL DESIGN LIMITS

Maximum Linear Heat Generation Rate (MLHGR)

The MLHGR is the maximum linear heat generation rate expressed in kW/ft for the fuel rod with the highest surface heat flux at a given nodal plane in the bundle. The MLHGR operating limit is fuel rod type dependent. The MLHGR can be monitored to assure that all mechanical design requirements will be met.

Maximum Average Planar Linear Heat Generation Rate (MAPLHGR)

The MAPLHGR is the maximum average linear heat generation rate (expressed in kW/ft) in any plane of a fuel bundle allowed by the plant Technical Specifications for that fuel type. This parameter is obtained by averaging the linear heat generation rate over each fuel rod in the plane, and its limiting value is selected such that:

(a) the peak clad temperature during the design basis loss-of-coolant accident will not exceed 2200°F in the plane of interest, and

(b) all fuel design limits specified in Reference 1, Section 2 will be met if the MLHGR is not monitored for that purpose.

Minimum Critical Power Ratio (MCPR)

The critical power ratio is defined as the ratio of the critical power (bundle power at which some point within the assembly experiences onset of boiling transition) to the operating bundle power. The critical power is determined at the same mass flux, inlet temperature, and pressure that exists at the specified reactor condition. Thermal margin is stated in terms of the minimum value of the critical power ratio, MCPR, which corresponds to the most limiting fuel assembly in the core.

Operating Limit MCPR

The MCPR operating limit is the minimum CPR allowed by the plant Technical Specifications for a given bundle type. The minimum CPR is a function of several parameters, the most important of which are bundle power, bundle flow, and bundle R-factor. The R-factor is dependent upon the local power distribution and details of the bundle mechanical design. The limiting value of CPR is selected for each bundle type such that, during the most limiting event of moderate frequency, the calculated CPR in that bundle is not less than the safety limit CPR. The MCPR operating limit is attained when the bundle power, R-factor, flow and other relevant parameters combine to yield the Technical Specification value.

TABLE 4.3-2 FLUENCE DETERMINATION FOR THE PEAK LOCATION IN THE FERMI 2 VESSEL

HISTORICAL DATA (Reference 10)

4.4. THERMAL-HYDRAULIC DESIGN

Most of the information in Section 4.4 is provided in the licensing topical report GESTAR II (Reference 1).

4.4.1. Design Basis

4.4.1.1. Safety Design Bases

Thermal-hydraulic design of the core shall establish the thermal-hydraulic safety limits for use in evaluating the safety margin relating the consequences of fuel cladding failure to public safety.

4.4.1.2. Requirements for Steady-State Conditions

For purposes of maintaining adequate fuel performance margin during normal steady-state operation, the MCPR must not be less than the required MCPR operating limit, the LHGR must be maintained below the required LHGR limit (MLHGR), and the APLHGR must be maintained below the required APLHGR limit (MAPLHGR). The steady-state MCPR, MLHGR, and MAPLHGR limits are determined by analysis of the most severe moderate frequency anticipated operational occurrences (AOOs) to accommodate uncertainties and provide reasonable assurance that no fuel damage results during moderate frequency AOOs at any time in life.

4.4.1.3. Requirements for Anticipated Operational Occurrences (AOOs)

The MCPR, MLHGR, and MAPLHGR limits are established such that no safety limit is expected to be exceeded during the most severe moderate frequency AOO event. The cycle-specific MCPR, MLHGR, and MAPLHGR limits are provided in the Core Operating Limits Report (COLR) and corresponding licensing basis in the cycle-specific supplemental reload licensing report.

4.4.1.4. Summary of Design Bases

In summary, the steady-state operating limits have been established to ensure that the design bases are satisfied for the most severe moderate frequency AOO. Demonstration that the steady-state MCPR, MLHGR, and MAPLHGR limits are not exceeded is sufficient to conclude that the design bases are satisfied.

4.4.2. Description of Thermal-Hydraulic Design of the Reactor Core

4.4.2.1. Summary Comparison

An evaluation of plant performance from a thermal and hydraulic standpoint is provided in Subsection 4.4.3.

A tabulation of thermal and hydraulic parameters of the core is given in Table 4.4-1 along with a comparison of Fermi 2 to others of similar design. Any changes for reload cores are provided in the cycle-specific supplemental reload licensing report.

4.4.2.2. Critical Power Ratio

A description of the critical power ratio and model used to calculate this ratio is provided in Subsection 4.4.4.1. Criteria used to calculate the critical power safety limit are given in Subsection 1.1.5 of Reference 1.

4.4.2.3. Average Planar Linear Heat Generation Rate (APLHGR)

Models used to calculate the APLHGR limit are given in Reference 1, Subsection 4.2.2, as pertaining to the fuel mechanical design limits and as pertaining to 10 CFR 50, Appendix K, limits provided in the Technical Specifications.

4.4.2.4. Void Fraction Distribution

The core average and maximum exit void fractions in the core at rated power conditions are calculated on a cycle-specific basis.

4.4.2.5. Core Coolant Flow Distribution and Orificing Pattern

The flow distribution to the fuel assemblies and bypass flow paths is calculated on the assumption that the pressure drop across all fuel assemblies and bypass flow paths is the same. This assumption has been confirmed by measuring the flow distribution in boiling water reactors (References 2 through 4). The components of bundle pressure drop considered are friction, local, elevation, and acceleration (Subsections 4.4.2.6.1 through 4.4.2.6.4, respectively). Pressure drop measurements made in operating reactors confirm that the total measured core pressure drop and calculated core pressure drop are in good agreement. There is reasonable assurance, therefore, that the calculated flow distribution throughout the core is in close agreement with the actual flow distribution of an operating reactor.

An iteration is performed on flow through each flow path (fuel assemblies and bypass flow paths), which equates the total differential pressure (plenum to plenum) across each path and matches the sum of the flows through each path to the total core flow. The total core flow less the control rod cooling flow enters the lower plenum. A fraction of this passes through various bypass flow paths. The remainder passes through the orifice in the fuel support plate (experiencing a pressure loss) where some of the flow exits through the fit-up between the fuel support and the lower tieplate and through the lower tieplate holes into the bypass flow region. All initial and reload core fuel bundles have lower tieplate holes. The majority of the flow continues through the lower tieplate (experiencing a pressure loss) where some flow exits through the flow path defined by the fuel channel and lower tieplate into the bypass region. This bypass flow is lower for those fuel assemblies with finger springs. The bypass flow paths considered in the analysis and typical values of the fraction of bypass flow through each flow path are given in Reference 5.

Within the fuel assembly, heat balances on the active coolant are performed nodally. Fluid properties are expressed as the bundle average at the particular node of interest and are based on 1967 International Standard Steam-Water Properties. In evaluating fluid properties a constant pressure model is used.

The relative radial and axial power distributions are used with the bundle flow to determine the axial coolant property distribution, which gives sufficient information to calculate the pressure drop components within each fuel assembly type. When the equal pressure drop criterion described above is satisfied, the flow distributions are established.

4.4.2.6. Core Pressure Drop and Hydraulic Loads

The components of bundle pressure drop considered are friction, local, elevation, and acceleration pressure drops. Pressure drop measurements made in operating reactors confirm that the total measured core pressure drop and calculated core pressure drop are in good agreement.

4.4.2.6.1. Friction Pressure Drop

Friction pressure drop is calculated with a basic model as follows:

$$\Delta P_f = \frac{w^2}{2g_c\rho_\ell}\frac{fL}{D_H A_{ch}^2}\phi_{TPF}^2 \qquad (4.4\text{-}1)$$

where

ΔP_f	=	friction pressure drop, psi
w	=	mass flow rate
g_c	=	acceleration of gravity
ρ_ℓ	=	average nodal liquid density
D_H	=	channel hydraulic diameter
A_{ch}	=	channel flow area
L	=	incremental length
f	=	friction factor
ϕ_{TPF}^2	=	two-phase friction multiplier

The formulation for the two-phase multiplier is similar to that presented in References 6 and 7 and is based on data that is taken from prototypical BWR fuel bundles.

4.4.2.6.2. Local Pressure Drop

The local pressure drop is defined as the irreversible pressure loss associated with an area change, such as the orifice, lower tieplate, and spacers of a fuel assembly.

The general local pressure drop model is similar to the friction pressure drop and is

$$\Delta P_L = \frac{w^2}{2g_c\rho_\ell}\frac{K}{A^2}\phi_{TPL}^2 \qquad (4.4\text{-}2)$$

where

ΔP_L = local pressure drop, psi

K = local pressure drop loss coefficient

A = reference area for local loss coefficient

ϕ^2_{TPL} = two-phase local multiplier

and w, g, and ρ_ℓ are defined in Equation 4.4-1. The formulation for the two-phase multiplier is similar to that reported in Reference 7. For advanced spacer designs, a quality modifier has been incorporated in the two-phase multiplier to better fit the data. Empirical constants were added to fit the results to data taken for the specific designs of the BWR fuel assembly. These data were obtained from tests performed in single-phase water to calibrate the orifice, the lower tieplate, and the holes in the lower tieplate, in both single- and two-phase flow to derive the best fit design values for the spacer and upper tieplate pressure drop. The range of test variables was specified to include the range of interest for BWRs. New test data are obtained whenever there is a significant design change to ensure the most applicable methods are used.

4.4.2.6.3. Elevation Pressure Drop

The elevation pressure drop is based on the relation:

$$\Delta P_E = \bar{\rho}\Delta L; \qquad (4.4\text{-}3)$$

$$\bar{\rho} = \rho_f(1-\alpha) + \rho_g\alpha$$

where

ΔP_E = elevation pressure drop, psi

ΔL = incremental length

$\bar{\rho}$ = average water density

α = nodal average void fraction

ρ_f, ρ_g = saturated water and vapor density, respectively

The void fraction model used is an extension of the Zuber-Findlay model (Reference 8), and uses an empirically fit constant to predict a large block of steam void fraction data. Checks against new data are made on a continuing basis to ensure the best models are used over the full range of interest of Boiling Water Reactors.

4.4.2.6.4. Acceleration Pressure Drop

A reversible pressure change occurs when an area change is encountered, and an irreversible loss occurs when the fluid is accelerated through the boiling process. The basic formulation for the reversible pressure change resulting from a flow area change in the case of single-phase flow is given by:

$$\Delta P_{ACC} = (1-\sigma_A^2)\frac{W^2}{2g_c\rho_\ell A_2^2} \qquad (4.4\text{-}4)$$

$$\sigma_A = \frac{A_2}{A_1} = \frac{\text{final flow area}}{\text{initial flow area}}$$

where

ΔP_{ACC} = acceleration pressure drop

A_2 = final flow area

A_1 = initial flow area

In the case of two-phase flow, the liquid density is replaced by a density ratio so that the reversible pressure change is given by:

$$\Delta P_{ACC} = (1 - \sigma_A^2)\frac{W^2 \rho_H}{2g_c \rho_{KE}^2 A_2^2} \quad (4.4\text{-}5)$$

where:

$$\frac{1}{\rho_H} = \frac{x}{\rho_g} + \frac{(1-x)}{\rho_\ell}$$, homogeneous density

$$\frac{1}{\rho_{KE}^2} = \frac{x^3}{\rho_g^2 \alpha^2} + \frac{(1-x)^3}{\rho_\ell^2 (1-\alpha)^2}$$, kinetic energy density

where:

α = void fraction at A_2

x = steam quality at A_2

and other terms are as previously defined. The basic formulation for the acceleration pressure change due to density change is:

$$\Delta P_{acc} = \frac{w^2}{gA_{ch}^2}\left[\left(\frac{1}{\rho_{M_{OUT}}}\right) - \left(\frac{1}{\rho_{M_{IN}}}\right)\right] \quad (4.4\text{-}6)$$

where

$$\frac{1}{\rho_{M_{OUT}}} = \frac{x_{OUT}^2}{\rho_g \alpha_{OUT}} + \frac{(1-x_{OUT})^2}{\rho_\ell (1-\alpha_{OUT})}$$

$$\frac{1}{\rho_{M_{IN}}} = \frac{x_{IN}^2}{\rho_g \alpha_{IN}} + \frac{(1-x_{IN})^2}{\rho_\ell (1-\alpha_{IN})}$$

and is evaluated at the inlet and outlet of each axial node. Other terms are as previously defined. The total acceleration pressure drop in Boiling Water Reactors is on the order of a few percent of the total pressure drop.

4.4.2.7. Correlation and Physical Data

General Electric Company has obtained substantial amounts of physical data in support of the pressure drop and thermal-hydraulic loads discussed in Subsection 4.4.2.6. Correlations have been developed to fit these data to the formulations discussed.

4.4.2.7.1. Pressure Drop Correlations

General Electric Company has taken significant amounts of friction pressure drop data in multi-rod geometries representative of BWR plant fuel bundles and correlated both the friction factor and two-phase multipliers on a best fit basis using the pressure drop formulations reported in Subsections 4.4.2.6.1 and 4.4.2.6.3. Tests are performed in single-phase water to calibrate the orifice and the lower tieplate, and in both single- and two-phase flow to arrive at best-fit design values for spacer and upper tieplate pressure drop. The range of test variables is specified to include the range of interest to BWRs. New data are taken whenever there is a significant design change to ensure the most applicable methods are in use at all times.

Applicability of the single-phase and two-phase hydraulic models discussed in Subsections 4.4.2.6.1 and 4.4.2.6.3 was confirmed by prototype flow tests. The typical range of the test data is summarized in Table 4.4-2.

4.4.2.7.2. Void Fraction Correlation

The void fraction correlation includes effects of pressure, flow direction, mass velocity, quality, and subcooled boiling.

4.4.2.7.3. Heat Transfer Correlation

The Jens-Lottes (Reference 9) heat transfer correlation is used in fuel design to determine the cladding-to-coolant heat transfer coefficients for nucleate boiling.

4.4.2.8. Thermal Effects of Anticipated Operational Occurrences

The evaluation of the core's capability to withstand the thermal effects resulting from anticipated operational occurrences (AOOs) is covered in Chapter 15 (Accident Analysis) and the cycle-specific reload analysis.

4.4.2.9. Uncertainties in Estimates

Uncertainties in thermal-hydraulic parameters are considered in the statistical analysis which is performed to establish the fuel cladding integrity safety limit documented in Subsection 4.4.4.1.1. The uncertainties considered and their input values for the analysis are shown in Table 4.4-3 and Reference 38.

4.4.2.10. Flux Tilt Considerations

For flux tilt considerations, refer to Subsection 4.3.2.2.

4.4.3. Description of the Thermal and Hydraulic Design of the Reactor Coolant System

4.4.3.1. Plant Configuration Data

4.4.3.1.1. Reactor Coolant System Configuration

The reactor coolant system is described in Section 5.1 and shown in isometric perspective in Figure 5.5-1. The piping sizes, fittings, and valves are listed in Table 5.5-1.

4.4.3.1.2. Reactor Coolant System Thermal-Hydraulic Data

The steady-state distribution of temperature, pressure, and flow rate for each flow path in the reactor coolant system is shown in Figure 5.1-1a and 5.1-1b.

4.4.3.1.3. Reactor Coolant System Geometric Data

Volumes of regions and components within the reactor vessel are shown in Figure 5.1-2.

Table 4.4-4 provides the flow path length, height, liquid level, minimum elevations, and minimum flow areas for each major flow path volume within the reactor vessel and for the recirculation loops of the reactor coolant systems.

Table 4.4-5 provides the lengths and sizes of all safety injection lines to the reactor coolant system.

4.4.3.2. Operating Restrictions on Pumps

Expected recirculation pump performance curves are shown in Figures 4.4-1 and 4.4-2. These curves are valid for all conditions with a normal operating range varying from approximately 20 percent to 115 percent of rated pump flow.

The pump characteristics, including considerations of net positive suction head (NPSH) requirements, are the same for the conditions of a two-pump and one-pump operation as described in Subsection 5.5.1. Subsection 4.4.3.3 gives the operating limits imposed on the recirculation pumps by cavitation, pump loads, bearing design flow starvation, and pump speed.

4.4.3.3. Power-Flow Operating Map

4.4.3.3.1. Limits for Normal Operation

A BWR must operate with certain restrictions because of pump NPSH, overall plant control characteristics, and core thermal power limits. A typical power-flow map for the power range of operation is shown in Figure 4.4-3. The nuclear system equipment, nuclear instrumentation, and the reactor protection system (RPS), in conjunction with operating procedures, maintain operations within the area of this map for normal operating conditions. The boundaries on this map are as follows:

a. Natural circulation line, A: The power-versus-flow operating state of the reactor moves along this line for the normal control rod withdrawal sequence in the absence of recirculation pump operation.

b. Recirculation pump minimum speed line, B: The minimum speed of the recirculation pumps is 20 percent as established by the mechanical stops.

Startup operations of the plant are normally carried out with the recirculation pumps operating at approximately 30 percent speed. The power-versus-flow operating state for the reactor follows the 30 percent speed line for the normal control rod withdrawal sequence.

c. APRM rod block line and APRM scram lines: The APRM rod block line represents a power level above which rod blocks will be encountered if the control rods are manipulated. This line is defined by the equation: Power = 0.62w + 57.4 percent, with a maximum of 110 percent, where w is the loop recirculation flow as a percentage of the loop recirculation flow which produces a rated core flow of 100 million lb/hr at 100 percent of rated thermal power. The APRM scram line represents a power level above which a reactor scram will occur. This line is defined by the equation: Power = 0.62w + 63.1 percent, with a maximum of 115.5 percent. The APRM rod block line is intentionally kept below the APRM scram line to prevent rod withdrawal before it causes a reactor scram.

d. Cavitation protection line: This line (minimum power line) results from the recirculation pump and jet pump NPSH requirements. The recirculation pumps are automatically switched to 30 percent speed when the feedwater flow drops below a preset value.

e. Maximum extended load line limit (MELLL) and increased core flow (ICF) lines: The MELLL line is above the 100 percent rod line and represents a region hereafter referred to as the MELLL region (References 9a, 9b, and 9c). The MELLL region allows rated power operation down to 83 percent of rated core flow. Below 83 percent of rated core flow, the boundary of the analyzed operating region is defined by an analytical approximation of the rod line which passes through the rated power and 83 percent core flow point.

   The ICF region allows rated power operation with core flows up to 105 percent of rated. Below 100% power, 105% core flow is held constant at 105% until power is 3430 MWth. Then the ICF boundary is expanded to allow for constant pump speed operation corresponding to 105 percent core flow at 3430 MWth. This expands the allowable operating map to 114 percent rated core flow at 36.0 percent rated power at which the expected recirculation pump cavitation region is encountered.

4.4.3.3.2. Performance Characteristics

Other performance characteristics shown on the power/flow operating map are

a. Recirculation pump constant speed line, C or D: These lines show the change in flow associated with power changes while maintaining constant recirculation pump speed

b. Constant rod lines: These lines show the change in power associated with flow changes while maintaining constant control rod position (for example, 50 percent rod density pattern line).

4.4.3.3.3. Regions of the Power/Flow Map

For normal operating conditions, the nuclear system equipment, nuclear instrumentation, and the RPS, in conjunction with operating procedures, maintain operation outside the exclusion areas of the power/flow map. The main regions of the power/flow map are discussed below to clarify operational capabilities.

a. Region I: This is the transition region between natural circulation operation and 20 percent pump speed operation. Steady-state conditions cannot exist in this area because the recirculation pumps cannot be operated below 20 percent speed. Normal startup is along the 30 percent pump speed line near this region

b. Region II: This region (including the increased core flow or ICF region) represents the normal operating zone of the power/flow map where power changes can be made, either by control rod movement or by core flow changes, achieved by changing recirculation pump drive speed. (The Technical Specifications contain limitations on operating in certain areas of Region II)

c. Region III: This is the low power area of the map where cavitation can be expected in the recirculation pumps and in the jet pumps. Operation within this region is precluded by system interlocks that set the recircula-tion pumps to 30 percent speed whenever feedwater flow is less than a preset value (typically 20 percent of rated flow).

4.4.3.4. Temperature-Power Operating Map (PWR)

Not applicable.

4.4.3.5. Load-Following Characteristics

The following simple description of BWR operation with recirculation flow control summarizes the principal modes of normal power range operation. Assuming the plant to be initially hot with the reactor critical, full power operation can be approached following the sequence shown as Points 1 to 6 in Figure 4.4-3. The first part of the sequence (1 to 3) is achieved with control rod withdrawal and manual, individual recirculation pump control. Individual pump startup procedures are provided that achieve 30 percent of full pump speed in each loop. Power, steam flow, and feedwater flow are increased as control rods are manually withdrawn until the feedwater flow has reached approximately 20 percent. An interlock prevents low-power/high-recirculation flow combinations that create recirculation pump and jet pump cavitation problems.

Reactor power increases as the operating state moves from Point 2 to Point 3 due to the inherent flow control characteristics of the BWR. Once the feedwater interlock is cleared, the operator can manually increase recirculation flow in each loop until the operating state reaches Point 3, the lower limit of the flow control range. At Point 3, the operator can switch to simultaneous recirculation pump control. Thermal output can then be increased by either control rod withdrawal or recirculation flow increase. For example, the operator can increase power in the ways indicated by Points 3a or 5c. With a slight rod withdrawal and an increase of recirculation flow to 90 percent rated flow, Point 3a can be achieved. If, however, it is desired to maintain the lowest recirculation flow, power can be increased by withdrawing control rods until Point 5c is reached. The recirculation system individual loop controllers are limited, and these limits established the operating state (refer to Section 7.7). The operating map is shown in Figure 4.4-3 with the designated flow control range expected.

The curve labeled "MELLL line" represents a typical steady-state power flow characteristic for a fixed rod pattern. It is slightly affected by xenon, core leakage flow assumptions, and reactor vessel pressure variations. However, for this example, these effects have been neglected.

Normal power range operation is along or below the MELLL and ICF line. If load-following response is desired in either direction, plant operation near 90 percent power provides most capability. If maximum load-pickup capability is desired, the nuclear system can be operated near Point 5c, with fast load response available all the way up to Point 6a, rated power.

The large negative operating reactivity and power coefficients that are inherent in the BWR provide important advantages as follows:

a. Good load following with well-damped behavior and little undershoot or overshoot in the heat transfer response

b. Load following with recirculation flow control

c. Strong damping of spatial power disturbances.

Design of the single-cycle BWR plant includes the ability to follow load demand over a reasonable range. This load-following capability is accomplished, under operator control, by variation of reactor recirculation flow. The reactor power level can be controlled by flow over approximately 35 percent power when on the 100% rod line.

To increase reactor power, it is necessary to increase the recirculation flow rate, which sweeps some of the voids from the moderator, causing an increase in core reactivity. As the reactor power increases, more steam is formed and the reactor stabilizes at a new power level with the transient excess reactivity balanced by the new void formation. No control rods are moved to accomplish this power level change. Conversely, when a power reduction is required, it is necessary only to reduce the recirculation flow rate. When this is done, more voids in the moderator automatically decrease the reactor power level to be commensurate with the new recirculation flow rate. Again, no control rods are moved to accomplish the power reduction.

Varying the recirculation flow rate (flow control) is more advantageous, relative to load following, than using control rod positioning. Flow variations perturb the reactor uniformly in the horizontal planes and ensure a flatter power distribution and reduced transient allowances. As flow is varied, the power and void distributions remain approximately constant at the steady-state end points for a wide range of flow variations. After adjusting the power distribution by positioning the control rods at a reduced power and flow, the operator can then bring the reactor to rated conditions by increasing flow, with the assurance that the power distribution will remain approximately constant. Section 7.7 describes how recirculation flow is varied.

4.4.3.6. Thermal and Hydraulic Characteristics Summary Table

The thermal-hydraulic characteristics are provided in Table 4.4-1 for the core and tables of Section 5.5 for other portions of the reactor coolant system.

4.4.4. Evaluation

The thermal-hydraulic design of the reactor core and reactor coolant system is based upon an objective of no fuel damage during normal operation or during anticipated operational occurrences. This design objective is demonstrated by analysis as described in the following sections.

4.4.4.1. Critical Power

The objective for normal operation and AOOs is to maintain nucleate boiling and thus avoid a transition to film boiling. Operating limits are specified to maintain adequate margin to the onset of the boiling transition. The figure of merit utilized for plant operation is the critical power ratio. This is defined as the ratio of the critical power (bundle power at which some point within the assembly experiences onset of boiling transition) to the operating bundle power. The critical power is determined at the same mass flux, inlet temperature, and pressure which exists at the specified reactor condition. Thermal margin is stated in terms of the minimum value of the critical power ratio, MCPR, which corresponds to the most limiting fuel assembly in the core. To ensure that adequate margin is maintained, a design requirement based on a statistical analysis was selected as follows:

> Moderate frequency AOOs caused by a single operator error or equipment malfunction shall be limited such that, considering uncertainties in manufacturing and monitoring the core operating state, more than 99.9 percent of the fuel rods would be expected to avoid boiling transition (Reference 10).

Both the transient (safety) and normal operating thermal limits in terms of MCPR are derived from this basis. A discussion of these limits follows.

4.4.4.1.1. Fuel Cladding Integrity Safety Limit

The generation of the Minimum Critical Power Ratio (MCPR) limit requires a statistical analysis of the core near the limiting MCPR condition. The statistical analysis is used to determine the MCPR corresponding to the transient design requirement given in Reference 1. The MCPR fuel cladding integrity safety limit applies not only for core wide AOOs, but is also applied to the localized rod withdrawal error AOO.

4.4.4.1.1.1. Statistical Model

The statistical analysis utilizes a model of the BWR core which simulates the plant process variables and the 3D-Monicore PANACEA core modeling function. This code produces a critical power ratio (CPR) map of the core based on inputs of power distribution, flow, and heat balance information. Details of the procedure are documented in Appendix IV of Reference 10 and Section 4 of Reference 38. Random Monte Carlo selections of all operating parameters based on the uncertainty ranges of manufacturing tolerances, uncertainties in measurement of core operating parameters, calculational uncertainties, and statistical uncertainty associated with the critical power correlations (References 11 through 13) are imposed upon the analytical representation of the core and the resulting bundle critical power ratios are calculated. Applications of critical power correlation uncertainties to critical power ratio calculations are presented in References 10, 14, 15, 38, 39 and 40.

The minimum allowable critical power ratio is set to correspond to the criterion that 99.9 percent of the rods are expected to avoid boiling transition by interpolation among the means of the distributions formed by all the trials.

4.4.4.1.1.2. Bounding BWR Statistical Analysis

Statistical analyses are performed for each operating cycle that provides the fuel cladding integrity safety limit MCPR. The analyses are performed for the specific core loading and the specific bundle design to be used in the given cycle. Core radial power distributions are selected to reasonably bound the number of bundles at or near thermal limits. The assumed local fuel pin power distribution is based on the specific bundle design. The analyses are performed for multiple exposure points throughout the cycle. Typically the most limiting value is applied over the entire cycle, but exposure-dependent values are technically correct and may be applied if necessary.

Uncertainties used in the analyses are listed in Table 4.4-3, including the uncertainty associated with the appropriate critical power correlation. The critical power correlation uncertainty used in the Safety Limit MCPR determination is that uncertainty associated with the operating regions that can be obtained during normal operation or during Anticipated Operational Occurrences (AOO).

The results of the analyses show that at least 99.9 percent of the fuel rods in the core are expected to avoid boiling transition if the MCPR is equal to or greater than the applicable value listed in the Core Operating Limits Report. Therefore, based on the results of the statistical analysis, the fuel cladding integrity safety limit is an MCPR equal to the values presented in the Core Operating Limits Report.

4.4.4.1.2. MCPR Operating Limit Calculational Procedure

A plant-unique MCPR operating limit is established to provide adequate assurance that the cycle specific fuel cladding integrity safety limit for that plant is not exceeded for any moderate frequency AOO. This operating requirement is obtained by addition of the maximum ΔCPR value for the most limiting AOO (including any imposed adjustment factors) from conditions postulated to occur at the plant to the cycle specific fuel cladding integrity safety limit.

4.4.4.1.2.1. Calculational Procedure for AOO Pressurization Events

Core-wide rapid pressurization events (turbine trip w/o bypass, load rejection w/o bypass, feedwater controller failure, and pressure regulator failure-closed with backup pressure regulator out of service) are analyzed using TRACG which has been approved for application to AOO transients. TRACG uses a multi-dimensional two-fluid model and a three-dimensional kinetics model consistent with the GEMINI method. The application of

TRACG is described in References 45 and 46. The set of methods used (GENESIS, GEMINI or TRACG) will be identified in the supplemental reload licensing report; however, application of a different approved method set may be used subsequently for the same cycle.

4.4.4.1.2.2. Calculational Procedure for AOO Slow Events

The slower core-wide anticipated operational occurrence, loss of feedwater heating, is analyzed using either the steady-state 3-D BWR Simulator Code (Reference 18 for GENESIS methods or Reference 21 for GEMINI methods), or the ODYN transient model as described in Reference 1. Inadvertent HPCI startup is not analyzed when its enthalpy is bounded by that of the loss of feedwater heating event (Reference 37). When necessary, it is analyzed using the ODYN transient model.

4.4.4.1.2.3. Rod Withdrawal Error Calculational Procedure

The reactor core behavior during the rod withdrawal error transient is calculated by doing a series of steady-state three-dimensional coupled nuclear-thermal-hydraulic calculations using the 3-D BWR Simulator (Reference 18 for GENESIS methods or Reference 21 for GEMINI methods).

4.4.4.1.2.4. Event Descriptions

Descriptions of the limiting AOO events are given in Chapter 15 for the cycle-specific reload analysis. The AOO descriptions given are used as a basis for the typical analyses performed. Some plant-unique analyses will differ in certain aspects from the typical calculational procedure. These differences arise because of utility-selected margin improvement options.

4.4.4.1.2.5. MCPR Operating Limit Calculation

The operating limit MCPR for rapid AOOs is calculated by using the GESAM computer program (Reference 45). Cycle-dependent plant initial conditions for the MCPR operating limit analysis and the resulting parameters are given in the cycle-specific supplemental reload licensing report.

4.4.4.1.2.6. MCPR Uncertainty Considerations

The deterministic ΔCPR value which results from ODYN/TASC or TRACG evaluations (for all rapid pressurization AOOs) must be adjusted such that a 95/95 ΔCPR/ICPR licensing basis is calculated (i.e., 95 percent probability with 95 percent confidence that the safety limit will not be violated). The NRC Safety Evaluation Report which describes these requirements and procedures is given in Reference 29.

Fermi 2 has the choice of operating under either Option A or Option B.

Option A Operating under Option A with the GENESIS set of methods, an NRC-imposed factor of 1.044 is applied to the MCPR for each event to account for code uncertainties. With the GEMINI set of methods, the MCPR for each event is determined using statistically evaluated scram times. Plants that do not demonstrate compliance with the statistically evaluated scram times must operate using a higher limit that does not take credit for these scram times. The higher limit will also be referred to as Option A. Details are provided in Reference 29.

Option B Under Option B, the ΔCPR/ICPR ratio for the pressurization events is evaluated on either a plant-unique or generic statistical basis per the methodology and procedures of References 29 and 30 for GENESIS, and Reference 31 for GEMINI. The generic basis utilizes adjustment factors which are dependent on plant and event type. Reference 29 summarizes these factors for the GENESIS set of methods. For the GEMINI set of methods, the adjustment factors and their application are described in Reference 31. Since both the GENESIS and GEMINI adjustment factors take credit for conservatism in the scram speed assumed for the transient analyses, each plant operating under Option B must demonstrate that its actual scram speeds are within the distribution assumed in the derivation of the adjustment factors. This conformance procedure is described in Reference 29.

The cycle-specific adjusted MCPR values for all rapid pressurization events are given in the cycle-specific supplemental reload licensing report.

If the ΔCPR is calculated by TRACG (References 45 and 46), the ΔCPR and the OLMCPR are calculated such that less than 0.1% of the fuel rods will be subject to boiling transition during the transient.

4.4.4.1.2.7. Low Flow and Low Power Effects on MCPR

The operating limit MCPR must be increased for low flow because, in the BWR, power increases as core flow increases, which results in a corresponding lower MCPR. If the MCPR at a reduced flow condition were at the 100 percent power and flow MCPR operating limit, a sufficiently large inadvertent flow increase could cause the MCPR to decrease below the fuel cladding integrity safety limit MCPR.

The plant is licensed for the average power range monitor (APRM), rod block monitor (RBM), Technical Specification improvement program (ARTS), and has both power and flow dependent limits imposed on the operating limit MCPR (OLMCPR) (References 9a and 9b). The flow dependent OLMCPR, $MCPR_f$, is defined as a function of the core flow rate. The plant specific $MCPR_f$ is shown in the Core Operating Limits Report (COLR). The power dependent OLMCPR, $MCPR_p$, is determined from the product of the OLMCPR at 100 percent power [OLMCPR (100)] with a power dependent term, k_p. For power between 25 percent rated and 29.5 percent rated (bypass for turbine stop valve and control valve fast closure scram signal) there are two values for $MCPR_p$, one for core flows > 50 percent rated and the other for core flows ≤ 50 percent rated, as shown in COLR. Once the power exceeds 29.5 percent, the $MCPR_p$ is determined from a single curve of k_p which must be multiplied by [OLMCPR (100)] to produce the reduced power OLMCPR, $MCPR_p$. The OLMCPR to be used is the most limiting value of either $MCPR_p$ or $MCPR_f$.

4.4.4.1.2.8. End-of-Cycle Coastdown Considerations

AOO analyses are performed at the full power, end-of-cycle (EOC), all-rods-out condition. Once an individual plant reaches this condition, it may shutdown for refueling or it may be placed in a coastdown mode of operation. In this type of operation the control rods are held in the all-rods-out position and the plant is allowed to coastdown to a lower percent of rated power while maintaining rated increased core flow. The power profile during this period is assumed to be a linear function with respect to exposure. It is expected that the actual profile will be a slow, exponential curve. An analysis to the linear approximation, however, will be conservative, since it overpredicts the power level for any given exposure.

In Reference 32, evaluations were made at 90 percent, 80 percent, and 70 percent power level points on the linear curve. The results show that the pressure and MCPR from the limiting pressurization AOO exhibit a larger margin for each of these points than the EOC full power, full flow case. MLHGR limits for the full power, rated increased core flow case are conservative for the coastdown period, since the power will be decreasing and rated increased core flow will be maintained. Therefore, it can be concluded that the coastdown operation beyond full power operation is conservatively bounded by the analysis at the EOC conditions. In Reference 33, this conclusion is confirmed for coastdown operation down to 40 percent power and is shown to hold for analyses performed with ODYN. In Reference 1, the conclusion of coastdown to 40 percent power also holds for analyses performed with TRACG.

4.4.4.2. Core Hydraulics

Core hydraulics models and correlations are discussed in Subsection 4.4.2.

4.4.4.3. Influence of Power Distributions

The influence of power distributions on the thermal-hydraulic design is discussed in Reference 10.

4.4.4.4. Core Thermal Response

The thermal response of the core for accidents and expected AOO conditions is given in Chapter 15 and cycle specific reload analysis.

4.4.4.5. Analytical Methods

The analytical methods, thermodynamic data, and hydrodynamic data used in determining the thermal and hydraulic characteristics of the core are documented in Subsection 4.4.4.1.2.

4.4.4.6. Thermal-Hydraulic Stability Analysis

4.4.4.6.1. Introduction

There are many definitions of stability, but for feedback processes and control systems it can be defined as follows: A system is stable if, following a disturbance, the transient settles to a steady, noncyclic state.

A system may also be acceptably safe even if it oscillates, provided that any limit cycle of the oscillations is less than a prescribed magnitude. Instability, then, is either a continual departure from a final steady-state value or a greater-than-prescribed limit cycle about the final steady-state value.

The mechanism for instability can be explained in terms of frequency response. Consider a sinusoidal input to a feedback control system which, for the moment, has the feedback disconnected. If there were no time lags or delays between input and output, the output would be in phase with the input. Connecting the output to subtract from the input (negative feedback or 180° out-of-phase connection) would result in stable closed-loop operation. However, natural laws can cause phase shift between output and input, and should the phase shift reach 180° the feedback signal would reinforce the input signal rather than subtract from it. If the feedback signal were equal to or larger than the input signal (loop gain equal to one or greater), the input signal could be disconnected and the system would continue to oscillate. If the feedback signal were less than the input signal (loop gains less than one), the oscillations would die out.

It is possible for an unstable process to be stabilized by adding a control system. In general, however, it is preferable that a process with inherent feedback be designed to be stable by itself before it is combined with other processes and control systems. The design of the BWR is based on the premise that individual system components are stable under expected operating conditions.

4.4.4.6.2. <u>Description</u>

Three types of stability considered in the design of BWRs are

a. Reactor core (reactivity) stability

b. Channel hydrodynamic stability

c. Total system stability.

Reactivity feedback instability of the reactor core could drive the reactor into power oscillations. Hydrodynamic channel instability could impede heat transfer to the moderator and drive the reactor into power oscillations. The total system stability considers control system dynamics combined with basic process dynamics. A stable system is analytically demonstrated if no inherent limit cycle or divergent oscillation develops within the system as a result of calculated step disturbances of any critical variable, such as steam flow, pressure, neutron flux, and recirculation flow.

The criteria to be considered are stated in terms of two compatible parameters. The first parameter is the decay ratio x_2/x_o, designated as the ratio of the magnitude of the second overshoot to the first overshoot resulting from a step perturbation. A plot of the decay ratio is a graphic representation of the physical responsiveness of the system which is readily evaluated in a time-domain analysis. The second parameter is the damping coefficient ζ_n, the definition of which corresponds to the pole pair closest to the j_ω axis in the s-plane for the system closed-loop transfer function. This parameter also applies to the frequency domain interpretation. The damping coefficient is related to the decay ratio as shown in Figure 4.4-4.

4.4.4.6.3. Stability Criteria

General Design Criterion 12 of 10 CFR 50, Appendix A, states that the reactor core and associated coolant, control, and protection systems shall be designed to assure power oscillations which can result in conditions exceeding specified acceptable fuel design limits are not possible or can be reliably and readily detected and suppressed.

The assurance that the total plant is stable, is demonstrated analytically when the decay ratio, x_2/x_o, is less than 1.0, or equivalently, when the damping coefficient, ζ_n, is greater than zero for each type of stability discussed. It is necessary to differentiate between stability related limit cycles and small, acceptable cyclic behavior that is always present, even in the most stable reactors. Acceptable cyclic behavior is caused by physical nonlinearities (deadband and striction) in real control systems and is not representative of inherent hydrodynamic or reactivity instabilities in the reactor. The ultimate performance limit criteria for the three types of dynamic performance are summarized below in terms of decay ratio and damping coefficient

a. Channel hydrodynamic stability: x_2/x_o less than 1, ζ_n greater than 0

b. Reactor core (reactivity) stability: x_2/x_o less than 1, ζ_n greater than 0

c. Total system stability: x_2/x_o less than 1, ζ_n greater than 0

To assure stable operation, these criteria should be satisfied for all attainable conditions of the reactor that may be encountered in the course of plant operation. For stability purposes, the most severe condition to which these criteria will be applied corresponds to the highest attainable rod-line intersection with natural circulation flow.

Under certain operating conditions, power oscillations induced by thermal-hydraulic instability have been observed in other BWR facilities. If power and flow oscillations become large enough, the MCPR Safety Limit could be challenged. Fermi 2 has implemented the BWROG Long Term Stability Solution Option III. An Oscillation Power Range Monitor (OPRM) Upscale Function is incorporated into each APRM channel to reliably and readily detect power oscillation which could result from thermal-hydraulic instability in the operating ranges where such instability has been determined to be credible. The OPRM Upscale Function generates a trip signal to RPS upon detection of power oscillations, which causes an automatic scram to suppress the oscillation while it is still small. This automatic detection and suppression methodology provides protection against violation of the MCPR Safety Limit for power oscillations. The OPRM Upscale Function is described in References 34 – 37.

4.4.4.6.4. Conclusion

Stability-based MCPR Operating Limits are calculated for each operating cycle. These calculated values validate the selected OPRM setpoints for a given core configuration. Thus, the core design, combined with hardware, software, and selected system setpoints for detection and suppression of thermal-hydraulic power oscillations conform to the requirements of General Design Criterion 12 of 10 CFR 20, Appendix A.

4.4.5. Testing and Verification

The testing and verification techniques used to ensure that the planned thermal and hydraulic design characteristics of the core have been provided, and will remain within required limits throughout core lifetime, are discussed in Chapter 14. A summary follows.

a. Preoperational testing: Tests are performed during the preoperational test program to confirm that construction is complete and that all process and safety equipment is operational. Baseline data are taken to assist in the evaluation of subsequent tests. Heat balance instrumentation, jet pump flow, and core temperature instrumentation are calibrated, and set-points are verified

b. Initial startup: Core performance (for example, peaking factors and LHGR) is evaluated periodically when the reactor is operating at greater than 25 percent power to verify the core expected and actual performance margins and to ensure that the reactor is operating within allowable limits.

4.4.6. Instrumentation Requirements

4.4.6.1. Operating Parameters

The reactor vessel instrumentation monitors the key reactor vessel operating parameters during planned operations. This ensures sufficient control of the parameters. The following reactor vessel sensors are discussed in Subsections 7.6.1.2 and 7.6.1.13:

a. Reactor vessel temperature

b. Reactor vessel water level

c. Reactor vessel coolant flow rates and differential pressures

d. Reactor vessel internal pressure

e. Neutron monitoring system.

4.4.6.2. Loose Parts Monitoring System

System has been abandoned.

[a] Reynolds Number.

TABLE 4.4-3 UNCERTAINTIES USED IN STATISTICAL ANALYSIS

Quality	Comment
Feedwater Flow	This is the largest component of total reactor power uncertainty.
Feedwater Temperature	These are the other significant parameters in core power determination.
Reactor Pressure	
Core Inlet Temperature	Affected quality annular flow length and boiling length.
Core Total Flow	Flow is not measured directly, but is calculated from jet pump ΔP[a].
Channel Flow Area	This accounts for manufacturing and service induced variations in the free flow area within the channel.
Friction Factor Multiplier	Accounts for uncertainty in the correlation representing two-phase pressure losses.
Channel Friction Factor Multiplier	Represents variation in the pressure loss characteristics of individual channels. Pressure loss variations affect the core flow distribution, influencing the mass flux.
TIP Readings Random Uncertainty	[b]
R Factor	This is a function of the uncertainty in local fuel rod power.

[a] This uncertainty is higher for single recirculation pump.
[b] For single recirculation pump, this uncertainty is higher.

Note:
Values for the uncertainties used in SLMCPR calculations are found in NEDC-32601P-A (Reference 38)

TABLE 4.4-4 REACTOR COOLANT SYSTEM GEOMETRIC DATA

	Flow Path Length (in.)	Height and Liquid Level (in.)	Elevation of Bottom of Each Volume[a] (in.)	Minimum Flow Area (ft.^{2})
A. Lower plenum	216.5	216.5 216.5	-161.5	92.5
B. Core	163.0	163.0 163.0	55.0	152.0
C. Upper plenum and separators	185.0	185.0 185.0	217.5	45.0
D Dome (above normal water level)	299.5	299.5 0	402.5	352.0
E. Downcomer area	311.0	311.0 311.0	-30.0	118.0
F. Recirculation loops and jet pumps (one loop)	97.0 ft	492.0 492.0	-472.5	0.538

[a] Reference point is recirculation outlet nozzle centerline.

4.5 REACTOR MECHANICAL DESIGN

4.5.1 Reactor Core Support Structures and Internals Mechanical Design

4.5.1.1 Design Bases

4.5.1.1.1 General Design Bases

4.5.1.1.1.1 Safety Design Bases

The reactor core support structures and internals meet the following safety design bases:

a. They are arranged to provide a floodable volume in which the core can be adequately cooled in the event of a breach in the nuclear system process barrier external to the reactor pressure vessel (RPV)

b. Deformation is limited to ensure that the control rods and core standby cooling systems can perform their safety functions

c. Mechanical design of applicable structures ensures that safety design bases items a. and b. are satisfied so that the safe shutdown of the plant and removal of decay heat are not impaired.

4.5.1.1.1.2 Power Generation Design Bases

The reactor core support structures and internals shall be designed in accordance with the following power generation design bases.

a. They provide the proper coolant distribution during all anticipated normal operating conditions to allow power operation of the core without fuel damage

b. They are arranged to facilitate refueling operations

c. They are designed to facilitate inspection.

4.5.1.1.2 Specific Design Characteristics

4.5.1.1.2.1 Design Loading Combinations

The design loading combinations of the RPV internals are covered in Subsection 4.5.1.3.1.1.

4.5.1.1.2.2 Stress, Deformation, and Fatigue Limits for Reactor Internals (Except Core Support Structures)

The stress, deformation, and fatigue criteria listed in Tables 4.5-1 through 4.5-4 are used or the criteria shall be based on the criteria established in applicable codes and standards for similar equipment, by manufacturers' standards, or by empirical methods based on field experience and testing. For the quantity SF_{min} (minimum safety factor) appearing in those tables, the following listed values shall be used.

Design Condition	SF_{min}
Normal	2.25
Upset	2.25
Emergency	1.5
Fault	1.125

4.5.1.1.2.3 Stress, Deformation, and Fatigue Limits for Core Support Structures

The stress, deformation, and fatigue criteria presented in Tables 4.5-5, 4.5-6, and 4.5-7 are used. These criteria are supplemented, where applicable, by the criteria for the reactor internals in the previous paragraph, but in no case shall the criteria presented in these tables be exceeded for core support structures.

4.5.1.1.2.4 Fuel Assembly Restraints

The fuel assembly structural design shall demonstrate sufficient dimensional stability and sufficient fuel rod support to maintain core geometry, thus avoiding fuel damage for both planned operation and abnormal operational transients.

4.5.1.1.2.5 Material Selection

The material used for fabricating most of the reactor core support and reactor internal structures is solution heat treated, unstabilized type 304 austenitic stainless steel conforming to ASTM specifications. Weld procedures and welders are qualified in accordance with the intent of Section IX of the ASME Boiler and Pressure Vessel (B&PV) Code. Further controls for stainless steel welding are covered in Subsection 5.2.5.

All the materials of construction exposed to the reactor coolant are resistant to stress corrosion in the BWR coolant. Conservative corrosion allowances are provided for all exposed surfaces of carbon or low-alloy steels.

Contaminants in the reactor coolant are controlled to very low limits by the reactor water-quality specifications. No detrimental effects occur on any of the materials from allowable contaminant levels in the high-purity reactor coolant. Radiolytic products in a BWR have no adverse effects on the construction materials.

4.5.1.1.2.6 Radiation Effects

Where feasible, the design is such that irradiation effects on the material properties are minimized. Where irradiation effects cannot be minimized, the design of the RPV internals either has provisions for replaceable components, or the design is shown to satisfy a set of stress and fatigue design limits that have been arrived at considering the effect of irradiation damage on the fracture toughness, ductility, and tensile properties of the materials.

4.5.1.1.2.7 Shock Loads

The components are designed so as to accommodate the loadings discussed in Section 3.9.

4.5.1.2 Description

The core support structures and RPV internals (excluding fuel, control rods, and in-core nuclear instrumentation) include the following components.

a. Core support structures

   1. Shroud
   2. Shroud support
   3. Core support and hold-down bolts
   4. Top guide (including wedges, bolts, and keepers)
   5. Fuel support pieces
   6. Control rod guide tubes.

b. Reactor pressure vessel internals

   1. Jet pump assemblies and instrumentation
   2. Shroud head and steam separator assembly (including shroud head bolts)
   3. Steam dryers
   4. Feedwater spargers
   5. Deleted
   6. Differential pressure and liquid control line
   7. In-core flux monitor guide tubes and stabilizers
   8. Surveillance sample holders
   9. Core spray lines and spargers.

The overall arrangement of the structures within the RPV is shown in Figure 4.1-l.

A general assembly drawing of the important reactor components is shown in Figure 4.5-1.

The floodable inner volume of the RPV can be seen in Figure 4.5-2. It is the volume inside the core shroud up to the level of the jet pump suction inlet.

The core support structure is used to form partitions within the RPV, to sustain pressure differentials across the partitions, to direct the flow of the coolant water, and to locate laterally and support the fuel assemblies, control rod guide tubes, and steam separators. Figure 4.5-2 shows the RPV internal flow paths.

4.5.1.2.1 Shroud

The core shroud is a stainless steel cylindrical assembly that provides a partition to separate the upward flow of coolant through the core from the downward recirculation flow. This partition separates the core region from the downcomer annulus, thus providing a floodable region following a recirculation line break.

The volume enclosed by the shroud is characterized by three regions. The upper shroud surrounds the core discharge plenum, which is bounded by the shroud head on top and the top guide below. The central portion of the shroud surrounds the active fuel and forms the longest section of the shroud. This section is bounded at the bottom by the core support. The lower shroud, surrounding part of the lower plenum, is welded to the RPV shroud support (Section 5.4).

4.5.1.2.2 Shroud Head and Steam Separator Assembly

The shroud head and steam separator assembly is bolted to the top of the upper shroud to form the top of the core discharge plenum. This plenum provides a mixing chamber for the steam/water mixture before it enters the steam separators. Individual stainless steel axial flow steam separators, shown in Figure 4.l-3, are attached to the top of standpipes that are welded into the shroud head. The steam separators have no moving parts. In each separator, the steam/water mixture rising through the standpipe passes vanes that impart a spin to establish a vortex separating the water from the steam. The separated water flows from the lower portion of the steam separator into the downcomer annulus.

4.5.1.2.3 Core Support Plate

The core support plate consists of a circular stainless steel plate with bored holes stiffened with a rim and beam structure. The plate provides lateral support and guidance for the control rod guide tubes, in-core flux monitor guide tubes, and peripheral fuel supports. The last item is also supported vertically by the core support plate.

The entire assembly is bolted to a support ledge between the central and lower portions of the core shroud. Alignment pins that engage slots and bear against the shroud are used to correctly position the assembly before it is secured.

The flow holes in the core support plate were plugged, and two holes for each fuel bundle were drilled in the lower tie plate. This modification reduces the channel box wear from flow-induced instrument tube vibrations caused by flow through the bypass holes in the lower core support plate. The above fixes are similar to that provided for Peach Bottom 2. A detailed discussion of the channel box wear problem and the solution is provided in Reference 1.

4.5.1.2.4 Top Guide

The top guide is formed by a series of stainless steel beams joined at right angles to form square openings, with the beams fastened to a peripheral rim. Each large opening provides lateral support and guidance for four fuel assemblies or, in the case of peripheral fuel, one or two fuel assemblies. Notches are provided in the bottom of the beam intersections to anchor the in-core flux monitors and startup neutron sources (all neutron sources were removed from the core during the first refueling outage).

4.5.1.2.5 Fuel Support

The fuel supports, shown in Figure 4.5-3, are of two basic types: namely, peripheral supports and four-lobed orificed fuel supports. The peripheral fuel support is located at the outer edge of the active core and is not adjacent to control rods. Each peripheral fuel support supports one fuel assembly and contains a single orifice assembly designed to ensure proper coolant flow to the fuel peripheral assembly. Each four-lobed orificed fuel support supports four fuel assemblies and is provided with orifice plates to ensure proper coolant flow distribution to each rod-controlled fuel assembly. The four-lobed orificed fuel supports rest in the top of the control rod guide tubes which are supported laterally by the core support. The control rods pass through slots in the center of the four-lobed orificed fuel support. A control rod and the four adjacent fuel assemblies represent a core cell (Subsection 4.1.2.1.4).

4.5.1.2.6 Control Rod Guide Tubes

The control rod guide tubes, located inside the RPV, extend from the top of the control rod drive (CRD) housing up through holes in the core support plate. Each tube is designed as the guide for a control rod and as the vertical support for a four-lobed orificed fuel support piece and the four fuel assemblies surrounding the control rod. The bottom of the guide tube is supported by the CRD housing (Section 5.4), which in turn transmits the weight of the guide tube, fuel support, and fuel assemblies to the RPV bottom head. A thermal sleeve is inserted into the CRD housing from below and is rotated to lock the control rod guide tube in place. A key is inserted into a locking slot in the bottom of the CRD housing to hold the thermal sleeve in position.

4.5.1.2.7 Jet Pump Assemblies

The jet pump assemblies are located in two semicircular groups in the downcomer annulus between the core shroud and the RPV wall. The design and performance of the jet pump are covered in detail in References 2 and 3. Each stainless steel jet pump consists of driving nozzles, suction inlet, throat or mixing section, and diffuser (Figure 4.5-4). The driving nozzle, suction inlet, and throat are joined together as a removable unit, and the diffuser is permanently installed. High-pressure water from the recirculation pumps (Subsection 5.5.l) is supplied to each pair of jet pumps through a riser pipe welded to the recirculation inlet nozzle thermal sleeve. A riser brace consists of cantilever beams extending from pads on the RPV wall.

The nozzle entry section is connected to the riser by a metal-to-metal, spherical-to-conical seal joint. Firm contact is maintained by a hold-down clamp. The throat section is supported laterally by a bracket attached to the riser. There is a slip-fit joint between the throat and diffuser. The diffuser is a gradual conical section changing to a straight cylindrical section at the lower end.

Evaluations performed by GE have shown that jet pump riser beam failures have resulted from intergranular stress corrosion cracking (IGSCC). Comparison of the failed BWR 3 beam with the BWR 4-6 beam structural design (i.e., the Fermi 2 design) has identified that the BWR 4-6 beam operates at a peak stress 14 percent lower than that of the BWR 3 design at the current joint preload. Because the time to crack initiation and subsequent failure increases with a decrease in stress, a reduction in preload was evaluated. The results of this evaluation, together with flow tests performed on prototypical components, have demonstrated the operational acceptability of a preload reduction to 25,000 lb. From relationships developed from field experience and laboratory stress corrosion tests, the minimum time to crack initiation for the Fermi 2 jet pump beam is estimated to increase by a factor of 4 with respect to the BWR 3 jet pump beam. In summary, Edison

a. Reduced the preload on all jet pump beams from 30,000 to 25,000 lb

b. Plans to inspect the jet pump beams during plant outages at a frequency to be determined from the surveillance of lead operating plants of this design.

By taking the above actions, the likelihood of beams developing cracks during the projected life of the plant is remote, and the likelihood of the cracks leading to beam failure before detection is extremely remote. However, if replacement beams that do not require periodic ultrasonic inspections are developed, Edison's position will be reevaluated.

In 1993, a jet pump hold-down beam failure occurred at a BWR-6. While previous failures occurred in the middle section of the beam, the recent failure occurred in the transition to the arms at the ends of the beam, with the cause of the failure identified as IGSCC. The most significant new findings resulting from this failure were that while the material and stress conditions were about the same at the beam middle and end sections, fracture mechanics evaluations indicated that crack growth to failure could occur in the beam ends in less than one 18-month operating cycle.

As a result of this failure, Edison elected to replace all jet pump hold down beams during the fourth refueling outage with replacement hold-down beam bolt assemblies. The new replacement beams received high temperature anneal (HTA) heat treatment during manufacturing and are less susceptible to IGSCC than the beams that were originally installed. Prior to and following installation in the RPV, the beam/bolt assemblies were inspected utilizing the latest inspection technology. The beams were preloaded to 25,000 lbs, consistent with the previous installation, and will be subjected to inservice inspection. The recommended inservice inspection interval provided in IE Bulletin 80-07 and NUREG/CR-3052 is once every 10 years. Subsequent UT and alternative inspections will be performed during future refueling outages based on industry experiences and the recommendations provided in NUREG/CR-3052.

If a crack is detected in a jet pump hold-down beam, that beam will be replaced by one of a suitable material and design before the return to power operation.

4.5.1.2.8 Steam Dryers

The steam dryers remove moisture from the wet steam leaving the steam separators. The extracted moisture flows down the dryer vanes to the collecting troughs, then flows through tubes into the downcomer annulus (Figure 4.1-4). A skirt extends from the bottom of the dryer vane housing to the steam separator standpipe, below the water level. This skirt forms a seal between the wet steam plenum and the dry steam flowing from the top of the dryers to the steam outlet nozzles.

4.5.1.2.9 Feedwater Spargers

The feedwater spargers are perforated stainless steel headers located in the mixing plenum above the downcomer annulus (Figure 4.1-1). A separate sparger is fitted to each feedwater nozzle and is shaped to conform to the curve of the RPV wall. Feedwater flow enters the center of the spargers and is discharged radially inward to mix the cooler feedwater with the downcomer flow from the steam separators before it contacts the RPV wall. The feedwater also serves to condense the steam in the region above the downcomer annulus and to subcool the water flowing to the jet pumps and recirculation pumps.

4.5.1.2.10 Core Spray Lines

The core spray lines are the means for directing flow to the core spray nozzles that distribute coolant so that peak fuel cladding temperatures of 2200°F are not exceeded during accident conditions.

Two core spray lines enter the RPV through the two core spray nozzles (Figure 4.1-1 and Section 6.3). The lines divide immediately inside the RPV. The two halves are routed to opposite sides of the RPV and are supported by clamps attached to the RPV wall. The lines are then routed downward into the downcomer annulus and pass through the upper shroud immediately below the flange. The flow divides again as it enters the center of the semicircular sparger, which is routed halfway around the inside of the upper shroud. The ends of the two spargers are supported by brackets designed to accommodate thermal expansion. The line routing and supports are designed to accommodate differential movement between the shroud and RPV. The other core spray line is identical except that it enters the opposite side of the RPV, and the spargers are at a slightly different elevation inside the shroud. The correct spray distribution pattern is provided by a combination of distribution nozzles pointed radially inward and downward from the spargers (Section 6.3).

4.5.1.2.11 Differential Pressure and Liquid Control Line

The differential pressure and liquid control line (Figure 4.l-l) serves a dual function within the RPV: to provide a path for the injection of the liquid control solution into the coolant stream (discussed in Subsection 4.5.2.4) and to sense the differential pressure across the core support plate (Section 5.4). This line enters the RPV at a point below the core shroud as two concentric pipes. In the lower plenum, the two pipes separate. The inner pipe terminates near the lower shroud with a perforated length below the core support plate. It is used to sense the pressure below the core support plate during normal operation and to inject liquid control solution if required. This location facilitates good mixing and dispersion. The inner pipe also reduces thermal shock to the RPV nozzle should the standby liquid control system (SLCS) be actuated. The outer pipe terminates immediately above the core support plate and senses the pressure in the region outside the fuel assemblies.

4.5.1.2.12 In-Core Flux Monitor Guide Tubes

The in-core flux monitor guide tubes provide a means of positioning fixed detectors in the core as well as providing a path for calibration monitors (traversing in-core probe or TIP system), and extend from the top of the in-core flux monitor housing (Section 5.4) in the lower plenum to the top of the core support plate. The power range detectors for the power range monitoring units and the dry tubes for the source range monitor and intermediate range monitor (SRM/IRM) detectors are inserted through the guide tubes. A latticework of clamps, tie bars, and spacers gives lateral support and rigidity to the guide tubes. The bolts and clamps are welded in place, after assembly, to prevent loosening during reactor operation.

4.5.1.2.13 Surveillance Sample Holders

The surveillance sample holders are welded baskets containing impact and tensile specimen capsules (Subsection 5.2.4.4). The baskets hang from the brackets that are attached to the inside wall of the RPV and extend to mid-height of the active core. The radial positions are chosen to expose the specimens to the same environment and maximum neutron fluxes experienced by the RPV itself while avoiding jet pump removal interference or damage.

4.5.1.2.14 Neutron Startup Source

The source assembly is comprised of two basic components: a source holder and a gamma source. The source holder is hollow, cylindrical, stainless steel sheathed, and spring loaded. It seals a beryllium tube from reactor water. The gamma source is a stainless-steel-sheathed assembly that houses neutron-irradiated antimony. In the neutron irradiation, some of the antimony is converted to ^{122}Sb, some to ^{124}Sb, and some remains unconverted. ^{122}Sb and ^{124}Sb emit gamma radiation.

Prior to startup, the gamma sources are inserted in the source holders. Neutrons are emitted from the beryllium as gamma radiation is absorbed. The gammas from the ^{124}Sb contribute almost all the generation of neutrons, as the half-life of ^{124}Sb is 60 days while the half-life of ^{122}Sb is 2.8 days. Most of the ^{122}Sb has decayed away during the postirradiation testing and shipment.

All sources assemblies were removed from the core during the first refueling outage.

4.5.1.3 Safety Evaluation

4.5.1.3.1 Evaluation Methods

To determine that the safety design bases are satisfied, responses of the RPV internals to loads imposed during normal, upset, emergency, and faulted conditions are examined. The effects on the ability to insert control rods, cool the core, and flood the inner volume of the RPV are determined.

4.5.1.3.1.1 Input for Safety Evaluation

The operating conditions that provide the basis for the design of the reactor internals to sustain normal, upset, emergency, and faulted conditions as well as combinations of design loadings that are accounted for in design of the core support structure are covered in Table 4.5-8.

In addition, each combination of operating loads is categorized with respect to either normal, upset, emergency, or faulted conditions as well as the associated design stress intensity or deformation limits.

The bases for the proposed design stress and deformation criteria are also specified in Chapter 3.

4.5.1.3.1.2 Events To Be Evaluated

Examination of the spectrum of conditions for which the safety design basis must be satisfied reveals three significant events.

a. Recirculation line break (LOCA) - The accident results in pressure differentials, within the RPV, that may exceed normal loads

b. Steam line break accident - This is a break in one main steam line between the RPV and the flow restrictor. The accident results in significant pressure differentials across some of the structures within the reactor

c. Earthquake - It subjects the core support structures and reactor internals to significant forces as a result of ground motion.

For other conditions existing during normal operation, abnormal operational transients, and accidents, the loads affecting the core support structures and reactor internals are less severe than these three postulated events.

4.5.1.3.2 Recirculation Line and Steam Line Break

4.5.1.3.2.1 Accident Definition

Both a recirculation line break (the largest liquid break) and an inside steam line break (the largest steam break) are considered in determining the design-basis accident (DBA) for the reactor internals. The recirculation line break is the same as the design-basis LOCA described in Section 6.3. A sudden, complete circumferential break is assumed to occur in one recirculation loop.

The analysis of the steam line break assumes a sudden, complete circumferential break of one main steam line between the RPV and the main steam line restrictor. This is not the same accident described in Section 15.6, which has greater potential radiological effects. A steam line break upstream of the flow restrictors produces a larger blowdown area and thus a faster depressurization rate than a break downstream of the restrictors. The larger blowdown area results in greater pressure differentials across the reactor assembly internal structures.

The steam line break accident produces higher pressure differentials across the reactor internal structures than does the recirculation line break. This results from the higher reactor depressurization rate associated with the steam line break. The depressurization rate is proportional to the mass flow rate and the excess of fluid escape enthalpy above saturated water enthalpy, h_f. Mass flow rate is inversely proportional to escape enthalpy, h_e, and therefore the depressurization rate is approximately proportional to $[1 - (h_f/h_e)]$. Consequently, depressurization rate decreases as $[1 - (h_f/h_e)]$ decreases; that is, the depressurization rate is less for mixture flow than for steam flow. Therefore, the steam line break is the DBA for internal pressure differentials.

4.5.1.3.2.2 Effects of Initial Reactor Power and Core Flow

For purposes of illustration, the maximum internal pressure loads can be considered to be composed of two parts: steady-state and transient pressure differentials. For a given plant, the core flow and power are the two major factors that influence the reactor internal pressure differentials. The core flow essentially affects only the steady-state part. For a fixed power, the greater the core flow, the larger the steady-state pressure differential. The core power affects both the steady-state and the transient parts. As the power is decreased there is less voiding in the core and consequently the steady-state core pressure differential is less. However, less voiding in the core also means that less steam is generated in the RPV and thus the depressurization rate and the transient part of the maximum pressure load are increased. Figure 4.4-3 is a power-flow map that defines the permissible operating conditions of the reactor (Subsection 4.4.3.3 discusses the boundaries on this map). From this range of operating conditions, it is necessary to determine the combination of core power and flow that results in the maximum internal pressure loads.

Consider the historical study where the power is 3430 MWt and the core flow is at 105 percent of rated conditions (the maximum point on the operating map). Since a decrease in power results in higher transient pressure differentials, a more severe initial condition might be the condition of 754.6 MWt, 116 percent flow. In going from 3430 MWt, 105 percent flow to 754.6 MWt, 116 percent flow condition, the steady-state pressure differential has a net decrease. There is an increase due to the slight increase in flow and a decrease due to the decrease in power (lower core pressure drop). The transient pressure differential increases due to the decrease in power. However, the maximum pressure load (steady-state plus transient) has a net increase for the low power condition. If the power is decreased below 754.6 MWt, the core flow must also be reduced. Analysis has shown that the decrease in flow and power reduces the steady-state part of the maximum pressure load more than the corresponding increase in the transient part. Hence, the maximum pressure loads (steady-state plus transient) are less if the core flow is reduced from its maximum value. Therefore, the maximum internal pressure loads occur following an inside steam line break from an initial condition in which the reactor is at the minimum power associated with the maximum core flow (754.6 MWt, 116 percent flow).

Table 4.5-9 lists the maximum pressure loads occurring across the reactor internals during the accident for two cases in the study. Case 1 is for an initial condition of (3694 MWt) and 105 percent core flow. Case 2 is for the maximum pressure loads that occur from the initial condition of (771 MWt), 116 percent flow. Comparison of Cases 1 and 2 illustrates the generalized statements made above concerning the relationship between the maximum internal pressure loads and core power and flow.

Realistically, if an inside steam line break were to occur, the maximum internal pressure loads would probably be closer to Case 1. This is because the plant will probably be operating at or near full power. Also, the Case 2 condition, although possible, is rather abnormal in that rated core flow is neither required nor desirable at such a reduced power condition.

4.5.1.3.2.3 <u>Break Size Spectrum Analysis</u>

It has been determined that the maximum internal pressure loads occur from an initial condition in which the reactor is at the minimum power associated with the maximum core flow. It has also been concluded that these maximum loads occur for an inside steam line break, the largest possible steam break. The initial reactor condition chosen for this break analysis is the worst case condition determined above (22 percent steam flow, 116 percent recirculation flow).

4.5.1.3.2.4 Conclusions

It is concluded from the above study, that the maximum pressure loads acting on the reactor internal components result from an inside steam line break occurring while the reactor is at 22 percent power associated with the 116 percent core flow (Table 4.5-9, Case 2).

It has also been pointed out that, although possible, it is not probable that the reactor would be operating at the rather abnormal condition of minimum power and maximum core flow. More realistically, the reactor would be at or near a full-power condition and thus the expected maximum pressure loads acting on the internal components would be as listed under Case 1 in Table 4.5-9.

4.5.1.3.2.5 Response of Structures Within the Reactor Pressure Vessel to Pressure Differences

The maximum differential pressures are used in combination with other structural loads to determine the total loading on the various structures within the reactor. The structures are then evaluated to assess the extent of deformation and buckling instability, if any. Of particular interest are the responses of the guide tubes and the metal channels around the fuel bundles, and the potential leakage around the jet pump joints.

Guide Tube

The guide tube is evaluated for buckling instability caused by externally applied pressure. Two primary modes of failure have been analyzed and are described in Subsection 4.5.2.1.3. For a guide tube with minimum wall thickness (t = 0.144 in.) and maximum allowed ovality, the pressure which causes yield stress is 93 psi compared to the design pressure of 37.5 psi. The design pressure is greater than the 21.1 psi maximum pressure differential the guide tube experiences, including accident conditions.

The stress the guide tube could experience has been calculated to be 6200 psi due to external pressure (30 psi - Reference 5), a 1.2g earthquake (include deadweight loading) and lateral loading due to coolant flow, while yield stress at 575°F is 17,450 psi. It is concluded that the guide tube does not fail under the assumed conditions. Additional guide tube analyses are given in References 6 and 7.

Fuel Channel

The fuel channel load resulting from an internally applied pressure is evaluated utilizing a fixed-beam analytical model under a uniform load. Tests to verify the applicability of the analytical model indicate that the model is conservative. A roller, at the top of some of the control rods, guides the blade as it is inserted. If the gap between channels is less than the diameter of the roller, the roller deflects the channel walls as it makes its way into the core. The friction force is a small percentage of the total force available to the CRDs for overcoming such friction, and it is concluded that the main steam line break accident does not impede the insertability of the control rod.

Marathon C (some), Ultra-MD, and Ultra-HD Control Rods without rollers have been designed to take reactor clearances into account. Evaluations of the roller-less control rods have concluded that there is no interference or fit issues related to this design.

Loads Assessment of Fuel Assembly Components

General Electric has prepared the licensing topical report NEDE-21175-3-P, "BWR Fuel Assembly Evaluation of Combined SSE and LOCA Loadings," dated July 1982, on behalf of the Licensing Review Group (LRG), to incorporate a detailed discussion of the fuel liftoff model and a bounding analysis applicable to Fermi 2 for combined faulted loads (safe-shutdown earthquake and LOCA annulus ρ) and transmitted this report to the NRC in a letter dated July 27, 1982, from J. F. Quirk of GE to Mr. Hal Bernard of the NRC. Subsection 3.9.1.5 provides additional information on the structural evaluation of Fermi 2 fuel assemblies under safe-shutdown earthquake (SSE) and LOCA loads. See Subsection 4.2.3 for further information.

Jet Pump Joints

Jet pump joints have been analyzed to evaluate the potential leakage from within the floodable inner volume of the RPV during the recirculation line break and subsequent low-pressure coolant injection (LPCI) reflooding. Because the jet pump diffuser is welded to the shroud support, the only remaining source of leakage from the lower plenum to the downcomer annulus is the jet pump throat-to-diffuser joint. These joints for all jet pumps leak no more than a total of 225 gpm.

The LPCI capacity is sized to accommodate 600 gpm leakage at these locations plus an additional 200 gpm to accommodate accepted internal flaws associated with the core baffle access hole cover and RS-1 jet pump riser. It is concluded that the RPV structures retain sufficient integrity during the recirculation line break accident to allow reflooding of the inner volume of the RPV and in sufficient time to prevent significant increases in cladding temperature.

4.5.1.3.3 Earthquake

The seismic loads acting on the structures within the RPV are based on a dynamic analysis of a model similar to that shown in Figure 4.5-7. Seismic analysis is performed by coupling this lumped mass model of the RPV and internals with the building model to determine the system natural frequencies and mode shapes. The relevant displacement, acceleration, and load response are then determined by the modal superposition time history method.

4.5.1.3.4 Conclusions

Response analyses of the reactor structures show that deformations are sufficiently limited to allow both adequate control rod insertion and proper operation of the emergency core cooling system (ECCS). Sufficient integrity of the structures is retained during accident conditions to allow successful reflooding of the RPV inner volume. The analyses considered various loading combinations, including loads imposed by external forces. Thus, safety design bases listed in Subsection 4.5.1.1.1.1 are satisfied.

4.5.1.4 Design Loading Categories

Refer to Table 4.5-8 and Section 3.9.

4.5.1.5 Design-Basis Criteria

The reactor core support structures and internals meet the safety requirements and power generation requirements in Subsection 4.5.1.1. This is accomplished without exceeding the design-basis conditions for normal, upset, emergency, and faulted conditions described in Table 4.5-8. The internals' and core support structures' design stress and deformation criteria are specified in Chapter 3.

4.5.2 Reactivity Control System

The reactivity control system consists of the control rods, the CRDs, the supplementary reactivity control, and the SLCS. Because of the nature of this material, each item is discussed in this subsection on a system basis.

4.5.2.1 Control Rods

4.5.2.1.1 Design Bases

4.5.2.1.1.1 General Design Bases

Safety Design Bases

The safety design bases are as follows.

a. The control rods shall have sufficient mechanical strength to prevent displacement of their reactivity control material

b. The control rods shall have sufficient strength and be designed to prevent deformation that could inhibit their motion

c. Each control rod shall have a device to limit its freefall velocity sufficiently to avoid damage to the nuclear system process barrier by the rapid reactivity increase resulting from a free-fall of one control rod from its fully inserted position to the position where the drive was withdrawn.

Power Generation Design Basis

The reactivity control mechanical design shall include reactivity control devices (control rods and gadolinia burnable poison) that contain and position the material that controls the excess reactivity in the core. Control rods should have the capability of being removed or replaced, as required.

4.5.2.1.1.2 Specific Design Characteristics

Control Rod Clearances

The basis of the mechanical design of the control rod blade clearances is that there will be no interference that restricts the passage of the control rod blade. A clearance study that generically applied to BWR 4 and BWR 5 C-lattice plants with 0.100 channels was issued in October 1975 (reference G.E. 767E667, Revision 0).

Mechanical Insertion Requirements

Mechanical insertion requirements during normal operation are selected to provide adequate operability and load-following capability, and to be able to control the reactivity addition resulting from burnout of peak shutdown xenon at 100 percent power.

Scram insertion requirements are chosen to provide sufficient shutdown margin to meet all safety criteria for plant operational transients described in Chapter 15.

Material Selection

The selection of materials for use in the control rod design is based on their in-reactor properties. The irradiated properties of type 304 austenitic stainless steel (which comprises the major portion of the assembly), type 304S "Rad Resist" stainless steel, boron carbide (B_4C) powder, hafnium metal, Inconel X750, and PH13-8Mo are well known and are taken into account in establishing the mechanical design of the control rod components.

Radiation Effects

The radiation effects on B_4C powder include the release of gaseous products, and the B_4C cladding is designed to sustain the resulting internal pressure buildup. The corrosion rate and the physical properties (density, modulus of elasticity, dimensional aspects) of austenitic stainless steel, Inconel-X, and hafnium are essentially unaffected by the irradiation experienced in the BWR reactor core. The effects on the mechanical properties, such as yield strength, ultimate tensile strength, elongation, and ductility on the high purity type 304S rad resist stainless steel cladding also are well known and are considered in mechanical design.

Positioning Requirements

Rod positioning increments (notch lengths) are selected to provide adequate power-shaping capability. The combination of rod speed and notch length must also meet the limiting reactivity addition rate criteria.

4.5.2.1.2 Description

The control rods perform the dual function of power shaping and reactivity control (see Figure 4.5-8). Power distribution in the core is controlled during operation of the reactor by manipulating selected patterns of control rods. Control rod displacement tends to counterbalance steam void effects at the top of the core and results in significant power flattening.

All the control rods consist of a cruciform array of stainless steel tubes filled with boron carbide powder or hafnium metal. Duralife 140 control rods are surrounded by a stainless steel sheath. Marathon C, Ultra-MD, and Ultra-HD control rods have absorber tubes that are edge welded to form the cruciform shape.

The control rod assemblies shall be full length. Control blade total span is nominally 9.81 inches. Control rods are separated uniformly throughout the core on a 12 inch pitch. Each control rod is surrounded by four fuel assemblies. The absorber material used in the original equipment control rods (the control rods originally supplied with the plant) is the boron carbide powder only. Some General Electric designs employ hafnium metal as an additional absorber to extend the service life of the control rods. The thicker sheath material used in the Duralife-140 model has allowed the removal of the stiffener rods in the original design without a loss of limiting mechanical load capability. The Duralife-140 model has an increased number of B_4C absorber tubes in each wing. In addition, the length of the B_4C absorber rods in the Duralife-140 has been reduced to accommodate a six inch hafnium plate (tip) at the top. The Marathon C model has replaced the absorber tubes and sheath arrangement with an array of square tubes. The Ultra-HD and Ultra-MD models replaced the Marathon C tube geometry with more cylindrical tubes that have increased wall thickness for improved strength.

For the Duralife 140 control rod model, the main structural member of a control rod is made of Type-304 stainless steel and consists of a top handle, a bottom casting with a velocity limiter and control rod drive coupling, a vertical cruciform center post, and four U-shaped absorber tube sheaths. The top handle, bottom casting, and center post are welded into a single skeletal structure. The U-shaped sheaths are fusion welded to the center post, handle, and castings on the newer designs to form a rigid housing to contain the absorber material. On the original equipment control rods resistance (spot) welding was employed. The fusion weld fabrication eliminates the overlap area between the sheath and the handle, tie rod and velocity limiter. By eliminating the overlap, the potential for crevice corrosion cracking in adverse water chemistry conditions is eliminated. Analyses and tests have shown that the fusion welded control rod is equal to or better than the spot welded control rod under all loading conditions. The bail handle on the newer control rods was extended (as an option) to minimize the use of blade guides during refueling outages. Rollers at the top and bottom of the control rod guide the control rod as it is inserted and withdrawn from the core. The control rods are cooled by the core bypass flow. The U-shaped sheaths are perforated to allow coolant to circulate freely about the absorber tubes. In addition, coolant grooves are included in the hafnium absorber plate at the top of the newer control rods. Operating experience has shown that control rods constructed as described above are not susceptible to dimensional distortions.

For the Duralife 140 control rod model, the boron carbide (B_4C) powder in the absorber tubes is compacted to about 70 percent of its theoretical density. The boron carbide contains a minimum of 76.5 percent by weight natural boron; the boron-10 (B-10) minimum content of the boron is 18 percent by weight. The absorber tubes in the originally supplied control rods were made of Type-304 stainless steel. The absorber tubes in the newer control rods are a high purity Type 304S "Rad Resist" stainless steel. The high purity stainless steel has an improved resistance to intergrannular stress corrosion cracking (IGSCC).

Each absorber tube of the Duralife 140 model is 0.188 inch in outside diameter. The Duralife 140 model has a 0.025-inch wall thickness. Absorber tubes are sealed by a plug welded into each end. The boron carbide is longitudinally separated into individual compartments by stainless steel balls at approximately 16 inch intervals. The steel balls are held in place by a slight crimp of the tube. Should boron carbide tend to compact further in service, the steel balls will distribute the resulting voids over the length of the absorber tube.

For Marathon C blades, each square absorber tube has an internal cylinder with 0.204 inside diameter with a nominal 0.021 inch wall thickness. These tubes are loaded with either B_4C powder or hafnium. B_4C powder is compacted to 70 percent of its theoretical density and is contained in capsules which are then loaded into the absorber tubes. The space between the capsules and the wall of the absorber tubes allows the B_4C to swell before contact is made with the absorber tubes, providing improved resistance to stress corrosion. These capsules are designed to securely contain the B_4C powder while allowing helium released from B_4C to migrate through the absorber tube. Empty capsules may be used in the absorber tubes to provide a plenum for helium released from other capsules within the absorber tubes. After the capsules are installed inside the absorber tubes the ends of the tube are seal welded. The square absorber tubes are welded lengthwise to form the four wings of the cruciform control rod blade.

Ultra-HD absorber tubes are loaded with either B_4C capsules or hafnium while the Ultra-MD absorber tubes are filled with B_4C only. B_4C capsules in Ultra-MD and Ultra-HD control rods are similar to B_4C capsules in the Marathon C control rods. However, the dimensions of the Ultra-MD and Ultra-HD B_4C capsule are sized such that clearance exists between the capsule and absorber tube, even at 100% local depletion. This, combined with a thicker capsule wall, results in slightly less B_4C powder mass in each capsule. The condition of clearance between capsule and absorber tube at 100% local depletion provides a significant structural advantage for the Ultra-MD and Ultra-HD designs over the Marathon C design, as no strain is induced in the absorber tube due to swelling of the B_4C capsule. Empty capsules may be used in the absorber tubes to provide a plenum for helium released from other capsules within the absorber tubes. After the capsules are installed inside the absorber tubes the ends of the tube are seal welded. The absorber tubes are welded lengthwise to form the four wings of the cruciform control rod blade.

The Duralife-140, Marathon C, Ultra-MD, and Ultra-HD are all Matched Reactivity Worth control rods. The Marathon C, Ultra-MD, and Ultra-HD models have a slight increase in cold reactivity worth due to the increased volume of boron carbide. The increase is small but in the conservative direction for increased shutdown margin. Because the increase is small, no changes in lattice physics calculation or 3D Monicore computer constants are required and no accident analyses are affected.

The nuclear operational lifetime of the control rods is determined by the burnup of ^{10}B from neutron absorption and local B_4C loss from B_4C swelling. The nuclear lifetime limit is reached when the quarter-segment depletion achieves a control rod cold reactivity worth (delta k/k) of 10% less than its zero-depletion cold reactivity worth. The mechanical lifetime limit for control rods due to B_4C swelling is bounded by the nuclear operational lifetime limit. The mechanical lifetime limit for GE-Hitachi BWR control rods is reached at 40 years of in-core residency time for all blade types.

The structural effect of helium gas buildup in the absorber rod, due to B-10 neutron absorption and radiolysis of small amounts of water vapor in the absorber rod, was evaluated by General Electric using a two-dimensional finite element computer model of the absorber tubing and end plug. The helium gas pressure was calculated using an empirical correlation for the helium release fraction from the B_4C matrix as a function of percent B-10 depletion, which varies from 4 percent to 30 percent.

The control rod velocity limiter (Figures 4.5-8 through 4.5-10) is an integral part of the bottom assembly of each control rod. This engineered safety feature (ESF) system protects against a high reactivity insertion rate by limiting the control rod velocity in the event of a control rod drop accident. It is a one-way device in that the control rod scram velocity is not significantly affected, but the control rod dropout velocity is reduced to a permissible limit.

Three different types of velocity limiters are employed. On the Duralife 140 model the velocity limiter is in the form of two nearly mated conical elements made from a single casting (Figure 4.5-9). The lower conical element is separated from the upper conical element by four radial spacers 90 degrees apart and is at a 15° angle relative to the upper conical element. The cast velocity limiter employs a single reversed jet. The velocity limiter on the Marathon C model has been redesigned to offset the weight of the hafnium absorber. This machined velocity limiter employs an optimized twin reversed jet (Figure 4.5-10). The velocity limiter on Ultra-HD and Ultra-MD control rods is a cast/fabricated hybrid called the FabriCast. The FabriCast velocity limiter uses a casting for the “vane” of the velocity limiter (Figure 4.5-10), which has identical geometry to the “vane” portion of the single piece cast velocity limiter. Because the geometry is the same, the FabriCast velocity limiter has the same drop speed and scram insertion performance as the original single piece cast velocity limiter design.

The hydraulic drag forces on a control rod are proportional to approximately the square of the rod velocity and are negligible at normal rod-withdrawal or rod-insertion speeds. However, during the scram stroke the rod reaches high velocity, and the drag forces must be overcome by the drive mechanism.

To limit control rod velocity during dropout but not during scram, the velocity limiter is provided with a streamlined profile in the scram (upward) direction. When a control rod with a cast velocity limiter is scrammed, water flows over the smooth surface of the upper conical element into the annulus between the guide tube and the limiter. For the redesigned velocity limiter, water flows over the conical element into the annulus between the element and the CRD coupling socket and the annulus between the guide tube and the limiter. In the dropout direction, however, for the cast velocity limiter, water is trapped by the lower conical element and discharged through the annulus between the two conical sections. For the machined velocity limiter, the trapped water is discharged in two directions. Because this water is jetted in a partially reversed direction into water flowing upward in the annulus, a severe turbulence is created, thereby slowing the descent of the control rod assembly to less than 5 ft/sec at 70°F (Appendix A of Reference 8).

4.5.2.1.3 Safety Evaluation

4.5.2.1.3.1 Materials Adequacy Throughout Design Lifetime

The adequacy of the materials throughout the design life was evaluated in the mechanical design of the control rods. The primary materials, B_4C powder, hafnium, and high purity Type 304S "Rad Resist" stainless steel, have been found suitable in meeting the demands of the BWR environment.

4.5.2.1.3.2 Dimensional and Tolerance Analysis

Layout studies are done to ensure that, given the worst combination of extreme detail part tolerance ranges at assembly, no interference exists that will restrict the passage of control rods. In addition, preoperational and operational verification is made on each control blade system to show that the acceptable levels of operational performance are met. See Subsections 4.5.2.1.4 and 4.5.2.2.4.

4.5.2.1.3.3 Thermal Analysis of the Tendency To Warp

The various parts of the control rod assembly remain at approximately the same temperature during reactor operation, negating the problem of distortion or warpage. What little differential thermal growth could exist is allowed for in the mechanical design. A minimum axial gap is maintained between absorber rod tubes and the control rod frame assembly for this purpose. In addition, dissimilar metals are avoided to further this end.

4.5.2.1.3.4 Forces for Expulsion

An analysis has been performed that evaluates the maximum pressure forces which could tend to eject a control rod from the core. The results of this analysis are given in Subsection 4.5.2.2.3.1. In summary if the collet were to remain open, which is unlikely, calculations indicate that the steady-state control rod withdrawal velocity would be 2 fps for a pressure-under line break, the limiting case for rod withdrawal.

4.5.2.1.3.5 Functional Failure of Critical Components

The consequences of a functional failure of critical components have been evaluated, and the results are covered in Subsection 4.5.2.2.3.1.

4.5.2.1.3.6 Precluding Excessive Rates of Reactivity Addition

In order to preclude excessive rates of reactivity addition, the design is based on analyses that have been performed both on the velocity limiter device and the effect of probable control rod failures (see Subsection 4.5.2.2.3.1).

4.5.2.1.3.7 Effect of Fuel Rod Failure on Control Rod Channel Clearances

The CRD mechanical design ensures a sufficiently rapid insertion of control rods to preclude the occurrence of fuel rod failures that could hinder reactor shutdown by causing significant distortions in channel clearances.

4.5.2.1.3.8 Mechanical Damage

Analysis has been performed for all areas of the control system showing that system mechanical damage does not affect the capability to continuously provide reactivity control.

In addition to the analysis performed on the CRD (Subsections 4.5.2.2.3.1 and 4.5.2.2.3.2), the following discussion summarizes the analysis performed on the control rod guide tube.

The guide tube can be subjected to any or all of the following loads:

a. Inward load due to pressure differential

b. Lateral loads due to flow across the guide tube

c. Dead weight

d. Seismic.

In all cases, analysis was performed considering both a recirculation line break and a steam line break, events that result in the largest hydraulic loadings on a control rod guide tube.

Two primary modes of failure were considered in the guide tube analysis: exceeding allowable stress and excessive elastic deformation. It was found that the allowable stress limit will not be exceeded and that the elastic deformations of the guide tube never are great enough to cause the free movement of the control rod to be jeopardized.

The first mode of failure is evaluated by the addition of all the stresses resulting from the maximum loads for the faulted condition. This results in the maximum theoretical stress value for that condition. Making a linear superposition of all calculated stresses and comparing this value to the allowable limit defined by the ASME B&PV Code yields a factor of safety of approximately three. Using the allowable limit for faulted conditions, the factor of safety is approximately 4.2.

Evaluation of the second mode of failure is based on clearance reduction between the guide tube and the control rod. The minimum allowable clearance is about 0.1 in. This assumes maximum ovality and minimum diameter of the guide tube and the maximum control rod dimension. The analysis showed that if the approximate 6000 psi for the faulted condition were entirely the result of differential pressure, the clearance between the control rod and the guide tube would reduce by a value of approximately 0.01 in. This gives a design margin of 10 between the theoretically calculated maximum displacement and the minimum allowable clearance.

Two types of instability were considered in the analysis of guide tube design. The first was the classic instability associated with vertically loaded columns. The second was the diametral collapse when a circular tube experiences external-to-internal differential pressure.

The limited axially applied load is approximately 77,500 lb resulting in a material compressive stress of 17,450 psi (code allowable stress). Comparing the actual load to the yield stress level gives a design margin greater than 20 to 1. From these values it is concluded that the guide tube is not an unstable column.

When a circular tube experiences external-to-internal differential pressure, two modes of failure are possible, depending on whether the tube is "long" or "short." In the analysis here the guide tube is taken to be an infinitely long tube with the maximum allowable ovality and minimum wall thickness. The conditions will result in the lowest critical pressure calculation for the guide tube (that is, if the tube were "short," the critical pressure calculation would give a higher number). The critical pressure is approximately 140 psi. However, if the maximum allowable stress is reached at a pressure lower than the critical pressure, then that pressure is limiting. This is the case for a BWR guide tube. The allowable stress of 17,450 psi will be reached at approximately 96 psi. Comparing the maximum possible pressure differential for a steam line break to the limiting pressure of 96 psi gives a design margin greater than 3 to 1. Therefore, the guide tube is not unstable with respect to differential pressure. References 6 and 7 provide a detailed discussion of analyses and design margins for the control rod guide tube.

4.5.2.1.3.9 Evaluation of Control Rod Velocity Limiter

The control rod velocity limiter limits the free-fall velocity of the control rod. This velocity is evaluated by the control rod drop accident analysis described in Subsection 15.4.9.

4.5.2.1.4 Testing and Inspection

The control rod absorber tube tests are examples of the quality control tests performed on the control rods. The absorber tube tests include the following:

a. The ^{10}B fraction of the boron content of each lot of boron carbide is verified

b. Weld integrity of the finished absorber tubes is verified by helium leak testing.

The Surveillance Test Program is described in Subsection 4.5.2.2.4.5 and in the Technical Specifications.

Fermi 2 procedures require replacement of control blades when a 10 percent reduction of rod worth occurs.

4.5.2.1.5 Instrumentation

The instrumentation for both the control rods and CRDs is defined by that given for the reactor manual control system (RMCS). The objective of the RMCS is to provide the operator with the means to make changes in nuclear reactivity so that reactor power level and power distribution can be controlled. The system allows the operator to manipulate control rods.

The design bases and further discussion are covered in Subsection 7.7.1.

4.5.2.2 Control Rod Drive System

4.5.2.2.1 Design Bases

4.5.2.2.1.1 Safety Design Bases

The CRD mechanical system shall meet the following safety design bases:

a. Design shall provide for a control rod insertion sufficiently rapid that no fuel damage results from any abnormal operating transient

b. Design shall include positioning devices, each of which individually supports and positions a control rod

c. Each positioning device shall

   1. Prevent its control rod from withdrawing as a result of a single malfunction

2. Be individually operated so that a failure in one positioning device does not affect the operation of any other positioning device

3. Be individually energized when rapid control rod insertion (scram) is signaled so that failure of power sources external to the positioning device does not prevent the positioning devices of other control rods from being inserted

4. Be locked to its control rod to prevent undesirable separation.

d. The CRD mechanisms and that part of the CRD hydraulic system necessary for scram shall be designed to Category I requirements.

4.5.2.2.1.2 Power Generation Design Basis

The CRD system design shall provide for positioning the control rods to control power generation in the core.

4.5.2.2.2 Description

The CRD system controls gross changes in core reactivity and neutron flux shape by incrementally positioning neutron-absorbing control rods within the reactor core in response to manual control signals. It is also required to shutdown the reactor by rapidly inserting withdrawn control rods into the core in response to a manual or automatic signal. The CRD system consists of locking piston, CRD mechanisms, and the CRD hydraulic system (including hydraulic control units, interconnecting piping, instrumentation, and electrical controls).

4.5.2.2.2.1 Control Rod Drive Mechanisms

The CRD mechanism (drive) used for positioning the control rod in the reactor core is a double-acting, mechanically latched, hydraulic cylinder using water as its operating fluid (Figures 4.5-11 through 4.5-14). The individual drives are mounted on the bottom head of the RPV. The drives do not interfere with refueling and are operative even when the head is removed from the RPV. The drives are also readily accessible for inspection and servicing. The bottom location makes maximum use of the water in the reactor as a neutron shield and gives the least possible neutron exposure to the drive components. Using water from the condensate treatment system or condensate storage tank as the operating fluid eliminates the need for special hydraulic fluid. Drives are able to use simple piston seals whose leakage does not contaminate the reactor water and does cool the drive mechanisms and their seals.

The drives are capable of inserting or withdrawing a control rod at a slow, controlled rate, as well as providing rapid insertion when required. A mechanism on the drive locks the control rod in 6-in. increments of stroke over the length of the core.

A coupling spud at the top end of the drive index tube (piston rod) engages and locks into a mating socket at the base of the control rod. The weight of the control rod is sufficient to engage and lock this coupling. Once locked, the drive and rod form an integral unit that must be manually unlocked by specific procedures before the components can be separated.

The drive holds its control rod in distinct latch positions until the hydraulic system actuates movement to a new position. Withdrawal of each rod is limited by the seating of the rod in its guide tube. Withdrawal beyond the full-out limit can be accomplished only if the rod and drive are uncoupled. Withdrawal past the full-out limit is annunciated by an over travel alarm.

The individual rod indicators, grouped in one control panel display, correspond to relative rod locations in the core. A separate, smaller display is located just below the large display on the vertical part of the benchboard. This smaller display presents the positions of the control rod selected for movement and its adjacent rods.

For display purposes, the control rods are considered in groups of four adjacent rods centered around a common core volume. Each group is monitored by four local power range monitor (LPRM) strings (Subsection 7.6.1). Rod groups at the periphery of the core may have less than four rods and less than 4 LPRM strings. The small rod display shows the positions, in digital form, of the rods in the group to which the selected rod belongs. A white light indicates which of the four rods is the one selected for movement.

4.5.2.2.2.2 Control Rod Drive Components

Figure 4.5-12 illustrates the operating principle of a CRD. Figures 4.5-13 and 4.5-14 illustrate the CRD in more detail. The main components of the CRD and their functions are described as follows.

The CRD piston is mounted at the lower end of the index tube. This tube functions as a piston rod. The CRD piston and index tube make up the main moving assembly in the CRD. The CRD piston operates between positive end stops, with a hydraulic cushion provided at the upper end only. The piston has both inside and outside seal rings and operates in an annular space between the fixed piston tube assembly and the drive inner cylinder tube. Because the type of inner seal used is effective in only one direction, the lower sets of seal rings are mounted with one set sealing in each direction.

A pair of nonmetallic bushings prevents metal-to-metal contact between the piston tube assembly and the inner cylinder surface. The outer piston rings are segmented step-cut seals with expander springs holding the segments against the cylinder wall. A pair of split bushings on the outside of the piston prevents piston contact with the inner cylinder wall. The effective piston area for downtravel, or withdrawal, is approximately 1.2 in.^{2} versus 4.1 in.^{2} for uptravel, or insertion. This difference in driving area tends to balance the control rod weight and ensures a higher force for insertion than for withdrawal.

The index tube is a long hollow shaft made of either nitrided type 304 or Grade XM-19 stainless steel. Circumferential locking grooves, spaced every 6 in. along the outer surface, transmit the weight of the control rod to the collet assembly.

The collet assembly serves as the index tube locking mechanism. It is located in the upper part of the drive unit. This assembly prevents the index tube from accidentally moving downward. The assembly consists of the collet fingers, a return spring, a guide cap, a collet housing (part of the cylinder, tube, and flange), and the collet piston.

The problem of IGSCC in the collet assembly is discussed in Subsection 4.5.2.2.4.5.

Locking is accomplished by fingers mounted on the collet piston at the top of the drive cylinder. In the locked or latched position, the fingers engage a locking groove in the index tube.

The collet piston is normally held in the latched position by a force of approximately 150 lb supplied by a spring. Metal piston rings are used to seal the collet piston from RPV pressure. The collet assembly will not unlatch until the collet fingers are unloaded by a short, automatically sequenced, drive-in signal. A pressure, approximately 180 psi above RPV pressure, must then be applied to the collet piston to overcome spring force, slide the collet up against the conical surface in the guide cap, and spread the fingers out so they do not engage a locking groove.

A guide cap is fixed in the upper end of the CRD assembly. This member provides the unlocking cam surface for the collet fingers and serves as the upper bushing for the index tube.

If reactor water is used during a scram to supplement accumulator pressure, it is drawn through a filter on the guide cap.

The piston tube is an inner cylinder, or column, extending upward inside the CRD piston and index tube. The piston tube is fixed to the bottom flange of the CRD and remains stationary. Water is brought to the upper side of the CRD piston through this tube. A series of progressively decreasing orifices at the top of the tube form the hydraulic buffer to cushion the CRD piston at the end of its scram stroke.

A stationary piston, called the stop piston, is mounted on the upper end of the piston tube. This piston provides the seal between RPV pressure and the space above the drive piston. It also functions as a positive end stop at the upper limit of control rod travel. A stack of spring washers just below the stop piston helps absorb the final mechanical shock at the end of control rod travel. The stop piston seal rings are similar to the drive piston outer seal rings. A bleed-off passage to the center of the piston tube is located between the two pairs of rings. This arrangement allows seal leakage from the RPV (during a scram) to be bled directly to the discharge line. The lower pair of seals is used only during the cushioning of the CRD piston at the upper end of the stroke.

The center tube of the CRD mechanism forms a well to contain the position indicator probe. This probe is an aluminum extrusion attached to an aluminum housing. Mounted on the extrusion are hermetically sealed, magnetically operated position indicator switches. Each switch is sheathed in a braided glass sleeve, and the entire probe assembly is protected by a thin-walled stainless steel tube. The switches are actuated by a ring magnet located at the bottom of the drive piston.

The drive piston, piston tube, and indicator tube are all of nonmagnetic stainless steel, allowing the individual switches to be operated by the magnet as the piston passes. One switch is located at each position corresponding to an index tube groove, thus allowing indication at each latching point. An additional switch is located at each midpoint between latching points to indicate the intermediate positions during drive motion. Thus, indication is provided for each 3 in. of travel. Duplicate switches are provided for the full-in and full-out positions. One additional switch (an overtravel switch) is located at a position below the normal full-out position. Because the limit of downtravel is normally provided by the control rod itself as it reaches the backseat position of the control rod guide tube, the CRD can pass this position and actuate the overtravel switch only if it is uncoupled from its control rod. A convenient means is thus provided to verify that the drive and control rod are coupled after installation of a drive or at any time during plant operation.

A flange and cylinder assembly is made up of a heavy flange welded to the CRD cylinder. A sealing surface on the upper face of this flange forms the seal to the drive housing flange. The seals contain reactor pressure and the two hydraulic control pressures. Teflon-coated, stainless steel rings are used for these seals. The CRD flange contains the integral ball, or two-way, check (ball-shuttle) valve. This valve directs either the RPV pressure or the CRD system driving pressure, whichever is higher, to the underside of the CRD piston. Reactor pressure vessel pressure is admitted to this valve from the annular space between the drive and drive housing through passages in the flange.

Water used to operate the collet piston passes between the outer tube and the cylinder tube. The inside of the cylinder tube is honed to provide the surface required for the drive piston seals.

Both the cylinder tube and outer tube are welded to the CRD flange. The upper ends of these tubes have a sliding fit to allow for differential expansion.

The upper end of the index tube is threaded to receive a coupling spud. The coupling (Figure 4.5-11) accommodates a small amount of angular misalignment between the CRD and the control rod. Six spring fingers allow the coupling spud to enter the mating socket on the control rod. A plug then enters the spud and prevents uncoupling.

Two means of uncoupling are provided. With the RPV head removed, the lock plug can be raised against the spring force of approximately 50 lb by a rod extending up through the center of the control rod to an unlocking handle located above the control rod velocity limiter. The control rod, with the lock plug raised, can then be lifted from the CRD.

The lock plug can also be pushed up from below, if it is desired to uncouple a drive without removing the RPV head for access. In this case, the central portion of the drive mechanism is pushed up against the uncoupling rod assembly, which raises the lock plug and allows the coupling spud to disengage the socket as the drive piston and index tube are driven down.

The control rod is heavy enough to force the spud fingers to enter its socket and push the lock plug up, allowing the spud to enter the socket completely and the plug to snap back into place. Therefore, the CRD can be coupled to the control rod using only the weight of the control rod. However, with the lock plug in place, a force in excess of 50,000 lb is required to pull the coupling apart.

<u>Materials of Construction</u>

Factors that determine the choice of construction materials are discussed in the following paragraphs.

The index tube must withstand the locking and unlocking action of the collet fingers. A compatible bearing combination must be provided that is able to withstand moderate misalignment forces. The reactor environment limits the choice of materials suitable for corrosion resistance. The column and tensile loads can be satisfied by either an annealed 300 series or Grade XM-19 stainless steel. The wear and bearing requirements are provided by hard facing the completed tube. To obtain suitable corrosion resistance, a carefully controlled process of surface preparation is employed.

The coupling spud is made of Inconel-750 that is aged for maximum physical strength and the required corrosion resistance. Because misalignment tends to cause chafing in the semispherical contact area, the part is protected by a thin chromium plating (electrolyzed). This plating also prevents galling of the threads attaching the coupling spud to the index tube.

Inconel-750 is used for the collet fingers, which must function as leaf springs when cammed open to the unlocked position. Colmonoy-6 hard facing provides a long-wearing surface, adequate for design life, to the area contacting the index tube and unlocking cam surface of the guide cap.

Graphitar-14 is selected for seals and bushings on the CRD piston and stop piston. The material is inert and has a low friction coefficient when water-lubricated. The Graphitar is relatively soft, which is advantageous when an occasional particle of foreign matter reaches a seal. The resulting scratches in the seal reduce sealing efficiency until worn smooth, but the CRD design can tolerate considerable water leakage past the seals into the RPV.

An alternate material approved for use in the seals and bushings in Graphitar-3030, due to its higher strength and superior wear resistance characteristics.

All CRD components exposed to RPV water are made of AISI 300 series stainless steel except the following.

a. Seals and bushings on the CRD piston and stop piston are either Graphitar-14 or Graphitar-3030

b. All springs and members requiring spring action (collet fingers, coupling spud, and spring washers) are made of Inconel-750

c. The ball check valve is a Haynes Stellite cobalt-base alloy

d. Elastomeric O-ring seals are ethylene propylene

e. Collet piston rings are Haynes-25 alloy

f. Certain wear surfaces are hard-faced with Colmonoy-6

g. Nitriding by a proprietary new hard facing process and chromium plating is used in certain areas where resistance to abrasion is necessary

h. The CRD piston head is made of ARMCO 17-4Ph.

i. An alternate material acceptable for the index and piston tube is nitrided Grade XM-19SS.

j. An equivalent piston tube assembly contains an anti-rotation pin made of nickel-chromium-iron wire per GE spec B14H19.

Pressure-containing portions of the CRDs are designed and fabricated in accordance with requirements of Section III of the ASME B&PV Code.

4.5.2.2.2.3 Control Rod Drive Hydraulic System

The CRD hydraulic system supplies and controls the pressure and flow to and from the drives through hydraulic control units (HCUs). The water discharged from the CRDs during a scram flows through the HCUs to the scram discharge volume (SDV). The water discharged from a CRD during a normal control rod positioning operation flows through the HCU and the exhaust header, and is dispersed into the RPV via the HCUs of other nonmoving drives.

The CRD hydraulic system also supplies water for the reactor vessel instrumentation reference leg backfill system.

The CRD hydraulic system design is shown in Figure 4.5-15. The hydraulic requirements, identified by the function they perform, are as follows:

a. Normal accumulator hydraulic charging pressure is required. Flow to the accumulators is required only during scram reset or system startup

b. Drive pressure of approximately 250 psi above RPV pressure is required. A flow rate of approximately 4 gpm to insert a control rod and 2 gpm to withdraw a control rod is required

c. Cooling water to the CRDs is required at approximately 6 to 30 psi above RPV pressure and at a flow rate of approximately 0.3 gpm times the number of drive units. Cooling water can be interrupted for short periods without damaging the drive

d. The SDV is sized to receive and contain all the water discharged by the CRDs during a scram. A minimum volume of 3.34 gal per CRD is required.

The CRD hydraulic systems provide the required functions with the pumps, filter, valves, instrumentation, and piping shown in Figure 4.5-15 (Sheets 1 and 2) and described in the following paragraphs.

Duplicate components are included, where necessary, to ensure continuous system operation if an inservice component requires maintenance.

One supply pump pressurizes the system with water from the condensate treatment system or condensate storage tank. One spare pump is provided for standby. A discharge check valve prevents backflow through the nonoperating pump. A portion of the pump discharge flow is diverted through a minimum flow bypass line to the condensate storage tank. This flow is controlled by an orifice and is sufficient to prevent immediate pump damage if the pump discharge is inadvertently closed.

The primary source of water for the CRD system is the condensate treatment system. There are two pump suction filters installed in parallel for each CRD pump. The CRD pump operation has been demonstrated for many years at this level of filtration. The drive water filters have cleanable elements. One drive water filter is operated at a time. There are Y-strainers downstream of the drive water filters that protect the CRD hydraulic system in the event of filter-element failure. A sampling of the CRD system water is continuously delivered to the reactor water-sampling station for monitoring. Necessary corrective actions would be taken if a significant change in CRD system water quality were to result from the failure of a drive water filter. The total pressure drop across the drive-water filters is continuously monitored with an alarm on high pressure differential.

The CRD pump provides water for the reactor vessel instrumentation reference leg backfill system. A small amount of water is injected into two reference legs to prevent the accumulation of noncondensable gases. The backfill lines are tapped to the CRD charging water header.

Provisions have been taken to keep the water in the CRD hydraulic system from freezing. The CRD system is completely contained within the reactor building. This building is well heated and ventilated; it also receives most of the heat loss from the reactor system. It is therefore incredible that the temperature would drop below freezing while the plant is operating. The CRD system water supply is normally taken from the condensate demineralizers via the torus water management system; no portion of this line is outside the building. Backup supply is provided by the condensate storage tank. Subsection 9.2.6 describes the procedure used to keep the tank from freezing. The valve pit from the tank is only partially above grade. Heat sources into this valve pit are sufficient to keep the temperature well above freezing. The lines from the pit to the turbine building are 42 in. or more below grade and, consequently, are not subject to freezing.

Accumulator charging pressure is established by the discharge pressure of the system supply pump. During scram the scram inlet (and outlet) valves open and permit the stored energy in the accumulators to discharge into the CRDs. The resulting pressure decrease in the water header allows the CRD supply pump to increase flow rate substantially into the CRDs via the charging water header. The flow sensing system upstream of the accumulator charging header detects high flow and closes the flow control valve. This action maintains increased flow through the charging water header.

Pressure in the charging header is monitored in the main control room with a pressure indicator and low-pressure alarm.

The failure of a CRD pump or the plugging of a drive water filter would result in a loss of pressure in the CRD charging water header, which directly feeds each hydraulic control unit accumulator. The effect that this can have on the ability to scram the rods is minimized for the following reasons:

a. At reactor pressures greater than 600 psig, the rods can scram with specified insertion times independent of the accumulator pressure

b. If header pressure were lost because of CRD pump failure, the operator could readily restore header pressure by bringing the second pump on line

c. If header pressure were lost because of filter plugging, the parallel filter could be brought into service

d. Accumulator depressurization is prevented by check valve No. 115 (see Figure 4.5-15) to retain accumulator scram capability, especially if reactor pressure is below 600 psig.

Each accumulator is monitored with a pressure switch that activates individual low pressure alarms that have setpoints which are above the limit established in the Technical Specifications. An alarm annunciates for any accumulator at or before the pressure reaches the setpoint value provided in the Technical Specifications. The setpoint value has been conservatively established by the design to assure a margin of accumulator operability sufficient to scram the associated control rod.

By design, control rod scram can be accomplished without the accumulator pressure when the reactor vessel pressure is at or above 600 psig. If the reactor were operating at a pressure of less than 600 psig, a manual scram would be required upon receipt of the first accumulator low pressure alarm that follows a loss of charging water header pressure. This design required manual scram is a very conservative action because the core is designed to be shut down from all operating conditions with the most reactive control rod fully withdrawn. The plant operating procedures call for a manual scram at a reactor pressure limit above the design 600 psig as required by the Technical Specifications in case of a loss of accumulator function. This additional conservatism of the Technical Specifications adds more margin to assure the scram function during plant power operation, startup or refueling when applicable.

The manual scram capability of the accumulators is periodically verified by a pressure drop surveillance to confirm that operators have at least 10 minutes of accumulator scram capability upon loss of control rod drive system hydraulic charging capability.

During normal operation, the flow control valve maintains a constant system flow rate. This flow is used for drive flow, drive cooling, and system stability.

Control rod drive water pressure required in the drive header is maintained by the drive pressure control valve, which is manually adjusted from the main control room. A flow rate of approximately 6 gpm (the sum of the flow rate required to insert and withdraw a control rod) normally passes from the CRD water pressure stage through two solenoid-operated stabilizing valves (arranged in parallel) and then goes into the cooling water line downstream from the drive/cooling-water pressure control valve. The flow through one stabilizing valve equals the drive insert flow; that of the other stabilizing valve equals the CRD withdrawal flow. When a CRD is operated, the required flow is diverted to that CRD while closing the appropriate stabilizing valve. Thus, flow through the CRD pressure control valve is always constant.

Flow indicators in the CRD water header and in the line downstream from the stabilizing valves allow the flow rate through the stabilizing valves to be adjusted when necessary. Differential pressure between the RPV and the CRD pressure stage is indicated in the main control room.

The cooling water header is located downstream from the drive/ cooling water pressure control valve. The cooling water pressure control valve is manually adjusted from the main control room to produce the required cooling water pressure. The flow through the flow control valve is virtually constant. Therefore, once adjusted, the drive/cooling water pressure control valve can maintain its required pressure independent of reactor pressure. Changes in setting of the pressure control valves are required only to adjust for changes in the cooling requirements of the CRDs, as their seal characteristics change with time.

Failure of the drive/cooling water pressure control valve in the full-open or full-closed position would cause some perturbation in CRD system operation, but it does not present a safety problem or affect the scram capability of the CRD system. If the pressure control valve (PCV) were to fail to a full-open position, the cooling water pressure would increase and the drive water pressure would decrease. The resulting cooling water pressure increase could cause control rods to drift inward. The existence of rod drifts would be alarmed to the control room operator for appropriate action. The resulting drop in drive water pressure would make normal control rod notch movements impossible, but would not affect the ability of the scram function. Conversely, if the PCV were to fail to a full-closed position, the cooling water pressure would decrease while the drive water pressure would increase. The reduction in cooling water pressure (and flow) would eventually lead to high CRD temperature being alarmed in the control room. In the limiting case, the resulting increase in drive water pressure would reach the shutoff pressure of the supply pump (1600 psig). The occurrence of this condition during withdrawal of a drive at zero reactor pressure will result in a drive pressure increase from 260 psig to no more than 1600 psig. Calculations indicated that the drive would accelerate from 3 in./sec to approximately 6 in./sec. The rod movement would stop as soon as the driving signal is removed. In both of the cases described above, the manually operated bypass PCV, in conjunction with isolation valves upstream and downstream of the primary PCV, would enable the operators to take corrective action.

A flow indicator in the main control room monitors cooling water flow. A differential pressure indicator in the main control room indicates the difference between RPV pressure and CRD cooling water pressure. The temperature of each CRD is recorded in the relay room, and excessive temperatures are annunciated by a control room alarm.

Exhaust water from a moving drive is dispersed to the RPV via the HCUs of nonmoving drives.

In order to eliminate the problem of cracking of the CRD return line (CRDRL), the CRDRL was removed and the CRDRL nozzles were capped. The modification meets the requirements of NRC (Reference 13), on the subject of CRDRL removal as follows:

a. Equalizing valves between the cooling water header and the normal drive movement exhaust water header have been incorporated

b. Exhaust water headers have been changed to stainless steel

c. The flow stabilizer loop is stainless steel and is routed directly to the cooling water header.

All modifications were constructed and inspected consistent with the applicable sections of the ASME B&PV Code.

Figure 4.5-15 shows the CRD hydraulic system with the return line eliminated. The reactor water makeup capability of the CRD system with this modification is 135 gpm at 1110 psig reactor vessel pressure (before the modification, the makeup capability was 170 gpm).

The SDV consists of header piping, which connects to each HCU and drains into an instrument volume. The header piping is sized to receive and contain all the water discharged by the CRDs during a scram, independent of the instrument volume. Each of the two sets of headers has a directly connected scram discharge instrument volume attached to the low point of the header piping. Thus, the large-diameter pipe of the instrument volume serves as a vertical extension of the SDV (although no credit is taken for it in determining scram discharge volume requirements).

During normal plant operation, the SDV is empty and vented to atmosphere through its open vent and drain valve. When a scram occurs, upon a signal from the safety circuit, these vent and drain valves are closed to conserve reactor water. Lights in the main control room indicate the position of these valves. Redundant vent and drain valves are provided to ensure against loss of reactor coolant from the SDV following a scram.

During a scram, the SDV partly fills with water discharged from above the drive pistons. While scrammed, the CRD seal leakage from the reactor continues to flow into the SDV until the discharge volume pressure equals the RPV pressure. A check valve in each HCU prevents reverse flow from the scram discharge header volume to the CRD. When the scram signals are cleared from the reactor protection system (RPS), the SDV signal is overridden with a keylock override switch, and the scram discharge volume is drained and returned to atmospheric pressure.

Remote manual switches in the pilot valve solenoid circuits allow the discharge volume vent and drain valves to be tested without disturbing the RPS. Closing the SDV valves allows the outlet scram valve seats to be leak tested by timing the accumulation of leakage inside the scram discharge volume.

Four liquid level switches and two level transmitters connected to each instrument volume monitor the volume for abnormal water level. They provide redundant and diverse inputs to the RPS scram function and provide inputs for control room annunciation and control rod withdrawal block functions (see Figure 4.5-15).

Each level transmitter provides input to actuate a trip unit. Three different level setpoints are used. At the lowest level, a level switch actuates to indicate that the volume is not completely empty during postscram draining or to indicate that the volume starts to fill through leakage accumulation at other times during reactor operation. At the second level, one level switch produces a rod withdrawal block to prevent further withdrawal of any control rod when leakage accumulates to approximately half the capacity of the instrument volume. The remaining two switches and two transmitter-actuated trip units are interconnected with the trip channels of the RPS and initiate a reactor scram should water accumulation fill the instrument volume.

Modifications of the SDV instrumentation and vent and drain valves were made to meet the criteria stated in the NRC's Generic Safety Evaluation Report BWR Scram Discharge System, dated December 1, 1980.

The design deficiencies in the SDV that were identified in the Safety Evaluation Report (SER) were

a. Inadequate hydraulic coupling between the SDV headers and the instrument volume

b. Complex vent and drain piping connections to the SDV

c. Failure mechanisms for the instrument volume level instrumentation

d. Failure of the control air system resulting in the potential inability to scram.

Items a. and d. were not applicable to Fermi 2 because adequate coupling is ensured by the integral coupling of the 12-in. instrument volume to the 8-in. SDV header.

Criteria of the BWR Owners subgroup were used in the design for items b. and c. The vent and drain valves are redundant and routed as dedicated lines. The instrumentation was upgraded on each instrument volume.

The instrumentation connections are made to the instrument volume and not to the drain line. Each instrument volume has one alarm, one rod block, and four scram level instruments. The two new scram level instruments are diverse.

Hydraulic Control Units

Each HCU furnishes pressurized water, on signal, to a CRD unit. The CRD then positions its control rod as required. Operation of the electrical system that supplies scram and normal control rod positioning signals to the HCU is described in Subsections 7.2.1 and 7.7.1.

The basic components in each HCU are manual, pneumatic, and electrical valves; an accumulator; related piping; electrical connections; filters; and instrumentation (Figures 4.5-15 and 4.5-16). The components and their functions are described in the following paragraphs.

The insert CRD valve is solenoid operated and opens on an insert signal. The valve supplies drive water to the bottom side of the main CRD piston.

The insert exhaust valve also opens by solenoid on an insert signal. The valve discharges water from above the CRD piston to the exhaust water header.

The withdraw CRD valve is solenoid operated and opens on a withdraw signal. The valve supplies drive water to the top of the drive piston.

The solenoid-operated withdraw exhaust valve opens on a withdraw signal and discharges water from below the main CRD piston to the exhaust header. The withdraw exhaust valve also serves as the settle valve. The valve opens following any normal CRD insert, the valve stays open a little longer on a withdrawal. This allows the control rod and its CRD to settle back into the nearest latch position.

The speed control valves regulate the control rod insertion and withdrawal rates during normal operation. They are manually adjustable flow-control valves used to regulate the water flow to and from the volume beneath the main drive piston. A correctly adjusted valve does not require readjustment except to compensate for changes in CRD seal leakage.

The scram pilot valves are operated from the RPS trip system. Two scram pilot valves control both the scram inlet valve and the scram exhaust valve by depressurizing the scram air header. The scram pilot valves are identical, three-way, solenoid-operated, normally energized valves. Upon a loss of electrical signal to the pilot valves, such as the loss of external ac power, the inlet ports close and the exhaust ports open on both pilot valves. The pilot valves (Figure 4.5-15) are arranged so that the trip system signal must be removed from both valves before air pressure can be discharged from the scram valve operators. This prevents the inadvertent scram of a single CRD in the event of a failure of one of the solenoid pilot valves.

The scram exhaust valve opens slightly before the scram inlet valve, exhausting water from above the CRD piston. The exhaust valve opens faster than the inlet valve because of a larger spring in the valve operator. Otherwise the valves are similar.

The scram inlet valve opens to supply pressurized water to the bottom of the CRD piston. This quick-opening globe valve is operated by an internal spring and system pressure. It is closed by air pressure applied to the top of its diaphragm operator. A position-indicator switch on this valve energizes a light in the main control room as soon as both of the valves start to open.

The scram accumulator stores sufficient energy to fully insert a control rod at lower RPV pressures. At higher RPV pressures, the accumulator pressure is assisted or replaced by RPV pressure.

The accumulator is a hydraulic cylinder with a free-floating piston. The piston separates the water on top from the nitrogen below. A check valve in the accumulator charging line prevents loss of water pressure in the event supply pressure is lost.

During normal plant operation, the accumulator piston is seated at the bottom of its cylinder. Loss of nitrogen decreases the nitrogen pressure, and this actuates a pressure switch that sounds an alarm in the main control room.

To ensure that the accumulator is always able to produce a scram, it is continuously monitored for water leakage. A float-type level switch actuates an alarm if water leaks past the piston barrier and collects in the accumulator instrumentation block.

4.5.2.2.2.4 Control Rod Drive System Operation

The CRD system performs rod insertion, rod withdrawal, and scram. These operational functions are described in the following paragraphs.

Rod insertion is initiated by a signal from the operator to the insert valve solenoids. This signal causes both insert valves to open. The insert CRD valve applies differential drive pressure of approximately 90 psi under the CRD piston. The insert exhaust valve allows water from above the CRD piston to discharge to the exhaust header.

As illustrated in Figure 4.5-12, the locking mechanism is a ratchet-type device and does not interfere with rod insertion. The speed at which the CRD moves is determined by the flow through the insert speed control valve, which is set for approximately 4 gpm for a shim speed (nonscram operation) of 3 in./sec. During normal insertion, the pressure is adjusted by the speed control valve to compensate for CRD pipe length losses.

Rod withdrawal is, by design, more involved than insertion. The collet finger (latch) must be raised to reach the unlocked position (see Figure 4.5-12). The notches in the index tube and the collet fingers are shaped so that the downward force on the index tube holds the collet fingers in place. The index tube must be lifted before the collet fingers can be released. This is done by opening the CRD insert valves (in the manner described in the preceding paragraph) for approximately 1 sec. The withdraw valves are then opened, applying driving pressure above the drive piston and opening the area below the piston to the exhaust header. As the piston rises, the collet fingers are cammed outward by the guide cap, away from the index tube.

The pressure required to release the latch is set and maintained at a level high enough to overcome the force of the latch return spring plus the force of reactor pressure opposing movement of the collet piston. When this occurs, the index tube is unlatched and free to move in the withdraw direction. Water displaced by the CRD piston flows out through the withdraw speed control valve, which is set to give the control rod a shim speed of 3 in./sec. The entire valving sequence is automatically controlled and is initiated by a single operation of the rod withdraw switch.

During a scram, the scram pilot valves and scram valves are operated as previously described. With the scram valves open, accumulator pressure is admitted under the CRD piston, and the area over the drive piston is vented to the SDV.

The large differential pressure (depending on charging water header pressure and RPV pressure) produces a large upward force on the index tube and control rod. This force gives the rod a high initial acceleration and provides a large margin of force to overcome any possible friction. After the initial acceleration is achieved, the CRD continues at a nearly constant velocity. This characteristic provides a high initial rod insertion rate. As the CRD piston nears the top of its stroke, the piston seals close off the flow passages (buffer orifices) in the piston tube, and the CRD slows.

Prior to a scram signal and assuming the accumulator is normally charged, the inlet scram valve opens and the full water-side pressure is available at the CRD acting on a 4.1-in.^{2} area. As CRD motion begins, this pressure drops to the gas-side pressure less line losses between the accumulator and the CRD. At low RPV pressures, the accumulator completely discharges with a resulting gas-side pressure of approximately 575 psig. At reactor operating pressure, the accumulator only partially discharges, with reactor pressure providing the necessary scram force when reactor pressure exceeds scram accumulator pressure.

The CRD accumulators are required to scram the control rod when the reactor pressure is low. When the reactor pressure is low, the accumulator retains sufficient stored energy to ensure the complete insertion of the control rod in the required time. The accumulator is not required in order to scram the control rod in time when the reactor is close to or at full operating pressure. In this instance, the reactor pressure alone scrams the control rod in the required time. However, the accumulator does provide an additional energy boost to the reactor pressure in providing scram action at RPV pressures less than accumulator pressures.

The CRD system, with accumulators, provides the following scram performances at full-power operation, in terms of elapsed time after deenergization of the scram pilot valve solenoids for the drives to attain the scram strokes listed in the table below. The scram insertion time is an analytical limit that assures the scram reactivity curve used in the transient analyses is met. Some control rods can be slower than the listed scram insertion times as long as others are faster so that the analytical scram reactivity curve is met. (Reference 12)

Position Inserted From Fully Withdrawn	Scram Insertion Time (sec)
46	0.457
36	1.084
26	1.841
6	3.361

The alternative rod insertion (ARI) feature provides an alternative means for initiating scram if there is a failure in the electrical portion of the RPS during an operational transient that normally requires a reactor scram. The ARI enables the insertion of reactor control rods by depressurizing the scram pilot valve air header through valves that are redundant and diverse from the RPS-initiated backup scram valves.

The redundant reactivity system signal to insert control rods results in energizing the eight ARI solenoid valves. Two ARI valves in series with the backup scram valves also have parallel functioning check valves to vent air from the air supply line in case an ARI valve fails. These two valves and four other ARI valves vent the A and B hydraulic control unit scram valve pilot air headers to the atmosphere in order to depressurize the headers and scram all rods. Two additional valves vent the portion of the scram air header that serves the scram discharge volume drain and vent lines, closing the vent and drain valves and isolating the SDV. (See also Subsection 7.6.1.18.)

4.5.2.2.3 Evaluation of Scram Time

The rod scram function of the CRD system provides the negative reactivity insertion required by the safety design basis (c.1) in Subsection 4.5.2.2.1.1. The scram time shown in the description is adequate as shown by the transient analyses of Section 15.1. Sufficient driving force is available to overcome the retarding force during a scram. The control rod weighs 154 lb in water and 183 lb in air. The index tube weighs 62 lb in water and 71 in air. Other moving parts weigh about 5 lb so the wet drive line weight is about 225 lb.

At the start of motion, assuming the accumulator is normally charged, the CRD pump will be supplying charging water at a pressure greater than RPV pressure at the inlet scram valve. This supplies a large differential to assist opening of the valve and exists until drive motion starts. Pressure at the CRD immediately drops to reactor pressure due to losses in the piping and valves, and reactor pressure is applied through the ball check valve in the CRD. This pressure is actually slightly less than reactor pressure caused by flow losses as the water comes down the annulus between the CRD and thermal sleeve. The pressure is applied to the 4.1-in.^{2} under piston area. The area above the piston, 1.25 in.^{2}, is vented to the SDV, and initially drops to atmospheric pressure. As soon as drive motion starts, line losses in the discharge line raise the pressure over the piston to about 180 psi. The balance of the over-piston area (4.1 minus 1.25 in.^{2}) is exposed to reactor pressure. Available force, assuming a stuck rod, reduces simply to 1.25 x 1000 or 1250 lb throughout the stroke after accumulator energy is expended. Since the available force is constant at 1250 lb from the beginning of motion to the end of the strokes, no plot of the force developed by the CRD mechanism versus stroke for a scram with the accumulator and RPV at nominal pressure is necessary.

4.5.2.2.3.1 Analysis of Malfunction Relating to Rod Withdrawal

There are no known single malfunctions that cause the unplanned withdrawal of even a single control rod. However, if multiple malfunctions are postulated, studies show that an unplanned rod withdrawal can occur at withdrawal speeds that vary with the combination of malfunctions postulated. In all cases the subsequent withdrawal speeds are less than that assumed in the control rod drop accident analysis as discussed in Subsection 15.4.9.

Therefore, the physical and radiological consequences of such rod withdrawals are less than those analyzed in the control rod drop accident.

Drive Housing Fails at Attachment Weld

The bottom head of the RPV has a penetration for each CRD location. A CRD housing is raised into position inside each penetration and fastened by welding. The CRD is raised into the CRD housing and bolted to a flange at the bottom of the housing. The housing material is seamless, type 304 stainless steel pipe with a minimum tensile strength of 75,000 psi. The basic failure considered here is a complete circumferential crack through the housing wall at an elevation just below the J-weld.

Static loads on the housing wall include the weight of the CRD and the control rod, the weight of the housing below the J-weld, and the reactor pressure acting on the 6-in.-diameter cross-sectional area of the housing and the CRD. Dynamic loading results from the reaction force during CRD operation.

If the housing were to fail as described, the following sequence of events is foreseen. The housing would separate from the RPV. The control rod, CRD, and housing would be blown downward against the support structure by reactor pressure acting on the cross-sectional area of the housing and the CRD. The downward motion of the CRD and associated parts would be determined by the gap between the bottom of the CRD and the support structure and by the deflection of the support structure under load. In the current design, maximum deflection is approximately 3 in. If the collet were to remain latched, no further control rod ejection would occur (Reference 9); the housing would not drop far enough to clear the RPV penetration. Reactor water would leak at a rate of approximately 180 gpm through the 0.03-in. diametral clearance between the housing and the RPV penetration.

If the basic housing failure were to occur while the control rod is being withdrawn (this is a small fraction of the total CRD operating time), and if the collet were to stay unlatched, the following sequence of events is foreseen: the housing would separate from the RPV and the drive and housing would be blown downward against the CRD housing support. Calculations indicate that the steady-state rod withdrawal velocity would be 0.3 fps. During withdrawal, pressure under the collet piston would be approximately 250 psi greater than the pressure over it. Therefore, the collet would be held in the unlatched position until driving pressure was removed from the pressure-over port.

Rupture of Hydraulic Line(s) to Control Rod Drive Housing Flange

There are three types of possible rupture of hydraulic lines to the CRD housing flange:

a. Pressure-under line break

b. Pressure-over line break

c. Coincident breakage of both of these lines.

For the case of a pressure-under line break, a partial or complete circumferential opening is postulated at or near the point where the line enters the housing flange. Failure is more likely to occur after another basic failure wherein the CRD housing or housing flange separates from the RPV. Failure of the housing, however, does not necessarily lead directly to failure of the hydraulic lines.

If the pressure-under line were to fail and if the collet were latched, no control rod withdrawal would occur. There would be no pressure differential across the collet piston and therefore no tendency to unlatch the collet. Consequently, the associated control rod could not be inserted or withdrawn.

The ball check valve is designed to seal off a broken pressure-under line by using reactor pressure to shift the check ball to its upper seat. If the ball check valve were prevented from seating, reactor water would leak to the atmosphere. Because of the broken line, cooling water could not be supplied to the CRD involved. Loss of cooling water would cause no immediate damage to the CRD. However, prolonged exposure of the CRD to temperatures at or near reactor temperature could lead to deterioration of material in the seals. High temperature would be indicated to the operator by the thermocouple in the position-indicator probe. A second indication would be high cooling water flow.

If the basic line failure were to occur while the control rod is being withdrawn, the hydraulic force would not be sufficient to hold the collet open, and spring force normally would cause the collet to latch and stop rod withdrawal. However, if the collet were to remain open, calculations indicate that the steady-state control rod withdrawal velocity would be 2 fps.

The case of the pressure-over line break considers the complete breakage of the line at or near the point where it enters the housing flange. If the line were to break, pressure over the CRD piston would drop from reactor pressure to atmospheric pressure. Any significant reactor pressure (approximately 600 psig or greater) would act on the bottom of the CRD piston and fully insert the CRD. Insertion would occur regardless of the operational mode at the time of the failure. After full insertion, reactor water would leak past the stop piston seals, the contracting seals on the drive piston, and the collet piston seals. This leakage would exhaust to the atmosphere through the broken pressure-over line. The leakage rate at 1000 psi reactor pressure is estimated to be 4 gpm nominal but not more than 80 gpm, based on experimental measurements. If the reactor were hot, drive temperature would increase. This situation would be indicated to the reactor operator by the drift alarm, by the fully inserted drive, by a high drive temperature (indicated and printed out on a recorder in the relay room), and by operation of the drywell sump pump.

For the simultaneous breakage of the pressure-over and pressure-under lines, pressures above and below the CRD piston would drop to zero, and the ball check valve would close the broken pressure-under line. Reactor water would flow from the annulus outside the CRD, through the RPV ports, and to the space below the drive piston. As in the case of pressure-over line breakage, the CRD would then insert (if the reactor were above 600 psi) at a speed dependent on reactor pressure. Full insertion would occur regardless of the operational mode at the time of failure. Reactor water would leak past the CRD seals and out the broken pressure-over line to the atmosphere, as described previously. Control rod drive temperature would increase. Indication in the main control room would include the drift alarm, the fully inserted CRD, the high CRD temperature printed out on a recorder in the relay room, and operation of the drywell sump pump.

For the evaluation of CRD hydraulic line failures outside the containment, see Subsection 3.6.2.2.6.

<u>All Control Rod Drive Flange Bolts Fail in Tension</u>

Each CRD is bolted to a flange at the bottom of a CRD housing. The flange is welded to the CRD housing. Bolts are made of AISI-4140 steel, with a minimum tensile strength of 125,000 psi. Each bolt has an allowable load capacity of approximately 15,700 lb. Capacity of the eight bolts is approximately 125,800 lb. As a result of the reactor design pressure of l250 psig, the major load on all eight bolts is approximately 45,000 lb.

If a progressive or simultaneous failure of all bolts were to occur, the CRD would separate from the housing. The control rod and the CRD would be blown downward against the support structure. Impact velocity and support structure loading would be slightly less than that for CRD housing failure, because reactor pressure would act on the CRD cross-sectional area only and the housing would remain attached to the RPV. The CRD would be isolated from the cooling-water supply. Reactor water would flow downward past the velocity limiter piston, through the large CRD filter, and into the annular space between the thermal sleeve and the CRD. For worst-case leakage calculations, the large filter is assumed to be deformed or swept out of the way so it would offer no significant flow restriction. At a point near the top of the annulus, where pressure would have dropped to 350 psi, the water would flash to steam and cause choke-flow conditions. Steam would flow down the annulus and out the space between the housing and the CRD flanges to the atmosphere. Steam formation would limit the leakage rate to approximately 840 gpm.

If the collet were latched, control rod ejection would be limited to the distance the CRD can drop before coming to rest on the support structure. There would be no tendency for the collet to unlatch, because pressure below the collet piston would drop to zero. Pressure forces, in fact, exert l435 lb to hold the collet in the latched position.

If the bolts failed during control rod withdrawal, pressure below the collet piston would drop to zero. The collet, with l650 lb return force, would latch and stop rod withdrawal.

<u>Weld Joining Flange to Housing Fails in Tension</u>

The failure considered is a crack in or near the weld that joins the flange to the housing. This crack extends through the wall and completely around the housing. The flange material is forged, type 304 stainless steel, with a minimum tensile strength of 75,000 psi. The housing material is seamless, type 304 stainless steel pipe, with a minimum tensile strength of 75,000 psi. The conventional, full-penetration weld of type 308 stainless steel has a minimum tensile strength approximately the same as that of the parent metal. The design pressure and temperature are l250 psig and 575°F. Reactor pressure acting on the cross-sectional area of the CRD; the weight of the control rod, CRD, and flange; and the dynamic reaction force during CRD operation result in a maximum tensile stress at the weld of approximately 6000 psi.

If the basic flange-to-housing joint failure occurred, the flange and the attached CRD would be blown downward against the support structure. The support structure loading would be slightly less than that for CRD housing failure, because reactor pressure would act only on the CRD cross-sectional area. Lack of differential pressure across the collet piston would cause the collet to remain latched and limit control rod motion to approximately 3 in. Downward CRD movement would be small; therefore, most of the CRD would remain inside the housing. The pressure-under and pressure-over lines are flexible enough to withstand the small displacement and remain attached to the flange. Reactor water would follow the same leakage path described above for the flange-bolt failure, except that exit to the atmosphere would be through the gap between the lower end of the housing and the top of the flange. Water would flash to steam in the annulus surrounding the CRD. The leakage rate would be approximately 840 gpm.

If the basic failure were to occur during control rod withdrawal (a small fraction of the total operating time) and if the collet were held unlatched, the flange would separate from the housing. The CRD and flange would be blown downward against the support structure. The calculated steady-state rod withdrawal velocity would be 0.13 fps. Because pressure-under and pressure-over lines remain intact, driving water pressure would continue to the CRD, and the normal exhaust line restriction would exist. The pressure below the velocity limiter piston would drop below normal as a result of leakage from the gap between the housing and the flange. This differential pressure across the velocity limiter piston would result in a net downward force of approximately 70 lb. Leakage out of the housing would greatly reduce the pressure in the annulus surrounding the CRD. Thus, the net downward force on the CRD piston would be less than normal. The overall effect of these events would be to reduce rod withdrawal to approximately one-half normal speed. With a 560-psi differential across the collet piston, the collet would remain unlatched; however, it should relatch as soon as the CRD signal is removed.

Housing Wall Ruptures

This failure is a vertical split in the CRD housing wall just below the bottom head of the RPV. The flow area of the hole is considered equivalent to the annular area between the CRD and the thermal sleeve. Thus, flow through this annular area, rather than flow through the hole in the housing, would govern leakage flow. The housing is made of type 304 stainless steel seamless pipe, with a minimum tensile strength of 75,000 psi. The maximum hoop stress of 5530 psi results primarily from the reactor design pressure (1250 psig) acting on the inside of the housing.

If such a rupture were to occur, reactor water would flash to steam and leak through the hole in the housing to the atmosphere at approximately 1030 gpm. Choke-flow conditions would exist, as described above for the flange-bolt failure. However, leakage flow would be greater because flow resistance would be less; that is, the leaking water and steam would not have to flow down the length of the housing to reach the atmosphere. A critical pressure of 350 psi causes the water to flash to steam.

No pressure differential across the collet piston would tend to unlatch the collet; but the CRD would insert as a result of loss of pressure in the CRD housing, causing a pressure drop in the space above the CRD piston.

If this failure occurred during control rod withdrawal, CRD withdrawal would stop, but the collet would remain unlatched. The CRD would be stopped by a reduction of the net downward force on the CRD line. The net force reduction would occur when the leakage flow of 1030 gpm reduces the pressure in the annulus outside the CRD to approximately 540 psig, thereby reducing the pressure acting on top of the CRD piston to the same value. A pressure differential of approximately 710 psi would exist across the collet piston and hold the collet unlatched as long as the operator held the withdraw signal.

Flange Plug Blows Out

To connect the RPV ports with the bottom of the ball check valve, a hole of 3/4-in. diameter is drilled in the CRD flange. The outer end of this hole is sealed with a plug of 0.812-in. diameter and 0.250-in. thickness. A full-penetration, type 308 stainless steel weld holds the plug in place. The postulated failure is a full circumferential crack in this weld and subsequent blowout of the plug.

If the weld was to fail, the plug was to blow out, and the collet remained latched, there would be no control rod motion. There would be no pressure differential across the collet piston acting to unlatch the collet. Reactor water would leak past the velocity limiter piston, down the annulus between the CRD and the thermal sleeve, through the RPV ports and drilled passage, and out the open plug hole to the atmosphere at approximately 320 gpm. Leakage calculations assume only liquid flows from the flange. Actually, hot reactor water would flash to steam, and choke-flow conditions would exist. Thus, the expected leakage rate would be lower than the calculated value. Control rod temperature would increase and initiate an alarm in the control room.

If this failure were to occur during control rod withdrawal and if the collet were to stay unlatched, calculations indicate that control rod withdrawal speed would be approximately 0.24 fps. Leakage from the open plug hole in the flange would cause reactor water to flow downward past the velocity limiter piston. A small differential pressure across the piston would result in an insignificant driving force of approximately 10 lb, tending to increase withdrawal velocity.

A pressure differential of 295 psi across the collet piston would hold the collet unlatched as long as the driving signal was maintained.

Flow resistance of the exhaust path from the CRD would be normal because the ball check valve would be seated at the lower end of its travel by pressure under the CRD piston.

<u>Ball Check Valve Plug Blows Out</u>

As a means of access for machining the ball check valve cavity, a 1.25-in.-diameter hole has been drilled in the flange forging. This hole is sealed with a plug of 1.31-in. diameter and 0.38-in. thickness. A full-penetration weld, utilizing type 308 stainless steel filler, holds the plug in place. The failure postulated is a circumferential crack in this weld leading to a blowout of the plug.

If the plug were to blow out while the drive was latched there would be no control rod motion. No pressure differential would exist across the collet piston to unlatch the collet. As in the previous failure, reactor water would flow past the velocity limiter, down the annulus between the drive and thermal sleeve, through the vessel ports and drilled passage, through the ball check valve cage, and out the open plug hole to the drywell. The leakage calculations indicate the flow rate would be 350 gpm. This calculation assumes liquid flow, but flashing of the hot reactor water to steam would reduce this rate to a lower value.

Drive temperature would rapidly increase and initiate an alarm in the control room.

If the plug failure were to occur during control rod withdrawal (it would not be possible to unlatch the drive <u>after</u> such a failure), the collet would relatch at the first locking groove. If the collet were to stick, calculations indicate the control rod withdrawal speed would be 11.8 fps. There would be a large retarding force exerted by the velocity limiter because of a 35-psi pressure differential across the velocity limiter piston.

Control Rod Drive Pressure Control Valve Closure (Reactor Pressure, 0 psig)

The pressure to move a CRD is controlled by adjustment of the drive/cooling water pressure control valve. This valve is motor-operated and adjusted to a fixed opening. The normal pressure drop across this valve is 230 psi.

If the flow through the CRD pressure control valve were to be stopped, as by a valve closure or flow blockage, the CRD pressure would increase to the shutoff pressure of the supply pump. The occurrence of this condition during withdrawal of a CRD at zero RPV pressure will result in a CRD pressure increase from 260 psig to no more than 1600 psig. Calculations indicate that the drive would accelerate from 3 in./sec to approximately 6 in./sec. A pressure differential of l670 psi across the collet piston would hold the collet unlatched. Flow would be upward, past the velocity limiter piston, but retarding force would be negligible. Rod movement would stop as soon as the driving signal was removed.

Ball Check Valve Fails To Close Passage to Reactor Pressure Vessel Ports

Should the ball check valve sealing the passage to the RPV ports be dislodged and prevented from reseating following the insert portion of a CRD withdrawal sequence, water below the CRD piston would return to the reactor through the RPV ports and the annulus between the CRD and the housing rather than through the speed control valve. Because the flow resistance of this return path would be lower than normal, the calculated withdrawal speed would be 2 fps. During withdrawal, differential pressure across the collet piston would be approximately 40 psi. Therefore, the collet would tend to latch and would have to stick open before continuous withdrawal at 2 fps could occur. Water would flow upward past the velocity limiter piston, generating a small retarding force of approximately 120 lb.

Hydraulic Control Unit Valve Failures

Various failures of the valves in the HCU can be postulated, but none could produce differential pressures approaching those described in the preceding paragraphs and none alone could produce a high velocity withdrawal. Leakage through either one or both of the scram valves produces a pressure that tends to insert the control rod rather than to withdraw it. If the pressure in the scram discharge volume should exceed reactor pressure following a scram, a check valve in the line to the scram discharge header prevents this pressure from operating the CRD mechanisms.

Collet Fingers Fail To Latch

The failure is presumed to occur when the drive withdraw signal is removed. If the collet fails to latch, the drive continues to withdraw at a fraction of the normal speed. This assumption is made because there is no known means for the collet fingers to become unlocked without some initiating signal. Because the collet fingers will not cam open under a load, accidental application of a down signal does not unlock them. (The drive must be given a short insert signal to unload the fingers and cam them open before the collet can be driven to the unlock position.) If the drive withdrawal valve fails to close following a rod withdrawal, the collet would remain open and the drive continue to move at a reduced speed.

Withdrawal Speed Control Valve Failure

Normal withdrawal speed is determined by differential pressures in the CRD and is set for a nominal value of 3 in./sec. Withdrawal speed is maintained by the pressure regulating system and is independent of RPV pressure. Tests have shown that accidental opening of the speed control valve to the full-open position produces a velocity of approximately 6 in./sec. The CRD system prevents rod withdrawal and it has been shown above that only multiple failures in a CRD unit and in its control unit could cause an unplanned rod withdrawal.

4.5.2.2.3.2 Scram Reliability

High scram reliability is the result of a number of features of the CRD system. For example

a. An individual accumulator is provided for each control rod drive with sufficient stored energy to scram at lower reactor pressures. The reactor vessel itself, at pressures above 600 psi, will supply the necessary force to insert a drive

b. Each drive mechanism has its own scram and pilot valves so only one drive can be affected if a scram valve fails to open. Two pilot valves are provided for each drive. Both pilot valves must be deenergized to initiate a scram

c. The RPS and the HCUs are designed so that the scram signal and mode of operation override all others

d. The collet assembly and index tube are designed so they will not restrain or prevent control rod insertion during scram

e. The SDV is monitored for accumulated water and will scram the reactor before the volume is reduced to a point that could interfere with a scram.

4.5.2.2.3.3 Control Rod Support and Operation

Each control rod is independently supported and controlled as required by safety design bases.

4.5.2.2.3.4 Common Mode Failures of Reactivity Control Systems

The CRD system and the standby liquid control system (SLCS), which is the backup reactivity control system, do not share any instrumentation or components. Thus, a common mode failure of the reactivity systems would be limited to an accident event that could damage essential equipment in the two independent systems.

A seismic event or the postulated accident environments are not considered potential common mode failures because the essential (scram) portions of the CRD system are designed to Category I standards and to operate as required under the environmental conditions of the postulated design-basis accident. The SLCS is tested and maintained as a safety-related system.

No common mode power failure is considered credible. The scram function of the CRD system is fail-safe on a loss of power and is designed to override any other function of the CRD system. The SLCS has two independent power supplies to its essential redundant pumps and valves. The power supplies to the SLCS are switched to the onsite standby diesels on a loss of normal power sources.

The design of the SDV incorporates separate instrument volumes for each division of CRDs. Each SDV 8-in. header is integrally coupled to its 12-in. instrument volume. This design is not susceptible to the common mode problem of earlier designs caused by a 2-in. line connecting the SDVs to a single instrument volume.

General Electric completed a reliability analysis of the BWR scram system in 1976. The overall probability of failure was assessed to be 5 x 10^{-6} per year. The major contributor to this failure probability value was a common mode failure in the electrical trip circuit. The analysis identified design modifications that were made and that reduced the failure probability value to less than 1 x 10^{-7} per year.

The most recent analysis of CRD system reliability, which takes into account the design changes directed at reducing the potential for common mode failure in the mechanical portion of the CRD system (i.e., changes in the SDV), reaffirms that the CRD unreliability value is still estimated to be less than 1 x 10^{-7} per year.

NOTE: General Electric defined failure to be noninsertion of the CRDs in the following manner: greater than 50 percent in a checkerboard pattern, greater than 31 percent in a random pattern, or more than 4 in a cluster.

4.5.2.2.4 Inspection and Testing

4.5.2.2.4.1 Development Tests

The development drive (one prototype) testing up to the submittal of the original FSAR included more than 5000 scrams and approximately 100,000 latching cycles. One prototype was exposed to simulated operating conditions for 5000 hr. These tests yielded the following results:

a. The drive easily withstands the forces, pressures, and temperatures imposed

b. Wear, abrasion, and corrosion of the nitrided type 304 stainless steel parts are negligible. Mechanical performance of the nitrided surface is superior to that of materials used in earlier operating reactors

c. The basic scram speed of the CRD has a satisfactory margin above minimum plant requirements at any RPV pressure

d. Usable seal lifetimes in excess of l000 scram cycles can be expected.

4.5.2.2.4.2 Factory Quality Control Tests

Quality control of welding, heat treatment, dimensional tolerances, material verification, and similar factors is maintained throughout the manufacturing process to ensure reliable performance of the mechanical reactivity control components. Some of the quality control tests performed on the CRD mechanisms and HCUs follow.

a. Control rod drive mechanism tests

    1. Pressure welds on the CRDs are hydrostatically tested in accordance with ASME codes

    2. Electrical components are checked for electrical continuity and resistance to ground

3. Control rod drive parts that cannot be visually inspected for dirt are flushed with filtered water at high velocity. No significant foreign material is permitted in effluent water
4. Seals are tested for leakage to demonstrate correct seal operation
5. Each CRD is tested for shim motion, latching, and control rod position indication
6. Each drive is subjected to cold scram tests at various reactor pressures to verify correct scram performance.

b. <u>Hydraulic-control unit tests</u>

1. Hydraulic systems are hydrostatically tested in accordance with the applicable code
2. Electrical components and systems are tested for electrical continuity and resistance to ground
3. Correct operation of the accumulator pressure and level switches is verified
4. The unit's ability to perform its part of a scram is demonstrated. Correct operation and adjustment of the insert and withdrawal valves are demonstrated.

4.5.2.2.4.3 <u>Operational Tests</u>

After installation, all rods and CRD mechanisms can be tested through their full stroke for operability.

During normal operation, each time a control rod is withdrawn a notch, the operator can observe the in-core monitor indications to verify that the control rod is following the CRD mechanism. All control rods that are partially withdrawn from the core can be tested for rod following by inserting or withdrawing the rod one notch and returning it to its original position, while the operator observes the in-core monitor indications.

To make a positive test of control rod to CRD coupling integrity, the operator can withdraw a control rod to the end of its travel and then attempt to withdraw the CRD to the overtravel position. Failure of the CRD to overtravel demonstrates rod-to-drive coupling integrity.

Hydraulic supply subsystem pressures can be observed from instrumentation in the main control room. Scram accumulator pressures can be observed on the nitrogen pressure gages.

4.5.2.2.4.4 <u>Acceptance Tests</u>

Criteria for acceptance of the individual CRD mechanisms and the associated control and protection systems were incorporated in specifications and test procedures covering three distinct phases: preinstallation, after installation prior to startup, and during startup testing.

The preinstallation specification defined criteria and acceptable ranges of such characteristics as seal leakage, friction, and scram performance under fixed test conditions, which must be met before the component can be shipped.

The after-installation, prestartup tests included normal and scram motion and were primarily intended to verify that piping, valves, electrical components, and instrumentation were properly installed. The test specifications included criteria and acceptable ranges for CRD speed, time settings, scram valve response times, and control pressures. These tests were intended more to document system condition than to test performance.

During initial preoperational testing, an observer who was in direct communication with the control room observed the operation of each individual control rod and verified that there was no binding or restriction to rod motion and listened for any scraping or binding noises that might signify rod misalignment. In addition, the friction of each CRD was measured as indicated by the differential pressure developed across the CRD piston during notch withdrawal. These differential pressure traces were compared against reference traces to ensure proper operation and the absence of abnormal friction.

As fuel was placed in the reactor, the startup test procedure was followed. The tests in this procedure are intended to determine that the initial operational characteristics meet the limits of the specifications over the range of primary coolant temperatures and pressures from ambient to operating. The initial testing program is described in Chapter 14.

4.5.2.2.4.5 Surveillance Tests

The surveillance requirements for the CRD system are included in the Technical Specifications.

To detect any increased friction of the control rods due to postulated bowing of the fuel channel boxes, Edison has committed to a surveillance program that includes guidelines for channel box rotation to minimize the potential for channel bowing. In addition, periodic channel box bow testing monitors for appropriate settle time and abnormal rod motion that can be attributable to bow. Settle time is assessed for every control rod movement from control rod position 46 to 00 during normal rod motion as well as during a test. Channel box friction measurements also monitor for channel bow. Analytical assessments are performed each cycle to keep track of high friction cells so mitigating actions can be employed to prevent control rod blade interference. Reference 15 details many of the acceptable channel box bow monitoring methods employed.

Fermi 2 has implemented a program that addresses a possible problem with IGSCC in the collet assembly of the CRD mechanism. The program is consistent with GE recommendations. It consists of the following three parts:

a. An augmented surveillance and inspection program

b. Modification of CRD operations to eliminate unnecessary thermal cycling

c. Modification of the CRD water supply to provide high-purity deaerated water to the CRD system during plant operation.

The Fermi 2 program consists of the following corresponding actions:

a. Each rod not fully inserted will be tested to confirm operability by inserting one or more notches in accordance with the frequency specified in the Technical Specifications.

   All CRDs removed from the reactor for maintenance or for access to inservice CRD housing inspections will have a dye penetrant examination made of the outer surface of the collet retainer tube. CRDMs which do not experience any performance problems and are removed for inspection undervessel, or to replace a flange o-ring, for example, will not require a dye penetrant examination. CRDMs that are rebuilt after seeing reactor service will receive a dye penetrant examination of the collet retainer tube. The criteria established by GE in Service Information Letter (SIL) 139 will be used to decide rejection. The term collet retainer tube refers to a portion of the outer tube, and replacement of a rejected collet retainer tube requires a new cylinder, tube, and flange subassembly

b. A CRD with a high-temperature alarm will not be cooled by giving it repeated drive signals.

c. The source of water for the CRD system has been changed to the condensate treatment system effluent with the condensate storage tank as backup. The water source is very pure and of very low oxygen content

   A flowing sample line downstream of the drivewater filter has been installed to provide for conductivity and oxygen grab sample measurement.

The use of high-purity deaerated water effects a significant increase in the time to crack formation. General Electric estimated that the time to crack initiation in current CRD collet retainer tubes may be increased by a factor of 100 with this reduction in dissolved oxygen content.

4.5.2.2.4.6 Instrumentation

The general functional requirements for the CRD are discussed in Subsection 4.5.2.1.5.

4.5.2.3 Supplementary Reactivity Control

4.5.2.3.1 Design Basis

The fuel rods containing supplementary reactivity control shall have sufficient mechanical strength to prevent displacement of their reactivity control material.

4.5.2.3.2 Description

The reactivity control requirements of the initial core load considerably exceed the equilibrium core requirements because all the fuel in the initial core loading is fresh. To meet the reactivity control requirements of the initial core load, or any core load with excess reactivity, gadolinia-urania fuel rods are placed in each enriched fuel assembly. Some assemblies contain more gadolinium than others to improve transverse power flattening.

Also, some assemblies contain axially distributed gadolinium to improve axial power flattening. For a detailed discussion of gadolinia fuels, refer to Subsection 4.3.2.

4.5.2.3.3 Safety Evaluation

The description shows that the gadolinia-urania fuel rods meet the design-basis requirements (Subsection 4.3.2).

4.5.2.3.4 Inspection and Testing

The same rigid quality control requirements observed for standard UO_2 fuel are employed in manufacturing gadolinia-urania fuel. Gadolinia-bearing UO_2 fuel pellets of a given enrichment and gadolinia concentration are maintained in separate groups throughout the manufacturing process. The percent enrichment and gadolinia concentration characterizing a pellet group are identified by a stamp on the pellet.

Fuel rods are individually numbered prior to loading of fuel pellets into the fuel rods for three reasons: to identify which pellet group is to be loaded in each fuel rod, to identify which position in the fuel assembly each fuel rod is to be loaded into, and to facilitate total material accountability for a given project. For the initial core, longer upper end plug shanks for gadolinia-bearing rods ensured their correct placement within the fuel assembly. For reload cores, a uniform end plug is used for all rods. Correct placement is ensured by an automated bundle assembly machine.

The following QC inspections are made.

a. Gadolinia concentration in the gadolinia-urania powder blend is verified

b. Sintered pellet UO_2-Gd_2O_3 solid-solution homogeneity across a fuel pellet is verified by examination of metallographic specimens

c. Gadolinia-urania pellet identification is verified

d. Gadolinia-urania fuel rod identification is checked.

All assemblies and rods of a given project are inspected to ensure overall accountability of fuel quantity and placement for the project.

4.5.2.4 Standby Liquid Control System

4.5.2.4.1 Design Bases

The standby liquid control system (SLCS) is a special-event plant capability system and is tested and maintained as a safety-related system. The system is designed with a high degree of reliability and with certain safety features; however, it is not required to meet the safety design-basis requirements of the safety systems. The SLCS process equipment, instrumentation and control essential for injection of the sodium pentaborate solution into the reactor are designed to withstand the safe shutdown earthquake.

The SLCS shall meet the following design bases:

a. Backup capability for reactivity control shall be provided, independent of normal reactivity control provisions in the nuclear reactor, to be able to shut down the reactor if the normal control ever becomes inoperative

b. The backup system shall have the capacity for controlling the reactivity difference between the steady-state rated operating condition of the reactor with voids and the cold shutdown condition, including shutdown margin, to ensure complete shutdown from the most reactive condition at any time in core life

c. The time required for actuation and effectiveness of the backup control shall be consistent with the nuclear reactivity rate of change predicted between rated operating and cold shutdown conditions. A fast scram of the reactor or operational control of fast reactivity transients is not specified to be accomplished by this system

d. Means shall be provided by which the functional performance capability of the backup control system components can be verified periodically under conditions approaching actual use requirements. A substitute solution, rather than the actual neutron absorber solution, can be injected into the reactor to test the operation of all components of the redundant control system

e. The neutron absorber shall be dispersed within the reactor core in sufficient quantity to provide a reasonable margin for leakage or imperfect mixing

f. The system shall be reliable to a degree consistent with its role as a control system; the possibility of unintentional or accidental shutdown of the reactor by this system shall be minimized

g. The system shall have the capability of controlling suppression pool pH following a LOCA in the event of fuel failure.

4.5.2.4.2 Description

The SLCS (Figure 4.5-17) is manually initiated from the main control room to pump a boron neutron absorber solution into the reactor if the operator believes the reactor cannot be shut down or kept shut down with the control rods. However, insertion of control rods is expected to ensure prompt shutdown of the reactor should it be required.

The SLCS is required to shut down the reactor and keep the reactor from going critical again as it cools. In addition, SLC is required to control suppression pool pH following a LOCA in the event of fuel failure.

The SLCS is needed in the improbable event that not enough control rods can be inserted in the reactor core to accomplish shutdown and cooldown in the normal manner.

The storage tank and active portion of the SLCS necessary for the injection of boron have been reclassified to identify that the SLCS was not originally intended, procured, designed, or classified as safety related, but is being maintained and tested as a safety-related system after completion of its preoperational tests.

The boron solution tank, the test water tank, the two positive-displacement pumps, the two explosive valves, and associated local valves and controls are mounted in the reactor building. The liquid is piped into the RPV and discharged near the bottom of the core shroud so it mixes with the cooling water rising through the core (Subsection 4.5.1.2 and Figure 4.5-2).

The boron absorbs thermal neutrons and thereby terminates the nuclear fission chain reaction in the uranium fuel.

The specified neutron absorber solution is enriched sodium pentaborate ($Na_2B_{10}O_{16} \cdot 10H_2O$) dissolved in demineralized water. An air sparger is provided in the tank for mixing. To prevent system plugging, the tank outlet is raised above the bottom of the tank.

Whenever it is possible to make the reactor critical, the SLCS shall be able to deliver enough sodium pentaborate solution into the reactor (Figure 4.5-18) to ensure reactor shutdown. This is accomplished by placing the required amount of sodium pentaborate in the standby liquid control tank and filling with demineralized water to at least the low-level alarm point.

The saturation temperature of the recommended solution is approximately 40°F. The SLC tank is installed in a room in which the air temperature is to be maintained within the range of 70°F to 100°F. High or low temperature, or high or low liquid level, causes an alarm in the main control room.

The lines and equipment from the storage tank to the explosive valves are insulated.

The SLCS is completely contained within the reactor building. This building is well heated and ventilated; it also receives most of the heat loss from the reactor system. It is therefore incredible for the water in the SLCS to freeze while the plant is operating.

Each positive displacement pump is sized to inject the solution into the reactor in 50 to 125 minutes, independent of the amount of solution in the tank. The pump and system design pressure between the explosive valves and the pump discharge is 1400 psig. The two relief valves are set slightly under 1400 psig. To prevent bypass flow from one pump in case of relief valve failure in the line from the other pump, a check valve is installed downstream of each relief valve line in the pump discharge pipe.

SLC is manually initiated upon indication of fuel failure following a LOCA to control suppression pool pH in order to prevent iodine re-evolution. The analysis shows that SLC injection and mixing within 6 hours of the beginning of the event will maintain suppression pool pH 7.0 or higher for the 30-day duration of the accident. The amount of sodium pentaborate solution that is required for reactivity control is sufficient for pH control.

The two explosive-actuated injection valves provide assurance of opening when needed and ensure that boron does not leak into the reactor even when the pumps are being tested.

Each explosive valve is closed by a plug in the inlet chamber. The plug is circumscribed with a deep groove so the end readily shears off when pushed with the valve plunger. This opens the inlet hole through the plug. The sheared end is pushed out of the way in the chamber; it is shaped so it does not block the ports after release.

The shearing plunger is actuated by an explosive charge with dual ignition primers inserted in the side chamber of the valve.

Ignition circuit continuity is monitored by a trickle current, and an alarm occurs in the main control room if either circuit opens. Indicator lights show which primary circuit opened.

The SLCS is actuated by a three-position keylocked switch on the main control room console. This ensures that switching from the "off" position is a deliberate act. Switching to either side starts an injection pump, actuates both of the explosive valves, and closes the reactor cleanup system outboard isolation valve to prevent loss or dilution of the boron. This action occurs only if the SLC system is lined up normally. If either SLC pump breaker is racked out, only one pump and explosive actuated injection valve will operate.

A green light in the main control room indicates that power is available to the pump motor contactor and that the contactor is open (pump not running). A red light indicates that the contactor is closed (pump running).

If the pump lights or explosive valve light indicate that the liquid may not be flowing, the operator can immediately turn the switch to the other side, which actuates the alternative pump.

Cross piping and check valves ensure a flow path through either pump and either explosive valve. Placing the local switch in its “off” position will not terminate pump operation if the switch in the main control room has been placed in the “run” position. This prevents the separation of the pump from the main control room. Pump discharge pressure is also indicated in the main control room.

Equipment drains and tank overflow are not piped to the radwaste system but to separate containers (such as 55-gal drums) that can be removed and disposed of independently to prevent any trace of boron from inadvertently reaching the reactor.

Instrumentation consisting of solution temperature indication, solution level, and heater system status is provided locally at the storage tank.

4.5.2.4.3 Safety Evaluation

The SLCS is a suppression pool pH control system and a redundant reactivity control system and is maintained in a standby operational status in the reactor modes 1 and 2. The system is not expected to be needed for safety reasons because of the large number of independent control rods available to shut down the reactor.

However, to ensure the availability of the SLCS, two sets of pumps and explosive valves are provided in parallel redundancy.

The system is designed to bring the reactor from rated power to a cold shutdown at any time in core life. The reactivity compensation provided reduces reactor power from rated to zero level and allows cooling the nuclear system to room temperature, with the control rods remaining withdrawn in the rated power pattern. It includes the reactivity gains that result from complete decay of the rated power xenon inventory. It also includes the positive reactivity effects from eliminating steam voids, changing water density from hot to cold, reducing Doppler effect in uranium, reducing neutron leakage from boiling to cold, and decreasing control rod worth as the moderator cools. The specified minimum final concentration of boron in the reactor core provides a margin of -0.033 Δk for calculational uncertainties and ensures subcriticality.

Fermi 2 meets the requirements of 10CFR50.62, ATWS Rule, by increasing the enrichment of boron-10 to a minimum of 65 atom percent. The current design of the SLC system is sufficient to handle the increased enrichment of sodium pentaborate solution because the enriched boron solution is chemically similar to the current solution. Using an enriched solution will not change any of the key SLC system process parameters, i.e., flow rate, discharge pressure, required NPSH, etc.

The specified minimum average concentration of natural boron in the reactor to provide the specified shutdown margin, after operation of the SLCS, is 720 ppm. This value is increased by 25 percent to 900 ppm to allow for imperfect mixing and leakage. Thus, calculation of the minimum quantity of sodium pentaborate to be injected into the reactor is based on 900 ppm average concentration in the reactor coolant, including recirculation loops and the RHR system in the shutdown cooling mode, at 70°F and reactor water Level 8.

Cooldown of the nuclear system requires a minimum of several hours to remove the thermal energy stored in the reactor cooling water and associated equipment. The controlled limit for the RPV cooldown is 100°F per hour, and normal operating temperature is approximately 550°F. Use of the main condenser and various shutdown cooling systems requires 10 to 24 hr to lower the RPV to room temperature (70°F). SLCS is designed to provide the capability of bringing the reactor, at any temperature and time in a cycle, to a subcritical condition with the reactor in the most reactive xenon-free state with all of the control rods in the full out condition.

The injection rate is limited to a range of 8 to 20 ppm/minute change in boron concentration in reactor water, based on the weight of water in the reactor and recirculation loops at normal water level and 70°F. The lower rate ensures that the boron is injected into the reactor in approximately 2 hr. This resulting reactivity insertion is considerably quicker than that covered by the cooldown. However, power cyclic oscillations from uneven mixing of boron in the core at high delivery rates is not a concern because of the steady boron concentration buildup observed in mixing tests, as documented in NEDC-30921.

The SLCS equipment essential for injection of neutron absorber solution into the reactor is designed to withstand the safe shutdown earthquake and is tested and maintained as safety-related equipment.

The SLCS is required to be operable in the event of a station power failure. Therefore, the pumps, valves, and controls are powered from the standby ac power supply. The pumps and valves are powered and controlled from separate buses and circuits.

The SLCS and pumps have sufficient pressure margin, up to the system relief valve setting of approximately 1400 psig, to ensure solution injection into the reactor above the normal pressure in the bottom of the reactor. The nuclear system relief and safety valves begin to relieve pressure above approximately 1100 psig. Therefore, the SLCS positive displacement pumps cannot overpressurize the nuclear system.

Only one of the two standby liquid control pumps and/or explosive actuated injection valves is needed for system operation. If one pump and/or injection valve is found to be inoperable, there is no immediate threat to shutdown capability, and reactor operation and/or rod movement can continue during repairs. The time during which one redundant component upstream of the explosive valves may be out of operation should be consistent with the following: the probability of failure of both the control rod shutdown capability and the alternative component in the SLCS; and the fact that nuclear system cooldown takes several hours while liquid control solution injection takes approximately 2 hr. Since this probability is small, considerable time is available for repairing and restoring the SLCS to an operable condition while reactor operation continues. Assurance that the system will still fulfill its function during repairs is obtained by maintaining the operable status of the redundant pump/valve combination.

Standard Review Plan (SRP) 4.6 states that the SLCS is reviewed by using SRP 9.3.5 to determine its adequacy to perform its function of reactivity control. The following summarizes the comparison of the Fermi 2 SLCS with the acceptance criteria listed in SRP 9.3.5:

a. The system is housed in the reactor building and therefore meets General Design Criterion (GDC) 2 for withstanding natural phenomena

b. The system is located in a missile-free area on the fourth floor of the reactor building. The system piping is studied for pipe whip and jet impingement effects both inside and outside primary containment. These studies show conformance with GDC 4

c. The SLCS meets the requirements for high functional reliability and inservice testability. However, the system design criteria do not specify a single-failure criterion for tanks and piping, but dual pumps and dual explosive valves are incorporated. The reliability criteria are further discussed elsewhere in this section and in Subsection 4.5.2.2.3.4

d. The SLCS is independent of other control systems and is capable of maintaining the core subcritical under cold conditions. Therefore, GDC 26 and GDC 27 are met

e. The classification of system components is given in Table 3.2-1.

f. The location of the SLCS renders it immune to the effects of flooding and tornado missiles. The system meets the criteria for breaks in piping systems outside the drywell.

A discussion in Subsection 4.5.2.2.3.4 addresses the vulnerability of the CRD system and SLCS to common mode failures. The two systems do not share any instrumentation or components. The probability of a common mode failure in the SLCS is dominated by the failure of an operator to actuate the system in a timely manner. The probability of this type of operator error is estimated to be in the range of 1×10^{-1} to 1×10^{-3} per demand, depending on the time required for system activation.

The amount of sodium pentaborate solution that is required for reactivity control is sufficient for pH control. SLC injection and mixing within 6 hours of the beginning of the event will maintain suppression pool pH 7.0 or higher for the 30-day duration of the accident.

4.5.2.4.4 Inspection and Testing

An operational test is performed on the SLCS on a once per fuel cycle frequency to:

a. Demonstrate that the pump relief valve setpoint is $\leq$ 1400 psig, and

b. Verify that the relief valve does not actuate during recirculation to the test tank.

Operational testing of the SLCS is performed in at least two parts to avoid inadvertently injecting boron into the reactor.

With the valves to and from the storage tank closed and the three valves to and from the test tank opened, demineralized water in the test tank can be recirculated by locally starting either pump.

The injection portion of the system can be functionally tested by valving the pump suction lines to the test tank and actuating the system from the main control room. Each pump loop and its injection valve are tested. System operation is indicated in the main control room.

After functional tests, the injection valve shear plugs and explosive charges must be replaced and all the valves returned to their normal positions as indicated.

After closing a local locked-open valve to the reactor, leakage through the injection valves can be determined by opening valves at a test connection in the line between the containment isolation check valves. Position indicator lights in the main control room indicate that the local valve is closed for tests or open and ready for operation. Leakage from the reactor through the first check valve can be detected by opening the same test connection when the reactor is pressurized.

The test tank contains demineralized water for approximately 3 minutes of pump operation. Demineralized water from the makeup system or the condensate storage system is available for refilling or flushing the system.

Should the boron solution ever be injected into the reactor, either intentionally or inadvertently, after it is made certain that the normal reactivity controls will keep the reactor subcritical, the boron is removed from the reactor coolant system by flushing for gross dilution followed by operating the reactor water cleanup (RWCU) system (Subsection 5.5.8). There is practically no effect on reactor operations when the boron concentration has been reduced below approximately 50 ppm.

The concentration of the sodium pentaborate in the solution tank is determined periodically by chemical analysis.

4.5.2.4.5 Instrumentation

The instrumentation and control system for the SLCS is designed to allow the injection of liquid poison into the reactor. The discussion of the SLCS instrumentation is included in Subsection 7.4.1.

4.5.3 Control Rod Drive Housing Supports

4.5.3.1 Safety Objective

The CRD housing supports prevent any significant nuclear transient in the event a drive housing breaks or separates from the bottom of the RPV.

4.5.3.2 Safety Design Bases

The CRD housing supports shall meet the following safety design bases:

a. Following a postulated CRD housing failure, control rod downward motion shall be limited so that any resulting nuclear transient could not be sufficient to cause fuel damage

b. The clearance between the CRD housings and the supports shall be sufficient to prevent vertical contact stresses caused by thermal expansion during plant operation.

4.5.3.3 Description

The CRD housing supports are shown in Figure 4.5-19. Horizontal beams are installed immediately below the bottom head of the RPV, between the rows of CRD housings. The beams are bolted to brackets welded to the steel form liner of the drive room in the reactor support pedestal.

Hanger rods, approximately 10 ft long and 1-3/4 in. in diameter, are supported from the beams on stacks of disk springs. These springs compress approximately 2 in. under the design load.

The support bars are bolted between the bottom ends of the hanger rods. The spring pivots at the top, and the beveled, loose-fitting ends on the support bars prevent substantial bending movement in the hanger rods if the support bars are overloaded.

Individual grids rest on the support bars between adjacent beams. Because a single-piece grid would be difficult to handle in the limited work space and because it is necessary that CRDs, position indicators, and in-core instrumentation components be accessible for inspection and maintenance, each grid is designed for in-place assembly or disassembly. Each grid assembly is made up of two grid plates, a clamp, and a bolt. The top part of the clamp guides the grid to its correct position directly below the respective CRD housing that it would support in the postulated accident.

When the support bars and grids are installed, a gap of approximately 1 in. at room temperature (approximately 70°F) is provided between the grid and the bottom contact surface of the CRD flange.

During system heatup, this gap is reduced by a net downward expansion of the housings with respect to the supports. In the hot operating condition, the gap is approximately 1/4 in.

In the postulated CRD housing failure, the CRD housing supports are loaded when the lower contact surface of the CRD flange contacts the grid. The resulting load is then carried by two grid plates, two support bars, four hanger rods, their disk springs, and two adjacent beams.

The American Institute of Steel Construction (AISC) Manual of Steel Construction, "Specification for the Design, Fabrication and Erection of Structural Steel for Buildings," was used as a guide in designing the CRD housing support system. However, to provide a structure that absorbs as much energy as practical without yielding, the allowable tension and bending stresses used were 90 percent of yield and the shear stress used was 60 percent of yield. These design stresses are 1.5 times the AISC allowable stresses (60 percent and 40 percent of yield, respectively).

For purposes of mechanical design, the postulated failure resulting in the highest forces is an instantaneous circumferential separation of the CRD housing from the RPV, with an internal pressure of 1250 psig (RPV design pressure) acting on the area of the separated housing. The weight of the separated housing, CRD, and blade, plus the pressure of 1250 psig acting on the area of the separated housing, gives a force of approximately 35,000 lb. This force is multiplied by a factor of three for impact, conservatively assuming that the housing travels through a 1-in. gap before it contacts the supports. The total force (105,000 lb) is then treated as a static load in design.

Selected CRD housing support hanger rods have TIP guide tube supports attached below the support bars.

All CRD housing support subassemblies are fabricated of ASTM-A-36 structural steel, except for the following items:

Item	Material
Grid	ASTM-A-441
Disk springs	Schnorr, Type BS-125-71-8
Hex bolts and nuts	ASTM-A-307
Structure tubing	ASTM-A-46

4.5.3.4 Safety Evaluation

For design purposes, the postulated failure resulting from an instantaneous circumferential separation of the CRD housing from the RPV, with an internal pressure of 1250 psig (RPV design pressure) acting on the area of the separated housing, is the governing design condition. The vertical force (dead load) of the separated housing, CRD, and blade plus the force of 1250 psig pressure acting on the area of the separated housing multiplied by an impact factor of three gives the design static load on the CRD housing support members. The effect of an earthquake on the design load is not considered in the design because the earthquake load is only 3 percent of the design load.

Downward travel of the CRD housing and its control rod following the postulated housing failure equals the sum of these distances:

a. The compression of the disk springs under dynamic loading

b. The initial gap between the grid and the bottom contact surface of the CRD flange. If the reactor were cold and pressurized, the downward motion of the control rod would be limited to the spring compression (approximately 2 in.) plus a gap of approximately 1 in. If the reactor were hot and pressurized, the gap would be approximately l/4 in. and the spring compression would be slightly less than in the cold condition. In either case, the control rod movement following a housing failure is substantially limited below one drive notch movement (6 in.). Sudden withdrawal of any control rod through a distance of one drive notch at any position in the core does not produce a transient sufficient to damage any radioactive material barrier.

The stress criterion (1.5 times the AISC allowable stresses) is considered desirable for this application and adequate for the "once in a lifetime" loading condition.

The CRD housing supports are in place during power operation and when the nuclear system is pressurized. If a control rod is ejected during shutdown, the reactor remains subcritical because it is designed to remain subcritical with any one control rod fully withdrawn at any time.

At plant operating temperature, a gap of approximately 1/4 in. exists between the CRD housing and the supports. At lower temperatures the gap is greater. Because the supports do not contact any of the CRD housing except during the postulated accident condition, vertical contact stresses are prevented.

4.5.3.5 Inspection and Testing

CRD housing supports are removed for inspection and maintenance of the CRDs. The supports for one control rod can be removed during reactor shutdown, even when the reactor is pressurized, because all control rods are then inserted. When the support structure is reinstalled, it is inspected for correct assembly with particular attention to maintaining the correct gap between the CRD flange lower contact surface and the grid.

TABLE 4.5-1 DEFORMATION LIMIT

(For Reactor Internal Structures Only)

Either One of (Not Both)[a]	General Limit
a. $\frac{DP}{DL}$	$\leq \frac{0.9}{SF_{min}}$
b. $\frac{DP}{DE}$	$\leq \frac{1.0}{SF_{min}}$

where

DP = permissible deformation under stated conditions of normal, upset, emergency, or faulted

DL = analyzed deformation that could cause a system loss of function[b]

DE = experimentally determined deformation that could cause a system loss of function

SF_{min} = minimum safety factor

---

[a] Equation b. is not used because equation a criteria are met. (Equation b. will not be used unless supporting data are provided to the NRC by GE.)

[b] "Loss of function" can only be defined quite generally until attention is focused on the component of interest. In cases of interest, where deformation limits can affect the function of equipment and components, they will be specifically delineated. From a practical viewpoint, it is convenient to interchange some deformation condition at which function is ensured with the loss of function condition if the required safety margins from the functioning conditions can be achieved. Therefore it is often unnecessary to determine the actual loss of function condition because this interchange procedure produces conservative and safe designs. Examples where deformation limits apply are control rod drive alignment and clearances for proper insertion and core support deformation causing fuel disarrangement or excess leakage of any component.

TABLE 4.5-2 PRIMARY STRESS LIMIT

(For Reactor Internal Structures Only)

Any One of (No More Than One Required)[a]		General Limit
a.	$\frac{PE}{PN}$	$\leq \frac{2.25}{SF_{min}}$
b.	$\frac{LP}{CL}$	$\leq \frac{1.5}{SF_{min}}$
c.	$\frac{PE}{US}$	$\leq \frac{0.75}{SF_{min}}$
d.	$\frac{EP}{US}$	$\leq \frac{0.9}{SF_{min}}$
e.	$\frac{LP}{PL}$	$\leq \frac{0.9}{SF_{min}}$
f.	$\frac{LP}{UF}$	$\leq \frac{0.9}{SF_{min}}$
g.	$\frac{LP}{LE}$	$\leq \frac{1.0}{SF_{min}}$

where

PE = primary stresses evaluated on an elastic basis. The effective membrane stresses are to be averaged through the load-carrying section of interest. The simplest average bending, shear, or torsion stress distribution that will support the external loading will be added to the membrane stresses at the section of interest

PN = permissible primary stress levels under normal or upset conditions under ASME Boiler and Pressure Vessel Code Section III

LP = permissible load under stated conditions of normal, upset, emergency, or faulted

CL = lower bound limit load with yield point equal to $1.5S_m$, where S_m is the tabulated value of allowable stress at temperature of the ASME III Code or its equivalent. The "lower bound limit load" is here defined as that produced from the analysis of an ideally plastic (nonstrain-hardening) material where deformations increase with no further increase in applied load. The lower bound load is one in which the material everywhere satisfies equilibrium and nowhere exceeds the defined material yield strength using either a shear theory or a strain energy of distortion theory to relate multiaxial yield to the uniaxial case

US = conventional ultimate strength at temperature or loading, which would cause a system malfunction, whichever is more limiting

EP = elastic-plastic evaluated nominal primary stress. Strain hardening of the material may be used for the actual monotonic stress-strain curve at the temperature of loading, or any approximation to the actual stress-strain curve that everywhere has a lower stress for the same strain than the actual monotonic curve may be used. Either the shear or strain energy of distortion flow rule may be used

PL = plastic instability load. The "plastic instability load" is defined here as the load at which any load-bearing section begins to diminish its cross-sectional area at a faster rate than the strain hardening can accommodate the loss in area. This type of analysis requires a true stress-true strain curve or a close approximation based on monotonic loading at the temperature of loading

UF = ultimate load from fracture analyses. For components which involve sharp discontinuities (local theoretical stress concentration < 3) the use of a "fracture mechanics" analysis where applicable, utilizing measurements of plane strain fracture toughness, may be applied to compute fracture loads. Correction for finite plastic zones and thickness effects as well as gross yielding may be necessary. The methods of linear elastic stress analysis may be used in the fracture analysis where its use is clearly conservative or supported by experimental evidence. Examples where "fracture mechanics" may be applied are for fillet welds or end-of-fatigue-life crack propagation

LE = ultimate load or loss of function load as determined from experiment. In using this method, account shall be taken of the dimensional tolerances that may exist between the actual part and the tested part or parts as well as differences that may exist in the ultimate tensile strength of the actual part and the tested parts. The guide to be used in each of these areas is that the experimentally determined load shall use adjusted values to account for material property and dimension variations, each of which has no greater probability than 0.1 of being exceeded in the actual part

---

[a] Equations e., f., and g. are not used because criteria a., b., c., and d. are met. (Equations e., f., and g. will not be used unless supporting data are provided to the NRC by GE.)

TABLE 4.5-3 BUCKLING STABILITY LIMIT

(For Reactor Internal Structures Only)

Any One of (No More Than One Required)[a]	General Limit
a. $\frac{LP}{PN}$	$\leq \frac{2.25}{SF_{min}}$
b. $\frac{LP}{SL}$	$\leq \frac{0.9}{SF_{min}}$
c. $\frac{LP}{SE}$	$\leq \frac{1.0}{SF_{min}}$

where

LP = permissible load under stated conditions of normal, upset, emergency, or faulted

PN = applicable code normal event permissible load

SL = stability analysis load. The ideal buckling analysis is often sensitive to otherwise minor deviations from ideal geometry and boundary conditions. These effects shall be accounted for in the analysis of the buckling stability load. Examples of this are ovality in externally pressurized shells or eccentricity of column members

SE = ultimate buckling collapse load as determined from experiment. In using this method, account shall be taken of the dimensional tolerances that may exist between the actual part and the tested part. The guide to be used in each of these areas is that the experimentally determined load shall be adjusted to account for material property and dimension variations, each of which has no greater probability than 0.1 of being exceeded in the actual part

[a] Equation c. is not used because criteria a. and b. are met. (Equation c. will not be used unless supporting data are provided to the NRC by GE.)

TABLE 4.5-4 FATIGUE LIMIT

(For Reactor Internal Structures Only)

Summation of Fatigue Damage Usage with Design and Operation Loads Following Miner Hypotheses[a]

Any One of (No More Than One Required)	Limit for Normal and Upset Design Conditions
a. Mean fatigue[b,c] cycle usage from analyses	≤ 0.05
b. Mean fatigue[b,c] cycle usage from test	≤ 0.33
c. Design fatigue cycle usage from analysis using the method of Table 4.5-5	≤ 1.0

a. Miner, M. A., "Cumulative Damage in Fatigue," Journal of Applied Mechanics, Vol. 12, ASME, 67, pp. A159-A164, September 1945.

b. Fatigue failure is defined here as a 25 percent area reduction for a load-carrying member which is required to function, or excess leakage, whichever is more limiting.

c. Equations a. and b. are not used because criterion c. is met. (Equations a. and b. will not be used unless supporting data are provided to the NRC by GE.)

TABLE 4.5-5 CORE SUPPORT STRUCTURES: STRESS CATEGORIES AND LIMITS OF STRESS INTENSITY FOR NORMAL AND UPSET CONDITIONS

STRESS CATEGORY	PRIMARY STRESSES		SECONDARY STRESSES	PEAK STRESSES
	MEMBRANE, P_m (NOTES 4, 7 & 8)	BENDING, P_b (NOTES 4, 7 & 8)	MEMBRANE AND BENDING SECONDARY, Q (NOTES 2, 4 & 6)	PEAK, F (NOTES 2, 4 & 6)
NORMAL AND UPSET	P_m S_m ELASTIC ANALYSIS (NOTE 6) OR $.67L_L$ LIMIT ANALYSIS (NOTE 10) OR $.44L_u$ TEST (NOTE 11)	$P_m + P_b$ $1.5S_m$ ELASTIC ANALYSIS (NOTE 6) OR $.67L_L$ LIMIT ANALYSIS (NOTE 10) OR $.44L_u$ TEST (NOTE 11)	$P_m + P_b + Q$ $3S_m$ ELASTIC ANALYSIS (NOTE 1) OR S_L PLASTIC ANALYSIS (NOTE 5) OR FOR CYCLES LESS THAN 1000, USE PEAK (NOTE 12)	$P_m + P_b + Q + F$ ELASTIC FATIGUE (NOTES 3 & 9) S_a $P_m + P_b + Q + F$ S_a ELASTIC-PLASTIC FATIGUE (NOTES 3, 9 & 12)

Note 1: This limitation applies to the range of stress intensity. When the secondary stress is due to a temperature excursion at the point at which the stresses are being analyzed, the value of S_m shall be taken as the average of the S_m values tabulated in Tables I-1.1, I-1.2, and I-1.3 of the ASME Boiler and Pressure Vessel Code Section III (ASME III) for the highest and the lowest temperature of the metal during the transient. When part of the secondary stress is due to mechanical load, the value of S_m shall be taken as the S_m value for the highest temperature of the metal during the transient.

Note 2: The stresses in Category Q are those parts of the total stress that are produced by thermal gradients, structural discontinuities, etc., and do not include primary stresses that may also exist at the same point. It should be noted, however, that a detailed stress analysis frequently gives the combination of primary and secondary stresses directly, and, when appropriate, this calculated value represents the total of $P_m + P_b + Q$, and not Q alone. Similarly, if the stress in Category F is produced by a stress concentration, the quantity F is the additional stress produced by the notch, over and above the nominal stress. For example, if a plate has a nominal stress intensity, $P_m = S$, $P_b = 0$, $Q = 0$, and a notch with a stress concentration K is introduced, then $F = P_m (K - 1)$, and the peak stress intensity equals $P_m + P_m (K - 1) = KP_m$.

TABLE 4.5-5 CORE SUPPORT STRUCTURES: STRESS CATEGORIES AND LIMITS OF STRESS INTENSITY FOR NORMAL AND UPSET CONDITIONS

Note 3: The value of S_a is obtained from the fatigue curves (Figures I-9.1 and I-9.2 of ASME III). The allowable stress intensity for the full range of fluctuation is $2S_a$.

Note 4: The symbols P_m, P_b, Q, and F do not represent single quantities, but rather sets of six quantities representing the six stress components σ_t, σ_l, σ_r, τ_{t1}, τ_{1r}, and τ_{rt}.

Note 5: The quantity S_L denotes the structural action of shakedown load, as defined in Paragraph NB-3213.18 of ASME III, calculated on a plastic basis as applied to a specific location on the structure.

Note 6: The triaxial stresses represent the algebraic sum of the three primary principal stresses ($\sigma_1+\sigma_2+\sigma_3$) for the combination of stress components. Where uniform tension loading is present, triaxial stresses are limited to $4S_m$.

Note 7: For configurations in which compressive stresses occur, the stress limits shall be revised to take into account critical buckling stresses [see Paragraph NB-3211(c) of ASME III]. For external pressure, the permissible "equivalent static" external pressure shall be as specified by the rules of Paragraph NB-3133 of ASME III. Where dynamic pressures are involved, the permissible external pressure shall be limited to 25 percent of the dynamic instability pressure.

Note 8: When loads are transiently applied, consideration should be given to the use of dynamic load amplification and possible change in the modulus of elasticity.

Note 9: In the fatigue data curves, where the number of operating cycles is less than 10, the S_a value should be used for 10 cycles; where the number of operating cycles is more than 10^6, the S_a value should be used for 10^6 cycles.

Note 10: The quantity L_L is the lower bound limit load with yield point equal to $1.5S_m$, where S_m is the tabulated value of allowable stress at temperature as contained in ASME III. The "lower bound limit load" is here defined as that produced from the analysis of an ideally plastic (nonstrain-hardening) material where deformations increase with no further increase in applied load. The lower bound load is one in which the material everywhere satisfies equilibrium and nowhere exceeds the defined material yield strength, using either a shear theory or a strain energy of distortion theory to relate multiaxial yielding to the uniaxial case.

Note 11: For normal and upset conditions, the limits on primary membrane plus primary bending need not be satisfied in a component if it can be shown from the test of a proto-type or model that the specified loads (dynamic or static equivalent) do not exceed 44 percent of L_u, where L_u is the ultimate load or the maximum load or load combination used in the test. In using this method, account shall be taken of the size effect and dimensional tolerances that may exist between the actual part and the test part or parts as well as the differences that may exist in

TABLE 4.5-5 CORE SUPPORT STRUCTURES: STRESS CATEGORIES AND LIMITS OF STRESS INTENSITY FOR NORMAL AND UPSET CONDITIONS

the ultimate strength or other governing material properties of the actual part and the tested part to ensure that the loads obtained from the test are a conservative representation of the load-carrying capability of the actual component under the postulated loading for normal and upset conditions.

Note 12: The allowable value for the maximum range of this stress intensity is $3S_m$, except for cyclic events that occur less than 1000 times during the design life of the plant. For this exception, in lieu of meeting the $3S_m$ limit, an elastic-plastic fatigue analysis in accordance with ASME III may be performed to demonstrate that the cumulative fatigue usage attributable to the combination of these low events, plus all other cyclic events, does not exceed a fatigue usage value of 1.0.

TABLE 4.5-6 CORE SUPPORT STRUCTURES: STRESS CATEGORIES AND LIMITS OF STRESS INTENSITY FOR EMERGENCY CONDITIONS

STRESS CATEGORY	PRIMARY STRESSES		SECONDARY STRESSES	PEAK STRESSES
	MEMBRANE, P_m (NOTES 1, 2 & 10)	BENDING, P_b (NOTES 1, 2 &10)	MEMBRANE AND BENDING SECONDARY, Q	PEAK, F
EMERGENCY (NOTE 9)	P_m $1.5S_m$ ELASTIC ANALYSIS (NOTE 3) OR L_L LIMIT ANALYSIS (NOTE 4) OR $1.5S_m$ PLASTIC ANALYSIS (NOTE 6) OR $.6L_e$ TEST (NOTE 7) OR S_E STRESS RATIO ANALYSIS (NOTE 8)	$P_m + P_b$ $2.25S_m$ ELASTIC ANALYSIS (NOTE 3) OR L_L LIMIT ANALYSIS (NOTE 4) OR $2.25S_m$ PLASTIC ANALYSIS (NOTES 5 & 6) OR $.5S_u$ (NOTE 5) OR $.6L_e$ TEST (NOTE 7) OR KS_E STRESS RATIO ANALYSIS (NOTE 8)	EVALUATION NOT REQUIRED	EVALUATION NOT REQUIRED

Note 1: The symbols P_m, P_b, Q, and F do not represent single quantities, but rather sets of six quantities representing the six stress components σ_t, σ_l, σ_r, τ_{r1}, τ_{1r}, and τ_{rt}.

Note 2: For configurations in which compressive stresses occur, stress limits shall be revised to take into account critical buckling stresses. For external pressure, the permissible "equivalent static" external pressure shall be taken as 150 percent of that permitted by the rules of Paragraph NB-3133 of the ASME Boiler and Pressure Vessel Code, Section III (ASME III). Where dynamic pressures are involved, the permissible external pressure shall satisfy the preceding requirements or be limited to 50 percent of the dynamic instability pressure.

Note 3: The triaxial stresses represent the algebraic sum of the three primary principal stresses ($\sigma_1+\sigma_2+\sigma_3$) for the combination of stress components. Where uniform tension loading is present, triaxial stresses should be limited to $6S_m$.

Note 4: The quantity L_L is lower bound limit load with yield point equal to $1.5S_m$ (where S_m is the tabulated value of allowable stress at temperature as contained in ASME III). The "lower bound limit load" is here defined as that produced from the analysis of an ideally plastic (nonstrain-hardening) material where

TABLE 4.5-6 CORE SUPPORT STRUCTURES: STRESS CATEGORIES AND LIMITS OF STRESS INTENSITY FOR EMERGENCY CONDITIONS

deformations increase with no further increase in applied load. The lower bound load is one in which the material everywhere satisfies equilibrium and nowhere exceeds the defined material yield strength, using either a shear theory or a strain energy of distortion theory to relate multiaxial yielding to the uniaxial case.

Note 5: The quantity S_u is the ultimate strength at temperature. Multiaxial effects on ultimate strength shall be considered.

Note 6: This plastic analysis uses an elastic-plastic evaluated nominal primary stress. Strain hardening of the material may be used for the actual monotonic stress-strain curve at the temperature of loading, or any approximation to the actual stress-strain curve that everywhere has a lower stress for the same strain than the actual monotonic curve may be used. Either the shear or strain energy of distortion flow rule shall be used to account for multiaxial effects.

Note 7: For emergency conditions, the stress limits need not be satisfied if it can be shown from the test of a prototype or model that the specified loads (dynamic or static equivalent) do not exceed 60 percent of L_e, where L_e is the ultimate load or the maximum load or load combination used in the test. In using this method, account shall be taken of the size effect and dimensional tolerances that may exist between the actual part and the tested part or parts as well as the differences that may exist in the ultimate strength or other governing material properties of the actual part and the tested parts to ensure that the loads obtained from the test are a conservative representation of the load-carrying capability of the actual component under postulated loading for emergency conditions.

Note 8: Stress ratio is a method of plastic analysis that uses the stress ratio combinations (combination of stresses that consider the ratio of the actual stress to the allowable plastic or elastic stress) to compute the maximum load and strain-hardening that the material can carry. The term K is defined as the section factor; $S_e \leq 2S_m$ for primary membrane loading.

Note 9: Where deformation is of concern in a component, the deformation shall be limited to two-thirds of the value given for emergency conditions in the design specification.

Note 10: When loads are transiently applied, consideration should be given to the use of dynamic load amplification and possible change in the modulus of elasticity.

TABLE 4.5-7 CORE SUPPORT STRUCTURES: STRESS CATEGORIES AND LIMITS OF STRESS INTENSITY FOR FAULTED CONDITIONS

STRESS CATEGORIES	PRIMARY STRESSES		SECONDARY STRESSES	PEAK STRESSES
	MEMBRANE, P_m (NOTES 1, 2 & 3)	BENDING, P_b (NOTES 1, 2 & 3)	MEMBRANE AND BENDING SECONDARY, Q	PEAK, F
FAULT (NOTE 7)	P_m $2.4S_m$ ELASTIC ANALYSIS OR $.75S_u$ (NOTE 5) OR $1.33L_L$ LIMIT ANALYSIS (NOTE 4) OR $.67S_u$ PLASTIC ANALYSIS (NOTES 5 & 6) OR $.8L_F$ TEST (NOTE 9) OR S_F STRESS-RATIO ANALYSIS (NOTE 8)	$P_m + P_b$ $3.0S_m$ ELASTIC ANALYSIS OR $1.33L_L$ LIMIT ANALYSIS (NOTE 4) OR $.75S_u$ PLASTIC ANALYSIS (NOTES 5 & 6) OR $.8L_F$ TEST (NOTE 7) OR KS_F STRESS-RATIO ANALYSIS (NOTE 8)	EVALUATION NOT REQUIRED	EVALUATION NOT REQUIRED

Note 1: The symbols P_m, P_b, Q, and F do not represent quantities but rather sets of six quantities representing the six stress components, σ_t, σ_l, σ_r τ_{tl},τ_{lr}, and τ_{rt}.

Note 2: When loads are transiently applied, consideration should be given to the use of dynamic load amplification and possible changes in the modulus of elasticity.

Note 3: For configurations where compressive stresses occur, stress limits take into account critical buckling stresses. For external pressure, the permissible "equivalent static" external pressure shall be taken as 2.5 times that given by rules of paragraph NB-3133 of the ASME Boiler and Pressure Vessel Code Section III (ASME III). Where dynamic pressures are involved, the permissible external pressure shall satisfy the preceding requirements or shall be limited to 75 percent of the dynamic instability pressure.

Note 4: The quantity L_L is the lower bound limit load with yield point equal to $1.5S_m$ (where S_m is the tabulated value of allowable stress at temperature as contained in ASME III). The "lower bound limit load" is here defined as that produced from the analysis of an ideally plastic (nonstrain-hardening) material where deformations increase with no further increase in applied load. The lower

TABLE 4.5-7 CORE SUPPORT STRUCTURES: STRESS CATEGORIES AND LIMITS OF STRESS INTENSITY FOR FAULTED CONDITIONS

bound load is one in which the material everywhere satisfies equilibrium and nowhere exceeds the defined material yield strength, using either a shear theory or a strain energy of distortion theory to relate multiaxial yielding to the uniaxial case.

Note 5: The quantity S_u is the ultimate strength at temperature. Multiaxial effects on ultimate strength shall be considered.

Note 6: This plastic analysis uses an elastic-plastic evaluated nominal primary stress. Strain hardening of the material may be used for the actual monotonic stress-strain curve at the temperature of loading, or any approximation to the actual stress-strain curve that everywhere has a lower stress for the same strain as the actual curve may be used; either the maximum shear stress or the strain energy of distortion flow rule shall be used to account for multiaxial effects.

Note 7: For faulted conditions, the stress limits need not be satisfied if it can be shown from the test of a prototype or model that the specified loads (dynamic or static equivalent) do not exceed 80 percent of L_F, where L_F is the ultimate load or load combination used in the test.

In using this method, account shall be taken of the size effect and dimensional tolerances as well as differences that may exist in the ultimate strength or other governing material properties of the actual part and the tested parts to ensure that the loads obtained from the test are a conservative representation of the load-carrying capability of the actual component under the postulated loading for faulted condition.

Note 8: Stress ratio is a method of plastic analysis that uses the stress ratio combinations (combination of stresses that consider the ratio of the actual stress to the allowable plastic or elastic stress) to compute the maximum load and strain-hardening that the material can carry. The term K is defined as the section factor; S_F is the lesser of $2.4S_m$ or $0.75S_u$ for primary membrane loading.

Note 9: Where deformation is of concern in a component, the deformation shall be limited to 80 percent of the value for faulted conditions in the design specifications.

TABLE 4.5-8 DESIGN LOADING CONDITIONS AND COMBINATIONS

Operating Condition and Stress Limits[a]	Design Loading Conditions and Combinations
Normal and upset	N and A_D or N and U
Emergency	N and R or other conditions which have a 40-year encounter probability from 10^{-1} to 10^{-3}
Faulted	N and A_m and $\overline{R}$ or other conditions which have a 40-year encounter probability from 10^{-3} to 10^{-6}

where

N = normal loads

U = upset loads excluding earthquake

A_D = operating-basis earthquake (OBE), including any associated transients

A_m = safe-shutdown earthquake (SSE), including any associated transients

R = any auxiliary pipe rupture loading, including any associated transients; pipe rupture loadings are not directly considered on piping itself because this is handled by a failure mode analysis

$\overline{R}$ = primary loadings which result from rupture of a main steam line or a recirculation line

[a] The design stress, deformation, and fatigue limits are for RPV and appurtenances - ASME Code Section III.

For core support structures - Refer to Tables 4.5-5, 4.5-6, and 4.5-7.

For reactor internal structures - Refer to Tables 4.5-1 through 4.5-4.

TABLE 4.5-9 PRESSURE DIFFERENTIALS ACROSS REACTOR PRESSURE VESSEL INTERNALS

Reactor Component	Pressure Difference Maximum Occurring During a Steam Line Break (psid) Case 1 (a)	 Case 2 (b)
Core plate and guide tube	22.5	25.5
Shroud support ring and lower shroud	45.0	45.0
Upper shroud and shroud head	26.0	26.0
Average channel wall (bottom)	14.0	10.6
Top guide	1.1	1.9

CHAPTER 5: REACTOR COOLANT SYSTEM AND CONNECTED SYSTEMS

5.1 SUMMARY DESCRIPTION

The reactor coolant system includes those systems and components that contain or transport fluids to or from the reactor core. These systems form a major portion of the nuclear system process barrier. This chapter provides information regarding the reactor coolant system and pressure-containing appendages out to and including isolation valving. This group of components is defined as the reactor coolant pressure boundary (RCPB), in Section 50.2(v) of 10 CFR 50 as follows:

Reactor coolant pressure boundary means all those pressure- containing components of boiling and pressurized water- cooled nuclear power reactors, such as pressure vessels, piping, pumps, and valves, which are

a. Part of the reactor coolant system

b. Connected to the reactor coolant system, up to and including all of the following:

   1. The outermost containment isolation valve in system piping which penetrates primary reactor containment

   2. The second of the two valves normally closed during normal reactor operation in system piping which does not penetrate primary reactor containment

   3. The reactor coolant system safety/relief valves.

Section 5.5 of this chapter also deals with various subsystems of the RCPB that are closely allied to it. These are briefly reviewed below.

The nuclear pressure relief system (NPRS) protects the RCPB from damage due to overpressure. To protect against overpressure, pressure-operated safety/relief valves are provided to discharge steam from the nuclear steam supply system (NSSS) to the suppression pool. The NPRS also acts to automatically depressurize the NSSS in the event of a LOCA in which the high pressure coolant injection (HPCI) system fails to maintain reactor pressure vessel (RPV) water level. Depressurization of the NSSS allows the low- pressure core cooling systems to supply enough cooling water to cool the fuel adequately.

The RCPB leak detection system, described in Subsection 5.2.7, detects system leakage inside the primary containment so that appropriate action can be taken before the integrity of the nuclear system process barrier is impaired.

The RPV and appurtenances are described in Section 5.4. The major safety functions of the RPV are to maintain water over the core and to act as a radioactive material barrier. The RPV meets the requirements of applicable codes and criteria. The possibility of brittle fracture is considered, and suitable design and operational limits are established that avoid conditions where brittle fracture is possible.

The reactor recirculation system (RRS) provides coolant flow through the core. Adjustment of the core coolant flow rate changes reactor power output, thus providing a means of following plant load demand without adjusting control rods. The arrangement of the RRS routing is such that a piping failure cannot compromise the integrity of the floodable inner volume of the RPV, thereby ensuring adequate core cooling following a LOCA.

The main steam line flow restrictors are venturi-type flow devices. One restrictor is installed in each main steam line inside the primary containment. The restrictors are designed to limit the loss of coolant resulting from a main steam line break outside the primary containment. The coolant loss is limited so that RPV water level remains above the top of the core during the time required for the main steam line isolation valves (MSIVs) to close. This action maintains the integrity of the fuel cladding (fuel barrier).

The MSIVs automatically isolate the nuclear system process barrier in the event a pipe break occurs, thereby limiting the loss of coolant and the release of radioactive materials from the NSSS. Two MSIVs are installed on each main steam line, one inside and the other outside the primary containment. Closure of either of the two MSIVs acts to seal the primary containment in the event that a main steam line break occurs there. A third stop valve (third MSIV) is in each steam line downstream of the outboard MSIVs.

The reactor core isolation cooling (RCIC) system provides makeup water to the core during a reactor shutdown in which feedwater flow is not available. The system is started either automatically upon receipt of a low reactor water level signal or manually by the operator. Water is pumped to the core by a turbine pump driven by reactor steam.

The residual heat removal (RHR) system includes a number of pumps and heat exchangers that can be used to cool the NSSS under a variety of situations. During normal shutdown and reactor servicing, the RHR system removes residual and decay heat. The RHR system allows decay heat to be removed whenever the main heat sink (main condenser) is not available. Another operational mode of the RHR system is low pressure coolant injection (LPCI). Low pressure coolant injection operation is an engineered safety feature (ESF) system for use during a LOCA. This operation is described in Subsection 6.3.2.2.4.

The reactor water cleanup (RWCU) system functions to maintain the required purity of reactor coolant by circulating coolant through a system of filter-demineralizers.

5.1.1 Schematic Flow Diagram

A schematic flow diagram of the reactor coolant system denoting all major components, principal pressures, temperatures, flow rates, and coolant volumes under normal steady-state full-power operating conditions is presented in Figures 5.1-1 and 5.1-2.

5.1.2 Piping and Instrumentation Diagram

A piping and instrumentation diagram for the NSSS is presented in Figure 5.1-3.

5.1.3 Elevation Drawing

Elevation drawings showing the containment system perspective and the principal dimensions of the reactor coolant system in relation to the containment are shown in Figures 5.1-4 and 5.1-5.

GENERAL ARRANGEMENT, PRIMARY CONTAINMENT SECTION

5.2 INTEGRITY OF REACTOR COOLANT PRESSURE BOUNDARY

5.2.1 Design of Reactor Coolant Pressure Boundary Components

5.2.1.1 Performance Objectives

5.2.1.1.1 Reactor Pressure Vessel and Appurtenances

The function of the reactor pressure vessel (RPV) design is to provide a volume in which the core can be submerged in coolant, thereby allowing power operation of the reactor. Design of the RPV and appurtenances provides the means for attaching pipelines to the RPV and for installing RPV internal components. All or portions of each of the following support systems interface with the RPV and form part of the reactor coolant pressure boundary.

5.2.1.1.2 Reactor Pressure Vessel Vent

The function of the RPV vent is to remove noncondensibles from the top dome of the reactor during power operation and to provide a vent path for floodup of the vessel prior to vessel head removal during refueling outages.

5.2.1.1.3 Nuclear Pressure Relief System

The function of the nuclear pressure relief system (NPRS) is to limit any overpressure that occurs during abnormal operational transients.

5.2.1.1.4 Main Steam Line Flow Restrictors

The function of the main steam line flow restrictors is to protect the fuel barrier by not allowing the core to be uncovered. The restrictors limit the loss of coolant from the RPV to a value that will ensure the core will remain covered with water before the main steam isolation valve closure, should rupture occur in a main steam line outside the primary containment. Additionally, the restrictors limit the depressurization rate of the reactor to a value which ensures that the steam dryer and other reactor internal structures will remain in place. This is to prevent fragments from the dryer to be blown down the steam lines that may prevent tight closure of the main steam isolation valves.

5.2.1.1.5 Main Steam Line Isolation Valves

The function of the MSIVs, one of which is on the drywell side while the other is just outside the primary containment, is to prevent damage to the fuel barrier by limiting loss of reactor coolant for a major steam piping leak outside the primary containment. Main steam isolation valves also limit radioactive releases to the plant environs.

5.2.1.1.6 Deleted

5.2.1.1.7 Feedwater System

The function of the feedwater system is to provide normal feed flow to the reactor pressure vessel during plant power operation. The feedwater inboard isolation valves also serve as the first isolation valve for return lines from the HPCI, RCIC and RWCU systems described below.

5.2.1.1.8 Reactor Recirculation System

The function of the reactor recirculation system (RRS) is to provide a variable moderator (coolant) flow to the reactor core for adjusting reactor power level.

5.2.1.1.9 Standby Liquid Control System

The function of the standby liquid control system (SLCS) is to provide backup reactivity control in the event the control rods do not completely shutdown the core following a scram initiation.

An additional function of the SLCS is to provide suppression pool pH control in the event of a loss-of-coolant accident in order to prevent iodine re-evolution.

5.2.1.1.10 Residual Heat Removal System

The function of the residual heat removal (RHR) system is as follows.

a. To remove decay heat and residual heat from the nuclear steam supply system (NSSS) so that refueling and NSSS servicing can be performed

b. To supplement the fuel pool cooling and cleanup system (FPCCS) capacity, when necessary, with additional cooling capacity

c. To provide containment (suppression pool) cooling and containment spray

d. To provide low-pressure coolant injection (LPCI) flow for RPV reflood and core cooling in the event of a DBA-LOCA

5.2.1.1.11 Core Spray System

The function of the core spray (CS) system is to provide low pressure coolant flow directly to the core fuel elements in the event of a loss-of-coolant accident.

5.2.1.1.12 High Pressure Coolant Injection System

The function of the high pressure coolant injection (HPCI) system is to provide high-pressure makeup to the RPV in the event of a small-break loss-of-coolant-accident.

5.2.1.1.13 Reactor Core Isolation Cooling System

The function of the reactor core isolation cooling (RCIC) system is to provide makeup water to the RPV during shutdown and isolation to ensure adequate core cooling.

5.2.1.1.14 Reactor Water Cleanup System

The function of the reactor water cleanup (RWCU) system is to maintain high reactor water purity to limit chemical and corrosive action, thereby limiting fouling and deposition on heat-transfer surfaces. It also removes excess reactor coolant during shutdown, startup, and hot standby conditions.

5.2.1.1.15 Nuclear System Leak Detection System

The function of the NSSS leak detection system (LDS) is to detect leakage from the nuclear system process barrier before predetermined limits are exceeded.

5.2.1.2 Design Parameters

Table 5.2-1 lists design temperature, pressure, and maximum test pressure for the reactor coolant pressure boundary (RCPB) structures and components. The specified operating transients used for the design of components within the RCPB are given in Table 5.2-2. A discussion of the input criteria for seismic design is contained in Subsection 3.7.1.

The design requirements established to protect the principal components of the reactor coolant system against environmental effects are discussed in Subsection 3.11.2.

5.2.1.3 Compliance With 10 CFR 50, Section 50.55a

Compliance with the guidelines of 10 CFR 50, Section 50.55a, "Code and Standards," is included in Tables 3.2-1 and 3.2-3 and in Section 3.2.

5.2.1.4 Applicable Code Cases

The RPV is designed in accordance with the 1968 ASME Boiler and Pressure Vessel (B&PV) Code Section III, Class A, with addenda through summer 1969. The steam and recirculation piping is designed in accordance with the 1969 ANSI B31.7 Nuclear Power Piping Code, Class I, including addenda ANSI B31.7b-1971. The recirculation system, motor-operated valves and pumps, and MSIVs are designed in accordance with the 1968 Draft ASME Code for Pumps and Valves for Nuclear Power, Class I. Main steam safety/relief valves comply with 1968 ASME B&PV Code, Secton III, 1969 Summer Addenda, Paragraph N911.4 for pilot-activated valves. Applicable code cases used in various aspects of the design are given in Table 5.2-3.

5.2.1.5 Design Transients

5.2.1.5.1 Loading and Stress Criteria for Reactor Coolant Pressure Boundary Components Designed by Rational Stress Analysis

The loading conditions may be divided into four categories: normal, upset, emergency, and faulted conditions. These categories are generically described in the ASME B&PV Code Section III, 1968 Edition, N-412. Representative loading combinations, design procedures, and acceptability criteria are listed in Tables 3.9-17 and 3.9-18. These tables apply only to the pressure-containing components of the RCPB. The seismic criteria for the RCPB are discussed in Subsection 3.7.2.

5.2.1.5.2 Components Designed Primarily by Empirical Methods

There are some structural and electrical nonpressure-containing parts of equipment that are not normally designed or sized directly by stress analysis techniques.

Simple stress analyses are sometimes used to augment the design of these components, but the primary design work does not depend on detailed stress analysis. These components are usually designed from tests and empirical experience. Field experience and testing are used to support the design. Where the structural or mechanical integrity of components is essential to safety, the components referred to in these criteria have been designed to accommodate the events of the safe-shutdown earthquake (SSE), a design-basis pipe rupture, or a combination of these events where appropriate. The reliability requirements of such components cannot be quantitatively described in a general criterion because of the varied nature of each component and its specific function in the system.

5.2.1.5.3 Detailed Analyses of Reactor Coolant Pressure Boundary Pressure Parts of the Reactor Pressure Vessel

The RPV is designed in accordance with the ASME B&PV Code (1968) Section III, its interpretations and applicable requirements for Class A vessels as defined therein, as of the summer 1969 addenda.

Both elastic and inelastic stress analysis techniques were used in the design of the RPV core support and reactor internal structures to show that stress limits were not exceeded, as described in Subsection 3.9.1.6.

Stress analysis requirements and load combinations for the RPV are evaluated as described in Tables 3.9-13 through 3.9-15. The RPV was designed for an operational life of 40 years. (Refer to Appendix B for evaluation of 60 years.)

5.2.1.6 Identification of Active Pumps and Valves

5.2.1.6.1 Classification of Pumps and Valves

Pumps and valves (NPS > 1-1/4 in.) within the RCPB are listed in Table 5.2-4. These components may be classified as either active or inactive.

Active components are those whose operability (e.g., valve opening or closure, pump operation or trip) is relied on to perform a safety function and/or reactor-shutdown function during or following the transient or event under consideration. Inactive components are those whose operability is not relied on to perform safety or shutdown functions during or following the transient or event under consideration.

There are no active pumps within the RCPB. The RCPB valves are generally assumed to be active during normal operating and seismic events and system functional evaluations performed only for accident conditions.

Leaktightness capability requirements for all RCPB valves are included in the applicable valve specifications. Valve parts forming the RCPB were pressure tested in accordance with the requirements of Nuclear Pump and Valve Code or ASME B&PV Code Section III. The maximum allowable leakage past valve seats is 2 cm^3/hr/in. of seat diameter for gate and globe type valves and 10 cm^3/hr/in. of seat diameter for check valves under the system design pressure during manufacturer's shop test.

5.2.1.6.2 Design Methods and Procedures for Pipe Rupture

The design objectives used to ensure that active RCPB components function as designed in the event of a pipe rupture are described in Section 3.6.

5.2.1.7 Design of Active Pumps and Valves

To ensure the functional performance of active valves of the RCPB, stringent design requirements were applied. Operability is ensured in the following manner.

All active valves were qualified for operability assurance by first being subjected to the following tests:

a. Shop tests, which include hydrostatic tests and seal leakage tests, were performed as specified in the applicable code

b. The valves are required to open and close within specified time limits when subjected to design or environmental conditions as required by applicable codes and regulatory guides. These valves were also subjected to cold hydrostatic tests and functional tests as part of the Preoperational Test Program.

Valves are designed to withstand the accelerations and/or loads predicted by the piping stress analysis. Assurance is therefore provided that the components will function as required when subjected to design loadings.

Finally, active valves are also required to be operated periodically, as required in the Technical Specifications. This repeated operability requirement throughout the life of the specified valve further provides assurance of reliable valve operation.

The representative combination of loads and analysis to ensure valve operability are summarized in Tables 3.9-17 and 3.9-18.

5.2.1.8 Inadvertent Operation of Valves

A discussion of the design-basis events and appropriate limits for this plant is given in Subsections 15.1.4, 15.2.2, 15.2.4, and 15.2.7. The events in Chapter 15 have been selected to envelop the most severe change in critical parameters from events that have been postulated to occur during planned operation.

5.2.1.9 Stress and Pressure Limits

Paragraphs NB-3655 and NB-3656 of ASME B&PV Code Section III are not directly applicable to pumps and valves. On the basis of the method of establishing design pressure, however, it can be stated that the requirements of Paragraph NB-3655.1 and NB-3656.1 of the above code are met for these components.

The allowable stress limits and design loads for NSSS components are summarized in Tables 3.9-8, 3.9-14, 3.9-17 through 3.9-26, 3.9-28 through 3.9-39, and 3.9-43.

5.2.1.10 Stress Analysis for Structural Adequacy

Stress analysis is used to determine structural adequacy of pressure components of the RCPB under various operating conditions and earthquakes. Significant discontinuities such as nozzles and flanges are considered. In addition to the design calculations required by the ASME Codes, stress analysis is performed by methods outlined in the code appendixes or by other methods applicable to the design condition through reference to analogous codes or other published literature.

Results of areas with potentially significant stress concerns are given for major components in Tables 3.9.17 through 3.9-26.

5.2.1.11 Analysis Method for Faulted Condition

Elastic stress analysis methods in conjunction with elastic system analysis were generally used for RCPB components. In the event that an inelastic stress analysis was performed, the analysis methods conform to the requirements of ASME B&PV Code Section III, Appendix F.

5.2.1.12 Protection Against Environmental Factors

The protection of the principal components of the reactor coolant system against environmental effects is discussed in Section 3.11. Missile protection is discussed in Section 3.5, and fire protection is discussed in Subsection 9.5.1.

5.2.1.13 Compliance With Code Requirements

For components that were constructed in accordance with Section III of the ASME B&PV Code Subsection NB, the analytical calculations or experimental testing was performed to demonstrate compliance with the code. Brief descriptions of the mathematical or test models and the methods of calculation or testing, including any simplifying assumptions with summary of results, are provided in Subsection 3.9.1 and in Table 3.9-13 and in Tables 3.9-18 through 3.9-24.

5.2.1.14 Stress Analysis for Emergency- and Faulted-Condition Loadings

The types of stress analysis that were used for the emergency and faulted conditions are given in tables in Section 3.9.

5.2.1.15 Stress Levels in Category I Systems

A representative list of Category I RCPB systems and associated stress levels is provided in Tables 3.9-13 through 3.9-24. Piping isometrics for the major systems are shown in Figures 3.9-6 through 3.9-15.

5.2.1.16 Analytical Methods for Stresses in Pumps and Valves

The methods and criteria for analysis of stresses and deformations in the pressure boundary portions of Class 1 pumps are as described in the ASME B&PV Code Section III and the Nuclear Pump and Valve Code.

The methods and criteria for design and acceptability of stresses and deformations, as determined for the pressure boundary portions of Class 1 line valves and safety/relief valves (SRVs), are those described in the applicable portions of the ASME B&PV Code Section III, and the Nuclear Pump and Valve Code.

Pumps, line valves, and safety/relief valves purchased for this project were constructed and designed in accordance with the categories explicitly addressed by the ASME Nuclear Pump and Valve Code and ANSI B-31.7 Nuclear Power Piping Code. In the event that components supplied with geometries or design conditions for which code limits had not been developed, a complete description of the analytical methods and criteria used for evaluation of stresses and deformations was submitted by the manufacturer.

The summary of the detailed analyses for selected RCPB components (analytical models, method of calculation, and a summary of results) is shown in Tables 3.9-17 and 3.9-18.

5.2.1.17 Analytical Methods for Evaluation of Pump Speed and Bearing Integrity

The Rayleigh's approximation method is used to calculate the combined pump and motor shaft critical speed. This procedure, which equates the inertial forces of the rotating masses to the elastic restoring forces in the shafts, yields the lowest possible frequency of resonant shaft excitation. The lowest vibration frequency thus calculated must be at least 130 percent of the maximum expected pump speed. The hydrodynamic bearings in the motor or pump are designed using "A Solution for Finite Journal Bearings and Its Application to Analysis and Design," by A. A. Raimondi and J. Boyd, ASME Transactions, Volume I, No. 1, April 1958 or by an equivalent method. If the pump has a hydrostatic bearing, the motor bearings are analyzed as above while the pump bearing is analyzed by use of a computer code which is the proprietary information of one of our pump vendors.

5.2.1.18 Operation of Active Valves Under Transient Loadings

The qualification test program to verify that active valves within the RCPB whose operability is relied upon to perform a safety function or to shut down the reactor operate under the transient loadings experienced during service life is described in the following subsections.

5.2.1.18.1 Motor-Operated Gate Valve

A motor operator built to the same design as the RRS gate valves has been tested to demonstrate its performance capability under expected operating conditions, including the containment environment after the LOCA. Performance was tested under maximum moisture, pressure, and temperature conditions after exposure to lifetime radiation dose and under design-basis seismic conditions.

5.2.1.18.2 Main Steam Line Isolation Valves

Components of the MSIVs that are required to operate during transient conditions and whose functional capabilities are sensitive to the abnormal ambient pressure and temperature associated with the transient were subjected to a test sequence that simulates the abnormal ambient conditions. Functional requirements were verified throughout the test sequence. Components prototypical of Fermi 2 valve components were tested.

5.2.1.18.3 Safety/Relief Valves

The SRVs were subjected to tests described in Subsection 5.2.2.6 that simulate conditions similar to those experienced during service life.

5.2.1.19 Field-Run Piping

All piping 2 in. in diameter and smaller was designed by Edison but was fabricated and installed in the field by the piping erection subcontractor. This includes all small process piping, instrument piping, and branches from large piping (2-1/2 in. and larger). Small piping exists in all Category I piping systems.

Design, materials procurement, fabrication, erection, and testing of field-run piping are done in accordance with documented process control procedures. Review and approval, particularly for Category I pipe routings, location, and identification of all shop and field welds, are required by these procedures.

Small RCPB piping is generally analyzed using the computerized elastic stress analysis techniques described in Section 3.9.

Hydrostatic testing, prior to erection, is required for any pipe spool that is embedded in concrete or installed in an inaccessible location.

5.2.1.20 Feedwater Sparger and Thermal Sleeve

Several distinct problems have been experienced with the feedwater nozzle and spargers of the design originally planned for Fermi 2. These problems resulted in sparger arm cracks, flow hole cracks, thermal sleeve cracks, and cracks in the feedwater nozzle itself. The causes for these problems were identified, solutions were investigated, and a new design for the feedwater thermal sleeve and sparger was developed.

General Electric prepared a detailed report on the problems, description of solutions, verification of solutions, and safety considerations. This report, "Boiling Water Reactor

Feedwater Nozzle/Sparger," NEDE-21821, March 1978, was submitted to the NRC. The report gives a considerable body of data to show the acceptability of the GE design.

Fermi 2 incorporates all elements of the new design.

The new sparger/thermal sleeve design meets the following objectives:

a. Protects the feedwater nozzle against the high-frequency thermal cycles that initiate nozzle cracks

b. Is immune to the vibration that causes sparger arm cracks

c. Eliminates low-flow stratification

d. Eliminates the nozzle flow separation that causes flow hole cracks.

In the spargers, top-mounted elbows, each with a converging discharge nozzle, replace the front discharge holes. These features solve two problems. The top-mounted elbows ensure that the sparger/thermal sleeve remains full of cold feedwater during low-flow conditions, thereby eliminating low-flow stratifica-tion. The converging discharge orifices eliminate the flow separation that was the cause of flow hole cracking.

The junction between the thermal sleeve and sparger arms uses a forged tee, which improves resistance to vibration-induced cracking.

The thermal sleeve configuration is drastically different from previous designs. The inner thermal sleeve is the feed pipe for the sparger and is sealed against the safe-end with a piston ring. The inner thermal sleeve is welded to the forged tee.

Since leakage will eventually occur past the primary seal, a means must be provided to protect the nozzle against this leakage. To provide the required protection, a second seal is provided downstream of the primary seal. This secondary seal is attached to an intermediate thermal sleeve, which is open to the reactor at its downstream end. The annulus between the inter-mediate and inner thermal sleeves has a low hydraulic resistance and serves to channel leakage to the reactor without impinging on the feedwater nozzle. As a further impediment to leakage and to provide damping against vibration, an interference fit is provided between the ring, which contains the secondary seal, and the nozzle safe end.

The two seal members are joined by a slotted member. This slotted member provides a structural tie between the two seal members, which allows radial thermal expansion while providing rigidity against the translational motion of vibration. The slots also provide a flow path for the primary leakage flow to enter the inner annulus.

Since the second seal is exposed to a very small pressure differential, its tendency to leak is very small.

Primary leakage flowing between the inner and intermediate sleeves would cool the intermediate sleeve and thereby produce a cold boundary layer on the outside of the intermediate sleeve. This boundary layer might then shed and produce nozzle thermal cycles. To preclude this, an outer sleeve is provided to isolate the nozzle against such shedding.

Thermal cycling is the cause for blend radii cracking. The presence of cladding increases thermal stresses by approximately a factor of 2. Most plants have elected to machine off the cladding in this region. The design and fabrication of the Fermi 2 vessel did not clad the feedwater nozzle and blend radii. Therefore, incorporation of the new design will not involve the task of removing cladding. Calculations and test program results show the potential for crack initiation is essentially zero for extended high-frequency, low differential-temperature thermal cycling, expected with the new design and unclad nozzles.

Preservice ultrasonic (UT) examinations of the blend radii were conducted by SWRI, and magnetic-particle examination was conducted by the RPV manufacturer. No recordable indications were found by either technique. The Fermi 2 feedwater sparger and thermal sleeve design is in conformance with NUREG-0619.

The Fermi 2 ISI NDE program requires performance of periodic feedwater nozzle inner radius examination as required by ASME Section XI and NUREG-0619, or other NRC approved alternative program, to detect service induced degradation (cracking).

In-service penetration (PT) examination of the nozzle blend radii area will not be performed because of very limited access and the possibility of damage to the thermal sleeve and sparger assemblies in preparing the surface for PT examination.

5.2.2 Overpressurization Protection

5.2.2.1 Location of Pressure-Relief Devices

Figure 5.1-3 shows the schematic location of all pressure-relieving devices for

a. The reactor coolant system

b. The primary side of the auxiliary or emergency systems interconnected with the primary containment system

c. All blowdown or heat dissipation systems connected to the discharge side of the pressure-relieving devices.

5.2.2.2 Mounting of Pressure-Relief Devices

5.2.2.2.1 Safety Design Bases

The NPRS is designed

a. To prevent overpressurization of the NSSS that could lead to the failure of the nuclear system process barrier

b. To provide automatic depressurization for small breaks in the NSSS so that the LPCI and the core spray systems can operate to protect the fuel barrier

c. To permit verification of its operability

d. To withstand adverse combinations of loadings and forces resulting from operation during abnormal, accident, or special-event conditions.

5.2.2.2.2 Power Generation Design Bases

The NPRS SRVs have been designed

a. To maintain reactor pressure below the ASME B&PV Code Section III allowable maximum pressure during abnormal operational transients

b. To provide automatic depressurization for small breaks in the NSSS occurring with maloperation of high pressure coolant injection (HPCI) so that the low pressure coolant systems (LPCI and core spray) can operate to protect the fuel barrier

c. To discharge to the primary containment suppression pool

d. To correctly reclose following operation so that maximum operational continuity can be obtained.

5.2.2.2.3 Description

The NPRS consists of SRVs located on the main steam lines between the RPV and the first isolation valve within the drywell. These valves protect against overpressurization of the NSSS.

The SRVs provide four main protection functions:

a. Overpressure-relief operation - The valves open by application of external power to limit a pressure rise. In the relief valve mode, any of these valves can be operated by manual action from the control room. No particular setpoint applies to this method of operation, as the operator may open a valve at his discretion for blowdown or test over a wide pressure range

b. Overpressure-safety operation - The valves function as safety valves and open to prevent NSSS overpressurization. These valves are self-actuated at their spring setpoint if not already opened for relief operation

c. Depressurization operation - Five valves are opened by indirectly operated devices (pneumatic) as part of the emergency core cooling system (ECCS) for events involving small breaks in the nuclear system process barrier. These valves, which are selected for automatic depressurization, are activated automatically

d. Post fire depressurization operation – Selected valves are manually operated from the control room using their pneumatic controls to enable use of low pressure makeup for certain post fire shutdowns.

Figure 5.1-3 shows the schematic location of the valves and piping. The SRVs are constructed and marked with data in accordance with the 1968 Draft of the ASME Nuclear Pump and Valve Code and addenda through March 1970. The popping-point tolerance, the pressure at which valves open by high steam pressure, conforms with the ASME B&PV Code Section III.

The majority of events that lead to actuation of the primary system SRVs are those that initially or eventually produce a NSSS pressure increase. These pressure-increase events result from sudden reductions of steam flow while the reactor is operating at power.

Table 5.2-5 shows the set pressures of the safety/relief valves. Once any SRV opens, subsequent actuations are controlled by two SRVs that are armed with the low-low set relief logic. The duration of each relief discharge should in most cases be less than 15 sec.

The SRVs are designed to operate in the accident environments stated in Table 3.11-1.

These conditions envelop the predicted pressure and temperature response of the containment following the design-basis LOCA (Subsection 6.2.1).

Each SRV discharges steam through a discharge line to a quencher device located below the minimum water level in the primary containment suppression pool. The SRV discharge piping is designed to limit valve outlet pressure to 40 percent of maximum valve inlet pressure with the valve wide open. Water in the line more than a few feet above suppression pool water level would cause excessive pressure at the valve discharge when the valve is again opened. For this reason, a vacuum relief valve is provided on each SRV discharge line to prevent drawing an excessive amount of water up into the line as a result of steam condensation following termination of relief operation. In addition, the safety/relief blowdown control system ensures that subsequent SRV discharges will not occur during periods of elevated water legs in the discharge piping (see Fig. 7.3-12, Sheet 1).

The selection of size of safety/relief line vacuum breakers for Fermi 2 was based on the following parameters:

a. Instant condensation of steam is assumed following SRV closure

b. The vacuum created must be equalized in 2 sec

c. The volume to be relieved is based upon the longest safety/relief line

d. The drywell pressure was its minimum value, 14.2 psia

e. Conservative L/Ds and C_v's were selected for the valve.

The Fermi 2 study selected 8-in. vacuum relief valves. The capacity, C_v, set pressure, and pressure drop at rated flow for these valves used in the study calculation were supplied by the vendor based on extrapolation of experimental data taken from smaller but similar valves. The calculations in the study showed that under the parameters selected above, the vacuum will be relieved in 1.5 sec (versus the recommended 2 sec), and that the water leg inside the line would rise less than 4.3 ft past the submerged end of the line in this time.

The SRVs are located on the main steam line piping, rather than on the RPV top head, primarily to simplify the discharge piping to the pool and to avoid the necessity of having to remove sections of this piping when the reactor head is removed for refueling. In addition, valves located on the steam lines are more accessible to correct possible valve malfunctions during a shutdown.

Each of the five SRVs provided for automatic depressurization system (ADS) is equipped with an accumulator and check valve arrangement. Each accumulator receives pneumatic pressure from the safety-grade Division I primary containment pneumatic supply lines, which also supplies pressure to the air operators of two non-ADS SRVs. Division I primary containment pneumatic supply is normally fed from the nitrogen supply system, with Division I noninterruptible control air (NIAS) available by operator action to be manually cross connected as a backup supply for the normal pneumatic supply. There is also a qualified connection located outside the secondary containment to permit bottled nitrogen to be supplied as an additional backup source for the Division I pneumatics. The sizing for the ADS accumulators allows about 17 hours for the recovery of a backup pneumatic supply under the most limiting postulated event conditions requiring ADS. Leakage from the accumulator assembly and the SRV air operator subassembly were considered in evaluating the accumulator sizing. Each accumulator has adequate storage capacity to allow five actuations of an SRV at the long-term drywell pressure of the design SBLOCA analysis (see Figure 6.2-15) without the recovery of backup pneumatic supply pressure. This provides adequate pneumatic storage to cover interruptions if the pneumatic supplies are switched from the normal to the emergency backup sources. There are also eight non-ADS SRVs supplied by Division II of the primary containment pneumatic supply system, which is a separate, fully qualified pneumatic subsystem, but does not include NIAS as a backup supply. Backup nitrogen is provided bottles located inside the secondary containment to allow the use of Division II SRVs for certain Appendix R post-fire shutdowns from the control room accompanied by a loss of offsite power. An additional separate qualified connection located outside the secondary containment is provided to permit bottled nitrogen to be supplied for a backup source of the Division II pneumatics. The backup pneumatic supplies of both divisions of primary containment pneumatic supply system, although no credit is taken for, would allow the ten non-ADS SRVs to be operated as a backup for reactor pressure relief. The ten non-ADS SRVs include two SRVs, one associated with each pneumatic division, which have accumulators for the Low-Low Set function (see Section 5.2.2.5.3). Refer to Figure 5.2-1 for a diagram of the primary containment pneumatic supply system. The drywell nitrogen pneumatic system is described in Section 9.3.6.

The NPRS automatically depressurizes the NSSS sufficiently to permit the LPCI and core spray systems to operate. Depressurization occurs when five of the SRVs are opened automatically (ADS).

Descriptions of the operation and features of the automatic depressurization system are found in Subsections 6.3.2 and 7.3.1.

The NSSS can be depressurized manually if the main condenser is not available as a heat sink after reactor shutdown. The SRVs are operated by remote manual controls from the main control room. Controls for two of the relief valves are located on the remote control panel, and can thus be operated outside the main control room.

5.2.2.3 Overpressure Protection Analysis

The vessel overpressure protection system is designed to satisfy the requirements of Section III, Nuclear Vessels, of the ASME Boiler and Pressure Vessel Code 1968. The general requirements for protection against overpressure, as given in Article 9 of Section III, recognize that reactor vessel overpressure protection is one function of the reactor protection system and allows the integration of pressure relief devices with the protection system of the nuclear reactor. Hence, credit is taken for the reactor protection system as a complementary pressure protection device. However, the vessel overprotection analysis for Fermi 2 takes credit only for reactor protection system signals which are indirectly derived.

Included in this subsection are the design bases for sizing of the SRVs, the overpressure protection analysis, and the effects on the vessel pressure transients of valve capacity. The overpressure protection analysis used the actual Fermi 2 scram characteristics (e.g., for BWR/4 scram and control rod drive (CRD) systems).

The head spray piping (Class 2 pipe in the drywell) is no longer connected with the RPV. Therefore, it is no longer protected by the RPV overpressure protection system. However, a blank flange is installed in the line, preventing any pressurization of the head spray pipe.

5.2.2.3.1 Design Basis

5.2.2.3.1.1 Safety/Relief Valve Sizing

The safety/relief valve capacity of the Fermi 2 plant is sized to limit the primary system pressure, including transients, to the requirements of the ASME Boiler and Pressure Vessel Code, Section III, 1968, Nuclear Vessels. The essential ASME requirements, which are all met by this analysis, are stated below.

It is recognized that the protection of vessels in a nuclear power plant is dependent upon many protective systems to relieve or terminate pressure transients. Installation of pressure relieving devices may not independently provide complete protection.

The safety/relief valve sizing evaluation assumes credit for operation of the reactor protection system. A scram may be initiated by any one of three sources; i.e., steam system isolation (i.e., direct), neutron flux, or reactor vessel pressure signal. The system isolation scram signal is derived from position switches mounted on the main steamline isolation valves or the turbine stop valves or from pressure switches mounted on the dump valve of the turbine control valve hydraulic actuation system. The position switches are actuated when the respective valves are closing and following 10 percent travel of full stroke. The pressure switches are actuated when a fast closure of the control valves is initiated. However, according to General Electric methodology, the safety/relief valve sizing evaluation does not assume credit for direct scram, only for the indirect flux scram. Further, no credit is allowed for power operated pressure relieving devices. Credit is taken only for the dual purpose safety/relief valves in their ASME Code qualified mode of safety operation.

The above considerations in the vessel overpressure analysis methodology require multiple equipment failures to occur. The probability of this many multiple failures (loss of direct scram and no automatic power operated relief valve actuation) is sufficiently low that the event should be considered, as a minimum, an “emergency” condition. However, the analysis applies the more conservative “upset” code requirements rather than the “emergency” limits such that the rated capacity of the pressure relieving devices is required to be sufficient to prevent a rise in pressure within the protected vessel of more than 110 percent of the design pressure (1.10 x 1250 = 1375 psig). All combination safety/relief valves discharge into the suppression pool through a discharge pipe from each valve which is designed to achieve sonic flow conditions through the valve, thus providing flow independence to discharge piping losses.

The ASME Boiler and Pressure Vessel Code requires the nominal pressure setting of at least one safety/relief valve connected to any vessel or system to not be greater than a pressure at the safety/relief valves corresponding to the design pressure (1250 psig) anywhere in the protected vessel. Valves which are additional to the one(s) set at or below design pressure, may be set higher, but in no case are any of these settings to exceed a pressure at the safety/relief valves corresponding to 105 percent of the design pressure anywhere in the vessel.

5.2.2.3.2 Method of Analysis

To design the pressure protection for the nuclear boiler system, a detailed analytical model representing all essential dynamic characteristics of the system is simulated on a computer. This model includes the hydrodynamics of the flow loop, the reactor kinetics, the thermal characteristics of the fuel and its transfer of heat to the coolant; and all the principal controller features, such as feedwater flow, recirculation flow, reactor water level, pressure, and load demand. These characteristics are represented with all their principal nonlinear features in a model that has evolved through extensive experience and favorable comparison of the analysis results with actual BWR test data. A detailed description of the model is documented in a General Electric licensing topical report.*

Typical capacity characteristics, as modeled, are represented in Figure 5.2-1(a) for the safety/relief valves. The associated bypass, turbine control valve, and main steam isolation valve (MSIV) characteristics are, of course, also represented fully in the model.

NOTE: * Report reference above is: General Electric Company, Qualification of the One-Dimensional Core Transient Model for Boiling Water Reactors, NEDO-24154, October 1978. (ODYN)

5.2.2.3.3 System Design

A parametric study was conducted to determine the required steam flow capacity of the safety/relief valves which satisfies the ASME Code requirements. The parameters used in the study have been updated to evaluate the impact of the 105% steam flow power uprate.

5.2.2.3.3.1 Analytic Conditions

Parameter	Value
Power level, MWt	3499 (102% of 3430)
Steam flow, lb/hr	15,200,000
Core flow, lb/hr	105×10^6
Vessel dome pressure, psig	1048
Doppler coefficient	(a)
Average fuel temperature, °F	1330
Dynamic void reactivity coefficient	(a)
Void fraction	(a)
Control rod scram speed	See Figure 5.2-1(b)
Scram reactivity curve	(a)
High neutron flux (APM) scram percent of initial power (3430 MWt)	124.4 (b)

High vessel dome scram pressure, psig	1126 [(b)]
High vessel dome pressure recirculation pump trip set point, psig	1135

(a) This input is calculated by ODYN analysis.
(b) Maximum safety limit.

The ATWS recirculation pump has been simulated in the overpressure analysis performed with ODYN.

5.2.2.3.3.2 Transients

The overpressure protection system must accommodate the most severe pressurization transient. Both the closure of all main steam isolation valves and a turbine trip with bypass failure produce severe transients. The evaluation of transient behavior with final plant configuration has shown that the isolation valve closure is slightly more severe when credit is taken only for indirect derived scrams, therefore, it is used as the overpressure protection basis event.

5.2.2.3.3.3 Scram

a. Direct reactor scram - Not credited (failure assumed)

b. Scram reactivity curve - This input is calculated by ODYN analysis

c. Control rod drive scram motion - See Figure 5.2-1(b)

5.2.2.3.3.4 Safety/Relief Valve Characteristics

Type	Target Rock
Number	15[a]
SRV capacity, steam flow	$87x10^4$ lb/hr at 1090 psig[b]
First safety relief analytical setpoint, psig	1169
Number of safety relief groups simulated	3
Increment in SRV setpoint between groups, psi	10
Valve response characteristics	See Figure 5.2-1(a)

a 11 SRVs were used in the overpressure protection analyses for power uprate.
b See Table 5.2-5 for SRV capacities and setpoints.

5.2.2.3.3.5 Safety/Relief Valve Sizing

The safety/relief valve capacity required for overpressure protection is determined from the minimum capacity that will provide an adequate margin between the peak vessel pressure and the vessel code limit (1375 psig) in response to the MSIV closure-flux SCRAM event. The number of safety/relief valves which provide a total capacity equal to or greater than the minimum required capacity constitutes the minimum safety valve requirement for overpressure protection.

The MSIV closure-pressure SCRAM event is evaluated as confirmation of the safety/relief valve capacity determined from the safety/relief valve sizing criteria and to demonstrate the overpressure protection capability of the safety/relief valve system at the highest level of indirect SCRAM.

5.2.2.3.4 Evaluation of Results

5.2.2.3.4.1 Safety/Relief Valve Capacity

The required SRV capacity is determined by analyzing the pressure rise from an MSIV closure with a flux scram transient. The plant is assumed to be operating at turbine-generator design conditions at a maximum vessel dome pressure of 1048 psig. The analysis hypothetically assumes the failure of the direct isolation valve position scram. The reactor is shut down by the backup, indirect, high-neutron flux scram. For the analysis, relief setpoints of the SRVs are assumed to be in the range of approximately 1169 to 1190 psig.

Under the general requirements for protection against overpressure as given in Section III of the ASME Code, credit can be allowed for a scram from the reactor protection system. As discussed in Section 5.2.2.3.1.1, the backup reactor high-neutron-flux scram is conservatively applied as a design basis for determining the required capacity of the pressure-relieving dual-purpose SRVs. The direct position scrams are not used in the design basis but could be since they qualify as acceptable pressure protection devices when determining the required SRV capacity of nuclear vessels under the provisions of the ASME Code.

The cycle specific overpressure protection analysis is included with the supplemental reload licensing report and Figure 5.2-1(c) shows the analytical results from TRACG, with only 11 of the 15 SRVs operating. Beginning with Cycle 16, the cycle specific overpressure analysis is performed with TRACG (References 23 and 24). The sequence of events assumed in this analysis was investigated to ensure that the ASME Code requirements were met and to evaluate the pressure relief system exclusively. The peak vessel (bottom) pressure for the MSIV transient with high-flux scram is less than the 1375 psig allowed by the ASME Code.

5.2.2.3.5 Safety/Relief Valve Characteristics

5.2.2.3.5.1 Schematic Arrangement

The schematic arrangements of the safety/relief valves are shown in Figures 5.2-1(d) and 5.2-1(e).

5.2.2.3.5.2 Pressure Drop in Inlet and Discharge

Pressure drop on the piping from the reactor vessel to the valves is taken into account in calculating the maximum vessel pressure reported above.

Pressure drop in the discharge piping to the suppression pool is limited by proper discharge line sizing to prevent back pressure on each safety/relief valve from exceeding 40 percent of the valve inlet pressure, thus assuring choked flow in the valve orifice and no reduction of valve capacity due to the discharge piping. Each safety/relief valve has its own separate discharge line.

5.2.2.3.5.3 Safety/Relief Valve Description

These valves were manufactured by Target Rock Corporation to ASME Section III, 1968 with 1970 Summer Addenda. They comply with ASME Section III, 1969 Summer Addenda, Paragraph N911.4 for pilot activated valves.

Valve quantities and Technical Specification set pressures are as follows: Note: These values are based on actual vendor test data, not analytical values.

Quantity	Set Pressure (psig)	ASME Rated Capacity at 103 Percent of Set Pressure (lb/hr minimum)
5	1135	904,400
5	1145	912,200
5	1155	920,100

5.2.2.3.6 Conclusions

Safety requirements have long demanded very high reliability in the reactor scram functions. Recognition of this reliability as being completely adequate justification for these functions to contribute to vessel pressure protection is reflected in the ASME Section III Code provisions. As discussed in subsection 5.2.2.3.1.1, actual General Electric design practice very conservatively applies the code provisions through use of margins even beyond those necessary to satisfy code limits. This further enhances the reliability of vessel pressure protection.

This design basis for sizing safety valves with indirect scram credit is technically sound and a most realistic approach. It is allowed under Section III of the ASME Boiler and Pressure Vessel Code, and has been adopted by the General Electric Company in the design of the Fermi 2 boiling-water reactor.

5.2.2.4 Main Steam Safety/Relief Valves

The Fermi 2 valves are the Target Rock Corporation Model 7567F, two-stage, pilot-operated SRVs. The pilot stage is designed for stable setpoint performance and high tolerance of pilot seat leakage.

5.2.2.4.1 Description

Figure 5.2-2 shows the top works for the two-stage valve. Reactor pressure is communicated through port (5) around the stabilizer disk (7) to the pilot disk (6). With the pilot disk (6) seated, pressure is supplied through the connecting port (10) to volume (3) against the main piston (4) which holds the main disk closed. When the reactor pressure reaches the pilot setpoint, the pilot lifts and the stabilizer disk seats. The stabilizer holds the pilot disk open as long as the stabilizer is against its own seat. The open pilot valve forms part of the path that releases the steam in volume (3) through ports (8), (9), and (10) The pressure in (3) drops quickly, and differential pressure across the main piston (4) opens the main stage valve.

SRV actuation is indicated by tailpipe pressure switches. The operations are displayed and recorded in the control room.

The principal features of the Target Rock two-stage design, and how they relate to improved performance, are described below:

a. The pilot valve is connected directly to the main piston chamber (3). If there is leakage past the pilot disk (6), it comes from the inlet pressure port (5) and through leakage passages around the main piston that maintain the pressure in chamber (3); leakage goes to the valve discharge line through port (9). Tests have shown that, even with leakage at 200 lb/hr, there is no appreciable effect on setpoint performance, and leakage will not cause the valve to open and blow down the reactor. Calculations show that the pilot leakage could reach a level greater than 1000 lb/hr without pilot lift or main-stage operation.

b. The 2-stage design has a direct-acting pilot with no pressure-sensing bellows and no need for a pressure switch. This feature resolves three problems that have occurred in earlier designs which used a leakage containing pilot bellows.

    1. Bellows leak

    2. Switch failures

    3. Short circuits in switch wiring.

c. The air actuator (11) is an integral part of the bonnet and has improved diaphragm-sealing characteristics. This change eliminates the need for grease or gaskets to effect an adequate seal. Tests and operational experience have shown delamination failures of the diaphragm in earlier designs. Tests under the same environmental conditions showed that the 2-stage pilot air operator diaphragm does not delaminate.

5.2.2.4.2 Materials

The topworks body is made of ASME-SA-105 as a forging. This combination of material and fabrication is code acceptable for this service.

5.2.2.5 Safety Evaluation

5.2.2.5.1 Introduction

The ASME B&PV Code requires that each RPV designed to meet Section III be protected from overpressure. The code allows a peak allowable pressure of 110 percent of RPV design pressure. The SRVs are set to open as a safety function in the range of 1135 to 1155 psig.

There are two major transients that represent the most severe abnormal operational transients resulting in an NSSS pressure rise. They are the closure of all MSIVs, and a turbine trip with coincident loss of condenser vacuum.

The transient produced by the closure of all MSIVs and the failure of direct scram represents the most severe operational pressure rise. The required relief valve capacity is determined by analyzing the pressure rise from such a transient. The plant is assumed to be operating at the turbine-generator design conditions at a maximum vessel dome pressure of 1048 psig. The analysis hypothetically assumes the failure of the direct isolation valve position scram. The reactor is shut down by the backup, indirect, high neutron flux scram. For the analysis, the self-actuated setpoints (safety function) of the SRVs are assumed to be in the range of approximately 1169 to 1190 psig. The analysis indicates that the design valve capacity is capable of maintaining adequate margin (at least 50 psi at the bottom of the RPV) below the peak ASME B&PV Code allowable pressure in the NSSS (1375 psig). The sequence of events assumed in this analysis was investigated to confirm conformance to code requirements and to evaluate the adequacy of the NPRS.

Under the general requirements for protection against overpressure as given in Paragraph NB-7000 of the ASME B&PV Code Section III, credit can be allowed for a scram from the reactor protection system (RPS). When determining the required SRV capacity, credit is also taken for the protection signals, which are indirectly derived. The backup reactor high neutron flux scram is conservatively applied as a design basis in determining the required capacity of the pressure-relieving dual-purpose SRVs.

Studies have been made on the loadings that the SRVs impose on the main steam line. The loadings considered include

a. Thermal expansion effects of the SRVs discharge piping

b. Dynamic effects of the SRVs and discharge piping due to earthquakes

c. The dynamic and jet force exerted on the SRVs during the first millisecond after the valve is opened and prior to the time that steady-state flow has been established. With steady-state flow, the dynamic flow reaction forces are self-equilibrated by the valve discharge piping. For the analysis and forcing function, refer to Subsection 3.9.2.5

d. Deleted

Thermal expansion analyses were made for several cases including the relief valve piping, both cold and hot, and jet forces.

The critical effect is the stress at the branch connection below the valve. In no case does the stress at this point exceed code specifications.

The analysis that forms the basis for the evaluation of the pressure relief function of the NPRS appears in Subsections 15.2.2, 15.2.3, and 15.2.4.

The setpoints of the relief valves are adjusted to operate in the range from 1135 to 1155, by self-actuation (i.e., overpressure relief function). The reactor is shut down by the normal trip scram (turbine stop valve closure scram).

System malfunctions that pose threats to the radioactive material containment barriers are presented in Chapter 15.

5.2.2.5.2 Two-Stage Target Rock Safety/Relief Valves

The special test programs have shown that the 2-stage pilot operated Target Rock SRV design has potential for improved reactor safety, plant availability, and capacity factor as compared to an earlier Target Rock design from the following considerations:

a. The probability of spontaneous valve opening because of pilot valve leakage has been made essentially zero. This problem has had a significant effect on availability and capacity factor

b. The possibility of setpoint changes because of bellows leakage has been eliminated completely. Actual setpoint changes caused by bellows leakage have been rare; however, leakage past bellows seals, switch failures, and related problems have reduced availability and capacity factors. (Note that the function of the seal bellows on the stem of the air operator of the two-stage valve is in no way related to the function of the pilot bellows of the three-stage valve).

c. The probability of air operator diaphragm failures has been reduced. This item has been of lesser concern than the first two, but it is a significant improvement

d. The integral air actuator has improved the pressure boundary, and reduced the probability of bending and/or sticking of the actuator shaft.

5.2.2.5.3 Reducing Stuck-Open Relief Valve Events

In response to NUREG-0737, Item II.K.3.16, GE, on behalf of the BWR Owners Group, has performed a study of the feasibility contraindications of reducing challenges to the SRVs by various methods. This study reviews the potential methods of reducing the likelihood of stuck-open relief-valve (SORV) events in BWRs and estimates the reduction in such events that can be achieved by implementing these methods. The results of this study have been provided to the NRC.

Although the NUREG-0737 position deals primarily with the reduction of challenges to SRVs, its clear intent is to reduce the incidence of SORV events. Reducing challenges is only one of three approaches to reducing SORV events. The other two are reducing the causes of spurious blowdowns and reducing the probability of SRVs to stick open when challenged. All three of these approaches present feasible and effective opportunities for reducing the incidence of uncontrolled blowdowns via SRV.

The following proposed modifications by the BWR Owners Group exist at Fermi 2:

a. Two-Stage Target Rock Valves

   The use of two-stage Target Rock valves at Fermi 2, as compared to the plants with 3-stage Target Rock valves, reduces the spurious blowdown events by 40 to 60 percent

b. Low-Low Set Relief

   Fermi 2 is equipped with a "low-low set" design feature that changes the setpoints of selected SRVs following the initial opening of a number of SRVs.

This ensures that following the initial pressurization, the pressure will be relieved by the low-low set valve alone, and the remaining SRVs will not experience any subsequent actuations. The purpose of low-low set at Fermi is to mitigate postulated loads caused by a second (after initial) opening of an SRV. However, the low-low set will also serve to reduce the frequency of SORV events.

According to the BWR Owners Group evaluation, these existing modifications at Fermi 2 are equivalent to a reduction in SRV challenges by a factor of almost 10 (Table 5.1, Reference 14).

In addition to these proposed modifications, Edison further reduced the SORV frequency by lowering the RPV water level isolation setpoint for MSIV closure from Level 2 to Level 1 and lowering the pressure setpoint for MSIV closure. This results in reduced SRV challenges by eliminating isolation cycling of the SRVs resulting from transients such as feedwater controller failure, trip of both recirculation pumps, and loss of feedwater flow.

The two-stage Target Rock valves and low-low set relief feature plus lowering the RPV water level isolation setpoint for MSIV closure from Level 2 to Level 1 and lowering the pressure setpoint for MSIV closure reduce the SORV frequency by a factor of more than 10 and meet the requirement of NUREG-0737, Item II.K.3.16.

5.2.2.6 Qualification Tests

5.2.2.6.1 Inspection and Testing

In November and December of 1976, GE performed a qualification/ life-cycle test program on one valve of the 2-stage pilot operated design. The program consisted of 300 valve cycles (150 manual and 150 pressure-induced operations). The objective of the life-cycle test was to verify the ability of the design to meet the requirements for (1) set pressure, (2) opening and closing response time, (3) blowdown, (4) seat tightness, and (5) achievement of flow-rated capacity lift (ASME). These tests were performed at reactor conditions, using a test facility that had the capability of providing full steam flow through the SRV when it opened. During the course of the test program, it was noted that the delay time on opening was erratic, and the pressure difference between the setpoint and reclosure was not large enough. All other performance parameters were acceptable, even at the extremes of low and high pressurization rates and the extremes of ambient temperatures. The same valve was operated another 150 cycles to identify the causes of the observed anomalies.

Minor design improvements were made to the 2-stage pilot operated valve design as a result of these tests, although the valve was functionally acceptable.

Because there had been design changes, a new qualification test program was begun in late 1977 by Target Rock Corporation. The program consisted of 300 cycles on one valve, and 60 cycles on each of three additional valves. These tests were completed satisfactorily. The tests showed that the valves produced consistently repeatable setpoint pressure operation, consistent delay times of less than, or equal to, 400 msec, and consistent reclosure ΔP's for a given back pressure.

Additional tests were performed to provide the data necessary for final selection of the seal bellows area. Note that these tests and the final selection comprise a "fine-tuning" improvement of a thoroughly tested and qualified valve.

The electric-pneumatic actuator assembly was subjected to a qualification aging test that consisted of (1) a reference frame test to determine leakage, response time, and solenoid electrical characteristics for subsequent comparison; (2) radiation aging to a cumulative radiation dose of 19.6 x 10^6 rads; (3) a reference frame test for the postradiation condition; (4) mechanical aging of 8000 cycles under normal ambient conditions of 150°F at 100 percent relative humidity; (5) thermal aging to 285°F at 100 percent relative humidity for 480 hr in air; (6) a reference frame test for the post-aging condition; (7) a simulated LOCA environment; (8) a reference frame test for the post-LOCA condition; (9) an accident radiation exposure of 13 x 10^6 rads; and (10) a final reference frame test. The qualification aging test established that the actuator assembly was compatible with the service environments.

In parallel with the latter part of the above testing, a seismic qualification test was performed consisting of a valve mounted on a shake table subjected to biaxial vibration, with statically applied moment loads at the valve flanges. The test program consisted of (1) resonant frequency determination, (2) nozzle loading, (3) a simulated operating-basis earthquake (OBE), (4) an SSE, and (5) reference frame tests. The valve was operated under reactor conditions using a restricted steam flow arrangement.

The qualification test results: (1) verified that the SRV design will be operable and is structurally sound under the various normal and abnormal environmental and dynamic conditions to which the valve may be subjected in service; (2) established the basis for confirming the installed and qualified life of the valve; and (3) provided information necessary to enhance the established quality assurance program to ensure that new valves are equivalent to the qualified design.

The vessel overpressure protection analysis in Subsection 5.2.2.3 shows that the peak vessel (bottom) pressure for the limiting MSIV transient with high-flux scram and position trip scram is less than the 1375 psig allowed by the ASME code. The cycle-specific results of the vessel overpressure protection analysis are reported in the cycle-specific Supplemental Reload Licensing Report. The deviation of setpoints by a common-mode failure after installation is highly unlikely because of the qualification and the established quality assurance program previously discussed. However, even considering the possibility of setpoint drift, the peak pressure for the limiting operational transient will still be less than the ASME Code limit.

In addition, in response to comments from the NRC on operation of relief valves during abnormal transients, Edison, together with the BWR Owners Group, undertook a special SRV testing program reported in Reference 1. The results of the BWR Owners Group evaluation indicated that there is one event and single-failure combination that would lead to the discharge of liquid from the SRVs. This event and single-failure combination leads to the alternative shutdown mode of operation that uses the SRVs as a return flow path for low-pressure liquid to the suppression pool. The evaluation demonstrated that all other events postulated to produce liquid or two-phase SRV flow, including events under high-pressure conditions, are either of sufficiently low probability or that consequences are concluded to be acceptable. As such, no testing is needed for these events.

The BWR Owners Group testing program included the testing of typical SRVs for BWR/2 through BWR/6 plants to demonstrate the ability to perform satisfactorily under the condition in which low-pressure (i.e., up to 250 ± 20 psig) water passes through the valve instead of saturated steam. This corresponds to conditions expected during the alternate shutdown cooling mode; that is, the mode in which low-pressure pumps are injecting cold water into the reactor vessel and this water is vented through the SRVs back to the suppression pool. A plant-specific evaluation (Reference 2) of the test data correlated the generic program test conditions to the alternate shutdown cooling mode conditions for Fermi 2.

For Fermi 2, the alternate shutdown cooling mode of passing water through the SRVs to the suppression pool is not an anticipated operating condition. The Fermi 2 design includes a parallel flow path (see section 5.5.7.3) inside containment for shutdown cooling employing a normally closed, remote manual isolation valve powered from the alternate division emergency power supply. In any case, the test results demonstrated that the Fermi 2 SRVs would be available and can accommodate adequate water passage for shutdown cooling in the extremely unlikely event that the normal shutdown cooling path and its backup are unavailable.

Also, Edison participates in a utility-sponsored performance evaluation program for SRVs.

5.2.2.6.2 <u>Inservice Inspection and Testing</u>

The following inservice test program is applied.

a. Fifty percent of the valves are to be removed from service and tested at least once per fuel cycle.

b. The remaining 50 percent are to be tested at least once per two fuel cycles.

The program for the in-place monitoring of valve performance is conducted by monitoring the discharge pipe thermocouples. Thermocouples, with continuous readouts, provide the signals that establish the leaktightness of the valve. In addition, a position monitoring system has been provided that meets the requirements of NUREG-0578.

The SRV inspection and overhaul program is developed from the manufacturer's recommendations to ensure the operability of these valves. The frequency of visual inspection and overhaul is in accordance with applicable ASME operating and maintenance standards for SRVs.

This testing and inspection will provide added confidence that the valves will operate reliably, and that there are no deficiencies that could cause them to function, in service, in an unsafe manner.

The SRVs are tested in accordance with Quality Control (QC) procedures to detect defects and to prove operability prior to installation. The following tests are conducted:

a. Hydrostatic test at ANSI-specified test conditions

b. Pneumatic seat leakage test at 90 percent of set pressure, with maximum permitted leakage of 30 bubbles per minute emitting from a 0.250-in.-diameter tube submerged 0.5 in. below a water surface, or an equivalent test using an approved test medium

c. Set pressure test with valve pressurized with saturated steam, or other approved test medium with the pressure rising to the valve set pressure

d. Response time test with each SRV tested to demonstrate acceptable response time.

The valves are installed as received from the factory. The setpoints are adjusted, verified, and indicated on the valves by the vendor. Specified manual and automatic actuation relief mode of each SRV pilot is verified during the Preoperational Test Program.

It is not feasible to test the SRV setpoints while the valves are in place or during normal plant operation. The valves are mounted on 6-in.-diameter, 1500-lb primary service rating flanges. They are removed for maintenance or bench checks and reinstalled during inspection periods.

The external surface and seating surface of all SRVs are 100 percent visually inspected when the valves are removed for maintenance or bench checks.

The SRV inspection and overhaul program is developed from the manufacturer's recommendations to ensure the operability of these valves. The frequency of visual inspection and overhaul will be in accordance with applicable ASME operating and maintenance standards for SRVs.

The improbable failure of the relief mode function of this valve will not cause failure of the safety mode function of the valve, and vice versa.

The automatic depressurization capability of the ADS is evaluated in Subsections 6.3.2 and 7.3.1.

5.2.2.7 Routing of Nuclear Pressure Relief System Valves to Torus

The NPRS valves could discharge to the drywell without exceeding drywell design conditions. However, such a discharge would cause undesirable high temperature and high moisture transients on drywell equipment. Consequently, all valves are routed to the torus with discharge below the water.

A separate discharge line is provided for each of the 15 valves. The isometric of one typical line is shown in Figure 5.2-3. The lines do not penetrate containment; they are routed to the torus through the drywell-to-torus vent lines. Inside the torus, they penetrate the vent line and terminate in a T-quencher. Details of a typical line inside the torus are shown in Figures 5.2-4 through 5.2-7.

The portions of the lines inside the drywell and the torus are designed and classified as Quality Group B,* Category I, QA Level I. The discharge lines are made of Schedule 80, seamless carbon steel pipe; joints are butt welded with a backing ring. Each line is equipped with an 8-in. vacuum breaker. The T-quenchers are designed and classified as Quality Group C, Category I, QA Level I.

The lines have been sized to be nonlimiting on flow; i.e., the back pressure at the relief valve is well below that which restricts the capacity of the valve. The lines are l0-in. nominal size in the drywell, 12-in. in the vents and torus. The discharge line supports are designed to handle the maximum reaction load. In addition, the supports in the torus are designed to accommodate the hydrodynamic loading conditions that occur during accident events. The evaluation is documented in Reference 2.

NOTE: * The portions of the lines in the vent line were originally installed as Quality Group D. These portions of the lines have been upgraded to include the requirements of Quality Group B components and are classified as Quality Group D+, Category I, QA Level I.

5.2.2.8 Pressure Isolation Valves

There are several safety systems connected to the RCPB that have design pressures below the rated reactor coolant system (RCS) pressure. There are also some systems which are rated at full reactor pressure on the discharge side of pumps but have pump suctions below RCS pressure. To protect these systems from RCS pressure, two or more isolation valves are placed in series to form the interface between the high-pressure RCS and the low-pressure systems. The leaktight integrity of these valves must be ensured by periodic leak testing to prevent exceeding the design pressure of the low-pressure systems, thus causing an inter-system LOCA.

5.2.3 General Material Considerations

5.2.3.1 Material Specifications

The principal pressure-retaining materials and the appropriate material specifications for the RCPB components are listed in Table 5.2-6.

5.2.3.2 Compatibility With Reactor Coolant

The construction materials exposed to the reactor coolant are

a. Solution-annealed austenitic stainless steels (both wrought and cast) types 304, 304L, 316, and 316L

b. Nickel base alloys, Inconel 600 and Inconel X750

c. Carbon steel and low alloy pressure vessel steel

d. Some 400 series martensitic stainless steel, all tempered at a minimum of 1100°F

e. Colmonoy and Stellite hardfacing materials.

f. Precipitation hardenable stainless steel material, XM-13.

All of these construction materials are resistant to stress corrosion in the BWR coolant. General corrosion on all materials except carbon and low alloy steel is negligible. Conservative corrosion allowances are provided for all exposed surfaces of carbon or low alloy steels.

Contaminants in the reactor coolant are controlled to very low limits by the reactor water quality specifications. No detrimental effects will occur on any of the materials from allowable contaminant levels in the high purity reactor coolant.

5.2.3.2.1 Steps To Minimize Stress Corrosion Cracking

In September 1974, cracking was experienced in the stainless steel piping at Dresden Nuclear Power Station Unit 2. This was the first of a series of incidents of intergranular stress corrosion cracking (IGSCC) that occurred in BWRs. The cracking occurred in weld heat-affected zones in type 304 stainless steel recirculation bypass piping systems and core spray lines.

In May 1984, during a recirculation piping system replacement at the Pilgrim Station, IGSCC was discovered and confirmed in the Inconel 182 butter welds for recirculation piping RPV nozzles. This was the first of several instances documenting IGSCC in Inconel buttering which was not directly attributed to resin intrusions or other causes. With the issuance of NUREG 0313, Revision 2, and NRC Generic Letter 88-01, Inconel 182 has been removed from the list of materials which were considered resistant to IGSCC (NUREG 0313, Revision 2. par. 2.1.1). Since most reactor pressure vessel (RPV) nozzles were "buttered" with Inconel 182 prior to welding the "safe-ends" to the nozzles and the nozzles to safe-end welds were made using Inconel 182 filler metal, these welds were reclassified as "susceptible" to IGSCC.

As a result of these incidents, studies were undertaken by the NRC, GE, and Electric Power Research Institute (EPRI). These studies have shown that such cracking is caused by a combination of the presence of significant amounts of oxygen in the coolant, high stresses, and some sensitization of metal adjacent to welds. Such cracks are not expected to occur outside the heat-affected zones adjacent to welds, provided that the pipe material is annealed properly.

Pipe runs containing stagnant or low-velocity fluids have been observed to be more susceptible during plant operation to stress corrosion cracking than pipes containing a continuously flowing fluid. Historically, these cracks have been identified either by volumetric examination, by leak detection systems, or by visual inspection. Because of the inherent high material toughness of austenitic stainless steel piping, stress corrosion cracking is unlikely to cause a rapidly propagating failure resulting in a design-basis LOCA.

Although the probability is extremely low that these stress corrosion cracks will propagate far enough to create a significant safety hazard to the public, the presence of such cracks is undesirable. Steps have been taken to minimize stress corrosion cracking in Fermi 2 piping systems, to eliminate this condition, and to improve overall plant reliability. The various mitigating programs used at Fermi 2 to minimize the potential for IGSCC fall into three major categories: (a) induction heating stress improvement (IHSI), (b) solution annealing, and (c) Mechanical Stress Improvement Process (MSIP).

The countermeasures using solution annealing are expected to remain effective for the life of the plant, since no sensitized material will be exposed to reactor water at these welds.

The IHSI treatment is also expected to remain effective for the life of the plant, since it was implemented prior to operation. Plants in Japan have been operating for approximately 5 years after having performed IHSI. Edison will monitor the applicable performance of these plants and will make adjustments accordingly.

The MSIP treatment results in the stress reversal at the weld root and is a permanent "life-of-plant" mitigation method.

The specific actions taken to minimize the potential for IGSCC are addressed in Subsections 5.2.3.2.1.1 through 5.2.3.2.1.5.

5.2.3.2.1.1 Piping Modifications

Operating experience has shown that the line most susceptible to IGSCC is the recirculation pump discharge valve bypass line. General Electric has developed operating procedures that do not require the use of this line, thereby enabling the line to be removed from the system. The 4-in. sweepolets in the 28-in. recirculation pipe are closed with caps clad with type 308L stainless steel. The design and installation of the caps include incorporation of geometries necessary for inservice UT examinations.

The other line susceptible to IGSCC cracking is the reactor core spray line. The initial design of this line for Fermi 2 specified carbon steel with a short stainless steel transition piece connected to the RPV stainless steel safe-end. This transition piece has been changed to carbon steel; the safe-end has been changed to Inconel with a carbon steel extension piece. Much of the IGSCC research done by GE concerned the recirculation system. This system is exposed to reactor coolant and is fabricated of type 304 stainless steel. Much of this system is 28-in. and 22-in. pipe. On the basis of GE studies, residual stress levels in welds in this pipe were thought to be below the threshold to develop IGSCC. To further reduce residual stress levels at field welds, special welding procedures were adopted that reduced the weld heat input to 50,000 joules per inch and which prohibited weld bead straightening. In addition, special restrictions were placed on internal grinding. To minimize susceptibility of the weld metal to IGSCC, the weld metal should contain at least 8 percent ferrite.

The GE studies show welds in 12-in. pipe in the recirculation system risers to be much closer to the IGSCC threshold. To minimize IGSCC susceptibility of these pieces, they were returned to the shop for solution annealing and for application of a nonsusceptible inlay to the ends. The inlay extends beyond the heat-affected zone from field welds. Thus, no sensitized 12-in. pipe is exposed to reactor coolant.

5.2.3.2.1.2 Recirculation Inlet Nozzles

The recirculation inlet nozzle configuration for Fermi 2 is shown in Figure 5.2-8. The thermal sleeve is type 304 stainless steel; the weld buildup pad on the nozzle is type 308.

This configuration is different from the ones which have developed IGSCC.

a. The thickness of the pressure retaining boundary at the attachment is 4.751 in. on Fermi 2 versus 0.5 in.; therefore, stresses are very much lower

b. The pad material on Fermi 2 is type 308 stainless steel versus Inconel. Type 308 is basically not susceptible to IGSCC.

Compared to the configuration that developed IGSCC, the lower stress and decreased vulnerability of the Fermi 2 configuration will greatly increase the time to IGSCC initiation (if any occurs at all) and slow the rate of growth if IGSCC is initiated.

The configuration of Fermi 2 recirculation line vessel nozzles is essentially the same as that on five other operating plants: Millstone, Pilgrim, Cooper, FitzPatrick, and Hatch 1.

The safe-end welds are scheduled to be examined as part of the ASME Section XI Inservice Inspection Program. In addition, welds selected in accordance with the rules of Section XI will receive an increased frequency of examination commensurate with the requirements of NUREG-0313 (Revision 2) and Generic Letter 88-01, or other NRC approved alternative program.

5.2.3.2.1.3 Induction Heating Stress Improvement

Operating experience has shown that many BWR plants have had problems with IGSCC in large-diameter recirculation system piping. To minimize the likelihood of IGSCC in portions of the recirculation system piping that had not received IGSCC remedies, IHSI was performed during July 1983. Induction heating stress improvement is recommended by both GE and EPRI as an effective IGSCC countermeasure, especially for plants under construction.

On completion of IHSI, only four welds in the recirculation system piping did not receive some IGSCC countermeasure. These welds have been included in the inservice inspection program and will be inspected on the inspection cycle detailed in NUREG-0313, Revision 2, and Generic Letter 88-01, or other NRC approved alternative program.

5.2.3.2.1.4 Mechanical Stress Improvement Process

During the first refueling outage, the Mechanical Stress Improvement Process (MSIP) was applied to twenty-one (21) reclassified RPV nozzle and safe-end welds, four (4) welds not treated by IHSI, and two (2) bi-metallic welds in the reactor water clean-up system, which, due to changes in the NUREG 0313, Revision 2, susceptibility criteria, were re-evaluated as IGSCC susceptible. On completion of the MSIP treatment of these twenty-seven welds, all ASME Section III welds which were evaluated as IGSCC susceptible have had an IGSCC mitigation method applied. All of the IGSCC susceptible welds have been included in the inservice inspection program and will be inspected on the inspection cycle detailed in NUREG 0313, Revision 2, and Generic Letter 88-01, or other NRC approved alternative program.

5.2.3.2.1.5 Control Rod Drive System Modifications

Some BWR plants have experienced IGSCC in the collet retainer tube in their CRDs. General Electric has attributed this cracking to thermal cycles during hot scrams, followed by exposure to oxygenated CRD cooling water that is aggressive to sensitized material.

The program adopted by Fermi 2 is consistent with GE recommendations. It consists of the following three parts:

a. An augmented surveillance and inspection program

b. Modification of CRD operations to eliminate unnecessary thermal cycling

c. Modification of the CRD water supply to provide high-purity deaerated water to the CRD system during plant operation.

Specifically, the Fermi 2 program consists of the following actions:

a. Each rod not fully inserted will be tested to confirm operability by inserting one or more notches in accordance with the frequency specified in the Technical Specifications.

b. All CRDs removed for maintenance will have a dye penetrant examination of the outer surface of the collet retainer tube. The criteria established by GE in Service Information Letter (SIL) 139 will be used to decide rejection. The term collet retainer tube refers to a portion of the outer tube, and replacement of a rejected collet retainer tube requires a new cylinder, tube, and flange subassembly

c. A CRD with a high-temperature alarm will not be cooled by giving it repeated drive signals

d. The source of water for the CRD system has been changed to the condensate treatment system effluent with the condensate storage tank as backup. The new water source is very pure and of very low oxygen content. (See torus water management system, Subsection 9.2.8.)

e. A flowing sample line downstream of the drivewater filter has been installed to provide for conductivity and oxygen grab sample measurement.

The use of high-purity deaerated water affects a significant increase in the time to crack formation. General Electric believes the time to crack initiation in current CRD collet retainer tubes may be increased by a factor of 100 with this reduction in dissolved oxygen content.

5.2.3.2.1.6 Inservice Inspection and Leak Detection

NUREG-0313, Revision 2, and Generic Letter 88-01, January 1988, present the technical bases for the NRC staff positions on materials, processes, and primary coolant chemistry to minimize and control IGSCC problems. Inspection schedules are comparable to those specified in Section XI of the ASME Boiler and Pressure Vessel Code in cases where the piping material is IGSCC resistant.

The modifications discussed in the previous subsections significantly reduce susceptibility to IGSCC. As detailed in Generic Letter 88-01, inspection schedules and inspection sample sizes are based on the susceptibility of weldments to initiation and propagation of IGSCC. Varying amounts of augmented inspections are specified for piping, with a greater susceptibility to cracking.

All applicable welds at Fermi 2 have been evaluated and classified according to the requirements of NUREG 0313, Revision 2, and Generic Letter 88-01. As required selected welds are included in the ASME Section XI Inservice Inspection Program.

The leak detection capability on Fermi 2 discussed in Subsection 5.2.7.3 is consistent with the 5 gpm rate discussed in NUREG-0313, Revision 2. As stated in Subsection 5.2.7.3, the unidentified leakage rate limit is established to allow time for corrective action before the nuclear system process barrier can be significantly compromised.

5.2.3.2.2 Steps To Maintain Occupational Exposure As Low As Reasonably Achievable

Steps taken in the selection of material to minimize and control the buildup, transport, and deposition of activated corrosion products in the reactor coolant and auxiliary systems follow:

The primary coolant system consists primarily of carbon steel (very low nickel and cobalt content), except for the use of austenitic stainless steel (in the recirculation loops) and low alloy steel. The nickel content of these materials is low and is controlled in accordance with the applicable ASME material specifications. Because the cobalt in steel usually appears as a small-percentage component of the nickel (usually, 2 percent of the nickel), the amount of cobalt in the primary system components is also very low.

A small amount of nickel base material (Inconel 600) is used in the RPV internals. Inconel 600 is required where components are attached to the reactor vessel shell, and the coefficient of expansion must match the thermal expansion characteristics of the low alloy vessel steel. Inconel 600 was selected because it provides the proper thermal expansion characteristics and adequate corrosion resistance, and can be fabricated and welded readily.

Hardfaced and wear-resistant materials having a high percentage of cobalt were restricted to applications in which no satisfactory alternative materials were available at the time of construction.

5.2.3.3 Compatibility With External Insulation and Environmental Atmosphere

The RCPB is insulated with an all-metal (stainless steel and aluminum) reflective-type insulation in compliance with Regulatory Guide l.36. This type of insulation does not contain any silica, fluorides, or chlorides. It does not contribute to surface contamination, and it has no effect on the stainless steel components of the RCPB. The insulation is designed to perform its intended function throughout the expected life of Fermi 2.

5.2.3.4 Chemistry of Reactor Coolant

The coolant chemistry requirements discussed in this subsection are consistent with the requirements of Regulatory Guide 1.56.

Reactor water chemistry limits are established to provide an environment favorable to materials in contact with the water. Limits are placed on conductivity and chloride concentrations. Conductivity is limited because it can be continuously and reliably measured by an in-line conductivity cell and gives an indication of abnormal conditions and the presence of potentially detrimental constituents in the coolant. Chloride limits are specified to minimize the potential of stress corrosion cracking of stainless steel. The accuracy of the conductivity cell is verified once per week by radiation chemistry personnel.

Several investigations have shown that in neutral solutions some oxygen is required to cause stress corrosion cracking of stainless steel, while in the absence of oxygen no cracking occurs. One of these is the chloride-oxygen relationship of Williams (Reference 3), where it is shown that at high chloride concentration little oxygen is required to cause stress corrosion cracking of stainless steel and at high oxygen concentration little chloride is required to cause cracking. These measurements were determined in a wetting and drying situation using alkaline-phosphate-treated boiler water and, therefore, are of limited significance to BWR conditions. They are, however, a qualitative indication of trends.

The water quality requirements are further supported by GE stress corrosion test data, summarized as follows:

a. Type 304 stainless steel specimens were exposed in a flowing loop operating at 537°F. The water contained 1.5 ppm chloride and 1.2 ppm oxygen at pH 7. Test specimens were bent beam strips stressed over their yield strength. After 2100 hr exposure, no cracking or failures occurred

b. Welded type 304 stainless steel specimens were exposed in a refreshed autoclave operating at 550°F. The water contained 0.5 ppm chloride and 1.5 ppm oxygen at pH 7. Uniaxial tensile test specimens were stressed at 125 percent of their 550°F yield strength. No cracking or failures occurred at 15,000 hr exposure.

Zirconium alloys and Inconel alloys are highly resistant to chloride stress corrosion cracking failure.

When conductivity is in its normal range, pH, chloride and other impurities affecting conductivity will also be within their normal range. When conductivity becomes abnormal, chloride measurements are made to determine whether or not they are also out of their normal operating values. This would not necessarily be the case. Conductivity could be high due to the presence of a neutral salt which would not have an effect on pH or chloride. In such a case, high conductivity alone is not a cause for shutdown. In some types of water-cooled reactors, conductivities are high because of the purposeful use of additives. In BWRs, however, where few additives are used and where near-neutral pH is maintained, conductivity provides a good and prompt measure of the quality of the reactor water. Significant changes in conductivity provide the operator with a warning mechanism so he can investigate and remedy the condition before reactor water limits are reached. Methods available to the operator for correcting the off-standard condition include operation of the reactor cleanup system in the blowdown mode, reducing the input of impurities, and placing the reactor in the cold-shutdown condition. The major benefit of cold shutdown is to reduce the temperature-dependent corrosion rates and to provide time for the RWCS to reestablish the purity of the reactor coolant.

Zinc is added to the reactor water, via the feedwater system, to control radiation buildup on out-of-core primary coolant piping. The amount of zinc that will be added to the reactor water will increase the conductivity of the reactor water. This will not impact the use of conductivity as a good and prompt measure of the quality of the reactor water. The increases above the new equilibrium conductivity value can still be used as an indicator of impurities entering the reactor. The zinc added can be accounted for in overall conductivity of the reactor water.

The conductivity and dissolved oxygen levels of the reactor coolant are continuously monitored. The samples of the coolant which are taken periodically serve as a reference for calibration of these monitors and are considered adequate to ensure accurate readings of the monitors. If conductivity is within its normal range, chlorides and other impurities will also be within their normal ranges.

The relationship of chloride concentration to specific conductance measured at 25°C for chloride compounds such as sodium chloride and hydrochloric acid can be calculated (Reference 4). Values for these compounds essentially bracket values of other common chloride salts or mixtures at the same chloride concentration. Surveillance requirements are based on these relationships. The sampling frequency when reactor water has a low specific conductance is adequate for calibration and routine audit purposes. When specific conductance increases, and higher chloride concentrations are possible, or when continuous conductivity monitoring is unavailable, increased sampling is provided.

Chloride analysis of the reactor coolant is performed as required or at least daily on grab samples. Approved radiation chemistry section procedures, using methods such as specific ion electrode or titration, are used to determine the chloride concentration.

The reactor water quality for plant design and operational control when operating at rated power is:

a. Conductivity - ≤1.0 μmho/cm at 25°C

b. Chlorides (as Cl^-) - ≤200 ppb

c. pH - 5.6 to 8.6 at 25°C.

Reactor water quality in excess of the limits specified above is limited to 72 hrs for any instance. Exceeding the maximum limits specified below shall be cause for shutdown and cool down to ambient temperatures until the water is within the quality limits specified above:

a. Conductivity - 10 μmho/cm at 25°C

b. Chlorides (as Cl^-) - 0.5 ppm

Reactor water quality is also limited based on time in excess of operational limits on conductivity and chlorides.

a. Time above 1 umho/cm - 2 weeks per 12-month period

b. Time above 200 ppb (Cl^-) - 2 weeks per 12-month period

The addition of zinc will add to the dissolved metals, total metals, and conductivity in the reactor water. The zinc will provide the beneficial outcome of controlling radiation build-up on out-of-core surfaces; however, overall metals concentration will still be maintained within the fuel warranty limits to ensure no impact on fuel performance. The amount of conductivity of the added zinc is much less than the 1 μS/Cm operating conductivity limits.

See Subsection 10.4.6 for further details.

5.2.4 Fracture Toughness

5.2.4.1 Compliance With Code Requirements

The ferritic pressure boundary material of the RPVs was qualified by impact testing in accordance with the 1968 edition of Section III of the ASME Code, with addenda to and including summer 1969 addenda. From an operational standpoint, the minimum temperature limits for pressurization are used as the basis for compliance with the 1968 Edition of the ASME Code Section III. (The minimum temperature limits for pressurization are defined by the summer 1972 addenda, Appendix G, Protection Against Nonductile Failure.)

5.2.4.2 Compliance With 10 CFR 50, Appendix G

5.2.4.2.1 Introduction

Versions of 10 CFR 50, Appendix G, prior to the 1983 edition had specific requirements for the preparation and testing of all reactor coolant pressure boundary materials. In lieu of these specific requirements, the present version of Appendix G requires that for a reactor vessel which was constructed in conformance with an ASME Code Section III earlier than the summer 1972 addenda of the 1971 edition, the fracture toughness data and data analyses must be supplemented in a manner approved by the Director, Office of Nuclear Reactor Regulation, to demonstrate equivalence with the present fracture requirements of Appendix G. The Fermi 2 reactor vessel was constructed in compliance with an ASME Code earlier than the summer 1972 addenda of the 1971 edition. The NRC has stated in Supplement 1 to NUREG 0798, the Fermi 2 Safety Evaluation Report, that the alternative methods proposed by Fermi 2 to demonstrate compliance with Appendix G has been reviewed, evaluated, and found to provide the safety margin required by Appendix G. Accordingly, Fermi 2 has supplied sufficient information to demonstrate equivalency with the fracture toughness requirements of the present version of 10 CFR 50, Appendix G, (1983 as amended November 1986 and October 1988).

A major condition necessary for full compliance with 10 CFR 50, Appendix G prior to the 1983 edition is satisfying the requirements of the summer 1972 addenda to Section III of the ASME Code. This is not possible with components that were purchased in accordance with earlier Code requirements.

Ferritic material complying with 10 CFR 50, Appendix G, must have both drop-weight tests and Charpy V-Notch (CVN) tests with the CVN specimens oriented transversely to the maximum material working direction to establish the RT_{NDT}. The CVN tests must be evaluated against both absorbed-energy and lateral-expansion criteria. The maximum acceptable RT_{NDT} must be determined in accordance with the analytical procedures of ASME Code Section III, Appendix G. Appendix G of 10 CFR 50 requires a minimum of 75-ft-lb upper shelf CVN energy for beltline material. It also requires at least 45-ft-lb CVN energy and 25 mils lateral expansion for bolting material at either the preload or lowest service temperature, whichever is lower.

By comparison, material for the Fermi 2 reactor vessel was qualified by either drop-weight tests or longitudinally oriented CVN tests (both not required), confirming that the material nil-ductility transition temperature (NDTT) is at least 60°F below the lowest service temperature. When the CVN test was applied, a 30-ft-lb energy level was used in defining the NDTT. There was no upper shelf CVN energy requirement of the Fermi unit beltline material. The bolting material was qualified to a 30 ft-lb CVN energy requirement at 60°F below the minimum preload temperature.

From the previous comparison, it can be seen that the fracture toughness testing performed on the reactor vessel material cannot be shown to comply with 10 CFR 50, Appendix G; however, to determine operating limits in accordance with 10 CFR 50, Appendix G, estimates of the beltline material RT_{NDT} and the highest RT_{NDT} of all other material were made, as explained in Subsection 5.2.4.2.3. The method for developing these operating limits is also described therein.

5.2.4.2.2 Method of Compliance

A detailed description of compliance with 10 CFR 50 Appendix G is included in General Electric Report 004N8586, Reference 21. The 1998 Edition of the ASME Boiler and Pressure Vessel code, including 2000 Addenda, was used in this evaluation. The P-T curve methodology includes the following: 1) the use of K_{IC} from Figure A-4200-1 of Appendix A to determine T-RT_{NDT}, and 2) the use of the M_m calculation in the ASME Code paragraph G-2214.1 for a postulated defect normal to the direction of maximum stress. NRC approved methodology was utilized as detailed in NEDC-33178P-A, Reference 26.

The pressure-temperature (P-T) curves are established to the requirements of 10 CFR 50, Appendix G to assure that brittle fracture of the reactor vessel is prevented. Part of the analysis involved in developing the P-T curves is to account for irradiation embrittlement effects in the core region, or beltline. The method used to account for irradiation embrittlement is described in Regulatory Guide 1.99, Rev. 2.

The beltline region in the Fermi Unit 2 vessel includes a thickness discontinuity between the lower and lower-intermediate shells. In addition to beltline considerations, there are non-beltline discontinuity limits such as nozzles, penetrations, and flanges that influence the construction of P-T curves. The non-beltline limits are based on generic analyses that are adjusted to the maximum reference temperature of nil ductility transition (RT_{NDT}) or the applicable Fermi 2 vessel components.

5.2.4.2.3 Method of Obtaining Operating Limits Based on Fracture Toughness

Operating limits that define minimum reactor-vessel metal temperatures versus reactor pressure during normal heatup, cooldown, inservice hydrostatic testing, and anticipated operational occurrences were initially established using the methods of Appendix G of Section III of the ASME B&PV Code, 1971 Edition.

Updated Operating limits that define minimum reactor-vessel metal temperatures versus reactor pressure during normal heatup, cooldown, inservice hydrostatic testing, and anticipated operational occurrences were established using the methods of Appendix G of Section III of the ASME B&PV Code, 1998 Edition (including 2000 Addenda). This later edition of the Code is discussed in section 5.2.4.2.2.

Weld material toughness test coupons were made with the exact same weld filler metal and procedure as for the actual vessel weld. However, these weld deposits were not necessarily made on the exact same heat of baseplate as in the vessel. Baseplate of the same specification was used for this purpose. This small difference in baseplate would not affect the testing of the weld metal since the Charpy specimen would be in the weld metal. Toughness testing of the exact baseplates in the vessel was done separately. As part of the BWRVIP Integrated Surveillance Program (ISP), materials irradiated in other vessels were utilized to provide verification of material properties as detailed in section 5.2.4.4. This information was utilized in the development of the pressure temperature curves per General Electric Report 004N8586 (Reference 21), and as shown in figures for 52 EFPY contained in the Pressure and Temperature Limits Report (PTLR) (Reference 25).

5.2.4.2.4 <u>Temperature Limits for Inservice Inspection Hydrostatic or Leak Pressure Tests</u>

The fracture toughness analysis for system pressure tests resulted in the curve labeled A shown in the figures contained in the PTLR (Reference 25). The beltline materials are less limiting even at end-of-service fluence levels, based on evaluation according to Regulatory Guide 1.99, Revision 2, where the predicted shift in the RT_{NDT} (based on the neutron fluence at 1/4 of the vessel wall thickness) has been added to the beltline curve to account for the effect of neutron embrittlement as detailed in Reference 21.

5.2.4.2.5 <u>Temperature Limits for Boltup</u>

The flanges and adjacent shell are required to be warmed to minimum temperatures of 72°F before they are stressed by the full intended bolt preload as shown on the figures contained in the PTLR (Reference 25).

5.2.4.3 <u>Operating Limits During Heatup, Cooldown, and Core Operation</u>

The fracture toughness analysis was done for the normal heatup or cooldown rate of 100°F/hr. The temperature gradients and thermal stress effects corresponding to this rate were included. The results of the analyses are a set of operating limits for non-nuclear heatup or cooldown shown as Curves labelled B in the PTLR (Reference 25). Curves labelled C in the PTLR (Reference 25), apply whenever the core is critical. The basis for curves labelled C is described in 10 CFR 50, Appendix G, January 1990 Edition, Paragraph IV.A.3.

5.2.4.4 <u>Surveillance Programs for the Reactor Pressure Vessel</u>

A surveillance program will be carried out to monitor the neutron radiation effects on the RPV base metal, the weld HAZ metal, and the weld metal from a steel joint that simulates a welded joint in the RPV beltline. Versions of 10 CFR 50, Appendix H, prior to the 1983 edition required that the surveillance program conducted prior to the first capsule withdrawal comply with the 1973 edition of ASTM E185. The present version of Appendix H requires that the surveillance program conducted prior to the first capsule withdrawal comply with the requirements of the edition of ASTM E185 that was current with respect to the ASME Code to which the reactor vessel was purchased.

The Fermi 2 surveillance program was shown to comply with the revised requirements of 10 CFR 50, Appendix H (1983 as amended November 1986 and October 1988).

Subsequent to development of the Fermi plant specific surveillance program, the BWR Vessel and Internals Project (BWRVIP) developed an integrated surveillance program to comply with the requirements of 10 CFR 50 Appendix H, Paragraph III.C. "Requirements for an Integrated Surveillance Program." No capsules from the Fermi 2 vessel are currently required to be withdrawn or tested as part of the BWRVIP Integrated Surveillance Program (ISP). Capsules from other plants have been removed, and specimens were tested in accordance with the ISP implementation plan. The results from these tests have provided the necessary data to monitor embrittlement of the Fermi 2 vessel as documented in Reference 21. A description of the BWRVIP ISP and its application to Fermi is contained in Section 5.2.4.4.3.

5.2.4.4.1 Original Program Content

The original Fermi program consisted of three baskets, each containing tensile and CVN specimens hermetically sealed in an inert gas environment in thin-wall austenitic stainless steel capsules. The capsules are not buoyant and thus present no handling problems. The three baskets have been placed near core midplane adjacent to the RPV wall where the neutron flux and temperature will simulate that of the RPV wall. The three baskets contain test specimens made from the original RPV beltline material in accordance with the requirements of ASTM E185-73. In total, the program consists of 108 impact and 22 tensile specimens. In addition, there are 51 impact and 18 tensile baseline and spare specimens. The specimens include the following.

a. Base metal impact, transverse and longitudinal

b. Weld metal impact

c. HAZ impact

d. Base metal tensile

e. Weld metal tensile

f. HAZ tensile.

The following general statements apply to these specimens:

a. Base metal impact and tensile specimens are taken from the 1/4 T planes of the specimen plate

b. HAZ impact and tensile specimens are all oriented parallel to the rolling direction

c. Weld metal impact specimens are all transverse to the axis of the weld; tensile specimens are parallel. The fracture areas consist of all weld metal.

Details of the manufacture of these specimens are given in Reference 7.

The specimens were taken from two plates trimmed from the lower intermediate shell section of the reactor vessel. The plate sections for the base material specimens were given a simulated stress relief for 40 hr at 1150°F to ensure that they represent the metallurgical condition of the lower intermediate shell plates of the reactor vessel after final fabrication. The plate sections for the weld and HAZ specimens were joined with a continuous central weld identical to the reactor vessel longitudinal weld. The welded plate was then given a simulated stress relief for 40 hr at 1150°F, similar to the base material plate. The weld was X-rayed to ensure quality; no repair to the weld was allowed by the specifications.

The surveillance specimens were not taken from alongside the ASME NB-2300 specimens. This was not considered critical, since they are just as representative of the material in the vessel as the NB-2300 specimens. The actual specimens in each capsule and capsule locations are the following.

	Tensile	Charpy V-Notch
Capsule 3 (azimuth 300°)	2 BM, long. 2 WM 2 HAZ	12 BM, longitude 12 WM 12 HAZ
Capsule 2 (azimuth 120°)	3 BM, long. 3 WM 2 HAZ	12 BM, longitude 12 WM 12 HAZ
Capsule 1 (azimuth 30°)	3 BM, long. 2 WM 3 HAZ	12 BM, transverse 12 WM 12 HAZ

Each capsule includes an iron, nickel, and copper flux wire. A separate neutron dosimeter was attached at azimuth 30° and contains three copper and three iron flux wires at the Capsule 1 location. The separate capsule was removed from the reactor during the first refueling outage and tested in 1990.

Capsule 3 was removed from the vessel at 8.1 Effective Full Power Years. Testing of this capsule was deferred due to the ongoing development of the BWRVIP Integrated Surveillance Program.

The attachment method of the capsules is in accordance with GE drawing 922D218. The assembly is attached to mounting brackets (upper and lower), and a bolt at approximately the center of the assembly can be adjusted to secure the holder firmly against the top and bottom brackets.

The lead factor is the relationship between the measured flux/ fluence at the surveillance sample and the peak flux/fluence at the inside surface of the vessel wall. This relationship has two variations. One variation is the axial variation from the elevation of the surveillance sample to the elevation peak flux.

The second variation is the variation of the flux as a function of angle from a position adjacent to the surveillance sample to the position of the peak flux.

The lead factor for the capsule calculated with respect to the inside surface location is the ratio of the flux greater than 1 MeV at the surveillance sample, divided by the flux greater than 1 MeV at the point of greatest flux in the vessel. For Fermi 2 this value is 0.90 as detailed in Table 4.3-2.

The peak fluence at one-quarter thickness was calculated from the peak inside surface fluence using the methods of Regulatory Guide 1.99, Revision 2. The peak inside surface fluence was predicted by an 'absolute' fluence calculation compliant with Regulatory Guide 1.190.

5.2.4.4.2 Withdrawal Schedule

The withdrawal schedule of the three sets of specimens in the reactor is planned as follows.

a. The first set was withdrawn at 8.1 EFPY which was approximately 25 percent of the original licensed reactor service life (i.e., 40 years) and remains onsite untested.

b. The second set will be a standby.

c. The third set will be a standby.

5.2.4.4.3 Description of BWRVIP Integrated Surveillance Program

A 1997 NRC review of a surveillance capsule report identified that a licensee lacked adequate unirradiated baseline Charpy V-notch (CVN) data for materials in their RPV surveillance program. This lack of baseline data could inhibit the ability to effectively monitor changes in the RPV fracture toughness properties as required per 10 CFR 50 Appendix G. Subsequent discussions between the NRC and the BWRVIP identified several plants (including Fermi 2) that potentially lacked adequate unirradiated baseline CVN data for materials in their plant specific RPV surveillance programs.

Subsequent to this concern, the BWRVIP developed a BWR RPV Integrated Surveillance Program (ISP) to meet the requirements of 10 CFR 50 Appendix H Paragraph III.C. This effort resulted in development of reports BWRVIP-78 and BWRVIP-86 (as amended by responses to NRC RAIs), that were submitted to the NRC for review and approval (References 15 through 18). The NRC approved these reports by issuing NRC Safety Evaluation as an attachment to NRC letter to Carl Terry dated February 1, 2002 (Reference 19).

BWRVIP-78 describes the technical basis related to material selection and testing for the ISP. The report defines the methodology utilized to identify existing plant specific surveillance capsules and surveillance capsules from the Supplemental Surveillance Program (SSP) required for the ISP. Required surveillance materials are those that best represent the actual limiting plate and weld materials from which BWR RPVs are fabricated. BWRVIP-78 establishes the connection between the required surveillance materials and the specific BWR RPV plate or weld materials which they represent and provide a test matrix for the ISP.

BWRVIP-86 establishes specific guidelines for ISP implementation. It addresses surveillance capsule withdrawal and testing dates, information dealing with ISP project administration, information on neutron fluence determination, information on data utilization and sharing, and information on licensing aspects of ISP implementation. The BWRVIP issued BWRVIP-86-A (Reference 20) to incorporate NRC Requests for Additional Information (RAI), industry responses to RAIs and to include a copy of the NRC Safety Evaluation accepting the ISP Program.

BWRVIP Report BWRVIP-135, Reference 22 provides a detailed discussion of the analysis performed by the BWRVIP (ISP) of irradiated material samples representative of the Fermi 2 reactor pressure vessel assembly. This information was utilized in the development of the new pressure-temperature curves that are detailed in Section 5.2.4.

The NRC has approved use of the BWRVIP ISP as an acceptable alternative to a plant specific RPV surveillance program; with two conditions. First, that licensees submit a license amendment requesting NRC approval of their participation in the ISP. Second, that BWRs commit to utilizing an acceptable neutron fluence calculation methodology. Section 4.3.2.8 provides information dealing with Fermi 2 neutron fluence calculation methodology. The NRC has approved the Fermi 2 participation in the ISP per License Amendment No. 152.

5.2.4.5 Reactor Vessel Annealing

In-place annealing of the reactor vessel because of radiation embrittlement should not become necessary because the predicted EOL value of adjusted reference temperature will not exceed 200°F and the EOL upper shelf energy should remain above 50 ft-lb.

5.2.5 Austenitic Stainless Steel

5.2.5.1 Cleaning and Contamination Protection Procedures

During fabrication, the stainless steel surfaces were cleaned by mechanical methods (grinding, brushing with stainless steel brushes, machining), solvent cleaners, or chemical cleaning agents. Caustic cleaners and other solvents and cleaners containing halogens, sulfides, or other harmful constituents were not used for cleaning parts that contain crevices or entrapment areas.

Stainless steel materials were not pickled unless they were in the solution heat-treated condition. Stainless steel components were suitably packaged and protected during shipment, storage, and construction, to prevent contamination from potentially corrosive agents.

Immediately prior to hydrostatic testing of the reactor vessel, all interior surfaces that would contact water during the hydrostatic test, all nozzle fixtures, all piping to be used to fill the vessel, and all external surfaces of stainless and nickel-chrome-iron components were cleaned of all halogen-bearing soils, grease, oil, penetrant materials, inks, chalk or crayon marks, and all dirt and debris. Testing and operation of components and systems were performed using either inhibited water or high-purity demineralized water to avoid exposure to detrimental contaminants.

All loose dirt and other foreign materials were removed by sweeping or vacuuming. Deposits of grease and oil were removed with an approved solvent. Tightly adhering soils were removed with the aid of stainless steel brushes or by grinding. The vessel interior was then cleaned with high-pressure water containing corrosion inhibiting additives. The vessel and water temperatures were less than 180°F during the cleaning step. The water pressure was a minimum of 6000 psi. Water was potable, containing less than 25 ppm chlorides, 10 ppm fluorides, and l ppm sulfides.

The cleanliness of the vessel was checked visually and with the aid of an ultraviolet light to ensure that the vessel is clean. The ultraviolet examination was conducted under darkened conditions with a lamp providing a minimum intensity of 100 foot candles. All fluorescent materials were removed from the surface.

All plumbing, welding, or testing work was performed prior to cleaning. During any entry of personnel into the vessel after cleaning was completed, shoe covers were worn and clean conditions were maintained in the reactor vessel.

5.2.5.2 Solution Heat Treatment Requirements

Solution heat treatment of austenitic stainless steel consisted of heating the material to 1950 +/- 50ºF, holding for 1/2 hr per inch of thickness (minimum 1/2 hr), and quenching in water to below 800°F. Stainless steel castings may have been heated to 2050°F maximum prior to quenching. Nickel-chrome-iron alloys that may have been subjected to temperatures in excess of 1700°F exclusive of welding were rechecked for grain size for information and specified mechanical properties for acceptance and reported to the buyer.

5.2.5.3 Material Inspection Program

The raw material inspection program used to verify that the unstabilized austenitic stainless steels were properly solution heat-treated and not susceptible to intergranular attack is as follows.

a. No testing was required if valid documentation was furnished proving that the stainless steel had been given a suitable water quench from a temperature above l800°F, and that no subsequent heating had been employed

b. If documentation to verify adequate water quenching was not available, the material was required to be tested in accordance with ASTM A-262 Practice E.

5.2.5.4 Unstabilized Austenitic Stainless Steels

The nonstabilized grades of austenitic stainless steels with a carbon content greater than 0.03 percent used for RCPBs are types 304 and 316.

5.2.5.5 Avoidance of Sensitization

5.2.5.5.1 Base Metal

Wrought and cast austenitic stainless steels used for the RPV system (except for RPV cladding) were supplied in the solution heat-treated condition and thereafter were not subjected to any heating above 800°F except for welding, IHSI, or re-solution heat treatment.

Sensitization of wrought austenitic stainless steel was avoided for piping and RCPB pumps and valves. Austenitic stainless steel was considered to be furnace-sensitized if it had been heated by means other than welding within the range of 800°F to 1800°F, regardless of subsequent cooling rate. Such stainless steel was required to either pass the requirements of ASTM A-262 Practice E or be re-solution heat-treated. When heated above 1800°F, the austenitic stainless steel was required to be rapidly cooled through the range 1800°F to below 800°F by agitated water quench to produce an acceptable grain structure. Since severe sensitization of austenitic stainless steel was to be avoided, AISI type 304 and type 316 (0.08 percent maximum carbon) materials were used. Where severe sensitization could not be avoided, such as for parts that were required to be hard surfaced, low carbon AISI type 304 cast material was used.

5.2.5.5.2 Welding Controls

During stainless steel welding, the interpass temperature is controlled to a maximum of 350°F. Weld layers are built up uniformly along the joint and across the width of the joint. Block welding is not permitted and weld stops and starts are staggered. Welds are cleaned free of slag, flux, and other foreign material prior to depositing subsequent beads.

Austenitic weld materials are selected and controlled to produce welds that contain a minimum of 3 percent ferrite. Ferrite content is determined by one of the following methods.

a. Actual chemical analysis compared to the Schaeffler and Schoefer

b. Magne-gage

c. Metallography

d. Severn-gage.

The stainless steel components and systems for which stainless steel welding was controlled by GE or Dravo, Inc., include the following.

a. RRS

b. CRD hydraulic return

c. CRD housing to flange

d. RCIC system (suction from condensate storage).

The GE equipment was ordered, fabricated, and, in most cases, delivered prior to the issuance of Regulatory Guide 1.31. Therefore, there was no test program specifically directed toward the inspection of welds for delta ferrite. However, the welds were made by long-established procedures that included control of ferrite content of filler materials and had proved adequate for consistently producing satisfactory welds without evidence of fissuring. General Electric BWR 4/5/6 Standard Safety Analysis Report, Subsection 5.2.3.4.2.1, as amended in May 1978, provides an acceptable testing program for control of ferrite. The indicated testing program of welds on five BWRs was produced under the same procedures as the Fermi 2 equipment and fully demonstrated the presence of a minimum of 3 percent delta ferrite in the welds.

Similarly, stainless steel welds fabricated by Dravo were made with weld material having 5 to 15 percent delta ferrite. Inspection of welds made since the Fermi 2 piping was fabricated, but using the same procedures, has also consistently demonstrated the presence of a minimum of 3 percent delta ferrite.

The field pipe erection contractors were required to incorporate the requirements of Regulatory Guide 1.31 into their stainless steel weld procedures, including procedures for inspection of fabricated welds. See Subsection A.1.31 for conformance by Edison's and piping contractor's welding procedures with Regulatory Guide 1.31.

5.2.5.6 Retesting Unstabilized Austenitic Stainless Steels Exposed to Sensitizing Temperatures

Welding procedures require control of heat input to avoid severe sensitization and susceptibility to intergranular attack. No retesting of "as-welded" unstabilized austenitic stainless steel is required or planned.

Unstabilized austenitic stainless steel subjected to heat in the range of 800°F to 1500°F by any means other than welding or IHSI is required to be retested in accordance with ASTM A-262, Practice E.

5.2.5.7 Control of Delta Ferrite

The procedures and requirements that are used for the control of delta ferrite in austenitic stainless steel welds are discussed in Subsection 5.2.5.5.1. Additional information on delta ferrite in austenitic stainless steel weldments may be found in Subsections 5.2.3.2.1.1, 5.2.5.5.1, and A.1.31.

5.2.6 Pump Flywheels

Pumps with flywheels are not used in Fermi 2.

5.2.7 Reactor Coolant Pressure Boundary Leak Detection System

5.2.7.1 Leak Detection Methods

5.2.7.1.1 General

The RCPB leak detection system consists of temperature, pressure, flow, and fission product sensors with associated instrumentation and alarms. This system detects and annunciates abnormal leakage in the following systems:

a. Main steam lines

b. RWCU system

c. RHR system

d. RCIC system

e. Reactor feedwater system

f. HPCI system

g. Reactor recirculation system.

A summary of isolation and/or alarm of affected systems and the methods used appear in Table 5.2-11.

Small leaks are generally detected by temperature and pressure changes, fillup rate of drain sumps, and fission product concentration inside the primary containment. Large leaks are also detected by changes in reactor water level and changes in flow rates in process lines.

Leakage into systems that are directly or indirectly connected to the RCPB is detected by the leak detection system (LDS). The RHR system service water, general service water, and reactor building closed cooling water (RBCCW) have been provided with process radiation monitors for the detection of intersystem leaks.

Leakage into systems that are normally connected to the RCPB through closed isolation valves is detected by pressure and temperature indications. The core spray, RCIC, and HPCI systems are in this category. Leakage into the RWCU system is detected by differential flow and temperature devices. The standby liquid control system (SLCS) is monitored for intersystem leakage by the system pressure and tank level indicators provided.

5.2.7.1.2 Detection of Abnormal Leakage Within the Primary Containment

Leaks within the primary containment are detected by monitoring for

a. Abnormally high pressure and temperature within the primary containment
b. Sump pump frequency of operation on floor and equipment drains
c. A decrease in the RPV water level
d. Hydrogen and oxygen concentration
e. High flow rate in process lines
f. High gaseous radiation levels in the primary containment atmosphere
g. Floor drain sump level rate of change.

Temperatures within the primary containment are monitored at various elevations. Excessive temperature in the primary containment, increased drain sump flow, and increased fission product radiation level are annunciated by alarms in the main control room. Low RPV water level and high drywell pressure are annunciated by alarm in the main control room and cause automatic isolation of the containment. In addition, low RPV water level isolates the main steam lines.

The systems within the drywell share a common area; therefore, their LDSs are common. Each LDS inside the drywell is designed with a capability of detecting leakage less than established leakage rate limits.

5.2.7.1.3 Leak Detection

5.2.7.1.3.1 General

The drywell floor drain sump measurement system monitors the normal design leakage collected in the floor drain sump consisting of leakage from the CRDs, valve flange leakage, closed cooling water, air cooler drains, and any leakage not connected to the equipment drain sump.

The design includes a supplementary drywell floor drain level monitor to enhance the leak detection capability of the drywell floor drain sump system. A continuous analog level measurement of the drywell floor drain level is provided to meet the sensitivity requirement of Regulatory Guide 1.45. This sump level monitor provides a rate-of-change measurement, which is qualified seismically and has the sensitivity to detect a 1-gpm leak integrated over a 1-hr interval.

The drywell equipment drain sump level monitors identify leakage collected in the equipment drain sump. The sump receives condensate drainage from pump seal leakoff. Collection in excess of background leakage would indicate reactor coolant leakage. The equipment drain sump temperature is also monitored. High temperature would indicate leakage of high temperature water.

Four basic leak detection methods are used to determine sump collection rates. As the water in each of the floor or equipment drain sumps is pumped out, the flow is metered by a flow integrator. Level switches are used to set fill time and pump-out time periods using adjustable reset timing devices. If the nominal pumping out or filling time for the particular sump is exceeded, an alarm is generated in the control room. In addition, if both pumps are started to handle the flow into the sump, an alarm is generated. The drywell sump sensitivity is 21 gal/in. of level. The sumps are located at the lowest elevation of the drywell area, and there are no areas that can act as a temporary reservoir.

The level switches can be functionally checked during plant operation by manually controlling the pumps. The operators use careful monitoring of the flow integrators and the actual pumping times to verify the operating condition of the level switches.

The primary containment is maintained at a slightly positive pressure during reactor operation. The pressure fluctuates slightly as a result of barometric pressure changes and outleakage. A pressure rise above the normally indicated values indicates the presence of a leak within the drywell.

The primary containment cooling system recirculates the primary containment atmosphere through heat exchangers (air coolers) to maintain the primary containment at its average operating temperature as given in the Technical Specifications. The RBCCW system provides cooling water to the air coolers. An increase in primary containment atmosphere temperature would increase the temperature rise in the cooling water passing through the coils of the air coolers. Thus, the RBCCW temperature difference increase between inlet and outlet to the air coolers indicates the presence of a reactor coolant or steam leakage. Also, a drywell ambient temperature rise above normal indicates the presence of reactor coolant or steam leakage.

The drywell cooler units have been provided to maintain the ambient drywell temperature at a relatively low value, and steam leaks will be condensed by contact with the relatively cold surfaces in the drywell. If the steam finds its way to the cooler units, condensation will definitely occur. The drains from the coolers are collected in the drywell sumps and can then be detected via the leak detection scheme. It is expected that the normal operating humidity will be at or near saturation, which will promote rapid condensation and subsequent detection. In addition, the airborne gaseous sampling system monitors the airspace and detects leaks in a very timely manner.

Radiation monitoring of the primary containment is provided as required by Criterion 30 of 10 CFR 50, Appendix A, and Regulatory Guide 1.45. The primary containment radiation monitoring system is part of the redundant LDS. The primary containment radiation monitoring system information is used in conjunction with the drywell floor drain sump level indicating system. It is provided to improve the total drywell LDS diversity and sensitivity.

However, since the supplementary drywell floor drain level monitor is seismically qualified, and meets the sensitivity requirement of Regulatory Guide 1.45, the particulate channel of the containment radiation monitor is not required as a leak detection system and has been removed from the leak detection system, but the gaseous monitor was retained to meet diversity requirements.

The design basis for the primary containment radiation monitoring system, and the associated instrumentation are presented in Subsections 7.1.2.1.22 and 7.6.1.12.1.

Additional components monitored are discussed below.

5.2.7.1.3.2 Reactor Pressure Vessel Head Seal

Leakage past the first of two RPV head closure seals is detected by monitoring the drain line connected to the region between the seals. Leakage is collected in a small-volume, normally closed system that can be drained to the equipment drain sump. When the pressure in this volume increases, an alarm in the main control room is actuated.

5.2.7.1.3.3 Reactor Recirculation System Pump Seal

Reactor recirculation system pump seal leaks are detected by monitoring the drain line. Leakage is indicated by high-flow alarms in the main control room. Leakage is piped to the equipment drain sump, as shown in Figure 5.5-2.

5.2.7.1.3.4 Safety/Relief Valves

Safety/relief valve leakage is detected by monitoring the discharge path. High temperature is alarmed in the main control room.

5.2.7.1.4 Detection of Abnormal Leakage Outside the Primary Containment

Outside the primary containment, the piping within each system monitored for leakage is in compartments or rooms, separate from other systems where feasible, so that leakage may be detected by area temperature indications. Each LDS discussed below is designed to detect leak rates that are less than the established leakage limits. The method used to monitor for leakage for each RCPB component is shown in Table 5.2-11.

5.2.7.1.4.1 Room Ventilation or Standby Cooler Temperature

A differential temperature-sensing system is installed in each area containing equipment that is part of the nuclear system process barrier. These areas are the RCIC, HPCI, RHR, and RWCU systems equipment rooms, as well as the suppression chamber room and main steam line tunnel.

Temperature sensors are placed in the inlet and outlet ventilation ducts or ventilation air flow paths. Other sensors are installed in the equipment areas to monitor ambient temperature. A differential temperature switch between each set of sensors and/or ambient temperature switch initiates an alarm in the main control room when the temperature reaches a preset value. Remote readouts from temperature sensors are indicated in the relay room.

Due to the design characteristics of the reactor building ventilation design, the differential temperature isolation provides an alarm function only on the RCIC and HPCI areas. Similarly, the temperature sensors for the torus subbasement area provide an alarm function only and do not trip either the RCIC or HPCI systems. The HPCI and RCIC trip function is provided by the (redundant) HPCI and RCIC area ambient sensors.

5.2.7.1.4.2 Reactor Building Sump Flow Measurement

Monitors indicate the amount of leakage into the reactor building floor drainage system. The normal design leakage collected in the system consists of leakage from the RWCU, FPCCS, RCIC, HPCI, core spray, CRD, RHR, feedwater, and main steam systems and from other miscellaneous vents and drains.

5.2.7.1.4.3 Visual and Audible Inspection

Accessible areas are inspected periodically. The temperature and flow indicators discussed above are monitored regularly. Any instrument indication of abnormal leakage is investigated.

5.2.7.1.4.4 Differential Flow Measurement for Reactor Water Cleanup System Only

Because of the RWCU system arrangement, differential flow measurement provides an accurate leak detection method. The flow from the RPV is compared with the flow back to the RPV. An alarm in the main control room and an isolation signal are initiated when higher flow out of the RPV indicates that a leak greater than the established leak rate limit may exist.

5.2.7.2 Indication in Main Control Room

Details of the LDS indications are included in Subsection 7.6.1.8.

5.2.7.3 Limits for Reactor Coolant Leakage

5.2.7.3.1 Total Leakage Rate

The total leakage rate consists of all leakage, identified and unidentified, that flows to the drywell floor drain and equipment drain sumps. The total leakage rate limit is well within the makeup capability of the RCIC system. The total leakage rate limit is established at 25 gpm.

The total leakage rate limit is also set low enough to prevent overflow of the drywell sumps. The equipment drain sump and the floor drain sump, which collect all leakage, are each drained by two 50-gpm pumps. The total leakage rate limit for each sump of 25 gpm is set below the removal capacity of one pump in each sump because of the possibility that most of the total leakage could flow into one sump.

5.2.7.3.2 Identified Leakage

The pump packing glands, valve stems, and other seals in systems that are part of the nuclear system process barrier and from which a normal design leakage of 20 gpm is expected are provided with drains or auxiliary sealing systems. Nuclear steam supply system valves and pumps inside the drywell are equipped with double seals and packings.

Leakage from the primary RRS pump seals is piped to the equipment drain sump. Leakage from the main steam line SRVs is identified by temperature sensors that transmit to the main control room. Any temperature increase above the drywell ambient temperature detected by these sensors indicates valve leakage. Leakage from the RPV head flange gasket is detected by a pressure switch, as described in Subsection 5.2.7.1.3.2.

Thus, the leakage rates from pumps and valve seals are measurable during plant operation. These leakage rates, plus any other leakage rates measured while the drywell is open, are defined as identified leakage rates.

5.2.7.4 Unidentified Leakage

5.2.7.4.1 Unidentified-Leakage Rate

The unidentified-leakage rate is the portion of the total leak-age rate received in the drywell sumps that is not identified as previously described. A threat of significant compromise to the nuclear system process barrier exists if the barrier contains a crack that is large enough to propagate rapidly. The unidentified-leakage rate limit must be low because the unidentified leakage might be emitted from a single crack in the nuclear system process barrier.

An allowance is made for normal plant operation leakage that does not compromise barrier integrity and is not identifiable. The unidentified-leakage rate limit is established at a 5-gpm rate to allow time for corrective action before the nuclear system process barrier could be significantly compromised. This proposed limit is based on a calculated flow from a critical crack in a primary containment system pipe.

5.2.7.4.2 Sensitivity and Response Times

Sensitivity, including sensitivity tests and response time of the LDS, is presented in Subsection 7.6.1.8.

5.2.7.4.3 Length of Through-Wall Flaw

Experiments conducted by GE and Battelle Memorial Institute (BMI) permit an analysis of critical crack size and crack opening displacement. This analysis relates to axially oriented through-wall cracks.

5.2.7.4.3.1 Critical Crack Length

Both the GE and the BMI test results indicate that theoretical fracture mechanics formulas do not predict critical crack length. However, satisfactory empirical expressions may be developed to fit test results. A simple equation that fits the data in the range of normal design stresses for carbon steel pipe is:

$$\ell_C = \frac{15000D}{\sigma h} \qquad (5.2\text{-}1)$$

where

ℓ_C = critical crack length (inches)

D = mean pipe diameter (inches)

σh = nominal hoop stress (psi)

Data correlation for Equation 5.2-1 is shown in Figure 5.2-11.

5.2.7.4.3.2 Crack Opening Displacement

The elasticity theory predicts a crack opening displacement of

$$W = \frac{2\ell\sigma}{E} \qquad (5.2\text{-}2)$$

where

ℓ = crack length

σ = applied nominal stress

E = Young's modulus

Measurements of crack opening displacement made by BMI show that local yielding greatly increases the crack opening displacement as the applied stress approaches the failure stress σ_f. A suitable correction factor for elasticity effects is:

$$C = \frac{\pi}{2}\frac{\sigma}{\sigma_f} \qquad (5.2\text{-}3)$$

The crack opening area is given by

$$A = C\frac{\pi}{4}W = \frac{\pi}{2}\frac{\sigma}{\sigma_f}\frac{\pi\ell\sigma}{2E} \qquad (5.2\text{-}4)$$

For a given crack length ℓ, $\sigma_f = 15{,}000\,{}^{D}/_{\ell}$

5.2.7.4.3.3 Leakage Flow Rate

The maximum flow rate for blowdown of saturated water at 1000 psi is 55 lb/sec/in.^{2}, and for saturated steam the rate is l4.6 lb/sec/in.^{2}. Friction in the flow passage reduces this rate, but for cracks leaking at 5 gpm (0.7 lb/sec), the effect of friction is small. The required leak size for a 5-gpm flow is:

a. A = 0.0126 in.^{2} (saturated water)

b. A = 0.0475 in.^{2} (saturated steam).

From this mathematical model, the critical crack length and the 5-gpm crack length have been calculated for representative BWR pipe sizes (Schedule 80) and pressure (1050 psi). Results are tabulated as follows.

Normal Pipe Size (Sch. 80) (in.)	Average Wall Thickness (in.)	Steam Line Crack Length ℓ (in.)	Water Line Crack Length ℓ (in.)
4	0.337	7.2	4.9
12	0.687	8.5	4.8
24	1.218	8.6	4.6

The ratios of crack length (ℓ) to the critical crack length (ℓ_c) as a function of nominal pipe size are

Nominal Pipe Size (Sch. 80) (in.)	Ratio ℓ/ℓC	
	Steam Line	Water Line
4	0.745	0.510
12	0.432	0.243
24	0.247	0.132

It is important to recognize that the failure of ductile piping with a long through-wall crack is characterized by large crack opening displacements that precede unstable rupture. Judging from observed crack behavior in the GE and BMI experimental programs involving both circumferential and axial cracks, it is estimated that leak rates of hundreds of gallons per minute will precede crack instability. Measured crack opening displacements for the BMI experiments were in the range of 0.1 to 0.2 in. at the time of incipient rupture, corresponding to leaks of the order of 1 in.^{2} in size for plain carbon steel piping. For austenitic stainless steel piping, even larger leaks are expected to precede crack instability, although there are insufficient data to permit quantitative prediction.

The results given are for a longitudinally oriented flaw at normal operating hoop stress. A circumferentially oriented flaw could be subjected to stress as high as the 550°F yield stress, assuming high thermal expansion stresses exist. A good mathematical model that is supported by test data is not available for the circumferential crack. Therefore, it is assumed that the longitudinal crack, subject to a stress as high as 30,000 psi, approaches "worst case" with regard to leak rate versus critical size relationships. Given the same stress level, differences between the circumferential and longitudinal orientations are not expected to be significant in this comparison.

Figure 5.2-12 shows general relationships among crack length, leak rate, stress, and line size, using the mathematical model described above. The asterisks denote conditions at which the crack opening displacement is 0.1 in., at which time instability is imminent. This provides a realistic estimate of the leak rate to be expected from a crack of critical size. In every case, the leak rate from a crack of critical size is greater than the 5-gpm criterion.

5.2.7.4.4 Margins of Safety

The margins of safety for a detectable flow to assume critical size are presented in Subsection 5.2.7.4.3. Figure 5.2-12 shows general relationships among crack length, leak rate, stress, and line size obtained using the mathematical model.

5.2.7.4.5 Criteria To Evaluate the Adequacy and Margin of the Leak Detection System

For process lines that are normally open, there are at least two different methods of detecting abnormal leakage from each system within the nuclear system process barrier located in the primary containment and reactor building (Table 5.2-11). The instrumentation can be set to provide alarms at established leakage rate limits and isolate an affected system when necessary. The alarm points are determined analytically or, where appropriate, are based on measurements of appropriate parameters made during startup and preoperational tests.

The unidentified leakage rate limit is based, with an adequate margin for contingencies, on the crack size large enough to propagate rapidly. The established limit is sufficiently low so that, even if the entire unidentified leakage rate were coming from a single crack in the nuclear system process barrier, corrective action could be taken before the integrity of the barrier would be threatened.

The LDS is able to satisfactorily detect unidentified leakage of 5 gpm.

Sensitivity, including sensitivity tests and response time of the LDS, is included in Subsection 7.6.1.8. Subsection 7.1.2 presents the criteria for shutdown when the leakage limits are exceeded.

5.2.7.5 Maximum Allowable Total Leakage

The total leakage rate is presented in Subsection 5.2.7.3.1.

5.2.7.6 Differentiation Between Identified and Unidentified Leaks

Subsection 5.2.7.1 describes the systems that are monitored by the LDS. The ability of the LDS to differentiate between identified and unidentified leakage is discussed in Subsection 7.6.1.8 and Subsections 5.2.7.1 through 5.2.7.4.

5.2.7.7 Sensitivity and Operability Tests

Testability of the LDS is discussed in Subsection 7.6.1.8.

5.2.7.8 Leakage Reduction Program

Edison has developed a leakage reduction program to reduce and maintain leakage to as-low-as-practical levels from systems outside the primary containment that could or would contain highly radioactive fluids during and after a serious transient or accident. In addition, the program is designed to reduce potential paths due to design and/or operation deficiencies. This program is based on Requirement 2.1.6a of NUREG-0578 (Reference 8) and the requirements of Item III.D.1.1 of NUREG-0660, NUREG-0694, and NUREG-0737, "Primary Coolant Sources Outside Containment" (References 9, 10, and 11, respectively).

Table 5.2-12 identifies systems included in the leakage reduction program. Table 5.2-13 lists systems to which the leakage reduction program is not applicable and further provides the justification for their exclusion. Only the systems listed in Table 5.2-12 are included in the program.

5.2.7.8.1 Program Description

The Edison leakage reduction program includes the following features.

a. A combination of periodic visual inspections of accessible portions of the systems and detailed system walkdowns to identify leakage into the secondary containment out of components such as valve stems, pump seals, fittings, relief valve discharge lines, drains, vents, and instrument loops. When possible, these inspections are performed with the systems at approximately operating pressure in a normal or test condition

b. An aggressive maintenance program to correct identified leakage problems and assign a high priority to leakage-related work requests for systems in this program. Essentially all leakage of concerned (i.e., those identified in Table 5.2-12) systems will be addressed. These preventive and corrective maintenance measures ensure minimum leakage on a continuing basis

c. Periodic leak-rate testing of systems listed in Table 5.2-12 and system components such as valves at intervals not to exceed each refueling outage. The general test methods used to determine leakage from systems within the scope of this leakage reduction program are provided in Subsection 5.2.7.8.2

d. Maintenance of records on inspections and tests to identify chronic or generic leakage problems to implement modifications and/or corrective maintenance measures. A summary report on program effectiveness will be provided to plant management within 90 days of the conclusion of each reactor refueling.

In addition to the testing program, system leakage tests will be performed on many of these systems as part of the 10 CFR 50, Appendix J, leakage testing program. The systems and components subject to this testing and that form part of the containment boundary are identified in Table 6.2-2. This leakage reduction program will be completed by the time Fermi 2 reaches full-power operation.

Prior to the start of the second fuel cycle, Edison will revise the general criteria to the extent necessary according to the experience gained during the first operating cycle of Fermi 2. These revised criteria will be used as the basis for the long-term leakage reduction/monitoring program for Fermi 2.

5.2.7.8.2 Test Methods

The following methods are used to test systems identified in Table 5.2-12 for leakage:

a. Liquid systems - Systems or portions of systems that could contain radioactive liquids during or after an accident are periodically placed into normal operation or a testing mode. During these test conditions, the systems are visually inspected for leakage with all results being recorded. All leakage detected during the periodic visual inspections, or the less frequent integrated leak-rate test, will be measured where possible and recorded. Techniques used for leakage measurement will include collection into a graduated container and estimation by equating drops per unit of time to a standard volume

b. Gaseous systems - For systems or portions of systems that may contain radioactive gases during or after an accident, a pressure drop or makeup gas rate test is used. Clean air or nitrogen is used for these tests. When leakage is indicated by a pressure drop or excessive makeup, visual inspection techniques are applied to components during pressurization.

   Gaseous systems are tested by pressurizing the system with air or nitrogen to a specified pressure (usually accident pressure of 56.5 psig or the system relief valve set pressure) and measuring to within 20 standard cm^3 per minute the flow required to maintain test pressure using a local leak-rate test panel. The makeup flow is equivalent to the system leakage rate. This method of leak testing is similar to that required by 10 CFR 50, Appendix J, for leak-rate testing of the primary containment. If flow is detected, each system component will be tested with a soapy liquid in accordance with the procedure to identify sources of leakage. Corrective action will be taken as warranted to reduce the leakage from each source, and the system will be retested to yield a quantitative indication of the leakage reduction achieved. This measuring methodology, leakage source identification procedure, and corrective action will ensure that leakage is reduced to the lowest practical level, as dictated by system hardware limitations. The application of the helium leak detection method of inspection may be considered for some gaseous systems.

5.2.7.8.3 Test Procedures

Each system identified in Table 5.2-12 has surveillance testing procedures. These test procedures contain the following elements as applicable:

a. A description of system and plant operating conditions necessary to conduct each leak test. Test boundaries are identified and include only those portions of the system that could contain radioactive fluids during or after an accident. For example, the core spray suction piping from the condensate storage tank would not be inspected as this suction line is used for test purposes only and would not contain radioactive fluid during or after an accident

b. Elaboration of special test methods necessary to supplement general test methods

c. Data sheets listing the specific areas to be inspected. The data sheets will identify isometric drawing numbers and provide spaces to record inspection results.

5.2.8 Inservice Inspection Program

5.2.8.1 Inservice Inspection Program for Class 1, 2, and 3 Components

The inservice inspection (ISI) program for Class 1, 2, and 3 components complies to the extent practicable with the requirements of the ASME Code Section XI. The program for the initial inspection interval complies with the requirements of the 1980 edition of the Code including the winter 1981 addenda except that the extent of examination for Class 2 piping welds will be determined by the 1974 edition, summer 1975 addenda. The initial 10-year inspection interval commenced with the start of commercial operation. When compliance with ASME Code Section XI was impracticable, relief was requested from the NRC in compliance with 10 CFR 50.55a(g)(5)(iii). The Fermi 2 inservice inspection program plan for the initial 10-year inspection interval was submitted to the NRC for review and was found to be acceptable and in compliance with the provisions of 10 CFR 50.55a(g)(4). The first ten year interval was completed February 16, 2000. Upon completion of the first inspection interval, the inservice inspection program was updated to include later Editions and Addenda of ASME Section XI as required by 10 CFR 50.55.a. Successive ten year updates will be similarly processed.

5.2.8.2 Provisions for Access to Reactor Coolant Pressure Boundary

Fermi 2 uses reflective metal insulation typical of that used by GE for this series of RCPB. The RCPB design has been reviewed in detail to ensure adequate access for inspection according to ASME B&PV Code Section XI, Articles IS 141 and 142. The insulation design has considered access for inservice inspection.

5.2.8.2.1 Reactor Pressure Vessel Access Provisions

In the region of the sacrificial shield, there is a nominal 12-in. annulus between the insulation and the outside surface of the RPV. Access to this annulus can be gained from the bottom at locations adjacent to the support skirt to the lower head weld, and from two 3 x 3-1/2-ft openings, 8 ft from the top of the shield, at azimuths 180° and 351°. Inservice inspection of longitudinal and circumferential welds in the RPV will be performed using mechanized equipment.

Vessel nozzles are accessible for inservice examination through openings in the sacrificial shield. Automatic scanning devices enable complete inspection while minimizing personnel exposure.

The bottom head contains the penetrations for the CRD system and in-core flux monitoring system. The spacing between these penetrations makes volumetric inspection impractical. These nozzles are partial-penetration welds, and, typically, have not been included in normal ISI schedules as they meet exception criteria under a postulated CRD ejection accident.

5.2.8.2.2 Piping Access Provisions

Insulation on Class 1 piping inside the primary containment is of the removable reflective-metal type. Removable nonmetallic insulation is used on the portion of Class 1 lines outside the primary containment. Welds requiring an ISI inspection have identification tags attached to the insulation covering each weld.

The preservice baseline examination of the ASME Class 1 piping has been performed in accordance with the ASME Code Section XI, 1974 edition, through summer 1975 addenda to the extent possible. The scope and extent of examination of Class 1 piping is in accordance with Table 5.2-14. The preservice inspection program identified all welds that have access limitations for examination. For all welds that cannot be examined ultrasonically, alternate means of examination were used (such as radiography, liquid penetrant or magnetic particle, supplemented by visual examination during hydrostatic testing). The preservice inspection program exempted from volumetric and surface examination certain portions of Class 1 piping in accordance with the provisions of IWB-1220(b)(1) and (2), "Component Connections, Piping and Associated Valves (and their supports) One Inch Nominal Pipe Size and Smaller." The exempt components were examined in accordance with IWA-5000 during the system hydrostatic pressure test required by IWB-5000.

In addition, limited space between the process and guard pipes in the primary containment penetrations makes it impractical to perform an ultrasonic examination of the process pipe-to-flued head weld.

The ASME Code incorporated inservice inspection requirements for Class 2 and 3 systems after most of the design and manufacture of these systems had been completed. In September 1976, Edison engaged SWRI to analyze the extent to which Fermi 2 could comply with these new sections of the ASME Code. The study was based on the latest edition of the ASME Code available which was the 1974 Edition, including addenda through summer 1976 and reported in Reference 12.

Reference 12 shows that the layout of these systems and the design of the system supports are such that welds and components requiring examination by the ASME Code are accessible with, basically, no exceptions. The examination of some welds is limited partially by the close proximity of fittings or lugs; a few welds have limited accessibility and can be inspected from only one side. All limitations were identified in the preservice inspection report.

5.2.8.3 Equipment for Inservice Inspection

All equipment used for inservice inspection of the RPV and piping has been proven reliable on other preservice and inservice inspections. Included in this equipment are mechanized and manual inspection devices.

Pipe butt welds will be inspected using conventional ultrasonic inspection equipment. Basically, this is a light-weight, portable UT flaw detection equipment package with manually held search units.

5.2.8.4 Mechanized Inspection Equipment

In general, the RPV will be ultrasonically examined by automated equipment. Typically, the data acquisition system contains a multichannel recorder, cathode ray tube (CRT) displays, a TV video camera, and a minicomputer.

The computer is the primary data recording/comparison system, and the other systems are intended for backup to be used when required.

Computer programs have been written to allow comparison of the data obtained on the subsequent inservice examinations.

5.2.8.5 Reactor Pressure Vessel Acceptance Standards

The acceptance standards that were used to establish acceptability of the RPV for service during preservice mapping of the RPV by ultrasonic examination were those standards required by the ASME B&PV Code.

5.2.8.6 Coordination of Inspection Equipment With Access Provisions

The access provisions are designed to accommodate currently available examination equipment. This equipment has been used successfully on other preservice and inservice inspections.

5.2.8.7 Inservice Testing Program for Pumps and Valves

The testing program for pumps and valves complies to the extent practicable with the requirements of the Code and Addenda identified in 10 CFR 50.55a at the time the program is updated to the next 10 year interval. The scope of the program encompasses those pumps and valves necessary to safely shut down the plant or mitigate the consequences of an accident. The scope also includes those valves that perform an isolation function between high-pressure and low-pressure portions of systems connected to the reactor coolant system.

When compliance with Code requirements is impractical, relief is requested from the NRC in compliance with 10 CFR 50.55a.

Table 5.2-15 lists the valves that perform an isolation function between high-pressure and low-pressure portions of systems connected to the RCS. These pressure isolation valves are categorized as A or AC and are tested in compliance with Technical Specifications and the ASME Inservice Testing Code and Addenda applicable to the current ten year interval. The testing program for the valves, which is referenced in the Technical Specifications, consists of the following methods.

a. Exercise the valve and verify the position in accordance with the IST Program.

b. Exercise the valve (full stroke) and measure stroke time (as applicable) in accordance with the IST Program.

c. Leak test the valve seat before reaching power operation during refueling and after valve maintenance before the return to service, in accordance with the IST Program.

These valves shall not be routinely exercised every 3 months during plant operation (except E4100F005 and E5100F014, which are exercised during quarterly surveillance and then verified closed) as required by ASME Code because of the following:

a. Such tests remove one of the two barriers protecting the low-pressure portion of the emergency core cooling system (ECCS)

b. The operators on testable check valves cannot overcome the force on the valve with reactor pressure on one side.

Instead, the valves will be exercised during cold-shutdown periods as time permits (but not more frequently than once every 3 months).

A routine surveillance test every 3 months to exercise the valve presupposes that the test can be done with the plant operating at full power (and pressure). The purpose of dual barriers is to provide pressure isolation and protection even if one of the barriers should be faulty. Should one of the barriers be faulty by being inoperable, the core cooling systems have sufficient redundancy to perform their function. In addition, an inoperable barrier would be found during the proposed tests made at cold shutdown.

However, should one of the barriers be faulty by having excessive leakage, the core cooling system connected to that barrier could be severely damaged. Therefore, the test could cause a significant loss of primary coolant. On the other hand, had the test not been performed for this latter case, the core cooling system would have performed its function normally.

The full closure of these valves, except for the HPCI and RCIC check valves, is verified in the control room by direct monitoring position indicators. In addition, these lines are equipped with overpressure detection and protection devices should pressure isolation valves leak; these are summarized in Table 5.2-16, which shows that every line is protected by a relief valve and has pressure monitoring.

For the HPCI and RCIC system, pressure isolation is provided by normally closed gate valves, E4150F006 and E5150F013, and check valves E4100F005 and E5100F014, which are leak tested. E4150F007 and E5150F012 are normally open and not credited for pressure isolation.

If there is excessive leakage through the normally closed gate and check valves, the operator will be alerted by the high pump suction pressure alarm indicated in Table 5.2-16. The operator will then be directed to close the normally open gate valve per the Alarm Response Procedure.

The inservice testing program (IST) for pumps and valves for Fermi 2 commenced March 20, 1985. The first 10-year interval commenced following the initial start of Fermi 2 commercial operation in accordance with ASME Section XI, Paragraph IWA-2420, 1980 Edition including winter 1980 Addenda. The second and subsequent ten-year intervals will be updated to include later editions of the Code as required by 10 CFR 50.55a.

5.2.8.8 Preservice Inspection Program

A preservice inspection program was performed on all Class 1 components (except the RPV) and other components noted in Table 5.2-14 in accordance with the requirements of the 1974 Edition of ASME Section XI, "Rules for Inservice Inspection of Nuclear Power Plant Components," with addenda through the summer of 1975 (74/S75). The preservice inspection program for some Class 1 components was performed in accordance with the requirements of ASME Section XI, 1980 Edition, winter 1981 addenda, for compatibility with the ISI program. These components are identified in the remarks column of Table 5.2-14. Preservice inspection of the reactor vessel was performed in accordance with the 1971 Edition of Section XI (reference Subsection 5.4.2).

Southwest Research Institute was engaged by Edison to be the inspection agent to perform preservice examinations of welds. Southwest Research Institute supplied inspectors, equipment, and procedures. The Hartford Steam Boiler Inspection and Insurance Company was engaged by Edison to be the Authorized Inspector.

In general, Table 5.2-14 outlines the preservice examination requirements for Class 1 components in accordance with Tables IWB-2500 and IWB-2600 of Section XI (IS-251 through IS-261 for the RPV).

Class 2 systems within the scope of the Section XI preservice inspection program are the following:

a. Residual heat removal, Division I and Division II
   1. ECC function in LPCI mode
   2. RHR function in RHR mode
   3. RHR function in containment spray mode
b. Core spray, ECC function
c. HPCI, ECC function
d. SLCS, up to the Class 1 boundary valve
e. Main steam system between the second and third isolation valves.

In accordance with 10 CFR 50.55(a), the 1974 Edition of ASME Section XI through the summer 1975 addenda was used for determining the extent of examination (the number of welds required to be examined) for Class 2 pipe welds in RHR systems, ECCSs, and containment heat removal systems. For all other Class 2 systems, either the 1974 Edition of Section XI through the summer 1975 addenda or the latest NRC-approved edition may be used. For consistency, the 1974 Edition through the summer 1975 addenda was used for determining the extent of the examination for the preservice inspection program for these other systems. This includes the head spray system and SLCS added to the Class 2 preservice inspection program.

The selection of the individual welds to be examined on each Class 2 system was based on the inspection philosophy identified in the 1980 Edition, winter 1981 addenda, of Section XI. The selection philosophy contained in the 1975 summer addenda is based on a random selection of welds and results in examining a particular weld only once in the plant's 40-year operational life. No trending of data is possible under the 1975 summer rules. The 1981 winter addenda identifies a selection philosophy that concentrates the examinations on those welds that historically have a greater probability of failure: namely, high-stress welds, welds at terminal ends, and dissimilar metal welds. In addition, the 1981 winter addenda requires examinations of the same welds in each 10-year interval so that meaningful data trending can be accomplished. There is general agreement in the industry that the 1981 winter addenda philosophy is superior to the random-selection approach identified in the 1975 summer addenda.

The criteria used for the selection of specific welds to be examined for the preservice inspection program were based on the following.

a. All high-stress welds defined as loading stresses greater than $0.8(1.2S_h + S_a)$ as per the 1981 winter addenda

b. All moderately stressed welds defined as loading stresses greater than $0.7(1.2S_h + S_a)$ and less than or equal to $0.8(1.2S_h + S_a)$. Inclusion of these moderately stressed welds in the Fermi 2, Class 2, preservice inspection program, is an added conservatism that exceeds the requirements of the ASME Section XI, 1980 Edition, winter 1981 addenda

c. All dissimilar metal welds

d. One terminal end of each type of terminal end within a system. (Note: This is a modified version of the ASME Section XI, 1980 Edition, winter 1981 addenda, Table IWC-2500-1, Category C-F, Footnote [1][b].) Edison has taken this approach to prevent skewing the weld examination sample to this particular type of weld. For example, the core spray system has four pumps, each with a terminal end at the suction and discharge attachment welds. To examine all eight terminal ends would be redundant. Therefore, to enable a more representative sample to be taken, only one pump suction terminal end weld and one pump discharge terminal end weld would be selected for examination

e. Additional random selections such that the total number of welds examined meets the number required by paragraph IWC-2411 of ASME Section XI, 1974 Edition, summer 1975 addenda.

Based on the above, Edison requested relief from two of the 1975 summer requirements for all the Class 2 system welds included in the preservice and inservice inspection programs. The first request for relief is to allow Edison to select those types of welds that historically have a higher probability of failure in lieu of the random-selection approach required by the 1975 summer addenda. The second request for relief was to allow repeated examination of the same welds in subsequent 10-year intervals in lieu of the requirements that different welds be inspected in each 10-year interval. This second relief request is applicable to the ISI-NDE program only.

The preservice inspection program delineated all required examinations, methods, code allowable exemptions, and relief requests. The preservice inspection program has been completed and is available for review by the NRC staff.

5.2.8.9 Snubber Program

The examination and testing program for snubbers complies to the extent practicable with the requirements of the Code and Addenda identified in 10 CFR 50.55a at the time the program is updated to the next 10 year interval. When compliance with Code requirements is impractical, relief is requested from the NRC in compliance with 10 CFR 50.55a. The examination and testing program for snubbers is described in the Snubber Program Plan, as required by Technical Requirements Manual (TRM) Section 5.1.1.

[a] Excluding shell test for valves according to Sections NB-3531-8 and NB-3531-9 of ASME B&PV Code Section III. The stress intensity ratio is interpreted from Section NB-6221 of the Code to be the ratio of the allowable stress; Sm, at test temperature to the allowable stress; Sm, at design temperature.

[b] Test pressure is 1.25 x design pressure x lowest stress intensity ratio.

[c] Test pressure is 1.50 x design pressure x lowest stress intensity ratio.

[d] Design and test conditions for the RCPB instrument lines are consistent with the conditions for the main pipeline they emanate from.

[e] The reactor recirculation system pump design pressure and temperature conditions envelop the system discharge piping design requirements.

[f] The reactor recirculation loop suction and discharge valves and the main steam isolation valves are tested per the 1968 ASME Pump and Valve Code, Article 7.

TABLE 5.2-2 REACTOR COOLANT PRESSURE BOUNDARY OPERATING THERMAL CYCLES

Normal, Upset and Testing Conditions

Event Description	Number of Cycles[a]	Analyzed Cycles for 60 Years[b]
Boltup	39	58
Design Hydrostatic Leak Test	55	75
Startup	183	246
Turbine Roll	152	201
Weekly Reduction to 50% Power	208	317
Loss of FW Heaters – Turbine Trip with 100% Bypass	7	10
Loss of FW Heaters – Partial FW Heater Bypass	15	19
SCRAM – Turbine Generator Trip	9	12
SCRAM – All Others	30	33
Control Rod Drive Isolation	32	47
Single Control Rod Drive Scram	32	47
Reduction to 0% Power	149	197
Hot Standby (Injections)	880	1307
SBFW Injection (Cold Injection into Hot Piping)	36	46
SBFW Injection (Cold Injection into Cold Piping)	11	18
RCIC Injection (Cold Injection into Hot Piping)	17	24
RCIC Injection (Cold Injection into Cold Piping)	779	1172
HPCI Injection (Cold Injection into Hot Piping)	23	29
HPCI Injection (Cold Injection into Cold Piping)	6	9
FW Injection (Cold Injection into Hot Piping)	5	10
FW Injection (Cold Injection into Cold Piping)	5	10
Shutdown	183	246
Hydrostatic Test (1563 psig)	1	2
Unbolt	39	58
Pre-Op Blowdown	2	3
SCRAM – Loss of FW Pumps	10	13
Loss of RWCU Flow	207	270
Core Spray Injection	3	4
Multiple SRV Actuation	7	9
Individual SRV Actuation (Sum)	1232	1851
RRS Pump Seal Injection On-Off-On	29	37[c]
RRS Single Loop Operation (SLO)	10	10/loop[d]
OBE (Operating Basis Earthquake)	1	2

TABLE 5.2-2 REACTOR COOLANT PRESSURE BOUNDARY OPERATING THERMAL CYCLES

Emergency Conditions

Event Description	Number of Cycles[a]
SCRAM – Single Safety/Relief Valve Blowdown	8
Reactor Overpressure with Delayed Scram, Feedwater Stays On, Isolation Valves Stay Open	1
Automatic Blowdown	1
Improper Start of Cold RRS loop	1
Sudden Start of Pump in Cold RRS loop	1
Improper Startup with Recirculation System Pumps Off and Drain Shut Off Followed by Turbine Roll and Increase to Rated Power	1
Natural Circulation Startup	3
Loss of AC Power, Natural Circulation Restart	5

Faulted Conditions

Event Description	Number of Cycles[a]
Pipe Rupture and Blowdown	1

Other Events with a Cyclic Limit

Event Description	Expected Duty[a]	Analyzed for 60 Years[b]
RRS Pump A Hot Standby (hours in SLO, idle with backflow)	464	697
RRS Pump B Hot Standby (hours in SLO, idle with backflow)	337	507
Main Steam Bypass Line – Time of Operation at 30-45% Valve Open Position (days)	72	100

[a] Expected number of cycles for a 40 year plant design life based on conservative projections of Fermi 2 operating history

[b] Analyzed number of cycles for License Renewal

[c] The Recirculation pump coolers were replaced in 1998. Through December 2012, 3 cycles had been experienced. The analysis input value for the coolers was 12 cycles.

[d] Per NEDC-32313P (Subsection 6.3, Reference 14), the 10 cycles are per loop. This analysis was not updated for License Renewal. This analysis applies to an isolated loop.

REACTOR RECIRCULATION System Pumps	B3101C001A&B	28 X 28 X 35 DVSS

TABLE 5.2-5 NUCLEAR STEAM SUPPLY SYSTEM SAFETY/RELIEF VALVES

Types of Valves	No. of Valves	Set Pressure (psig)	ASME Rated Capacity at 103 Percent Set Pressure (lb/hr each)[b]
Safety/relief	5	1135	904,400
Safety/relief	5	1145	912,200
Safety/relief	5[a]	1155	920,100

[a] Indicates the number of safety/relief valves actuated to provide automatic depressurization. This provides sufficient flow capacity to satisfy automatic depressurization requirements, assuming that one valve fails to open.

[b] Flow capacity = W = 51.5 x K x 0.9 x A x P

where

K = 0.8 (friction coefficient)

A = $\pi/4 \times 5.125^2$ (flow area)

P = set pressure with 103 percent accumulation

This information is obtained from the Safety and Safety Relief Valve Relieving Capacity Certification - Target Rock Corporation, the National Board of Boiler and Pressure Vessel Inspectors, June 6, 1975.

TABLE 5.2-6 REACTOR COOLANT PRESSURE BOUNDARY MATERIALS

Component	Form	Material	Specification (ASTM/ASME)
Reactor pressure vessel heads, shells	Rolled plate or forgings	Low alloy steel	SA-533 Grade B, Class 1
	Welds	Low alloy steel	SFA-5.5
Closure flange	Forged ring	Low alloy steel	SA-508 Class 2
	Welds	Low alloy steel	SFA-5.5
Nozzles	Forged shapes	Low alloy steel	SA-508 Class 2
	Welds	Low alloy steel	SFA-5.5
Cladding	Weld overlay	Austenitic stainless steel	SFA-5.9 and SFA-5.4 TP 308, 309 and 312 carbon content of final surface limited to 0.8 percent maximum
Control rod drive stub tubes	Pipe	Incone1	SB-167
	Welds	Incone1	SFA-5.11 TP ENiCrFe-3
Control rod drive housing	Pipe	Austenitic stainless steel	SA-312 TP 304
	Welds	Stainless steel	SFA-5.9 TP 308
In-core housing	Pipe	Austenitic stainless steel	SA-213 TP 304
	Welds	Stainless steel	SFA-5.9 TP 308

Additional RCPB component materials and specifications used are specified below.

Depending on whether impact tests are required and depending on the lowest service metal temperature when impact tests are required, the following ferritic materials and specifications were used:

TABLE 5.2-6 REACTOR COOLANT PRESSURE BOUNDARY MATERIALS

Pipe	SA-106 Grade B; SA-333 Grade 6 and SA-155 Grade KCF-70
Valves	SA-105 Grade II; SA-350 Grade LF1 and SA-216 Grade WCB
Fittings	SA-105 Grade II; SA-350 Grade LF1; SA-234 Grade B; and SA-420 Grade WPL1 or WPL6
Bolting	SA-193 Grade B7; SA-194 Grades 7 and 2H; and SA-540 Grade B22, B23 and B24
Welding material	SFA-5.1 (E-7015, E-7016, E-7018) SFA-5.5 (E-7010A1, E-7015, E-7016, E-7018) SFA-5.17, SFA-5.18
Other material	SA-516, Grade 70

For those systems or portions of systems, such as the reactor recirculation system, which require austenitic stainless steel, the following materials and specifications were used:

Pipe	SA-376 Type 304; SA-312 Type 304; SA-358 Type 304
Valves	SA-182 Grade F-304; SA-351 Grades CF-8 and CF-8M
Pump	SA-182 Grade F-304; SA-351 Grades CF-8 and CF-8M
Flanges	SA-182 Grade F-316
Bolting	SA-193 Grade B7; SA-194 Grades 7 and 2H; SA-540 Grades B22, B23 and B24
Welding material	SFA-5.4 (E308-15, E308L-15, E316-15); SFA-5.9 (ER-308, ER-308L, ER-316)

- Control rod drive discharge headers
- Containment sampling system

TABLE 5.2-13 SYSTEMS OUTSIDE PRIMARY CONTAINMENT THAT WOULD NOT CONTAIN HIGHLY RADIOACTIVE FLUIDS

System	Comment
RHR fuel pool cooling	Not directly affected by accident.
Standby liquid control	Injects fluid and does not circulate reactor coolant.
General service water / emergency equipment service water	Do not circulate reactor coolant and could become contaminated only due to system leaks.
Reactor building closed cooling water / emergency equipment cooling water	Do not circulate reactor coolant and could become contaminated only due to system leaks.
Condensate storage	Could become contaminated only due to isolation valve leakage.
Demineralized water makeup	Could become contaminated only due to isolation valve leakage.
Torus water management	Isolated during LOCA and not required for accident mitigation.
Control air/station air	Would require system or interface required for accident mitigation.
Fuel-pool cooling and cleanup	Not directly affected by accident.
Main steam lines	Would require failure of MSIVs.
Feedwater lines	Would require failure of isolation valves.
Drywell cooling system	Uses RBCCW of EECW and is not needed for safe shutdown of plant.
Reactor building floor/equipment drains	Not required for accident mitigation. Minimizing leakage from systems in Table 5.2-12 minimizes input to the system.
Radwaste	Not required for accident mitigation.
Supplemental cooling chilled water	Does not circulate reactor coolant and could become contaminated only due to system leaks.
Combustible gas control system	Could become contaminated only due to isolation valve leakage.

5.3 THERMAL HYDRAULIC SYSTEM DESIGN

5.3.1 Analytical Methods and Data

The analytical methods and thermodynamic and hydrodynamic data used to determine the thermal and hydraulic characteristics of the reactor coolant system are presented in Section 4.4.

5.3.2 Operating Restrictions on Pumps

The operating restrictions imposed on the coolant pumps to meet net positive suction head (NPSH) requirements are contained in Subsection 4.4.3.

5.3.3 Power-Flow Operating Map

A power-flow operating map that indicates the permissible operating range is contained in Subsection 4.4.3.

5.3.4 Load-Following Characteristics

The load-following characteristics are described in Subsection 4.4.3.

5.3.5 Transient Effects

The transient effects are presented in Chapter 15.

5.3.6 Thermal and Hydraulic Characteristics Summary Table

Thermal and hydraulic characteristics are summarized and compared in Table 4.4-1.

5.4 REACTOR PRESSURE VESSEL AND APPURTENANCES

5.4.1 Protection of Closure Studs

The Fermi 2 design and inspection procedures are in conformance with the requirements of Regulatory Guide 1.65 except those in regulatory positions 2b, 2e, and 3.

Studs were examined in accordance with the requirements of ASME Boiler and Pressure Vessel (B&PV) Code Section III, N-325 (1968 edition including Summer 1969 Addenda in effect at time of contract). Bored blank nuts were ultrasonically examined by both the longitudinal and shear wave methods. Shear wave examination on the nuts was performed in both the axial and circumferential directions.

Regulatory position 3 recommends provision for adequate corrosion protection during venting and filling of the vessel, and while the head is removed. General Electric supplies thread protectors that prevent stud damage, but stud holes are not plugged, and neither stud nor flange threads are protected from exposure to water. In practice this has been found to be adequate for studs complying with Regulatory Guide 1.65 Regulatory Position 1 & 2, as exposure to applied loads and operating and servicing environments has not required the replacement of any BWR studs (which were in compliance as stated above) or flange threads. No corrosion protection for studs is proposed.

5.4.2 Special Processes for Fabrication and Inspection

The product forms of the materials used to fabricate the reactor pressure vessel (RPV) are as follows.

Vessel Part	Product Form
Cylindrical shell	Rolled plate
Heads	Rolled plate
Main closure flanges	Forged rings
Closure bolting	High-strength bolting
Nozzles	Forgings
Nozzle safe ends	Forgings (stainless steel)
Nozzle safe ends	Forgings (carbon steel)

The rolled plate for vessel shells and head section was hot- formed, quenched, and tempered. These sections were welded into four rings for the vessel shell, and sections were welded to make up the top and bottom head. For a typical shell ring, the sequence of assembly is to weld the longitudinal seams, clad the inside diameter, and finally weld in the nozzles. The methods of fabrication used on the Fermi 2 reactor vessel are all allowed by the ASME B&PV Code and are not considered special or unusual.

From the standpoint of vessel inspection, normal radiographic techniques were used for the inspection of welds during fabrication. In addition, a preservice volumetric inspection using ultrasonic techniques was conducted in the fabrication shop.

This inspection was carried out in accordance with Section XI of the ASME Code, 1970 edition including winter 1971 addenda.

5.4.3 Features for Improved Reliability

No special features are incorporated in Fermi 2 that were not used before.

5.4.4 Quality Assurance Surveillance

The RPV was fabricated for GE by Combustion Engineering and was subject to Edison's QA audit.

Quality Assurance surveillance procedures were used to ensure that purchased material, equipment, and services associated with the RPV and appurtenances conformed to the requirements of the purchase documents. These procedures included provisions for source evaluation and selection, objective evidence of quality, inspection at the vendor source, and examination of the RPV upon delivery at the construction site.

5.4.5 Materials and Inspections

The materials that were used in the RPV are shown in Table 5.2-6.

The RPV was subject to the inspection requirements in accordance with the ASME B&PV Code Section III, 1968 edition with addenda through summer 1969, and the UT inspection discussed in Subsection 5.4.2.

The ASME Code Section XI baseline (preservice) inspection of the reactor vessel has been completed. One hundred percent of all RPV welds are included in the baseline. The Authorized Inspector has certified this inspection. The examination was conducted in the manufacturer's shop. It was completed on May 25, 1974.

At the site, during the preservice examination of piping, a new baseline was obtained on certain vessel welds because the inservice inspection program requires them to be examined from a surface different than the shop examination. These are

a. Top girth seam weld of head flange to reactor shell

b. Nozzle inter-radius areas.

At the time of fit and function of the mechanical equipment for the inservice inspection work, several typical areas were compared with the baseline data for assurance of baseline validity and reproducibility.

5.4.6 Reactor Pressure Vessel Design

5.4.6.1 Safety Design Bases

Design of the RPV appurtenances meets the following safety design bases.

a. The RPV and appurtenances shall withstand adverse combinations of loading and forces resulting from operation under abnormal and accident conditions

b. To minimize the possibility of brittle fracture of the nuclear system process barrier, the following is required.

   1. Maximum impact properties at temperatures related to RPV operation shall be specified for materials used in the RPV

   2. Expected shifts in nil ductility transition temperature (NDTT) during design life as a result of environmental conditions, such as neutron flux, shall be considered in the design. Operational limitations ensure that NDTT shifts are accounted for in reactor operation

   3. Operational margins to be observed with regard to the NDTT shall be specified for each mode of operation.

5.4.6.2 Power Generation Design Basis

Design of the RPV and appurtenances meets the following power generation design basis:

a. The RPV shall be designed for an operational life of 40 years (Refer to Appendix B for evaluations of 60 years)

b. External and internal supports that are integral parts of the RPV shall be located and designed so that stresses in the RPV and supports that result from reactions at these supports are within ASME Code limits

c. Design of the RPV and appurtenances shall allow for a suitable program of inspection and surveillance.

5.4.6.3 Description

5.4.6.3.1 Reactor Pressure Vessel

The RPV, shown in Figure 5.4-1, is a vertical, cylindrical pressure vessel with hemispherical heads of welded construction. The vessel design data are listed in Table 5.4-1. The RPV operating thermal cycles are listed in Table 5.2-2. The RPV is designed, fabricated, tested, inspected, and stamped in accordance with the ASME B&PV Code Section III, 1968, Class 1, up to and including summer 1969 addenda. Design of the RPV and its support system meets Category I equipment requirements.

The cylindrical shell and bottom head of the RPV are fabricated of low-alloy steel, the interior of which is clad with stainless- steel weld overlay. Internal surfaces of nozzles that connect to stainless-steel pipe are also clad.

Inplace annealing of the RPV because of radiation embrittlement is unnecessary, as described in Subsection 5.2.4.5.

Quality Assurance methods used during the fabrication and assembly of the RPV and appurtenances ensure that design specifications are met.

The RPV top head is secured to the RPV by studs and nuts. These nuts are tightened with a stud tensioner. The RPV flanges are sealed with two concentric metal seal rings. To detect seal failure, a vent tap is located between the two seal rings. A monitor line is attached to the tap to provide an indication of leakage from the inner seal ring.

Thermocouples are located on the exterior of the RPV. In some cases, thermocouples are attached to the RPV by magnets. At other thermocouple locations, two pads are provided. One is an end pad to hold the end of a 3/16-in. diameter thermocouple, and the other is a clamp pad equipped with a set screw to secure the thermocouple. These thermocouple locations provide a means of observing RPV temperature in response to changes in RPV coolant flow rate. Because RPV metal thickness and the thermal time constant cause the temperature of the RPV surface to lag the coolant temperature, measurements of surface temperature do not afford an effective means of monitoring thermal stresses in the RPV.

Procedural controls on plant operation are necessary to hold these thermal stresses within acceptable ranges. These restrictions on coolant temperature are

a. The average rate of change of reactor coolant temperature during normal heatup and cooldown shall not exceed 100°F during any 1-hr period

b. The RRS pumps shall not be operated unless the coolant temperatures in the upper and lower regions of the RPV are within 145°F of each other

c. The pump in an idle reactor recirculation system (RRS) loop shall not be started unless the coolant temperature in that loop is within 50°F of reactor coolant temperature.

The limit regarding the normal rate of heatup and cooldown described in Item a. ensures that the RPV closure, closure studs, RPV support skirt, control rod drive (CRD) housing, and stub tube stresses and usage remain within acceptable limits. The RPV temperature limit on RRS pump operation restriction described in Item b. augments the Item a. limit in further detail by ensuring that the RPV bottom head region will not be warmed at an excessive rate caused by rapid sweepout of cold coolant in the RPV lower head region by RRS pump operation. Cold coolant can accumulate as a result of CRD inleakage and/or low recirculation flow rate during startup or hot standby. The Item c. limit further restricts operation of the RRS pumps to avoid high thermal stress effects in pumps and piping, while also minimizing thermal stresses on the vessel nozzles.

5.4.6.3.2 Shroud Support

The shroud support is a circular plate welded to the RPV wall. This support is designed to carry the weight of the shroud, shroud head, core support plate, top guide, steam separators, and jet pump system, and to laterally support the fuel assemblies. Design of the shroud support also accounts for pressure differentials across the shroud support plate, for the restraining effect of components attached to the support, and for earthquake loadings. The shroud support design is specified to meet appropriate ASME Code stress limits.

5.4.6.3.3 Reactor Pressure Vessel Supports

5.4.6.3.3.1 Vessel Support Assembly

The RPV support assembly consists of a ring girder, sole plates, and the various bolts, shims, and set screws necessary to position and secure the assembly between the RPV support skirt and the support pedestal. The concrete and steel support pedestal is constructed integrally with the building foundation. Steel anchor bolts are set in the concrete with the threads extending above the surface. The sole plates are bolted to the underside of the RPV ring girder. The sole plate-ring girder assembly is set, leveled, and grouted to the top of the RPV pedestal.

The anchor bolts extend through both the sole plates and the ring girder bottom flange. High-strength bolts are used to bolt the flange of the RPV support skirt to the top flange of the ring girder. The ring girder is ASTM A-36 and the sole plates ASTM A-588 structural steel, both fabricated according to appropriate AISC Specifications.

The top of the pedestal is haunched slightly on the inside to accommodate the anchor bolts. The haunch size has been kept to a minimum to reduce stress concentrations. Reinforcing steel has been provided completely encircling the anchorage area of the bolts to transfer the bolt loads into the main part of the pedestal. The reinforcing details for the haunch have been reviewed and approved by the AEC (Reference 1).

5.4.6.3.3.2 Reactor Pressure Vessel Stabilizers

The RPV stabilizers are designed to permit radial and axial vessel expansion, to limit horizontal vibration, and to resist seismic and jet reaction forces. The stabilizers are connected between the RPV and the top of the shield wall surrounding the RPV to provide lateral stability for the upper part of the RPV. Eight stabilizer brackets are attached by full-penetration welds to the RPV at evenly spaced locations around the RPV below the flange. Each RPV stabilizer consists of a stabilizer rod threaded at the ends, springs, washers, a nut, a plate, and a bumper bracket with tapered shims. The stabilizers are attached to each bracket and apply tension in opposite directions. The stabilizers are evenly preloaded with tensioners to the values of the residual loads.

5.4.6.3.4 Control Rod Drive Housings

The CRD housings are inserted through the CRD penetrations in the RPV bottom head and are welded to stub tubes extending into the RPV. Each housing transmits a number of loads to the bottom head of the reactor. These loads include the weights of a control rod, a CRD, a control rod guide tube, a four-lobed fuel support piece, and the four fuel assemblies that rest on the fuel support piece. These loads are taken into account in designing the bottom head of the reactor. The housings are fabricated of type 304 austenitic stainless steel.

5.4.6.3.5 In-Core Neutron Flux Monitor Housings

Each in-core neutron flux monitor housing is inserted through the in-core penetrations in the bottom head of the RPV and is welded to the inner surface of the bottom head.

An in-core flux monitor guide tube is welded to the top of each housing, as described in Subsection 4.2.2. Either a source range monitor/intermediate range monitor (SRM/IRM) drive unit or a local power range monitor (LPRM) is bolted to the seal- ring flange at the bottom of the housing, as described in Subsection 4.2.2.

5.4.6.3.6 Refueling Bellows

The refueling bellows forms a seal between the RPV and the surrounding primary containment drywell to permit flooding of the space (reactor well) above the RPV during refueling operations. The refueling bellows assembly consists of a type 304 stainless steel bellows, a backing plate, a spring seal, and a removable guard ring. The backing plate surrounds the outer circumference of the bellows to protect it and is equipped with a tap for testing and for monitoring leakage. The self energizing spring seal is located in the area between the bellows and the backing plate. This seal is designed to limit water loss in the event of a bellows rupture by yielding to make a tight fit to the backing plate. This seal is designed to limit water loss in the event of a bellows rupture by yielding to make a tight fit to the backing plate when subjected to full hydrostatic pressure. The guard ring attaches to the assembly and protects the inner circumference of the bellows. The guard ring can be removed from above to inspect the bellows. The assembly is welded to the reactor bellows support skirt and the reactor well seal bulkhead plate. The reactor bellows support skirt is welded to the RPV shell flange. The reactor well seal bulkhead plate bridges the distance to the primary containment drywell wall. This plate contains eight 12-in. holes for air circulation and two 30-in. holes for manways. Each hole is equipped with a watertight cover. For normal operation, the covers on the eight 12-in. holes are opened and removable air supply ducts are inserted into four of them. For refueling operations, all holes are covered.

IE Bulletin 84-03, Refueling Cavity Water Seal, was reviewed by Edison and deemed not to be applicable, since the design of the bellows described above differed markedly from the seal that failed and was reported in IE Bulletin 84-03.

5.4.6.3.7 Reactor Pressure Vessel Insulation

The RPV insulation has an average maximum heat transfer rate of approximately 0.2-Btu/hr/ft^2/°F at the operating conditions of 550°F for the RPV and 134°F for the drywell air. The insulation panels for the cylindrical shell of the RPV are held in place by the sacrificial shield. The insulation is designed to be removable where inspection is required for inservice inspection. Shell course welds will be inspected remotely.

5.4.6.3.8 Reactor Pressure Vessel Nozzles

All piping connected to the RPV nozzles, including instrument piping, has been designed so as not to exceed the allowable loads on any nozzle.

The RPV nozzles are low-alloy steel forgings made in accordance with the ASME Code SA-508, Class 2. Nozzles of nominal size larger than 2 in. are full-penetration welded to the vessel. Nozzles of 2 in. nominal size and under may be partial-penetration welded, as permitted by ASME B&PV Code Section III. Nozzles that are partial-penetration welded are low-alloy steel or carbon steel forgings made in accordance with ASME Code SA-508, SA-105, or SA-106.

The RPV top head nozzles are provided with flanges with small groove facing. The drain nozzle is of the full-penetration weld design and extends below the bottom outside surface of the RPV. The RRS inlet nozzles (Figure 5.4-1), the feedwater inlet nozzles, and the core spray inlet nozzles all have thermal sleeves. For more information on the feedwater sparger and thermal sleeve design, see Subsection 5.2.1.20.

Nozzles connected to stainless piping have safe ends made of stainless steel. These safe ends are normally welded to the nozzles after the RPV has been heat treated to avoid furnace sensitization of the stainless steel. The material used is compatible with the material of the mating pipe. For more information on the safe ends, see Subsection 5.2.3.2.

The nozzle for the core differential pressure and liquid control pipe is designed with a transition so that the stainless-steel outer pipe of the differential pressure and liquid control line can be socket welded to the inner end of the nozzle and so that the inner pipe passes through the nozzle. This design provides an annular region between the nozzle and the inner liquid control line to minimize thermal shock effects on the RPV in the event that use of the standby liquid control system (SLCS) is required.

5.4.6.4 Safety Evaluation

The RPV design pressure of 1250 psig is based on an analysis of margins. The margins include additional allowances to accommodate transients above the operating pressure without initiating safety valve action. The RPV design temperature of 575°F is based on the saturation temperature of water that corresponds to the design pressure.

To withstand external and internal loadings while maintaining a high degree of corrosion resistance, a high-strength, low-alloy steel is used as the base metal, and an internal cladding of stainless steel is applied using weld overlay. Use of ASME B&PV Code Section III, Category I, RPV design criteria ensures that a vessel designed, built, and operated within its design limits has an extremely low probability of failure as a result of any known failure mechanism.

Stress analysis and load combinations for the RPV were evaluated for the cycles listed in Table 5.2-2, with the conclusion that ASME Code limits are satisfied.

5.4.7 Reactor Pressure Vessel Schematic

The RPV schematic is contained in Figure 5.4-2. The relation of the RPV to the biological shield is shown in Figure 5.1-4. Normal water level and high and low levels for alarm and trip are shown in Figure 7.3-12.

5.5 COMPONENT AND SUBSYSTEM DESIGN

This section presents discussions of the performance requirements and design features to ensure overall safety of the various components within the reactor coolant pressure boundary (RCPB) and those subsystems closely allied with the reactor coolant system but not a portion of the RCPB. The subsystems and components discussed in this section are the reactor core isolation cooling (RCIC) system; residual heat removal (RHR) system; reactor water cleanup (RWCU) system; main steam lines, feedwater piping, and drains, valves, and component supports. The portions of these subsystems which are within the RCPB are discussed in Subsections 5.5.1 through 5.5.4.

5.5.1 Reactor Recirculation System and Pumps

5.5.1.1 Safety Design Bases

The reactor recirculation system (RRS) is designed to meet the following safety design bases.

a. An adequate fuel barrier thermal margin shall be ensured during postulated transients

b. A failure of piping integrity shall not compromise the ability of the reactor pressure vessel (RPV) internals to provide a refloodable volume

c. The RRS shall maintain pressure integrity during adverse combinations of loadings and forces occurring during abnormal, accident, and special event conditions.

5.5.1.2 Power Generation Design Bases

The RRS meets the following power generation design bases:

a. The RRS shall provide sufficient flow to remove heat from the fuel

b. System design shall minimize maintenance situations that would require core disassembly and fuel removal.

5.5.1.3 Description

The RRS consists of the two RRS pump loops external to the RPV. These loops provide the piping path for the driving flow of water to the RPV jet pumps, as shown in Figures 5.5-1 and 5.5-2. Each external loop contains one variable-speed motor-driven RRS pump, two motor-operated gate valves, and a motor-generator set to control RRS pump speed. Each pump discharge line contains a venturi-type flow meter nozzle.

The RRS loops are part of the nuclear system process barrier and are located inside the primary containment structure. The jet pumps are RPV internals. Their location and mechanical design are discussed in Subsection 4.5.1.2.7. However, certain operational characteristics of the jet pumps are discussed in this subsection. Table 5.5-1 summarizes the design characteristics of the RRS.

The recirculated coolant consists of saturated water from the steam separators and dryers that has been subcooled by incoming feedwater. This water passes down the annulus between the RPV wall and the core shroud. A portion of the coolant flows from the RPV, through the two external RRS loops, and becomes the driving flow for the jet pumps. Each of the two external RRS loops discharges high pressure flow into an external manifold from which individual recirculation inlet lines are routed to the jet pump risers within the RPV. The remaining portion of the coolant mixture in the annulus becomes the driven flow for the jet pumps. This flow enters the jet pump at suction inlets and is accelerated by the driving flow. The flows, both driving and driven, are mixed in the jet pump throat section and result in partial pressure recovery. The balance of recovery is obtained in the jet pump diffusing section shown in Figure 5.5-3. The adequacy of the total flow to the core is discussed in Subsection 4.4.3. Documented tests show that the jet pump design is sound and that jet pump operation is stable and predictable.

The original design for Fermi 2 included a 4-in. bypass line around each pump discharge valve. The line was to be used during the startup of a loop to equalize the pressure across the discharge valve, to preheat the piping loop by reverse flow, and to prevent the pump from overheating prior to opening the discharge valve. Operating plants have found this line to be very susceptible to intergranular stress corrosion cracking. General Electric has developed a circuit for controlling the opening of the discharge valve that eliminates the need for the bypass line. Employment of this circuit enables the removal of the bypass line.

Based on this experience at other plants, the decision was made not to install the 4-in. bypass lines on Fermi 2 and to incorporate the controlled opening (jogging) circuit. Caps are welded onto the bypass line tees.

There is a very low probability that a RRS loop that has been allowed to cool would need to be placed in service again when the nuclear system is hot. The only valid reason for closing both the pump discharge valve and the suction valve is to prevent leakage out of that portion of the RRS loop between the valves; e.g., excessive leakage through the pump mechanical seal. A leak of this nature cannot be repaired without shutting the plant down to permit access to the drywell. The nuclear system would, in all probability, be cooled prior to repairing the leak.

Since the removal of RRS valve internals without alternate isolation capability requires unloading of the nuclear fuel, the valves are provided with high-quality back seats and a trim to facilitate stem-packing renewal and to provide adequate leaktightness. Alternative RRS loop isolation devices (plugs) have been approved for use only during Mode 5 to support maintenance activities without unloading the nuclear fuel.

The feedwater flowing into the RPV annulus during operation provides subcooling for the fluid passing to the RRS pumps, thus determining the additional net positive suction head (NPSH) available beyond that provided by the pump location below the RPV water level. If feedwater flow is below the minimum value that provides adequate NPSH for full speed RRS pump operation, the pump speed is automatically limited. This limit is chosen to prohibit pump cavitation. Operation with the suction pressure available only from the RPV provides adequate NPSH.

The RRS pumps can be operated during nuclear steam supply system (NSSS) heatup for hydrostatic tests. At this time, they act in conjunction with any contribution from reactor core decay heat to raise NSSS temperature above the limit imposed on the RPV by nil ductility transition temperature (NDTT) considerations so that the hydrostatic test can be conducted.

Each RRS pump is a single-stage, variable-speed, vertical, centrifugal pump equipped with mechanical shaft seal assemblies. In order to preclude shaft cracking due to thermal stress, the pumps have been upgraded to the 4^{th} generation design.

The pump is capable of stable and satisfactory performance while operating continuously at any speed corresponding to a power supply frequency range from 11.5 to 57.5 Hz. For loop startup, each pump operates at a speed corresponding to a power supply frequency of 11.5 Hz.

Each RRS pump motor is a standard ac induction motor which is operated as a variable-speed pump driver by using a variable frequency power supply. The power supply is provided by a motor-generator set with a fluid coupler which allows continuous generator speed adjustment so that the output power frequency may be varied from 11.5 to 57.5 Hz. The pump motor design is capable of operating at any speed within the power supply frequency range corresponding to a pump speed control range from 20 percent to 102 percent rated pump speed. The electrical equipment is designed, constructed, and tested in accordance with the applicable sections of the NEMA Standards.

The variable-frequency ac motor-generator sets for both RRS pumps are located outside the drywell. The pump motors are electrically connected to the generators. Pump start begins when the generator excitation field breaker of the motor-generator set is closed.

The RRS pump shaft seal assembly consists of two individual seals built into a cartridge or cartridges, which can be readily replaced without removing the motor from the pump. The seal assembly is designed to require minimum maintenance over a long period of time, regardless of whether the pump is stopped or is operating at various speeds, with water at various pressures and temperatures. Each individual seal in the cartridge is capable of sealing against pump design pressure so that any one seal can adequately limit leakage in the event that the other seal should fail. Reduced clearances in the pump casing reduce leakage in the event of a gross failure of both shaft seals. Leakage due to massive seal failure will remain insignificant as compared to the available makeup supply. Provision is made for monitoring the pressure drop across each individual seal as well as the cavity temperature of each seal. Provision is also made for piping the seal leakage to a flow measuring device.

The effective inertias of the RRS pump and motor, motor-generator set, and variable speed coupling are specified in the following form, which takes into account the torque and speed conditions on each rotating shaft.

$$\sum_{\substack{\text{ALL}\\\text{SHAFTS}}} \frac{\text{Inertia } (\text{lb}-\text{ft}^2) \text{x Speed (radian/sec)}}{\text{g} \left(\frac{\text{ft}}{\text{sec}^2}\right) \text{xTorque (ft}-\text{lb)}}$$

The design objective for the RRS pump is to provide a unit that will not require removal from the system for rework or overhaul at intervals of less than one operating cycle. Pump casing overhaul and valve bodies are designed for a 40-year operational life. The pump drive motor, impeller, and wear rings are designed for as long a life as is practical. Pump mechanical seal parts are expected to have a life exceeding one operating cycle to afford convenient replacement during refueling outages.

The RRS piping is of all-welded construction and is designed and constructed to meet the requirements of the ANSI B31.7 Nuclear Power Piping Code-1969, Class 1.

The RRS is designed as Category I. The pump is assumed to be filled with water for the analysis. Vibration snubbers located at the top of the motor and at the bottom of the pump casing are designed to resist the horizontal reactions.

The RRS piping, valves, and pumps are supported by hangers to avoid the use of piping expansion loops that would be required if the pumps were anchored. In addition, the RRS loops are provided with a system of restraints designed so that reaction forces associated with any split or circumferential break do not jeopardize containment integrity. This restraint system provides adequate clearance for normal thermal expansion movement of the loop. Because possible pipe movement is limited to slightly more than the clearance required for thermal expansion movement, no impact loading on limit stops is considered.

The RRS piping, valves, and pump casings are covered with thermal insulation having a total average heat transfer rate of 65 Btu/hr/ft^2 with the system at rated operating conditions.

The insulation is the all-metal reflective type and is prefabricated into components for field installation. Removable insulation is provided at various locations to permit periodic inspection of equipment and inservice inspection access to components (Subsection 5.2.3.3).

5.5.1.4 Safety Evaluation

RRS malfunctions that pose threats of damage to the fuel barrier are described and evaluated in Subsections 15.3.1 and 15.3.3. It is shown in Subsections 15.3.1 and 15.3.3 that none of the malfunctions, including pump trip or pump seizure, result in fuel damage.

The core flooding capability of the RRS and the core flooding capability of a jet pump design plant are discussed in detail in Reference 1.

Piping and pump design pressures for the RRS are based on peak steam pressure in the reactor dome, appropriate pump head allowances, and the elevation head above the lowest point in the RRS loop. Piping and related equipment pressure parts are chosen in accordance with applicable codes. Use of the applicable code design criteria listed in Tables 3.9-17, 3.9-18, 3.9-43, and 3.9-44 ensures that a system designed, built, and operated within design limits has an extremely low probability of failure caused by any known failure mechanism.

GE purchase specifications require that reactor coolant pressure boundary (RCPB) integrity of the pump case be maintained through all conditions. In addition, dynamic loads are transmitted by piping suspension system components attached to the motor. The parts of the pump and motor that withstand seismic loads as part of the piping suspension system are the pump lugs, pump case, bolting between the pump case and the motor stand, motor stand, bolts attaching the motor stand to the motor, motor frame and motor seismic lugs.

Analyses performed to determine if the RRS pump can become a missile indicate that, for the postulated full double-ended pipe break LOCA in the RRS pump suction line, destructive pump and motor overspeed could occur (Reference 2). In the event of motor failure, the motor stator and frame structure would prevent the release of any missiles. Given the postulated accident, RRS pump impeller destructive overspeed could occur. However, impeller missiles will not penetrate the pump case (Reference 3). Missiles could be ejected from the open end of the broken pipe. Analyses of the effects of missiles ejected from the broken pipe are contained in Reference 4. Additional piping restraints were added to prevent the potential missile exit points in the pipe from developing.

A comparison of break locations using the Fermi 2 recirculation piping stress report has confirmed that no unacceptable damage consequences can occur as a result of potential recirculation pump missiles.

The consequences of the loss-of-component cooling water to both the recirculation pumps have been evaluated. The cooling water is supplied from the reactor building closed cooling water (RBCCW) system during normal plant operation in all modes. Cooling water to the recirculation pump motors and seals is supplied through the divisional emergency equipment cooling water (EECW) system piping which is routed into the drywell from external supply and return flow tie-ins with RBCCW. Each pump is supplied through a different EECW piping division so that both pumps cannot simultaneously lose component cooling, except by closure of both divisions of the EECW supply line outboard isolation valves on an ECCS high drywell pressure signal. High drywell pressure would also cause a reactor protection system signal to initiate a reactor trip and to close the RRS pump seal purge supply flow drywell isolation valves.

If there were a gradual loss of cooling water to the pump motor, the following sequence of alarms would come into the control room.

a. Motor bearing oil cooling water discharge

b. Motor thrust bearing lower face

c. Motor thrust bearing upper face

d. Upper guide bearing

e. Motor windings

f. Lower guide bearing

A loss of RBCCW/EECW flow for pump seal cooling will also cause a low flow alarm to annunciate in the control room. Alarms would also come into the control room through the recirculation pump motor temperature recorder. As these alarms start to come in, the operator would respond by dropping the power level and changing the flow rates to minimize the transient in case it were to become necessary to trip the overheated pump. If the operator were to receive confirmation that the pump motor bearings or the pump seals were overheating, he would trip the pump.

On a sudden loss of cooling water to the pump motor, as could occur on high drywell pressure isolation of the EECW supply line, the motor bearings would begin to incur damage after 90 seconds of full speed operation. As the bearings fail, the pump motor trip would occur from an overcurrent protective relay opening when the loss of rotor stability causes the rotor to contact the stator. This would occur within 2 to 3 minutes from the loss of cooling.

The high drywell pressure isolation would also cause the secondary cooling supply to the pump shaft seals by the seal purge flow to be cut off. During the continued operation of the pump motor, the seals would be protected by the residual cooling capacity of the cooler. The bearing failure will not result in damage to the pump shaft seals due to the structural support of the motor and pump. Following the pump trip, seal cavity circulation would be lost and the seal cavity will gradually heat up. If cooling is restored within 10 to 15 minutes, the shaft seals will not be significantly damaged. However, the exposure to higher temperatures will shorten the operable life of the elastomereic components of the seals. If cooling cannot be restored, the resulting seal leakage rate would be 18 gpm loss of reactor coolant. This coolant loss rate is within the capacity of the normal operating and isolation mode plant makeup systems. The fuel thermal limits would not be exceeded and the seal leakage does not lead to further degradation of the RCPB barrier.

5.5.1.5 Inspection and Testing

Quality control (QC) methods are used during fabrication and assembly of the RRS to ensure that design specifications are met. The reactor coolant system is thoroughly cleaned and flushed before fuel is loaded initially.

Prior to the Preoperational Test Program, the RRS was given a hydrostatic test at 125 percent of RPV design pressure. Preoperational tests on the RRS were performed as described in Chapter 14.

During the Startup Test Program, horizontal and vertical motions of the RRS piping and equipment are observed, and supports are adjusted, as necessary, to ensure that components are free to move as designed. The NSSS responses to RRS pump trips at rated temperatures and pressure are evaluated during the startup tests, and plant power response to recirculation flow control is determined.

Inservice inspection, in accordance with ASME Boiler and Pressure Vessel (B&PV) Code Section XI, 1971 edition including winter 1971 addenda was considered in the design of the RRS to ensure adequate working space and access for inspection of selected components. The criteria for selecting the components and locations to be inspected are based on the probability of a defect occurring or enlarging at a given location, including areas of known stress concentrations and locations where cyclic strain or thermal stress might occur. The RRS pump casings, valve bodies, and piping connection welds are visually inspected and given other nondestructive inspections from at least one side on a periodic basis. The inservice inspection program is described in Section 5.2.8.

5.5.2 Steam Generators

The steam generators are not applicable to the BWR.

5.5.3 Reactor Coolant Piping

The RRS loops are shown in Figures 5.5-1 and 5.5-2. The design characteristics are presented in Table 5.5-1.

5.5.4 Main Steam Line Flow Restrictors

5.5.4.1 Safety Design Bases

The main steam line flow restrictors are designed

a. To limit the loss of coolant from the RPV following a steam line rupture outside the primary containment to the extent that the RPV water level does not fall below the top of the core within the time required to close the main steam isolation valves (MSIVs)

b. To withstand the maximum pressure difference expected across the restrictor, following complete severance of a main steam line.

5.5.4.2 Description

A main steam line flow restrictor is provided for each of the four main steam lines, as shown in Figure 5.5-4. The restrictor is a complete assembly welded into the main steam line. It is located between the RPV and the first MSIVs and is downstream of the main steam line safety/relief valves. The restrictor limits the coolant blowdown rate from the RPV in the event a main steam line break occurs outside the primary containment to the maximum (choke) flow specified. The restrictor assembly consists of a venturi-type nozzle insert welded, in accordance with applicable code requirements, into the main steam line. The restrictor assembly is self-draining in that it contains low point pockets which are drained internally to the main steam line. The flow restrictor is designed and fabricated to ANSI B31.7.

The flow restrictor has no moving parts. Its mechanical structure can withstand the velocities and forces associated with a main steam line break. The maximum differential pressure is ASME Code limit pressure. The rated capacity of the RPV pressure relieving devices shall be sufficient to prevent a rise in pressure within the protected vessel of more than 110 percent of the design pressure (1.10 x 1250 = 1375 psig).

The ratio of venturi throat diameter to steam line diameter, approximately 0.55, results in a maximum pressure differential of 10 psi at rated flow. This design limits the steam flow in a severed line to approximately 200 percent rated flow, yet it results in a negligible increase in steam moisture content during normal operation. The restrictor is also used to measure steam flow and to initiate closure of the MSIVs when the steam flow exceeds preselected operational limits.

5.5.4.3 Safety Evaluation

In the event a main steam line should break outside the primary containment, the critical flow phenomenon would restrict the steam flow rate in the venturi throat to 200 percent of the rated value. Prior to isolation valve closure, the total coolant losses from the RPV are not sufficient to cause core uncovering. Thus, the core is adequately cooled at all times. Analysis of the steam line rupture accident shows that the core remains covered with water and that the amount of radioactive materials released to the environs through the main steam line break does not exceed the guideline values of 10 CFR 100. This accident analysis is described in Chapter 15.

Tests on a scale model determined final design and performance characteristics of the flow restrictor. The characteristics include maximum flow rate of the restrictor corresponding to the accident conditions, irreversible losses under normal plant operating conditions, and discharge moisture level. The tests showed that flow restriction at critical throat velocities is stable and predictable.

If moisture forms in the nozzle throat due to a momentary large static pressure reduction, the droplets of wet steam would have to be at saturation temperature corresponding to throat static pressure. When proceeding to the downstream region where vapor temperatures are higher, the droplets of wet steam vaporize somewhat and reach equilibrium with vapor at a lower pressure. The moisture is reduced and actually is negligible. It has negligible corrosion effect on the highly corrosion-resistant material (A-351 stainless steel) used for the inlet and throat sections. High velocity steam also has negligible erosion effect on this material.

The steam flow restrictor is exposed to steam of 1/10 to 2/10 percent moisture flowing at velocities of 150 ft/sec (steam piping inside diameter) to 600 ft/sec (steam restrictor throat). ASTM-A351 (type 304) cast stainless steel was selected for the steam flow restrictor material because it has excellent resistance to erosion-corrosion in this environment.

5.5.4.4 Inspection and Testing

Because the flow restrictor forms a permanent part of the main steam line piping and has no moving components, no testing program is planned. Only very slow erosion will occur with time, and such a slight enlargement will have no safety significance. Stainless steel resistance to corrosion has been substantiated by turbine inspections at the Dresden Unit 1 facility, which have shown no noticeable effects from erosion on the stainless-steel nozzle partitions.

Calculations show that even if the erosion rates are as high as 0.004 in. per year, after 40 years of operation the increase in restrictor-choked flow rate will be no more than five percent (Refer to Appendix B for evaluation of 60 years). A five percent increase in the radiological dose calculated for the postulated main steam line break accident is not significant (Subsection 15.6.4).

5.5.5 Main Steam Line Isolation Valves

5.5.5.1 Safety Design Bases

The MSIVs, individually or collectively, meet the following safety design bases.

a. The MSIVs shall close the main steam lines within the time established by design-basis accident analysis to limit the release of reactor coolant

b. The MSIVs shall close the main steam lines slowly enough that simultaneous (inadvertent) closure of all steam lines will not exceed the NSSS design limits

c. The MSIVs shall close the main steam line when required, despite single failure in either valve or in the associated controls, to provide a high level of reliability for the safety function

d. The MSIVs shall use separate energy sources as the motive force to independently close the redundant isolation valves in the individual steam lines

e. The MSIVs shall use local stored energy (compressed air and springs) to close at least one isolation valve in each steam pipeline without relying on the continuity of any variety of electrical power to furnish the motive force to achieve closure

f. The MSIVs shall be able to close the steam lines, either during or after seismic loadings, to ensure isolation if the nuclear primary system is breached

g. The MSIVs shall have the capability for being tested, during normal operating conditions, to demonstrate that the valves will function.

5.5.5.2 Description

Two isolation valves are welded in a horizontal run of each of the four main steam pipes. One valve is as close as possible to the primary containment barrier and inside it, and the other is just outside the barrier. When closed, the valves form part of the nuclear system process barrier for openings outside the containment and part of the pressure barrier for nuclear system breaks inside the containment.

Figure 5.5-5 shows a typical MSIV, which does not necessarily reflect the actual detailed valve configuration utilized at Fermi 2. Each is a 26-in., Y-pattern, globe valve. Design steam flow rate through each valve is 3.72×10^6 lb/hr. The main disk or poppet is attached to the lower end of the stem. Normal steam flow tends to close the valve, and higher inlet pressure tends to hold the valve closed.

The bottom end of the valve stem closes a small pressure- balancing hole in the poppet. When the hole is open, it acts as a pilot valve to relieve differential pressure forces on the poppet. Valve stem travel is sufficient to give flow areas past the wide open poppet approximately equal to the seat port area. The poppet travels approximately 90 percent of the valve stem travel; approximately the last 10 percent of travel closes the pilot hole. The air cylinder can open the poppet with a maximum differential pressure of 200 psi across the isolation valve in a direction that tends to hold the valve closed.

A 45° angle permits the inlet and outlet passages to be stream-lined. This minimizes pressure drop during normal steam flow and helps prevent debris blockage. The pressure drop at rated flow is approximately 7 psi. The valve stem penetrates the valve bonnet through a stuffing box utilizing a live-loading configuration and graphite packing to help prevent leakage through the stem packing. The live-loading configuration consists of Belleville disc springs installed on the packing gland studs and the packing gland plate. This creates additional elasticity to the loading of the stuffing box packing. When the gland stud nuts are tightened to load the packing, the disc springs are compressed. As the packing consolidates inservice, the springs expand to maintain a relatively constant load on the packing providing a continual inservice adjustment.

Attached to the upper end of the stem is an air cylinder that opens and closes the valve and a hydraulic dashpot that controls its speed. The speed is adjusted by a valve in the hydraulic return line bypassing the dashpot piston. Valve closing time is adjustable to between 3 and 10 sec.

The air cylinder is supported on the valve bonnet by actuator support and spring guide shafts. Helical springs around the spring guide shafts with air pressure from either normal or accumulator sources are required together to close the valve.

The motion of the spring seat member actuates switches at fully open, 90 percent open and fully closed valve positions.

The valve is operated by pneumatic pressure and by the action of compressed springs. The control unit is attached to the air cylinder. This unit contains three types of control valves: pneumatic, ac, and dc. These control valves open and close the main valve and exercise it at slow and fast speed. Remote manual switches in the main control room enable the operator to operate the valves.

Operating air is supplied to the outboard valves from the plant interruptible control air system via accumulators protected by check valves. The accumulator tank between the control valve and the check valve provides a pneumatic reserve for the closing of each valve. Each valve is designed to accommodate saturated steam at 1250 psig and 575°F, with a moisture content of approximately 0.23 percent, an oxygen content of 30 ppm, and a hydrogen content of four ppm.

In the "worst case" condition of the main steam line rupturing downstream of the valve, steam flow would quickly increase to 200 percent of rated flow. Further increase is prevented by the venturi flow restrictor upstream of the valves.

During approximately the first 75 percent of closing, the valve has little effect on flow reduction because the flow is choked by the venturi restrictor upstream of the valves. After the valve is approximately 75 percent closed, flow is reduced as a function of the valve area versus travel characteristic.

The design objective for the valves is a minimum of 40 years of service at the specified operating conditions. Operating cycles are estimated to be 120 startup cycles, 120 shutdown cycles, and 180 scram cycles in the expected 40-year plant life. The valves shall be capable of actuating a minimum of 50 full cycles per year. The result of an updated evaluation for 60 years of projected cycles is contained in Reference 11.

In addition to minimum wall thickness required by applicable codes, a corrosion allowance of 0.120-in. minimum is added to provide for 40 years of service.

Design specification ambient conditions for normal plant operation are 135°F normal temperature, 150°F maximum temperature, 100 percent humidity, in a radiation field of 15 rads per hour due to radiation gamma and 25 rads per hour due to neutron plus gamma radiation, continuous for design life. The inside valves are not continuously exposed to maximum conditions, particularly during reactor shutdown, and valves outside the primary containment and shielding are in ambient conditions that are considerably less severe.

In addition, they are designed to close and remain closed under the post accident environment conditions listed in Table 3.11-1.

To sufficiently resist the response motion from the safe-shutdown earthquake (SSE), the MSIV installations are designed as Category I equipment. The valve assembly is manufactured to withstand the design-basis forces applied at the mass center, assuming the cylinder/spring operator is cantilevered from the valve body and the valve is located in a horizontal run of pipe. The stresses caused by horizontal and vertical forces are assumed to act simultaneously and are added directly. The stresses in the actuator supports caused by loads are combined with the stresses caused by other live and dead loads, including the operating loads. The allowable stress for this combination of loads is based on the ordinary allowable stress set forth in applicable codes. The parts of the MSIVs that constitute a process fluid pressure boundary are designed, fabricated, inspected, and tested as required by the ASME Nuclear Pump and Valve Code.

5.5.5.3 Safety Evaluation

In a direct cycle nuclear power plant, the reactor steam goes to the turbine and to other equipment outside the reactor containments. Radioactive materials in the steam are released to the environs through process openings in the steam system or they escape from accidental openings. A large break in the steam system can drain the water from the reactor core faster than it is replaced by feedwater.

The analysis of a complete, sudden steam line break outside the primary containment is described in Subsection 15.6.4. The analysis shows that the fuel barrier is protected against loss of cooling if MSIV closure takes 10.5 sec or less. This 10.5 sec limitation includes as much as 0.5 sec for the instrumentation to initiate valve closure after the break. The calculated radiological time effects of the radioactive material assumed to be released with the steam are shown to be well within the guideline values for such an accident.

The shortest closing time, approximately 3 sec, of the MSIVs is also shown in Subsection 15.2.4 to be satisfactory. The switches on the valves initiate reactor scram when several valves are more than 10 percent closed. The pressure rise in the system from stored and decay heat may cause the NSSS relief valves to open briefly, but the rise in fuel cladding temperature will be insignificant. No fuel damage results.

The ability of this 45°, Y-design globe valve to close in a few seconds after a steam line break, under conditions of high pressure differentials and fluid flows with fluid mixtures ranging from mostly steam to mostly water, has been demonstrated in a series of tests in dynamic test facilities. Dynamic tests with a 1-in. valve show that the analytical method is valid. A fullsize, 20-in. valve was tested in a range of steam-water blowdown conditions simulating postulated accident conditions (Reference 5).

The following specified hydrostatic, leakage, and stroking tests, as a minimum, are performed by the valve manufacturer in shop tests:

a. To verify its capability to close between 3 and 10 sec, each valve is tested at pressure (1000 psig) and no flow. The valve is stroked several times, and the closing time is recorded. The valve test logic closes the valve by spring only then the combination of air cylinder and springs. Usually the closing time is slightly greater when closure is by springs only

b. Leakage is measured with the valve seated. The specified maximum seat leakage, using cold water at design pressure, is 2 cm^3/hr/in. of nominal valve size. In addition, an air seat leakage test is conducted using 50 psi pressure upstream. Maximum permissible leakage is 0.1 scfh per inch of nominal valve size. The valve stem is operated a minimum of three times from the closed position to the open position, and the packing leakage must still be zero by visual examination

c. Each valve is hydrostatically tested in accordance with the requirements of the ASME Nuclear Pump and Valve Code. During valve fabrication, extensive nondestructive tests and examinations are conducted. Tests include radiographic, liquid penetrant, or magnetic particle examinations of casting, forgings, welds, hardfacings, and bolts

d. The spring guides, the guiding of the spring seat member on the support shafts, and rigid attachment of the seat member ensure correct alignment of the actuating components. Binding of the valve poppet in the internal guides is prevented by making the poppet in the form of a cylinder longer than its diameter and by applying stem force near the bottom of the poppet.

After the valves are installed in the NSSS, each valve is tested several times in accordance with the Preoperational and Startup Test procedures. Two isolation valves provide redundancy in each steam line so that either can perform the isolation function, and either can be tested for leakage after the other is closed. The inside valve, the outside valve, and their respective control systems are separated physically.

The isolation valves and their installation are designed as Category I equipment. The design of the isolation valve has been analyzed for earthquake loading. These loads are small compared with the pressure and operating loads that the valve components are designed to withstand. The cantilevered support of the air cylinder, hydraulic cylinder, springs, and controls is the key area. The increase in loading caused by the specified earthquake loading is negligible at the joints between the support shafts and the valve bonnet.

Electrical equipment that is associated with the isolation valves and operates in an accident environment is limited to the wiring, solenoid valves, and position switches on the isolation valves. The expected containment pressure and temperature transient following an accident is discussed in Section 6.2.

5.5.5.4 Inspection and Testing

Inspection and testing of the MSIVs will be conducted periodically in accordance with the Technical Specifications. Additional information on MSIV testing is contained in Subsection 6.2.6.4.

5.5.6 Reactor Core Isolation Cooling System

5.5.6.1 Safety Design Bases

The RCIC system meets the following safety design bases.

a. The system shall ensure that adequate core cooling takes place to prevent the reactor fuel from overheating in the event the reactor isolation is accompanied by loss of flow from the reactor feedwater system

b. The system shall operate automatically in time to maintain sufficient coolant in the RPV so that the integrity of the radioactive material barrier is not compromised

c. Piping and equipment, including support structures, shall be designed to withstand the effects of an earthquake without a failure that could lead to a release of radioactivity in excess of the guideline values in published regulations.

5.5.6.2 Power Generation Design Bases

The RCIC system meets the following power generation design bases.

a. The system shall operate automatically in time to maintain sufficient coolant in the RPV so that the low-pressure core standby cooling systems (low-pressure coolant injection [LPCI] and core spray systems) are not actuated

b. Design shall provide for remote-manual operation of the system by an operator

c. To provide a high degree of assurance that the system shall operate when necessary

   1. The power supply for the system shall be from immediately available energy sources of high reliability

   2. Design shall provide for periodic testing during plant operation.

5.5.6.2.1 Equipment and Component Description-Design Conditions

Operating parameters for the components of the RCIC system are shown in Figure 5.5-6. The RCIC components are the following.

a. One 100 percent-capacity turbine and accessories

b. One 100 percent-capacity pump assembly and accessories

c. Piping, valves, and instrumentation for

   1. Steam supply to the turbine

   2. Turbine exhaust to the suppression pool

   3. Makeup supply from the condensate storage tank to the pump suction

   4. Makeup supply from the suppression pool to the pump suction

   5. Pump discharge to the feedwater line, including a test line to the condensate storage tank, a minimum flow bypass line to the suppression pool, and a coolant water supply to accessory equipment.

The design conditions are from the ASME Section III, Nuclear Power Plant Components.

5.5.6.2.2 Design Parameters

Design parameters for the RCIC system components are listed below. See Figure 5.5-7 for cross-reference of component numbers.

1. <u>RCIC Pump Operation (C001)</u>

Flow rate	Injection flow, 600 gpm Cooling water flow, 16 gpm Total pump discharge, 616 gpm
Water temperature range	40°F to 140°F
NPSH	20 ft minimum
Developed head pressure	2915 ft at 1184-psia reactor pressure 525 ft at 165-psia reactor pressure
BHP, not to exceed	700 HP at 2915-ft developed head 100 HP at 525-ft developed head
Design pressure	1515 psia
Design ambient	148°F, maximum (Actual conditions to which this equipment is environmentally qualified under the Fermi 2 EQ program are documented in EQ0-EF2-018.)

2. <u>RCIC Turbine Operation (C002)</u>

	High-Pressure Condition	Low-Pressure Condition
Reactor pressure (saturated temperature)	1184 psia	165 psia
Steam inlet pressure	1169 psia, minimum	150 psia, minimum
Turbine exhaust pressure	25 psia, maximum	25 psia, maximum
Design inlet pressure	1250 psig at saturated temperature	
Design exhaust pressure	165 psig at saturation temperature	

3. <u>RCIC Orifice Sizing</u>

Coolant loop orifice (D009)	Sized with piping arrangement to ensure maximum pressure of 75 psia at the lube-oil cooler inlet and a minimum pressure of 45 psia at the spray nozzles at the barometric condenser.
Minimum flow orifice	Sized with piping arrangement to ensure minimum flow of 75 gpm with MO-F019 fully open.
Test return orifice (D006)	Sized with piping arrangement and drag valve E41-F011 to simulate pump discharge pressure required when the RCIC system is injecting design flow with the reactor vessel pressure at 165 psia.

Leak-off orifices (D008 and D010)	Sized for 1/8-in. diameter minimum; 3/16-in. diameter maximum.
Warm-up bypass orifice (D011)	Sized at 5/16-in. to insure sufficient steam supply to spin the turbine.

4. Valve Operation Requirements

Steam warm-up bypass valve (F095)	Open and/or close against 1169 psid pressure within 10 sec.
Steam supply valve (F045)	Open and/or close against maximum expected differential pressure within 45 sec.
Pump discharge valve (F013)	Open and/or close against maximum expected differential pressure within 30 sec.
Pump minimum flow bypass valve (F019)	Open and/or close against 1296 psid pressure within 25 sec.
Steam supply isolation valves (F007 and F008)	Close against maximum expected differential pressure within 15 sec.
Cooling water relief valve (F018)	Sized to prevent over-pressurizing piping, valves, and equipmentin the coolant loop in the event of failure of pressure control valve F015.
Pump discharge out-board isolation valve (F012)	Open against 1000 psid pressure within 15 sec (valve normally open and deenergized).
Pump test return valve (F022)	Capable of open and/or close against 1000 psi differential pressure.
Relief valve barometric condenser (F033)	Relief valve is capable of retiaing 10 in. of mercury vacuum at 140°F ambient, with a set pressure of 5 to 7 psig and flow of 20 gpm at 25 percent accumulation.
Turbine Exhaust isolation valve (F001)	Opens and/or closes against 50 psi differential pressure at a temperature of 267°F. Physically located as close to the containment as practical.
Vacuum pump discharge isolation (F002)	Opens and/or closes against 50 psi differential pressure at a temperature of 267°F. Physically located as close to the containment as practical.
Check valve turbine exhaust (F040)	Located at a high point in the line on a horizontal run, with adjacent piping arranged to provide a continuous downward slope, form the upstream side of the check valve to the turbine exhaust drain pot.

Vacuum breaker isolation valves (F062 and F084)	Open and/or close against a differential pressure of 50 psi.
Vacuum breaker check valves (F063 and F064)	Open with a minmum pressure drop (less than or equal to 0.5 psi) across the valve seat.

5. Rupture Disk Assemblies (D001 and D002)

Used for turbine casing protection; includes a mated vacuum support to prevent rupture disk reversing under vacuum conditions.

Rupture pressure	150 psig ± 10 psig
Flow capacity	60,000 lb/hr at 165 psig

6. Condensate Storage Requirements

150,000 gap (Total reserve storage for both HPCI and RCIC systems, see Section 6.3.2.6.)

7. Piping RCIC Water Temperature

The maximum water temperature range for continuous system operation does not exceed 140°F. However, due to potential short-term operation at higher temperatures, piping expansion calculations were based on 170°F.

8. Turbine Exhaust Vertical Reaction Force

Unbalanced pressure due to discharge under the suppression pool water level is described in Reference 6.

9. Ambient Condition

	Temperature	Relative Humidity
Normal plant operation	60° to 100°F	95 percent
Isolation conditions	148°F	100 percent

5.5.6.3 Description

5.5.6.3.1 General

The RCIC system consists of a steam-driven turbine-pump unit and associated valves and piping capable of delivering makeup water to the RPV. A schematic diagram is shown in Figure 5.5-7 and Figure 5.5-8. Logic diagrams are provided in Figure 7.4-1, Sheets 1 through 6.

The pump discharges either to the feedwater line or to a full flow test return line to the condensate storage tank. The discharge lines are full of water and remain flooded because they are connected to the feedwater line. The lines upstream of the normally closed HPCI and RCIC injection valves are kept full due to the static head provided by the condensate storage tank. The elevation of the injection valves is lower than the low level of the condensate storage tank, providing the static head. A minimum flow bypass line to the suppression pool is provided to protect the pump during startup and shutdown. The makeup water is delivered into the RPV through the feedwater line. Cooling water for the RCIC turbine lube-oil cooler and barometric condenser is supplied from the discharge of the pump, as shown in Figure 5.5-7.

Following any reactor shutdown, steam generation continues because of heat produced by the radioactive decay of fission products. Initially, the rate of steam generation can be as much as approximately 6 percent of rated flow and is augmented during the first few seconds by delayed neutrons and some of the residual energy stored in the fuel. Steam normally flows to the main condenser through the turbine bypass or, if the condenser is isolated, to the suppression pool. The fluid removed from the RPV is normally made up by the feedwater pumps supplemented by cooling water flow from the CRD system. If makeup water is required to supplement these primary sources of water, the RCIC turbine-pump unit starts automatically on receipt of a RPV low water level (L2) signal (Figure 7.4-1) or is started by the operator from the main control room. The RCIC delivers its design flow within 50 sec after actuation.

The RCIC makeup capacity is sufficient to avoid the need for the ECCS. Pump suction is usually lined up to the condensate storage tank but is automatically switched to the suppression pool on low condensate storage tank level. See Subsection 5.5.6.3.3.

Based upon normal condensate storage tank level of greater than 11’-0”, the volume of water stored for the RCIC (140,000 gal) is sufficient to allow operation for 8 hr after shutdown, assuming that none of the steam generated in the RPV is returned to the RPV as condensate. Other systems that use the condensate storage tank and could jeopardize the availability of this quantity of water can be isolated. However, manual actions are not required to protect the condensate storage tank inventory since, upon low level, RCIC suction is automatically transferred to the safety-related water source which is the suppression pool.

The RCIC system is sized to prevent actuation of the low level signal (L1) for RPV isolation incidents. Prevention of this signal ensures core cooling and prevents ADS actuation, thus preventing inadvertent blowdown of the RPV for this situation.

Quantitative information on steam and delivery water conditions is provided in Figure 5.5-6 for all operating modes of the RCIC system.

The backup supply of cooling water for the RCIC is the suppression pool. The turbine pump assembly is located below the level of the condensate storage tank and below the minimum water level in the suppression pool to ensure positive suction head to the pump.

All components required for initiating the RCIC are completely independent of auxiliary ac power, plant service air, and external cooling water systems. These components require only power derived from the station battery to operate the valves and logic. The power source for the turbine-pump unit is the steam generated in the RPV by the decay heat in the core. The steam is piped directly to the turbine, and the turbine exhaust is piped to the suppression pool.

Throughout the period of RCIC operation, the exhaust from the RCIC turbine is condensed in the suppression pool, which results in a slow temperature rise of approximately 3°F per hour in the pool. One RHR heat exchanger can be used to cool the suppression pool, if necessary. If for any reason the RCIC is unable to supply sufficient flow for core cooling, the emergency core cooling system (ECCS) provides the required boundary protection. A further discussion of this is found in Section 6.3.

The RCIC turbine-pump unit is located in a shielded area to ensure that personnel access areas are not restricted during RCIC operation. The turbine controls provide for automatic shutdown of the RCIC turbine on receipt of the following signals

a. RPV high water level - indicates that core cooling requirements are satisfied

b. Turbine overspeed - prevents damage to the turbine and turbine casing

c. Pump low suction pressure - prevents damage to the turbine pump unit that results from loss of cooling water

d. Turbine high exhaust pressure - indicates turbine or turbine control malfunction

e. System isolation signal - indicates need to shut down equipment.

Because the steam supply line to the RCIC turbine is a pressure containment boundary, certain signals automatically isolate this line and cause shutdown of the RCIC turbine.

The RCIC turbine has a speed governor that is positioned by the demand signal from the flow controller. Maximum output from the controller corresponds to maximum turbine speed.

The RCIC system may provide the ability to mitigate the consequences of small pipe breaks, but it is not provided primarily for such purpose. The ECCS provides redundant protection for the entire spectrum of pipe breaks. For small breaks this protection would be provided by HPCI and automatic depressurization.

Both the RCIC and HPCI systems provide decay heat removal capability when the main condenser is unavailable (i.e., isolated from the nuclear system) for heat sink purposes. The HPCI is a subsystem of the ECCS; however, the RCIC is not a subsystem of the ECCS.

Long-term heat removal capability may be provided by the RCIC or HPCI during the following operational events: scram, pressure relief, core cooling, RPV isolation, and restoration of ac power. The RHR system may be used for long-term heat removal during any long-term isolation. These events are all situations in which the RPV is isolated from the main condenser. None of these events are pipe break (loss of coolant) situations requiring immediate reactor water level restoration.

To ensure HPCI or RCIC system availability for the operational events noted previously, certain design considerations are used in the design of both systems.

5.5.6.3.2 Reactor Core Isolation Cooling Following Main Condenser Isolation (See Figure 5.5-9)

A reactor shutdown is accompanied by the isolation of the main condenser from the reactor vessel; the fission product decay heat results in an increase in the reactor vessel pressure. The pressure increase is limited by or manual operation of the relief valves, which serve to dump steam to the suppression pool. In the event the feedwater pumps and control rod drive leakage cannot provide sufficient water to make up for that lost by the steam dumping, the RCIC begins to operate by either a low reactor water signal or a manual start. For normal operation, the RCIC turbine-driven pump takes water from the condensate storage tank and injects it into the feedwater line. The steam supply for the RCIC turbine is from a main steam line using decay-heat-generated steam; exhaust is to the suppression pool. During RCIC operation, the desired reactor vessel pressure is maintained by manual control of the relief valves.

When RCIC is initiated, automatic actions will take place as described in Subsections 5.5.6.3.6 and 5.5.6.7. Also for RCIC operation, the turbine control system must function properly and there can be no turbine trip signals present. The RCIC can deliver its design flow within 50 sec of the initiation signal. Based on normal condensate storage tank level of greater than 11’-0”, the volume of water stored in the condensate storage tank for the RCIC (135,000 gal) is sufficient to allow operation of the RCIC for 8 hr after a shutdown. After this time, the system is sufficiently depressurized to allow the shutdown cooling mode of the RHR system to operate. The flow rate of water from the RCIC pump to the reactor vessel is 600 gpm, which is approximately equal to the reactor water boiloff rate 15 minutes after shutdown. This flow rate is sufficient to prevent the reactor vessel water level from dropping down to the top of the core.

5.5.6.3.3 Reactor Core Isolation Cooling Backup Mode (See Figure 5.5-10)

The RCIC can also take water from the suppression pool if the condensate storage tank level becomes too low. Transfer of the pump suction to the suppression pool is an automatic operation which follows the receipt of a low level signal from the condensate storage tank. The transfer requires the opening of normally closed valves (E51) F029 and (E51) F031 located in the pump suction line to the suppression pool. The opening of these valves causes the automatic closure of (E51) F010 located in the pump suction line leading to the condensate storage tank. Panel status information is provided for the operator in the form of valve position indication and an alarm if the operator closes either suppression pool suction valve while the condensate storage tank level is low.

5.5.6.3.4 Reactor Core Isolation Cooling Test Flow Mode (See Figure 5.5-11)

The RCIC system is designed commensurate with the safety importance of the system and its equipment. Each component is individually tested to confirm compliance with system requirements. The system as a whole is tested during both the startup and preoperational phases of the plant to set a base mark for system reliability. To confirm that the system maintains this mark, functional and operability testing is performed at predetermined intervals throughout the life of the reactor plant.

A design flow functional test of the RCIC system may be performed during normal plant operation by drawing suction from the condensate storage tank and discharging through a full flow test return line to the condensate storage tank. The discharge valve to the feedwater line remains closed during the test, and reactor operation remains undisturbed. All components of the RCIC system are capable of individual functional testing during normal plant operation. System control provides automatic return from test to operating mode if system initiation is required. There are three exceptions:

a. Auto/manual initiation on the flow controller. This feature is required for operator flexibility during system operation

b. Steam inboard/outboard isolation valves. The closing of either or both of these valves requires operator action to properly sequence their opening. An alarm sounds when the controls for either of these valves is operated to direct the valves to close

c. Other parts of the system that have been bypassed or deliberately rendered inoperable. These shall be indicated in the control room at the system level.

5.5.6.3.5 Reactor Core Isolation Cooling Minimum Flow Mode (See Figure 5.5-12)

A minimum flow bypass line is provided for protection of the RCIC pump. A flowmeter in the pump discharge line provides a signal for initiating the minimum flow mode for low flow and stopping its operation for a sufficient flow. Pump discharge pressure also must be sensed by PS N020 to allow minimum flow bypass valve F019 to open.

5.5.6.3.6 Auxiliary Heat Removal Operation

If the main feedwater system is not operable, a reactor scram will automatically be initiated when reactor water level falls to Level 3. Reactor water level will continue to decrease from boil-off until the low-low-level setpoint, Level 2, is reached. At this point, the HPCI system and the RCIC system will be automatically initiated to supply makeup water to the reactor pressure vessel. These systems will continue automatic injection until the reactor water level reaches Level 8, at which time the HPCI and RCIC turbines are tripped. These systems (HPCI/RCIC) will restart automatically once the high-level trip signal clears and a low-low-level (Level 2) signal is received.

The RCIC system will start automatically upon receipt of the initiation signal from the reactor vessel low-water-level sensor. During startup from standby, the following events occur automatically. (See Figure 7.4-1.)

a. Turbine speed control given to RCIC system flow indicator controller

b. RCIC test bypass valve to condensate storage tank closes (if open)

c. Steam supply valves to turbine open

d. Barometric condenser condensate pump discharge isolation valve closes

e. Pump discharge valve to feedwater line opens

f. Barometric condenser vacuum pump starts

g. Cooling water supply valve to lube oil cooler opens.

The turbine starts as soon as the steam supply valve opens, since the turbine trip throttle valve and control valve are open. The minimum flow bypass valve to suppression pool opens when pump discharge pressure increases. System flow starts when pump discharge pressure exceeds feedwater line pressure. As pump discharge pressure and steam inlet pressure change, the control signal adjusts the turbine to maintain constant pump flow. When pump flow reaches a prescribed value, the minimum flow bypass valve closes.

On occurrence of a low water level in the condensate storage tank, the suction to the RCIC pump changes automatically from condensate storage tank to the suppression pool.

The operator can switch the flow controller to the manual position and decrease flow rate to stabilize the water level in the reactor vessel. This would be done before reaching the high-water-level isolation. Even if the operator does not manually take control and the RCIC trips on high level, the RCIC will restart automatically once the high-water-level isolation signal clears and a Level 2 low-low-water-level signal is received.

The following sequence of events occurs in the case of an automatic initiation of the HPCI system (see Figure 7.3-2).

a. Steam supply outboard isolation valve opens

b. HPCI suction valve from condensate storage opens (if closed)

c. HPCI pump discharge inboard and outboard isolation opens

d. deleted

e. HPCI steam inlet valve opens

f. HPCI lube-oil cooling water supply valve opens

g. HPCI auxiliary oil pump starts

h. HPCI condenser vacuum pump starts (if initiation is by Level 2 low-low-water-level signal only)

i. HPCI test return valves close (if open).

With the turbine stop valve and control valves open, steam is admitted to the turbine, accelerating it quickly to speed.

On the occurrence of either a low water level in the condensate storage tank or a high level in the suppression pool, the suction valve to the HPCI pump changes over from condensate storage tank to the suppression pool.

The operator can switch the flow controller to the manual position and decrease flow rate to stabilize the water level in the reactor vessel. This would be done before reaching the high-water-level isolation. Even if the operator does not manually take control and the HPCI trips on high level, the HPCI will restart automatically once the high-water-level isolation signal clears and a Level 2 low-low-water-level signal is received.

For the loss-of-feedwater transient, the HPCI/RCIC systems are used to automatically provide the required makeup flow. No manual operations are required.

With the MSIVs closed, reactor pressure may rise to the setpoint of the safety/relief valves that will operate to reduce reactor pressure.

The heat added to the suppression pool from the operation of the safety/relief valves and the RCIC and HPCI systems will cause the suppression pool to heat up. As the average temperature of the suppression pool rises, the operator will initiate the suppression pool cooling mode of the residual heat removal (RHR) system to reduce this temperature before reaching the Technical Specifications limit.

Reactor vessel heat removal may also be accomplished through the manual actuation of any of the 15 safety/relief valves. In the event that reactor vessel pressure reduction and heat removal is required through safety/relief valve operation, the remote actuation of the safety/relief valves is available and would be used in conjunction with the suppression pool cooling mode of the RHR system. The operator actions necessary to place the RHR system in the suppression cooling mode emergency operations are as follows:

a. Verify RHR and RHRSW systems are in Standby condition
b. Open the associated RHR Torus Isolation Valve
c. Start the associated RHR pump
d. Throttle open the associated RHR Torus Cooling Isolation Valve
e. Start the associated RHRSW Pumps
f. Throttle the associated RHR HX Bypass and RHR HX Outlet Valves to control cooldown rate.

With the RHR system in the suppression pool cooling mode, the operator may actuate the required safety/relief valves while maintaining the required suppression pool temperature and heat distribution limits.

During this mode of operation, the automatic depressurization system remains fully operational and will automatically initiate if the conditions necessary for automatic depressurization should occur.

5.5.6.3.7 Physical Independence

The RCIC and HPCI systems are located in separate rooms in different corners of the reactor building. Piping runs are separated and the water delivered from each system enters the RPV via different nozzles.

5.5.6.3.8 Control Independence

Control independence is secured by using different battery systems to provide control power to the RCIC and HPCI systems.

5.5.6.3.9 Environmental Independence

The RCIC and HPCI systems are designed to meet Category I requirements. Environment in the equipment rooms is maintained by separate auxiliary systems.

5.5.6.4 Safety Evaluation

To ensure that the RCIC operates when necessary and in time to prevent inadequate core cooling, the power supply for the system is taken from immediately available energy sources of high reliability. Added assurance is given in the capability for periodic testing during station operation. Evaluation of the instrumentation configuration for the RCIC shows that no failure of a single initiating sensor either prevents or falsely starts the system.

The RCIC piping within the drywell up to and including the outer isolation valve is designed in accordance with ASME B&PV Code Section III. The RCIC, including the RCIC turbine speed control system, is also designed as Category I equipment. (See Subsection 7.3.2 for isolation signals.)

5.5.6.5 Inspection and Testing

A design flow functional test of the RCIC is performed during plant operation by taking suction from the condensate storage tank and discharging through the full flow test return line back to the condensate storage tank. The discharge valve to the feedwater line remains closed during the test, and reactor operation is undisturbed. Control of the pump discharge valve is obtained by first closing the upstream discharge valve. Control system design provides automatic return from test to operating mode when system operation is required during testing. Routine maintenance and tests, based on the manufacturer's recommendations and/or operating/maintenance experience, will be scheduled in accordance with the plant preventive maintenance program, including periodic inspection of the RCIC suppression pool suction strainer. Valve position indication and instrumentation alarms are displayed in the main control room.

5.5.6.6 Isolation

Arrangements of isolation valves include the following.

a. Two RCIC lines penetrate the reactor coolant pressure boundary. The first RCIC line is the RCIC steam line that branches off one of the main steam lines between the reactor vessel and the main steam isolation valve. This line has two automatic motor-operated isolation valves. One is located inside and the other outside the primary containment. The isolation signals noted earlier close these valves

b. The RCIC pump discharge line is the other line; however, it indirectly penetrates the reactor pressure vessel. This line enters the main feedwater line, described elsewhere, which provides required isolation valves inside the primary containment. The RCIC system provides the automatic motor-operated valve outside the primary containment for isolation

c. The RCIC turbine exhaust line vacuum breaker system line has two automatic motor-operated valves and two check valves. This line runs between the suppression pool air space and the turbine exhaust line downstream of the exhaust line check valve. Positive isolation shall be automatic via a combination of low reactor pressure and high drywell pressure

   The vacuum breaker valve complex is placed outside the primary containment due to a more desirable environment. In addition, the valves are readily accessible for maintenance and testing

d. The RCIC pump suction line, minimum flow pump discharge line, and turbine exhaust line all penetrate the primary containment and are submerged in the suppression pool. The isolation valves for the lines are all outside the primary containment and require remote-manual operation, except for the minimum flow valves, which actuate automatically. Additionally, the turbine gland seal system vacuum pump discharges beneath the suppression pool after penetrating the primary containment. The isolation valve for the line is located outside the primary containment and requires remote-manual operation.

5.5.6.7 Interlocks

The following define the various electrical interlocks (see Figure 7.4-1).

a. The steam line isolation valves, F007 and F008, are keylocked in the open position. The valves can still automatically close on a steam line isolation signal, but can be manually operated only when the keylock is placed in the "operate" position

b. The F029 and F031 limit switches activate when fully open, and close F010 and F022

c. The F001 limit switch activates when fully open, and clears the F045 and the F095 permissives so both F045 and F095 can open. The F045 and F095 valves are signaled to close if F001 moves to a position other than fully open

d. The F045 limit switch activates when fully closed and permits F004, F005, F025, and F026 to open, and closes F013 and F019

e. The turbine trip throttle valve (part of C002) limit switch activates when fully closed and closes F013 and F019

f. The combined pressure switches at reactor low pressure and high drywell pressure, when activated, close F062 and F084

g. A high turbine exhaust pressure, low pump suction pressure, or an isolation signal actuates and closes the turbine trip throttle valve

h. A 122.3 percent overspeed trips both the mechanical trip at the turbine and the trip throttle valve. The former is reset at the turbine and then the latter is reset by a combination of control room and local (near the RCIC skid) operator action

i. An isolation signal closes F007, F008, and other valves as noted above in Items e. and g

j. An initiation signal opens F010 and F012 if closed; opens F095, F045, F046, and F013 and starts the barometric condenser vacuum pump; and closes F022, if open. Drain isolation valves F004, F005, F025, and F026 will close automatically on receipt of F045 limit switch "not full closed" signal

k. High and low inlet RCIC steam line drain pot levels, respectively, open and close F054

l. The combined signal of low pump flow plus high pump discharge pressure opens F019. The F019 valve closes on a pump flow signal above the minimum flow setpoint

m. A reactor low water level (Level 1) or high drywell pressure signal trips the barometric condenser condensate and vacuum pumps

n. The F013 limit switch activates when not full closed and closes F022 and prevents F022 from opening

o. CST low level signal opens F029 and F031.

5.5.6.8 Limiting Single Failure

The most limiting single failure of the RCIC system and its HPCI backup system is the failure of HPCI. With an HPCI failure, if the capacity of the RCIC system is adequate to maintain reactor water level, the operator follows Subsection 5.5.6.3.2. If, however, the RCIC capacity is inadequate, the operator may also initiate the ADS system described in Subsection 6.3.2.2.2.

5.5.7 Residual Heat Removal System

5.5.7.1 Safety Design Bases

The RHR system meets the following safety design bases.

a. The system shall act automatically, in combination with other subsystems of the ECCS, to restore and maintain the coolant inventory in the RPV so that the core is adequately cooled to preclude fuel cladding temperatures from exceeding the acceptance criteria temperature of 2200°F following a design basis LOCA

b. The system, in conjunction with other subsystems of the ECCS, shall have such diversity and redundancy that only a highly improbable combination of events could result in the inability to adequately cool the core

c. The source of water for restoring RPV coolant inventory shall be so located within the primary containment as to establish a closed cooling water path

d. To ensure that the RHR system operates satisfactorily during a LOCA, each active component shall be testable during operation of the NSSS

e. A closed loop flow path between the suppression pool and the RHR heat exchangers shall be established so that the heat removal capability of these heat exchangers can be utilized for long-term containment heat removal.

See Subsection 3.1.2.4.5 for a discussion of conformance to General Design Criteria (GDC) 34. The RHR system design conforms to the single-failure requirement of GDC 34.

5.5.7.2 Power Generation Design Bases

The RHR system is designed to meet the following power generation design bases.

a. The system shall have enough heat removal capacity to cool down the reactor to 125°F within 20 hr after shutdown

b. Fuel pool connections shall be provided so that the RHR heat exchangers can be used to supplement the fuel pool cooling capacity

c. A closed loop flow path between the suppression pool and the RHR heat exchangers shall be established so that the heat removal capability of these heat exchangers can be used to cool the suppression pool.

5.5.7.3 Description

5.5.7.3.1 Summary

The RHR system is designed for three modes of operation to satisfy all the objectives and bases. To provide clarity to the information presented herein, each mode of operation is defined as a subsystem of the RHR system and is discussed separately. It is shown how each subsystem contributes toward satisfying all the objectives and bases of the RHR system.

The major equipment of the RHR system consists of two heat exchangers, four main system pumps, and four service water pumps. The equipment is connected by associated valves and piping, and the controls and instrumentation are provided for proper system operation. A schematic diagram of the RHR system is shown in Figure 5.5-13. A description of the controls and instrumentation is presented in Subsections 7.3.1.2.4 and 7.4.1.3. A description of how operation of the equipment in the RHR system in conjunction with other subsystems of the ECCS protects the core in case of a LOCA is presented in Section 6.3.

The main system pumps are sized for the flow required during LPCI operation, which is the subsystem that requires the maximum flowrate. Subsection 6.3.2 contains a discussion of the LPCI. The pumps are arranged and located so that adequate suction head is ensured for all operating conditions. The pump motor is air-cooled by the ventilation system.

The heat exchangers were originally sized on the basis of their required duty for the shutdown cooling function. The heat exchanger shell and tube sides are provided with drain connections. The shell side is provided with a vent to remove noncondensible gases. Thermal relief valves on the heat exchanger shell side and a relief valve on the RHR pump discharge protect the heat exchanger from overpressure.

The RHR heat exchanger duty for the shutdown cooling mode of operation is 41.6×10^6 Btu/hr.

The most limiting duty is that duty associated with torus cooling mode. See Section 6.2.2.3.

Detailed classification information for the RHR heat exchanger is presented in Table 3.2-1.

The RHR system can be connected to the fuel pool cooling and cleanup system, as shown in Figure 5.5-13, so that the RHR heat exchangers can assist fuel pool cooling during overload conditions. Subsection 9.1.3 contains a description of the fuel pool cooling and cleanup system.

One loop, consisting of a heat exchanger, two main system pumps in parallel, and associated piping, is located in one area of the reactor building. The other heat exchanger, pumps, and piping, all of which form a second loop, are located in another area of the reactor building to minimize the possibility of a single physical event causing the loss of the entire system. The two loops of the RHR system are cross-connected by a single header, making it possible to supply either loop from the pumps in the other loop. Water is supplied through a low pressure regulator and two check valves to ensure that the RHR discharge piping is continuously filled. This arrangement precludes water hammer effects. Figure 5.5-14 shows the RHR valve positions during normal reactor operation. Figures 5.5-15 through 5.5-17 show the RHR valve positions for the three RHR modes of operation as described in Subsections 5.5.7.3.2 and 5.5.7.3.3.

5.5.7.3.2 Shutdown Cooling

The shutdown cooling system is an integral part of the RHR system. It is operated during a normal shutdown and cooldown.

The RHR lines can be flushed prior to initiation of the shutdown cooling mode. Flushing is accomplished by establishing flow through the warm-up line to the suppression pool. Flow in this line is limited to approximately 500 gpm by a restricting orifice. The warm-up line isolation valve (F026B) is manually closed after flushing. If the operator fails to close the warm-up line valve, the potential loss of mass inventory could cause water level to drop. The low reactor water level isolation will automatically close the shutdown cooling valves and interrupt the outflow of water. Although it is preferred to flush the lines before RPV injection, no significant consequences will occur if flushing is omitted. The RHR piping will normally be filled with demineralized water or water from the suppression pool. The quality of the suppression pool water is maintained by the torus water management system.

The initial phase of nuclear system cooldown is accomplished by dumping steam from the RPV to the main condenser. When the nuclear system temperature has decreased to where the steam supply pressure is not sufficient to maintain the turbine shaft gland seals, the vacuum in the main condenser cannot be maintained and the RHR system is placed in the shutdown cooling mode of operation. The shutdown cooling system is able to complete cooldown to 125°F within 20 hours after the control rods have been inserted, and can maintain the nuclear system at 125°F for reactor refueling and servicing.

The allowable cooldown rate of the reactor coolant system should not exceed 100°F per hour. To achieve this condition, the heat exchanger's shell-side bypass valve (F048) is throttled to control the cooldown rate.

The RHR shutdown cooling mode is shown in Figure 5.5-15. Reactor coolant is pumped from one of the RRS loops by one or both of the RHR main system pumps and is discharged through the RHR heat exchangers, where cooling occurs by heat being transferred to the service water. Reactor coolant can be returned to the RPV through either RRS loop. When transitioning between the RRS and RHR shutdown cooling, a single RRS pump may be kept in operation while an RHR pump is started. During this time of simultaneous operation the operating RHR pump and the operating RRS pump may not inject into the same loop.

The high RPV water level provides conduction cooling to most of the mass of metal of the RPV and therefore limits thermal stress in the RPV during cooldown.

During a nuclear system shutdown following a scram, the decay heat level decreases rapidly enough that one RHR heat exchanger is capable of accommodating the entire shutdown cooling load.

FPCCS and natural circulation have been analyzed to be capable of serving as an alternate method of decay heat removal to enable RHR Shutdown Cooling to be taken out of service for maintenance during refueling (References 7 and 8). When operating in this alternate shutdown cooling mode, the fuel pool gates are removed and the RPV cavity is flooded. Entry into this mode requires satisfying the refuel technical specification associated with high RPV water level. FPCCS is normally operated with two pumps and two heat exchangers in service. In this capacity, FPCCS and natural circulation maintain FPCCS suction temperature less than 140°F, cooling both the old and freshly off-loaded assemblies in the fuel pool as well as those remaining in the RPV. RWCU may also be placed in operation with the regenerative heat exchanger bypassed to provide additional cooling and in-vessel mixing. This ability to enter this mode of FPCCS operation for RHR maintenance activities is evaluated on a per cycle basis using the expected vessel and spent fuel pool heat loads. The activity is managed such that normal shutdown cooling can be restored within 8 hrs. This is an arbitrary time frame that conservatively assures cooling can be restored prior to the onset of pool and core boiling. In addition, the operation of this mode restricts the operation of temporary auxilliary pool water filtration units such that the flow discharge does not interfere with the core exit flow and thereby impede natural circulation cooling.

5.5.7.3.3 Containment Cooling Subsystem

The containment spray cooling subsystem provides containment cooling for postaccident conditions (see Figure 5.5-16). Water pumped through the RHR heat exchangers can be diverted to spray headers in the drywell and above the suppression pool. The spray removes energy from drywell atmosphere by condensing the water vapor. The spray collects in the bottom of the drywell until the water level rises to the level of the pressure suppression chamber vent lines. The water then overflows to the suppression pool. Approximately 5 percent of this flow can be directed to the suppression chamber spray ring to cool any noncondensible gases collected in the free volume above the suppression pool.

The RHR system is serviced by an automatic fill system that maintains the containment spray lines filled up to the outermost containment isolation valves.

NRC Generic Letter (GL) 2008-01, “Managing Gas Accumulation in Emergency Core Cooling , Decay Heat Removal, and Containment Spray Systems” requested each licensee evaluate the licensing basis, design, testing, and corrective action programs for the Emergency Core Cooling Systems (ECCS), Decay Heat Removal (DHR) systems, and Containment Spray systems, to ensure that the piping systems are maintained full of water, and that appropriate action is taken when gas accumulation is discovered. Fermi’s initial response to this GL is documented in Ref. 9. During the GL response effort, NRC clarified the meaning of the phrase “full of water” (Ref. 10). The NRC concluded that when some voids are discovered in piping, the system can be considered filled with water as long as reasonable expectation of the system’s ability to perform its specified function is established.

The containment spray cooling subsystem of the RHR system normally cannot be operated unless the core flooding requirements of the LPCI subsystem have been satisfied. The operator can bypass these requirements by using a keylock switch in the main control room (Subsection 7.3.1.2).

On initiation of the RHR containment spray mode, the inner isolation valve is fully opened. The outermost isolation valve is a throttling-type valve, and the extent of the valve opening is determined by the time the open pushbutton is kept depressed. The valve open, mid-open, or closed indications are provided on the control panels to inform the operator of the valve position. The operators for the outermost valves are designed to open slowly. After a steady-state condition has been reached, the outermost isolation valve is fully opened. In this manner, dynamic loadings imposed on the empty portions of the containment spray lines and on the system supports and restraints are limited to within design values during the initial spray period as well as during the steady-state operating condition.

The suppression pool cooling subsystem (see Figure 5.5-17) cools the suppression pool by using the RHR pumps and heat exchangers in a closed loop with the suppression pool. The suppression pool cooling subsystem is put into operation to limit the water temperature immediately after a blowdown to 170°F when reactor pressure is above 135 psig. During this mode of operation, water is pumped from the suppression pool through the RHR system heat exchanger and back to the suppression pool.

The equipment purchase specifications for the RHR heat exchangers that are used for the containment cooling and suppression pool cooling modes specify fouling factors.

The fouling factors are a function of the nature of the fluids, the temperatures involved, and the fluid velocities. The heat exchanger designer includes the fouling factor in calculating the overall thermal resistance and provides sufficient surface area to allow the required heat transfer rate while in the fouled condition.

The heat exchanger performance data sheets supplied by the heat exchanger designer/manufacturer show the expected (designed) performance of the heat exchanger under fouled conditions. Fouling beyond the extent specified in the purchase specification and used during the heat exchanger design will result in a decrease in the heat transfer rate.

5.5.7.3.4 Low Pressure Coolant Injection System

The LPCI system is an integral part of the RHR system. It operates to restore and, if necessary, maintain the coolant inventory in the RPV after a LOCA. A description of the salient features of the LPCI system is given in Sections 6.3 and 7.3.

The LPCI is a low-head, high-flow function that delivers its rated flow to the RPV through one of the RRS loops. It is designed to reflood the RPV to at least two-thirds core height and to maintain this level. After the core has been flooded to this height, the capacity of one RHR main system pump is sufficient to make up for shroud leakage and boiloff. The LPCI subsystem operates in con-junction with the HPCI system, ADS, and the core spray system to restore and maintain the coolant inventory in the RPV after a LOCA.

The HPCI is a high-head, low-flow system that can pump water into the RPV when the NSSS is at high pressure. If the HPCI fails to deliver the required flow of cooling water to the RPV, the automatic depressurization feature of the overpressurization protection system described in Subsection 5.2.2 functions to reduce nuclear system pressure so that LPCI and core spray may operate to inject water into the RPV. The HPCI turbine is manually shut down after both core spray and LPCI are in operation. When RHR is lined up in the shutdown cooling mode and RPV pressure is less than or equal to the cut in pressure, manual operation is required to permit LPCI to align and initiate. This includes manually lining up the suction path from the torus for the loop which is in shutdown cooling. Otherwise, these operations are carried out automatically.

During LPCI operation, the RHR system pumps take suction from the suppression pool and discharge to the RPV into the core region through one of the RRS loops. Instrumentation is provided to detect the undamaged path for injection of LPCI flow (Subsection 7.3.1.2). Any spillage through a break in the lines within the primary containment returns to the suppression pool through the pressure suppression vent lines. A minimum-flow bypass line to the suppression pool is provided so that the pumps are not damaged if operating with the discharge valves shut.

Service water flow to the RHR heat exchangers is not required immediately after a LOCA because heat rejection from the containment is not necessary during the time it takes to flood the reactor. Power for the main RHR and RHRSW pumps normally comes from an auxiliary ac power bus; but if offsite power is lost, power is made available from the standby ac power source to supply the RHR and RHRSW pumps.

To provide a source of water if any postaccident flooding of the primary containment is required, a cross tie exists from the piping on the discharge side of a pair of service water pumps to the discharge piping on the shell side of an RHR heat exchanger. This connection is provided with redundant valving appropriate to a primary containment penetration. The valves are remotely operable from the main control room. The pair of service water pumps that provide this function can add water to either RRS loop through the cross-connection between the piping of each RHR loop.

5.5.7.3.5 Residual Heat Removal System Overpressure Protection

The design basis for overpressure protection in the RHR system is the conformance of the entire system to applicable portions of ANSI B31.7.

Failures due to overpressurization can result from the inadvertent opening of reactor coolant system (RCS) pressure boundary valves or RCS pressure boundary valve leakage. The RHR low-pressure piping is connected to the RCPB at the RHR shutdown suction and discharge connections to the recirculation system. Each of these lines is discussed in the following paragraphs.

a. The RHR suction from the recirculation system: This line has an inside containment isolation valve and an outside containment valve. Each valve is interlocked with a separate pressure switch that prohibits opening of the associated valve if the recirculation pressure exceeds the shutdown range. The design complies with GDC 55.

b. The RHR shutdown return line: This line has two valves outside containment. Each valve is interlocked to at least a control permissive of low reactor pressure. The line also has a testable check valve inside the containment that functions automatically to prevent outflow from the vessel. This design complies with GDC 55.

Reactor coolant system pressure boundary isolation valve leakage is accommodated by 1-in. or larger relief valves. This size of the valve is considered large enough to accommodate any postulated leakage. Valve F029 relieves shutdown cooling isolation valve leakage pressure; valves F025A and F025B relieve injection isolation valve leakage pressure. The heat exchangers contain their own relief valves, and the suction piping is relieved by valves F030A, F030B, F030C and F030D whenever the respective pool suction valves are closed.

5.5.7.4 Safety Evaluation

Because the LPCI and containment cooling subsystems act with other subsystems of the ECCS to satisfy the safety objective, they are evaluated in conjunction with the other subsystems of the ECCS in Section 6.3. The safety evaluation of the controls and instrumentation of the LPCI system is contained in Subsection 7.3.1.

There are two complete containment cooling systems. The RHR pumps in each of these systems receive power from ac power buses having standby power source backup supply. The two RHR pump motors and their associated motor-operated valves receive power from two separate buses. The pump's piping, controls, and instrumentation are separated and protected so that any single physical event or missile cannot make both loops inoperable.

The Fermi 2 design includes two parallel ac-powered inboard isolation valves (F009 and F608) fed from opposite electrical power divisions (F009 from Division I and F608 from Division II) and a dc-powered outboard isolation valve (F008) fed from Division II power. To prevent any inadvertent valve opening, the power fuses of the outboard isolation valve E1150F008 are removed during normal plant operation.

The following assumptions are used for the analyses of the procedures for attaining cold shutdown in the shutdown cooling mode.

a. The vessel is at about 70 psig and in a saturated condition

b. No offsite power is available

c. A worst single failure is assumed to occur (i.e., loss of a division of emergency power).

If a single failure (loss of Division II ac and dc power) were to cause an outboard suction valve (F008) to fail in the closed position, a handwheel is provided on the valve to allow manual operation. The shutdown would then continue in a normal manner using Division I of the RHR system.

Because manual operation cannot compensate for an electrical failure applied to inboard suction valve F009 (loss of Division I), the operator would open parallel valve F608, which is fed from the opposite division (Division II). Administrative controls would be used to enable the opening of valve F608 only when valve F009 could not be opened. These administrative controls require operation of a local key lock switch, the control room key lock switch and a push-button switch (in the control room) to open the valve. The local key lock switch prevents the valve opening from Multiple Spurious Operation (MSO). An auditory and visual feedback is provided by a control room alarm following the key lock switch operation. This is to prevent any inadvertent valve opening. Once valve F608 is open, the shutdown continues in the normal manner using Division II of the RHR system.

Thus, RHR system design conforms to the single-failure requirement of GDC 34.

5.5.7.5 Inspection and Testing

A design flow functional test of the RHR main system pumps is performed for each pump during normal plant operation by taking suction from the suppression pool and discharging through the test lines back to the suppression pool. The discharge valves to the RRS loops remain closed during this test, and reactor operation is undisturbed. An operational test of these discharge valves is performed by shutting the upstream valve after it has been satisfactorily tested, thereby establishing the RCPB at the downstream valve, and then operating the discharge valve. The discharge valves to the containment spray headers are checked in a similar manner by operating upstream and downstream valves individually. All these valves can be actuated from the main control room using remote manual switches. Control system design provides automatic return from test to operating mode if LPCI initiation is required during testing.

Testing of the sequencing of the LPCI mode of operation is performed after the reactor is shut down. Testing the operation of the valves required for the remaining modes of operation of the RHR system is performed as stated in the Technical Specifications and the pump and valve testing program (see Subsection 5.2.8.7).

Routine maintenance and tests, based on the manufacturers' recommendations and/or operating/maintenance experience, will be scheduled in accordance with the plant preventive maintenance program for the main system pumps, pump motors, and heat exchangers.

Preoperational tests are conducted during the final stages of plant construction prior to initial startup. These tests ensure correct functioning of all controls, instrumentation, pumps, piping, and valves. System reference characteristics such as pressure differentials and flow rates are documented during the preoperational testing and are used as base points for measurements obtained in subsequent operational tests.

For the containment spray cooling system, preoperational tests confirm that the containment spray headers and piping are clear of obstructions and the spray nozzles are capable of delivering rated flow. Air is injected into the drywell spray header via the blind flange connection on the outside of the primary containment. Unrestricted flow is verified through each spray nozzle. The spray nozzles in the suppression pool are checked with water during the suppression pool cooling tests.

For the suppression pool cooling system, the preoperational tests verify that the RHR heat exchanger shell-side design flow rate can be obtained while circulating water from the suppression pool. During the test, head versus flow curves are developed for reference in evaluating the future performance of the suppression pool cooling mode and the RHR pumps.

During plant operations, the pumps, valves, piping, instrumen-tation, wiring, and other components outside the primary containment can be inspected visually at any time. Components inside the primary containment can be inspected when the drywell is open for access. Testing frequencies are correlated with testing frequencies of the associated controls, and instrumen-tation is tested by the same action. When a system is tested, operation of the components is indicated by installed instrumentation.

The leak testing of all valves performing an isolation function between the high-pressure and the low-pressure boundary in the RHR system cannot be performed at the frequency prescribed in Section XI of the ASME Code. Because the testing removes one division of the RHR system from service, it is prudent to test only near the end of refueling outages or during maintenance on these systems. The Technical Specifications specify requirements for continued plant operation should the other division become inoperable.

Leakage tests are performed on these valves with high-pressure water. In every case, the low-pressure portion of the system is protected from overpressure with relief valves. The criterion for leakage tests is between 0.4 and 10 gpm which are values far below the capacity of the relief valves.

These valves cannot be exercised to any degree during plant operation. The exercising program for the gate and globe valves is part of the system functional tests described in the Technical Specifications. The check valves also are exercised at this time, using a mechanical exerciser as described in IWV-3522(b).

The RHR relief valves are removed as scheduled at refueling outages for bench tests and setting adjustments.

RHR heat exchanger tube leakage will be determined on a monthly basis by monitoring the service water return radiation levels. The effluent will be sampled such that significant leakage of reactor water into the RHR service water will be detected. Appropriate corrective actions will then be taken.

5.5.8 Reactor Water Cleanup System

5.5.8.1 Power Generation Design Bases

The principal function of the RWCU system is to provide a means for reducing the concentration of radioactive and corrosive species in the reactor.

The RWCU system shall

a. Discharge excess reactor water during startup, shutdown, and hot standby conditions

b. Minimize reactor heat loss during system operation, except when used for Decay Heat Removal.

c. Remove solid and dissolved impurities from recirculated reactor coolant

d. Minimize temperature gradients in the RRS piping and vessel during periods of low flow rates.

e. Assist decay heat removal and coolant mixing during periods when the Reactor Pressure Vessel is under 250°F.

5.5.8.2 Description

The RWCU system, shown in Figure 5.5-19, continuously purifies the reactor water. The system continuously removes water from the suction line of each RRS pump and from the reactor bottom head and returns it to the feedwater system. Water may also be sent to the main condenser (preferably) or to the radwaste system.

A regenerative heat exchanger is provided to maintain thermal efficiency during most operating modes of RWCU. However, a bypass line may be opened during times when the Reactor Pressure Vessel is under 250°F to allow cooled water to return to the reactor vessel. The RWCU system is operated at all times, when possible.

The major equipment of the RWCU system, located in the reactor building, includes pumps, regenerative and nonregenerative heat exchangers, and two filter-demineralizers with supporting equipment. The entire system is connected by associated valves and piping; controls and instrumentation provide proper system operation. Design data for the major pieces of equipment are presented in Table 5.5-2.

Reactor water is cooled in the regenerative and/or nonre-generative heat exchangers (or the nonregenerative heat exchangers alone when the shell side of the regenerative heat exchanger is bypassed), then filtered, demineralized, and returned to the reactor feedwater system through the shell side of the regenerative heat exchanger. A process diagram of the RWCU system is shown on Figure 5.5-20.

Because the maximum temperature of the filter-demineralizer units is limited by the ion exchange resin operating temperatures (Table 5.5-2), the reactor coolant must be cooled before being processed in the filter-demineralizer units. The regenerative heat exchanger transfers heat from the influent water to the effluent water. The nonregenerative heat exchanger cools the influent water further by transferring heat to the reactor building closed cooling water (RBCCW) system. The nonregenerative heat exchanger is designed to maintain the required filter- demineralizer operating temperature, even when the effectiveness of the regenerative heat exchanger is reduced by diversion of excess reactor water from the filter-demineralizer effluent to either the main condenser or the radwaste system or the regenerative heat exchanger is bypassed. A motor-operated valve in the suction line to the RWCU pumps automatically closes to prevent damage of the filter-demineralizer resins if the outlet temperature of the nonregenerative heat exchanger is high.

The filter-demineralizer units shown in Figure 5.5-21 are pressure-precoat type filters using mixed ion-exchange resins and fiber as a filter and ion-exchange medium. Spent resins are backwashed from a filter-demineralizer unit to a resin receiver tank from which they are transferred to the radwaste system for processing and disposal.

The suction line of the RCPB portion of the RWCU system contains two motor-operated isolation valves which automatically close in response to signals from the RCPB leak detection system. This action prevents the loss of reactor coolant and the release of radioactive material from the reactor. Subsections 7.6.1 and 5.2.7 and Table 5.2-11 describe the RCPB leak detection system.

The outermost isolation valve also automatically closes to prevent removal of liquid poison in the event of standby liquid control system actuation. These isolation valves may be remote manually operated to isolate the system equipment for maintenance or servicing.

A remote manually operated gate valve on the return line to the reactor provides long-term backup isolation of the system for the reactor. Instantaneous reverse-flow isolation is provided by two check valves in the RWCU return line, as shown in Figure 5.5-19. A motor operated isolation valve is provided in the RWCU line as shown in Figure 5.5-19. This valve automatically closes to isolate the RWCU system upon receipt of an isolation signal, or it may be remote manually operated.

5.5.8.3 Safety Evaluation

To minimize the introduction of resins into the reactor in the event of septa failure in a filter-demineralizer, a strainer is installed on the outlet of each filter-demineralizer unit. Each strainer has a main control room alarm that is energized by high differential pressure. A bypass line is provided around the filter-demineralizer units for bypassing the units when necessary.

In the event of low flow or loss of flow in the system, flow is maintained through each filter-demineralizer by its own holding pump. Sample points are provided in the influent header and effluent line of each filter-demineralizer unit for continuous indication and recording of system conductivity. High conductivity is annunciated in the main control room. The alarm setpoints for the conductivity meters are 0.5 and 0.9 μ S/cm for the inlet and 0.09 μ S/cm for the outlet. The influent sample point is also used as the normal source of reactor coolant samples. Sample analysis also indicates the effectiveness of the filter-demineralizer units.

Operation of the RWCU system is controlled from the main control room except for the regenerative heat exchanger bypass. The manual bypass line isolation valve is administratively controlled and locked-closed during periods of nonuse. Figure 7.6-1 shows the RWCU system instrumentation and control logic.

Resin-changing operations, which include backwashing and precoating, are controlled from a local control panel in the reactor building.

5.5.8.4 Inspection and Testing

Because the RWCU system is usually in service during plant operation, satisfactory performance is demonstrated without the need for any special inspection or testing beyond that specified in the manufacturers' instructions.

5.5.9 Main Steam Lines and Feedwater Piping

5.5.9.1 Safety Design Bases

To satisfy the safety design bases, the main steam lines and feedwater piping have been designed

a. To accommodate operational stresses, such as internal pressures and earthquake loads, without a failure that could lead to the release of radioactivity in excess of the guideline values in published regulations

b. With suitable access to permit inservice testing and inspections.

5.5.9.2 Power Generation Design Bases

The main steam lines and feedwater piping meet the following power generation design bases.

a. The main steam lines shall conduct steam from the RPV over the full range of reactor power operation

b. The feedwater lines shall conduct water to the RPV over the full range of reactor power operation.

5.5.9.3 Description

The main steam lines, consisting of four 24-in. diameter lines, are described in Section 10.3.

The feedwater piping is shown in Figure 10.4-10; at the drywell penetrations, it consists of two 20" lines. Each line includes two containment isolation valves. One simple check valve is inside the drywell. The isolation valve outside the drywell is an air actuated spring assist to close check valve. An additional check valve is located outside the drywell between the drywell wall and the spring assist to close check valve. In addition, a stop valve is provided between the isolation check valve and the reactor so that maintenance can be performed on the isolation valving and the HPCI system when the reactor is out of service. The design pressure and temperature of the feedwater piping between the reactor and the outermost isolation valve are 1275 psig and 450°F. The design pressure and temperature of the remaining reactor feedwater system are 1750 psig and 450°F. The Category I design requirements are placed on the feedwater piping from the reactor through the outboard isolation check valves and connected piping of 2-1/2 in. or larger nominal pipe size, up to and including the first valve that is either normally closed or capable of automatic closure during all modes of normal reactor operation.

The materials used in the piping are in accordance with the applicable design code and supplementary requirements described in Section 3.2.

The reactor feedwater system is described in Subsection 10.4.7.

The penetration assemblies serve as a flexible joint, pressure boundary, and pipe jacket for process piping that penetrates the primary containment and its surrounding biological shield. The penetration assemblies, which are part of the primary pressure boundary, located between the inboard and outboard containment isolation valves, are rated as Class 1 in accordance with l0 CFR 50, Paragraph 50.55(a). Type I penetrations serve the primary pressure boundary process lines. Use of a flexible bellows and a penetration anchor is required because of fluctuations in operating temperature. Type I penetrations are provided with a hinged guard pipe around the process pipe to protect the bellows and the penetration sleeve from the effects of a postulated pipe rupture (Subsection 6.2.1.2.1.4).

The design, materials, and fabrication of the penetration assemblies are in accordance with the ASME B&PV Code Section III, 1971 edition, including the 1971 summer and winter addenda.

5.5.9.4 Safety Evaluation

Differential pressure on reactor internals under the assumed accident condition of a ruptured steam line is limited by the use of flow restrictors and by the use of four main steam lines. All main steam and feedwater piping is designed in accordance with the requirements defined in Section 3.2. Design of the piping in accordance with these requirements ensures meeting the safety design bases.

5.5.9.5 Inspection and Testing

Inspection and testing are carried out in accordance with Subsections 10.3.4 and 10.4.7. Inservice inspection is considered in the design of the main steam and feedwater piping. This consideration ensures adequate working space and access for the inspection of selected components.

The penetration assemblies are tested and inspected in accordance with the 1971 ASME Code Sections III and XI. They are designed for a 40-year service life.

5.5.10 Pressurizer

This subsection is not applicable to BWRs.

5.5.11 Pressurizer Relief Tank

This subsection is not applicable to BWRs.

5.5.12 Valves

Components beyond the RCPB that are part of systems or subsystems closely allied with the reactor coolant system consist of

a. Reactor feedwater system
b. RHR system
c. RCIC system
d. RWCU system
e. HPCI system
f. Standby liquid control (SLC) system
g. Core spray (CS) system.

5.5.12.1 Safety Design Bases

Line valves such as gate, globe, and check valves are located in the fluid systems to perform a mechanical function. Valves are components of the system pressure boundary and, having moving parts, are designed to operate efficiently to maintain the integrity of this boundary.

The valves shall operate under the internal pressure/temperature loading as well as the external loading experienced during the various system transient operating conditions. Table 3.9-27 lists the code class and design pressures and temperatures. The design criteria are described in Subsection 3.9.2.

5.5.12.2 Description

Class 2 and Class 3 line valves are designed in accordance with MSS-SP-66 or ANSI-B16.34. Original plant valves were procured in accordance with the then applicable ANSI-

B16.5 design. Materials used for Class 2 valves conform to the requirements of NC-3512 (a) and (b), and for Class 3 valves to ND-3512 (a) and (b). All materials, exclusive of seals and packings, are selected for 40-year plant operational life under full service conditions. Stress analyses show that Class 2 valves with motor, diaphragm, and piston operators only do not become inoperative under static seismic acceleration of 5g in the horizontal plane and 3g in the vertical plane.

Valve operators are sized to operate successfully under the maximum differential pressure determined in the design specification.

5.5.12.3 Safety Evaluation

Line valves are shop tested by the manufacturer for performability. Pressure-retaining parts shall be subject to the testing and examination requirements of the appropriate ASME Code. To minimize internal and external leakage past seating surfaces, maximum allowable leakage rates are stated in the valve specifications for both the valve stem as well as the main seat for gate and globe valves.

Valve construction materials are compatible with the maximum anticipated radiation dosage for the service life of the valves.

5.5.12.4 Inspection and Testing

Inspection and tests of line valves shall be in accordance with the applicable Code Class of the ASME B&PV Code Sections III and XI.

Valves that serve as containment isolation valves and that must remain closed or open during normal plant operation may be partially exercised during this period to ensure their operability at the time of an emergency or faulted condition. Other valves, serving as system block or throttling valves, may be fully exercised without jeopardizing system integrity for the same reason.

5.5.13 Safety and Relief Valves

Overpressurization protection, in the form of relief valves, is provided to systems and subsystems closely related to the reactor coolant system, such as

a. CS system

b. HPCI system

c. RCIC system

d. RHR system and its subsystems

e. SLC system

f. Control rod drive (CRD) system

g. RWCU system

h. Reactor recirculation seal purge subsystem.

The safety/relief valves of the reactor primary coolant system are discussed in Subsection 5.2.2. Table 5.5-3 shows relief valve characteristics for the above systems.

5.5.13.1 Safety Design Bases

The piping systems that are normally isolated by at least two power-operated isolation valves or one check valve and one power-operated valve from the RCPB are provided with relief valves to protect the piping from overpressurization caused by one or more of the following mechanisms.

a. Isolation valve leakage

b. Pump operation with system isolation

c. External radiant heat

d. Hot fluid impingement from broken pipes.

The relief valves are conservatively sized and designed by taking into account all the possible causes of overpressurization and their effects.

These valves are designed in accordance with the requirements of ASME B&PV Code Section III, NC-7000. Relief valves in Group D piping are exempt from the ASME B&PV Code Section III requirements.

5.5.13.2 Description

5.5.13.2.1 Core Spray System Relief Valves

The core spray pump suction lines and discharge lines are equipped with relief valves. The setpoints and capacities for these valves are shown in Table 5.5-3. The core spray system is not subject to any kind of energy input, except pump motor energy when pumps are operating against closed valves. The piping system is designed to withstand the shutoff head of the pumps. All relief valves installed in the system provide thermal relief for isolable portions of the system, with sufficient capacities to relieve the volume change of the entrapped fluid due to thermal expansion.

5.5.13.2.2 High Pressure Coolant Injection System Relief Valves

The HPCI pump suction line and the line to the gland seal condenser are equipped with relief valves to prevent overpressurization of the lines.

The setpoints and capacities for these valves and rupture disks are listed in Table 5.5-3.

The HPCI system is not subject to any kind of energy input except the hydraulic oil pump motor and the motors for the gland seal condenser vacuum and drain pumps.

5.5.13.2.3 Reactor Core Isolation Cooling System Relief Valves

The RCIC pump suction line and the cooling water line to the gland seal condenser are provided with relief valves with the capacities and setpoints listed in Table 5.5-3.

There is a rupture disk on the steam turbine for the turbine casing protection with the setpoint at 150 ± 10 psig and the capacity of 60,000 lb/hr at 165 psig.

The RCIC system is not subject to any kind of energy input, except when the pumps operate with closed valves.

5.5.13.2.4 Residual Heat Removal System Relief Valves

The RHR pump suction and discharge lines are provided with a relief valve in each line. The setpoints and capacities are listed in Table 5.5-3.

The overpressure protection relief valves have sufficient capacity to relieve the volume change of the entrapped fluid that results from thermal expansion in isolable portions of the system. The piping is designed to withstand the shutoff head of the pumps.

The RHR heat exchangers are also provided with a relief valve in each heat exchanger as listed in Table 5.5-3.

5.5.13.2.5 Standby Liquid Control System Relief Valves

A relief valve is provided in the discharge line of each pump. The setpoint and capacity of each valve are listed in Table 5.5-3.

5.5.13.2.6 Control Rod Drive System Relief Valves

The CRD pump suction lines are equipped with relief valves. The setpoints and capacities are listed in Table 5.5-3.

5.5.13.2.7 Reactor Water Cleanup System Relief Valves

The relief valves are installed on the shell and tube sides of the heat exchangers and on the line to the condenser.

The setpoints and capacities of the relief valves are listed in Table 5.5-3.

5.5.13.2.8 Feedwater System Relief Valves

The feedwater system is designed to the maximum pressure of the reactor coolant system up to and including the outermost isolation valve. Beyond the outermost isolation valve, the system is designated as a nonsafety class. Details of the feedwater system are discussed in Section 10.4.

5.5.13.3 Safety Evaluation

The assumptions made in the evaluation of the adequacy of the relief valves provided are conservative, and the setpoints and capacities of the valves are sufficiently conservative to protect the system and subsystem pipings and components from the effects of overpressurization.

Some of the conservative assumptions made are

a. Conservative isolation valve leakage values are used in sizing the relief valves

b. The system is considered isolated with the pump(s) operating at shutoff conditions. A 100 percent energy conversion from the pump motor horsepower to heat is assumed, neglecting heat losses and mechanical work

c. Jet impingement of steam from a nearby broken pipe is taken into account in sizing the relief valves. To be conservative, heating of the piping is assumed to be from the condensation of steam by the piping

d. The piping subject to heating is assumed to be uninsulated

e. Reaction force on the piping from relief valve operation is assumed to be R = 2 x P x A, where R is the reaction force, P is the pressure setting of the valve, and A is the area of the valve inlet.

The radiation fields considered for the EQ Program relief valve designs are given in Table 3.11-5. Other valve characteristics can be found in Table 5.5-3.

5.5.13.4 Inspection and Testing

Inspection and testing were carried out in accordance with ASME (PTC) 25.2, ASME B&PV Code Section III. Inservice inspection of ASME Class 1, 2, and 3 valves will be performed in accordance with ASME B&PV Code Section XI.

5.5.14 Component Supports

Support elements are provided for those components beyond the RCPB that are in systems or subsystems closely allied with the reactor coolant system. These systems include

a. Reactor feedwater system

b RHR system

c. RCIC system

d. RWCU system

e. HPCI system

f. SLC system.

5.5.14.1 Safety Design Bases

The design procedures, design loading, and acceptability criteria are as described in Subsection 3.9.2. Flexibility calculations and seismic analysis for Class 2 and 3 components are made in accordance with NC/ND 3600 of the ASME B&PV Code Section III. Support types, materials used for fabricated support elements, and recommended pipe support spacing are in accordance with established industry practice and AISC Specifications.

5.5.14.2 Description

The use and location of rigid-type supports, variable or constant spring-type supports, and anchors or guides are determined by flexibility and stress analysis. Component support elements are manufacturers' standard items. Direct weldment to thin-wall pipe is avoided where possible.

5.5.14.3 Safety Evaluation

Design loadings used for flexibility and seismic analysis toward the determination of adequate component support systems include all transient loading conditions expected by each component.

Provisions are made to restrain spring-type supports for the initial deadweight loading due to hydrostatic testing of steam systems to prevent damage to this type of support.

5.5.14.4 Inspection and Testing

After completion of the installation of a support system, hanger elements will be visually examined to ensure that they are in correct adjustment to their cold setting position. Thermal expansion testing for selected piping systems will be conducted during the preoperational and startup phases. Spring-type hangers will be inspected to ensure that they will function properly between their hot and cold setting positions.

5.6 INSTRUMENTATION REQUIREMENTS

The functional requirements for the reactor coolant system instrumentation are discussed in the following subsections. Details of the design and logic of the instrumentation are discussed in Chapter 7.

5.6.1 Neutron Monitoring System

This system is described in Subsection 7.1.2.1.4.

5.6.2 Reactor Pressure Vessel Instrumentation

Reactor pressure vessel (RPV) instrumentation is designed to provide the operator with sufficient indication of reactor core flow rate, RPV water level, RPV pressure, and nuclear system leakage to maintain proper operating conditions.

5.6.2.1 Reactor Pressure Vessel Temperature

The RPV temperature is determined on the basis of reactor coolant temperature. Temperatures needed for operation and for compliance with the Technical Specifications operating limits are obtained from one of several sources, depending on the operating condition. During normal operation, either reactor pressure and/or the inlet temperature of the coolant in the RRS loops can be used to determine the RPV temperature. Below the operating span of the temperature detectors in the RRS loop, the pressure is used for determining the temperature. Below 212°F the coolant temperature in the RPV, and thus the RPV temperature, is reasonably determined by the reactor water cleanup (RWCU) system inlet temperature.

5.6.2.2 Reactor Pressure Vessel Water Level

The number of RPV water level indications is sufficient to provide the operator with information to determine the adequacy of the coolant inventory to cool the fuel. In addition, by verifying that RPV water level is not rising to an abnormally high level, the operator is ensured that turbines are not endangered by the possibility of water carried into the steam lines. The common zero reference point for all vessel level instruments at Fermi 2 is the top of the active fuel.

5.6.2.3 Reactor Pressure Vessel Coolant Flow Rates and Differential Pressures

Flow instruments, differential pressure instruments, and recorders are provided so that the core coolant flow rates and the hydraulic performance of RPV internals can be determined.

5.6.2.4 Reactor Pressure Vessel Internal Pressure

Pressure switches, indicators, and transmitters detect RPV internal pressure from the same instrument lines used for measuring RPV water level.

5.6.2.5 Reactor Pressure Vessel Top Head Flange Leak

A connection is provided on the RPV flange into the annulus between the two metallic seal rings used to seal the RPV and top head flanges. This connection permits detection of leakage past the inner seal ring, and is described further in Subsection 5.2.7.

CHAPTER 6: ENGINEERED SAFETY FEATURES

6.1 GENERAL

Engineered safety feature (ESF) systems are provided to mitigate the consequences of postulated accidents. The following ESF systems are discussed in this chapter:

a. Containment structures

   1. Primary

   2. Secondary.

b. Containment systems

c. Emergency core cooling system

   1. High pressure coolant injection system

   2. Automatic depressurization system

   3. Core spray system

   4. Low pressure coolant injection mode of residual heat removal system.

d. Main control room habitability systems.

In addition to the ESF systems discussed in this chapter, other ESF systems discussed elsewhere are provided to limit the consequences of postulated accidents. The ESF systems are covered in Chapter 6 and those other locations referenced in Table 6.1-1.

The information provided herein demonstrates the following:

a. The concepts upon which the operation of each system is predicated have been proven by tests under simulated accident conditions and/or by conservative extrapolations from present knowledge and experience

b. Component reliability, system independency, redundancy, and separation of components or portions of systems ensure that the feature will accomplish its intended purpose and will function for the period required

c. Provisions for test, inspection, and surveillance have been made to ensure that the feature will be dependable and effective upon demand

d. The material used will withstand the postulated accident environment, including radiation levels, and the radiolytic decomposition products which may occur will not interfere with ESF systems.

6.2 CONTAINMENT SYSTEMS

6.2.1 Containment Functional Design

On September 9, 1992, the NRC issued Amendment 87 to the Fermi 2 operating license authorizing a change in the thermal power limit from 3293 MWt to 3430 MWt, a 4.2 percent increase in the thermal power and a 5 percent increase in steam flow. The Fermi 2 Power Uprate Program followed GE Nuclear Energy guidelines and evaluations for BWR power plants (References 1, 2, 3, and 4).

On February 10, 2014, the NRC issued Amendment 196 to the Fermi 2 operating license authorizing a change in the thermal power limit from 3430 MWt to 3486 MWt, a 1.64 percent increase in thermal power and a 1.88 percent increase in steam flow. This changed the net electrical capacity from 1150 MWe to approximately 1170 MWe. This power uprate was performed in accordance with 10 CFR 50, Appendix K and reflects the improvement in feedwater flow measurement. The Fermi 2 Measurement Uncertainty Recapture (MUR) power uprate followed the GE generic guidelines and evaluations for BWR plants provided in GEH Topical Report NEDC-32938P-A, “Generic Guidelines and Evaluations for General Electric Boiling Water Reactor Thermal Power Optimization,” Revision 2, May 2003 (Reference 30). The analyses performed at 102% of the pre-MUR licensed thermal power (3430 MWt) remain applicable at the MUR uprated thermal power (3486 MWt) because the 2% uncertainty factor discussed in Regulatory Guide 1.49 is effectively reduced by the improvement in feedwater flow measurements.

Short-term and long-term containment analyses results are reported in Subsection 6.2.1.3. The short-term analysis is directed primarily at determining the drywell pressure responses during the initial blowdown of the reactor vessel inventory to the containment following a large break inside the drywell. The long-term analysis is directed primarily at the pool temperature response, considering the decay heat addition to the pool.

6.2.1.1 Design Bases

The containment system design meets the following safety design bases:

a. The containment systems shall have the capability to withstand the peak transient pressures and temperatures that could occur due to a postulated design-basis accident (DBA), intermediate-break accident (IBA), or small-break accident (SBA). The assumptions and criteria used to conservatively predict the short-term pressure and temperature response of the containment system drywell and suppression chamber during these accident conditions are provided in the Mark I Owners Group Load Definition Report (Reference 5), the Fermi 2 Plant Unique Load Definition Report (Reference 6), and in NUREG-0661 (Reference 7). The reevaluation of containment response for power uprate is provided in References 3 and 4. The long-term response of the drywell and suppression chamber is described in Subsection 6.2.1.3.3.

   No one accident results in the simultaneous occurrence of the maximum values of pressure and temperature (drywell design pressure and temperature, suppression chamber design pressure and temperature)

b. The containment systems shall accommodate the effects of metal/water reactions and other chemical reactions following the postulated DBA to values consistent with Regulatory Guide 1.7

c. The containment shall have the capability to maintain its functional integrity indefinitely after a postulated DBA, IBA, or SBA

d. The containment design shall permit filling the containment system drywell with water to a level above the reactor core

e. The containment system shall be protected against missiles from internal or external sources and excessive motion of pipes that could directly or indirectly endanger the integrity of the containment

f. The containment shall withstand jet forces associated with the flow from the postulated rupture of any pipe within the containment

g. The containment shall limit leakage during and following a postulated accident to values less than leakage rates that would result in offsite doses greater than the limits established in 10 CFR 50.67 or 10 CFR 100

h. It shall be possible to periodically conduct such leakage tests as may be appropriate to confirm the integrity of the containment at calculated peak pressure resulting from the accident condition that produces the maximum pressure response (DBA)

i. There shall be means to direct the flow from postulated pipe ruptures to the pressure suppression pool, to distribute such flow uniformly throughout the pool, to condense the steam portion of the flow rapidly, and to limit the pressure differentials between the drywell and the wetwell during the various postaccident cooling modes. The hydrodynamic events of pool swell, condensation oscillation, and chugging that occur during these flow and steam condensation regimes are defined by NUREG-0661 (Reference 7) and the Mark I Owners Group Load Definition Report (Reference 5). The design basis of the containment system includes the loading conditions associated with these hydrodynamic events

j. Capability for rapid closure or isolation of all pipes or ducts that penetrate the containment shall be provided by means that provide a containment barrier in such pipes or ducts sufficient to maintain leakage within permissible limits

k. There shall be the means for stable steam condensation of safety/relief valve (SRV) discharges into the suppression pool during transient and accident plant conditions. The containment system design basis includes the SRV actuation events, associated hydrodynamic loading conditions, and pool temperature limits described in NUREG-0661 (Reference 7), NUREG-0783 (Reference 8), and the Mark I Owners Group Load Definition Report (Reference 5)

    l. During the DBA, with the minimum emergency core cooling system (ECCS) pumps operating, and the available service water at the design maximum temperature, the long-term peak pool temperature shall not exceed the design temperature.

6.2.1.2 System Design

There are two passive provisions for containment of possible postaccident airborne contamination, the primary containment system and the secondary containment system. A perspective drawing illustrating these systems and their relationship is presented in Figure 5.1-4.

In addition to these two passive containment systems, the gases in either the primary or secondary containment can be exhausted through the standby gas treatment system (SGTS). This arrangement ensures that any accident-related discharge will be filtered by the SGTS before release. The SGTS is discussed in Subsection 6.2.3.

6.2.1.2.1 Primary Containment

The primary containment is a pressure suppression system. It consists of a drywell that houses the reactor pressure vessel (RPV); reactor coolant recirculating loops, and other branch connections of the reactor coolant system; a pressure suppression chamber that stores a large volume of water; a vent system connecting the drywell and the pressure suppression chamber water; a vacuum relief system; isolation valves; and service equipment.

In the event of a process system piping failure within the drywell, reactor water and steam would be released into the drywell. The resulting increased drywell pressure would force a mixture of air, steam, and water through the vents into the pool of water that is stored in the suppression chamber. The steam would condense in the suppression pool, resulting in a rapid pressure reduction in the drywell. The hydrodynamic events of pool swell, condensation oscillation, and chugging associated with the venting and steam condensation processes are described in NUREG-0661 (Reference 7) and the Mark I Owners Group Load Definition Report (Reference 5). Noncondensable gases trans-ferred to the suppression chamber pressurize the chamber and are subsequently vented back to the drywell to equalize the pressure between the two vessels. Cooling of the primary containment under accident conditions is provided by the containment cooling and spray modes of the residual heat removal (RHR) system, as discussed in Subsection 6.2.2. Appropriate isolation valves are actuated to ensure containment of radioactive materials that might otherwise be released from the primary containment.

Detailed design information of the primary containment is given in Subsection 3.8.2 and in References 9 and 10. The information given there includes the dynamic loads that could be imposed on the torus, the vent system, the torus internal structures, and the torus attached piping following a LOCA. Also given there is a description of the methods used to determine these loads and how these loads were incorporated in the structural and attached piping design. A summary of important design parameters of the primary containment is presented in Table 6.2-1. The more important features of the primary containment system are described below.

6.2.1.2.1.1 Drywell

The drywell is a steel pressure vessel with a spherical lower portion, 68 ft in diameter, and a cylindrical upper portion, 38 ft 10 in. in diameter. The overall height is approximately 114 ft 8 in. The drywell design pressure is 56 psig at a temperature of 281°F. The design temperature is 340°F with a coincident pressure of 25 psig.

The design, fabrication, inspection, and testing of the drywell vessel comply with requirements of the ASME Boiler and Pressure Vessel (B&PV) Code Section III, Nuclear Vessels, 1968 Edition with Summer 1969 Addenda, Subsection B, Requirements for Class B Vessels, which pertain to containment vessels for nuclear power plants. The steel head and shell of the drywell are fabricated of SA-5l6GR70 steel plate, firebox quality, aluminum-killed to SA-300 requirements. Thermal stress in the steel shell due to temperature gradients is considered in the design. Special procedures not required by code have been used in the fabrication of the steel drywell shell. For seams exceeding 1-1/4-in. thickness, the plate was heated to a minimum temperature of 200°F prior to welding. For seams 1-1/4 in. or less, the plate was heated to a minimum temperature of l00°F if the ambient temperature was below 40°F.

Charpy V-notch impact tests were performed on specimens of all plate and forged materials.

Plates, forgings, and pipes of the drywell have an initial nil ductility transition (NDT) temperature of approximately 0°F when tested in accordance with the appropriate code for these materials. It can be reasonably expected that the drywell will not be pressurized or subjected to a substantial stress at temperatures below 30°F.

The drywell is enclosed in reinforced concrete for shielding purposes. Resistance to deformation and buckling of the drywell is provided over areas where the concrete backs up the steel shell. Above Elevation 572 ft 1 in., the drywell is separated from the reinforced concrete by a gap of approximately 2 in. This gap is filled with a compressible polyurethane material to allow for movement between the drywell and concrete. The bottom portion of the shell is totally embedded in concrete and therefore is not subject to significant thermal stresses. The transition zone (below Elevation 572.5 ft) is backed by compacted sand to allow for thermal expansion and to aid in the drainage of condensate that may accumulate in the gap outside the drywell. Sand in the four drain lines at azimuths 0, 90, 180, and 270 degrees have been removed up to the pipe upstream of the 90 degree elbow. Sand in the sand cushion or transition zone is still intact.

Provisions for protection of the drywell against earthquakes, missiles, and pipe whip, which could damage the primary containment, are discussed in Chapter 3.

6.2.1.2.1.2 Pressure Suppression Chamber

The pressure suppression chamber is a steel pressure vessel, in the shape of a torus, below and encircling the drywell. It has a major diameter of 112 ft 6 in. and a cross-sectional diameter of 30 ft 6 in. It contains a total volume of approximately 251,980 ft^3. The suppression chamber is supported vertically by inside and outside columns and by a saddle support that spans the inside and outside columns. The support system transmits dead weight and seismic and hydrodynamic loading to the reinforced-concrete foundation slab of the reactor building. Space is provided outside the chamber for inspection and maintenance.

The pressure suppression chamber is designed for a temperature of 281°F and a pressure of 56 psig. The suppression chamber was originally designed to the same material and code requirements as the drywell vessel. The suppression chamber has been subsequently reevaluated for the effects of LOCA-related loads and SRV-discharge-related loads defined by the NRC Safety Evaluation Report NUREG-0661, the GE Reports NEDO-21888 (Mark I Containment Program Load Definition Report) and NEDC-31897P-1 (Generic Guidelines for General Electric Boiling Water Reactor Power Uprate). The criteria set forth in NUREG-0661 have been applied as the basis for acceptance of the analysis methods and the suppression chamber design. A detailed discussion of these reevaluations and their results is provided in the Fermi 2 Plant Unique Analysis Report (References 9 and 10) and in the Power Uprate Safety Analysis (Reference 3). All materials have an initial NDT temperature of approximately 0°F.

Where safety/relief valves terminate inside the suppression chamber, T-quencher devices are provided to aid in mitigating the associated SRV discharge loads in the suppression chamber. Reference 5 contains a description of the T-quencher design and its performance.

6.2.1.2.1.3 Vent Systems

Eight vent pipes connect the drywell and the pressure suppression chamber. Each pipe has a diameter of 6 ft 0 in. The vent pipes are designed for an internal pressure of 56 psig at 281°F. They will withstand an external pressure of 2 psig. Jet deflectors are provided in the drywell at the inlet of each vent pipe to prevent possible damage from jet forces, which might accompany a pipe break in the drywell. The vent pipes are fabricated of SA-516GR70 steel plate, firebox quality, aluminum-killed to SA-300 requirements, and comply with requirements of the ASME B&PV Code Section III, Subsection B. The pipes are enclosed with sleeves and provided with expansion joints to accommodate differential motion between the drywell and suppression chamber.

These vent pipes connect to a vent header in the form of a torus located in the air space of the suppression chamber. The vent header is nominally 1/4-in. thick and has an inside diameter of 4 ft 3 in. Near the vent line-vent header intersection, the vent header has an inside diameter of 6 ft 0 in. Conical transition segments connect the smaller and larger diameter portions of the vent header.

The vent header and downcomer system inside the torus was designed, fabricated, and erected in accordance with ASME B&PV Code Section III, 1968 Edition through winter 1969 addenda, Class B requirements but it is not leak tested.

Projecting downward from the header are 80 downcomer pipes, each 24 in. in diameter and terminating below the surface of the water in the suppression chamber pool. The pool water level is maintained to ensure a 3.00- to 3.33-ft submergence of the downcomer pipes. The header is designed to meet the same temperature and pressure requirements as the vent pipes.

The vent system has also been evaluated for the effects of LOCA-related loads and SRV-discharge-related loads defined by NUREG-0661 and NEDO-21888. As with the suppression chamber discussed above, a detailed discussion of these evaluations is provided in References 3 and 9.

Vacuum breakers discharge from the suppression chamber into the vent header system. Vacuum breaker sizing is based on the Moss Landing (Reference 11) test configuration.

Both the drywell and the pressure suppression chamber can be vented to the atmosphere through the SGTS or reactor building ventilation system.

6.2.1.2.1.4 Pipe Penetrations

Primary containment penetrations are designed for peak transient conditions to be expected during a LOCA. They will withstand, or are shielded from, the forces caused by impingement of fluid from the rupture of the largest local pipe or connection. Specific evaluations of the suppression chamber penetrations to address the requirements of NUREG-0661 are described in Reference 10.

These penetrations are designed to accommodate, without failure, any combination of thermal and mechanical stresses, which may be encountered during all modes of operation. (Refer to Subsection 3.8.2.1.3.)

Primary containment system piping penetrations are enumerated in Table 6.2-2. Electrical penetrations are listed in Table 6.2-3.

Relative movement between the containment penetrations and the drywell is accommodated by using bellows-type expansion joints (Figure 6.2-1). For this type of penetration, a sleeve passes through concrete and is welded to the primary containment vessel. The process line that passes through the penetration is anchored to allow only radial thermal expansion. A guard pipe surrounds the process line to protect the bellows and maintain containment integrity should the process line fail within the penetration. Insulation and air gaps are provided to reduce radiant heating of the guard pipe and the penetration sleeve and bellows. The dual-ply bellows arrangement permits periodic leak testing of these penetrations at a pressure equal to the primary containment DBA pressure (see Subsection 6.2.1.4) as well as continuous monitoring capability.

Figure 6.2-1 presents the containment penetration configuration for a typical process line of the reactor coolant pressure boundary (RCPB). As it passes through the drywell containment vessel and the concrete biological shield, the process line is enclosed in a guard pipe that is attached to it through a multiple head fitting. This fitting is a one-piece forging with integral flues or nozzles made to SA-105, Grade II requirements, and designed to meet all requirements of the ASME B&PV Code Section III, Class l. The guard pipe design is based on 90 percent of the material yield stress when pressurized to 1250 psi due to process line rupture. The process line penetration sleeve is welded to a bellows which in turn is welded to the guard pipe. The bellows assembly accommodates the differential thermal expansion and seismic movements between the process pipe and the drywell in the three mutually perpendicular directions.

Pipe penetrations for those applications not requiring provisions for relative movement between pipe and containment shell are illustrated in Figures 6.2-2 and 6.2-3.

The design of the penetrations takes into account the simultaneous stresses associated with normal thermal expansion, live and dead loads, seismic loads, and loads associated with LOCAs within the drywell. For all of these conditions, including appropriate combinations of these loads, the resultant combined stresses in the pipe and penetration components do not exceed design limits allowable by applicable codes. If, in addition, the jet force loadings resulting from random failures of the steam pipe are included, the resultant stresses in the pipe and penetration do not exceed allowable code stresses for fault conditions.

Cold piping and ventilation duct penetrations are welded directly to the sleeves. Bellows and guard pipes are not necessary in these applications because the thermal stresses are small and accounted for in the design of the weld joints.

6.2.1.2.1.5 Electrical Penetrations

Figure 6.2-4 shows a typical electrical penetration used for transmitting electric power, and instrumentation and control signals from the reactor building into the primary containment. Separation of divisions is obtained by locating penetrations on the semi-peripheries of the containment at Elevation 604 ft. The division boundary is the east-west diameter. Division I is on the north half; Division II, the south half.

One group of six penetrations is used to transmit power to two 7100-hp, three-phase, 3920-V reactor coolant recirculation pump motors.

One group of two penetrations is used for low-voltage power, motor control three-phase, 480-V, 208-V, and single-phase 120-V, and 125-V-dc loads.

One group of two penetrations is used for 120-V signals for limit and level switches. These penetrations also contain an isolated penetration within a penetration for the reactor protection system (RPS).

One group of six penetrations is used for low-voltage instrumentation cable to transmit control and temperature signals for control rod position from reactor to recorders and computer.

One penetration is used for analog signals, to be used for vibration tests and miscellaneous primary signals.

One group of two penetrations for low-voltage shielded instrumentation thermocouple extension lead wire is used to transmit RPV and other equipment temperature signals to recording and readout equipment.

One group of four penetrations is used for neutron monitoring. The penetrations include the following coaxial and triaxial cables per penetration:

a. Three triaxial - for intermediate-range monitors

b. Two triaxial - for source range monitor

c. 48 coaxial - for local power range monitor.

All penetrations are sized for a 12-in.-diameter nozzle and are hermetically sealed, with provisions for continuous leak detection at design pressure. The penetrations are factory assembled, prewired and tested, and do not require field welding for installation due to the flange mount design. Radiation shielding is integral, thus minimizing radiation shine, and eliminating overhanging moments which would occur if shielding were mounted externally.

Edison made a review of the primary containment electrical penetrations to determine that the electrical penetration assemblies were designed to withstand, without the loss of mechanical integrity, the maximum available fault current versus time conditions that could occur, given single random failures of circuit overload devices as recommended by Regulatory Guide 1.63, Revision 1.

In making the review, the following assumption was primary: The I^2t characteristics of the penetration conductors as furnished by Conax Corp. were used as a basis for determining integrity. The I^2t curves as furnished by Conax Corp. were conservative in nature and the I^2t curve points were not necessarily the points of damage to the mechanical integrity of the penetrations.

The following positions are in line with the guidelines set forth in Regulatory Guide 1.63, which were taken by Edison, based on the results of this review.

a. For low-energy penetrations, maximum fault current does not approach the I^2t of the penetration conductor. No backup or redundant protection is provided

b. On low-voltage power penetrations where maximum fault current versus time will exceed the I^2t of the penetration conductor (considering single random failure of the primary protection), backup protection is provided by one of the two following methods:

   1. If adequate backup protection can be obtained from the feeder position and the fault can be cleared in sufficient time to prevent reaching the I^2t of the penetration conductor - no additional redundant protective devices are provided

   2. Where the feeder position cannot provide adequate clearing time, an additional protective device, fuse or breaker as necessary, is provided.

There are six medium voltage power penetrations, and they are used for the reactor recirculation pump motor M-G set output from the generator to the pump motors. In these cases the primary protection is provided by tripping the main M-G set motor drive incoming circuit breaker positions. Backup protection is provided by tripping the generator field breakers. Proper relaying ensures operation of the field breaker.

Loads to the primary containment not necessary for reactor operation (i.e., lighting and welding) are maintained in a deenergized condition.

6.2.1.2.1.6 Traversing In-Core Probe Penetrations

A total of five traversing in-core probe (TIP) guide tubes and two spare penetrations pass through the primary containment. Penetrations of these guide tubes through the primary containment are sealed with a Class I drywell penetration seal weld which meets the requirements of the ASME B&PV Code Section III. These seals also meet the intent of Section III of the Code even though the Code has no provisions for qualifying the procedures or performance.

6.2.1.2.1.7 Personnel and Equipment Access Lock

One personnel access lock is provided for access to the drywell (Figure 6.2-5). The lock has two gasketed doors in series. The inner door has a double seal gasket and the outer door a single gasket. The doors are designed and constructed to withstand the drywell design pressure. The doors are mechanically interlocked to ensure that at least one door is locked. The locking mechanisms are designed so that a tight seal will be maintained when the doors are subjected to either internal or external pressure. The seals are capable of being tested for leakage. Two equipment access hatches and a control rod drive (CRD) removal hatch are in the spherical portion of the drywell. These hatches have double testable seals and are bolted in place (Figure 6.2-6).

6.2.1.2.1.8 Access To the Pressure Suppression Chamber

Access from the reactor building to the pressure suppression chamber is provided at two locations. These are two 4-ft-diameter manhole entrances with double-gasketed bolted covers connected to the chamber by 4-ft-diameter steel pipes. These access ports are bolted closed when the primary containment is secured.

6.2.1.2.1.9 Access for Refueling Operations

The head or top portion of the drywell vessel is removed during refueling operations. This head is held in place by studs and is sealed with a double seal. It is closed when the primary containment is required and is opened only when the primary coolant temperature is below 212°F and the pressure suppression system is not required to be operational.

A double seal on the head flange is provided to permit checking leaktightness after the drywell head has been replaced.

6.2.1.2.1.10 Venting and Vacuum Relief System

The primary containment is designed for an external pressure of 2 psi. It can be vented through the SGTS or the reactor building ventilation system to limit pressure fluctuations caused by temperature changes during various operating modes. For normal operation, this can be accomplished through the small dedicated lines of the containment atmospheric control system that controls the venting or makeup of nitrogen. During normal operation, the primary containment is maintained at a slightly positive pressure by the Nitrogen Inerting System as described in Subsection 9.3.6.1. Containment pressure is monitored as described in Subsection 7.6.1.12.3.1. The same penetrations that are used for makeup nitrogen are also used to vent the containment for pressure control. The large ventilation purge connections are normally closed while the reactor is at a temperature greater than 212°F, except for inerting or purging. Vacuum breakers are between the drywell and the suppression chamber. Automatic vacuum relief devices are used to prevent the external primary containment pressure from exceeding the design value. The drywell vacuum relief valves draw gas from the pressure suppression chamber, and the pressure suppression chamber vacuum relief device draws air from the reactor building.

A vacuum breaker in series with an air-operated normally closed butterfly valve is used in each of two lines from the suppression chamber to the reactor building atmosphere. One valve (a pilot-operated butterfly valve) is actuated by a differential pressure signal. The second valve is a self-actuating vacuum breaker, opening at a maximum differential pressure of 0.5 psid. The valves are sized to provide sufficient mass flow rate to equalize the pressure between the suppression chamber and the reactor building in case of an inadvertent operation of the suppression chamber spray. The flow rate calculation assumed that the vacuum breaker valves failed to open until the differential pressure reached 1.0 psid. The two separate lines are redundant in that either can provide adequate venting.

The vacuum breakers connecting the suppression chamber and the drywell are sized on the basis of the pressure suppression system test program conducted for Bodega Bay at Moss Landing (Reference 11). The vacuum breaker flow area is proportional to the flow area of the vents connecting the drywell and suppression pool. Their chief purpose is to prevent excessive water-level variation in the portion of the vent discharge line that is submerged in suppression pool water. The tests relating to vacuum breaker sizing were conducted by simulating a small system rupture, which tended to cause vent water-level variation as a preliminary step in the large rupture test sequence. The vacuum breaker capacity selected on this test basis is more than adequate (typically by a factor of four) to limit the suppression chamber-drywell pressure differential during postaccident drywell cooling operations to within containment system design values.

The Fermi 2 vacuum breakers are described in Table 6.2-4. The number of suppression-chamber-to-drywell vacuum breaker valves was chosen so that 25 percent (three of 12) could fail to open and adequate venting would still be provided.

The vacuum breaker valves are provided with a magnetic latch that holds the valve disk against the seat so that vibration does not cause the valve to chatter. The close limit switches, located near the bottom of the valve body, are actuated directly by the pallet. This design allows a precise adjustment of the limit switch setpoint to a very slight opening of the pallet. The transfer point of the switch from the closed to open position is measured electrically using an ohm meter or other continuity device. With the switch properly adjusted, the maximum distance the valve may be unseated and still indicate the closed position is 0.03 in. After limit-switch adjustment, the opening gap of the pallet at the switch is verified to be less than or equal to 0.03 in. Inspection of vacuum breaker instrumentation during reactor refueling will include verification of the opening gap for switch actuation. The bypass opening for the suppression-chamber-to-drywell vacuum breaker corresponding to a 0.03-in. disk opening is 0.009 ft^2, well within the maximum allowable leakage area of 0.25 ft^2 discussed in Subsection 6.2.1.3.6.

A suppression-chamber-to-drywell vacuum breaker valve similar to the Fermi 2 vacuum breaker valves has also been tested by the Mark I Owners Group in the full-scale test facility (FSTF). During several FSTF tests, the pressure fluctuations in the vent system produced during downcomer chugging caused the vacuum breaker to cycle open and closed. The measured FSTF pressure data have been used to evaluate the expected structural performance of the Fermi 2 vacuum breaker valves. The results of this evaluation are described in the report, Mark 1 Wetwell to Drywell Differential Pressure Load and Vacuum Breaker Response for the Fermi Atomic Power Plant Unit 2, by Continuum Dynamics, Inc., submitted to the NRC by Edison letter NE-85-0707 (Reference 12).

The secondary containment to torus vacuum breaker open and closed valve disk positions are indicated by lights on the main control room panel H11-P808. The drywell-to-torus vacuum breakers are provided with open and closed position indicators on panel H11-P808, and a second set of closed position indicators on panel H11-P817. The drywell-to-torus closed indicating circuits are powered by Class 1E power supplies and are wired to meet the requirements of IEEE 279-1971.

There is no annunciation of the valve position. The position switches and circuits do not control or affect the operation of the vacuum breakers. Any single failure of the indicating circuits or switches will not prevent proper action of the vacuum breakers.

The drywell-to-torus and the secondary containment to torus vacuum breakers are equipped with pneumatic actuators operated by pushbuttons from the main control room. The purpose of these actuators is to enable verification of the operability of the vacuum breakers by observing the response of limit switches. The operability of the vacuum breakers will be verified as required by the Technical Specifications.

The actuators are sized such that they have insufficient power to open the vacuum breakers if a backflow differential pressure exists. The drywell-to-torus vacuum breakers and test actuator supports are designed to Category I criteria. The drywell-to-torus vacuum breaker nitrogen supply components downstream of the testing actuator solenoids are designed to Category II/I criteria. The drywell-to-torus vacuum breaker test actuator solenoids meet QA1 and Category I seismic requirements and are environmentally qualified because they form part of the primary containment inboard closed boundary associated with penetrations X204A – M. The secondary containment-to-torus vacuum breakers and test actuators (including actuator supports) are also designed to seismic Category I criteria.

A negative pressure analysis was performed to demonstrate the adequacy of the containment vacuum relief system (Reference 13).

The most severe negative pressures in containment would result from events that challenge the vacuum relief system. The events are associated with operation of the containment spray mode of the RHR system under accident and transient conditions which result in high depressurization rates.

The bounding accident events involve actuation of the drywell spray following a steam leak in the drywell (small-break accident) and following a DBA. All intermediate-line break events are enveloped by these cases. The inadvertent drywell spray actuation during plant operation has been evaluated. The inadvertent drywell spray scenario is an event characterized by multiple operator errors and was not part of the original License application and review. The confirmatory evaluation of this event takes credit for both reactor building to suppression chamber vacuum breakers being operable and assumes the initial drywell ambient temperature of 145°F as described in License Amendment 20. The assumed scenarios and respective bases that lead up to the initial condition for these three cases and the analysis of these three cases are described in Reference 13.

The drywell and torus pressure/temperature responses resulting from these three cases were calculated using a computer program for the calculation of mass and energy balances at successive time intervals using basic thermodynamic, flow, and ideal gas law equations.

The mass flow of spray water through each loop increases in proportion to the opening flow characteristic of the outboard drywell spray isolation valve E1150F016A(B). The model employed assumes a linear valve flow characteristic that is scaled appropriately to accurately model the actual flow as a function of valve position. A linear ramp assuming 60 sec to reach maximum flow accurately reproduces the flow characteristic for a spray isolation valve having a 98-sec open stroke time. In order to model the flow characteristic of spray isolation valves having shorter opening stroke times, the time used to calculate the linear coefficient of mass flow acceleration is based on the 60-sec value scaled by the ratio of the actual minimum value of the valve open stroke time to 98 sec.

Many conservative assumptions are made in the calculational model. The spray is not accounted for in the drywell mass balances and only serves as a heat sink. The addition of water mass to the control volume atmospheres would tend to increase pressure and some vaporization of the spray would be expected. The butterfly valve opening setpoint was arbitrarily set at 0.5 psi. The actual setpoint is 0.25 psi. Any delay in butterfly valve opening time tends to increase depressurization.

The small break accident case was determined to be the most severe of the three bounding cases considered. A resulting drywell pressure of (-1.87 psid) was predicted for this case. This value is below the design pressure for the containment structures of (-2.00) psid.

6.2.1.2.2 Secondary Containment System

The reactor building completely encloses the reactor and its pressure suppression primary containment.

This building provides secondary containment when the primary containment is closed and in service, and provides primary containment when the primary containment is open, as it is during refueling. The reactor building houses the refueling and reactor servicing equipment; new- and spent-fuel storage facilities, and reactor auxiliary and service equipment, including the reactor core isolation cooling (RCIC) system; reactor cleanup demineralizer system, standby liquid control system (SLCS), CRD system equipment, emergency core cooling system (ECCS), and electrical equipment components.

The reactor building includes the "tunnel" containing the outboard main steam isolation valves (MSIVs), the main steam lines up to the turbine building, the feedwater lines, and the outboard feedwater line isolation valves. The tunnel is equipped with hinged doors which, upon pressure buildup due to a break in one of these lines, will relieve the steam pressure to the first and second floors of the turbine building. The net volume of the secondary containment is 2.8×10^6 ft^3.

The reactor building is a Category I structure designed and constructed in accordance with all applicable local and state building code requirements.

Substructures and exterior walls of the building up to the refueling floor consist of poured-in-place, reinforced concrete. The building structure above the refueling floor is a steel frame covered with insulated metal siding and is sealed against leakage. The building is designed for an external pressure of 0.295 psig and for low inleakage and outleakage (depending on wind conditions) during reactor operation.

6.2.1.2.2.1 Reactor Building Penetrations

Access openings for personnel and equipment are equipped with weather-strip-type seals, except for the railroad bay entry, for airtightness to meet secondary containment negative building pressure requirements. The railroad bay entry doors have inflatable seals which provide the airtightness requirements as well as site flood protection. The railroad bay rail pockets have seals which provide the airtightness requirements as well as site flood protection. Personnel entrances to the secondary containment are at the following locations:

a. The reactor core isolation cooling system/core spray pump room at Elevation 551 ft 0 in.

b. The auxiliary building basement from the CRD pump room at Elevation 551 ft 0 in.

c. Between the turbine and auxiliary building at Elevation 564 ft 0 in.

d. Outdoor entry to the reactor building at 583 ft 6in.

e. Railroad bay entry to the reactor building at 583 ft 6 in.

f. Between the reactor building and the auxiliary building at Elevation 613 ft 6 in.

g. Between the reactor building refueling floor and the auxiliary building at Elevation 684 ft 6 in.

h. Between the reactor building refueling floor and the auxiliary building at Elevation 701 ft 0 in.

All of these entries have a vestibule with double doors to maintain secondary containment integrity. The double doors are administratively controlled to prevent both doors from being open at the same time, thus maintaining secondary containment integrity. Additionally, as an administrative aid, the doors have either interlocks to prevent the opening of one door until the other door is closed or one of the doors is key locked closed. The interlock feature is not considered QA1 safety related. Failure of these interlock circuits would not cause the doors to open on their own accord. Keys for the locked closed doors are administratively controlled by the Shift Manager. In the case of the railroad bay airlock, the doors have inflatable seals which are considered active components. Therefore, to meet single failure criteria and maintain secondary containment integrity, the inner door seal is supplied from Division I of non-interruptible control air and the outer door seal is supplied from Division II of non-interruptible control air. The railroad bay airlock doors also have low seal pressure alarms which are monitored in the main control room.

Penetrations for piping and ducts are designed for leakage characteristics consistent with containment requirements for the entire building. Electrical cables and instrument leads pass through ducts sealed into the building wall.

6.2.1.2.2.2 Reactor Building Ventilation Systems

The reactor building has two ventilation systems: the normal ventilation system and the SGTS. During normal power operation, shutdown, or refueling, the normal ventilation system provides outside filtered air to all levels and building equipment rooms. This system provides a minimum of one reactor building free volume change of air per hour. Air flows from the filtered supply to uncontaminated areas, to potentially contaminated areas, and then to the release vent (a short stack) on the reactor building roof.

The fans for the normal ventilation system are automatically shut down in the event a high radiation level in the building exhaust ducts is detected by the radiation monitoring system (RMS), or if there is high pressure in the drywell, low RPV water level, or high static pressure in the building, or if high radiation is detected by the east or west fuel pool radiation monitors. The normal ventilation may be isolated manually from the control room.

Shutting down the fans closes the dual ventilation duct isolation dampers. The fans are controlled from the main control room.

During emergencies when the normal ventilation system is not operating, the reactor building is ventilated through the SGTS. The SGTS filters and exhausts the atmosphere of the reactor building via the roof vent.

6.2.1.2.2.3 Bypass Leakage Paths

One purpose of the secondary containment (reactor building) is to collect and filter leakage from the primary containment prior to release to the environment and thereby reduce offsite doses after a LOCA. This purpose is accomplished by

a. Minimizing reactor building leakage

b. Maintaining the reactor building at a negative pressure

c. Passing all exhaust from the reactor building through the SGTS after a LOCA.

A study has been made to evaluate the secondary containment system and determine all potential paths that could result in a fraction of the primary containment leakage going directly to the environment (i.e., without passing through the SGTS). The study encompasses three areas

a. Lines that are connected to the primary containment and pass through the secondary containment

b. Electrical penetrations

c. Reactor building leakage.

Primary Containment Lines

Lines that are connected to the primary containment and pass through the secondary containment are potential paths for leakage of radioactivity directly from the primary containment to the environment, bypassing the SGTS. The containment penetrations through which potential bypass leakage paths are possible are identified in Table 6.2-2.

All the bypass leakage paths listed in Table 6.2-2 will not contribute more leakage than 10 percent L_A, where L_A is the maximum allowable leak rate in the Type A containment integrated leak rate test (see Subsection 6.2.4.4). The radiological impacts of MSIV leakages of up to 100 scfh per steam line, and up to 250 scfh of total MSIV leakage are analyzed separately from L_A controlled leakages. Fermi 2 uses air or water sealing systems that eliminate leakage through certain valves:

a. The torus water management system suction lines (penetrations X-213A and B) are sealed with water in the torus

b. The high pressure coolant injection system suction line from suppression chamber (penetration X-225) and reactor core isolation cooling system suction line from suppression chamber (penetration X-226) are sealed with water in the torus.

The bypass leakage program will maintain a running total of leak rate measurements through all other bypass leakage paths as listed in Table 6.2-2 and will compare it with the maximum allowable. Valve maintenance will be performed when necessary.

With the exception of two leakage paths, all the valves in the bypass leakage program are containment isolation valves, and, as such, leak rates will be measured in accordance with 10 CFR 50, Appendix J, Type C tests (see Subsection 6.2.4.4). These paths accordingly are protected by redundant and diversely powered isolation valves. In the case of the reactor vessel instrument line backfill system leakage through the CRD piping when the CRD pressure is lost, certain noncontainment isolation valves are used in the program to meet criteria equivalent to those met by the other leakage paths. These valves will be tested in accordance with Section XI, Category A, of the ASME Code.

In summary, the following valves are encompassed in the bypass leakage program for Fermi 2:

System	Valve	Test
Reactor Feedwater	B2100F010A	Appendix J, Type C
	B2100F010B	Appendix J, Type C
	B2100F076A	Appendix J, Type C
	B2100F076B	Appendix J, Type C

	P34F406A	Appendix J, Type C

The EECW penetrations are normally open. The listed valves are Remote Manual Isolation valves that are closed by the Operators responding to alarm response procedures. The EECW leakage detection equipment and other EECW system indications will provide the required information to the Operators. The analysis of the available sealing water in the EECW/RBCCW systems indicate that over two hours is available prior to required Operator actions to close these valves. Closure of these valves will ensure that this path will not exceed measured bypass leakage.

Leakage through the primary containment exhaust lines is collected by the SGTS and is not discharged through the exhaust fans. The large purge/inert lines and the small "on-line" pressure control lines are tied to both the reactor building ventilation system and the SGTS. High radiation in the reactor building heating, ventilation, and air conditioning (RBHVAC) exhaust isolates these valves and starts the SGTS. A suction line to the SGTS is connected to the inerting supply line as shown in Figure 9.3-14. This line collects any leakage past the containment isolation valve and processes it through the SGTS.

Category I design requirements are met (1) on the main steam piping from the reactor, up to and including the third set of MSIVs, and (2) on all branch piping, up to and including the first valve that is either normally closed or capable of automatic closure during all modes of normal nuclear steam supply system (NSSS) operation.

Electrical Penetrations

Electrical cables exit from the primary containment via penetrations sealed at both internal and external ends; the external end is within the secondary containment. The cables leaving these penetrations run in cable trays. Thus there are no electrical wiring conduits or ducts that go directly from the primary containment to the environment, bypassing the secondary containment.

Reactor Building Leakage

The reactor building, under both normal and emergency conditions, is maintained at a negative pressure so that leakage is inward. The reactor building is maintained at 0.25 in. plus or minus 0.125 in. water gage. However, due to the kinetics of gas at high velocities, the pressure on the leeward side of the building will be negative at high wind speeds. Consequently, above a threshold wind speed, air could be drawn from the reactor building, bypassing the SGTS.

An exfiltration/infiltration analysis has been made on the building to determine inward and outward leakage rates as a function of wind speed. The analysis was based on the following:

a. The SGTS maintains the building at l/4 in. H_2O negative pressure

b. Leakage to the environment occurs only through the metal siding and only when the pressure differential across the siding is outward

c. The rate of leakage is 0.015 $ft^3/minute/ft^2$ at 1/4 in. H_2O and varies as the square root of pressure differential. The leakage rate is the same for positive and negative differentials

d. The wind force acts on two sides of the building; the other two sides are at a negative pressure

e. The positive and negative pressures due to wind are based on the equation

$$P = 0.002558\ S\ (GV)^2$$

where

P	=	wind pressure (lb/ft^2)		
S	=	shape factor	=	0.9 windward s
G	=	gust factor	=	1.1
V	=	wind velocity (mph)		

The study shows the threshold wind velocity for any leakage outward from the building is 30 mph. The study also shows that the net leakage (inward) through the siding is not a strong function of wind velocity; consequently, the operating parameters of the SGTS are independent of wind velocity.

Since there is siding only above the refueling floor, this leakage path is not directly from the primary containment to the environment, but rather from the secondary containment the reactor building. The estimate of the fraction of primary leakage bypassing the SGTS will be conservative if this fraction is assumed to be equal to the fraction of building leakage to total discharge from the reactor building. This statement can be expressed by the following equation:

$$B = \frac{S}{S+G}$$

Where:

B	=	fraction of primary leakage bypassing SGTS
S	=	outward leakage rate of siding (function of wind speed) (scfm)
G	=	discharge rate of SGTS (scfm)

The results of this study are summarized in the following table:

Wind Velocity (mph)	Fraction of Time per Year**	Reactor Building Leakage* Total Outward From Siding (scfm)	Reactor Building Leakage* Fraction of Primary Leakage Bypassing SGTS
0	0.65	0	0
10	0.34	0	0
20	0.01	0	0
30	0.001	52	0.017
40	--	246	0.076
50	--	370	0.110

*The radiological dose from exfiltration will result in inconsequential increases, i.e., less than 1 percent, in the total calculated doses since the fraction of time the leakage occurs is so very small. In addition, if an atmospheric dispersion parameter (χ/Q), which is inversely proportional to wind speed, is calculated for the higher wind speeds associated with exfiltration, it will further decrease the dose values.

**Winds of 15-minute duration as measured from the 10-m level on the 60-m tower during the 12-month period from June 1, 1974, to May 31, 1975.

6.2.1.3 Design Evaluation

6.2.1.3.1 Introduction

In the design of the primary containment vessel, certain extreme conditions were hypothesized; the design then proceeded so that maximum stress levels under these conditions did not exceed the maximum allowable values specified in the appropriate code.

The key parameters of stress are vessel temperature, pressure, and hydrodynamic loads. The containment vessel for Fermi 2 was designed under ASME B&PV Code Section III, Nuclear Vessels (1968), including Summer 1969 Addenda. This code specifies that the internal pressure used for design conditions shall not be less than 90 percent of the maximum containment internal pressure, and that the design temperature shall not be less than the maximum containment temperature at the coincident maximum containment pressure.

The containment vent system and suppression shell, supports, internals, and attachments have been reevaluated (References 9 and 10) to include the hydrodynamic loading events and analysis methods defined by GE Topical Report NEDO-21888 (Mark I Containment Program Load Definition Report) and the NRC Safety Evaluation Report, NUREG-0661. The appropriate edition of, Section III of the ASME Code and service-level limits specified in NUREG-0661, have been applied in the reevaluation.

The maximum drywell pressure occurs during the reactor blowdown phase of a LOCA. It is dependent upon the rate at which primary system energy and fluid enter the drywell. The largest pipe in the primary coolant system is the 28-in.-diameter main recirculation line. The instantaneous guillotine rupture of this pipe is the DBA for the containment design pressure. The same pressure is conservatively used for suppression chamber design.

The most severe drywell temperature condition would occur as a result of a small primary system rupture above the reactor water level that results in the blowdown of reactor steam to the drywell. Because of the nature of the blowdown process, this would produce high-temperature steam in the drywell.

The blowdown phase of an intermediate-size break was also evaluated to demonstrate that breaks smaller than the rupture of the largest primary system pipe can be accommodated safely without any of the containment design parameters being exceeded.

In Subsections 6.2.1.3.2 through 6.2.1.3.8, the various extreme conditions that have been hypothesized and analyzed as part of the original licensing basis for the containment design are described as modified by power uprate. The initial conditions, assumptions, and break flow model applied in these analyses maximize the containment temperatures and pressures that could be expected during postulated LOCAs. The discussions of the analysis results in these subsections include the conservatively predicted short-term and long-term response of the containment. However, as part of the Fermi 2 Mark I containment long-term program (References 9 and 10), and the subsequent reevaluation of limiting events for the Power Uprate Safety Analysis (Reference 3), the spectra of postulated pipe breaks have been reinvestigated to determine the worst loading conditions for each of the affected containment structural elements. The loading conditions associated with the long-term program analyses included pool swell, condensation oscillation, chugging, and safety/relief valve discharge. To establish a conservative load basis, the initial conditions, assumptions, and models differed, in some cases, from those used in the original licensing-basis containment analyses. The load bases and application methods used in the Mark I containment analyses are completely described in Reference 5 and have been accepted by the NRC in NUREG-0661 (Reference 7). The plant-unique load definition (Reference 6) describes the pressure and temperature responses of the drywell, vent system, and suppression chamber volumes used in the Fermi 2 containment longterm program analyses. Since the long-term program-related loads occur early in the postulated LOCA events, Reference 6 only describes the short-term containment responses (less than 1100 sec). The break flow model used in the plant-unique load definition analyses is described in Reference 14.

6.2.1.3.2 Recirculation Line Break - Short-Term Response

The instantaneous guillotine rupture of a main recirculation line results in the maximum flow rate of primary system fluid and energy into the drywell. This in turn results in the maximum containment differential pressure. Figure 6.2-7 is a diagram showing the location of a recirculation line break.

Immediately following the rupture, the flow out both sides of the break will be limited to the maximum allowed by critical-flow considerations. Figure 6.2-7 shows a schematic view of the flow paths to the break. In the side adjacent to the suction nozzle, the flow will correspond to critical flow in the nozzle pipe cross section. In the side adjacent to the injection nozzle, the flow will correspond to critical flow at the 10 jet pump nozzles associated with the broken loop. In addition, there is a 4-in. cleanup line cross tie that will add to the critical flow area, yielding a total of approximately 4.1 ft^2.

The short-term analysis was performed for the limiting DBA/LOCA which assumes a double-ended guillotine break of a recirculation suction line that results in the maximum flow rate of primary system fluid and energy into the drywell. The analysis predicted the peak drywell pressure at 49.9 psig which is less than the containment allowable design limit of 62 psig. The peak drywell pressure of 49.9 psig is bounded by the Technical Specification value of 56.5 psig which has not been changed.

The short-term analysis covers the blowdown period during which the maximum drywell pressure and differential pressure between the drywell and wetwell occurs. The analysis assumed 102 percent power (102 percent of 3430 MWt, 3499 MWt) and was done using the M3CPT computer code which is used to model short-term containment pressure and temperature response. The M3CPT code is based on References 14 and 15 and has been reviewed and accepted by the NRC (Reference 7) during the Mark I Long Term Program (LTP) for application to the Mark I plants, including Fermi 2. The inputs for the short-term analysis (M3CPT code) are shown in Table 6.2-1, Section II.

Figure 6.2-8 shows the blowdown flow rates from the primary system to the containment. Table 6.2-5 shows the primary system energy distribution at the time of the break. (Reference 31)

The calculated primary containment pressure and temperature responses to this DBA/LOCA are shown in Figures 6.2-9 and 6.2-10.

The calculated peak drywell pressure is 49.9 psig. After the discharge of primary coolant from the RPV into the drywell, the temperature of the suppression chamber water approaches

135°F and the suppression chamber pressure stabilizes at approximately 25 psig. The drywell pressure stabilizes at a slightly higher pressure, the difference being equal to the downcomer submergence. During the RPV depressurization phase, most of the noncondensable gases in the drywell initially are forced into the suppression chamber. However, the noncondensables will redistribute between the drywell and suppression chamber via the vacuum breaker system as the drywell pressure is decreased by steam condensation.

The LPCI and/or core spray system removes decay heat and stored heat from the core, thereby controlling core heatup and limiting any metal/water reaction. The RPV is flooded to the height of the jet pump nozzles and the excess flow discharges through the recirculation line break into the drywell. This flow of water transports the core decay heat out of the RPV, through the broken recirculation line in the form of hot water that flows into the suppression chamber via the drywell-to-suppression chamber vent pipes. Steam flow is negligible. This flow, in addition to heat losses to the drywell walls, offers considerable cooling to the drywell atmosphere and causes a depressurization of the containment as the steam in the drywell is condensed.

The LPCI/RHR pumps that are used to flood the core are also used as the containment spray and cooling pumps. Prior to activation of the containment cooling mode (arbitrarily assumed at 20 minutes after the accident), all of the LPCI pump flow may be used only to flood the core. After 20 minutes, the RHR pump flow will have to be diverted from the RPV to the containment cooling mode. This is a manual operation. Actually, the containment spray need not be activated at all to keep the containment pressure below the containment peak allowable pressure. As discussed above, the peak drywell pressure is less than the containment design limit of 62 psig.

6.2.1.3.3 Recirculation Line Break Long Term Response

The primary purpose of this analysis is to calculate the peak suppression pool temperature following a DBA/LOCA. The GE SUPERHEX (SHEX) code is used to predict the long-term containment response following a DBA/LOCA event.

The limiting case assumes that one RHR loop is operating in the containment cooling mode at partial pumping capacity. This includes one RHR heat exchanger, one RHR main system pump, and two service water pumps. During this mode of operation the RHR pump draws suction from the suppression pool and discharges flow through the RHR heat exchangers where it is cooled and then injected back into the suppression pool. Core cooling is provided by the core spray system and the RHR/LPCI pump prior to activation of the containment cooling mode at 20 minutes after the accident.

The long term analysis using the SHEX code with conservative input values yielded a peak post DBA/LOCA pool temperature of 196.5°F. This temperature shows margin remains to the controlling limit of 198°F which comes from NPSH requirement for pumps taking suction from the suppression pool with no credit for containment pressure per Regulatory Guide 1.1 (Subsection 6.3.2.14).

The input parameters for the long term response are shown in Table 6.2-1, Section III. Figures 6.2-11, 6,2-12, and 6.2-13 show the drywell and wetwell airspace pressure response, the drywell and wetwell airspace temperature response, and the suppression pool temperature response, respectively. The accident chronology is shown in Table 6.2-7. The conservatisms built into some of the inputs are described below.

<u>Service Water</u>

a. The Technical Specification limit for cooling tower reservoir temperature is 80°F. An energy balance calculation was used to determine the post-LOCA RHRSW temperature increase as a function of time from the initial condition of 80°F to the cooling tower maximum design temperature of 90°F. The temperature profile, which is non-linear, was conservatively bounded by a linear profile with the initial temperature of 80°F increasing in a linear way to 90°F over an 8-hour period. (Note: The current maximum analyzed service water supply temperature is below the assumed maximum 90°F).

b. The minimum technical specification RHR reservoir water level was used. This is conservative because it minimizes the heat capacity of the reservoir and maximizes the reservoir heatup.

c. Evaporative and drift losses were used to reduce reservoir inventory during the heatup period.

d. Complete mixing is assumed in the reservoir. This is conservative because hot water is discharged into the cooling towers and is sprayed down to the surface of the reservoir. Cooler water is drawn from the bottom of the reservoir where the pump suctions are located. No credit is taken for temperature stratification which lowers the reservoir discharge temperature profile.

<u>Suppression Pool Volume</u>

A pool volume of 117,161 ft^3 is used for the long-term containment analysis. The technical specification minimum value is 121,080 ft^3. This lower pool volume of 117,161 ft^3 adds conservatism to the calculated pool temperature, since a lower initial pool volume results in higher calculated values for pool temperature.

<u>Initial Pool Temperature</u>

The initial pool temperature of 95°F was used in the analysis. The 95°F is the Technical Specification limit for normal operation.

<u>Feedwater Addition</u>

For conservatism the analysis includes all water in the feedwater system that can contribute to higher calculated pool temperatures. This was achieved by adding all feedwater in the feedwater system during normal operation that has a temperature greater than the maximum expected pool temperature. This translates to all feedwater through feedwater heaters nos. 3, 4, 5, and 6.

In addition, a conservative calculation of the energy in the feedwater piping is added to the RPV/containment system. This water mass and energy addition assures that the pool temperature calculation conservatively reflects the effect of feedwater temperature on suppression pool temperature.

Initiation Time for Containment Cooling

The plant emergency operating procedures require that containment cooling be started for any suppression pool temperature greater than 95°F (that is within the first few minutes of a DBA/LOCA). However, the UFSAR does not take credit for operator action for the first 10 minutes into the accident. Added conservatism is built into the analysis by assuming containment cooling is initiated at 20 minutes resulting in a higher pool temperature than will be obtained with the 10 minute initiation time. Also the RHR heat exchangers providing cooling to the suppression pool water are assumed to be fouled, adding more conservatism.

Decay Heat

The decay heat based on the ANS 5.1 model (Reference 16) as described in Appendix B of Reference 17 has been used for the containment long-term analysis. This decay heat includes contributions due to fission heat induced by delayed neutrons, decay heat from fission products, decay heat from actinides (heavy elements), and decay heat from irradiated structural materials. For conservatism additional margin which corresponds to two standard deviations (10%) was added to the decay heat as described in Reference 17, Appendix B.

6.2.1.3.4 Intermediate Breaks

Intermediate breaks were not reanalyzed for power uprate since they were not the limiting case. The analysis presented below is based on the original power of 3358 MWt (102 percent of 3293 MWt).

The failure of a recirculation line results in the most severe pressure loading on the drywell structure. However, as part of the containment performance evaluation, the consequences of intermediate breaks are also analyzed. This classification covers those breaks for which operation of the ECCS will occur during the blowdown and which result in reactor depressurization. These breaks can involve either reactor steam or liquid blowdown. This section describes the consequences to the containments of a 0.l-ft^2 break below the RPV water level. This break area was chosen as being representative of the intermediate-break-area range. Figures 6.2-15 and 6.2-16 show the drywell and suppression chamber pressure and temperature response.

Following the 0.1-ft^2 break, the drywell pressure increases at 0.5 psi/sec. This drywell pressure transient is sufficiently slow so that the dynamic effect of the water in the vents is negligible and the vents will clear when the drywell-to-suppression chamber differential pressure is equal to the vent submergence pressure. For this containment design, the distance between the pool surface and the bottom of the vents is 3 ft 4 in. maximum. Thus, the water level in the vent will reach this point when the drywell-to-suppression chamber pressure differential reaches 1.5 psi, i.e., approximately 3 sec after the 0.1-ft^2 break occurs. At this time, air, steam, and water will start to flow from the drywell to the suppression pool; the steam will be condensed and the air will enter the suppression chamber free space. After 3 sec there will be a constant pressure differential between the drywell and the suppression chamber. The continual purging of drywell air to the suppression chamber will result in a gradual pressurization of the latter. By approximately 300 sec, all the drywell air will have been swept over to the suppression chamber and the pressure increase terminated. After this time, the drywell and wetwell pressures will remain relatively constant and all the steam being released to the drywell will be condensing in the pool. Some continuing containment pressurization will occur because of the continued pool heatup. The ECCS will be initiated by the 0.1-ft^2 break via high drywell pressure and will provide emergency cooling of the core. The operation of these systems is such that the reactor will be depressurized in approximately 600 sec.

This will terminate the blowdown phases of the transient. The drywell will be at approximately 25 psig and the suppression chamber at approximately 23 psig.

In addition, the suppression pool temperature will be the same as from the recirculating line break because essentially the same amount of primary system energy would be released during the blowdown. After reactor depressurization, the flow through the break will condense the drywell steam and will eventually cause the drywell and suppression chamber pressures to equalize in the same manner as following a recirculation line rupture.

The subsequent long-term suppression pool and containment heatup transient that follows is essentially the same as for the recirculation break without containment spray.

From this description, it can be concluded that the consequences of an intermediate break are less severe than a recirculation line rupture over short time periods and essentially the same over a long time period.

Additionally, as discussed in Subsection 6.2.1.3.1, the containment response due to intermediate breaks has also been calculated using the bases provided in References 5 and 7. The corresponding short term containment response is reported in Reference 6. These predicted results also support the above conclusions.

6.2.1.3.5 Small Breaks

Small breaks were not reanalyzed for power uprate since they were not the limiting case. The analysis presented below is based on the original power of 3358 Mwt (102 percent of 3293 MWt).

This subsection discusses the containment transient associated with small primary system blowdowns. The sizes of primary system blowdowns in this category are those blowdowns that will not result in reactor depressurization due either to loss of reactor fluid or automatic operation of the ECCS equipment. The underlying assumption is that, following the manifestation of a break of this size, the reactor operators will initiate an orderly shutdown and depressurization of the plant.

The thermodynamic process associated with the blowdown of primary system fluid is one of constant enthalpy. If the primary system break is below the water level, the blowdown flow will consist of reactor water. Upon depressurizing from reactor pressure to the drywell pressure, approximately one-third of this water will flash to steam and two-thirds will remain as liquid. Both phases will be at saturated conditions corresponding to the drywell pressure. Thus, if the drywell is at atmospheric pressure, the steam and liquid associated with a liquid blowdown would be at 212°F. Similarly, if the containment is assumed to be at its maximum allowable pressure, the reactor liquid would blow down to approximately 309°F steam and water. If the primary system rupture is located so that the blowdown flow consists of reactor steam, the resultant steam temperature in the containment is significantly higher than the temperature associated with liquid blowdown. This is because a constant enthalpy decompression of high-pressure, saturated steam will result in a superheat condition. For example, decompression of 1000 psia steam to atmospheric pressure will result in 298°F superheated steam (86°F of superheat).

The conclusion is that a small reactor steam leak will impose the most severe temperature conditions on the drywell structures and the safety equipment in the drywell. The superheat temperature for large steam-only blowdowns would be the same as for small breaks, but the duration of the high temperature condition would be less. This is because the larger breaks will depressurize the reactor more rapidly than the orderly reactor shutdown that is assumed to terminate the small break.

For drywell design evaluation, the following sequence of events was assumed to occur. With the reactor and containment operating at the maximum normal conditions defined in Table 6.2-1, a small break occurs that allows blowdown of reactor steam to the drywell. The resulting pressure increase in the drywell will lead to a high-drywell-pressure signal that will scram the reactor and activate the containment isolation system. The drywell pressure will continue to increase at a rate dependent upon the size of the assumed steam leak. This pressure increase will depress the water level in the vents until the level reaches the bottom of the vents. At this time, air and steam will start to enter the suppression pool. The steam will be condensed and the air will pass to the suppression chamber free space. The latter will result in a gradual pressurization of the containment at a rate dependent upon the air carryover rate. Eventually, the entrainment of the drywell air in the steam flow through the vents will result in all the drywell air being carried over to the suppression chamber. At this time, pressurization of the containment will cease and the system will reach an equilibrium condition with the drywell pressure at 25 psig and the suppression chamber at approximately 23 psig. The drywell will be full of superheated steam. Continued blowdown of reactor steam will be condensed in the pool.

The reactor operators will be alerted to the incident by the high-drywell-pressure signal and the reactor scram. For the purposes of evaluating the duration of the superheat condition in the drywell, it is assumed that their response is to shut the reactor down in an orderly manner using the safety/relief valves, or main condenser, and limiting the reactor cooldown rate to 100°F per hour. This will result in the reactor primary system being depressurized within 6 hr. At this time, the blowdown flow to the drywell will cease and the superheat condition will be terminated. If the plant operators elect to cool down and depressurize the reactor primary system more rapidly than at 100°F per hour, then the drywell superheat condition will be shorter.

The temperature resulting from the blowdown is determined by finding the combination of primary system pressure and containment pressure that produces the maximum superheat temperature. These are 450 psia, 35 psig, and 340°F, respectively. This temperature is assumed to exist for the initial 3 hr of the blowdown.

Additionally, as described in Subsection 6.2.1.3.1, the containment response due to small breaks has also been calculated using the bases provided in References 5 and 7. The corresponding short-term response is reported in Reference 6. Assumed operator actions that will minimize cyclic loads on suppression chamber and vent system structures are discussed in Reference 9.

6.2.1.3.6 Steam Bypass

The Fermi 2 containment has been examined to determine what leakage between the drywell and suppression chamber can be tolerated as a function of primary system break area; i.e., what leakage will result in a peak pressure equal to the maximum allowable pressure for the system. For this calculation, the following assumptions were made:

a. Flow through the postulated leakage path is pure steam. For a given leakage path, postulating that the leakage flow consisted of a mixture of liquid and vapor would increase the total leakage mass flow rate but would decrease the steam flow rate. Since it is the steam entering the suppression chamber free space that is resulting in the containment pressurization, this is a conservative assumption

b. There is no condensation of the leakage flow on either the suppression pool surface or the torus and vent system structures. Since any condensation results in less steam being in the suppression chamber free space, this is a conservative assumption. In practice, there would be condensation, especially for the larger primary system breaks when there will be vigorous agitation at the pool surface during blowdown.

Leakage capacity is expressed in terms of A, the area of the leakage flow path, and K, the geometric loss coefficient. These terms are interrelated such that the allowable leakage capacity for a system is expressed in units of $A/\sqrt{K}$.

The calculation shows that the limiting leakage capacity occurs for a primary system break area of 0.4 ft^2. For this break area, the allowable leakage capacity is 0.147. Typically, the geometric loss factor K would be three or greater; thus, the maximum allowable leakage area would be about 0.25 ft^2. This corresponds to a 7-in. line.

Primary system breaks greater than about 0.4 ft^2 will result in rapid system depressurization, and, for the given primary allowable leakage area, would result in the containment pressure being less than the maximum allowable pressure at the end of the reactor blowdown period.

Primary system breaks less than about 0.4 ft^2 will not result in rapid primary system depressurization and some operator action is required to terminate the pressure rise in the containment. The operators have several options available to them. If the source of the leakage is undefined, they would probably depressurize the primary system via either the main condenser or relief valves, or they could activate the suppression chamber or drywell sprays.

6.2.1.3.7 Small-Break Temperature Consideration

The Fermi 2 containment vessel was designed in accordance with the ASME B&PV Code Section III, Nuclear Vessels (1968), including the Summer 1969 Addenda. The primary containment design parameters, as shown in Part I of Table 6.2-1, were chosen on the basis of conditions discussed in the Fermi 2 PSAR. The design-basis conditions have since changed, as discussed in Subsection 6.2.1.3.2. However, no change in design pressure was necessary.

A small steam leak inside the primary containment, followed by an orderly shutdown and RPV depressurization, presents a different drywell atmosphere temperature transient. This situation is discussed in Subsection 6.2.1.3.5. The drywell temperature is calculated to be 340°F for 3 hr, and 320°F for 6 hr. During this period the calculated maximum drywell pressure is 35 psig, and during the following 24-hr period the temperature is 250°F with a pressure maximum of 25 psig. The containment vendor has analyzed the containment capability and found it adequate for these conditions.

6.2.1.3.8 Line Breaks in Sacrificial Shield Annulus

6.2.1.3.8.1 Description of System Configuration

The sacrificial shield is approximately 49-ft high cylindrical shell, with a 25 ft 7 in. inside diameter, a 29 ft 1 in. outside diameter, and a thickness of 1 ft 9 1/4 in. It has steel liners on its exterior and interior surfaces, and is meridionally stiffened by 12 vertical steel columns. The steel liner plates are welded to the columns, and the annular space between these plates is filled with concrete. The wall is rigidly attached to the reactor support at the bottom and attached to the drywell and RPV at the top by means of stiff leg supports and snubbers, respectively. The RPV sits inside the sacrificial shield with annular clearance of approximately 18 in. Of this 18 in., approximately 3 in. is occupied by insulation and 3 in. by a ventilation space between the shield and the insulation. This leaves a 12-in. annular space between the insulation and the RPV.

A detailed description of the sacrificial shield is given in Subsections 3.8.3.1.1 and 3.8.3.3.1. Openings are provided in the shield for the passage of lines from the RPV to the drywell. Those openings which lie within an area 9 ft above and 16 ft below the centerline of the core are required to be shielded and are equipped with shielding doors; these doors are locked closed and will not open during a pipe break within the annulus. The openings above and below this band have no shielding requirements; they are covered with a light-weight rupture diaphragm designed to help relieve the annulus pressure should a break occur.

The nozzles of the RPV are connected to the main piping using a short transition piece called a safe-end. The postulated break is the weld at either end of the safe-end. There are 26 penetrations in the wall, of which 17 occur where shield doors are required. Of these 17 lines, the major ones are the two 28-in. diameter recirculation outlet lines and the ten 12-in. recirculation inlet lines. The safe-end welds for these nozzles lie within the thickness of the shield wall or in the annular space. These two sets of lines were considered the critical cases, because the rest of the lines either are smaller, or may vent directly to the drywell because of the absence of any shield doors. One more case was considered: the feedwater line safe- end break. Because this line is located at the top of the sacrificial shield, forces generated during a postulated line break have a large moment which can lead to high stresses. The analysis requires modeling the system to predict what forces and pressures are generated following a postulated failure of safe- ends from these three lines and then using these in a structural design assessment.

Subsection 3.9.1.5 presents the GE analysis of the loads on the reactor vessel and internals due to a line break in the sacrificial shield annulus. Part of that work also includes computation of forces and moments for the RPV pedestal, RPV anchor bolts, and stabilizer truss. For these components, Sargent & Lundy used the larger of the stresses computed from their analysis or the GE analysis. This procedure has been incorporated in Revision 2 to SL-3647, dated March 14, 1980 (Reference 18).

The conclusion of Reference 18 states that the existing design of the sacrificial shield, reactor pedestal, stabilizer truss, RPV, and shield anchor bolts can safely accommodate the effects of annulus pressurization resulting from a postulated safe-end break.

6.2.1.3.8.2 Summary of Study

A study was performed in 1973 using state-of-the-art methods. A detailed report of that study was filed with the AEC in response to Open Item No. 12 and Question 12.4, Amendment 11 of the PSAR (Refer to Reference 15 in Section 3.8). During the review of the original FSAR, the NRC questioned whether certain aspects of the model used to predict the pressure distribution were adequately conservative and requested that the calculation be repeated using models currently available.

The recalculation was broken down into three tasks: calculation of mass energy release, calculation of annulus pressure distribution history, and the structural design assessment.

Mass Energy Release

This task was performed using a method developed by GE. The method assumes that the initial fluid velocity is zero. After the break, a finite time is required to accelerate the fluid to steady-state velocities; this is called the inventory period. The flow rate during this period is computed by two methods; one includes the effect of inventory and subcooling on flow in the pipe, the other accounts for the finite break opening time. The smaller of the two flow rates at any time is used. Both methods produce maximum flow rates based on different limiting areas. The transfer from one curve to the other represents a change in the point where the flow is choked. Following the inventory period, the flow is assumed to be choked at the limiting cross-sectional flow area. Mass flux is calculated using the Moody steady-slip flow model with subcooling. Results of this calculation are in Reference 20.

Annulus Pressurization

The computation of pressure distribution in the annulus following these breaks was based on the use of the computer code COMPARE. The model for Fermi 2 used 42 nodes in the annulus and four nodes in the drywell. The analysis considered movement of insulation at penetrations and the resulting venting of fluid to the drywell. The code was modified to account for variable junction area as a function of time. A Moody multiplier of 0.6 was used for all junctions except that from the break to the annulus, where 1.0 was used. All junctions had an inertia term, and sub-critical flow was calculated on the basis of a solution to the momentum equation with constant density. Reference 20 is the report of this work.

Structural Design Assessment

The structure was analyzed using the Sargent & Lundy thin-shell- of-revolution computer code, DYMAX. The Fermi 2 model for this study consisted of 76 nodes. Reference 18 is the report of this work.

The loads included in the study were:

a. Annulus pressurization

b. Jet impingement

c. Pipe-whip reaction

d. Dead load

e. Thermal effect due to accident

f. Seismic effect due to operating-basis earthquake (OBE) and safe-shutdown earthquake (SSE).

The structural components assessed were:

a. Sacrificial shield

b. Reactor pedestal

c. Stabilizer truss

d. Reactor anchor bolts

e. Sacrificial shield anchor bolts.

6.2.1.4 Inspection and Testing

6.2.1.4.1 Primary Containment

The Fermi 2 containment has been designed and constructed as a Class B vessel in compliance with Section III of the ASME Code, 1968 Edition, including the Summer 1969 Addenda. The containment vent system and suppression shell, supports, internals, and attachments have also been reevaluated (References 9 and 10) to include the hydrodynamic loading events and analysis methods defined by GE Topical Report NEDO-21888 (Mark I Containment Program Load Definition Report) and the NRC Safety Evaluation Report, NUREG-0661. The appropriate edition of Section III of the ASME Code and service-level limits specified in NUREG-0661 have been applied in the reevaluation. All inspections and tests prescribed by these editions of the Code have been successfully completed.

Containment boundary integrity has been verified during the construction of the Fermi 2 plant using the reference-vessel method. This method involves measuring the pressure differential between the containment vessel and a reference system of copper vessels that are interconnected with copper tubing and located in the upper and lower portions of the drywell and in the suppression chamber. This initial test, begun March 3, 1973, was performed in accordance with 10 CFR 50, Appendix J, and ANSI N45.4-1972, "Leakage Rate Testing of Containment Structures for Nuclear Reactors." The leak rate was determined to be 0.079 ±0.035 percent per 24 hr at 56 psig.

A preoperational, integrated leak-rate test using the absolute method was performed at the peak containment pressure calculated from DBA considerations in accordance with 10 CFR 50, Appendix J. This integrated leak-rate test was a Type A test. The test was conducted over a minimum of 8 hr with at least 20 value data points.

Type A tests will be performed periodically throughout the life of the plant in accordance with Fermi 2 Technical Specifications.

Permanently installed piping penetrations are provided through the containment structure for both the compressor system and the pressure-indication piping required for the Type A tests. An electrical penetration is provided for the leads to the temperature instrumentation in the containment.

Containment atmosphere-circulation fans are operable during the elevated-pressure conditions of the Type A tests to minimize local variations in temperature and humidity.

Personnel entry into the containment is not required during the Type A tests. Therefore, no provisions have been made for this kind of activity.

6.2.1.4.1.1 Penetrations

Airlock doors, access hatches, and the drywell head are equipped with double seals and instrument taps which permit pressurization of the space between them to verify seal integrity.

Piping penetrations with bellows seals which allow relative movement between pipe and containment wall are provided with double bellows and a space between them which can be pressurized. These penetrations are equipped with test fittings necessary to facilitate pressurization and testing of the penetration boundaries without pressurizing the entire containment.

Electrical penetrations are equipped with double seals and test connections and are capable of being tested at containment design pressure without pressurization of the containment.

6.2.1.4.1.2 Isolation Valves

Tests will be performed on isolation valves including reactor-building-to-torus vacuum breakers to verify their operability, pressure boundary integrity, and seat-and-stem leaktightness. Design provisions have been made when possible to accommodate the specific leak-test requirements of 10 CFR 50, Appendix J, Type C tests. Alternative methods are used where necessary and technically justifiable. The alternative methods are identified and discussed in Table 6.2-2.

Edison performed opening force tests on the Fermi 2 vacuum breakers during preoperational testing and will include these tests in the inservice testing. With the valve air cylinder properly adjusted using a predetermined air pressure, the pallet will close smoothly, without banging, in 2 to 5 sec. The closing time of the pallet is measured and set as part of the normal valve inspection and adjustment during refueling. This testing, along with the opening force measurement, provides assurance that the pallet is not binding and the valve will open with the proper opening time.

6.2.1.4.1.3 Pressure Suppression System

Drywell-to-suppression-chamber gross-leak tests will be conducted periodically as defined in the Technical Specifications to ensure that bypass of the pressure suppression feature of the containment has not developed. The test will be based on determination of the rate of change of pressure in the suppression chamber and drywell at a drywell-to-suppression-chamber differential pressure of 1 psi. In addition, individual drywell-to-torus vacuum breakers will be inspected and their position-switch setting will be verified. During plant operation, these valves will be periodically exercised to verify the operability of the valve and the closed-position instrumentation. These tests are documented in the Technical Specifications.

6.2.1.4.1.4 Test Frequencies

Test frequencies for the Type A test will be in accordance with Fermi 2 Technical Specifications. Type B and C test frequencies are based on the requirements of 10 CFR 50, Appendix J, Option B.

Data, data reduction, and test acceptability requirements for all tests are described in ANSI/ANS 56.8-2002 or other alternative testing methods that have been approved by the NRC and are based on the requirements of 10 CFR 50, Appendix J, Option B.

If the result of any test indicates that leakage exceeds the limits established in the Technical Specifications, repairs shall be made and a retest performed. In addition, for unsuccessful Type A tests, the provisions of 10 CFR 50, Appendix J, Option B, shall apply.

6.2.1.4.2 Secondary Containment

The reactor building leakage rate may be tested by complete isolation of the building except for the effluent from the SGTS. The SGTS is placed in operation and the system will maintain a constant flow. The building inleakage is small enough to ensure that the building negative pressure exceeds the value required by the Technical Specifications. The rate at which air is exhausted through the system is an accurate measure of building inleakage.

Visual inspection of reactor building penetrations will be possible. Penetration leakage is determined as a part of the gross reactor building inleakage as discussed above.

Frequency of these tests and inspections as defined in the Technical Specifications is based upon expected lifetime of the various seals, components, and penetrations and anticipated failure modes. The test and inspection schedule is intended to ensure that gross failures do not occur and that such failures, should they occur, are discovered and corrected within a reasonable time.

6.2.1.5 Instrumentation

6.2.1.5.1 Primary Containment

The primary containment monitoring system is designed to make available to the plant operators sufficient information to permit normal operation, to assist the operator in assessing the consequences of an accident or an incident, and to determine the effectiveness of control actions taken to mitigate the effects of the postulated event.

Functions of the primary containment monitoring system include multipoint measurement and recording of hydrogen and oxygen concentrations, gaseous radiation levels, pressure, temperatures, and water levels in the drywell and pressure suppression chamber. Suppression chamber water temperatures and drywell vessel wall and atmospheric temperatures are also measured and recorded. This system provides information for operator control of suppression pool cooling. Details of the primary containment monitoring system, its subsystems, sensors, and logic are described in Subsections 7.1.2 and 7.6.1.

Radiation monitors and pressure transmitters and the logic associated with the initiation of primary containment isolation as well as actuation of the ECCS and other engineered safety feature (ESF) systems are described in Subsections 7.1.2 and 7.3.2. The primary containment high-range radiation monitors are discussed in Subsection 11.4.3.

6.2.1.5.2 Secondary Containment

Secondary containment pressure is normally controlled by the reactor/auxiliary building ventilation system. Pressure sensors outside the building are arranged so that the lowest pressure on the building (due to wind) is compared with the building internal pressure which is maintained at 0.25 in. of water below the lowest outside pressure. The building fans are shut down in the event that a differential pressure of approximately ±2 in. occurs. Time-delay relays prevent spurious shutdown of the ventilation system caused by wind gusts.

The secondary containment is isolated on the same signals that actuate the SGTS; i.e., high drywell pressure, level 2 low reactor water level, reactor building ventilation exhaust radioactivity high, fuel pool area ventilation exhaust radioactivity high, or a manual pushbutton in the control room.

The SGTS is also actuated, and the secondary containment isolated, upon Loss of Offsite Power (LOOP). A LOOP causes a failure of the radiation monitors located in the reactor building ventilation exhaust system and in the fuel pool ventilation exhaust system which initiates a downscale trip signal. The radiation monitors' downscale trip signal isolates the reactor building ventilation (RBHVAC) exhaust system and initiates the SGTS system.

The systems whose signals initiate secondary containment isolation are discussed in Subsections 7.3.2 and 7.6.1.

6.2.1.6 Materials

Organic materials used in the Fermi 2 primary and secondary containments have been selected for extended life during normal operation and for resistance to expected accident environmental conditions. Thermal insulations used are inorganic and are not sensitive to high radiation fields, steam, or high temperature.

Table 6.2-8 lists the type of protective coatings used, their thicknesses, and their locations within the primary and secondary containments.

Table 6.2-9 lists organic materials used for wiring insulation in the primary and secondary containments.

Table 6.2-10 lists other organic materials of significant quantity and the amounts used in the primary and secondary containments.

Evaluations of these materials have been made. It has been determined that they will satisfactorily endure accident environmental conditions and that their expected products of decomposition, if any, will not adversely affect the operability of any ESF system.

The following paragraphs describe the coatings and paint used within the primary containment, including pertinent information regarding the following:

a. Identification of material used, location, and function

b. Physical and chemical characteristics

c. Performance under accident conditions including washdown, radiation, steam, temperature, and jet impingement effects

d. Data on effect of any coating material that may be dissolved or carried by the fluids that flow in the spray systems of the ECCS that may affect the functioning of the systems

e. Effect of coating on core and heat exchanger heat-transfer surfaces

f. Clogging and other effects on fluid flows in Class 1 systems from coatings.

Additional information is available in Reference 21.

<u>Reactor Vessel Support Pedestal</u>

The inside and outside surfaces of the reactor vessel support pedestal are coated with Ameron Nu-klad surfacer 110 AA primer and one finish coat of Ameron polyamide epoxy 66. Damaged areas of Ameron Nu-klad 110 AA are repaired with Ameron Nu-klad 111. The function of this coating system is to protect and seal the pedestal surfaces against attack by either demineralized (aggressive) water or radiation contamination and to facilitate washdown.

The physical and chemical characteristics of the Ameron Nu-klad surfacer 110 AA primer are excellent adhesion to clean concrete and good adhesion to steel, resistance to attack by demineralized water or hot condensate, excellent abrasion resistance, considerable radiation resistance, excellent chemical resistance, and indefinite repairability. Both primer and finish are modified epoxy. Ameron polyamide epoxy 66 has properties similar to those of the primer. Both coatings withstand temperatures to 200°F continuously and to 300°F intermittently.

Required DBA testing has been performed, and the coating system is capable of withstanding the rigors of a LOCA. A washdown removes contamination.

The coating effect on the core and heat-transfer surfaces is negligible because the coating system is nonleachable.

No clogging or other effects on fluid flow in Class 1 systems are expected since the coating is nonleachable and has excellent adhesion.

The Ameron 66 top coat has been applied in accordance with the recommendations of Regulatory Guide 1.54 and ANSI N101.4 and the coating system has met the pull-test requirements of ANSI N5.12. The coating of the reactor vessel support pedestal and other concrete surfaces of the drywell have been designated as a QA Level 1, safety-related activity. The coating system as described above is a qualified coating.

Drywell Concrete Floors and Walls

The concrete surfaces of the drywell floors and walls are coated with Ameron Nu-klad surfacer 110 AA primer and a top coat of Ameron polyamide epoxy 66. The function, physical and chemical characteristics, and other properties of this coating are discussed under "Reactor Vessel Support Pedestal" above.

Sacrificial Shield Wall

The exterior surface of the sacrificial shield is coated with Carboline Carbozinc 11 and repaired with Carboline Carbozinc 11 SG. This is a self-curing, zinc-filled, inorganic, two-part basic zinc silicate complex that readily accepts top coats. The function of this coating is to provide long-term protection against corrosion, attack by radiation or radioactive water, and to facilitate washdown.

The physical characteristics are a hard surface resistant to aggressive water, very good impact resistance, and a temperature use range up to 750°F continuous and 800°F intermittent. Flexibility is fair. Chemical characteristics are insolubility in water and resistance to aggressive water and solvents. Relatively wide application temperatures (0-200°F) and humidity ranges (to 95 percent) are permissible.

Contaminants on the coated surface can be easily washed down with water. The coating has high radiation resistance, resists steam to 180°F, and has excellent temperature resistance up to 750°F.

The coating has no effect on core heat transfer or heat exchanger heat-transfer surfaces since it is not soluble.

Carbozinc 11 and Carbozinc 11 SG coatings have been subjected to extensive DBA testing for a variety of application techniques and were found acceptable for use in BWR environments under LOCA conditions.

Report DECO 12 2191 notes that some particle separation could occur under accident conditions in areas subjected to continuous scouring by water and steam spray. Such scouring would occur only in the immediate vicinity of a pipe break. In such areas, the coating is not lost in large flakes, however, but rather in particles less than 20 microns in size. ECCS suction strainer head loss calculations include the recommended Utility Resolution Guidance (NEDO-32686) for qualified paint assumed to degrade from a direct steam jet impingement.

Most of the initial Carbozinc 11 coatings in the primary containment were applied in accordance with the original 1969 specification, prior to the issuance of Regulatory Guide 1.54 and ANSI N101.4. The industry standard at that time was to apply Carbozinc 11 in accordance with the manufacturer's recommendations. This type of coating has been successfully used in operating BWRs and for years has withstood a variety of adverse conditions.

In 1984, the commercial name of the Carbozinc 11 coating was changed to Carbozinc 11 SG. Consequently, in cases where repairs to the original Carbozinc 11 coating were needed after 1984, Carbozinc 11 SG was used.

Drywell Interior Steel

All exposed interior surfaces of the drywell pressure boundary, including the drywell jet deflectors and surfaces in contact with concrete, are coated with Carboline Carbozinc 11 and repaired with Carbozinc 11 SG. The function of this coating system is to protect the surfaces from corrosion, from attack by aggressive water, radioactive water, or radiation, and to facilitate washdown.

Those coatings which cover the drywell pressure boundary are maintained under Fermi 2 QA Level I criteria to ensure long-term corrosion protection for the pressure boundary. This coating is not considered to be in full compliance with ANSI N101.4.

Drywell Interior Structural Steel

The primary structural steel within the drywell is coated with Carboline Carbozinc 11 and repaired with Carboline Carbozinc 11 SG. The purpose of the coating is to provide long-term protection against corrosion and to facilitate washdown.

The Drywell dado region was recoated with Carboline Carboguard 890 N, and is classified as an acceptable coating (as defined in ASTM D4538).

Substantial modifications were made to the primary structural members in two separate phases due to load reevaluations that resulted in varying degrees of surface preparation. Welding and nondestructive examination procedures necessitated removing existing coatings at tie-ins and welded connections. Due to completed installation of equipment, generally very tight working quarters, and complex components placement, sandblasting and recoating of steel members were not routinely completed.

Surfaces of Suppression Chamber

The interior surfaces of the suppression chamber, including the exterior surfaces of the downcomers and vent header, the exterior surfaces of the vent pipes, vent header supports, ring girders, catwalks, monorail, stiffeners, supporting steel, piping, hangers, and penetration nozzles, are coated with the Wisconsin Protective Coating Plasite 7155 system above elevation 558’-2” and with the Carboline Carboguard 6250 N system below elevation 558’-2”. The Carboguard coating overlaps the Plasite coating at the intersection of the coatings. The interior surface of the downcomers is coated with Plasite 7155. The Plasite coating is a water-resistant phenolic coating cross-linked with epoxy resin and polymerized with an alkaline curing agent. The Carboguard coating is a solventless epoxy novolac coating designed to handle exposures inside nuclear containment facilities. The function of these coatings is to provide long-term protection from corrosion and radiation, and to facilitate washdown.

These coatings resist temperatures up to 400°F intermittently, develop good hardness and abrasion resistance, can withstand cyclic thermal shock, and provide a broad range of long-term chemical resistance.

The Plasite coating was applied in accordance with Regulatory Guide 1.54, ANSI N101.4, meets pull-test requirements of ANSI N5.12, Section 6.4, has been DBA tested, and is considered a fully qualified coating capable of withstanding accident conditions. Its application is a safety-related, QA Level 1 activity.

The Carboguard tie-in band that overlaps the Plasite coating is considered unqualified. There are additional minor areas in the wetwell with unqualified Carboguard coating. The unqualified coatings are tracked as indicated in Table 6.2-8. The unqualified coating amounts have been evaluated and are within established limits for unqualified coatings inside containment. The remainder of the Carboguard 6250 N coating is in accordance with Regulatory Guide 1.54 and ANSI N101.4 except that later ASTM standards endorsed by Revision 2 of Regulatory Guide 1.54 were used for test panel preparation, radiation qualification testing, chemical resistance qualification testing, and test panel evaluation. The coating, except for the tie-in band, is considered a fully qualified coating capable of withstanding accident conditions. Its application is a safety-related, QA Level 1 activity.

The interior surface of the vents from the drywell shell down to a transition point approximately 20 in. from the vent header is coated with Carboline Carbozinc 11 SG coating system. The remainder of the interior surface of the vents (from the transition point to the vent header) and the interior of the vent header are coated with a qualified Carboline Carboguard 6250 N coating system. A small qualified overlap band of Carboguard 6250 N over Carbozinc 11 SG exists at the transition point between the two coating systems. The interior surface of the vacuum breaker extensions and downcomers are coated with Plasite 7155 coating system described above in this section. The Carboline Carboguard 6250 N coating overlaps the Plasite 7155 coating on the inside surface of each downcomer and vacuum breaker penetration in the vent header. The Carboguard 6250 N coating in this overlap band is classified as an acceptable coating (as defined in ASTM D4538).

Touch-up repairs to the suppression chamber interior coating under submerged or dry conditions are made using compatible safety-related coatings complying with the original requirements and standards.

<u>Miscellaneous Coatings</u>

Coatings on miscellaneous equipment and components in the drywell are discussed below. These coatings were included in the evaluation of the Fermi 2 primary containment coatings, and will not impair plant operation under normal or abnormal conditions.

a. Galvanized Surfaces

   The drywell cooling system ducting and dampers are completely galvanized without any further coatings. At welded joints, the galvanized surface was ground off to clean metal, and in some locations these ground areas were touched up with Galvanox I or Galvanox V, zinc-rich coatings similar in properties to Carboline Carbozinc 11. In addition, all electrical conduit, terminal boxes, cable trays, and supporting unistruts are galvanized. The only exceptions are some large flexible conduits made of stainless steel

b. Hangers and Supports

   Hanger and support components, including clamps, rods, spring cans, snubber attachments, pipe-whip restraint components, and secondary support steel, were originally coated with Carboline Carbozinc 11. Significant changes in the hanger and support design resulted in addition of secondary support steel, change-out of hanger components, and welding of attachments. Coating repair and touch-up of these areas is not safety related

c. Piping

Most of the piping within the drywell is insulated with reflective metallic insulation panels (Mirror Insulation), consisting of removable sections and having an outer cover of stainless steel. Encapsulated NUKON or encapsulated silicon (Min-K) is used where clearance restrictions exist, i.e., drywell penetrations and spaces between pipe whip restraints and pipe. Normally, cold fluid system piping is not insulated or coated. The uninsulated carbon steel piping was shop coated with a protective varnish. Tight mill scale and some rust is apparent on the piping surfaces. The varnish and mill scale are considered unqualified coatings

d. Unidentified and Unqualified Coatings

These coatings consist largely of manufacturer's shop coatings and primers such as red lead, aluminum base, enamels, polymer, and phenolic paints. These coatings are present on valve bodies, yokes and bonnets, motor and air operators, handwheels, electric motors, etc. Another category of unqualified coatings consists of identification marking and banding of electrical conduit, terminal boxes, and trays.

Coatings of this category that have thicknesses of 3 mils or less are postulated to fail in small particles and will not clog strainers.

Unqualified coatings greater than 3 mils DFT have either been removed, and the surfaces have been recoated with Carbozinc 11 where appropriate (see Reference 21 for additional information); or have been evaluated for use in the primary containment. Design calculations have been prepared to evaluate the addition of materials to the primary containment. These are updated as necessary as part of the plant’s response to NRC Generic Letter 98-04.

6.2.2 Primary Containment Heat Removal System

6.2.2.1 Design Bases

Containment heat removal is provided by operating the RHR system in the suppression pool cooling mode or the containment spray mode. The system meets the following safety design bases:

a. The source of coolant inventory shall be located within the containment so as to establish a closed cooling water path

b. A closed-loop flow path between the suppression pool and the RHR heat exchangers shall be established so that the heat-removal capability of these heat exchangers can be utilized

c. This system, in conjunction with other ESF systems, shall have diversity and redundancy such that no single failure can result in its inability to cool the containment adequately

d. Each active component shall be testable during operation of the nuclear system. Testing is described in Section 5.5.7.5.

6.2.2.2 System Design

The containment cooling subsystem is an integral part of the RHR system, as described in Subsection 5.5.7. Redundancy is achieved by having two complete containment cooling systems.

Consideration of the fouling of heat exchangers and the selection of temperatures for heat exchanger design is discussed in Subsection 5.5.7.

6.2.2.3 Design Evaluation

The discussion in this subsection has been updated for power uprate conditions.

In the event of the postulated LOCA, the short-term energy release from the reactor primary system will be dumped to the suppression pool. Subsequent to the accident, fission product decay heat will result in a continuing energy dump to the pool. Unless this energy is removed from the containment system, it will eventually result in unacceptable suppression pool temperatures and containment pressures. The containment cooling mode of the RHR system is used to remove heat from the suppression pool, the suppression chamber, and the drywell.

When the RHR system is in the containment cooling mode, the pumps draw water from the suppression pool, pass it through the RHR heat exchangers, and inject it back into the suppression pool or into the containment via sprays.

The adequacy of the RHR system has been evaluated considering, two sequences of events with different assumed single active failures. Both scenarios assume the occurrence of a LOCA coincident with a loss of offsite power with the reactor initially at maximum power. The original licensing and design basis scenario assumes a loss of offsite power occurs and the single failure of one divisional power supply for the duration of the accident. Immediately following the accident, the ECCS initiates automatically as designed in response to the accident initiation signals.

Under the original scenario, due to the assumed loss of offsite power and one division of onsite power, two core spray pumps and two RHR pumps will be operating. (Section 6.3 describes the ECCS equipment.) Twenty minutes later the plant operators activate one RHR heat exchanger in order to start containment heat removal. This involves shutting down one of the two LPCI pumps and starting up the service water pumps for the heat exchanger. Once containment cooling has been established (including RHR cooling towers), no further operator actions are required.

Subsequent to the original plant analysis it was determined that a single failure of an RHRSW isolation valve to open would result in the same available suppression pool cooling capability (namely one RHR heat exchanger) but would result in additional operating ECCS pumps – four RHR pumps and four core spray pumps; thus, resulting in additional ECCS pump heat to the suppression pool. Consistent with the original containment analysis, this scenario assumes plant operators activate the remaining operable RHR heat exchanger and the associated division of the Ultimate Heat Sink [See Section 9.2.5] twenty minutes after the initiating event.

The evaluations of both scenarios use the SUPERHEX (SHEX) code to calculate the long-term containment response for Fermi 2 with power uprate (Reference 22). SUPERHEX evolved from two previously approved codes (Reference 14 and 15) and was shown to give equivalent pool temperature response to the predecessor code. The long-term analysis for Fermi 2 with the SUPERHEX computer code using conservative inputs yields a peak post DBA/LOCA pool temperature of 196.5°F. This temperature shows margin remains to the controlling limit of 198°F which comes from NPSH requirement for pumps taking suction from the suppression pool with no credit for containment pressure per Regulatory Guide 1.1.

The input parameters used for SUPERHEX for the long-term containment response analyses for Fermi 2 with power uprate are identified in Table 6.2-1.

Service Water Temperature

The original containment analysis used a constant RHR service water (RHRSW) temperature of 90°F which is the maximum design cooling tower outlet temperature. The Technical Specifications prohibit operation with the cooling tower reservoir temperature above 80°F. An energy balance calculation was used to determine the post LOCA RHRSW temperature increase as a function of time from the initial condition of 80°F to the cooling tower maximum design temperature of 90°F. The temperature profile, which is non-linear, was conservatively bounded by a linear profile which was used in the containment analysis (Table 6.2-1). The following are the important assumptions used in the energy balance. (Note: The current maximum analyzed service water supply temperature is below the assumed maximum 90°F).

a. The maximum Technical Specification reservoir temperature of 80°F was used as an initial condition.

b. The maximum design cooling tower outlet temperature of 90°F was used.

c. The minimum Technical Specification RHR reservoir water level was used. This is conservative because it minimizes the heat capacity of the reservoir and maximizes the reservoir heatup.

d. Evaporative and drift losses were used to reduce reservoir inventory during the heatup period.

e. Complete mixing was assumed in the reservoir. This is conservative because hot water is discharged into the cooling towers and is sprayed down to the surface of the reservoir. Cooler water is drawn from the bottom of the reservoir where the pump suctions are located. No credit was taken for temperature stratification which would have lowered the reservoir discharge temperature profile.

Suppression Pool Volume

The initial suppression pool volume used for the power uprate long-term containment analysis was 117,161 ft^3 which is less than the pool volume of 121,080 ft^3 that corresponds to the Technical Specification minimum value. The lower pool volume of 117,161 ft^3 adds conservatism to the calculated pool temperature since a lower initial pool volume results in higher calculated values for pool temperature.

Initial Pool Temperature

The initial pool temperature for the containment analysis was set at 95°F which is the Technical Specification limit for normal operation.

Feedwater Addition

All water in the feedwater system which could contribute to higher calculated pool temperatures was added to the RPV and containment system for the power uprate analysis. This was achieved by adding all feedwater which is in the feedwater system during normal operation that has a temperature greater than the maximum expected pool temperature. This translates to all feedwater through Feedwater Heaters Nos. 3, 4, 5, and 6.

In addition, a conservative calculation of the energy in the feedwater piping is added to the RPV/containment system. This water mass and energy addition assures that the pool temperature calculation conservatively reflects the effect of feedwater addition on suppression pool temperature.

Initiation Time for Containment Cooling

The long-term containment response analysis has assumed that the containment cooling is initiated at twenty minutes.

Decay Heat

The original analysis identified decay heat values used for the long-term containment analysis which correspond to the May-Witt decay heat model values after 60 seconds. For the power uprate analysis a more realistic decay heat has been included. This decay heat is based on the ANS 5.1 model (Reference 16) and is described in Appendix B of Reference 17. This decay heat includes contributions due to fission heat induced by delayed neutrons, decay heat from fission products, decay heat from actinides (heavy elements), and decay heat from irradiated structural materials. For conservatism additional margin which corresponds to two standard deviations (10%) was added on the decay heat as described in Reference 17, Appendix B, for the Fermi 2 long-term containment power uprate analysis.

Suppression Pool Temperature Response

The suppression pool temperature response has also been evaluated following several other plant transient events in which steam is discharged to the suppression pool. General Electric Report NEDC-24388-P (Reference 23) describes transient events, the assumed RHR system modes of operation, and the predicted pool temperature results. The report concludes that the peak pool temperatures in the vicinity of SRV discharge quencher devices are below the limit established to ensure stable steam condensation.

6.2.2.4 Testing and Inspections

The preoperational and operational testing and the periodic inspection of components of the containment heat removal system are described in Subsection 5.5.7.5.

6.2.2.5 Instrumentation Requirements

The containment spray and the suppression pool cooling modes of the RHR system are manually initiated. Once initiated, containment cooling performance is monitored by monitoring pump performance, flow and pressure, and coolant temperature.

6.2.2.6 Materials

Materials used are reviewed and evaluated with regard to radiolytic and pyrolytic decomposition and attendant effects on safe operation of the system. For example, fluorocarbon plastic (Teflon) is not permitted in environments that attain temperatures greater than 300°F, or radiation exposures above 10^4 rads. Only inorganic thermal insulation, which does not decompose due to radiation or temperature, is used in these environments. An inorganic zinc primer is used on all exterior surfaces of carbon steel components that are treated. All paints used are suitable for the temperature conditions expected.

6.2.3 Secondary Containment Air Purification and Cleanup System

The SGTS is designed to minimize the release-related offsite dose rates by permitting the venting and purging of both the primary and the secondary containment atmospheres under accident or abnormal conditions, and at the same time containing any airborne particulate or halogen contamination that might be present.

6.2.3.1 Design Bases

Under postaccident conditions, it is possible that the primary containment atmosphere could become contaminated with radioactive particulates and halogens. Any air from this volume finding its way to the secondary containment is therefore likely to be similarly contaminated. The SGTS is designed to permit controlled ventilation of this area by maintaining it under slightly negative pressure with respect to the outside atmosphere to ensure that any air leaving is filtered to remove particulates and halogens. The system is also capable of filtering gases exhausted from the primary containment and the HPCI barometric condenser. The system is designed to function under postaccident conditions of high radiation levels, temperatures, and relative humidity.

The SGTS flow rate is sufficient to provide a secondary containment air volume change at least once per day and to maintain the reactor building at approximately negative 1/4-in. water pressure for accident and abnormal conditions.

Particulate- and halogen-removal capability permits venting of the primary and secondary containment volumes following an accident while maintaining offsite dose rates well within the guidelines set by 10 CFR 100. For those design basis accidents reanalyzed per Regulatory Guide 1.183, SGTS limits offsite dose within the limits of 10 CFR 50.67.

The SGTS is designed to operate with influent air temperatures up to 135°F and relative humidity up to 100 percent. The system is periodically tested such that a decontamination efficiency of 99 percent can be assumed for removal of all forms of gaseous and particulate iodine. System retention capacity, originally based on the requirements of Regulatory Guide 1.3 and TID-14844, and amounts of up to 1300 gm (Reference 24), is currently evaluated against the 2.5 mg/g Regulatory Guide 1.52 limit for 30-day post-accident iodine accumulation based on the Regulatory Guide 1.183 Alternative Source Term. (Reference 26)

The SGTS is a Quality Level I, Category I ESF system meeting all applicable portions of IEEE 344; IEEE 308; ORNL-NSIC 65; UC-80 Reactor Technology, "Design, Construction and Testing of High Efficiency Air Filtration Systems for Nuclear Application;" ASME B&PV Code Section IX, "Welding Qualifications" (1971); Air Moving and Conditioning Association (AMCA), "Standard Test Code for Air Moving Devices" and "Standards Handbook;" and Savannah River Laboratory Report DP-812, "Application of Moisture Separators and Particulate Filters in Reactor Containment."

The SGTS meets the intent and functional objective requirements of Regulatory Guide 1.52. Some detail design requirements of this guide, however, are not met because system fabrication was commenced before the guide was issued. All areas of noncompliance have been reviewed and in each case it has been determined that design and hardware changes required to bring these areas into compliance would not improve the system performance or capability to meet the design objectives. (See Appendix A, Subsection A.1.52.)

6.2.3.2 System Design

The SGTS is a 100 percent-redundant ESF system and is shown schematically in Figure 6.2-20. Major system components are listed and briefly described in Table 6.2-11. The system is designed to meet reactor building containment tests.

The SGTS consists of two separate and parallel 100 percent capacity trains. In addition to its associated ducts, controls, instrumentation, isolation valves, and protection systems, each train consists of the following items listed sequentially and in the direction of air flow:

a. A moisture separator to remove entrained water droplets, thus minimizing water loading of the prefilter. The moisture separator meets design requirements specified in Savannah River Laboratory Report DP-812

b. A prefilter to reduce the loading on the absolute filter. The prefilter is fire resistant and capable of operation at temperatures up to 250°F

c. An electric heater to reduce the relative humidity of the influent air to 70 percent or less under the "worstcase" conditions

d. A high-efficiency particulate air (HEPA) filter with a design DOP filtration efficiency of 99.97 percent for particles 0.3 μm in diameter or larger. Four parallel filter elements, each rated at 1000 scfm, are provided. These elements meet the intent of Military Specification MIL-F-51068-C. They are Underwriters Laboratories (UL) approved, fire resistant, and suitable for service under the temperatures, mass, and heat loading expected. The filters are mounted and sealed in a welded steel frame to ensure against possible bypass flow. The filters are tested periodically for bypass leakage such that a 99 percent decontamination efficiency can be assumed for removal of particulate iodine

e. A deep-bed, gasketless, all-welded construction adsorber containing activated carbon

f. A HEPA filter identical to the one described above to trap charcoal fines and decay daughters entrained by the air stream

g. An exhaust fan designed for 4000 ft^3/minute

h. A cooling air fan installed in parallel with the exhaust fan, designed and built to the same standards and codes as the exhaust fan. The purpose of this blower is to provide cooling air flow to the charcoal filter in order to maintain charcoal temperature below 310°F under design loading conditions, in the event of high charcoal adsorber bed temperature.

Piping connections and valving exist between the SGTS and the secondary containment building ventilation system, the primary containment drywell, the suppression chamber, and the HPCI turbine barometric condenser vacuum pump discharge.

When the cooling air fan is in use, suction is taken from a roof vent. Discharge under both modes is to a vent located on the reactor building roof.

Full access and interior compartment lights with external light switches are provided for the spaces between filter train components where required to facilitate inspection, testing, and replacement of components.

Injection nozzles, sample points, and pressure taps are provided to facilitate periodic inservice inspection tests.

6.2.3.3 Design Evaluation

6.2.3.3.1 General

The SGTS is designed to permit controlled venting of the primary or secondary containment following an accident or abnormal occurrence which might cause abnormally high airborne contamination in these areas.

Achievement of acceptable offsite dose rates following a DBA depends on the proper functioning of the SGTS. Therefore, the system, along with its power supplies and surrounding structures, has been designed to meet ESF system standards. All necessary equipment and surrounding structures are of Category I design. The equipment is powered from essential buses which will supply power to the SGTS in the event of a loss of offsite power. All power and control circuits meet the requirements of IEEE 279. Redundant active components are provided where necessary to ensure that a single failure does not impair or prevent system operation. An SGTS failure analysis is presented in Table 6.2-12.

The SGTS removal efficiency was successfully tested (Reference 24) for radioactive and nonradioactive forms of iodine and for particulate matter 0.3 mm or larger. The thyroid dose at the site boundary and low-population zone has been calculated on the basis of iodine-removal efficiency of 99 percent. Credit for 99 percent removal efficiency is dependent on in-place testing per Regulatory Guide 1.52, as stated in the Technical Specifications.

6.2.3.3.2 Secondary Containment Pressurization During Design Basis LOCA

The pressure of the secondary containment volume after a LOCA has been studied. The analysis included infiltration and thermal loads from the primary containment, operating equipment, and emergency lighting.

The SGTS is designed to maintain a secondary containment pressure of -0.25 in. of water, thus ensuring that any airborne radioactive material in the secondary containment is not released to the surrounding atmosphere without passing through the SGTS filters. In the event of a design-basis LOCA, loss of offsite power is assumed; consequently, there is a delay from the start of the event to the activation of the SGTS and the emergency area coolers.

During the delay, the secondary containment pressure increases because of heat generated by emergency equipment and other sources. Upon initiation of the SGTS and emergency area coolers, a short time is required to reduce the secondary containment pressure to a negative pressure at or below -0.25 in. of water.

The purpose of the calculation was to generate the secondary containment pressure response during a design-basis LOCA and to determine the period of time when the secondary containment pressure is above -0.25 in. of water. The method of analysis and the assumptions and results are described in the following paragraphs.

Method of Analysis and Assumptions

The computer code GOTHIC (Reference 25) was used to generate the secondary containment pressure response.

All major assumptions are given below:

a. No credit was taken for exfiltration from the secondary containment

b. Infiltration to the secondary containment was included in the pressure response analysis

c. No heat transfer was allowed to the outdoor atmosphere

d. Heat transfer to interior secondary containment walls, floors, and ceilings was included

e. Heat transfer from the torus room to the secondary containment is based on flow through the pressure relieving doors in the corner room basement walls

f. Only one SGTS filter train is available with a minimum volumetric flow rate of 3800 cfm

g. Offsite power is lost at the start of the design-basis LOCA event

h. The activation of the SGTS is delayed by 33 sec and the activation of the emergency area coolers is delayed by 38 sec (see Table 8.3-5)

i. The RHR, core spray, and RCIC pump rooms in the reactor building subbasement are treated separately from the main secondary containment volume. These rooms have their own emergency coolers to handle emergency equipment and lighting heat loads. Because the heat loads and cooling are confined to partially enclosed volumes at the very bottom of the secondary containment, the area coolers will absorb the heat loads within the confines of the corner rooms

j. The heat loads from the RHR, core spray, and RCIC pump rooms will not affect the main secondary containment volume before the initiation of the area coolers. The RHR pumps are activated 13 sec after the start of the design-basis LOCA event (see Table 8.3-5). The emergency coolers are activated at 38 sec. For the heat loads to affect the main volume, the pumps, piping, and subsequently the corner room atmospheres must heat up. After the corner room atmospheres have heated up, the only mode of heat transfer to the main volume is natural convection. Considering that natural convection is a rather slow process, no significant heat transfer to the main secondary containment volume from the corner rooms is expected during the 25 sec from the initiation of the RHR pumps to the initiation of emergency cooling

k. An outdoor temperature of 95°F was used in the analysis

l. The reactor building closed cooling water system is inoperable and both divisions of the emergency equipment cooling water system are operating

m. All ECCS equipment starts

n. The fuel pool cooling and cleanup system, the reactor water cleanup system, and the recirculation pump motor-generator set cooling system are shut down

o. The fuel pool is at an operating temperature of 125°F.

   Any increase in fuel pool temperature in the range of 125°F to 130°F will have negligible effects on the results of the analysis

p. An initial secondary containment pressure of 0.0 in. water gage was assumed.

<u>Results</u>

The secondary containment response due to a design-basis LOCA is shown in Figure 6.2-21. During the first 33 sec, the pressure increases to a slightly positive value. With the activation of the SGTS at 33 sec and the activation of the area coolers at 38 sec, the pressure decreases slightly.

At approximately 50 seconds, pressure-relieving doors on the common wall between the torus room and the corner rooms open and allow heated torus room air to enter the rest of the secondary containment. This step input of heat into the secondary containment appears as a sharp pressure spike in Figure 6.2-21.

The pressure then decreases past -0.25 in. of water to a steady-state secondary containment pressure. Less than 1020 sec elapses from the start of the design-basis LOCA event to the point where the secondary containment pressure decreases to and subsequently stays below -0.25 in. of water. For conservatism, the 1020 sec (17 minutes) is maintained for the LOCA dose assessment (Subsection 15.6.5.5.2).

6.2.3.4 Tests and Inspections

The SGTS and its components are thoroughly tested in a program consisting of the following classifications:

a. Predelivery and component qualification tests

b. Onsite preoperational acceptance tests

c. Operational surveillance tests.

Written test procedures establish acceptance criteria for all test results. Operational test results are recorded and compared with previous performance records, thus enabling early prediction of end of component life and appropriate corrective action.

For the various components of the system, the following predelivery qualification tests were applied:

a. Equipment Train Housing - Leak tests at +20 in. of water internal pressure. Magnetic-particle or liquid-penetrant testing of all welds and discontinuities which could cause bypass leakage around the HEPA filters or adsorber beds

b. Demister - Qualification test or objective evidence to demonstrate compliance with requirements specified in Savannah River Laboratory Report DP-812

c. HEPA Filters - Qualification test to demonstrate a minimum of 99.97 percent efficiency when measured using a 0.3 mm DOP aerosol in conformance with MIL-STD-282

d. HEPA Filter Frames - Soap-bubble leak test across filterless covered bank

e. Adsorber Beds - Available objective evidence demonstrates acceptable flow-pressure characteristics and channeling effects

f. Adsorbent -

   1. Ignition test

   2. Methyl iodide removal test

   3. Hardness test

   4. Impregnant content test.

To demonstrate the integrity of the potassium iodide impregnated charcoal, required factory tests have been performed by the manufacturer prior to acceptance

g. Fans - Fan tests in accordance with the latest revision of AMCA Standard 210, "Air Moving and Conditioning Association Test Code for Air Moving Devices," to establish characteristic curves

h. Prefilter - Objective evidence and certification that NBS efficiency specified is attained

i. Valves, Dampers, and Actuators - Shop tests demonstrating seal effectiveness and ability to perform intended functions under the anticipated conditions.

Onsite preoperational tests for the SGTS are listed in Subsection 14.1.3.2.47.

Onsite periodic testing will be performed. Items such as design conditions of flow, drawdown time, and differential pressure will be verified during these routine tests performed in compliance with the Technical Specifications.

6.2.3.5 Instrumentation and Controls

Each SGTS unit and its controls, power supplies, valves, dampers, and auxiliary equipment are designed and installed so that they are both physically and electrically independent. The system conforms to single-failure criteria outlined in IEEE 279.

A separate control system is provided for each SGTS unit, including all items necessary for control and for determining the status of all components. The SGTS instrumentation is presented in Figure 6.2-20, a brief summary of which is presented below.

Differential pressure indicators are provided to measure the pressure drop across each filter and charcoal bed. Differential pressure switches are provided to signal abnormal conditions.

Each adsorber bed is equipped with the following controls:

a. Charcoal adsorber bed high-temperature-detection temperature element to actuate CO_2 injection

b. Charcoal adsorber bed overheat temperature element to actuate standby cooling fan

c. Charcoal adsorber bed temperature controller to operate dryer (heater).

Fire protection for the adsorber bed is provided by a CO_2 system which is actuated automatically by adsorber bed high temperature. Actuation of the system is signaled in the main control room.

Every isolation valve is supplied with position switches to provide positive indication of valve status.

High-temperature cutouts are provided as an integral part of the single-stage electric heaters. Local temperature indication is provided upstream and downstream of the electric heaters.

Flow signals are transmitted to the main control board for indication and record. The flow transmitter directly controls the flow-control valve.

Manual switches are provided on the main control panel for each fan.

A continuous isokinetic sample is taken from the discharge of the operating filter train and processed through radiation detectors, a particulate filter, and an adsorber bed, and is returned to the SGTS roof vent.

High radiation levels are indicated by audible and visible alarms in the main control room.

The SGTS electrical equipment and instrumentation required to function in a postaccident harsh environment are environmentally qualified and in compliance with NUREG-0588.

When the SGTS filter units are shut down (auto standby mode with no actuation signal), all valves are closed and exhaust fans are deactivated. The charcoal adsorber blanket heater may or may not be on, depending on the charcoal temperature.

Standby cooling fans and associated valves will automatically be activated on high charcoal bed temperature. The system is actuated and put into service automatically in response to any one of the following signals:

a. Auto standby mode

1. High drywell pressure
2. Low reactor water level
3. Reactor building ventilation exhaust radioactivity high
4. Fuel pool area ventilation exhaust radioactivity high.

b. Manual mode.

On actuation in the auto standby mode, both trains are started. The SGTS can be manually started by placing the control switch for the selected train in the run position.

The exhaust fans start, associated isolation valves open, normal reactor building ventilation system is tripped, and valves are automatically realigned to exhaust into the SGTS.

Adsorber-blanket heaters are automatically shut down if they were operating prior to system startup.

Activation of the SGTS in either mode is accompanied by audible and visible alarms in the main control room. The operator would then manually shut down one of the operating trains, leaving the other to perform as intended.

In the event of failure of the operating train for any reason, that train would be shut down and isolated by the operator in the main control room, and the redundant filter train would manually be put into service.

Main control room visible and audible alarms include the following:

a. Both SGTS trains "Auto Start"
b. High relative humidity ahead of charcoal bed
c. Low system flow rate (interlocked with primary blower "Run" signal)
d. High airborne contamination at the roof vent
e. Failure of either train to start up and operate on signal
f. Cooling fan "Auto Start"
g. Carbon dioxide fire protection system actuation.

Functions that can be accomplished manually from the main control room include the following:

a. Startup or shutdown of either or both SGTS trains
b. Startup of alternative SGTS train upon failure of operating train
c. Startup or shutdown of either standby cooling air fan

d. Isolation of SGTS train upon manual shutdown command from main control room.

Automatic functions include the following:

a. Startup of both SGTS trains and proper alignment of isolation valves

b. Activation of adsorber heater on low temperature

c. Startup of standby cooling air fan system when adsorber temperature exceeds its setpoint

d. CO_2 injection on high adsorber bed temperature

e. CO_2 shutoff when adsorber bed temperature is below its setpoint.

6.2.3.6 Materials

Materials for fabrication, coating, and sealing the SGTS are chosen because of their capability for a satisfactory normal service life of 40 years, and 6 months of service under post-LOCA conditions at the maximum cumulative radiation exposure, without any adverse effects on service, performance, operation, or appearance. All materials of construction, including metal components, seals, gaskets, lubricants, and finishes, such as paints, are compatible with these objectives and are capable of satisfactory service under the expected radiation exposure.

Gaskets and seal pads are unicellular, ozone-resistant, oil-resistant neoprene or silicone-rubber sponge, Grade SCE-43, in accordance with ASTM Dl056.

Only adhesives listed and approved in AEC Health and Safety Bulletin 306, dated March 31, 1971, or Military Specification MIL-F-5l068C, dated June 8, 1970, are used.

Organic compounds included in the filter train are as follows.

a. Charcoal

b. HEPA filter media binder - The total weight of media binder per filter element is approximately 4 lb, or a total of 32 lb per equipment train

c. Filter adhesive - Approximately 1 liquid qt of fire-retardant neoprene adhesive is used to manufacture each HEPA filter

d. HEPA filter, pre-filter and coverplate gaskets - Filter and coverplate gaskets are unicellular neoprene per ASTM Dl056, Grade SCE-43

e. Door and access port gaskets - Door and access port gaskets are unicellular neoprene per ASTM D735-SCE-516, or ASTM D2000-BC-516

f. All painted metals (inside and out) are coated with 0.003-in. MOBIL 13R56B primer and 0.003-in. MOBIL VALCHEM Series 89 white top coat. Stainless components are not painted

g. Wire Coatings and Insulation - Approximately 15 lb of Cerro Products "Rockbestos" silicone rubber is used. Of this amount, less than 0.5 lb is inside the SGTS. Approximately 10 lb of EPR neoprene is used, none of which is inside the SGTS.

6.2.4 Containment Isolation System

6.2.4.1 Design Bases

The containment isolation system consists of valves and controls required for the isolation of lines penetrating the primary containment. The primary objective of this system is to provide protection against release of radioactive materials to the environment as a result of accidents occurring to the nuclear steam supply system (NSSS), auxiliary systems, and support systems. This objective is accomplished by automatic isolation of appropriate lines that penetrate the primary containment. The containment isolation system is actuated automatically when specific limits are reached.

The containment isolation system, in general, closes fluid penetrations that support those systems not required for emergency operation. Fluid penetrations supporting ESF systems have remote manual isolation valves which may be closed from the main control room, if necessary. The automatic isolation valves close on receipt of an isolation signal from a sensor. For example, the main steam isolation valves (MSIVs) may be closed by signals indicating low water level in the reactor, main steam line tunnel high temperature, high steam flow, low steam line pressure, or low condenser vacuum. Isolation signals for each valve are specified in Table 6.2-2.

It is neither necessary nor desirable that every isolation valve close simultaneously with a common isolation signal. For example, if a process pipe were to rupture in the drywell, it would be important to close all lines that are open to the drywell and some effluent process lines, such as the main steam lines. However, under these conditions it would be essential that the containment and core cooling systems be operable. Therefore, several specific signals are used for isolation of various process and safety systems.

The design of isolation valving for lines penetrating the containment conforms to the intent of 10 CFR 50, Appendix A, General Design Criteria (GDC) 54, 55, 56, and 57. Redundancy and physical separation are provided in the electrical and mechanical design to ensure that no single failure in the containment isolation system prevents the system from performing its intended functions.

Where a penetration is part of a redundant train in an ESF system, isolation valves for that train may receive power from a single electrical division. This is desirable so that a single failure of an electrical division cannot disable both trains of the ESF system. In these cases a redundant mechanical barrier (i.e., closed systems beyond the isolation valves) exists so that containment isolation is not lost as a result of a single electrical failure.

Protection of primary containment isolation system components from missiles, and the integrity of these components to withstand seismic occurrences without loss of operability, was considered in the design of this system. The containment isolation system is Category I.

On signals of high drywell pressure or low water level in the reactor vessel all isolation valves that are part of systems not required for emergency shutdown of the plant are closed. The same signals initiate the operation of systems associated with the emergency core cooling system (ECCS). Isolation valves that are part of the ECCS may be closed remote manually from the control room.

Criteria for the design of the containment isolation control system are listed in Subsection 7.1.2.1.2. The bases for assigning certain signals for primary containment isolation are listed and explained in Chapter 7.

6.2.4.2 System Design

The containment isolation system is designed to provide a minimum of one protective barrier between the reactor and the environs under all postulated conditions. A detailed discussion of the controls associated with the containment isolation system is included in Subsection 7.3.2. Table 6.2-2 specifies the plant protection system signals that initiate closure of the containment isolation valves.

6.2.4.2.1 Design Requirements

Containment isolation valves were designed in accordance with the requirements of the ASME B&PV Code Section III, in effect at the time of purchase as required by 10 CFR 50, Section 50.55. Where necessary, a dynamic system analysis, which includes the impact effect of rapid valve closure under operating conditions, is included in the design specifications of piping systems that require containment isolation valves. Quality Assurance (QA) procedures are followed to ensure compliance with these specifications.

All containment isolation valves are located inside either the drywell or the secondary containment. Both structures are of Category I design and are protected against damage from missiles. The primary containment vessel is enclosed completely in a reinforced-concrete structure having a thickness of 4 to 7 ft. This concrete structure provides a major mechanical barrier for protection against missiles that may be generated external to the primary containment. Protection against damage from missiles is provided for isolation valves, actuators, and controls. Refer to Section 3.5 for a discussion of missile protection. Section 3.6 contains a discussion of protection provided against the dynamic effects of pipe whip, while Section 3.7 contains a discussion of the design analyses performed on containment penetration piping.

Each containment isolation valve is designed to ensure its performance under all anticipated environmental conditions including maximum differential pressure, extreme seismic occurrences, steam-laden atmosphere, high temperature, and high humidity. Section 3.11 presents a discussion of the environmental conditions, both normal and accident, for which the containment isolation system is designed.

Closed systems used as an isolation barrier, either inside or outside the primary containment, meet the following requirements:

a. The systems are protected against postulated missiles and pipe whip

b. The systems are designed to Category I

c. The systems are at least Quality Group B, except for specific instrument line applications noted in Table 6.2-2 (Note 12)

d. The systems are designed to at least the maximum temperature and pressure of the containment.

In addition, closed systems inside the containment meet the following requirements:

a. They are designed to withstand external pressure from the containment structural acceptance test

b. They are designed to withstand the design-basis accident and accompanying environment

c. They do not communicate with either the reactor coolant system or the containment atmosphere.

Power-operated containment isolation valves have limit switches that indicate valve position in the main control room. Containment isolation valves are designed to fail in the safe position. Containment isolation valves are either automatically actuated by the signals shown in Table 6.2-2 or are remote manually operated. Some containment isolation check valves inside containment are provided with supplemental air operators to verify free disk movement during opening and closing and zero pressure differentials across the valves. This arrangement provides a means by which to periodically verify valve operability.

Containment isolation valves that are remote manually operated are required to be provided with a leakage detection capability or be administratively closed (Standard Review Plan [SRP] 6.2.4). Table 6.2-13 lists the remote manual containment isolation valves that have a leak detection capability.

Remote manual containment isolation valves that are locked closed (and are thus under administrative control) are as follows.

Penetration	Valve
X-12	V8-3407
X-21	V5-2006
	V5-2007

The only other containment isolation valves with a remote manual primary actuation mode are the N_2 supply to the drywell-to-torus vacuum breakers, penetrations X-204A-M (valves V4-2036, V4-2065, V4-2075, V4-2077, V4-2082, V4-2084, V4-2086, V4-2088, V4-2090, V4-2092, V4-2094, and V4-2096). (Table 6.2-2 provides the F valve numbers.) These valves are locked closed to comply with Technical Specification 3.6.1.3.2 and are opened during the testing of the drywell-to-torus vacuum breakers. These valves are under administrative control and considered locked closed as defined in SRP 6.2.4 to preclude the possibility of their being inadvertently opened during normal reactor operations. Thus, as all remote manual containment isolation valves are either provided with leak detection capability or locked closed, Fermi 2 meets the guidance set forth in SRP 6.2.4.

6.2.4.2.2 Conformance To General Design Criteria

As stated in Subsection 6.2.4.1, the design of isolation valving for lines penetrating the containment follows the intent of GDC 54 through 57. Isolation valving for instrument lines that penetrate the containment follows the guidance of Regulatory Guide 1.11. Those cases where literal interpretation of GDC 54 through 57 has not been followed are included in the discussions in the following subsections.

6.2.4.2.2.1 General Design Criterion 54

General Design Criterion 54 in 10 CFR 50 states

> Piping systems penetrating primary reactor containment shall be provided with leak detection, isolation, and containment capabilities having redundancy, reliability, and performance capabilities which reflect the importance to safety of isolating these piping systems. Such piping systems shall be designed with a capability to test periodically the operability of the isolation valves and associated apparatus and to determine if valve leakage is within acceptable limits.

Criterion 54 Conformance

All piping penetrations meet the intent of GDC 55, 56, or 57. In doing so, they also conform to the intent of GDC 54 to the extent that all piping systems penetrating the primary containment are provided with leak detection, isolation, and containment capabilities which reflect the importance to safety of isolating these piping systems. In addition, each piping penetration is designed to be tested periodically in accordance with 10 CFR 50, Appendix J, as described in Table 6.2-2. Specifically, the following systems have containment isolation provisions consistent with the provisions of GDC 54.

Traversing In-Core Probe (TIP) System (Penetrations X-35B, C, D, E, F

The TIP system detector signal and drive cable neither comprise a portion of the reactor coolant pressure boundary nor directly communicate with the primary containment atmosphere. Thus, GDC 55 and 56 are not directly applicable to this specific class of lines. The basis on which TIP system lines are designed is described more closely in GDC 54, which states, in effect, that systems penetrating the primary containment are to be provided with isolation capabilities commensurate with the importance of isolating the system. Thus, even though the failure of TIP system lines presents no safety hazard, additional conservatism is provided in TIP system isolation capabilities, which reflects the intent of GDC 55.

The TIP system detector signal and drive cable are stored outside the primary containment behind a normally closed ball valve and an explosively actuated shear valve. The valves are located outside the containment for inspection and maintenance accessibility, and the position of each is indicated in the control center. The ball valve remains closed at all times except during operation of the associated TIP system channel. Prior to use of the TIP system, the ball valve is manually opened. All five TIP machines may be used simultaneously, however any one guide tube is used, at most, only a few hours per year.

After TIP system cable retraction, the ball valve is manually closed. Should a containment isolation signal be received while the TIP system cable is inserted, the cable will withdraw automatically, and this will be followed by automatic closure of the ball valve.

The function of the shear valve is to ensure the integrity of the containment in the unlikely event that the ball valve should fail to close or the drive cable should fail to retract from the guide tube during the time containment isolation is required. The valve is designed to shear the TIP drive cable and seal the drive tube upon command from the control center. In addition to valve position, the condition of each shear valve dc firing circuit is monitored continuously in the control center. Additional testing requirements are discussed in Note 17 to Table 6.2-2.

Control Rod Drive Insert and Withdrawal Lines (Penetrations X-37A, B, C, D and X-38A, B, C, D)

Control rod drive (CRD) insert and withdrawal lines penetrate the primary containment, but they neither directly communicate with the containment atmosphere nor comprise part of the reactor coolant pressure boundary. Thus, GDC 55 and 56 are not directly applicable to this class of lines. The basis on which the CRD lines are designed is described more closely in GDC 54, which requires such systems to have isolation capabilities commensurate with the importance of isolating the system. Since these lines are necessary for the scram function, the reliability of their operation is of utmost concern. Thus, isolation valves should not be incorporated in the design of this system. The probability of reliable and timely operation is enhanced by simplicity of design and by minimizing, where possible, the introduction of possible failure mechanisms. Even though multiple breaks postulated and analyzed in Section 4.0 pose no threat to public health and safety, CRD insert and withdrawal isolation capabilities were designed to reflect the conservative intent of GDC 55.

Both the CRD insert and withdrawal lines are provided with normally closed, fail-closed, solenoid-operated directional control valves, which open only during routine movement of their associated control rod. The normally closed, fail-open, air-operated scram inlet and exhaust valves open only when required to effect a rapid reactor shutdown (scram). In addition, manual shutoff valves are provided for positive isolation in the unlikely event of a pipe break within a hydraulic control unit. (These units and the valves described above are located outside the containment to satisfy testing, inspection, and maintenance requirements.) In addition, each CRD insert line is provided with an automatically actuated flange ball check valve inside containment; the flange ball check valve is part of the CRD mechanism.

During post-LOCA, the scram inlet and outlet valves will remain open if the scram cannot be reset. Therefore, due to CRD seal leakage, the scram discharge volume (SDV) could experience reactor vessel pressure. To ensure the integrity of the SDV, it will be included in the Type A tests.

6.2.4.2.2.2 General Design Criterion 55

General Design Criterion 55 in 10 CFR 50 states:

> Each line that is part of the reactor coolant pressure boundary and that penetrates primary reactor containment shall be provided with containment isolation valves as follows, unless it can be demonstrated that the containment isolation provisions for a specific class of lines such as instrument lines, are acceptable on some other defined basis:
>
> (1) One locked closed isolation valve inside and one locked closed isolation valve outside containment; or
>
> (2) One automatic isolation valve inside and one locked closed isolation valve outside containment; or

(3) One locked closed isolation valve inside and one automatic isolation valve outside containment. A simple check valve may not be used as the automatic isolation valve outside containment; or

(4) One automatic isolation valve inside and one automatic isolation valve outside containment. A simple check valve may not be used as the automatic isolation valve outside containment.

Isolation valves outside containment shall be located as close to containment as practical and upon loss of actuating power, automatic isolation valves shall be designed to take the position that provides greater safety.

Other appropriate requirements to minimize the probability or consequences of an accidental rupture of these lines or of lines connected to them shall be provided as necessary to assure adequate safety. Determination of the appropriateness of these requirements, such as higher quality in design, fabrication, and testing, additional provisions for inservice inspection, protection against more severe natural phenomena, and additional isolation valves and containment, shall include consideration of the population density, use characteristics, and physical characteristics of the site environs.

Criterion 55 Conformance

The reactor coolant pressure boundary (RCPB) (as defined in 10 CFR 50, Section 50.2[v]) consists of the reactor pressure vessel (RPV), pressure-retaining appurtenances attached to the RPV, and valves and pipes that extend from the RPV up to and including the outermost isolation valve. The lines of the RCPB that penetrate the primary containment are capable of isolation, thereby precluding any significant release of radioactivity. Similarly, lines that do not penetrate the primary containment but form a portion of the RCPB (such as connecting lines up to and including the second isolation valve) are designed to ensure that isolation of the reactor pressure boundary can be achieved.

6.2.4.2.2.2.1 Influent Lines

Influent lines that penetrate the primary containment and connect directly to the RPV are equipped with two isolation valves: one inside the containment, the other outside the containment. Both valves are located as close to the containment as practical. Influent lines which comprise part of the RCPB are listed below and discussed in detail in the remainder of this section.

Penetration No.	System
X-9A	Feedwater HPCI supply
X-9B	Feedwater RCIC supply RWCU return
X-13(A, B)	RHR pump discharge to recirculation loops
X-16(A, B)	Core spray pump discharge to core spray spargers

Penetration No.	System
X-42	Standby liquid control system
X-49A and X-51A	Recirculation pump seal purge

Feedwater System

The feedwater line penetrating the primary containment is part of the RCPB. This penetration is supplied with one automatic isolation valve inside and one automatic isolation valve outside the containment. The isolation valve inside the containment is a check valve. The isolation valve outside the containment is an air-operated, spring-to-close, positive-acting check valve.

Should a break occur in the feedwater line, the valves will prevent significant loss of fluid inventory and offer immediate isolation. During the postulated LOCA, it is desirable to maintain reactor coolant makeup from all sources of supply. For this reason, the outer containment isolation valve does not automatically isolate on a signal from the containment isolation system. However, the valve is capable of remote closure from the control room to provide long-term leakage protection when, based on operator judgment, continued makeup from the feedwater system is no longer necessary. A second check valve is located outside the containment--between the air-operated isolation valve and the containment wall--for added isolation capability.

RWCU, HPCI, and RCIC Systems

Influent lines that use the feedwater piping and penetrations in order to transfer fluid to the RPV consist of the reactor water cleanup (RWCU) return, and reactor core isolation cooling (RCIC), high-pressure coolant injection (HPCI) supply, and standby feedwater. Each of these lines can be isolated by the feedwater check valve inside the containment. The RCIC and HPCI supply lines each have an isolation valve outside the containment. These valves are normally closed, dc power-operated, remote manually actuated gate valves. The RWCU return line has a motor operated, normally open, ac power-operated gate valve as its isolation valve outside the containment. This valve is capable of remote closure from the control room. Two check valves are provided between the isolation valve and the containment wall. Should a break occur in the RWCU line, these check valves will prevent significant loss of fluid inventory from the feedwater side.

RHR and Core Spray Systems

The residual heat removal (RHR) pump discharge lines to the recirculation system (low-pressure coolant injection and shutdown cooling modes) and the core spray pump discharge lines have testable check valves inside the containment that provide for immediate isolation in the event of a break upstream of these valves. The outer containment isolation valves are remote manually actuated gate valves. However, no licensing credit is taken for the containment isolation feature of the RHR inboard check valves (see Reference 25a). Each valve will receive an automatic opening signal in the event of the postulated LOCA.

Standby Liquid Control System

The standby liquid control line uses a check valve as the isolation valve inside, as well as outside, the primary containment. General Design Criterion 55 states that a simple check valve may not be used as the automatic isolation valve outside the containment; however, should insertion of the liquid poison become necessary, it is imperative that the injection line be open. In the design of this system, it has been accepted practice to omit an automatic valve that opens on signal, as this introduces a possible failure mechanism. As a means of providing assurance for reliable and timely actuation, an explosive valve is used.

In this manner, the availability of the line is ensured. Because the standby liquid control line is a normally closed and non-flowing line, rupture of this line is a very remote possibility.

Recirculation Pump Seal Purge System

The recirculation pump seal purge lines use two air-operated globe valves, one inside the containment and one outside the containment. The valves isolate automatically on high drywell pressure or low vessel water level (level 2).

6.2.4.2.2.2.2 Effluent Lines

With the exception of the postaccident pressurized reactor coolant sample lines, effluent lines that form part of the RCPB and penetrate the primary containment are equipped with two isolation valves, one inside the containment and the other outside the containment. Both valves are located as close to the containment as practical. Effluent lines that comprise part of the RCPB are listed below, and are discussed in detail in the remainder of this section.

Penetration No.	Section
X-7(A,B,C,D)	Main steam lines
X-8	Main steam line drains
X-10	Steam to RCIC turbine
X-11	Steam to HPCI turbine
X-12	RHR pump suction for recirculation piping (shutdown cooling mode)
X-28Cf	Postaccident pressurized reactor coolant sample
X-29A	Reactor water sample line
X-40Dd	Postaccident pressurized reactor coolant sample
X-43	Reactor water cleanup suction

Main Steam System

The MSIVs are air-operated, automatically actuated, Y-pattern globe valves. Two valves are provided in each line: one inside and one outside the containment. There is a third valve in each line outside the containment that is a gate valve.

The main steam drain line is provided with two automatic, motor-operated gate valves: one inside and one outside the containment. These valves are closed during normal reactor operation.

RCIC System

Both isolation valves in the RCIC steam supply line are normally open, remote manually actuated gate valves. These valves close automatically on indication of an RCIC system piping failure.

HPCI System

The isolation valves in the HPCI steam supply line consist of two gate valves and a 1-in. globe valve. All are remote manual motor-operated valves. The isolation valve inside the containment is open normally. The normally open, 1-in. globe valve bypasses the normally closed system supply valve outside the containment to keep the HPCI steam supply line warm. All HPCI steam supply line valves close automatically on indication of an HPCI system piping failure.

RHR System

The RHR shutdown cooling suction line is provided with two normally closed, automatically actuated, motor-operated gate valves and a locked-closed bypass valve. The bypass valve provides assurance that the normal shutdown cooling method will be available if the normally used valve fails. There is also a 3/4-in. bypass line with two check valves in series, which allows heated water trapped inside the RHR line to be relieved to the reactor vessel.

Reactor Coolant Sample System (Non-Postaccident)

The reactor water sample line is provided with two automatic, air-operated, fail-closed isolation globe valves: one inside and one outside the containment. These valves are closed during normal reactor operation, but receive an automatic closure signal in case they are open when containment isolation is required.

Postaccident Pressurized Reactor Coolant Sample

The two postaccident reactor coolant sample lines are connected to jet pump instrumentation lines outside the containment. Each line is provided with a solenoid-operated globe isolation valve outside the containment. These valves are closed during normal reactor operation and are opened only during postaccident conditions.

RWCU System

The RWCU suction line is provided with two normally open, automatic, motor-operated gate valves. These valves will close on receipt of a containment isolation or RWCU system piping failure signal.

Leak detection is provided for each line that has remote manual containment isolation valves and is evaluated against GDC 55.

6.2.4.2.2.3 General Design Criterion 56

General Design Criterion 56 in 10 CFR 50 states

> Each line that connects directly to the containment atmosphere and penetrates primary reactor containment shall be provided with containment isolation valves as follows, unless it can be demonstrated that the containment isolation provisions for a specific class of lines, such as instrument lines, are acceptable on some other defined basis:
>
> (1) One locked closed isolation valve inside and one locked closed isolation valve outside containment; or
>
> (2) One automatic isolation valve inside and one locked closed isolation valve outside containment; or
>
> (3) One locked closed isolation valve inside and one automatic isolation valve outside containment. A simple check valve may not be used as the automatic isolation valve outside containment; or
>
> (4) One automatic isolation valve inside and one automatic isolation valve outside containment. A simple check valve may not be used as the automatic isolation valve outside containment.

Isolation valves outside containment shall be located as close to the containment as practical and upon loss of actuating power, automatic isolation valves shall be designed to take the position that provides greater safety.

Criterion 56 Conformance

The lines that penetrate the primary containment and communicate with the containment atmosphere can be grouped into two categories: (1) pipes that penetrate the primary containment and connect directly to the suppression pool; and (2) pipes that penetrate the primary containment and connect directly to the drywell atmosphere.

6.2.4.2.2.3.1 Lines Connecting To the Suppression Pool

Lines in this category are listed below:

Penetration No.	System
X-205(A,B)	Torus to secondary containment vacuum breakers
X-205C	Suppression pool N_2 and air purge inlet
X-205D	Suppression pool exhaust and N_2 inlet
X-206(A, B, C, D, E, F)	Suppression pool water level and pressure instrumentation
X-210(A, B)	RHR minimum flow line RHR heat exchanger thermal relief RHR test line Torus water management return RHR suction thermal relief RHR heat exchanger discharge header thermal relief Postaccident liquid sample return RHR warmup and return
X-211(A, B)	RHR to suppression pool spray
X-212	RCIC turbine exhaust line
X-213(A, B)	Torus water management supply
X-214	RCIC vacuum breaker line
X-215	HPCI vacuum breaker line Combustible gas control suction Postaccident gaseous sample return

Penetration No.	System
X-217	Grab sample line
X-218	Combustible gas control return
X-219	Combustible gas control suction
X-220	HPCI turbine exhaust line
X-221	HPCI turbine exhaust drain
X-222	RCIC vacuum pump discharge
X-223(A, B, C, D)	RHR pump suction RHR pump suction header thermal relief
X-224(A, B)	Core spray pump suction
X-225	HPCI pump suction
X-226	RCIC pump suction
X-227(A, B)	Core spray pump suction thermal relief Core spray pump discharge header thermal relief Core spray pump minimum flow line Core spray pump test line Torus water management return HPCI minimum flow line RCIC minimum flow line
X-230	Primary containment monitoring system Post accident suppression pool atmosphere sample
X-231	Primary containment monitoring system
X-231	Postaccident suppression poolatmosphere sample

As stated in GDC 56, two isolation valves--one inside and one outside the containment--are required in lines that penetrate the primary containment and connect directly to the containment atmosphere. However, GDC 56 allows for alternatives to these explicit isolation requirements where the acceptable basis for each alternative is defined. The following are alternatives to explicit conformance with GDC 56. Notes in Table 6.2-2 identify the alternative basis to which each penetration is designed.

Two Isolation Valves Outside Containment

The primary containment radiation monitor system (PCRMS) is associated with Division I of the primary containment atmosphere monitoring system (PCAMS). The nonessential

PCRMS has two isolation valves on the inlet and two isolation valves on the outlet. These isolation valves are a normally open spring-to-close solenoid operated globe valve and an air operated ball valve. These inlet and outlet lines are connected to the containment atmosphere via PCAMS piping during normal operation. The isolation valves receive a containment isolation signal on a LOCA (see Subsection 6.2.4.2.2.3.2).

For lines that connect to the suppression pool, an isolation valve located inside the containment would necessitate placement of the valve either under water or in a high-humidity, nonaccessible area. Such placement would subject these valves to an extremely hostile environment, which could compromise their reliability and prevent routine inspection and maintenance. Thus, as an alternative to the explicit requirements of GDC 56 for lines in ESF or ESF-related systems, both isolation valves are located outside, and as close to, the containment wall as practical.

Relief Valves as Isolation Valves

Relief valves are provided in the RHR, core spray, HPCI, RCIC, and combustible gas control (CGC) systems as overpressureprotection devices. These valves are required for the design of Class B systems according to the ASME B&PV Code, Subsection NC-7000. The valves are installed in a manner that ensures their correct operation and reliability. Further, the Code requires that no stop valves or other devices be placed (in relation to a pressure relief device) so that it could impair the overpressure protection offered by the relief valve itself. Relief valves installed in these lines provide this required level of protection, and, if required to operate, would route the diverted fluid to the suppression pool.

Because of the orientation required, each of these relief valves is an isolation valve for the applicable penetration. The piping and valve designs are Quality Group B, Category I, and will withstand temperatures and pressures at least equal to the containment design pressure and temperature. Should the postulated LOCA occur, containment pressure would be felt on the downstream side of the relief valve, and would act in conjunction with the spring pressure setting of the relief valve to further enhance seating.

Remote Manual Isolation Valves

Remote manual valves are used as containment isolation valves in ESF and ESF-related systems. These systems include RHR, core spray, HPCI, RCIC, and reactor building closed cooling water (RBCCW) Emergency Equipment Cooling Water (EECW) systems. In each case, leak detection is provided.

Closed Systems Outside the Containment

The RHR, core spray, HPCI, and RCIC systems are closed-loop systems outside the containment. These systems can accommodate a single active failure and still maintain containment integrity. The systems are designed to Category I standards, are classified as Quality Group B, and will maintain their integrity should the containment experience its design temperature and pressure transient. Thus, as an alternative to the explicit requirements of GDC 56 for such lines in ESF or ESF-related systems, a single isolation valve is used outside the containment to enhance system reliability.

Lines that are not Quality Group B but that connect to these closed-loop systems are itemized in Table 6.2-14. By necessity, some of the valves in these lines are located near system pumps and are subject to missile damage should the pump fail. Should this occur, the system would be isolated either manually or automatically, and, therefore, failure of these valves as a result of missile damage would not constitute a breach of the primary containment.

Other Systems

The CGC, purge and inerting systems each use two isolation valves in series outside the suppression pool. Installing one of these valves inside the suppression pool could compromise reliability and prevent routine inspection and maintenance. These systems are built to the same quality standards as the primary containment and are protected against postulated missiles and pipe whip. The CGCS PCIVs are permanently de-energized and locked-closed.

The vacuum breakers to the secondary containment are essential for primary containment integrity. Isolation is provided through a power-to-close, spring-to-open butterfly valve and a testable check valve. Power from divisional electrical buses is applied to the butterfly valve to keep the valves closed, except when air is required to relieve a vacuum inside the primary containment. The butterfly valve will open on loss of power or degraded voltage but closes automatically once power is restored or voltage recovers. During a LOCA concurrent with a Loss of Offsite Power (LOP), the butterfly valves will de-energize and open until power is restored to the divisional electrical buses. Upon restoration of power, the butterfly valves will re-energize and reposition, closing the valves. During a LOCA concurrent with a low grid voltage, insufficient voltage during the time Core Spray and RHR pumps start may cause the Division I butterfly valve to pen. Once nominal voltage is restored after RHR and Core Spray pump starts, the butterfly valve will close. In either scenario, the time the butterfly valve is open is less than the 108 second allowed stroke time for containment isolation valves established in the accident analysis. The vacuum breaker testable check valves provide containment isolation and remain closed during the accident unless negative differential pressure exists. These lines and valves are Category I, Quality Group B and are located in missile-free areas.

6.2.4.2.2.3.2 Lines Connecting To the Drywell

Lines in this category are listed below and discussed in the remainder of this section. The lines are Category I and Quality Group B at least through the outermost containment isolation valve.

Penetration No.	System
X-15	CGC suction
X-17	Abandon RHR head spray
X-18	Drywell floor drain sump pump discharge
X-19	Drywell equipment drain sump pump discharge
X-20	Demineralized service water to drywell

Penetration No.	System
X-22	Control air and N_2 to drywell
X-23	RBCCW/EECW supply
X-24	RBCCW/EECW return
X-25	Drywell exhaust
X-26	Drywell N_2 and air inlet
X-27(a, b, c, d, e)	Containment atmosphere sample and postaccident drywell atmosphere sample (X-27b only)
X-27f	Drywell pressure instrumentation
X-29B (b,c)	Reactor protection system
X-29Be	Drywell instrumentation
X-31Ba	Drywell on line pressure control
X-34(A, B)	RBCCW/EECW supply and return
X-36	N_2 to dry
X-39(A, B)	RHR to containment spray header
X-44	CGC suction
X-47(a,b)	Reactor protection system
X-47e	Drywell instrumentation Nitrogen inerting instrumentation
X-48(a,b,c,d,e,f)	Containment atmosphere sample and postaccident drywell atmosphere sample (X-48f only)

Regulatory Guide 1.7 was revised in March 2007 to reflect the amended 10 CFR 50.44. The Combustible Gas Control System (CGCS) has been retired in place with its electrical circuits de-energized and fluid process piping isolated from primary containment with redundant locked-closed isolation valves. The valves are located external to the primary containment, and are accessible for inspection and testing during normal reactor operation.

Penetration X-17 for the abandoned RHR head spray line now conforms to the requirements of GDC-56 since the line is no longer directly connected to the RPV. Two normally closed motor operated valves are located in this line, one inside containment and one outside containment.

The drywell equipment and floor drain sump pump discharge lines each have a motor-operated, normally open gate valve inside the containment, and an air-operated, normally closed gate valve outside the containment. These valves receive containment isolation signals on the postulated LOCA. Rupture disc overpressure protection is installed to limit the pressure rise from LOCA heatup of the isolated penetrations per GL 96-06. The rupture disc discharges into a small discharge tank which provides a sealed closed barrier for containment isolation.

Demineralized service water line has an isolation valve inside containment and a spectacle flange assembly with blank installed outside containment. Control air and nitrogen lines have isolation valves inside and outside the drywell. The demineralized service water isolation valve is the only manual valve in this group. The valve remains locked closed at all times during reactor operation.

The drywell exhaust and air purge lines have isolation valves inside and outside the containment. The valves are either automatically or remote manually actuated. Leak detection is provided to inform the control room operator when closure of the remote manual valves is required.

The RHR pump discharge to the containment spray lines contains two isolation valves outside the containment. Since the spray header is integral to the drywell wall, placing an isolation valve inside the containment could compromise the structural integrity of the containment spray headers.

The RBCCW/EECW supply lines each have a check valve inside the containment and a motor-operated gate valve outside the containment. These motor-operated gate valves are remote, manually actuated and close on a high drywell pressure EECW initiation signal. The RBCCW/EECW return lines each have a remote, manually actuated, diverse electrically powered motor-operated gate valve inside and outside the containment.

The drywell instrumentation, nitrogen-inerting instrumentation, reactor protection system, and containment atmosphere sample systems are closed-loop systems outside the containment. These systems can accommodate a single active failure and still maintain containment integrity. The systems are designed and installed as Quality Group B, up to and including the isolation valves. The balance of the instrument piping is designed to meet Quality Group B design criteria. These design criteria include stress analysis with consideration given to deadweight, thermal, and seismic conditions. The systems are seismically supported.

Nuclear-grade materials are used throughout the fabrication of the piping system. They will maintain their integrity should the containment experience its design temperature and pressure transient. Thus, as an alternative to the explicit requirements of GDC 56 for such lines in ESF or ESF-related systems, a single air-operated isolation valve or solenoid-operated isolation valve is used outside the containment to enhance system reliability.

The lines that connect the nonessential PCRMS to Division I of the closed outside containment loop of the PCAMS have two isolation valves outside containment for both the inlet and outlet of the PCRMS. The PCRMS utilizes common piping of PCAMS; therefore, the valves are outside containment and placed as close as practical to the PCAMS piping loop. All other requirements of GDC 56 are met.

The drywell postaccident atmosphere sample lines contain two solenoid-operated globe isolation valves outside the containment. These lines are connected to the normal containment atmosphere sample system lines outside the containment. These valves are closed during normal reactor operation and are opened only during postaccident conditions.

6.2.4.2.2.4 General Design Criterion 57

General Design Criterion 57 in 10 CFR 50 states

> Each line that penetrates primary reactor containment and is neither part of the reactor coolant pressure boundary nor connected directly to the containment atmosphere shall have at least one containment isolation valve which shall be either automatic, or locked closed, or capable of remote manual operation. This valve shall be outside the containment and located as close to the containment as practical. A simple check valve may not be used as the automatic isolation valve.

Criterion 57 Conformance

Penetrations X-204 (A through M) for the drywell-to-torus vacuum breaker nitrogen supply and their associated isolation valves conform to the locked closed requirements of GDC 57 to comply with Technical Specification 3.6.1.3.2. A locked closed, air-operated globe valve as defined is SRP 6.2.4 is located in each line outside the containment.

6.2.4.2.3 Containment Isolation Dependability

Fermi 2 meets the NRC requirements developed for reliable containment isolation as follows.

a. The containment isolation design complies with the recommendation of SRP 6.2.4 in that there is diversity in the parameters sensed for the initiation of containment isolation. Safety-grade signals are provided for the detection of abnormal conditions in the reactor coolant system and containment; these are low reactor vessel water level and high drywell pressure

   Several lines are not isolated on the high-drywell- pressure signal in order to retain system availability for small breaks or leaks. Justification for these cases is given under Comments in Table 6.2-15

b. Essential and nonessential systems containing piping systems that penetrate the containment are identified in Table 6.2-16. Those systems identified as essential are regarded as indispensable or are backup systems in the event of a LOCA. The nonessential systems have been judged to be not required in LOCA situations

c. Nonessential lines that are a possible open path out of the containment are automatically isolated by the containment isolation signals, by check valves that prevent flow out of the containment, or by manual valves that are normally closed. Normally closed valves are under administrative control to ensure that valves are closed during startup, power, hot-standby, and hot-shutdown modes of operation

   For instrument lines connected to the RCPB, each line is equipped with a flow-restricting orifice located as close as practical to the point of connection to the RCPB. A manual shutoff valve is located outside the containment and is located as close as practical to the containment wall. An excess-flow check valve is provided immediately downstream of the manual valve. This design and installation follows the guidance of Regulatory Guide 1.11

d. The resetting of containment isolation signals does not result in the automatic reopening of containment isolation valves. Deliberate operator action is required to reopen a containment isolation valve once the containment isolation signals are reset

e. Drywell high pressure initiates the containment isolation of nonessential systems and lines. The Technical Specifications specify the drywell high-pressure trip-point setting

f. The Fermi 2 purge valves satisfy the operability criteria set forth in Branch Technical Position (BTP) CSB 6-4, Revision 1, and Staff Interim Position dated October 23, 1979. The Fermi 2 position relative to BTP CSB 6-4 is provided in Subsection 6.2.5.2.5. Fermi 2 complies with the Staff Interim Position as follows: (1) the purge valves are intended to be operated only for inerting, deinerting, or pressure control in accordance with the Technical Specifications; and (2) the Fermi 2 valves are operable for DBA flows

g. Containment purge and ventilation isolation valves close automatically upon the detection of high airborne radiation in the reactor building exhaust line. This high-radiation isolation signal is in addition to the diverse containment isolation signals.

6.2.4.2.4 Valve Closure Times

Proper valve closing time is achieved by appropriate selection of valve type, operator type, and operator size. Isolation valve closing times were verified during the functional performance tests prior to reactor startup and are periodically retested at intervals specified in the Technical Specifications. The design of piping systems penetrating the reactor containment includes provisions for operability and leakage testing of isolation valves.

Motive power for the valves on process lines that require two valves is supplied from physically independent power sources to provide a high probability that no single event could interrupt power to both closure devices. Loss of valve actuation power is detected and annunciated in the main control room.

In general, isolation valves located outside the primary containment receive dc power from the Division II power supply, or alternate division ac power, while those located inside the primary containment receive ac power from the Division I power supply.

6.2.4.2.5 Instrument Lines Penetrating the Primary Containment

All instrument lines connected to the reactor coolant pressure boundary are Category I and Quality Group A. Physical separation is provided for redundant instrument lines to the extent practical, so that the failure of one line will not induce failure in another. The response time for all sensors connected to instrument lines is not affected by the valves or orifices in the line. The design and installation of instrument lines follows the guidance of Regulatory Guide 1.11 (Safety Guide 11).

The instrument-sensing lines listed below penetrate the primary containment and connect to the RCPB.

Number of lines	Instrument Description
24	Jet pump flow
1	Jet pump
14	RPV level/pressure*
8	Recirculation inlet to RPV DP
2	Recirculation system pressure
8	Recirculation system flow
4	Recirculation Pump DP
4	Recirculation pump seal pressure
4	Steam flow to HPCI turbine
4	Steam flow to RCIC turbine
16	Main steam flow
2	Feedwater pressure**

* The portion of the instrument line passing through the containment is part of a penetration assembly that is part of the containment and thus is Quality Group B, consistent with the Containment Quality Group.

Two check valves are provided in series for the isolation of each division of the reactor vessel instrument-sensing line backfill system from the RPV level/pressure instrument reference legs.

** These lines do not penetrate the containment. They tap in between the containment and the outer isolation valve.

Each line, except for the feedwater pressure-sensing line, is equipped with a flow-restricting orifice located as close as practical to the point of connection to the RCPB. No such device is necessary for the feedwater pressure-sensing lines because they tap in outside the containment, and the isolation valve inside the containment (check valve) serves the function of the restricting orifice. A manual shutoff valve is located outside the primary containment and is installed as close as practical to the containment wall or pipe (in the case of feedwater). An excess-flow check valve is provided immediately downstream of the manual valve. The excess-flow check valve will close automatically in the event of a line break downstream. Indicating lights on a control room panel monitor excess-flow-check-valve position. These valves may be reopened by actuation of a solenoid valve, which is operated from a local control panel, after repairs are made. This design and installation follows the guidance of Regulatory Guide 1.11. There are no instrument lines that penetrate both the primary and the secondary containments.

The postulated break of an instrument line attached to the RCPB is discussed and evaluated in Subsection 15.6.2. Leakage from such a rupture upstream of the excess-flow check valve is minimized by the restricting orifice in the line. The integrity and functional performance of the secondary containment and standby gas treatment systems are not impaired by this event, and the calculated potential offsite exposures are substantially below the guidelines of 10 CFR 100.

Each instrument line except the jet pump instrument lines is provided with a 0.25-in.-diameter orifice in addition to the excess-flow check valve. The jet pump lines are 0.25 in. diameter from the RPV nozzles to the jet pump taps. This orifice will restrict the coolant loss to a value whose equivalent steam volume is much less than the capacity of one standby gas treatment system (SGTS) train. Therefore, pressurization of the secondary containment will not result from an instrument line break and a failure of the associated excess-flow check valve to isolate the ruptured line. Coolant lost from such a break is inconsequential when compared to the makeup capabilities of the feedwater or RCIC system.

6.2.4.2.6 Leak Detection

For systems penetrating the primary containment, major leaks in the pipe are located by increased temperature, radiation, sump level, changes in pressure, differential pressure, process line flow, etc. These indications are monitored in the control room to alert the operator when remote manual valves should be closed. In addition, certain indications of leakage will cause automatic valves to close in response to a system accident.

Leak detection is further discussed in Sections 5.2 and 7.6.

6.2.4.2.7 Leak Rate Testing

The reactor containment and containment penetrations are designed to permit periodic leak rate testing in accordance with GDC 52 and 53, and Appendix J to 10 CFR 50. See also Subsection 6.2.4.4.

Testing requirements for piping penetration isolation barriers and valves have been established by using the intent of GDC 54 as interpreted in Appendix J to 10 CFR 50. Exceptions taken to Appendix J Type C tests are described in Table 6.2-2.

The primary containment isolation system is scheduled to undergo periodic testing during reactor operation. The functional capabilities of power-operated isolation valves are tested remote manually from the main control room. By observing position indicators and changes in the operation of the affected system, the closing ability of a particular isolation valve is demonstrated. Testable check valves are provided on influent lines whose operability is relied upon.

Test capabilities, incorporated in the primary containment system to permit leak testing of containment isolation valves, are separated into two categories. The first category consists of pipelines that open into the containment and do not terminate in closed loops outside the containment, but do contain two isolation valves in series. Test taps are provided between the two valves to permit leakage monitoring. The second category consists of pipelines that connect to the reactor cooling system and that also contain two isolation valves in series. A leakoff line is provided between the two valves, and a drain line is provided downstream of the outboard valve. This arrangement permits leakage monitoring of both the inboard and outboard valves. Valves subject to Type C testing are shown in Table 6.2-2.

Excess-flow check valves can be tested by opening a test drain valve downstream of each valve and verifying proper operation.

As these valves are outside the primary containment and are accessible, periodic visual inspection can be performed in addition to the operational check.

The only systems circulating contaminated water after a postulated LOCA are the core spray system (to cool the reactor core) and the RHR system (to remove the heat from the emergency coolant).

The potential sources for leakage are the pump mechanical seals. The available data indicate the leakage from the pump seals to be essentially zero. This is based on the manufacturer's design criteria, its technical manuals, and industrywide experience. Therefore, specifying a leakage limit would be quite arbitrary.

Only a seal failure could result in any significant leakage. This leakage would be indicated by the operation of the sump pumps in either one of the equipment drain sumps or the floor drain sumps located in each of the four corner rooms of the reactor building subbasement. Sump pump startup is indicated in the control room. Following sump pump startup and operator investigation, the leaking emergency core cooling system (ECCS) pump would be isolated.

Following a postulated LOCA, either one LPCI pump or two core spray pumps are required for core cooling and one RHR pump is required for long-term containment cooling. Should seal failure occur in one of these, there is sufficient redundancy to allow the leaking pump to be removed from service and isolated. Four RHR pumps and four core spray pumps are provided.

Radioactivity releases and resultant doses from this postulated seal leak would be negligible.

6.2.4.2.8 Environmental Qualification Tests

Qualification tests required to ensure the performance of the isolation valves under adverse environmental conditions are discussed in Section 3.11.

6.2.4.3 Design Evaluation

One of the basic purposes of the primary containment system is to provide a minimum of one protective barrier between the reactor and the environs. To fulfill its role as a barrier, the primary containment is designed to remain intact before, during, and subsequent to any failure involving process systems either inside or outside the primary containment. Where process lines penetrate the primary containment, the penetration has the same integrity as the primary containment structure itself. In addition, the process line isolation valves perform the containment isolation function for leakage through the process lines.

Since a rupture of a large line connected to the reactor coolant system and penetrating the primary containment may be postulated, isolation valves for lines of this type are required to be located within the primary containment. These isolation valves are required to close automatically on various indications of reactor coolant loss. A certain degree of additional reliability is added if a second valve, located outside and as close as practical to the primary containment, is included. This second valve also closes automatically. A single active failure can be accommodated since a second valve is available to perform the containment isolation function. By physically separating the two valves, there is less likelihood that a failure of one valve would cause failure of the second. Series valves of this type are provided with independent power sources.

As an example, the ability of the main steam line penetrations and the associated steam line isolation valves to fulfill the containment isolation objective for several break conditions in the steam line is shown by consideration of various assumed main steam line break locations.

a. The failure occurs inside the drywell, upstream of the inner isolation valve. Steam from the reactor is released into the drywell, and the resulting sequence is similar to that of the design-basis accident (DBA) except that the pressure transient is less severe since the reactor blowdown rate is slower. Both isolation valves close on receipt of a signal indicating low water level in the RPV. This action provides two barriers within the steam pipe passing through the penetration and prevents further flow of steam to the turbine. Thus, when the two isolation valves close subsequent to this postulated failure, containment integrity is attained and the reactor is effectively isolated from the external environment

b. The failure occurs inside the drywell, and it is assumed that the inner isolation valve is inoperable. Again, reactor steam will blow into the primary containment. The outer isolation valve will close on receipt of a signal indicating low water level in the RPV, and the reactor will become isolated within the primary containment, as delineated above

c. The failure occurs downstream of the inner isolation valve either inside the drywell or within the guard pipe. Both isolation valves will close on receipt of a signal indicating low water level in the RPV. The guard pipe is designed to accommodate such a failure without damage to the drywell penetration bellows. In addition, the design of the pipeline both supports and protects its welded juncture to the drywell vessel. Thus, the RPV is isolated within the primary containment by the inner isolation valve, and the primary containment integrity is main-tained by closure of the outer isolation valve. It should be noted that this condition provides two barriers between the reactor core and the external environment

d. The failure occurs outside the primary containment between the penetration and the outer isolation valve. Steam will blow directly into the pipe tunnel until the isolation valves are closed automatically. Closure of the inner isolation valve places a barrier between the reactor core and the external environment. This barrier serves to isolate the reactor and maintain containment integrity

e. The failure occurs outside the primary containment, and it is assumed that the outer isolation valve is inoperable. Containment isolation is established by the inner isolation valve, and containment integrity is maintained as described in Item d., above

f. The failure occurs outside the primary containment between the outer isolation valve and the turbine. Steam will blow directly into the pipe tunnel or the turbine building until both isolation valves are closed automatically. This action isolates the reactor, completes containment integrity, and places two barriers in series between the reactor core and the outside environment

Exceptions to the arrangement of isolation valves described above for lines connected directly to the primary containment atmosphere or reactor coolant system are made only in cases in which the above arrangement would lead to a less desirable situation because of required operation or maintenance of the system in which the valves are located.

Isolation valves must be closed before significant amounts of fission products are released from the reactor core during the DBA. Because the amount of radioactive material in the reactor coolant is small, a sufficient limitation of fission product release will be accomplished if the isolation valves are closed before the coolant drops to a level below the top of the reactor core. For a discussion of closure times for Class A and Class B isolation valves, refer to Section 7.3.2.2.

Valves, sensors, and other automatic devices essential to containment isolation are provided with means for periodic testing of their functional performance. Such tests provide reasonable assurance that the primary containment isolation system will perform properly when required.

6.2.4.4 Leak Rate Testing

A testing program has been implemented to measure containment leakage rates prior to initial operation of the unit, and to test the primary containment periodically throughout the operating life. The purpose of the testing is to verify that the leakage rate is within allowable limits given in the Technical Specifications and in the Inservice Testing Program for Pumps and Valves (Subsection 5.2.8.7).

The testing program includes performance of Type A tests to measure the overall integrated leakage rates, Type B tests to detect and measure local leakage from certain components, and Type C tests to measure valve leakage rates.

The leakage tests are performed in accordance with the Fermi 2 Primary Containment Leakage Rate Testing Program as defined in the Technical Specifications. The program, which is based on the requirements of 10 CFR 50 Appendix J, Option B, retains certain previously approved exemptions, and utilizes the approach as defined in Regulatory Guide 1.163 (see Appendix A, Subsection A.1.163).

6.2.4.4.1 Type A Tests

Type A tests are intended to measure the primary reactor containment overall integrated leakage rate after the containment has been completed and is ready for operation and at periodic intervals thereafter.

After the preoperational leakage rate test, testing will be scheduled in accordance with Fermi 2 Technical Specifications.

The Type A test will be performed using the Absolute Method or other alternative testing methods that have been approved by the NRC, and verification will be achieved by the Superimposed Leak Method, as described in ANSI/ANS 56.8-2002.

Prior to Type A testing, all lines are either isolated or drained and vented to reflect their status following a postulated LOCA. This ensures that Type A test results accurately reflect the most restrictive LOCA conditions. Systems that are provided with isolation capabilities to satisfy GDC 55 or 56 are either normally open to the containment atmosphere or will be vented to the containment during Type A tests. Exceptions to this are systems that must be in operation during the test.

The primary containment is pressurized and depressurized using existing system piping and equipment to the extent possible. Appropriate pressure controls are provided to attain the test pressure and for controlled depressurization to the plant vent stack via existing adsorber filters. Pressurization is carried out under conditions that will minimize containment air humidity and temperature.

Temperature-sensing devices are distributed throughout the containment and at different parts of the structure wherever local temperature variations are expected in the course of the test. Fans are used for air circulation as required to equalize temperatures.

Measurements are taken during each test period to provide a sufficient amount of data to determine leakage rates for the following tests.

a. Preoperational Leakage Rate Test

1. Peak Pressure Test

   A test was performed at pressure P_a (where P_a is the calculated peak containment internal pressure related to the DBA) to measure the leakage rate L_{am} (where L_{am} is the total measured leakage rate at pressure P_a obtained from testing the containment with equipment and systems in a state as close as practical to that which would exist under DBA conditions)

2. Acceptance Criteria

   L_{am} shall be no greater than L_d (where L_d is the design leakage rate at pressure P_a, as specified in the Technical Specifications), which conforms to the requirement of 10 CFR 50 Appendix J, Option B that L_{am} shall be less than 0.75 L_a (where L_a is the maximum allowable leakage at pressure P_a). See Table 6.2-1 for pressure and leakage values

3. Results

   The preoperational leak rate test was concluded on December 7, 1984. The calculated leak rates at the 95 percent confidence level were below the acceptance criterion of 0.375 weight percent/day. The Appendix J acceptance criterion at 95 percent confidence level is 0.75 L_a = (0.75)(0.50 weight percent/day) = 0.375 weight percent/day. The accuracy of the test was verified by means of a supplemental test.

b. Periodic Leak Rate Tests

1. The peak pressure tests shall be conducted at P_a

2. Acceptance Criteria - same as Item 2 above.

The accuracy of Type A tests will be verified by a supplemental test. The verification is intended to be conducted by the Superimposed Leak Method.

Results from the supplemental test are acceptable provided the difference between the supplemental test data and the Type A data is within 0.25 L_a.

If this should not be the case, the reason shall be determined, corrective action taken, and a successful supplemental test performed.

6.2.4.4.2 Type B Test

The Type B test is intended to detect local leaks and to measure leakage across each pressure-containing or leakage-limiting boundary for the following primary containment penetrations:

a. Contained penetrations whose design incorporates resilient seals, gaskets, or sealant compounds, piping penetrations fitted with expansion bellows, and electrical penetrations fitted with flexible metal seal assemblies

b. Air-lock door seals, including door-operating mechanism penetrations that are part of the containment pressure boundary

c. Doors with resilient seals or gaskets, except for seal-welded doors.

Table 6.2-2 lists those penetrations that require Type B testing. A detailed description of those penetrations is found in Subsection 6.2.1.2.1.

Type B tests (except the test for the air lock) shall be performed and scheduled in accordance with the Primary Containment Leakage Rate Testing Program as described in the Technical Specifications, based on 10 CFR 50 Appendix J, Option B. Air locks shall be tested at 30-month intervals or after maintenance is performed on the air lock. Additionally, the interior and exterior door seals of the air locks shall be tested after each air-lock opening in accordance with the Primary Containment Leakage Rate Testing Program as described in the Technical Specifications, based on 10 CFR 50 Appendix J, Option B.

All components subject to Type B testing are equipped with test connections to allow pressurization with a test medium.

Soap-bubble testing at design pressure P_a will be used, if necessary, to provide a sensitive and rapid method for qualitative determination of leakage over large areas. The quantitative leakage measurements are made by pressurizing the component to be tested with air or nitrogen to design pressure P_a and measuring the amount of gas required to maintain that pressure.

The personnel access lock and equipment access doors are tested for leakage in accordance with approved written procedure, specifically, the Type B test procedures. The drywell personnel access lock has two mechanically interlocked, gasketed doors. These are designed and fabricated to withstand drywell design pressure.

The Type B test for the personnel access lock is conducted in three steps:

a. The exterior door seals are tested by connecting the local leak-rate test (LLRT) panel to a pressure tap, which has been provided, pressurizing the space between the door's testable gasket to design pressure, and measuring the leak rate

b. The interior door seals are tested in a manner similar to that of the external door seals

c. The space between the shut interior and exterior doors is tested by connecting the LLRT panel to a pressure tap, which has been provided, pressurizing to design pressure, and measuring the leak rate. Prior to conducting this step, tie-downs are installed on the interior door to ensure proper seating of the interior door's testable gasket when pressure is applied in a direction that is not normally expected. By design, both the interior and exterior doors seal with internal pressure, thereby providing a better seal as the drywell pressure increases.

When the tie-downs are installed on the interior door, the air lock cannot be operated from within.

The tie-downs are adjusted to permit compression of the gasket until the door is about 1/16 in. away from the frame. The forces exerted on the door during the leak-rate test (Type B) are the sum of the forces caused by the mechanical tie-downs and the forces attributable to the test pressure.

6.2.4.4.3 Type C Test

Table 6.2-2 lists all containment isolation valves that require Type C testing, plus a sketch of piping configurations and test connections.

Type C tests will be performed and scheduled in accordance with the Primary Containment Leakage Rate Testing Program as described in the Technical Specifications, based on 10 CFR 50 Appendix J, Option B.

The boundaries for each test will be established with consideration for minimizing the test volume. Test connections for venting, draining, and pressurization are provided on penetration piping that includes valves requiring Type C testing. To the extent practicable, the piping between the containment penetrations and the test connection isolation valves is minimized.

The tests shall be performed by local pressurization applied in the same direction that the valve would be required to perform its safety function, unless it has been determined that applying the pressure in the opposite direction will provide equal or more conservative results.

Valves listed in Table 6.2-2 as being Type C tested, except those having a water seal which can be maintained for at least 30 days after an accident requiring containment isolation, shall be pressurized with air or nitrogen to the design pressure P_a. Valves that have a water seal shall be pressurized with that fluid to a pressure of not less than 1.10 P_a.

Type C LLRT testing is not required for containment isolation valves that are located in piping of systems which penetrate the Torus and terminate below the minimum water level in the Torus when the systems are closed both inside and outside of containment. The Torus is designed and operated so that it is always filled with water. The supply of water in the Torus is assured during all design basis post-accident modes of operation. Consequently, the subject isolation valves will remain “sealed” by the water.

The water seal inside the Torus, in conjunction with the design of the piping associated with the penetrations, is a passive post-accident containment bypass leakage barrier. It precludes any direct communication between the post-accident Primary Reactor Containment atmosphere and the subject Containment Isolation Valves, thereby eliminating the possibility of post-accident containment bypass leakage. The torus is assured to maintain its level 30 days post accident, as described in Section 6.2.4.4.3. As such, the torus is not a “seal-water fluid system” as intended by Appendix J. Therefore, 10 CFR 50, Appendix J, Type C water leak rate testing for the lines and valves is not appropriate and is not necessary to ensure post-accident, containment integrity.

The combined leakage rate for all penetrations and valves subject to Type B and C tests shall be less than 0.60 L_a. Leakage from those valves that are sealed with a fluid from a seal system may be excluded when determining the combined leakage rate provided that

a. The fluid leakage limit is based on a radiological analysis of the plant site

b. The installed isolation valve seal system fluid inventory is sufficient to ensure sealing function for at least 30 days at a pressure of 1.10 P_a.

Test, vent, and drain (TVD) connections on Class 1 systems which are a part of the containment boundary are provided with at least two isolation valves and are sealed with a threaded pipe cap except for the vents on the RHR return piping inside the drywell which are provided with one isolation valve and a threaded cap. All other TVD connections which are a part of the containment boundary are provided with at least one isolation valve and sealed with a threaded pipe cap. Test, vent, and drain connections shall be under administrative control, and they shall be subject to periodic surveillance to verify their integrity and to verify the effectiveness of the administrative controls in ensuring closure.

There are six types of valves that are not tested in the accident direction: globe valves, gate valves, ball valves, relief valves, stop check valves, and butterfly valves. Each valve type is discussed separately in the following paragraphs.

Globe Valves (Note 2, Table 6.2-2)

All globe valves that are tested in the reverse direction have test pressure applied beneath the disk. The seating force of a globe valve is the vector sum of the actuator force and the fluid force on the valve plug. For all globe valves being considered, accident pressure is above the seat and is thus acting in the same direction as the actuator force, tending to close the valve. When a valve of this configuration is tested in the reverse direction (pressure under the seat), test pressure will be acting in opposition to the actuator force, thus tending to unseat the valve. Therefore, the resultant force on the seating surface will be less when test pressure is applied in the reverse direction than when pressure is applied in the accident direction. As there is only one seating surface where the fluid pressure is applied in a direction opposite to the actuator force, leakage will tend to increase due to the reduced seating load. Because leakage during a test in the reverse direction tends to be greater than when fluid pressure is applied in the accident direction, a test in the reverse direction is conservative.

Gate Valves (Note 4, Table 6.2-2)

All gate valves that are not tested in the accident direction are wedge-disk-type gate valves. In lieu of testing these valves in the accident direction, Edison tests them through the bonnet. The gate valve may be tested through a body/bonnet tap. This valve has a tap through which the body/bonnet area is pressurized. Leakage is measured through both seating surfaces along with leakage through the bonnet and packing. Compared with testing in the accident direction, this method of leakage testing is more conservative.

Butterfly Valves (Note 11, Table 6.2-2)

Twenty-seven butterfly valves serve as containment isolation valves and are subject to Type C leak testing. Twelve of the valves are inboard isolation valves, and the remaining 15 are outboard isolation valves.

During Type C testing, the pipe volume or test volume between the inboard and outboard valves will be pressurized. Pressurizing between the valves is necessary because test volumes cannot be established on the containment side of the inboard isolation valve given the present valve and line configurations. Thus, the inboard valves will have the test differential pressure applied in the reverse direction to the accident pressure.

Of the ten inboard valves located outside the primary containment, eight of the valves will have their pipe-to-valve flanges nearest containment seal welded to ensure a leaktight pressure boundary. Because of this seal weld, the inboard valves will have to be maintained in place. In order to change the valve seat, access from the disk side of the valve is necessary. Therefore, for all inboard valves that are located outside the primary containment, the valve disk must face away from the primary containment. There are 10 inboard valves located outside the primary containment. With this orientation, stem leakage of the inboard valves is not measured while pressurizing the test volume. Additionally, two of the inboard containment isolation valves are located inside the primary containment and are flanged into place.

For Type C testing, the stem leakage is measured by pressurizing to P_a through the stem vent and adding this stem leakage to the test volume leakage. The valve manufacturer has stated that the leakage through the stem is not dependent on the direction of the differential pressure. Consequently, pressurizing through the stem vent will yield stem leakage results that are conservative or equivalent to applying the pressure differential in the accident direction.

There are two inboard isolation valves on the inside of the containment. These valves have the disk facing the containment so that the valve seats are accessible. Pressurizing the test volume between the inboard and outboard valves will provide the stem leakage along with the seat leakage.

All the outboard valves have the disk facing toward the containment; thus test and accident differential pressures are in the same direction.

Relief Valves (Note 29, Table 6.2-2)

In addition to the safety/relief valves on the main steam lines, there are 17 relief valves that blow down to the pressure suppression chamber and therefore are classified as isolation valves. During a LOCA, containment pressure will be acting over the relief valve seat. Therefore, the direction of the accident pressure differential will tend to seat the valves.

Of the 17 relief valves, 15 of them will not be Type C LLRT tested. These 15 relief valves are located in piping of systems which penetrate the Torus and terminate below the minimum water level in the Torus. The Torus is designed and operated so that it is always filled with water. The supply of water in the Torus is assured during all design basis, post-accident modes of operation. Consequently, the subject isolation valves will remain "sealed" by the water.

The water seal inside the Torus, in conjunction with the design of the piping associated with the penetrations, is a passive, post-accident containment bypass leakage barrier. It precludes any direct communication between the post-accident Primary Reactor Containment atmosphere and the subject CIVs, thereby eliminating the possibility of post-accident containment bypass leakage. The Torus is assured to maintain its level 30 days post accident, as described in Section 6.2.4.4.3. As such, the torus is not a "seal-water fluid system" as intended by Appendix J. Therefore, 10 CFR 50, Appendix J, Type C water leak rate testing for the lines and valves is not appropriate and is not necessary to ensure post-accident containment integrity.

The two remaining valves in the CGC system will be in-situ tested in the accident direction at a pressure of P_a.

Stop Check Valves (Table 6.2-2)

There are four stop check valves in the HPCI and RCIC systems. All of these stop check valves have uncoupled globe style disks and motor operators.

Operating procedures provide instructions for closing these stop check isolation valves following a post-LOCA event when the HPCI and RCIC systems are no longer needed.

These four stop check valves will not be LLRT Type C tested. All four are located in piping of systems which penetrate the Torus and terminate below the minimum water level in the Torus. The Torus is designed and operated so that it is always filled with water. The supply of water in the Torus is assured during all design basis, post-accident modes of operation. Consequently, the subject isolation valves will remain "sealed" by the water.

The water seal inside the Torus, in conjunction with the design of the piping associated with the penetrations, is a passive, post-accident containment bypass leakage barrier. It precludes any direct communication between the post-accident Primary Reactor Containment atmosphere and the subject Containment Isolation Valves thereby eliminating the possibility of post-accident containment bypass leakage. The torus is assured to maintain its level 30 days post accident, as described in Section 6.2.4.4.3. As such, the torus is not a "seal-water fluid system" as intended by Appendix J. Therefore, 10 CFR 50, Appendix J, Type C water leak rate testing for the lines and valves is not appropriate and is not necessary to ensure post-accident, containment integrity.

Ball Valves (Note 13, Table 6.2-2)

There are 23 ball valves used for containment isolation; 10 of these are tested in the forward direction and 13 are tested in the reverse direction. All of these valves were manufactured by Jamesbury and are air operated and spring assisted to fail in the closed position.

Valves of this type have the same sealing characteristics in either direction. Consequently, test results obtained in the present configuration (i.e., reverse direction) are equivalent to testing in the accident direction. Additionally, these valves have a "corner seal" design on the stem and stem packing. This design eliminates stem leakage.

The spring assist merely rotates the ball valve in its seat. It does not increase the seat pressure; therefore, the spring assist has no effect on the leakage regardless of the test direction.

6.2.5 Primary Containment Combustible Gas Control

The NRC amended 10 CFR 50.44, “Standards for combustible gas control system in light-water-cooled power reactors” on October 16, 2003 to eliminate the requirements for hydrogen recombiners. The hydrogen recombiner Technical Specification requirements were subsequently removed by License Amendment 159, dated March 15, 2004. Regulatory Guide 1.7 was revised in March 2007 to reflect the amended 10 CFR 50.44. The Combustible Gas Control System (CGCS) has been retired in place with its electrical circuits de-energized and fluid process piping isolated from primary containment with redundant locked-closed isolation valves. Combustible gas control of the primary containment is provided by inerting the primary containment with nitrogen.

General Design Criterion 41 of 10 CFR 50, Appendix A, requires that systems be provided to control the concentration of hydrogen or oxygen and other substances that might potentially be released to the containment atmosphere. Title 10 CFR 50, Section 50.44, establishes the standards for these systems. In Fermi 2, no substances of a combustible nature (other than hydrogen and oxygen) would potentially be released in significant amounts to the containment atmosphere under LOCA conditions. To ensure that containment integrity is not potentially impaired due to buildup of combustible gases following a LOCA, Fermi 2 has an inert containment atmosphere with mixing capability. Hydrogen and oxygen concentrations are monitored. A purge system that uses the reactor building ventilation system or the SGTS is available. The purge system is not required to be a qualified system.

6.2.5.1 Deleted

6.2.5.2 System Design

6.2.5.2.1 Deleted

6.2.5.2.2 Design Features

The CGCS is retired, but all components remain in place as shown in the piping and instrumentation diagram in Figure 6.2-23. The primary containment isolation valves associated with the CGCS have been manufactured, fabricated, and tested in accordance with the requirements of the ASME B&PV Code Section III, Class 2, 1971 edition, summer 1973 addenda.

6.2.5.2.3 Hydrogen/Oxygen Monitoring

Because Fermi 2 has an inerted primary containment atmosphere during reactor operation, the oxygen concentration, in the event of a LOCA, is the limiting parameter. The hydrogen and oxygen concentrations are continuously monitored, and are displayed in the main control room. Grab samples are obtained on a weekly basis to ensure the correct operation of the monitoring system. Samples are also taken prior to containment entry. Subsection 7.6.1.12 contains a description of the hydrogen/oxygen monitoring system. To ensure representative sampling, multiple ports allow gas to be drawn into the monitoring system from several locations in the containment. An alarm indicates when the oxygen concentration reaches a preset level.

6.2.5.2.4 Deleted

6.2.5.2.5 Containment Purge

Containment purge capability is provided for the purpose of removing fission product activity from the containment atmosphere and pressure control. Containment purge can also be utilized for combustible gas control following a significant beyond design-basis accident. Piping and valves are provided, connecting the containment atmospheres to the SGTS or reactor building heating, ventilation, and air conditioning (HVAC) system as shown in Figure 9.3-14. The purge system is comprised of the large purge piping used for purging and inerting and a smaller on-line purge system used for nitrogen vent/makeup and pressure control. Isolation valves and piping at the primary containment boundary meet the requirements of Section III ASME B&PV Code, Class 2, and are designed in conformance with Category I requirements. The SGTS treats the containment atmosphere prior to its release to the environment.

The drywell air purge inlet and vent outlet lines are 24 in. in diameter while the suppression chamber purge and vent lines are 20 in. in diameter. Both suppression chamber and drywell outboard isolation valves are supplied with a 6-in. bypass for use when the larger valve is to remain closed. The drywell bypass valve and suppression chamber bypass valve will isolate automatically.

During a power increase and drywell temperature increase, the drywell vent bypass line is opened periodically to maintain a constant drywell pressure. The drywell vent bypass line is also used to alleviate pressure buildup due to leakage from pneumatic solenoid valves. The purge system is not used during normal reactor operation to reduce airborne activity in the primary containment.

Containment vent line effluents are directed to the reactor building ventilation exhaust duct or to the SGTS for release. See Figure 6.2-20. The purge lines can open to the secondary containment volume, which is processed by the SGTS.

Because purging is initiated under the reactor operator's control, and the effluent from the SGTS is monitored for radioactivity, the incremental dose at the low-population zone during the purging will be controlled to ensure that the purge dose does not cause the total dose (LOCA plus purge dose) to exceed the limit specified in 10 CFR 100. High-radiation monitors prior to the reactor building HVAC exhaust fans isolate the containment purge valves and initiate the SGTS. The purge/inert valves comply with BTP CSB 6-4 of SRP 6.2.4. as follows:

a. The design basis for the valves includes the higher post-LOCA pressures

b. The operation of Fermi 2 containment purge and vent valves is in accordance with the Technical Specifications and is consistent with the guidance of the BTP for use of a single supply and exhaust line

c. The nitrogen purge supply valves for the torus and drywell are 6-in. and 10-in. valves, respectively. The exhaust line from both the torus and drywell are provided with 6-in. valves in parallel with the outboard isolation valve

d. Automatic isolation occurs on low reactor water level (level 2), high drywell pressure, or high radiation. The air-operated isolation valves fail closed on loss of air. The motor-operated isolation valves fail as is, but are only used in series with an air-operated isolation valve. Table 6.2-2 defines which of the above criteria are applicable to each specific isolation valve. The valves are listed in this table under penetration numbers X-25, X-26, X-205C, X-205D

e. The purge and vent valve closure times are consistent with the 5-sec requirement of the BTP

f. Debris screens have been provided for the purge valves inside the drywell to prevent debris from becoming entrained in the valves

g. The purge and vent system is not relied on for temperature and humidity control. The drywell cooling system is described in Subsection 9.4.5, and the vent/makeup of nitrogen for the containment is described in Subsection 9.3.6

h. Isolation valve testing of specific purge and inlet isolation valves is indicated in Table 6.2-2. The testing program is described in Subsection 6.2.4.4. The operability of the isolation function and the purge valve leakage rate are verified in accordance with the Technical Specifications

i. The radiological consequences of a LOCA while purging have been evaluated both specifically for Fermi 2, and generically by the NRC. Both a Fermi 2 specific analysis and the NRC's "Generic Evaluation of the Radiological Consequences of Accidents While Purging or Venting at Power-Multi-Plant Action Item B-24" indicate that while venting or purging at power, the dose contribution through open valves is small

j. The SGTS is downstream of the purge system isolation valves. Operation of the SGTS while purging will be limited and controlled to protect the SGTS from loss of function from the environment created by the escaping air and steam. The Technical Specifications delineate the limits on the use of the SGTS while purging or venting. This limit is further controlled by the Technical Specifications, which require that only one division of the SGTS be used.

k. Fermi 2 net positive suction head (NPSH) requirements for emergency core cooling system (ECCS) pumps are in conformance with Regulatory Guide 1.1. The Regulatory Guide allows no credit for positive containment pressure in the NPSH calculations. Therefore, a reduced containment pressure due to purging has no safety consequence on ECCS pump NPSH margins.

6.2.5.2.5.1 Hardened Torus Vent System

A hardened torus vent system has been installed at Fermi 2 under the 10 CFR 50.59 process in response to NRC Generic Letter 89-16, "Installation of Hardened Wetwell Vent".

During severe accidents which are outside the design basis, plant emergency procedures direct the operators to vent the wetwell airspace to prevent exceeding the primary containment pressure limit. Venting permits controlled releases by preventing permanent damage to the drywell. In addition, venting from the wetwell scrubs fission products from the effluent and reduces radioactive releases. The benefits of venting over a rupture of the drywell are reduced radiological consequences. The purpose of a hardened wetwell vent system is to provide a reliable design consistent with the safety objective of the plant emergency procedures.

The vent is sized to meet or exceed the BWR Owners Group (BWROG)/NRC general design criteria which require that under the conditions of (1) a constant heat input at a rate equal to 1.1 percent of rated thermal power and (2) containment pressure is equal to the primary containment pressure limit (PCPL), the exhaust flow through the vent is sufficient to prevent the containment pressure from increasing.

The hardened torus vent system consists of a 10-inch, Schedule 40, carbon-steel pipe routed from the 24-inch standby gas treatment system (SGTS) inlet header on the fifth floor Reactor Building through the Reactor Building siding into a stack which discharges at an elevated location. The 10-inch pipe contains two torus vent secondary containment fail closed isolation valves (TVSCIV), T4600F420 and T4600F421. The TVSCIVs air-operated butterfly valves (AOVs) are normally supplied by Division II non-interruptable control air supply (NIAS). The AC solenoid valves are normally powered by the reactor protection system (RPS) and divisionally separated. The inboard AOV is powered by Division I RPS and the outboard AOV is powered by the Division II RPS. Spectacle flanges, to facilitate maintenance of the AOVs, are installed upstream and downstream of the AOVs, with one outboard spectacle flange located outside the Reactor Building. Controls and position indications for the AOVs are located in the control room and are keylocked to prevent inadvertent positioning.

The piping from the first spectacle flange downstream from the existing header up to and including the second spectacle flange is Class D, QA Level I, and Seismic Category I. This is consistent with the original classification of SGTS. From the second spectacle flange through the remainder of the stack is QA Level 1M and Seismic II/I. The TVSCIVs maintain secondary containment integrity and are Class D, QA Level 1, Seismic Category I, and fail safe. The valves have been environmentally qualified to NUREG-0588 Category 2B (Mechanical) for pressure boundary integrity purposes. The leak tightness of the TVSCIVs is ensured by performing the secondary containment drawdown test at regular intervals.

Air supply for the primary containment isolation valves T4600F400, F401, and F412 in the SGTS has been changed from interruptable air supply (IAS) to Division 2 NIAS to improve venting reliability.

The pilot AC solenoid valves for the TVSCIVs are supplied by NIAS and are Class D, QA Level I, Seismic Category I, and have been environmentally qualified to NUREG-0588 Category 2B (Mechanical) and 2C (Electrical) to maintain the pressure boundary integrity of NIAS. The limit switches are QA Level non-Q, Seismic Category II/I.

A radiation monitor is installed on the 4th floor of the Auxiliary Building to enable monitoring of any radiological releases when the vent is open. The monitor is QA Level 1M, Seismic Category II/I, and has indication and alarm in the control center to alert the operators of a radiological release. The monitor also has an interface with the Integrated Plant Computer System (IPCS). Arrangement details are shown in Figure 11.4-4. The details of the radiation monitoring system are described in Subsection 11.4.3.11.3.

The torus hardened vent system components which require electrical power are the radiation monitor, solenoid valves, and the controls of the hardened vent air operated isolation valves. There are two TVSCI valves in series that are keylock switch controlled and fail closed. To preclude any inadvertent opening of the vent line to the atmosphere and jeopardizing secondary containment integrity due to a single failure, the two TVSCIV pilot solenoid valves are powered by different Divisions of RPS. The radiation monitor is powered as described in Subsection 11.4.3.11.3.

The hardened vent system is designed to be used for events that are outside the design basis of the plant. Therefore, the system does not comply with the design basis described in Subsection 6.2.5.1. The RPS power supply is selected to power the above components for reliable operation of the system. The RPS branch circuits feeding the hardened vent system components are adequately protected through properly coordinated safety grade fuses. Since RPS is a fail-safe system and the branch circuits used in the hardened vent system are properly protected, any single failure in the hardened vent system cannot prevent the RPS' ability to scram the reactor when it is needed. The power supply to each of these valves is divisionally separated and each valve control circuit is defeated through a normally open contact of a qualified keylocked selector switch; thus no single failure can inadvertently open the vent path nor can it prevent the ability of the RPS system from performing the scram action when it is needed. Furthermore, the RPS power to non-safety grade torus hardened vent system components is consistent with Fermi 2 design practices and by design any potential of full scram due to single failure or non-Q component failure in the hardened vent system is avoided. Therefore, the RPS system's intended design function to safely shut down the reactor is not compromised.

Beyond Design Basis Events:

As part of the response to the Fukushima Event, the NRC issued Order EA-13-109 and Interim Staff Guidance (ISG) JLD-ISG-2013-02 which requires Licensees:

a. Provide a reliable Hardened Containment Vent System (HCVS) to assist in preventing core damage when heat removal capability is lost.

b. Ensure that venting functions are also available during sever accident conditions. Sever accident conditions involving extensive core damage include elevated temperatures, pressures, radiation levels and combustible gas concentrations, such as hydrogen and carbon monoxide. This includes accidents involving a breach of the reactor vessel by molten core debris.

To comply with this order Fermi has modified the existing HCVS as follows:

a. Installed an alternate pneumatic gas supply to containment isolation valves, TVSCIVs and boundary valves associated with the Hardened Vent to allow control during and after a severe event.

b. Provided required panels, 130 VDC power supply, 120 VAC power supply, required instruments, and indications at panels outside and inside the control room.

c. Modified the HCVS exhaust stack to lengthen the stack, install a check valve to preclude backflow of air into the pip, and install a weather shroud.

During normal plant operation and during Design Basis Accidents the Hardened Containment Vent Equipment is de-energized and/or isolated. Upon declaration of a Hardened Containment Venting Scenario, the necessary hardened vent equipment is activated to support mitigation of the event. The intent being to address the station needs for the first 24 hours until the FLEX equipment can be brought on-line.

The provision of these modifications establishes alternate means of providing motive force (compressed gas) and electric power to assure the capability of the Hardened Vent to remain operable during and after a severe accident.

6.2.5.3 Safety Evaluation

The corrosion of containment materials was considered as a potential source of hydrogen. The corrosion of aluminum, zinc, and zinc-base paints located either in the drywell or torus was evaluated for a potential source of hydrogen. It was determined that these potential sources were insignificant for the following reasons:

1. The containment spray solution, if used, does not contain any chemical additives. The pH of the spray solution is 6.5 to 7.0

2. Aluminum corrosion is highly pH dependent. The Oak Ridge National Laboratory (ORNL) experiments described in Reference 29 have determined that at high pH (approximately 9.3), the corrosion of aluminum was about 100 times greater than at a pH 6.5 to 7.5, which was shown to be negligible

3. Although the corrosion of zinc does not exhibit the same pH dependence as aluminum, the corrosion of both zinc and aluminum is highly temperature dependent. The post-LOCA time/temperature profile in the drywell and torus is much less severe than that experienced in typical BWR

containments. The magnitude, as well as duration, of elevated temperature, is short-lived as shown in Figures 6.2-27, 6.2-29, 6.2-30, and 6.2-16

Because of these reasons, the corrosion of aluminum and zinc is relatively insignificant and does not represent a significant source of hydrogen.

6.2.5.4 Deleted

6.2.5.5 Deleted

6.2.5.6 Materials

There are no materials in the CGC system subject to radiolytic or pyrolytic decomposition under the conditions that would exist following a postulated LOCA. The principal materials used are

a. The heated components forming the containment boundary of the system are type 304 (or equivalent) stainless steel in accordance with the appropriate ASME material specifications, and Section III, Class 2 requirements

b. Unheated components forming the containment boundary conform with Section III, Class 2 of the ASME Code. Carbon steel, per SA-106, Grade B or SA-333, Grade 6, is used for piping, SA-216 for castings, and code allowable carbon steels for plate, forgings, weld rod, and other components, as appropriate.

6.2.6 Main Steam Isolation Valve Leakage Control System

Note: As a result of the re-analysis of the Loss-of-Coolant Accident (LOCA) using an Alternative Source Term (AST) methodology, it is no longer necessary to credit the Main Steam Isolation Valve Leakage Control System (MSIVLCS) for post-LOCA activity leakage mitigation.

6.2.6.6 Design of Main Steam System Piping and Valves

The main steam piping system, from the outboard MSIV to the appropriate anchor positions of all branch lines downstream of the third MSIV, is seismically qualified. The main portion of the main steam system is located in the turbine building, which is seismically qualified to withstand the effects of an operating-basis earthquake (OBE) or a safe-shutdown earthquake (SSE) event.

The main steam system has been seismically analyzed to ensure its integrity after either an OBE or an SSE event. The section of main steam piping analyzed begins at the anchor outside the primary containment and ends at the anchor in each of the branch lines downstream of the third MSIV. The seismic analysis of this portion of the main steam piping and included valves verifies that piping structural and pressure integrity will be maintained, and that included valves will remain in the elastic stress range after either an OBE or an SSE event.

6.2.6.6.1 Main Steam Lines

The main steam lines and branch connections downstream from the outboard containment isolation valve are classified as Group D, where these sections of pipes shall meet all pressure integrity requirements of Group D.

6.2.6.6.2 Valves in Branch Lines Connected To Main Steam Lines

The block valve(s) in branch lines connected to the main steam lines downstream of the outboard MSIV shall meet all the pressure integrity requirements of Group D.

Nominal downcomer diameter, ft	2
Drywell free volume/pressure suppression chamber free volume	1.25
Deleted	
Containment heat removal capability per loop, using 85°F service water and 165 °F pool temperature; 1 RHR and 2 service water pumps, Btu/hr	66.5×10^6

VII. Recirculating Line Break Accident Initial Conditions and Calculated Response

	Value
Effective accident break area (total), ft^2	4.1

TABLE 6.2-1 CONTAINMENT PARAMETERS[a]

Componentsof effective break area	
Recirculation line (area), ft^2	3.5
Equalizer line (area), ft^2	N/A
RWCU line (area), ft^2	0.07
Jet pumps (area), ft^2	0.55
Break area/ vent area $\frac{4.1}{226}$ =	0.018
Reactor pressure vessel and attached piping initial liquid volume, ft^3	13,706
Drywell	
Initial temperature, °F	145
Initial pressure, psig	0.75
Relative humidity, percent	20
Suppression pool	
Initial temperature, °F	95
Initial pressure, psig	0.75
Relative humidity, percent	100
RHR complex reservoir initial temperature, °F	80 – 90[b]
Calculated peak drywell pressure, psig	49.9
Calculated drywell margin, percent	19.5[c]
Calculated peak suppression pool pressure, psig	28.3
Calculated suppression pool margin, percent	54.35c
Calculated peak deck differential pressure margin, psig	N/A
Calculated deck differential pressure margin, percent	N/A
Peak pool temperature during blowdown, °F	≈135

TABLE 6.2-1 CONTAINMENT PARAMETERS[a]

Long-term peak pool temperature from accident, °F (with degraded containment cooling system)	196.5

[a] This list of parameter and results corresponds to those referred to in Subsection 6.2.1.2, Primary Containment System Design.

[b] RHR service water varies linearly from 80 °F to 90 °F over a period of 8 hours.

[c] Percent below maximum allowable pressure of 62 psig.

TABLE 6.2-2 SUMMARY OF PRIMARY CONTAINMENT PENETRATIONS AND ASSOCIATED ISOLATION VALVES

CODES AND SYMBOLS

Penetration Details

Standard mechanical symbols are employed to represent piping details. Each penetration detail provides the following information:

Symbol	Description
1. ◇	- Penetration details in numerical order
2. (TC)	- Test connection for Type C testing
3. (TV)	- Test vent for Type C testing
4. TB	- Test Barrier

Valve Type

The following codes are used to identify valve type:
CHK - Check
GAT - Gate
GLB - Globe
BFY - Butterfly
REG - Regulating
BAL - Ball
REL - Relief
EFC - Excess Flow Check
SCK - Stop Check
BCK - Ball Check
SHR - Shear

Actuator Type

The following codes are used to identify valve actuator type:

AO - Air Operator
SO - Solenoid Operator
MO - Motor Operator
M - Manual
SA - Self Actuated
EX - Explosive

Valve Position

The following codes are used to identify different valve positions:

O - Open
C - Closed
AIS - As Is
LC - Locked Closed
LO - Locked Open

Miscellaneous

A dash (-) indicates that technical information is not applicable to this column

This column references the appropriate General Design Criteria of 10 CFR 50, Appendix A (or other defined basis) with which the penetration is in compliance.

Bypass Leakage

Bypass leakage paths are identified in this table by a "Yes or a "No". Bypass leakage paths are further discussed in Section 6.2.1.2.2.3.

Primary/Secondary Actuation Modes

These columns indicate the nature of the containment isolation signal as follows:
A - Automatic
RM - Remote Manual
RF - Reverse Flow
M - Manual
HF - High Flow

Engineered Safety Feature

Valves in Engineered Safety Feature systems are identified in this column by a "yes" entry. An "R" entry identifies a valve in an Engineered Safety Feature-related system. Such Systems are not required to function following the design basis loss-of-coolant accident. However, if the system is available, it can be used to accomplish a function similar to an Engineered Safety Feature system.

Containment/Accident Isolation Signals

The following codes are used to abbreviate isolation signals:

Signal	Description
A	Reactor Vessel Low Level 1
B	Reactor Vessel Low Level 2
C	Reactor Vessel Low Level 3
D	Main Steam Line High Radiation
E	Main Steam Line High Flow
F	Main Steam Line Tunnel High Temperature
G	Main Steam Line Low Pressure
H	Torus Pressure ≥ Secondary Containment Pressure
J	Low Condenser Vacuum
K	High Drywell Pressure
L	High Reactor Vessel Pressure
M	High-High Sump Level Torus Area or High-High Drywell Floor Drain Sump Level
N	High Sump Level or High Sump Temperatures
P	Turbine Building High Temperatures
R	Reactor Building Exhaust Radiation High
W	RWCU System Line 1) SLCS Initiation (Outboard Valve Only) 2) High RWCU Differential Flow 3) High RWCU Area Temperature 4) High RWCU Area Ventilation Differential Temperature 5) Reactor Vessel Low Water Level 2
X	HPCI System Steam Lines 1) HPCI Space High Temp. 2) High Steam Flow 3) High Turbine Exhaust Pressure 4) HPCI Steam Line Low Pressure
Y	RCIC System Steam Lines 1) RCIC Space High Temp 2) High Turbine Exhaust Pressure 3) High Steam Flow 4) RCIC Steam Line Low Pressure
Z	Closes Through Electrical Interlocks With Other System Valves of Pump Motors

NOTES

Note	Description
1.	This piping consists of the eight vent pipes that connect the drywell and pressure suppression chamber. As part of the primary containment structure, they are Type A tested.
2.	Globe valve tested in the reverse direction. Results obtained in this test configuration are conservative since test pressure tends to unseat the valve disk.
3.	These valves will be tested at a differential pressure of 25 psi with the reactor at atmospheric pressure (i.e., 25 psig).
4.	Gate valve tested through the bonnet. This valve has a bonnet tap through which the bonnet area is pressurized. Leakage is measured through both seating surfaces along with leakage through the bonnet. Compared with testing in the accident direction, the bonnet test leakage is conservative.
5.	Air-operated, spring-to-close, positive-acting check valve. Can be closed by remote manual operation from the control room when system isolation is required.
6.	Remote manual containment isolation valve in an ESF-related system. Provisions are made to detect leakage from this line outside the containment. See Table 5.2-11.
7.	Remote manual containment isolation valve in an ESF system. Provisions are made to detect leakage from this line outside the containment. See Table 5.2-11.
8.	Valve isolates when reactor pressure exceeds 75 psig.
9.	Manual or remote manual valve that is locked closed and remains closed after a LOCA.
10.	Two containment isolation valves located outside the containment. Due to the design of both the containment and the system, it is not practical to locate one of the two valves inside the containment. Both valves are located outside the containment as close as practical to the containment wall.
11.	Butterfly valve tested in the reverse direction. Reverse flow tests are designed to provide equivalent or conservative results compared with testing in the accident direction. In cases where stem leakage is not measured by the leakage out of the test volume, stem leakage is determined by testing through the stem vent and this leakage is added to the test volume leakage. Additional tests on purge system butterfly valves are set forth in the Technical Specifications.
12.	Single isolation valve and closed system outside the containment. This line contains a single isolation valve based on a. The line is in an ESF or ESF-related system b. System reliability is greater with one isolation valve c. The system is a closed system outside the containment d. A single active failure can be accommodated with one isolation valve in the line. The specific closed system requirements met by this system outside the containment include missile protection, Category I, and Quality Group B design standards. For instrumentation piping, the systems are designed and installed as Quality Group B, up to and including the isolation valves. The balance of the instrument piping is designed to meet Quality Group B design criteria. These design criteria include stress analysis with consideration given to dead-weight, thermal, and seismic conditions. The systems are seismically supported. Nuclear grade material is used throughout the fabrication of the piping system. The design temperature and pressure ratings of the systems are greater than those of the containment.
13.	Ball valve tested in the reverse direction. Results obtained in this configuration are equivalent to testing in the accident direction, since valves of this type have the same sealing characteristics in either direction.
14.	Jet pump flow instrumentation lines are provided with manual globe valves and excess-flow check valves outside the containment. Also, flow is restricted to a 1/4-in. orifice at the nozzle. Therefore, these instrumentation lines are designed in accordance with the recommendations of Regulatory Guide 1.11 (Safety Guide 11). All instrument line penetrations will be Type A tested.
15.	Instrumentation penetration. Standard instrumentation penetrations are provided with six instrument tubes. In this table, only those tubes that are utilized by instrument lines are addressed. All other instrument tubes associated with the penetration are spares and are Type A tested.
16.	Instrument lines of this type are provided with a flow-restricting orifice inside the containment and a manual globe valve and excess-flow check valve outside the containment in accordance with the recommendations of Regulatory Guide 1.11 (Safety Guide 11). All instrument line penetrations will be Type A tested.
17.	The TIP system lines do not communicate freely with the containment atmosphere or the reactor coolant. General Design Criteria 55 and 56 are not directly applicable to this specific class of lines. The basis to which these lines are designed is more closely described by GDC 54, which states in effect that the isolation capability of a system should be commensurate with the safety importance of that isolation. Furthermore, even though the failure of the TIP system lines presents no safety consideration, the TIP system guide tubes have redundant isolation capabilities. The safety features have been reviewed by the NRC for BWR/4 (Duane Arnold), BWR/5 (Nine Mile Point) and BWR/6 (GESSAR), and it was concluded that the design of the containment isolation system meets the objectives and intent of the GDC. The TIP guide tube assembly and the portion of the tubing between the guide tube assembly and the containment flange are considered to be instruments and as a result are not classified as ASME components but are purchased and installed as safety-related assemblies. A valve system is provided with a valve on each guide tube entering the primary containment. These valves are closed except when the TIP system is in operation (open an average of 15 hr/month). A ball valve and a cable-shearing valve are mounted in the guide tubing just outside the primary containment. They prevent the loss of containment integrity. The ball valve position is indicated in the control room. The shear valve is used only if containment isolation is required when the TIP is beyond the ball valve and when power to the TIP system fails. The shear valve, which is controlled by a manually operated keylock switch, can cut the cable and close off the guide tube. The shear valves are actuated by detonation squibs. The continuity of the squib circuits is monitored by indicator lights in the main control room. Identical-design shear valves are shop tested by statistical

TABLE 6.2-2 SUMMARY OF PRIMARY CONTAINMENT PENETRATIONS AND ASSOCIATED ISOLATION VALVES

Note	Description
	sampling methods to ensure operability and leaktightness. The Technical Specification testing requirements for the TIP shear and ball valves are a. Verifying the continuity of the explosive charges at least every 31 days b. Initiating one of the explosive charges once every fuel cycle. The replacement charge shall be from the same manufactured batch as the one fired or from another batch that has been certified by having one of -that batch successfully fired c. Replacing all charges according to the manufacturer's recommended lifetime for the charges d. Performing Type C tests on the ball valves in accordance with a performance based leak testing program in Technical Specification 5.5.12.
18.	A plant modification, EDP-4940, changed the routing of the nitrogen purge supply line to the TIP system. The nitrogen source is taken from a primary containment pneumatic system line inside the drywell. Penetration X-35G thus becomes a spare, the pipe penetrating the drywell is capped and welded, and GDC 56 no longer applies.
19.	The control rod drive (CRD) insert and withdrawal line. Each of the 185 CRD withdrawal lines is separated from the RPV by a redundant seal design in the CRD units. Each of the 185 CRD insert lines has a CRDM flange ball check valve that isolates the line from the RPV following a scram. The redundant seal system, the CRDM flange ball check valve, and a manual isolation valve provide adequate isolation in the event of a line break in the hydraulic control unit (HCU) or the scram discharge volume (SDV). During a scram, the 185 outlet scram valves open and the four SDV vent and drain valves close. If the scram system is not reset, thus closing the scram inlet and outlet valves, CRD seal leakage could slowly pressurize the SDV to the RPV pressure. Therefore, the SDV vent and drain valves along with 185 drive and 185 cooling water ball check valves will be Type A tested. Leakage from the CRD system into the reactor building is detected for the full spectrum of leakage rates. Small leaks will be detected by observation during daily inspection rounds of the control unit areas by operators. Large leaks will be detected by duty timers on the reactor building floor drain sump pumps. A large leak of reactor coolant from any insert line will be automatically isolated by the ball check valve in the CRD housing. Leaks of CRD supply water will be indicated by increased flow as continuously recorded in the control room. The CRD directional control valves are normally closed and are automatically closed upon a reactor scram signal. Excessive leakages through the scram valves will be detected by duty timers on the sump pumps.
20.	The residual heat removal (RHR) system discharge line to the containment spray header receives an automatic containment isolation signal. The operator may, however manually override the isolation signal as needed to reduce containment temperature and pressure.
21.	Due to system configuration, the test pressure is not in the same direction as the pressure existing when the valve is required to perform its containment isolation function. The valve will be tested in the correct direction during the Type A tests.
22.	The standby liquid control system (SLCS) has been designed to reflect the importance of the functions it may perform. The probability of reliable and timely actuation of this system is enhanced by inclusion of fewer valves and simplicity of design. The use of a check valve outside the containment is consistent with these system design requirements.
23.	This is a penetration of the vent pipe inside the torus and thus is not a bona fide containment penetration. It is included in this table for completeness only.
24.	This butterfly valve is normally closed and opens automatically to prevent formation of negative pressure in the torus. This butterfly valve closes automatically upon increasing torus pressure and remains closed during containment high-pressure conditions. Upon loss of power or degraded voltage, the butterfly valve will open but closes automatically once power is restored or voltage recovers.
25.	Secondary containment to torus vacuum breaker. This vacuum breaker opens automatically to prevent formation of a negative pressure in the torus. This line is essential to ensure primary containment structural integrity. The probability of system operation is enhanced by using fewer valves and by the simplicity of design. The use of a check valve outside containment is consistent with these system design requirements.
26.	The flow path associated with this penetration inside containment terminated below the low water level in the suppression pool. A water seal is assured during normal plant operation and for more than 30 days following an accident requiring containment isolation. It is not credible that these isolation valves will be exposed to the containment atmosphere at any time following the accident. These penetration containment isolation valves will be Type C seat leak tested using water or air as the test medium. In some cases, due to system configuration, the Type C test pressure will not be in the same direction as the pressure existing when the valve is required to perform the containment isolation function. The valves will be a part of the periodic Type A tests where the test pressure is applied in the correct direction.
27.	Relief valve used as a containment isolation valve. The construction and orientation of this valve is such that increased containment pressure acts in conjunction with spring pressure to increase the seating force of the valve and tends to reduce leakage. Thus the relief valve setpoint has no bearing on containment isolation.
28.	Flange on relief valve discharge to be Type B tested.
29.	Due to system configuration, the test pressure on the relief valve is not in the same direction as the pressure existing when the relief valve is required to perform its containment isolation function. The test pressure is applied under the relief valve seat. This is conservative since it tends to unseat the relief valve.
30.	Not used.
31.	These valves do not close on the containment isolation signals, but automatically close on accident isolation signal as identified in Table 6.2-2.
32.	These valves close on the containment isolation signals but are also provided with a manual override to these signals to reopen the valves. This is done to provide divisional control air/nitrogen for the controls of pneumatic equipment/instruments inside the drywell.
33.	Flanged portion of the residual heat removal head spray piping, between reactor pressure vessel and the refueling floor bulkhead penetration, is permanently removed. Remaining line within the drywell is blind flanged.
34.	Valve closes on a high drywell pressure signal to isolate the drywell heat load.
35.	SLCS initiation signal is not a containment isolation signal. This signal prevents removal of liquid poison in the event of standby liquid control system actuation.
36.	Penetrations X-13A and X-13B will have a 30-day water seal during and following a postulated LOCA. Therefore valves E1100-F050A, F610A, F050B, and F610B are not considered containment isolation valves and therefore are not subject to Type C testing (see TS Amendment 98).
37.	30-day water seal for penetrations X-13A and X-13B (during and following a postulated LOCA) requires external water leakage, through valves E1150-F015A and F015B, to be less than 5 ml/min. at 1.1 Pa, i.e., 62.2 psig. As these valves will be subjected to a more conservative PIV test that demonstrates external leakage less than 5 ml/min. at a pressure of 1045 psig, TS Amendment 98 exempts these valves from Type C air test.
38.	Flexible wedge gate valve tested in the accident direction and through a body\bonnet tap from a single test connection. Leakage is measured past the outboard seating surface.
39.	Single isolation valves on a closed system both inside and outside of containment. The flow path associated with this penetration inside containment terminates below the low water level in the suppression pool. A water seal is assured during normal plant operation and for more than 30 days following an accident requiring containment isolation. It is not credible that these isolation valves will be exposed to the containment atmosphere at any time following the accident. Also many of the valves are required to be open post-accident to fulfill their safety function. Type C LLRT testing is not required when the valve is located on a closed system and on a line which terminates below the minimum water level of the suppression chamber.
40.	Valve is interlocked to inhibit opening on low reactor water level signal (Level 1) to ensure all RHR flow is directed to the reactor vessel.
41.	A plant modification, EDP 33297, modified the service air piping to the drywell. The pipe penetrating the drywell is plugged and welded and GDC 56 no longer applies.
42.	A plant modification, EDP 35267, plugged the Main Steam Isolation Valve Leak Control System at the Main Steam Line interface. Therefore, GDC 55 no longer applies.
43.	In case of a loss of power event, T5000F420B can be reopened using a DC solenoid valve with a dedicated nitrogen supply system.
44.	In case of a Beyond Design Basis External Event, T4600F400 and T4600F401 can be reopened using a 3-way piloted shuttle valve with a dedicated nitrogen supply system.
45.	The Combustible Gas Control System (CGCS) has been retired in place with its electrical circuits de-energized and fluid process piping isolated from primary containment with redundant isolation valves. These valves are locked closed and can only be operated locally.

TABLE 6.2-4 DRYWELL TO SUPPRESSION CHAMBER VACUUM BREAKER VALVE DATA

1.	Number of drywell-to-suppression chamber vacuum breaker valves	12
2.	Valve size	20 in. seat x 18 in. flanged outlet
3.	Valve location	
	Elevation	Valve centerline 562 ft 8.5 in.
	Position	Two valves on each drywell support chamber downcomer with azimuth locations 22° - 30', 67° - 30' 112° - 30', 247° - 30', 292° - 30', and 337° - 30'
4.	Differential pressure to open	0.5 psid
5.	Valve manufacturer	GPE Controls of Morton Grove, Illinois
6.	Design temperature	350 °F
7.	Design pressure	62 psig
8.	Hydrostatic test pressure	87 psig
9.	Valve position indication	Limit switches, circuitry, and indicator lights. Closed limit switches are redundant
10.	Main control room panel number	Indicating lights are on panel H11-P808 and H11-P817

TABLE 6.2-5 PRIMARY SYSTEM ENERGY DISTRIBUTION AT THE TIME A RECIRCULATION LINE BREAK ACCIDENT OCCURS

Fluid Energy[a]	Energy (10^6 Btu)
1. Steam	30.6
2. Liquid	346.8
Sensible Energy	
1. Reactor pressure vessel	103
2. Reactor internals (less core)	78.9
3. Core	7.5

[a] All energy values are based on a 32 °F datum. Fuel energy is based on a datum of 285 °F.

TABLE 6.2-6 HAS BEEN INTENTIONALLY DELETED

TABLE 6.2-7 ACCIDENT CHRONOLOGY DESIGN BASIS RECIRCULATION LINE BREAK ACCIDENT

		Time (sec) Minimum ECCS Available
1.	Vents cleared	0.2
2.	Drywell reaches peak pressure	4.6
3.	Maximum positive differential pressure occurs	4.6
4.	Initiation of the ECCS	60**
5.	Vessel reflooded	220*
6.	Introduction of RHR heat exchanger	1200
7.	Containment reaches peak secondary pressure	1×10^4 (2.8 hr)

* This value taken from the containment analysis models; it is onlysignificant in confirming that core reflooding occurs before pool cooling or other RHR functions are needed.

** The containment analysis was based on a 30-sec maximum analyzed HPCI response time. The HPCI design basis has been subsequently revised to incorporate a 60-sec maximum system response time. The containment analysis is not impacted by increasing the HPCI response time from 30 sec to 60 sec. The short-term containment analysis calculates a peak containment pressure before the HPCI injects. The long-term calculation assumes one RHR loop is operating in the containment cooling mode at partial pumping capacity. Core cooling is provided by the core spray system and the RHR/LPCI pump and no credit was taken for the HPCI system (UFSAR Section 6.2.1.3.3) for long-term core makeup.

TABLE 6.2-8 PRIMARY AND SECONDARY CONTAINMENTS SURFACE COATING SCHEDULE PRIMARY CONTAINMENT[f]

Type of Coating	Location	Approx. Average DFT[a] (mils)	Approx. Total Surface (ft^2)
Carbozinc 11	Drywell interior steel Interior structural steel hangers and supports Vent line interior	7	120,000
Plasite 7155[bc]	Torus interior	12	38,000
Carboguard 6250 N[b,c,e]	Torus interior Vent header interior Vent line interior tie-in to vent header	40	34,300
Ameron 66 and Surfacer[b]	RPV support pedestal Drywell concrete floors Drywell concrete walls	1/16 in. plus10 mils	7,380
Unqualified Paints[e]	Miscellaneous	Note e	Note e
Carboguard 890N	Drywell dado region	6	232

SECONDARY CONTAINMENT

Location	Area(ft^2)	Primer	Thickness, Approx. (in.)	Top Coat	Thickness, Approx. (in)
Drywell exterior steel	36,200	Carbozinc 11	0.002 ± 0.002 0.001	None	-
Torus exterior steel	84,000	Carbomastic 15	0.002 - 0.009	None	-
Secondary containment concrete	109,200	Carboline 295	0.020 - 0.040	Carboline 288	0.008
Secondary containment structural steel	29,000	Type II red lead[d]	0.001 to 0.00153	Cook's Amercote Enamel[d]	0.002

[a] DFT = Dry Film Thickness.

[b] Qualified Coating; other coatings are unqualified.

[c] Other compatible touch-up coatings are used inside the torus.

[d] Other compatible coatings per Specification 3071-055 per painting system PS-2 are used on top or in lieu of Cook's Amercote Enamel and Type II red lead.

[e] For current unidentified and unqualified coating totals, see the design calculations for the Torus strainers.

[f] Coating materials listed in this table are estimated quantities of significant coating materials inside containment. Actual coating materials and quantities inside containment are managed as indicated in design calculations for the Torus strainers.

TABLE 6.2-9 WIRING INSULATION

	Type	Approximate Amount (lb)
Primary Containment Cable		
Power and control cable	EPR Hypalon Silicone Rubber	5,340
		25
Instrument	Cross-linked Polyethylene or Polyolefin	
		5
Thermocouple	Polyamide Capton	18
Secondary Containment Cable		
Power	EPR Hypalon and Neoprene	137,000[a]
Control	EPR Hypalon and Neoprene	14,000[a]
Instrument	Cross-linked Polyethylene by Raychem	99,000[a]
Thermocouple	Polyamide Capton	25

[a] In addition to the amounts shown here in cable trays, there is an approximate additional 15 percent in conduit.

TABLE 6.2-10 OTHER ORGANIC COMPOUNDS

	Commercial Name	Compound	Quantity (approx.)
Primary Containment			
Shell to concrete joints	Dow Corning/ DOWSIL 790*	Silicone rubber	1900 $in.^3$
Concrete floor to wall joints	Carboline 225	Epoxy polysulfide	400 $in.^3$
Secondary Containment			
Steel wall panel gaskets	Blanchard Foam Guard	Polyvinyl chloride	40 ft^3-340 lb to 620 lb
Steel wall panel caulking	3M THIOKOL Weatherban	Polysulfide rubber	40 ft^3-580 lb
Concrete floor joints	Carboline 225	Epoxy polysulfide	14 ft^3

* Note: Dow Corning 790 is retained as a historic information as Dow Corning 790 product name was rebranded to DOWSIL 790.

TABLE 6.2-11 STANDBY GAS TREATMENT SYSTEM MAJOR COMPONENT DESCRIPTION

Filter Train	
Type	Multiple filters for removal or particulates, elemental iodine, and organic iodine from air
Quantity	Two 100 percent-capacity trains
Capacity, scfm air	4000 each
Demister (Each Train)	
Type	Impingement
Quantity	One
Water removal rate, lb/min	20
Static resistance at design flow in. H_2O	1 max at 4000 scfm with 0.005 lb/ft^3 of free moisture
Prefilter (Each Train)	
Type	Dry disposable cartridge
Quantity	One bank
Capacity, scfm air	4000
Media	Glass fiber
Efficiency, percent	85 (NBS dust spot)
Heater (Each Train)	
Type	Electric, open, single-stage, on-off
Quantity	One
Capacity, kW	24
Accessories	Overload cutout
HEPA Filters (Each Train)	
Type	High-efficiency, dry

TABLE 6.2-11 STANDBY GAS TREATMENT SYSTEM MAJOR COMPONENT DESCRIPTION

Quantity	Two banks (one before and one after charcoal absorber)
Elements per bank	Four
Capacity, scfm air	4000
Media	Waterproof, glass
Separator material	Aluminum
Frame material	Steel
Charcoal Adsorber Bed (Each Train)	
Type	Deep bed
Quantity	One
Capacity, scfm air	4000
Media	Impregnated Carbon
Quantity of media, lb	1250-1500 lbm (nominal)
Efficiency	Lab tested to ensure 99.9 percent removal efficiency for methyl iodide. Installed and tested in the adsorber housing such that an overall decontamination efficiency of 99 percent is assumed for removal of all forms of gaseous iodine.
Charcoal volume, ft^3	50 (approximately)
Charcoal density, lb/ft^3	23.7 Min^m
Depth of bed, in.	6
Face velocity, ft/minute	40
Residence time, seconds	0.75
Ignition temperature, °F	625 (approximately)
Iodine desorption temperature, °F	355

16	40 percent
18	5 percent
Fines	1 percent

SGTS Exhaust Blower (Each Train)

Quantity and type	One Centrifugal (with inlet vanes)
Capacity, scfm	4000
Static pressure, in. H_2O	20
Drive	V-belt
Motor, hp	25

Standby Cooling Air Fan

Quantity and type	One centrifugal
Capacity, scfm air	1000
Static pressure, in. H_2O	18
Drive	V-belt
Motor, hp	10

TABLE 6.2-12 STANDBY GAS TREATMENT SYSTEM EQUIPMENT FAILURE ANALYSIS

Component	Failure	Failure Detected By	Action
SGTS primary blower	Monitor burnout, drive shaft break, trip, etc.	Flow monitor – low pressure switch	Main control board alarm Operating equipment train shutdown (manual) Redundant train startup (manual)
Electric heating coil	Element overheat	High temperature cutout on coil	Circuit trip
Electric heating coil	Element burnout	Temperature indicator or moisture detector upstream of adsorber	High moisture alarm Operating equipment train shutdown (manual) Redundant train startup (manual)
Standby cooling fan	No start or failure results in high charcoal adsorber temperature	Temperature switches	Alarm sounds in main control room (automatic if setpoint achieved) CO_2 is auto backup to cooling fan if charcoal bed temperature raises to 310 °F
Flow-control valve	Falls in open position	High ΔP indicator across filters, demisters, and adsorber	Main control board alarm
		High building vacuum alarm	Operating equipment train shut-down (manual) Redundant train startup (manual) Isolation valves positioned (automatic)
Isolation valve	Falls in open position	Local indicator light	No automatic action. Requires backflow prevention and building isolation accomplished by series valves

TABLE 6.2-12 STANDBY GAS TREATMENT SYSTEM EQUIPMENT FAILURE ANALYSIS

Component	Failure	Failure Detected By	Action
	Falls in closed position	Flow monitor – low-pressure switch	Main control board alarm Operating equipment train shutdown (manual) Redundant train startup (manual) Isolation valve positioned (automatic)
HEPA filter	High particulate loading	High ΔP indication	Operating equipment train shutdown (manual) Redundant train startup (manual) Isolation valves positioned (automatic)
Charcoal filter	High temperature	Temperature elements	Alarm sounds start cooling fan

	To process sampling system	1/2	AOV, AOV (1)
	From FLEX supply piping Div 1	8	LCV
	From FLEX supply piping Div 2	8	LCV
Reactor core isolation cooling	Turbine exhaust drain to barometric condenser	3/4	MV, MV, MV

TABLE 6.2-14 PRIMARY CONTAINMENT PENETRATION PIPE LINES CONNECTING CLOSED-LOOP QUALITY GROUP B SYSTEMS TO QUALITY GROUP D SYSTEMS

System	Line	Line Diameter (in.)	Separation Valve
	Discharge to lube oil cooler	2	MOV
	Condensate to radwaste	1	CV, AOV, AOV (1)
	Suction from condensate storage	6	CV, MOV (1)
	Steam drain to main condenser	1	SOV, SOV (1)
Combustible gas control	None		

Symbols:

SOV = solenoid-operated valve

MOV = motor-operated valve

CV = check valve

AOV = air-operated valve

LCV = locked-closed valve

TC = testable check valve

MV = manual valve

(1) = on isolation panel

(NC) = normally closed

TABLE 6.2-15 ESSENTIAL/NONESSENTIAL LINES

Containment Penetration Number	System/Line	Valve Number	Classification	Containment Isolation Signals[a]	Comments
X-7A	Main steam line A MSIV leakage control	B2103F022A B2103F028A	Nonessential Nonessential		These lines provide a heat- sink path for the reactor pressure vessel. It is desirable to keep the MSIVs open for this function during postulated small leaks or breaks. Therefore, high drywell pressure has been deliberately omitted from isolation of main steam lines. The MSIVs and the main steam line drains also isolate on signals D, E, F, G, J, P, and RM.
X-7B	Main steam line B MSIV leakage control	B2103F022B B2103F028B	Nonessential Nonessential		
X-7C	Main steam line C MSIV leakage control	B2103F022C B2103F028C	Nonessential Nonessential		
X-7D	Main steam line D MSIV leakage control	B2103F022D B2103F028D	Nonessential Nonessential		
X-8	Main steam line drains	B2103F016 B2103F019	Nonessential Nonessential		
X-9A	Feedwater line A	B2100F010A B2100F032A	Essential Essential		The portion of the feed-water line that is Class 1 is essential. During the postulated LOCA, it is desirable to maintain reactor coolant makeup from all sources of supply.
		B2100F076A	Essential		This valve is provided for long-term leaktightness only. Remote manual control is provided in the control room to close the valve upon indication of loss of feedwater flow.
X-9A	High-pressure coolant Injection	E4150F006	Essential		Automatically opens and closes with HPCI pump operation.
X-9B	Feedwater line B	B2100F010B B2100F032B	Essential Essential		The portion of the feedwater line that is Class 1 is essential. During the postulated LOCA, it is desirable to maintain reactor coolant makeup from all sources of supply.
		B2100F076B	Essential		This valve is provided for long-term leaktightness only. Remote manual control is provided in the control room to close the valve upon indication of loss of feedwater flow.
X-9B	Reactor core isolation Cooling	E5150F013	Essential (safety system)		Automatically opens and closes with RCIC pump operation.
X-9B	Reactor water cleanup	G3352F220	Nonessential		Inadvertent isolation of this line due to inclusion of the high drywell pressure signal is undesirable, as it results in reactor coolant chemistry problems, fuel leaks, and RPV bottom thermal problems. RWCU is desirable for post-accident sampling of reactor coolant. The system includes break detection mechanisms that will automatically isolate on unbalanced flow or high temperature. Therefore, isolation on high drywell pressure is not needed.
X-10	Steam to RCIC turbine	E5150F007 E5150F008	Essential Essential		

TABLE 6.2-15 ESSENTIAL/NONESSENTIAL LINES

Containment Penetration Number	System/Line	Valve Number	Classification	Containment Isolation Signals[a]	Comments
X-11	Steam to HPCI turbine	E4150F002 E4150F003 E4150F600	Essential Essential Essential		
X-12	RHR/RHR pump suction from recirculation piping	E1150F009 E1150F608 E1150F008	Nonessential Nonessential Nonessential		High drywell pressure has been deliberately omitted from this line's isolation initiation to avoid the loss of the shutdown cooling mode of RHR for small breaks or leaks.
X-13A	RHR/RHR pump discharge to recirculation loop	E1100F050B E1150F015B	Essential Essential		Not a containment isolation valve.
X-13B	RHR/RHR pump discharge to recirculation loop	E1100F050A E1150F015A	Essential Essential		Not a containment isolation valve.

TABLE 6.2-16 ESSENTIAL/NONESSENTIAL SYSTEMS

System	Classification	Comments
Main Steam	Nonessential	Not required for shutdown.
Feedwater	Nonessential	Not required for shutdown. Portion that is Class 1 is essential.
Reactor core isolation cooling	Essential	Necessary for core cool-down following isolation from the turbine condenser and feedwater makeup.
Reactor water cleanup	Nonessential	Not required during and immediately following an accident.
High pressure coolant injection	Essential	Safety system.
Core spray	Essential	Safety system.
Standby liquid Control	Essential	Should be available as a post LOCA pH control system and backup to CRD system.
Drywell floor/equipment drains	Nonessential	Not necessary for core cooldown.
Torus water management	Nonessential	Not required for reactor shutdown cooling.
Primary containment monitoring system	Essential	Required for postaccident monitoring of containment atmosphere hydrogen concentration.
Primary containment radiation monitoring system	Nonessential	Not required during or immediately after an accident.
Residual heat removal		
Heat exchangers	Essential	Main heat sink during isolation.

TABLE 6.2-16 ESSENTIAL/NONESSENTIAL SYSTEMS

System	Classification	Comments
Shutdown cooling	Nonessential	Nonessential, but desirable to use if available. Not redundant, but safety grade.
Drywell/suppression pool spray	Essential	Necessary to control pressure.
LPCI function	Essential	Safety function.
Keep-filled system	Nonessential	Not required after accident.
Control rod drive	Essential	Necessary for shutdown. No credit taken for reflood, but is desirable.
Emergency equipment cooling water	Essential	Necessary to cool safety system pumps and motors.
Station and control air		
Pneumatic supply to primary containment	Essential	For safety/relief valves on steam lines and ADS accumulators.
Demineralized service water	Nonessential	Not assumed available in ECCS analysis.
Nitrogen inerting	Nonessential	Not required during and immediately after accident.
Reactor building closed cooling water	Nonessential	Used for normal operation only.
Reactor recirculation	Nonessential	Not required because core can be cooled by natural circulation.
Traversing in-core probe	Nonessential	Not required for reactor shutdown cooling.

TABLE 6.2-16 ESSENTIAL/NONESSENTIAL SYSTEMS

System	Classification	Comments
Primary containment (vacuum breakers between secondary containment and suppression pool)	Essential	Vacuum breakers automatically open to prevent formation of excessive negative pressure in the suppression pool chamber. They close automatically upon increasing suppression pool chamber pressure and remain closed during all containment high-pressure conditions.
Reactor building heating, ventilation and air conditioning	Nonessential	Reactor building purge and vent functions are nonessential. Essential cooling is provided by equipment outside primary containment.

MAIN STEAM ISOLATION
VALVE LEAKAGE CONTROL SYSTEM

6.3 EMERGENCY CORE COOLING SYSTEMS

Four systems are provided to protect the core against various sizes of hypothetical pipe breaks. Three of these inject emergency core cooling water into the reactor and one is a reactor pressure vessel (RPV) automatic depressurization system (ADS). The three injection systems consist of the high-pressure coolant injection (HPCI), low-pressure coolant injection (LPCI), and core spray system. The protection afforded by these systems meets the NRC criteria given in 10CFR 50.46.

6.3.1 Design Bases

The objective of the emergency core cooling systems (ECCS), in conjunction with the containment, is to limit the release of radioactive materials should a LOCA occur, so that resulting radiation exposures are kept within the guideline values given in 10 CFR 50.67 or 10 CFR 100 as applicable.

Safety design bases for the subsystems of the ECCS are given in the following subsections.

6.3.1.1 Range of Coolant Ruptures and Leaks

The ECCS provides adequate core cooling in the event of any break or leak in the piping of the nuclear system process barrier up to and including the double-ended break of the largest line connected to the RPV. The selection of break sizes and break locations is discussed in Subsection 6.3.3.7.3.

6.3.1.2 Fission Product Decay Heat

In the event of a LOCA, the ECCS removes delayed neutron fission heat, residual stored heat, and radioactive decay heat from the reactor core at a rate that limits the maximum fuel cladding temperature to a value less than the 10 CFR 50.46 limit of 2200°F. The amount of heat to be removed is discussed in Subsection 6.2.1.3.8.

6.3.1.3 Reactivity Required for Cold Shutdown

The reactor is designed to be in the cold-shutdown condition with the control rod of highest reactivity worth fully withdrawn and all other control rods fully inserted. Refer to Subsection 4.3.2 for a complete discussion.

6.3.1.4 Capability To Meet Functional Requirements

The following functional requirements are met:

a. The ECCS is provided with sufficient capacity, diversity, reliability, and redundancy to cool the reactor core under all accident conditions

b. The ECCS is initiated automatically by conditions that indicate the potential inadequacy of the normal core cooling

c. The ECCS is capable of startup and operation regardless of the availability of offsite power supplies and the normal generating system of the plant

d. Action taken to effect containment integrity does not negate the ability to achieve core cooling. All ECCS pumps are designed to operate without benefit of containment pressure

e. The components of the ECCS within the RPV are designed to withstand the transient mechanical loadings during a LOCA so that the required core cooling flow is not restricted

f. The equipment of the ECCS is designed to withstand the physical effects of a LOCA so that the core can be effectively cooled. Effects considered are missiles, fluid jets, pipe whip, high temperature, pressure, humidity, and seismic acceleration

g. A reliable supply of water for the ECCS is provided. The prime source of liquid for cooling the reactor core after a LOCA is a stored source located within the containment. The source is located so that a closed cooling water path is established during ECCS operation

h. The flow rate and sensing networks of each ECCS are testable during reactor shutdown. All active components are testable during normal operation of the nuclear system.

6.3.2 System Design

6.3.2.1 Emergency Core Cooling System Design

The bounds within which system parameters must be maintained and the acceptable inoperable components are discussed in the Technical Specifications.

The ECCS, containing four separate subsystems, is designed to satisfy the following performance objectives:

a. To limit the peak cladding temperature to 2200°F, to prevent a cladding metal/water reaction in excess of 1 percent of the cladding, and to maintain long-term coolability of the core in the event of a mechanical failure of the piping or the nuclear system process barrier, up to and including a break equivalent to the largest nuclear steam supply system (NSSS) pipe

b. To provide this protection by at least two independent, automatically actuated cooling systems

c. To function with or without external (offsite) power sources

d. To permit testing of the ECCS by acceptable methods, including, wherever practical, testing during power plant operations.

The aggregate of the ECCS is designed to protect the reactor core against fuel clad damage in excess of the limits set forth in 10 CFR 50.46 across the entire spectrum of line break accidents.

The operational capabilities of the various subsystems of the ECCS meet the functional requirements and performance objectives described below. Table 6.3-1 lists the types of LOCAs and the ECCS that would operate in response to each.

During the first 10 minutes following the initiation of operation of the ECCS, the functional requirement is satisfied for all combinations of single active component failures and single pipe breaks, including pipe breaks in any ECCS subsystem which might partially or completely disable that subsystem.

After the first 10 minutes following the initiation of operation of the ECCS, and in the event of an active or passive component failure in the ECCS or its essential support system, long-term core and containment cooling is provided by any one LPCI or core spray loop delivering water to the RPV and by one residual heat removal (RHR) pump supported by one RHR heat exchanger with 100 percent service water flow. Containment cooling, using one RHR pump supported by one RHR heat exchanger, can be delayed up to twenty minutes following the DBA LOCA.

The power for operation of the core spray and LPCI is from regular ac power sources. Upon loss of the regular power, operation is from onsite standby ac power sources. Standby sources have sufficient diversity and capacity so that all core spray and LPCI requirements are satisfied. One core spray loop and one LPCI loop are powered from one ac division and the other core spray loop and LPCI loop are powered from a second and separate ac division. Four diesel generators are the site backup power supplies, with two diesel generators and two buses per division.

With the exception of LPCI while lined up in shutdown cooling and RPV pressure is less than or equal to the cut in pressure, all systems start automatically. The starting signal comes from independent and redundant sensors of drywell pressure and low RPV water level. Refer to Subsection 7.3.1 for a complete discussion of the ECCS instrumentation and starting and control logic.

Piping and instrumentation diagrams for the subsystems and components that constitute the ECCS are provided and referenced under the discussion of the subsystem or component.

6.3.2.2 Equipment and Component Descriptions

The four types of core cooling systems (HPCI, ADS, core spray, and LPCI) are described in this section with reference to the appropriate piping and instrumentation diagrams and system process diagrams.

6.3.2.2.1 High Pressure Coolant Injection System

The HPCI system is provided to ensure that the reactor core is adequately cooled to meet the design bases in the event of a small break in the nuclear system and loss of coolant that does not result in rapid depressurization of the RPV. Liquid breaks up to approximately 0.1 ft^2 break area and steam breaks up to approximately 0.5 ft^2 break area are within the capability of the HPCI system alone. This permits the plant to be shut down while maintaining sufficient RPV water inventory until the RPV is depressurized. The HPCI system continues to operate until RPV pressure is below the maximum pressure at which LPCI operation or core spray system operation can maintain core cooling.

The HPCI system consists of a steam turbine assembly driving a constant-flow pump assembly and system piping, valves, controls, and instrumentation. The HPCI piping and instrumentation diagram is shown in Figure 7.3-1. The HPCI system process and valve lineup diagrams are shown in Figures 6.3-1 through 6.3-5. The schematic drawing is shown in Figure 6.3-1.

The principal HPCI equipment is installed in the reactor building. The turbine-pump assembly is located in a shielded area to ensure that personnel access to adjacent areas is not restricted during operation of the HPCI system and to be protected from the physical effects of design-basis accidents (DBAs) such as pipe whip, flooding, and high temperature.

The pump assembly is located below the level of the condensate storage tank and below the water level in the suppression pool to ensure positive suction head to the pumps.

Two sources of water are available. The HPCI system initially injects water from the condensate storage tank (see Figure 6.3-2). When the water level in the tank falls below setpoint level or when suppression pool level is high, the pump suction is auto-matically transferred to the suppression pool. This transfer may also be made from the main control room using remote controls. The transfer requires the opening of normally closed valves F041 and F042 in the pump suction line leading from the suppression pool. The opening of these valves automatically closes valve F004 in the pump suction line leading from the condensate storage tank. When the pump suction has been transferred to the suppression pool, a closed loop is established for recirculation of water escaping from a break (see Figure 6.3-3).

Injection water is piped to the reactor feedwater pipe at a T-connection.

The HPCI turbine is driven by steam from the RPV which, after reactor shutdown, is generated by decay and residual heat. The steam is extracted from a main steam line upstream of the main steam isolation valves (MSIVs). The HPCI inboard isolation valve (F002) and the bypass valve around the HPCI outboard isolation valve (F600) in the steam line to the HPCI turbine are normally open to keep the piping to the turbine at elevated temperatures. This permits rapid startup of the HPCI system. Signals from the HPCI control system open (with oil pressure available) or close the turbine control/stop valve.

A condensate drain pot is provided upstream of the turbine steam admission valve to prevent the HPCI steam supply line from filling with water. The drain pot normally routes the condensate to the main condenser, but upon receipt of a HPCI initiation signal or a loss of non-interruptible control air pressure, isolation valves on the condensate line automatically close.

The turbine has two devices for controlling power. One is a speed governor that limits turbine speed to its maximum operating level, and the other is a control governor with automatic speed setpoint control that is positioned by a demand signal from a flow controller to maintain constant flow over the pressure range of HPCI operation.

As reactor steam pressure decreases, the HPCI governor valves open further to pass the steam flow required to provide the necessary pump flow. The capacity of the system is selected to provide sufficient core cooling to prevent excessive clad temperatures while the pressure in the RPV is above the pressure at which core spray and LPCI become effective.

Startup of the HPCI system is completely independent of ac power. Only dc power from the station battery and steam extracted from the nuclear system are necessary. The HPCI controls automatically start the system and bring it to design flow rate within 60 sec from receipt of a primary containment (drywell) high-pressure signal or an RPV low water level signal. This time interval for HPCI injection is used in the Fermi 2 TRACG-LOCA analyses that demonstrate conformance to 10 CFR 50.46 (Reference 42).

High-pressure coolant injection operation automatically actuates the following valves:

a. HPCI pump discharge shutoff valve

b. HPCI steam supply shutoff valves

c. HPCI turbine stop valve

d. HPCI turbine control valves

e. HPCI steam line drain isolation valves

f. HPCI pump suction valve from condensate storage.

Startup of the hydraulic oil pump and proper functioning of the hydraulic control system is required to open the turbine valves. Operation of the barometric condenser components is functionally illustrated in Figure 7.3-2 and their failure does not prevent the HPCI system from fulfilling its core cooling objective. The same initiating signal automatically starts the turbine oil pump, and when sufficient oil pressure is developed, the stop valve begins to open. Contacts actuated by the HPCI turbine stop and turbine steam supply valve limit switches initiate the speed control ramp generator which slowly increases the control valve position from closed to the value demanded by the flow controller. As a result, the turbine smoothly accelerates from rest to the speed at which rated pump flow is developed. When rated flow is established, the flow controller signal adjusts the setting of the control governor so that rated flow is maintained as nuclear system pressure decreases.

A minimum flow bypass is provided for pump protection (see Figure 6.3-4). The bypass valve (F012) automatically opens when a low flow combined with a high discharge pressure signal is sensed. It automatically closes on a high-flow signal or if the closing of either the turbine stop valve or steam inlet valve is sensed. Pump discharge pressure is sensed by PS N027, and flow is sensed by FS N006. When the bypass is open, flow is directed to the suppression pool.

A full-flow functional test of the HPCI can be performed during plant operation by drawing suction from the condensate storage tank and returning the water to the tank through a full-flow test line (see Figure 6.3-5). During this test, a signal to initiate the HPCI automatically stops the test mode and starts the water injection to the feedwater line. This transfer from the test mode to the accident mode requires the closing of the normally closed (but open for the test mode) valves F008 and F0ll located in the test line connecting the pump discharge and the condensate storage tank.

A cross connection is provided from the HPCI Test Line piping to the GSW piping to be used as part of the Flexible and Diverse Coping Strategy (FLEX) to mitigate Beyond Design Basis External Events (BDBEE) in response to NRC Order EA-12-049.

Exhaust steam from the HPCI turbine is discharged to the suppression pool. A drain pot at the low point in the exhaust line collects moisture present in the steam. Collected moisture is discharged to the suppression pool or bypassed to the barometric condenser.

The HPCI turbine gland seals are vented to the barometric seal condenser. Noncondensable gases from the barometric condenser are pumped to the standby gas treatment system (SGTS).

A redundant system of check valves and isolation valves has been installed as a vacuum breaker line that connects the air space in the suppression pool with the HPCI turbine exhaust line. This eliminates any possibility of water from the suppression pool being drawn into the HPCI turbine exhaust line. The two isolation valves (electrically separated) in series in this vacuum breaker line operate automatically via a combination of low reactor pressure and high drywell pressure. Test connections are provided on either side of the two check valves.

The system component classifications plus additional requirements are described in Chapter 3. The pump is designed and tested in accordance with the standards of the Hydraulic Institute.

The system is designed for a service life of 40 years, accounting for corrosion, erosion, and material fatigue. The various operations of the HPCI components are summarized below.

The HPCI turbine is shut down automatically by any of the following signals:

a. Turbine overspeed--prevents damage to the turbine casing

b. Reactor pressure vessel high water level--indicates that core cooling requirements are satisfied

c. High-pressure coolant injection pump low suction pressure--prevents damage to the pump due to loss of flow

d. High-pressure coolant injection turbine exhaust high pressure--indicates a turbine or turbine control malfunction.

If an initiation signal is received after the turbine is shut down, the system will restart automatically if no shutdown signals exist.

Because the steam supply line to the HPCI turbine is part of the nuclear system process barrier, certain signals automatically isolate this line, causing shutdown of the HPCI turbine. Automatic shutoff of the steam supply is described in Section 7.3. However, automatic depressurization and the low-pressure systems of the ECCS act as backup, and automatic shutoff of the steam supply does not negate the ability of the ECCS to satisfy the safety objective.

In addition to the automatic operational features of the system, provisions are included for remote manual startup, operation, and shutdown (provided automatic initiation or shutdown signals do not exist). Remote controls for valve and turbine operation are provided in the main control room. The controls and instrumentation of the HPCI system are described, illustrated, and evaluated in detail in Section 7.3.

6.3.2.2.2 Automatic Depressurization System

In case the capability of the feedwater pumps, control rod drive (CRD) pumps, reactor core isolation cooling (RCIC) system, and HPCI system is not sufficient to maintain the reactor water level, the ADS functions to reduce the reactor pressure to a value low enough (<300 psig) to allow the LPCI and core spray systems to pump water to the RPV in time to cool the core consistent with the design bases.

The ADS uses five of the 15 safety/relief valves of the nuclear system pressure relief system to achieve the automatic blowdown to the suppression pool. The capacity of each relief valve is about 900,000 lb/hr at set pressure. The ADS starts operating soon enough after failure of the HPCI and dumps steam fast enough to ensure that the LPCI and core spray systems begin to operate and cool the fuel adequately.

To activate, the ADS must have drywell high pressure (2 psig) and RPV low water level (level 1) signals. Simultaneous occurrence of these drywell high pressure and RPV low water level conditions initiate a time delay of 120 seconds to allow the HPCI system time to recover level. After that time delay, ADS safety relief valves will operate if at least one RHR pump or both core spray pumps in either division are running (developing pressure). RPV low water level (level 1) signal also activates a bypass timer set for 8 minutes. This bypass time delay is provided to bypass the drywell pressure high logic circuit. If for some reason the drywell high pressure is not detected, the RPV low water level signal alone will activate the ADS safety relief valves after the 8 minute bypass time delay, plus the original 120 second time delay, provided that appropriate discharge pressure signals are present. The values shown above are based on analysis (Reference 34); refer to Technical Requirements Manual Table 3.5.1-1 for operating setpoints.

Opening of the relief valve requires pneumatic pressure to the valve's diaphragm actuator. This pneumatic supply is controlled by a solenoid-operated pilot valve. For the ADS to function, this valve control system must be operable, and there must be a pneumatic supply. The accumulator associated with the relief valves used with the ADS has sufficient capacity to allow for five operations of the pilot valves to cover interruptions if the pneumatic supplies are switched from the normal to the emergency backup sources. The relief valve pneumatic supply and backup supply systems are capable of performing their function for the long-term period of 100 days following an accident as required by NUREG-0737, Item II.K.3.28. (See also Section 5.2.2.2.3 for a description of the accumulator system.) The accumulator and pneumatic supply systems are capable of performing their design function during and following exposure to a harsh environment and/or a seismic event. In the automatic depressurization mode, the relief valves do not reset to normal safety/relief valve setpoints on low RPV pressure. To ensure proper cooling under all circumstances, including a postulated failure of ADS, reactor pressure relief can still be provided by operation of the non-ADS safety/relief valves. This ensures that the low pressure systems can be actuated with a HPCI failure and one additional single failure of the ADS, since any single failures affecting ADS will not impair remote operation of eight non-ADS safety relief valves.

The ADS valves stay open once activated until the reactor pressure is 50 psi higher than the containment pressure. These valves close when the reactor pressure decays to less than 50 psi above the containment pressure, and reopen when the reactor pressure is 100 psi above the containment pressure. Thus, the maximum pressure that can exist during the long-term period following a LOCA is 100 psi plus containment pressure.

The design, description, and evaluation of the pressure relief valves are discussed in detail in Subsection 5.2.2. See Section 7.3 for details on instrumentation and control.

The relief valve setpoints cannot be tested while they are in place on the steam lines. The safety/relief valves are designed to allow removal for bench testing of the setpoints during shutdown.

6.3.2.2.3 Core Spray System

The core spray system protects the core in the event of a large break in the nuclear system if the feedwater pumps, the CRD pumps, the RCIC, and the HPCI systems are unable to maintain RPV water level.

The protection provided by the core spray system also extends to a small break if the feedwater pumps, CRD pumps, RCIC, and HPCI systems are all unable to maintain the RPV water level and the ADS has operated to lower the RPV pressure so that LPCI and the core spray system provide core cooling.

Two independent loops are provided as a part of the core spray system. Each loop consists of two single-stage, in-line water pumps with suction and discharge connected in parallel and each pump driven by an 800-hp electric motor; a spray sparger in the RPV above the core; piping and valves to convey water from the suppression pool to the pumps and to the sparger; and the associated controls and instrumentation. Figures 6.3-7 through 6.3-11 show the schematic process and valve lineup diagrams of the core spray system. The piping and instrumentation diagram is shown in Figure 7.3-7.

In case of low water level in the RPV or high pressure in the drywell, the core spray system automatically starts and the pumps in the two core spray loops are signaled to start after a 5-sec delay on auxiliary ac power. This signal also starts without delay the diesel generator set and the LPCI system. In case auxiliary ac power is lost, the pumps start in sequence (with time delay) on standby ac power. Pump suction valves F001A, B, C, and D are normally locked open to ensure a positive suction head for the pumps. The test bypass motor-controlled valves F0l5A and B, normally closed, are signaled to close if open. When the reactor pressure is permissive (<500 psig), valves F004A and B (normally open) and F005A and B are signaled to open automatically. The pumps take water from the suppression pool and discharge to the sparger ring and nozzle spray. This condition is shown in Figure 6.3-8.

When the system is actuated, water is taken from the screened suction line in the suppression pool. Flow then passes through a normally open, motor-operated valve. A keylock switch is installed in the control circuit with position indication available in the main control room. This valve is located in the core spray pump suction line as close to the suppression pool as practical. It can be closed by a remote manual switch from the main control room to isolate the system from the suppression pool in case of a leak from the core spray system.

The four core spray pumps are located in the reactor building below the water level in the suppression pool to ensure positive pump suction. The pumps, piping, controls, and instrumentation of each loop are separated and protected so that any single physical event, or missile generated by rupture of any pipe in any system within the containment drywell, cannot make both core spray loops inoperable. The switchgear for each loop is in a separate emergency bus room for the same reason.

A vent line with two normally closed valves is provided from the pump casing for filling the pump with water. A shaft seal drain is provided, which drains to the radwaste system, along with the vent line. Leakage from the drain line is measured during primary containment leakage tests.

A low-flow bypass line is provided from the pump discharge to below the surface of the suppression pool. The bypass flow is required to prevent the pump from overheating when pumping against a closed discharge valve. An orifice limits the bypass flow. A manual valve that is normally locked open is used to close the bypass line for maintenance. A motor-operated valve on the bypass line closes upon receipt of a signal from a flow switch in the main discharge line.

Two relief valves, set for 500 psig, protect each low pressure core spray system loop upstream of the outboard shutoff valve from reactor pressure. The relief valves discharge to the suppression pool.

Two motor-operated valves are provided to isolate the core spray system from the nuclear system when the core spray pump is not running. These valves admit core spray water to the inboard check valve when signaled to open at approximately 500-psig RPV pressure. Both valves are installed outside the drywell to facilitate operation and maintenance, but as close as practical to the drywell to limit the length of line exposed to reactor pressure. The valve nearer the containment is normally closed to back up the inside check valve for containment purposes. The outboard valve is normally open to limit the equipment needed to operate in an accident condition. A test line is normally closed with two normally closed valves and a pipe cap to ensure containment.

A check valve is provided in each core spray line just inside the primary containment to prevent loss of reactor coolant outside containment in case the core spray line breaks. A normally locked-open manual valve is provided downstream of the inside check valve to shut off the core spray system from the reactor during shutdown conditions for maintenance of the upstream valves. The two core spray system pipes enter the RPV through nozzles l20° apart. Each pipe then divides into a semicircular header with a downcomer at each end which turns through the shroud near the top. A semicircular sparger is attached to each of the four outlets to make two practically complete circles, one above the other inside the shroud head. Short elbow nozzles are spaced around the spargers to spray the water radially into the tops of the fuel assemblies.

Core spray piping upstream of the outboard shutoff valves F004A and B is designed for the lower pressure and temperature of the core spray pump discharge. The outboard shutoff valve and downstream piping are designed for RPV pressure and temperature. The pumps, piping, and valves are designed to meet requirements described in Chapter 3. The pumps are also designed and tested in accordance with the standards of the Hydraulic Institute. Pump operability testing under the plant technical specifications and the in-service testing program ensures pump operation at or above the minimum required performance assumed in the plant safety analyses. Pump test acceptance criteria developed for this purpose are required to include consideration of the lowest allowed emergency diesel generator (EDG) operating frequency based on the maximum allowed frequency control tolerance as well as pressure and flow test instrument accuracies.

The core spray pumps and all automatic valves can be operated individually by manual switches in the main control room. Operating information is provided in the main control room with pressure indicators, flowmeters, and indicator lights. Automatic signals to start the system preempt all other signals while the system is in auto mode. In the manual condition, the pump or valve will be under total operator control. The manual condition is indicated to the operator in the main control room.

6.3.2.2.3.1 Core Spray Test Mode During Plant Operation

A test line for the rated core spray system flow rate is provided to route the suppression pool water from the pump discharge to the suppression chamber without entering the reactor pressure vessel (see Figure 6.3-9). During reactor operation, the core spray injection valves are normally closed. The pumps are started by the operator using the remote manual control in the main control room. Valves F015A and B in the test lines are opened partially to achieve the rated flow through the test lines. This mode of operation permits testing of pump operation and ensures that rated flow is achieved. It also permits testing of control and operation of components of the low pressure section of the core spray system.

6.3.2.2.3.2 Core Spray Test During Plant Shutdown

To provide for system testing during a plant shutdown (see Figure 6.3-10), a connection is provided from the condensate storage tank to the pump suction. This condensate is used for flow testing of the spray nozzles inside the pressure vessel. A normally closed manual valve is provided between the condensate storage tank and the pump suction line to minimize the possibility of communication of the condensate to the suppression pool and to avoid extension of the primary containment.

During plant shutdown, the core spray system can be tested by manually opening valves F002A and B. The pumps are started by remote manual control, and valves F004A and B and F005A and B are opened by remote manual switch. System operation including sparger rings can be tested in this manner during shutdown conditions. Any system maintenance or repairs may be made on the core spray system during plant shutdown by manually closing valves F007A and B, which are normally locked open.

System operability is determined by performing a system functional test which includes simulated automatic actuation of the system throughout its emergency operating sequence and verifying that each automatic valve in the flow path actuates to its correct position. Actual injection of coolant into the reactor vessel may be excluded from this test, which is performed every 24 months. Such testing was performed during initial plant startup and periodic performance is not needed as the continued operability of the LPCS header is assured by means of the break detection logic discussed in Subsection 7.3.1.2.3.9.

6.3.2.2.3.3 Core Spray Minimum Flow Bypass Mode

The pump discharge line is provided with a low-flow bypass line to protect the core spray pumps from overheating during operation at high vessel pressure (see Figure 6.3-11). Flow-measuring element FE N002 is coupled to flow switch FS N006, which at a nominal flow rate of less than 2100 gpm, signals bypass line motor-operated valve F031 to open automatically. Water from the suppression pool is then routed through the bypass lines back to the suppression pool. As soon as flow is established in the pump discharge lines, the signal from FS N006 signals the minimum bypass motor-operated valves F03lA and B to close automatically.

6.3.2.2.4 Low Pressure Coolant Injection System

In case of low water level in the reactor or high pressure in the containment drywell, the LPCI mode of operation of the RHR system pumps water into the RPV in time to cool the core consistent with the design bases. The core spray system starts from the same signals and operates independently to achieve the same objective. The isolation valves for these two systems are opened when reactor pressure is less than 500 psig, but injection flow does not occur until the differential pressure across the check valves permits. This occurs when the RPV pressure is less than 300 psig.

Low-pressure coolant injection operation provides protection to the core for the case of a large break in the nuclear system when the feedwater pumps, the CRD pumps, and RCIC and HPCI systems are unable to maintain RPV water level. Manual override of LPCI operation is prevented by two keylocked switches. Conditions for manual override of LPCI operation are described in the Fermi 2 Containment Control Emergency Procedures.

Protection provided by LPCI also extends to a small break in which the feedwater pumps, CRD pumps, and RCIC and HPCI systems are all unable to maintain the RPV water level, and the ADS has operated to lower the reactor vessel pressure so that LPCI and core spray systems start to provide core cooling.

In the event of a break in one of the two reactor recirculation system loops, logic is provided to sense the broken loop and to inject the LPCI flow into the unbroken loop. Thus, the flows from the two LPCI system loops are interconnected by valving. Since electrical power to each LPCI loop is isolated (Divisions I and II), it is necessary to have a swing bus arrangement that permits the valves of an LPCI loop that has been disabled by a single failure of a divisional electrical supply to be energized. This feature preserves the ability of the LPCI to cross-connect flow and inject into the unbroken recirculation loop.

The Fermi 2 LPCI valve logic also provides for closing only the valve in the discharge side of the unbroken reactor recirculation loop as opposed to earlier logic that closed both the discharge and suction valves in the unbroken reactor recirculation system loop. The logic change provides for continued depressurization (permitting coolant injection by the core spray system) in the event that the single failure is the LPCI logic that selects the broken reactor recirculation system loop.

6.3.2.2.4.1 Accident Mode

Valves F048A and F048B open automatically. Also, valves F015 and F017 in the loop corresponding to the undamaged recirculation loop receive a signal to open automatically upon receipt of reactor vessel low pressure (<500 psig) signal. See Figure 6.3-14.

The system pumps take water from the suppression pool and pump it into the core region of the reactor vessel through the undamaged recirculation loop. The system pumps are rated at 10,000 gpm per pump. The rated flow of 30,000 gpm is delivered with three-pump operation at 20 psid pressure difference between the reactor vessel and the primary containment. A redundancy of pumps is provided so there is one more pump available than the number required for the rated flow in the LPCI. The core is flooded to an adequate height and the level maintained by the LPCI operating alone with three of four pumps operating.

Soon after the LOCA (assuming offsite power is also lost), the high-drywell-pressure or reactor-low-water signal initiates the selected valves in the LPCI and core spray systems to open. These valves receive power as soon as it is restored by the emergency diesel generators. The LPCI system pumps are also signaled to start. The core spray system pumps start with 5-sec delay, i.e., within 18 sec of the accident. The LPCI injection valves are fully open and the recirculation loop discharge valve (in the undamaged loop) closes within 77 seconds. This interval is the maximum allowable time from the high drywell pressure initiating signal to pump at rated speed and ready to inject flow to the vessel with emergency power that is used in Fermi 2 TRACG-LOCA analyses (Reference 42).

6.3.2.2.4.2 Low Pressure Coolant Injection Loop Selection Logic

This system is described in Subsection 7.3.1.2.4.

6.3.2.2.4.3 Low Pressure Coolant Injection Test Mode

A design flow (10,000 gpm per pump) functional test of the RHR system pumps is performed for each pair of pumps during plant operation by taking suction from the suppression pool and discharging through the test lines back to the suppression pool (see Figure 6.3-15). Discharge valve F015 to the reactor recirculation line remains closed, and reactor operation is undisturbed. The upstream and downstream valves for the containment spray headers (F016 and F021) are tested or exercised individually by remote manual switches in the main control room.

The control system is designed to provide automatic return from test mode to operating mode if LPCI injection is required during testing.

6.3.2.2.4.4 Low Pressure Coolant Injection Minimum Flow Bypass Mode

This mode of operation is provided to protect the system pumps from overheating at low flow rates, by routing the pump flow through the minimum bypass lines to the suppression chamber. A single motor-operated valve F007 in each bypass line automatically opens upon sensing low flow after either RHR pump within the associated division is started. This valve automatically closes whenever the flow from either of the associated main system pumps is above the low-flow setting. One switch (N021) is used for each loop. (See Figure 6.3-16).

Low-pressure coolant injection pump and piping equipment is described in detail in Subsection 5.5.7, which also describes the other functions served by the same pumps if not needed for the LPCI function.

6.3.2.2.5 Emergency Core Cooling System Discharge Line Fill System

One design requirement of any core cooling system is that cooling water flow to the RPV be initiated rapidly when the system is called on to function. This quick-start system characteristic is provided by quick-opening valves and quick-start pumps. By always keeping the HPCI, LPCI, and core spray pump discharge lines full, the lag between the signal for pump start and the initiation of flow into the RPV can be minimized. If for some reason these lines were empty when the systems were called for, not only would the lag time be increased, but also the lines would be subjected to unnecessarily large momentum forces associated with accelerating fluid into an empty pipe. To prevent draining of the ECCS-discharge lines, a fill system is provided to keep the core spray lines charged with demineralized water and the RHR lines charged with condensate water by a pressure regulating valve. A system is provided to maintain the HPCI pump discharge piping between the normally closed injection valve and pump discharge check valve charged with condensate water.

Since the core cooling pumps are located in the subbasement of the reactor building, approximately 75 ft below the point where the discharge piping enters the RPV, check or stop-check valves are provided near the pumps to prevent backflow from emptying the lines into the suppression pool. These valves will leak slightly, producing a small backflow that will eventually empty the discharge piping. The core spray lines are kept charged with demineralized water and the RHR lines are kept charged with condensate water by a pressure regulating valve. The HPCI pump lines are charged by the head (gravity) from the condensate storage tanks. The HPCI pump discharge piping valves up to the normally closed injection valve are also kept charged with condensate water. Alarms are provided for RHR and core spray fill line low pressure.

The demineralized water storage system supplies water to the reactor building, turbine building, radwaste building, auxiliary steam boilers, and core spray fill systems from a common manifold. The demineralized water supply from the manifold to the fill system is controlled by the pressure regulating valve. The water supply to the manifold is pumped from the demineralized storage system by a demineralized water jockey pump (DWJP) and, as required, by one or two demineralized water transfer pumps (DWTP).

The condensate water storage system supplies water to the RHR keep fill system from a reactor building second floor header. The condensate water supply from the header to the fill system is controlled by a pressure regulating valve. The water supply to the header is from the condenser pumps through a 4-inch supply line located downstream of the polishing demineralizers. During a plant shutdown, condensate is supplied by the condensate storage jockey pump and as required by the normal hotwell supply Pump.

When the demand for demineralized water is less than 20 gpm, the DWJP maintains the manifold pressure at 82 psig. If the quantity of water supplied by the DWJP exceeds 20 gpm, the manifold pressure drops. When the pressure reaches a defined setpoint, a pressure switch on the common manifold activates and one of the two DWTPs automatically starts. Should the demineralized water demand exceed the capability of the DWJP and one DWTP, the manifold pressure would continue to drop. At a lower setpoint, a second switch would activate to start the second DWTP and activate an alarm in the main control room.

The RHR fill system consists of two fill lines (branching from a single valve) supplied with condensate water from the header and terminates at the connections to the RHR pump discharge lines.

The core spray fill system consists of two fill lines (involving one pressure control valve in each line) supplied with demineralized water from the common manifold and terminates at the connections to the core spray pump discharge lines.

Vent and drain connections have been incorporated at all high and low points in the RHR and core spray piping systems. Prior to initial start (such as after maintenance to the RHR or core spray system) the discharge lines are filled by manually venting the high-point vents of the RHR and core spray discharge lines to avoid any trapped air pockets in the discharge lines. The pressure control valve keeps the lines filled after initial filling.

The suction and discharge piping to the RCIC system is kept full up to the normally closed RCIC injection valve by static head from the condensate storage tanks and by appropriate high-point venting during initial fill and as required periodically by the Technical Specifications. The elevation of the injection valve is lower than the low level of the condensate storage tanks.

The HPCI piping from the discharge of the pump, through the check valves up to the normally closed injection valve is kept full from the static head of the Condensate Storage Tank (CST), and by appropriate high-point venting during initial fill and as required periodically by Technical Specifications. The elevation of the injection valve is below the minimum level of the CST, and any leakage from the system is made up by CST water. The relative height of the feedwater line connection for HPCI is such that the water in the feedwater lines keeps the remaining portion of the HPCI discharge line full of water.

However, the HPCI system discharge piping near the injection valve to the feedwater system absorbs heat from feedwater via conduction and valve leakage, that has the potential to form a localized steam void. When the HPCI turbine-driven pump is started, rapid pressurization of this line causes the void to collapse and produce a momentum transient which stresses the piping and related supports.

The momentum transient that is present during HPCI start has been analyzed and shown not to produce any damage to the HPCI piping, components, and supporting structure. However, the condensate water storage system is utilized to maintain the HPCI discharge piping between the normally closed injection valve and pump discharge check valve charged with condensate water to prevent possible void formation and minimize momentum transient effects. The pressure of the condenser pumps, connected to the HPCI discharge piping by a supply line located downstream of the condensate polishing demineralizers, maintains the piping charged with condensate water to prevent steam void formation.

In addition, the HPCI pump discharge piping just upstream of the injection valve is provided with cooling fins to remove heat and provide additional subcooling margin in the area of void formation.

6.3.2.2.6 Emergency Equipment Cooling Water System

The emergency equipment cooling water system (EECWS) consists of two (redundant) systems that supply cooling water to emergency equipment that is automatically operable on high drywell pressure, low reactor building closed cooling water system (RBCCWS) differential pressure, or on a loss of offsite ac power or that may be manually initiated upon failure of the RBCCWS. In addition, the EECWS may be manually initiated with the non-essential loads subsequently restored to facilitate RBCCW heat exchanger cleaning, to enhance drywell cooling during high lake water (GSW) temperature, for testing, or to provide RHR Reservoir freeze protection during extreme cold weather. The system diagram is presented in Figure 9.2-2. The EECWS is designed to provide equipment cooling and ventilation space cooling for HPCI, RCIC, RHR, and core spray systems.

Each of the two supply and return cooling loops (Division I and Division II) consists of one circulating pump of sufficient capacity to circulate water through the system and return the cooling water to a full capacity heat exchanger. The demineralized water in the system is cooled by the emergency equipment service water system (EESWS).

Both the EECWS and the EESWS are discussed in Subsection 9.2.2.

6.3.2.2.7 Emergency Core Cooling System Suction Lines

The two core spray, four RHR, and HPCI suction lines have remote manual motor-operated gate valves.

The piping is classified as Class 2 piping in accordance with ASME Boiler and Pressure Vessel (B&PV) Code Section III, 1971, and has been stress analyzed for thermal and deadweight flexibility and seismic dynamic response. This analysis established nozzle loads on the torus connections which in turn are analyzed in accordance with ASME B&PV Code Section III-B. As these connections are situated below the torus, they are protected against possible missiles originating from the slab above the torus or any high-pressure lines situated above the torus.

To prevent the loss of torus water due to an ECCS suction line break, a leak-detection system is provided. Any postulated break in the ECCS pump suction line is detected and the appropriate isolation valve can be activated to isolate the break.

The maximum distance between the containment nozzle and the center line of the isolation valve occurs on the four 24-in. RHR suction lines. This distance is 11 ft 8 in.

Leak detection for the ECCS suction lines is provided by a system that measures the rate of change of the liquid level in the sump of the floor drain. The operator can isolate the leaking line and verify that the leak is stopped by observing the sump level.

6.3.2.3 Applicable Codes and Classification

All ECCS piping, components, and system designs comply, as a minimum, with applicable codes, code cases, and addenda in effect at the time the equipment was procured. These systems are designed and constructed in accordance with Category I criteria and Quality Assurance Level 1.

The RHR/LPCI, HPCI, and core spray systems are each divided into two classes.

The Class 1 portion of each system includes all piping and components that are a part of the reactor system pressure boundary out to and including the second isolation valve.

The Class 1 portions of the RHR/LPCI, core spray systems, and HPCI are designed and constructed in accordance with Subsection NB of ASME B&PV Code Section III, 1971 or later issue and addenda of this code in effect at the date of purchase order, and conform with 10 CFR 50.55a, whichever is more restrictive.

The remaining portions of the RHR/LPCI, HPCI, and core spray systems are designated Class 2 and are designed and constructed in accordance with Subsection NC of ASME B&PV Code Section III, 1971 or later addenda in effect at the date of purchase order. The only exceptions to the foregoing are

a. The RHR/LPCI and core spray pumps were purchased in 1970 and therefore meet the requirements of Section B ASME Code for pumps and valves for nuclear power (1968 draft issue)

b. The shell sides of the RHR heat exchangers are designed and constructed in accordance with ASME B&PV Code Section III (1968), Class C, and Tubular Exchanger Manufacturers Association (TEMA) Class C Standard

c. The tube sides of the RHR heat exchangers are designed and constructed in accordance with ASME Section VIII, Division I, and TEMA Class C Standard

d. Relief valve code and standards are defined in Chapter 5

e. The HPCI turbine is a non-ASME component per ASME B&PV Section III, 1971 Edition, Article NE-1130

f. The HPCI barometric condenser is designed and constructed in accordance with the ASME B&PV Code Section VIII.

6.3.2.4 Materials Specifications and Compatibility

Subsection 5.2.3 discusses general material considerations. Refer to Table 5.2-6 for a presentation of the specifications that generally apply to the selection of materials used in the ECCS. Nonmetallic materials such as lubricants, seals, packings, paints, primers, and insulation, as well as metallic materials, are selected as a result of an engineering review and evaluation for compatibility with other materials in the system and the surroundings with concern for chemical, radiolytic, mechanical, nuclear radiation, and temperature effects.

Subsection 6.3.2.19 contains a discussion by commercial name of materials in the primary containment that may conceivably interfere with ECCS performance as a result of their deterioration under LOCA conditions.

Materials for the principal components are listed in Table 6.3-2.

6.3.2.5 Design Pressures and Temperatures

The design pressures and temperatures at various points in the system during each of several modes of operation of the ECCS subsystems can be obtained from the information blocks on the following process diagrams: Figures 6.3-1 through 6.3-5 for the HPCI system, Figures 6.3-7 through 6.3-11 for the core spray system, and Figures 6.3-14 through 6.3-16 for the LPCI. The operational characteristics of the ADS valves are presented in Chapter 5.

6.3.2.6 Coolant Quantity

The HPCI system normally takes suction from the condensate storage tank. This tank is designed so that the last 150,000 gal is reserved for use by the HPCI or RCIC systems by the tank's standpipe design. Not all of this 150,000 gal is usable since the suction is switched to the suppression pool automatically upon a condensate storage tank low level (equivalent to about 45,000 gal of water in the tank based on a nominal trip setpoint). However, while the plant is operating, the condensate storage tank is maintained at a normal level considerably higher than that required to provide 150,000 usable gallons. The HPCI suction is also switched to the suppression pool upon suppression pool high level signal (approximately 3.5

in. above normal water level) or at any time manually. The suppression pool contains approximately 880,000 gal of water. The core spray and LPCI systems take suction from the suppression pool.

The residual heat removal service water (RHRSW) system serves as the ultimate heat sink. Its design includes two 3,465,000-gal reservoirs (described in detail in Section 9.2). They are sized in accordance with the recommendations of Regulatory Guide 1.27.

6.3.2.7 Pump Characteristics

The HPCI pump is driven by a high-pressure turbine fed by reactor steam. The rated horsepower of the turbine at high speed (4100 rpm) is 4750 hp. The turbine produces 1000 hp at low speed (2100 rpm).

The core spray pump is driven by an open, drip-proof, induction motor rated at 800 hp. Power required is 102 amp at 4160 V ac.

The RHR pumps are each driven by a type-K, squirrel cage, induction motor rated at 2000 hp. Power required is 255 amp at 4l60 V ac.

6.3.2.8 Heat Exchanger Characteristics

There are no heat exchangers in the closed cooling water path associated with the emergency core cooling subsystems. The heat exchangers in the RHR system are discussed in Section 5.5.

6.3.2.9 Emergency Core Cooling System Flow Diagram

A schematic diagram, the flow rates, and the pressures of the various ECCS subsystems can be obtained from the information blocks on the following process diagrams: Figures 6.3-1 through 6.3-11, and Figures 6.3-14 through 6.3-16. These parameters are presented for several modes of operation, including LOCA and test conditions.

6.3.2.10 Relief Valves and Vents

The RHR/LPCI and the core spray systems are not designed to withstand normal reactor system pressures. Relief valves are provided to protect the low-pressure portions of these subsystems against possible overpressurization due to valve leakage and pump heat input. Pressurized portions of the HPCI system are designed for service at reactor pressure and therefore do not require overpressure protection.

The design basis for the relief valves to protect the core spray and RHR systems from overpressurization is given in Subsection 5.5.13.

6.3.2.11 System Reliability

The ECCS reliability has been achieved through an evolutionary process. Initially a proposed system configuration was submitted for evaluation. A reliability model of the proposed system was constructed and an estimate of the system success probability was made. Reliability models were then constructed for alternative ECCS configurations and a comparative trade-off study yielded the most reliable system configuration. Upon completion of the final design, a formal reliability analysis was performed to

a. Determine the expected system availability (average reliability)

b. Set safe system test intervals and allowable repair times

c. Qualitatively evaluate the system for conformance to the original design concepts, as well as existing industry standards and criteria for reactor protection and safety systems.

System availability is evaluated and selected test intervals and allowable repair times were determined by well-established reliability/availability methods. The qualitative analysis includes a functional system failure modes and effects analysis (FMEA). The FMEA results are used to verify conformance to industry criteria, develop reliability models, and ensure that the original design redundancy and diversity have been retained.

Availability, as applied to the ECCS, is defined as the probability that the system is operable when required. The ECCS availability is a function of the component system test intervals and the failure rates of the component parts used in the systems. The component parts used in the ECCS have low failure rates, as evidenced by historical field operating experience. The ECCS availability required to ensure adequate plant safety is established as a system design requirement. To ensure adherence to the availability design requirement, the periodic test intervals and allowable repair times for inoperable systems are defined in the Technical Specifications.

The power sources required for successful system operation are arranged in redundant configurations such that the power availability is not a limiting factor in determining the overall system success probability.

6.3.2.12 Protection Provisions

The ECCS piping and components are designed to accommodate the effects of movement, missiles, thermal stresses, the effects of the LOCA, and the safe-shutdown earthquake (SSE).

The reactor coolant pressure boundary (RCPB) has been analyzed for four categories of design transients: normal, upset, emergency, and faulted conditions. These categories are generally described in the ASME B&PV Code Section III, 1968 Edition. Subsection 5.2.1 contains details of this analysis.

Protection of the mechanical, instrumentation, and electrical portions of the engineered safety feature (ESF) system and reactor protection systems (RPS) against environmental conditions is discussed in Section 3.11.

Subsection 6.3.2.2.5 describes the features protecting against water-hammer effects in ECCS discharge lines.

The components of the core spray system, the HPCI, the LPCI, and the RHR systems are protected from becoming functionally inoperative as a result of flooding the lower levels of the reactor building due to excessive leakage from the ECCS complex. Section 3.4 describes design protection against flooding.

Response 3.1.2, Amendment 11 of the Fermi 2 PSAR discusses thermal stresses generated by high-temperature and high-pressure jet streams impinging on spherical plate sections. Also presented is an analysis of the uplift force on the RPV associated with a main steam line break. The methods used to provide assurance that thermal stresses do not cause damage to the ECCS are described in Subsection 6.3.3.9.

The ECCS is protected against the effects of the pipe whip, which might result from piping failures up to and including the LOCA, by separation barriers, pipe-whip restraints, or energy-absorbing materials. One or more of these three methods have been applied to provide protection against cascading damage to piping and components of the ECCS that could otherwise result in a reduction of ECCS effectiveness to an unacceptable level. Section 3.6 describes the design protection and analysis performed for pipe whip.

The ECCS piping and components located outside the containment are protected from internally and externally generated missiles by the reinforced-concrete structure of the ECCS pump rooms. In addition, the watertight construction of the ECCS pump rooms below grade level protects against damage by flooding. Section 3.5 describes design protection against postulated missile damage.

6.3.2.13 Provisions for Performance Testing

a. High pressure coolant injection system

    1. A full-flow test line is provided to route water from and to the condensate storage tank without entering the RPV

    2. Instrumentation is provided to indicate system performance during normal and test operations

    3. All motor-operated and air operated valves are capable of manual operation, either local or remote for test purposes

    4. Drains are provided to leak test the major system valves.

b. Core spray system

    1. A full-flow test line is provided to route water from and to the suppression pool without entering the RPV

    2. In the event the torus is unavailable to provide suction, a test line from the condensate storage tank provides reactor grade water to test pump discharge to simulate injection into the RPV. Direct injection to the vessel is not performed (Subsection 6.3.2.2.3.2)

    3. Instrumentation is provided to indicate system performance during normal and test operations

    4. All motor-operated valves, air-operated valves, and check valves are capable of manual operation for test purposes

    5. Relief valves are removable for bench testing.

c. Low pressure coolant injection system

1. Discharge test lines are provided for the four pumps to route suppression pool water back to the suppression pool without entering the RPV
2. Instrumentation is provided to indicate system performance during normal and test operations
3. All motor-operated valves, air-operated valves, and check valves are capable of manual operation for test purposes
4. Shutdown cooling lines taking suction from the recirculation system are provided to allow testing of pump discharge into the RPV during normal plant shutdown
5. All relief valves are removable for bench testing.

d. Automatic depressurization system

Actual operation of each safety/relief valve pilot valve associated with the ADS was verified during the Preoperational Test Program.

6.3.2.14 Net Positive Suction Head

The RHR/LPCI and core spray pump systems are designed to ensure adequate net positive suction head (NPSH) margin availability under all combinations of foreseeable adverse conditions. The point of minimum margin for all pumps occurs at the peak suppression pool temperature, calculated on the basis of conservative assumptions. No dependence is placed upon positive containment pressure. The Regulatory Position stated in Regulatory Guide 1.1, dated November 2, 1970, is met.

The conditions assumed for calculating the peak suppression pool temperature and the available NPSH margin are as follows:

a. Reactor at 3499 MWt (102% of 3430 MWt)
b. Suppression pool volume is 117,161 ft^3
c. Initial suppression pool water temperature 95°F
d. Temperature of RHRSW reservoir varies linearly from 80°F to 90°F over 8 hours and stabilizes at 90°F
e. Pump suction strainers plugged to maximum design per UFSAR Section A.1.82
f. All of the energy in the RPV is absorbed by the suppression pool water following a LOCA
g. Pumps operating at rated flows
h. The heat loads considered were pump heating; Zr-H_2O reaction; peak sensible heat in RPV, steam, all water in the feedwater system, recirculation loops, fuel; and decay heat

i. The primary containment long-term response to a recirculation line break LOCA scenario in Subsection 6.2.1.3.3

j. Bounding minimum RHR heat exchanger heat transfer coefficient is 366 BTU/sec-°F

k. RHR system is placed in the suppression pool cooling mode 20 minutes after LOCA

The analysis yielded a peak suppression pool temperature of 196.5°F which occurs approximately 5 hours after LOCA. This temperature is less than the suppression pool temperature of 198°F used in the RHR and the core spray NPSH margin calculations described below. The NPSH margins for the RHR and core spray pump systems using a peak suppression pool temperature of 198°F and other conservative calculational methods are positive, even allowing for instrument tolerances to cause flow to be above nominal design values. The 198°F pool temperature for NPSH is the controlling limit for the bulk pool temperature.

A hydraulic analysis has been performed for each RHR operating mode shown in the General Electric process diagram (Figure 6.3-14, Sheet 2). The NPSH required was obtained by using the most conservative RHR pump performance curve and corresponds to the flow rate through the pump. In calculating the NPSH available for each mode, the design conditions on the process diagram were used and the suction strainers were assumed to be plugged to maximum design per UFSAR Section A.1.82. The results of the RHR hydraulic analysis are as follows, assuming pumps with maximum allowed degradation:

Mode	Description	GE Nominal Design Flow per Pump (gpm)	NPSH Required (ft absolute)	NPSH Available (ft absolute)
A	LPCI accident, three pumps, RPV pressure equals 20 psig	10,000	15	30
B	LPCI accident, two pumps, RPV pressure equals 20 psig	13,000	17	27
C2	Containment spray, one pump, RPV pressure equals 0 psig	10,000	12.8	13.9*
D2	Suppression pool Cooling, one pump	10,000	12.8	31 14*
E	Shutdown cooling, two pumps, RPV pressure equals 97 psig	9,625	13	49

F	Shutdown cooling, two pumps, RPV pressure equals 0 psig	9,750	13	76
G	LPCI accident, two pumps, RPV pressure equals 0 psig	13,000	17	19**
H	LPCI test, one pump	10,300	13	42
J2, J4	Minimum flow bypass, two pumps	480	8	44

* Suppression pool at 198°F

** Margin consistent with GE process diagram fluid temperature. Long-term operation at the higher suppression pool design maximum temperature of 198°F requires throttling flow consistent with EOP procedures consistent with UFSAR Section 6.3.2.17.

From the above cases, it is apparent that Modes C2 and G have the lowest NPSH margin. Since NPSH margin is typically reduced at higher flow rates, Modes C2 and G were also examined using LPCI pumps operating on the vendor supplied pump curve (not degraded) and with 2% over-frequency applied. Under this condition, while NPSH margin is reduced to less than 1 ft for the worst case pump, the margin remains positive without containment overpressure.

The RHR pump suction strainers are 11-gage perforated plate stacked discs with 1/8-in.-diameter holes. Therefore, the largest particles that could pass through the strainers are 1/8 in. in diameter.

After a postulated LOCA, debris released to the suppression pool would tend to sink to the bottom of the pool. The accumulation of this debris on the RHR pump suction strainers is minimized because the strainer is located at a 45° angle above the bottom of the pool, with a 10° mitre bend between the suction flange and the strainer flange. Any particles that could pass through the strainer perforations are not of sufficient size to affect RHR pump suction flow.

Local heating in the suppression pool is a phenomenon that occurs when high-energy steam is released into the suppression pool for quenching. The most severe local heating occurs during a safety/relief valve discharge. In general, local-to-bulk temperature differences at the time of maximum temperatures are about 15° for cases where two RHR loops are assumed available and about 30° for cases where one RHR loop is assumed available. The pool temperature during normal plant conditions is limited by Technical Specifications so that localized heating from safety/ relief valve discharges will not nullify the NPSH of the ECCS pumps, even for prolonged operation of the valves.

Local heating also occurs during the RPV depressurization stage of a postulated LOCA when steam and noncondensable gases are blown through the downcomers into the suppression pool. Local heating during this event will be significantly less than the temperature achieved during safety/relief valve blowdown because of lower energy in the steam and high turbulence in the water.

As described in Subsection 6.2.1.3.2, at about 100 sec after the design-basis accident (DBA), hot water only will be discharged out of the break; at 1200 sec, the suppression pool temperature has reached 168°F. Thus, up to this point, there would be a very large margin on NPSH even if local heating were significant. At the time the suppression pool reaches its peak temperature, approximately 5 hr after LOCA, local heating cannot be significant for the small ΔT in the water being discharged is quickly blended with the pool water.

The preceding conditions describe the containment system after full blowdown following a large break. Consequently, they are not applicable to the HPCI system. The HPCI pump is located below the level of the condensate storage tank (CST), from which suction is normally taken, and below the water level in the suppression pool.

A low-water level in the condensate storage tank (2 ft 8 in. above the bottom of the tank) or a high-water level in the suppression pool (3.5 in. above normal level), would cause the two normally closed, motor-operated gate valves located in the suppression pool suction line to automatically open. The normally open, motor-operated gate valve located in the condensate storage tank suction line would remain open until the two suppression pool suction valves fully open. At that time, the condensate storage tank suction valve would close. In this way, NPSH is maintained.

In the case of an ECCS passive failure such as pump seals or valve seals, the operator has adequate time to take corrective action and isolate the failure before the NPSH would become inadequate for the remaining ECCS pumps due to reduced suppression pool level.

Adequate minimum submergence is available to prevent vortex formation and air ingestion during operation. With the exception of suction from the CST, minimum required submergence is computed in accordance with NUREG/CR-2772 as endorsed in Reg. Guide 1.82 Rev. 2. Under the RHR RUNOUT scenario, available submergence is sufficient to ensure minimal air entrainment and still meet NPSH requirements under Regulatory Guide 1.82, Rev. 2 for the minimum required compliment of pumps. The predicted CST suction minimum submergence is acceptable based on analytical analysis and the use of mechanical vortex suppression assemblies. The analytical method establishes the minimum submergence for straight (non-circular) spill over flow into the suction piping in accordance with Reference 2. For circular flow or vortex flow considerations, mechanical vortex suppression assemblies are installed that eliminate flow vortexes from introducing the potential for air entrainment into the pump suction. The pertinent data are summarized below:

System	Suction Source	Available Submergence (ft)	Predicted Submergence for Incipient Air Ingestion (ft)
RHR	Suppression pool	8.7	7.35 (LPCI) 9.0 (LPCI RUNOUT)†
Core spray	Suppression pool	9.2	3.9
HPCI	Suppression pool	8.2	1.2
HPCI	Condensate storage tank	1.45 (including 0.44 foot silt block)	0.98

† Under the limiting RUNOUT condition, the minimum submergence of the most limited of four available RHR pumps is not sufficient to ensure zero air ingestion. Here, the LPCI function is not credited to meet 10CFR50.46 ECCS performance requirements. With consideration of the standard applied NPSH penalties one or more RHR pumps have sufficient NPSH. This ensures RHR is available for subsequent use to provide long-term containment cooling in suppression pool cooling mode.

A postulated minimum level of 14 in. below the torus centerline was used to determine the level of suppression pool submergence.

The precaution taken to preclude vortex formation in the HPCI-RCIC condensate storage tank suction is to transfer suction to the suppression pool on low tank level. This is supplemented by the installation of a vortex suppression assembly over the suction intake for the HPCI-RCIC systems to mechanically preclude vortex formation.

6.3.2.15 Residual Heat Removal Pump Runout Evaluation

The Fermi 2 design was reexamined also to determine whether a failure in the LPCI logic could disable the RHR pumps. The single failures that potentially could disable the RHR pumps have been identified as the following.

Case A The LPCI logic correctly selects the unbroken loop, but a single failure causes inadvertent opening of LPCI injection valve E11-F015 into the broken loop. This condition results in four RHR pumps injecting into both recirculation loops with one loop broken

Case B All four RHR pumps start for LPCI injection, but a single failure causes the LPCI loop selection logic to select the wrong (broken) loop. This condition results in all four RHR pumps injecting into the broken recirculation loop

Case C The LPCI logic correctly selects the unbroken loop, but a single failure causes the recirculation pump discharge valve B31-F031 to remain unclosed. This condition results in four RHR pumps injecting into the vessel through one recirculation loop inlet and discharge lines.

Under the above conditions, the RHR pump operation was examined for cavitation, pump motor overload, and emergency diesel generator overload.

6.3.2.15.1 Analysis Assumptions

As shown in Figure 6.2-13, the initial LOCA blowdown causes an almost immediate temperature increase to approximately 135°F in the torus with a continued increase to 168°F after 20 minutes. A water temperature of 168°F was assumed for the entire time period and for each of the cases (A, B, and C) listed above.

As described in Subsection 6.3.2.1, after 10 minutes the operator begins the post-LOCA manual control of the RHR system, which includes throttling the RHR system and initiating containment cooling. However, the operator can delay the containment cooling for up to 20 minutes. Therefore, it is assumed that the RHR pump runout condition occurs during the 0- to 20-minute part of the DBA.

Although the LOCA blowdown will cause a pressure increase in the primary containment, the drywell and torus pressure assumed for the analysis is 0 psig.

Reactor vessel pressure was determined from the LPCI process diagram Figures 6.3-14 through 6.3-16. A vessel pressure of 20 psig given in mode A was assumed, because the runout condition lasts only during the short term portion of the LOCA analysis. The RHR suction strainers were assumed to be plugged.

For Case B, no jet pump resistance is available as the broken injection loop bypasses the normal injection path through the jet pumps. For Cases A and C, an equivalent jet pump resistance value was determined and used in the analysis.

The reactor core level was assumed to flood to two-thirds of the core height.

The Technical Specifications allow only 7 days of continuous plant operation with an inoperable LPCI pump. Therefore, the analysis did not consider any pumps to be out of service for maintenance.

6.3.2.15.2 Calculation Procedure and Results

From the description of cases A, B, and C, it is clear that case A is the limiting case. This is because case A allows all four pumps to pump into parallel paths consisting of both the normal injection path and to the broken loop. Case A bounds case B, since case B simply eliminates the parallel path to the desired injection line. Case C is the least limiting. Like case B, case C involves only one flow path, but it would inject against a greater residual pressure in the reactor and intact recirculation loop piping. Therefore, only case A is analyzed in detail. The vendor-certified RHR pump performance curves provided a record of pump performance test data up to a pumping condition of 14,000 gpm. Operating conditions beyond this point were assessed using extrapolated vendor pump performance curves and data from the preoperational testing for RHR pumps. The results for each case are discussed below.

Case A

Case A results in four RHR pumps pumping into both LPCI loops, with one loop broken. Under the most limiting scenario for minimum overall available NPSH, the RHR pumps are required to operate at approximately 15,500 gpm. The analysis of the available NPSH margins for this condition determines that adequate margins are available for torus water temperatures less than 168°F consistent with the time available for operators to take action to establish containment cooling within 20 minutes in accordance with the plant design as described in Section 6.3.2.14. For the Case A pump operating condition, pump motor and emergency diesel generator overloads will not be experienced.

6.3.2.15.3 Conclusion

A failure of the LPCI logic will not result in RHR pump operating conditions that would allow pump cavitation, pump motor overload, or emergency diesel generator overload. The limiting case failure does allow the pumps to operate at a point that is not part of the manufacturer's performance test data. Extrapolated performance data were used as a basis for the analysis conclusion. The extrapolated data has been confirmed by expanding the scope of the preoperational testing for the RHR pumps to provide performance data for the 14,000-gpm to 15,300-gpm range. No design changes to the RHR system are required; therefore, the performance of the RHR system, with respect to process diagram requirements, has not changed and there is no impact on the Appendix K analysis discussed in Subsection 6.3.3.

6.3.2.16 Motor-Operated Valves and Controls

The LPCI and the core spray systems are not designed to withstand reactor system pressures. Provisions have therefore been made to ensure that these ESF systems are not subjected to damaging pressures. These provisions include appropriate relief valves, discussed in Subsection 6.3.2.10, and isolation valves with system interlocks and alarms that are discussed below. Refer to Section 7.3 for a further discussion of controls for these valves. The LPCI/RHR system is isolated from the reactor system by the following:

Valves	Line Isolation	Isolation Signal
F008	RHR pump suction	Pressure trip unit B31-N611B signals “close” above permissive pressure
F009	RHR pump suction	Pressure trip unit B31-N611A signals “close” above permissive pressure
F022	RPV head spray (RHR pump discharge)	Pressure trip unit B31-N611A signals “close” above permissive pressure
F015A, B	RHR pump discharge to RPV	B21-N690A, B and logic signal prevent opening above interlock pressure
F050A, B	RHR pump discharge to RPV	Check valve (air operator on valve for testing)

If either trip unit B31-N611A or B31-N611B fails in a nonconservative manner, the system is still protected because the other unit sends a "close" signal to the valve in series with the valve controlled by the failed trip unit. In the event of valve leaks, the system is protected by the pressure relief valves as outlined in Subsection 6.3.2.10.

Provisions have been made to allow for thermal expansion of water trapped between valves F008 and F009 (penetration X-12), by way of a line that returns the trapped water to the RPV.

The core spray system is isolated from the reactor system by the following

Valves	Line Isolation	Logic
F005A, B	Core spray pump discharge	Manual control room pushbutton to close
F006A, B	Core spray pump discharge	Check valve

Check valves are backed up by normally closed motor-operated valves. In the event of operator failure and check valve leak, the system is protected by relief valves as outlined in Subsection 6.3.2.10.

All motor-operated ECCS valves have position indication in the control room.

6.3.2.17 Manual Actions

With the exception of LPCI while RHR is in the shutdown cooling mode, the initiation of the ECCS is completely automatic. No operator action is required for the initiation of postaccident modes of operation. When RHR is lined up in the shutdown cooling mode and RPV pressure is less than or equal to the cut in pressure, manual operation is required to permit LPCI to align and initiate. This includes manually lining up the suction path from the torus for the loop which is in shutdown cooling. No manual valve is required to change position to accomplish a safety-related mode of any ECCS. Manual valves generally do not have position indication in the control room. Administrative procedures require the position of any critical manual valve to be verified and recorded after each time it is operated and the position of critical manual valves to be verified and recorded during a refuel outage prior to plant operation following refueling. Thus, all critical manual valves are under rigid administrative control.

Following is a list of manual valves critical to the operation of ECCS that are controlled by administrative procedures:

Safety System	Valve Number(s)
HPCI system	P1100-F042
LPCI mode of RHR	E1100-F034 A (B, C, D)
Core Spray	E2100-F001 A (B, C, D)
	E2100-F037 A (B, C, D)

Operators are instructed and trained to observe the values and rates of change of the plant parameters that have the greatest significance for plant safety (e.g., RPV water level, containment pressure, torus temperature, radiation monitors, operation of ECCS, standby gas treatment system, emergency diesel generator loads, etc.). From these parameters, together with his training and use of the symptom-oriented emergency operating procedures, the operator is able to logically evaluate the condition of the plant and is prepared to take appropriate action at the end of the initial interval.

A timer is used in each ADS logic. The time-delay setting before actuation of the ADS is long enough that the HPCI system has time to operate, yet not so long that the LPCI and core spray systems are unable to adequately cool the fuel if the HPCI system fails to start. Manual reset circuits are provided for the ADS initiation signal. By resetting this signal manually, the delay timers are recycled. The operator can use the reset pushbuttons to delay or prevent automatic opening of the relief valves if such delay or prevention is necessary.

A manual inhibit switch is also provided for each ADS trip system. These switches allow the operator to inhibit ADS operation without repeatedly pressing the reset pushbuttons. Operation of the manual inhibit switch will activate a white indicating light and an annunciator to alert the operator of the inhibit action. Enabling the inhibit function will not terminate an ADS logic actuation after the 120 second time delay has elapsed. At this point, only the reset pushbutton can be used to affect the ADS operation. Guidance is contained in the Emergency Operating Procedures.

6.3.2.18 Process Instrumentation

Sufficient instrumentation is available to the operator in the main control room to assist him in accurately assessing the post-LOCA conditions if LOCA should occur. Basically, these indications are of two varieties: those that indicate the pressures, temperatures, and levels in the RPV and containment, and those that provide indication of operations of the ECCS position of valves and circuit breakers, flows, temperatures, and pressures of ECCS.

The most significant instruments in the first category are

a. Reactor pressure vessel level

b. Reactor pressure vessel pressure

c. Containment pressure

d. Containment temperature

e. Suppression pool level

f. Suppression pool temperature.

The most significant instruments in the second category are as follows.

a. LPCI flow and pressure

b. Core spray flow and pressure

c. HPCI flow and pressure.

Other available instrumentation is listed on the piping and instrumentation diagram included with the description of the above system in Chapter 5. Discussion of instrumentation also appears in Chapter 7. See Subsection 7.5.1.4.2 for a detailed listing of the process information available in the main control room that permits accurate assessment of postaccident conditions.

6.3.2.19 Materials

Materials used in or on the ECCS are reviewed and evaluated with regard to radiolytic and pyrolytic decomposition and attendant effects on safe operation of the ECCS. For example, fluorocarbon plastic (Teflon) is not permitted in environments that attain temperatures greater than 300°F or radiation exposures above 10^4 rads.

Organic materials used in the Fermi 2 primary and secondary containments have been selected for extended life during normal operations for their resistance to expected accident environmental conditions. Thermal insulation used is inorganic and is not sensitive to high radiation fields, steam, or high temperature.

Evaluations of the protective coatings used within the containment (Subsection 6.2.1.6) have been made. It has been determined that they will satisfactorily endure accident environmental conditions and their expected products of decomposition, if any, will not adversely affect the operability of any ESF system.

6.3.2.20 Maintenance and Operability

The capability of the ECCS to provide core cooling is verified by regularly scheduled functional tests on each component and system. Subsection 6.3.4 discusses these tests and the testing program.

The configuration of the ECCS systems has placed most of the components in concrete cubicles so that maintenance on any component has a minimum of complications due to radiation from the primary system or from other components (see Figures 1.2-6 and 1.2-8). Drains for all pumps, heat exchangers, and low points in piping runs are piped directly to radwaste collection points. Flushing and makeup are provided from the demineralized water or CSTs.

Because of these features, maintenance of ECCS components during a long-term LOCA mode of operation may be possible depending upon which component has failed. However, special facilities for this situation have not been provided, since the system designs inherently account for component failures without overall loss of intended function (usually by redundancy of systems, see Subsection 3.12.2.2). In addition, the following design provisions have been included to increase system operational reliability during a LOCA:

a. All components essential to ECCS operation are capable of continued operation under LOCA conditions of pressure, temperature, and radiation

b. Suction strainers have been provided on all ECCS pumps to prevent pump seizure due to entrained foreign particulates

c. Adequate fouling factors have been included in the determination of the design heat transfer capacities of the RHR heat exchangers.

The core spray and RHR pumps and motors are designed for the operating life of the plant (40 years) and for a postulated single continuous operation of 100 days for an accident during that 40-year operating life.

The following table shows the maximum expected accumulated operating time of these pumps for the life of the plant (40 years):

Mode of Operation	RHR (hr)	Core Spray (hr)
In-shop testing	4	4
Preoperational testing	168	168
Monthly testing	480	480
Yearly testing	40	40
Post LOCA	2,400	2,400
Shutdown	28,800	N/A
Total	31,892	3,092

The severe operating conditions to which the HPCI pumps are exposed are temperatures to 212°F, radiation, and dynamic loads from seismic and hydrodynamic effects. The pumps are mainly fabricated of metallic materials that will not be degraded by the temperature and radiation environment. The nonmetallic gaskets and seals are made of materials with a demonstrated resistance to the environment. The dynamic load inputs are addressed analytically and evaluated against appropriate criteria to ensure operation of the pump while undergoing dynamic loading. The above ensures that the expected service life will exceed the expected operating time of 500 hr. (Surveillance tests are performed once a month for 40 years equaling 480 tests plus a possible 20 real starts equaling 500 operating hours.)

CS pumps are analyzed for the effects of dynamic loads resulting from seismic and hydrodynamic effects. Operability under the worst loadings is ensured by the operability assurance program described in Section 3.9.4.3.

6.3.3 Emergency Core Cooling System Performance Evaluation

The performance of the ECCS was determined originally by applying the 10 CFR 50, Appendix K, evaluation models and then showing conformance to the acceptance criteria of 10 CFR 50, Section 50.46. Reference 3 provided a complete description of the LOCA events and the methods used to perform the original calculations.

The original methodology was updated (Reference 4) for the power uprate program (Reference 5) for GE11 (Reference 19), and for the GE14 fuel introduction (Reference 16). The LOCA analysis was then revised using the SAFER/PRIME-LOCA analytical model and methodology (Reference 39). Then the TRACG-LOCA evaluation model replaced the SAFER/PRIME-LOCA for the ECCS-LOCA analysis for the GNF3 fuel introduction (Reference 42). The updated methodology and a description of the LOCAs are summarized here.

The ECCS performance is evaluated for the entire spectrum of break sizes for postulated LOCAs. The discussion includes information on the radiological consequences of the following events:

a. Feedwater piping break, Subsection 15.6.6

b. Spectrum of BWR steam system piping failures outside containment, Subsection 15.6.4

c. Loss-of-coolant accidents, Subsection 15.6.5.

Cycle-specific reload information is in Reference 15.

6.3.3.1 Emergency Core Cooling System Bases for Technical Specifications

The maximum average planar linear heat generation rates (MAPLHGR) calculated in this performance analysis provide the basis for Technical Specifications designed to ensure conformance with the acceptance criteria of 10 CFR 50, Section 50.46. Minimum ECCS functional requirements are specified in Subsections 6.3.3.4 and 6.3.3.5; testing requirements are discussed in Subsection 6.3.4. Limits on minimum suppression pool water level are discussed in Section 6.2.

The plant is licensed for average power range monitor (APRM) rod block monitor (RBM) Technical Specification (ARTS) improvement program (Reference 6, 7, 8, and 20) and has both power and flow dependent limits imposed on the operating limit MAPLHGR (Reference 8 and 20). The flow dependent MAPLHGR, $MAPLHGR_f$, is determined from the product of the standard MAPLHGR and a flow dependent term, $MAPFAC_f$, which is defined as a function of the core flow rate and positioning of the scoop tube on the recirculation pump motor. The plant specific $MAPFAC_f$ versus flow curve is shown in the Core Operating Limits Report (COLR).

The power dependent operating limit MAPLHGR, $MAPLHGR_p$, is determined from the product of the standard MAPLHGR and the power dependent term, $MAPFAC_p$. For powers between 25 percent rated and the bypass point for the turbine stop valve/turbine control valve fast closure scram signal (29.5 percent rated), there are two values for $MAPFAC_p$, one for core flows >50 percent rated and one for core flows ≤50 percent rated, as shown in the COLR. Once the power exceeds this bypass point, the $MAPFAC_p$ is determined from a single curve which must be multiplied by the standard MAPLHGR to produce the reduced power operating limit MAPLHGR, $MAPLHGR_p$.

The operating limit MAPLHGR to be used becomes the most limiting value of either $MAPLHGR_f$ or $MAPLHGR_p$.

6.3.3.2 Acceptance Criteria for Emergency Core Cooling System Performance

The applicable acceptance criteria, quoted from 10 CFR 50, Section 50.46, "Acceptance Criteria for Emergency Core Cooling Systems for Light-Water-Cooled Nuclear Power Reactors," are listed here. A detailed description of the methods used to show compliance are in Subsection 6.3.3.7 and Reference 1.

a. Criterion 1, peak cladding temperature - "The calculated maximum fuel element cladding temperature shall not exceed 2200°F." Conformance to Criterion 1 is shown in Table 6.3-4

b. Criterion 2, maximum cladding oxidation - "The calculated total local oxidation of the cladding shall nowhere exceed 0.17 times the total cladding thickness before oxidation." Conformance to Criterion 2 is shown in Table 6.3-4

c. Criterion 3, maximum hydrogen generation - "The calculated total amount of hydrogen generated from the chemical reaction of the cladding with water or steam shall not exceed 0.01 times the hypothetical amount that would be generated if all the metal in the cladding cylinder surrounding the fuel, excluding the cladding surrounding the plenum volume, were to react." Conformance to Criterion 3 is shown in Table 6.3-4

d. Criterion 4, coolable geometry - "Calculated changes in core geometry shall be such that the core remains amenable to cooling." As described in Reference 1, conformance to Criterion 4 is demonstrated by conformance to Criteria 1 and 2

e. Criterion 5, long-term cooling - "After any calculated successful initial operation of the ECCS, the calculated core temperature shall be maintained at an acceptably low value and decay heat shall be removed for the extended period of time required by the long-lived radioactivity remaining in the core." Conformance to Criterion 5 is demonstrated in Reference 9. Briefly summarized, the core remains covered to at least the jet pump suction elevation, and the uncovered region is cooled by spray cooling and/or by steam generated in the covered part of the core.

6.3.3.3 Single-Failure Considerations

The functional consequences of potential operator errors, single failures, and the potential for submerging valve motors in the ECCS are discussed in Subsection 6.3.2. This Subsection includes information on errors that could cause any manually controlled, electrically operated valve in the ECCS to move to a position that could adversely affect the ECCS. There it was shown that all potential single failures are no more severe than one of the single failures identified in Table 6.3-5.

It is therefore only necessary to consider each of these single failures in the emergency-core-cooling-system performance analyses.

The specific analysis (Reference 42) included break sizes ranging from the minimum size that meets the definition of a LOCA to 200% of the largest applicable pipe cross-sectional area. Different single failure assumptions were investigated in order to identify the limiting case. Non-recirculation line breaks were found to be non-limiting. The feedwater line break accident analysis assumes operator actions are required to depressurize the reactor during a Division I battery failure. This assumption was reviewed and accepted by the NRC per the Ref. 24 SER.

The TRACG LOCA analysis (Reference 42) indicates that the small recirculation line breaks with Division II DC Power Source (Div II Battery) failure are limiting. This analysis was performed at maximum core thermal power, including uncertainty allowance (see Table 6.3-6, Section A Plant Parameters).

6.3.3.4 System Performance During the Accident

In general, the system response to an accident can be described as

a. Receiving an initiation signal

b. A small lag time (to open all valves and have the pumps up to rated speed)

c. Finally the ECCS flow entering the vessel.

Key ECCS actuation setpoints and time delays for all the ECCSs are provided in Table 6.3-6. The minimization of the delay from the receipt of signal until the ECCS pumps have reached rated speed is limited by the physical constraints on accelerating the diesel generators and pumps. The delay time resulting from valve motion in the case of a high-pressure system provides a suitably conservative allowance for valves available for this application. In the case of the low-pressure system, the time delay for valve motion is such that the pumps are at rated speed before the vessel pressure reaches the pump shutoff pressure.

Simplified piping and instrumentation and functional control diagrams for the ECCS are provided in Subsection 6.3.2. The operational sequence of ECCS for the DBA is shown in Table 6.3-7.

Operator action is not required, except as a monitoring function and as noted in Section 6.3.3.3, during the short-term cooling period following a LOCA. During the long-term cooling period, the operator will take action as specified in Subsection 6.2.2.3 to place the containment cooling system into operation.

6.3.3.5 Use of Dual Function Components for Emergency Core Cooling System

With the exception of the LPCI system, the systems of the ECCS are designed to accomplish only one function: to cool the reactor core following a loss of reactor coolant. To this extent, components or portions of these systems (except for pressure relief) are not required for operation of other systems that have emergency core-cooling functions, or vice versa. Because either the ADS initiating signal or the overpressure signal opens the safety/relief valve, no conflict exists.

The LPCI subsystem, however, uses the RHR pumps and some of the RHR valves and piping. When the reactor water level is low, the LPCI subsystem has priority through the valve control logic over the other RHR subsystems for containment cooling. When RHR is lined up in the shutdown cooling mode and RPV pressure is less than or equal to the cut in pressure, manual operator action is required for LPCI injection. Immediately following a LOCA, the RHR system is directed to the LPCI mode.

6.3.3.6 Limits on Emergency Core Cooling System Parameters

The limits on the ECCS parameters are discussed in Subsection 6.3.3.1 and Subsection 6.3.3.7.1.

Any number of components in any given system may be out of service, up to and including the entire system. The maximum allowable out-of-service time is a function of the level of redundancy and the specified test intervals. The limiting conditions for operation and surveillance requirements are given in the Technical Specifications.

6.3.3.7 Emergency Core Cooling System Analyses for Loss-of- Coolant Accident

6.3.3.7.1 Loss-of-Coolant Accident Analysis Procedures and Input Variables

The procedures approved for LOCA analysis conformance calculations were originally performed and approved in accordance with the methodology described in Reference 3. This methodology has been updated in accordance with the procedures in detail in Reference 40, commonly referred to as SAFER/PRIME methodology. The SAFER/PRIME methodology has been replaced with the procedures in Reference 41, commonly referred to as TRACG-LOCA, for GNF3 and GE14 fuel types. The new methodology, which is an ECCS evaluation model developed to analyze BWR LOCA in accordance with 10 CFR 50.46, is a best estimate plus uncertainty type of evaluation model. Potentially limiting break locations, initial conditions, and ECCS performance are determined using inputs that correspond to the "nominal" trial associated with the statistical analysis in the break spectrum calculations. Statistical analyses are performed for at least the most limiting small break, intermediate break, and double-ended guillotine break (DEGB).

Two primary computer models were used to determine the LOCA response for plant Fermi 2 using the TRACG-LOCA method. These models are PRIME and TRACG, which are described below.

a. DELETED

b. DELETED

c. PRIME

   The PRIME model provides the parameters to initialize the fuel rod fission gas inventory and rod internal pressure at the onset of a postulated LOCA for input to TRACG. PRIME also provides the initial pellet-cladding gap conductance and other parameters used by TRACG to calculate the transient gap conductance.

d. TRACG

   TRACG calculates the system response of the reactor and the detailed fuel rod heat transfer over a complete spectrum of hypothetical break sizes and locations. TRACG is compatible with the PRIME fuel rod model for gap conductance and fission gas release. A simplified form of the PRIME fuel thermal conductivity model is built into TRACG. TRACG calculates the core and vessel water levels, system pressure response, ECCS performance, and other thermal-hydraulic phenomena occurring in the reactor as a function of time. TRACG conservatively models the sources of heat in the core such as fission power, decay heat, and metal-water reaction. TRACG realistically models all regimes of heat transfer to calculate the transient cladding temperatures and oxidation.

The significant input variables used by the LOCA codes are listed in Table 6.3-6.

6.3.3.7.2 Accident Description

A detailed description of the LOCA calculation is provided in Reference 40 and is supplemented by Reference 42. With the TRACG-LOCA methodology, the limiting break is the limiting small recirculation suction line break. The limiting single failure is the one which results in the highest PCT. This is the failure of the Division II DC power (battery).

Table 6.3-8 provides a listing of figures which summarizes LOCA results.

6.3.3.7.3 TRACG-LOCA Break Spectrum Calculations

The break spectrum calculations were performed in Reference 42 to determine all potentially limiting initial conditions, single failures, break locations, and break size combinations. All calculations were performed for both GNF3 and GE14 fuel, and all calculations were performed with a loss of offsite power coincident with the break. All break spectra were calculated assuming a maximum core thermal power corresponding to the current licensed thermal power, plus power uncertainty, of 3,499 MW with an initial dome pressure of 1045 psia.

Only three limiting single failures are evaluated for the standard LOCA analysis, which are Division I Battery, Division II Battery and LPCI Injection Valve. The other three single failures, which are Diesel Generator (DG), HPCI and One ADS Valve, result in more ECCS systems available than at least one of the three limiting single failures and, therefore, are not considered in the break spectrum calculations.

For Division I Battery Failure, the core spray line (CSL), feedwater line (FWL), recirculation suction line (RSL), recirculation discharge line (RDL), Main Steam Line (MSL) and Reactor Water Cleanup (RWCU) breaks are considered. The limiting break sizes are 0.3185, 0.3154, and 0.3743 ft^2 for RDL, RSL and FWL, respectively. The CSL, MSL and RWCU are clearly non-limiting compared to the recirculation line breaks.

For Division II Battery Failure, the CSL, FWL, RSL, RDL, MSL and RWCU breaks are considered. The limiting break sizes are 0.1280, 0.1056, and 0.4491 ft^2 for RDL, RSL and FWL, respectively. The CSL, MSL and RWCU are clearly non-limiting compared to the recirculation line breaks.

For LPCI Injection Valve Failure, the RSL, RDL and CSL breaks are considered. The limiting break sizes are 0.7924 and 0.7848 ft^2 for RDL and RSL, respectively. Other breaks are not included for this failure because they are not limiting.

The Double Ended Guillotine Break (DEGB) peak cladding temperature (PCT), vessel pressure, and water level for GNF3 are provided in Figures 6.3-79, 6.3-80, and 6.3-81. The PCT, vessel pressure, and water level at the most limiting break for GNF3 are provided in Figures 6.3-82, 6.3-83, and 6.3-84.

6.3.3.7.4 TRACG-LOCA Statistical Analyses

Based on the break spectra calculations, potentially limiting breaks were chosen for statistical analysis in Reference 42. The results of the statistical analyses are shown in Table 6-3.4, with the overall maximum peak cladding temperature, maximum local oxidation (MLO), and core wide oxidation (CWO) for GE14 and GNF3 fuel types.

6.3.3.7.5 Compliance Evaluations

The licensing basis PCT, maximum local fuel cladding oxidation (MLO), and total fraction of fuel cladding oxidized in the core (CWO) for GE14 and GNF3 are determined based on the results from the statistical analyses. The licensing basis PCT, MLO and CWO values are identified in Table 6.3-4.

6.3.3.7.6 Operating Mode Considerations

The ECCS performance (Reference 42) was also evaluated for the following operating mode considerations:

a. Maximum Extended Operating Domain (MEOD) - The MEOD and Maximum Extended Load Line Limit Analysis (MELLLA) provide an expanded operating rod line and an increased core flow range operating domain as shown in Figure 4.4-3.

b. Partial Feedwater Heating (PFH) - The Feedwater Heaters Out-of-Service (FWHOOS) and Final Feedwater Temperature Reduction (FFWTR) mode of the PFH mode of operation (References 6 and 7).

c. Single Loop Operation (SLO) - SLO is permitted when operation is below 66.1% of rated power with recirculation pump speed limited to 75% (References 12 and 14).

d. Out-of-Service Equipment - The Fermi-2 Technical Specifications allows the turbine bypass, moisture separator reheater and several SRVs to be inoperable without requiring a plant shutdown. The unavailability of the turbine bypass and moisture separator has no impact on the results of the ECCS analysis because no credit for these systems has been taken in the ECCS evaluation. The availability of SRVs does not impact the calculated licensing basis PCT results since the limiting break events produce only a mild pressurization during the early time period of the event.

6.3.3.8 Loss-of-Coolant Accident Analysis Conclusions

Having shown compliance with the applicable acceptance criteria of Subsection 6.3.3.2, it is concluded that the ECCS will perform its function in an acceptable manner and meet all of the 10 CFR 50, Section 50.46 acceptance criteria.

6.3.3.9 Thermal Shock Considerations

The ECCS pumps starting at some time after the accident are at ambient (greater than 40°F) and could be heated rapidly as they draw their suctions from the suppression pool.

The HPCI pump and piping system considers a rapid rise in suction temperature from ambient (greater than 40°F) to the maximum operating temperature. The suction is normally from the condensate storage tank (less than 100°F), but can be switched to the suppression pool. If the reactor is not depressurized, the suppression pool temperature rises slowly, providing ample time for the operator to either depressurize and use the LPCI and/or core spray, or to cool the suppression pool with the containment cooling subsystem of the RHR system.

The design of the ECCS pumps (except HPCI), therefore, considers the differences in the rate of expansion between stationary and rotating parts in order to ensure operability during the transients (sudden change in water temperature from 40° to 170°F).

The piping design similarly considers this thermal shock. The steam line in the HPCI turbine is kept warm since it is normally open from the reactor with a drain pot at the turbine end of the line. A design requirement for the turbine itself is for rapid start, i.e., admission of hot steam to a cold turbine. The turbine vendor has considered the possible thermal shock effects in his design. The turbine exhaust increases rapidly from ambient (greater than 40°F) to operating (300°F) temperature, which is considered in both turbine and piping design.

The output of these ECCS subsystems into the reactor introduces relatively cold water into a hot RPV, and thermal shock is considered in the design of the reactor vessel, its nozzles, and the feedwater lines. The LPCI discharges via the hot recirculation line, so this thermal shock is also considered in the recirculation system piping design.

Section 5.2 contains a summary of results of the cold water injection thermal stress analyses.

6.3.4 Inspection and Testing

Each active component of the ECCS required to operate in a DBA is designed to be operable for test purposes during normal operation of the nuclear steam supply system (NSSS).

Regular tests are performed on the system to verify operability. If a test shows some element of the system to be inoperative, repairs are made to return the system to fully operative status. A failure of the system occurring between tests may have serious consequences, depending on whether or not a need to function occurs before the next test is performed. There is, therefore, a direct relationship between the system unreliability, the rate of occurrence of system failures from all causes, and the testing interval for the system.

It has been shown that the test frequency as well as the failure rate affect system reliability. There are practical limits on test frequency, such as the possibility of wearing out system components with too much testing. The test frequency outlined in the Technical Specifications is based upon these considerations.

The HPCI system, ADS, and core spray system have no normal process uses, and therefore are tested periodically to provide assurance that the ECCS will operate to effectively cool the reactor core in an accident. The four LPCI pumps may be placed in use as part of the RHR system and, if so, their status is known from normal process uses. However, the LPCI pumps should be tested no less frequently than the rest of the ECCS. Other parts of the LPCI, such as the two testable check valves inside the primary containment drywell and the four shutoff valves outside the drywell, are intended for use only in an accident, so they are also tested periodically.

Preoperational tests of the ECCS were conducted during the final stages of plant construction prior to initial startup. These tests ensured the proper functioning of all controls and instrumentation, pumps, piping, and valves. System reference characteristics such as pressure differentials and flow rates were documented during the preoperational tests and will be used as base points for measurements obtained in the subsequent operational tests.

During plant operations, the pumps, valves, piping, instrumentation, wiring, and other components outside the primary containment can be visually inspected at any time. Components inside the primary containment can be inspected when the drywell is open for access. When the RPV is open, for refueling or other purposes, the spargers and other internals can be inspected. The testing frequencies of most components of the ECCS are correlated with the testing frequencies of the associated controls and instrumentation. When a pump or valve control is tested, the operability of the pump or valve and the associated instrumentation is also tested by the same action.

When the system is tested, the operation of most of the components is indicated in the main control room. There are exceptions that require local observation at the component and may require special tests for which there are special provisions and methods.

Pressure-operated relief valves may leak after operation and it is not advisable to overpressurize the system for test, so relief valves are removed as scheduled at refueling outages for bench tests and setting adjustments. Bench tests of automatic depressurization valves are discussed in Subsection 5.2.2.

A pressure-operated control valve such as the one upstream of the HPCI system barometric condenser is functionally tested and adjusted in place, in accordance with the valve manufacturer's manual and the system specification for pressure setting. A test pressure connection is provided to check and adjust the setting.

Reverse flow and excess flow check valves in the ECCS are tested periodically in accordance with the Technical Specifications and the Inservice Testing Program.

Test lines are provided between pairs of containment isolation valves in the ECCS to measure leakage when the containment is pressurized for tests. The test line is also used to pressurize between the closed valves to identify which one is leaking. Allowable valve leakage is in accordance with Section 6.2 and the Technical Specifications.

Allowable valve seat leakage during shop hydrostatic tests for nuclear Class 1, 2, and 3 gate, globe, and ball valves associated with these systems is 2 cm^3/hr/in. of seat diameter during hydrostatic test at design pressure. Leakage for check and stop- check valves is 10 cm^3/hr/in. diameter of valve seat at the design differential pressure across the valve. Valve packing leakage during the hydrostatic test is specified as "no visible leakage."

Pumps for the ECCS are equipped with face-type mechanical shaft seals.

A design flow functional test of the HPCI system up to the normally closed pump discharge valve is performed during normal plant operation by pumping water from the condensate storage tank and back through the full-flow test return line. The HPCI system turbine pump is driven at its rated output by steam from the reactor. The suction valves from the suppression pool and discharge valves to the reactor feedwater line remain closed.

The HPCI system test conditions are tabulated on the HPCI system process diagram, Figures 6.3-1 through 6.3-5. If an initiation signal occurs while the HPCI system is being tested, the system returns to the automatic startup mode and supplies water to the reactor.

The HPCI may be tested at full flow with condensate at any time except when the reactor vessel water level is low, the condensate level in the condensate storage tank is below the reserve level, or the valves from the suppression pool to the pump are open.

During the HPCI flow test, the minimum-flow bypass valve opens/closes as required per the logic. The turbine steam valves and the flow test valves to the condensate storage tank are opened to support the HPCI flow test.

To ensure proper operation of the valves when pumping from the suppression pool, the HPCI suction valve auto transfer test is performed to meet Technical Specification requirements. Credit is taken for the RHR and CS testing from the suppression pool as an indication of strainer performance/degradation.

The RHR, CS and HPCI suppression pool suction strainers are inspected periodically in accordance with the plant preventive maintenance program.

Each loop of the core spray systems may be tested during reactor operation. The test conditions are tabulated on the core spray system process diagram, Figures 6.3-7 through 6.3-11. The normal system test does not inject cold water into the reactor because the testable check valve is held closed by the reactor pressure which is higher than core spray pump pressure. To test the injection portion of the system, using demineralized water, the reactor must be shut down and depressurized. This prevents unnecessary thermal stresses.

To test the core spray pumps at rated flow, the pump suction valve from the suppression pool is open, the pump is started using the remote manual switches in the main control room and the test bypass valve is opened to the suppression pool. Proper operation is determined by observing the instruments in the main control room. The core spray system outside the drywell is checked for leaks.

The two motor-operated injection valves outside the drywell and the air-operated testable check valve inside the drywell are tested as described in the Fermi 2 Inservice Testing Program.

If an initiation signal occurs during the test, the core spray system is signaled to start and the system returns to the automatic startup mode and is ready to deliver water to the reactor.

Similarly, LPCI pumps and valves are tested periodically during reactor operations. With the injection valves closed and the return line open to the suppression pool, full-flow pumping capability is demonstrated. The injection valves are tested, and the testable check valves are operated, as described previously for the core spray valves. The system test conditions during reactor shutdown are shown on the RHR/LPCI system process diagram, Figures 6.3-14 through 6.3-16. The portion of the LPCI outside the drywell is inspected for leaks during tests. Controls and instrumentation are tested as described in Section 7.3.

On receipt of an LPCI initiation signal during tests, the valves in the test bypass lines and in the shutdown cooling system are closed automatically to ensure that the LPCI pump discharge is routed properly to the reactor vessel.

Detailed specifications for ECCS component testing are contained in Chapter 14 and the Technical Specifications.

The valves performing an isolation function between high-pressure and low-pressure portions of systems connected to the RCS are tested in accordance with the Technical Specifications.

Table 6.3-9 lists the valves that perform an isolation function between high-pressure and low-pressure portions of systems connected to the RCS. These pressure isolation valves meet the requirements of the ASME Code Section XI, Pump and Valve Testing Program, and are categorized as A or AC. The testing program for the valves, which is referenced in the Technical Specifications, consists of the following methods:

a. Exercise the valve and verify the valve position during refueling and after maintenance before the return to service in accordance with IWV-3300 or IWV-3522(b)

b. Exercise the valve (full stroke) for operability during the cold-shutdown mode as time permits, but not more frequently than once every 3 months

c. Measure the full-stroke time (not for check valves)

d. Leak test the valve seat before reaching power operation following refueling and after valve maintenance before the return to service.

These valves will not be routinely exercised every 3 months during plant operation as required by IWV-3410 because of the following.

a. Such tests remove one of the two barriers protecting the low-pressure portion of the ECCSs

b. The operators on testable check valves cannot overcome the force on the valve with reactor pressure on one side.

Instead, the valves will be exercised during cold-shutdown periods as time permits (but not more frequently than once every 3 months). If there is excessive leakage through the normally closed gate and check valves, the operator will be alerted by the high pressure alarm indicated in Table 6.3-10. The operator will then be procedurally required to close the normally open gate valve from the control room to effect isolation.

6.3.5 Instrumentation Requirements

Design details and logic of the instrumentation for the ECCS are discussed in Section 7.3.

6.3.5.1 High Pressure Coolant Injection Actuation Instrumentation

The HPCI is automatically actuated by the following sensed variables: (1) RPV low water level; or, (2) drywell high pressure.

In addition, the HPCI can be manually actuated from the main control room.

6.3.5.2 Automatic Depressurization System Actuation Instrumentation

The ADS is automatically actuated when the RPV low water level is coincident with drywell high pressure. A time delay is incorporated as discussed in Chapter 7. In addition, two core spray pumps or an RHR pump must be running. Each ADS valve can be manually actuated from the main control room.

6.3.5.3 Core Spray Actuation Instrumentation

The core spray is automatically actuated by the RPV low water level or drywell high pressure. In addition, the core spray can be manually actuated from the main control room.

6.3.5.4 Low Pressure Coolant Injection Actuation Instrumentation

The LPCI is automatically actuated by the RPV low water level or drywell high pressure. In addition, the LPCI can be manually actuated from the main control room.

Emergency Procedures contain adequate caution to deter the operator from premature LPCI flow diversion. The Emergency Procedures caution the operator against diversion unless adequate core cooling is assured. The containment cooling modes of the RHR are secondary to core cooling requirements except in those instances outside the design envelope involving multiple failures, for which maintenance of containment integrity is required to minimize risk to the environment.

TABLE 6.3-1 SHUTDOWN COOLING AND EMERGENCY CORE COOLING SYSTEM OPERATION

Accident or condition	Required Operation	RHR or ECCS Subsystems and Components Used	Redundancy Provided Within System	Backup System(s)
Shutdown Cooling	For a normal shutdown and cooldown, the main condenser is used to condense decay-heat-generated steam until the condenser vacuum is lost. Makeup water is provided as for condenser isolation. When the condenser is no longer effective, primary system cooling is continued by taking water from one of the recirculation loops, through the RHR heat exchangers, and back to the recirculation loop using the RHR pumps. Should the reactor be isolated from the condenser by operation of the isolation valve (not a normal operation) steam is first dumped to the suppression pool rather than to the condenser (below).	Main condenser RHR heat exchangers, RHR main pumps	Two RHR heat exchangers (one heat exchanger sufficient) Four RHR pumps (two pumps sufficient)	RHR cooling subsystem backs up the main condenser used for shutdown cooling
Isolation of condenser (occurs when a reactor scram is accompanied by containment isolation)	Upon the closing of the main steam line valve following a scram, automatic operation of relief valves causes steam to be dumped to the suppression pool, the RHR removes heat from the pool. The single RCIC steam-driven pump takes water from condensate storage and discharges to the feedwater line. Signal: low reactor vessel water level.	Relief valves RHR heat exchangers RCIC pump Condensate (reserve storage)	Total of 15 safety/relief valves available (nine sufficient) Two RHR heat exchangers (one sufficient)	1. RCIC[a] 2. HPCI[a] 3. Control rod drive water systema 4. Core spray and LPCI[a]
Small leaks (accident condition)	First Level Feedwater system and control rod drive system can provide some makeup water.			Second level HPCI and/or RCIC
	Second Level The single HPCI steam-driven pump takes water from condensate storage and discharges to a feedwater line. Signal: low reactor vessel water level or high drywell pressure. The decay-heat-generated steam flows to the HPCI turbine and is exhausted to the suppression pool.	HPCI steam-driven pump, station battery (no ac required, 5000gpm) Five safety/relief valves	RCIC pump (600gpm) Water can also come from suppression pool Manual actuation of any of 15 safety/relief valves	Third level
	Third Level Automatic depressurization system vents steam to the suppression pool. With decreased pressure LPCI and core spray systems can provide water signals: low reactor vessel level and high drywell pressure and core spray or RHR pump running.	Three of four pumps of LPCI Two loops of core spray system (alternate) Standby ac power supply		At low pressure (RV approximately 300 psi) both LPCI and core spray can operate. SRVs
Large leaks (accident condition)	Core spray system pumps water from the suppression pool to core. Signal: low reactor vessel water level or high drywell pressure.	Pumps with electric motors, spray sparger, standby ac bus; different for each spray loop (6350 gpm per core spray system and 10,000 gpm per LPCI/RHR pump)	Two independent core spray systems standby ac bus available	LPCI
	LPCI operates. Three of the four RHR main pumps take water from the suppression pool and delivers it to a recirculation loop. Signal: low reactor vessel level or high drywell pressure.	Pumps and motors. Power from standby ac bus (30,000 gpm for 3 LPCI pumps plus 12,700 gpm for two core spray systems)	Three of the four RHR pumps required. All have ac standby as backup power source (four pumps are signaled to start)	Core spray

[a] Systems used for reactor water inventory control.

TABLE 6.3-2 MATERIALS FOR THE PRINCIPAL EMERGENCY CORE COOLING SYSTEM COMPONENTS

Item	Supplier	Impeller	Casing	Shaft
LPCI pump	Byron Jackson	Martensite SS	Carbon steel	Austenite SS
Core spray pump	Byron Jackson	Martensite SS	Carbon steel	Austenite SS
HPCI pump	Byron Jackson	Martensite SS	Carbon steel	Martensite SS
HPCI turbine	Terry	Low-alloy steel	Carbon steel	Low-alloy steel

TABLE 6.3-3 HAS BEEN INTENTIONALLY DELETED

TABLE 6.3-4 SUMMARY OF RESULTS OF LOSS-OF-COOLANT ACCIDENT ANALYSIS

	Parameters	Results	Results	Acceptance Criteria
1.	Fuel Type	GE14 Fuel	GNF3 Fuel	
2.	Limiting Break	Recirculation Suction Small Break	Recirculation Suction Small Break	
3.	Limiting Failure	Division II DC Power (Battery)	Division II DC Power (Battery)	
4.	Peak Cladding Temperature (Licensing Basis)	< 1980 °F	< 2150 °F	≤ 2200 °F
5.	Maximum Local Oxidation	< 6.0 %	< 9.5 %	≤ 13 %[a]
6.	Core-Wide Metal-Water Reaction	< 0.02 %	< 0.02 %	≤ 1.0 %
7.	Coolable Geometry	Items 4 and 5	Items 4 and 5	PCT ≤ 2200 °F and Maximum Local Oxidation ≤ 13 %[a]
8.	Long Term Cooling	Core flooded above top of active fuel	Core flooded above top of active fuel	Core temperature acceptably low and long-term decay heat removed

[a] The MLO calculated by TRACG-LOCA is limited to 13% to ensure the 10CFR50.46 limit of 17% is satisfied.

TABLE 6.3-5 EMERGENCY CORE COOLING SYSTEM SINGLE - FAILURE EVALUATIONS[a]

Assumed Failure[b]	Suction Break Systems Remaining[c,d]
LPCI valve	All ADS, 2 core spray, HPCI
Divisional diesel generators (EDG)	All ADS, 1 core spray, HPCI, 2 LPCI
Battery (Division I)	HPCI, 2 LPCI, 1 core spray
Battery (Division II)	All ADS, 1 core spray, 2 LPCI
HPCI	All ADS, 4 LPCI, 2 core spray
One ADS valve	All ADS minus one, 2 core spray, HPCI, 4 LPCI

[a] This table shows the single active failures considered in the ECCS performance evaluation.

[b] Other postulated failures are not specifically considered because they all result in at least as much ECCS capacity as one of the above assumed failures.

[c] Systems remaining, as indentified in this table, are with concurrent loss-of-offsite power and are applicable to all non-ECCS line breaks. For a LOCA from an ECCS line break, the systems remaining are those listed, less the ECCS in which the break is assumed.

[d] Analyses performed with one ADS valve assumed unavailable in addition to the single failure (Table 6.3-6).

6.4 HABITABILITY SYSTEMS

Control center habitability systems ensure that the main control room can be occupied under normal, accident, and postaccident conditions. Habitability systems include the systems, components, facilities, supplies, and equipment required for safe habitation of the main control room.

6.4.1 Habitability Systems Design Bases

The bases for the functional design of the habitability systems are given below. The bases result in systems that ensure compliance with General Design Criterion 19, 10 CFR 50, Appendix A. Under any design-basis conditions, the environment within the main control room is safe, with personnel protected from radiation, fire, toxic gases, and noxious substances.

6.4.1.1 Radiation Shielding and Air Filtration

The total radiation dose to main control room personnel is the dose received while occupying the control center. Doses received while in the main control room are due to the radiation that penetrates the biological shielding and to the isotopes that enter the control center through the ventilation system or through inleakage. Source terms and individual contributions to total doses are given in Chapter 15, along with a further discussion of the assumptions, the physical models, and the methods of analysis.

Sufficient radiation shielding and air filtration are provided to ensure that radiation exposures of main control room personnel do not exceed 5 rem whole-body, or its equivalent to any part of the body, for the duration of a design-basis accident (DBA). For the DBA-LOCA and the Fuel Handling Accident, the dose to main control room personnel does not exceed 5 rem TEDE.

Following is a list of principal assumptions used in determining the control center personnel doses:

a. The plant personnel occupying the control center at the time the LOCA occurs remain in the control center for a period of 24 hr after that occurrence

b. Control center personnel shift changes occur twice per day, starting 24 hr after the occurrence

c. The occupancy factor is 1 for 0-1 day, 0.6 for 1-4 days, and 0.4 for 4-30 days

d. The breathing rates of the main control room personnel are 3.47×10^{-4} m^3/sec as specified by the International Committee on Radiation Protection (ICRP) (Reference 1)

e. In the event of a LOCA, the control center mode in operation is automatically shut down and the emergency makeup air filtration system is placed in operation.

f. When emergency makeup air is supplied to the main control room, the rate of introduction of outside air is 1800 cfm maximum

g. Radiation monitors in the reactor/auxiliary (i.e., fuel pool ventilation exhaust ducting) building detect airborne radiation concentrations above those specified in the Technical Specifications and cause the control center air conditioning system to automatically switch to its emergency mode of operation

h. Filter trains are provided for emergency makeup air as well as recirculated air. The filter trains are located outside the main control room

i. Charcoal filters (described in Table 9.4-1) have a assigned decontamination efficiency of 95 percent for removal of all forms of iodine; 99 percent efficiency could be claimed for the recirculation charcoal adsorber according to Regulatory Guide 1.52, but only 95 percent efficiency is claimed to avoid the more frequent testing and replacement of charcoal

j. Control center filter banks are in service throughout the course of the LOCA, filtering outside air makeup l800 cfm maximum and recirculated air 1200 cfm for a total filtered airflow of 3000 cfm

k. The mechanisms for introduction of radioisotopes into the main control room are

    1. Intake through filter trains during periods of air makeup

    2. Infiltration of outside air or exchange of inside-outside air due to opening and closing of main control room doors at shift-change times. The total quantity of unfiltered inleakage is not more than 173 cfm.

l. A radiation monitor in the control center air intake ducting, before filtration by the emergency makeup air intake and recirculation filter trains, provides radiation level information to the operators.

The assumed atmospheric dispersion factors and radioactive source terms used for each accident analysis are listed in Chapter 15.

Table 15.6.5-4 presents the doses to the control room operator from occupancy of the control room for the 30-day course of a LOCA. Table 12.1-14 presents the direct doses through the concrete walls and ceilings for the 30-day course of a LOCA as experienced by main control room personnel.

6.4.1.2 Physical Environment

Systems and controls are provided to ensure that the environment in the control center is safe and comfortable. The thermal environmental conditions are within the comfort range specified in American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE) Comfort Standard 55-66 (Reference 2), with a nominal dry bulb temperature of 75°F and a relative humidity not exceeding 60 percent, except for the mechanical equipment room (MER) and SGTS room which are discussed in Subsection 9.4.1.1. The emergency operating modes of the air conditioning system are designed to meet single-failure criteria and ensure l00 percent backup for the entire system, with the exception of the common ductwork and filters. The smoke/Halon dampers to the relay room, cable spreading room or computer room will close due to a single active failure in the Halon fire protection system.

Sufficient time is available to take manual action to reestablish airflow. Ventilation capability is provided by the air conditioning system in both the normal mode and the emergency air makeup mode of operation. Main control room environmental conditions, including radiation levels, are monitored. The air volume of the control center envelope is approximately 252,731 ft^3, which is sufficient to allow closing of the makeup air intake for a period of more than 28 days without exceeding permissible carbon dioxide concentrations when three workers occupy the main control room.

6.4.1.3 Fire Protection

Noncombustible and flame-retardant materials are used where practical, and equipment, electrical components, and control instrumentation are designed to minimize fire hazards. Fire and smoke detection and alarm systems are provided as required. Applicable NFPA codes and standards used for guidance are listed in Subsection 9.5.1.

Portable fire extinguishers are located in the main control room. The equipment is adequate to control fires that could originate inside the main control room. The air conditioning system has a purging capability to expedite the discharge of smoke from the main control room.

The control center can be isolated to prevent admission of smoke or noxious fumes resulting from a postulated fire outside the main control room. The control center is designed to be protected against exterior fire exposure by the 3-hr-rated walls. Personnel are not harmed and safety-related equipment is not damaged by the proper use of the portable fire extinguishers in the main control room.

Personnel training ensures that plant operators are cognizant of the proper use of fire extinguishers and know the emergency procedures to be taken in the event of fire.

6.4.1.4 Personnel Protection and First Aid

The control center contains emergency safety breathing apparatus for personnel use, as well as first aid supplies for immediate emergency use.

6.4.1.5 Utilities and Sanitation

Normal communications, lighting, kitchen, and sanitary facilities are provided in the control center to ensure habitability. The onsite power system supplies power for the main control room habitability systems when offsite power is not available.

6.4.2 System Design

6.4.2.1 Radiation Shielding

Accessibility to the main control room during normal operation is unlimited, with sufficient shielding provided to ensure that normal radiation levels are below 0.3 mrem/hr. In addition to its function during normal operation, the main control room shielding reduces direct radiation doses from the LOCA to levels that permit controlled occupancy by operating personnel following that accident.

Control center shielding is ordinary concrete. The actual floor of the main control room is 1 ft thick but, as a result of other structures, it has an effective thickness of 8 ft 4 in.; the outside (north) wall is 2 ft thick; the roof of the main control room is 5 ft thick over one portion and 1 ft thick over the remaining portion, with the total effective concrete thickness over the main control room varying, however, between 6 ft 6 in. and 10 ft 6 in.; the wall facing the reactor is 4 ft 4 in. thick, with an additional 7 ft of concrete biological shielding surrounding the reactor.

Section 12.1 includes a layout drawing of the control center, as well as a scaled isometric view of the main control room and its associated shielding. Section 12.1 also presents detailed descriptions of shield thicknesses, justifications for the thicknesses of shielding provided, descriptions of the geometric and physical models used, and information relative to the assumptions and data used in the design.

6.4.2.2 Radiation Monitoring System

The functional design of the radiation monitoring system (RMS) provides adequate and reliable radiological data for the evaluation of habitability of the main control room.

The outputs from area and process radiation monitors associated with main control room habitability are displayed, alarmed, and recorded, if necessary, in the main control room.

The area radiation monitor provides measurements of dose rates in the main control room. Location and the design criteria used in their selection are described in Subsection 12.1.4 along with operational characteristics, including type of detector, sensitivity, range, method of calibration, and setpoints.

Process monitors continuously monitor the levels of radioactivity in main control room ventilation systems. Inlet makeup air is monitored upstream of the filters in the emergency air makeup and recirculation systems. Airborne radioactivity monitoring is described in Subsection 12.2.4, which gives the locations and design criteria of the fixed instruments, as well as the criteria used to determine the necessity for and the location of the equipment. That section also provides information on the operational characteristics of the monitors, the detector type, the sensitivities, the ranges, and setpoints and their bases.

Personnel dosimetry under normal and under accident conditions is described in detail in Subsection 12.3.4.

6.4.2.3 Air Conditioning System

6.4.2.3.1 System Description

The control center air conditioning system (CCACS) is described in Section 9.4, which includes system, water control, and airflow diagrams.

The air conditioning system provides year-round comfort and safety from airborne radioactivity for control center personnel. The individual components of the Category I system are designed for an operational life of 40 years, accounting for corrosion and material fatigue. Electrical power for motor operation is supplied from the reactor building engineered safety feature (ESF) buses, maintaining separation and redundancy, and common-mode failure is prevented by physical separation.

The system is capable of maintaining the control center at a nominal temperature of 75°F and at a maximum relative humidity of 60 percent during normal operation, except for the mechanical equipment room (MER) and SGTS room which are discussed in Subsection 9.4.1.1. Noise level in the main control room, when measured in accordance with Appendix E1 of NUREG-0700, Guidelines for Control Room Design Reviews, does not exceed 65 dB(A). The noise level in the washroom and kitchen, on the same measurement basis, also does not exceed 65 dB(A). Conditioned air is supplied directly to the main control room, while the kitchen and washroom are conditioned by exhausting air that is drawn from the main control room.

There are four operating modes for the CCACS as follows:

a. Normal mode: A minimum of 2769 cfm outside air mixes with recirculated ventilating air, bypassing the emergency makeup and recirculation filters

b. Purge mode: 100 percent outside air is circulated through the control center and exhausted to the atmosphere to purge any smoke or fumes within the control center

c. Recirculation mode: A maximum of 1800 cfm outside air is filtered and mixes with 1200 cfm recirculated air; it is filtered again and mixed with recirculating ventilation air to prevent intrusion and to provide continuous removal of contaminants during a radiation-release emergency

d. Chlorine mode: All outside intakes are closed to prevent ingress during a chlorine-release emergency. Ventilating air is recirculated with 1200 cfm passing through the emergency recirculation filter.

Normal Operation Mode

During normal operation, the control center air conditioning system serves the main control room and several other areas. The supply airflow to the control center is 31,510 cfm and the return airflow is 30,440 cfm. Normal makeup air is passed through an electronic air cleaner and a roll-type filter.

The master selector switches in the main control room activate all components in the Division I or Division II system. The mixture of return and outside air is filtered, then cooled, heated, and dehumidified, as required, by a multizone air conditioning supply unit. Each zone thermostat modulates zone mixing dampers to obtain the supply-air temperature necessary to satisfy the zone cooling or heating requirements. Positive pressure is maintained in the control center by throttling the exhaust air-modulating damper. Exhaust fans are provided in the kitchen and washrooms.

Manual override is provided such that an operator in the main control room is able to select the purge mode, which opens the outside air dampers and closes the return air dampers.

Recirculation Mode

Upon an automatic isolation signal from the reactor protection system or the RMS, the CCACS is automatically transferred to the recirculation mode. Under emergency conditions, airflow rate into the control center is 31,510 cfm including 1800 cfm maximum makeup air to offset supply air lost through room leakage (maintaining the control center positive pressure of 1/4 ± 1/8-in. water gage). The kitchen and washroom individual exhaust ducts each contain dual isolation valves that are closed under emergency conditions.

During an emergency, the control center is isolated from all other areas of the plant. All air supplies to the standby gas treatment rooms and the normal operation of air intake and exhaust ducts are dampered closed.

The multizone air-handling unit, the chiller, chilled water pump and the return air fan continue to operate as during normal operation. The return air damper assumes a full-open position. Cooling water is supplied from the emergency equipment cooling water (EECW) system. The fan in the mechanical equipment room fan-coil cooling unit is also energized under room thermostat control. Chilled- water flow through the cooling coil of the unit continues unimpeded as during normal operation.

The emergency recirculation air fan is energized and the dampers on the emergency intake air duct are opened and the kitchen and washrooms exhaust fans are deactivated.

The emergency recirculation air filter train consists of a prefilter, a high-efficiency particulate air (HEPA) filter, a charcoal filter, another HEPA filter, and redundant fans. The emergency makeup air filter train consists of a filtering-type demister, two electric heaters, a HEPA filter, a charcoal filter, and another HEPA filter. Detailed descriptions of the filter trains are presented in Subsection 9.4.1, with summary descriptions of the train components given below:

a. The demister removes entrained water droplets and serves as a prefilter for the downstream HEPA filter. The demister meets design requirements specified in Savannah River Laboratory Report DP-812

b. The electric heater reduces the relative humidity of influent air under worst conditions to 70 percent or less

c. The HEPA filters have a design DOP filtration efficiency of 99.97 percent for particles 0.3 μm in diameter or larger. The elements meet the requirements of ANSI N509-1980. They are UL-approved fire resistant and suitable for service under the temperatures and mass peak loadings expected. The filters are installed and field tested such that a 95 percent decontamination efficiency can be assumed for removal of particulate iodine.

d. The charcoal adsorber in the emergency makeup air filter train is a deep-bed unit, as is that in the recirculation air filter train. These units contain impregnated activated carbon. Representative samples of the carbon are lab tested prior to installation and periodically while in service to demonstrate that the carbon is 99 percent efficient in removing methyl iodide. The carbon is installed and field tested for by-pass leakage such that a 95 percent decontamination efficiency can be assumed for removal of all forms of gaseous iodine.

e. Downstream HEPA filters are identical to the upstream HEPA units and serve to trap charcoal fines and decay daughters entrained in the air stream.

The CCACS design provides redundant alarms for main control room high/low pressure to ensure that a positive pressure in the main control room is maintained at all times. Additionally, alarms are provided in the control room to alert operators for large pressure drops across the CCHVAC emergency make-up and recirculation filters indicating the filter airflow is degrading.

Chlorine Mode

In the event that chlorine gas is detected, control room personnel will place CCHVAC in the chlorine mode, whereupon the normal intake and discharge isolation dampers would close and the emergency intake isolation dampers would remain closed; all other dampers and equipment would function as described in the recirculation mode. In this mode, airflow is circulated throughout the control center at the emergency flow rate, but the outside air intake and exhaust ducts are closed by dampers.

For all operating modes, damper position indications in the main control room allow continuous monitoring of the system performance and confirm all remote manual control actions taken.

Purge Mode

The air conditioning system has a smoke purge mode. In this mode, fresh air is brought into the main control room and no air is recirculated. This mode is initiated automatically when the gaseous fire suppression system actuates, or it can be initiated manually by the operator.

Ionization-type smoke detectors provide an alarm indicating conditions that require isolation of the control center.

For heat and smoke removal from the control center complex in the event of a fire in any of the air-conditioning zones, the fire- detection system will activate alarms in the control center. The control room operator can remote manually initiate the purge mode.

6.4.2.3.2 Control Center Air Intakes

The control center air conditioning system consists of two 100 percent-capacity air-conditioning supply units, an air- distribution system, and an emergency filtration system. The control center is heated, cooled, and pressurized by a recirculating air system. Figures 9.4-1 and 9.4-2 show the ventilating air circulating flow path, rates, and dampers and their positions for the different operating modes. The emergency filtration system processes control center recirculated air and makeup air through charcoal filters if the control center is subjected to airborne radioactive contamination. This system consists of two separate emergency air intakes. The intake that draws from the area having the lowest level of contamination is manually selected for operation.

The physical orientation between the normal and emergency intake openings and the potential source points of radiation are described in Section 2.3.4.2.4.

Each emergency intake has two parallel paths containing redundant dampers. One path in each intake contains two Division I isolation dampers and one Division I modulating damper, which maintains the control center at approximately 1/4 ± 1/8-in. water gage positive pressure in the recirculation mode. The other path contains identical dampers powered by Division II.

For normal operation, a separate normal intake supply is used, allowing the makeup and emergency filters to remain on standby with full filtering capacity available for emergencies. Two air- operated isolation dampers are provided on the normal air intake duct and on the system exhaust vent. One damper in each duct is designated as a Division I damper; the other damper in each duct is designated as a Division II damper. Each damper will close within 5 sec after an isolation signal is initiated and is designed to achieve "bubble-tight" full shutoff.

Two return air fans are provided and each fan is sized to return 95 percent of the total air supplied to the control center. One fan is for Division I and the other for Division II. In the normal mode, the exhaust air damper is modulated to maintain approximately 1/4 ± 1/8 in. of water difference between the lower of the outside ambient pressure or the turbine building pressure and the control center pressure when the system is in the normal operating mode.

6.4.2.4 Fire Protection System

The fire protection system is described in detail in Subsection 9.5.l. Portable fire extinguishers are provided at strategic locations in the main control room. High-sensitivity, ionization-type detectors for combustion products are located in the ceiling space. The fire protection system and specific construction materials are identified in the fire hazards analysis referenced in Subsection 9.5.1.

6.4.2.5 Personnel Protective Equipment and First Aid and Emergency Supplies

Operator respiratory protection in the main control room consists of a mask-hose apparatus connected to a bottled air supply. The supply is 3600 ft^3, which is adequate for 30 manhours of heavy work, with a 20 percent contingency. The size of the supply is based on the data supplied in Reference 3. This handbook indicates that an adult man performing heavy work requires 39.3 to 45.2 liters of air per minute. The size of the supply is based on the larger of these figures.

The supply consists of a rack outside the main control room containing 12 air cylinders (300-ft^3) connected to a manifold. This supply is piped to a five connection manifold in the main control room. Located at the manifold are five individual dual purpose airline/self-contained breathing apparatus (SCBA) respirator units with a length of hose adequate to permit operator movement throughout the main control room area.

The dual purpose airline/SCBA respirator may be attached to either the emergency air system via the manifold, or function independently via the on-board air supply. This provides the operators the capability to move about, and exit the main control room. Two spare bottles per SCBA are also maintained adjacent to the main control room. These units are of the type tested and approved by the Bureau of Mines and by the National Institute for Occupational Safety and Health (NIOSH), and supply fresh air for a period of approximately 20 minutes.

Possible first aid needs are met by a kit in the main control room.

A five-man-day supply of food is stored in the main control center complex and can be used for an emergency. In addition, sufficient potable water is reserved to provide a five-man-day supply during an emergency. Under the conditions that would exist in the event of long-duration accidents, the main control room is accessible for shift changes so that additional food and water can be brought to the main control room.

6.4.2.6 Utilities and Sanitation

The plant communications system is described in Subsection 9.5.2. This diverse system, which includes telephones, portable two-way radios, an intercom system, and a public address system, provides assurance that there is a means of communication between the main control room and plant or offsite areas.

Subsection 9.5.3 contains a description of the normal lighting system and the emergency lighting system. The design criteria and failure analysis ensure that these systems, in conjunction with the power supply system (Section 8.3), will provide adequate lighting for the main control room.

The kitchen area of the main control room contains an electric range, a refrigerator, a water heater, and cooking and eating utensils. The main control room washroom contains toilets, washing facilities, housekeeping supplies, and waste containers.

6.4.3 Design Evaluation

Operating systems that serve to ensure main control room habitability are discussed in detail in the following sections and subsections.

a. Control center air conditioning system - 9.4.l

b. Fire protection system - 9.5.l

c. Communications system - 9.5.2

d. Lighting system - 9.5.3

e. Onsite power systems - 8.3

f. Radiation monitoring systems - 12.1.4 and 12.2.4.

As the referenced sections and subsections state, the systems or portions of systems essential for main control room habitability meet the seismic, the component redundancy, and the power-supply redundancy requirements that ensure satisfactory performance under normal and accident conditions.

Summary evaluations of the designs of the systems that contribute to main control room habitability are provided in the following subsections.

6.4.3.1 Radiation Monitoring System

The design of the radiation monitoring equipment essential for main control room habitability meets all of the functional requirements given in Subsection 6.4.2.2. The monitor locations, types, sensitivities, ranges, and setpoints ensure that necessary information is available to main control room personnel and that those main control room habitability systems, which are actuated automatically, will receive initiation signals.

The portable radiation monitoring equipment applicable to main control room habitability is readily available as required. The equipment is described in Subsection 12.3.2, and personnel dosimetry is discussed in Subsection 12.3.4.

6.4.3.2 Air Conditioning System - Control of Main Control Center Thermal Environment

The CCACS is operated on a continuous basis to maintain a safe and comfortable thermal environment in the main control room. The state of readiness of this system is indicated by the system performance, as reflected in the main control room temperature and relative humidity. With the exception of the common ductwork and filters, the system has 100 percent backup and meets single- failure criteria. The smoke/Halon dampers to the relay room, cable spreading room or computer room will close due to a single active failure in the Halon fire protection system. Sufficient time is available to take manual action to reestablish airflow. The air conditioning system emergency mode and all essential components are designed to Category I requirements.

The air-conditioning functions provided include cooling, heating, humidification, air filtration, forced air circulation, exhaust, and positive pressure control. In normal operation, air filtration is provided by an electronic air cleaner and a fiberglass media roll filter. After the mixture of return and outside air is filtered, it is cooled and heated by the multizone air-handling unit.

The air conditioning system, sized in accordance with ASHRAE recommendations, is designed for an ambient temperature of 95°F dry bulb and 75°F wet bulb during summer operation and -10°F dry bulb for winter operation. The ambient temperature range specified prevails 99 percent, or more, of the total time at the plant location.

The total system flow is 31,510 cfm, of which 11,350 cfm is supplied directly to the main control room. The supply of conditioned air ensures that the thermal environment within the main control room permits habitation under any weather or plant conditions.

6.4.3.3 Air Conditioning System - Control of Main Control Room Airborne Radioactivity

During an emergency, the control center is isolated from all other areas of the plant. All air supply to the standby gas treatment rooms and the normal-operation air intake and exhaust ducts are dampered or valved closed. The multizone air-handling unit and the return air fan continue to operate as during normal operation, with the emergency air-handling system placed in operation by automatic or manual opening of the emergency air intake dampers and energizing the emergency recirculation air fan.

The 1800 cfm maximum emergency outside air required for pressurization and personnel physiology is drawn through the emergency outside air intake filter train. A mixture of filtered outside air and the emergency recirculation air is passed through the emergency recirculation filter train. The kitchen and washroom exhaust air ducts will be closed during emergency operation.

Airborne and fuel pool radioactivity levels in the reactor/ auxiliary building ventilation and exhaust air ducts are monitored. If the activity exceeds acceptable levels, isolation dampers or valves in the control center normal intake and exhaust air ducts and in the air conditioning equipment and standby gas treatment system (SGTS) room air ducts are actuated, placing the control center air conditioning system in an emergency recirculation mode. In this mode, air is brought in through the emergency makeup air filter train (1800 cfm maximum), mixed with 1200 cfm minimum recirculated air, and put through a 3000 cfm recirculation filter train.

Redundant and separate isolation dampers or valves are installed in all ducts of the air conditioning system that affect the isolation of the main control room from other building areas; the emergency intake air duct and the kitchen and washroom exhaust air ducts are also equipped with redundant isolation dampers.

The system design, the isolation capabilities, and the efficiencies of the components used in the emergency filter trains ensure that airborne radioactivity in the main control room does not rise to levels that prohibit habitability.

6.4.3.4 Air Conditioning System - Control of Main Control Room Chemical Environment

Adverse chemical effects on the main control room environment could result from the following three events:

a. A chlorine accident off the plant site

b. A fire outside the main control room

c. A fire inside the main control room

There are shipments of hazardous chemicals by rail and road routes within a 5-mile radius of the plant. The closest transportation line lies about 3.5 miles from the plant. At this distance, a release of a hazardous chemical is not a threat to Fermi 2 control room habitability. In accordance with the provisions of Regulatory Guide 1.78, Revision 1, control center habitability was analyzed for the rupture of a 90-ton chlorine railroad tankcar.

It was determined that the probability of a chlorine railcar accident and a spill resulting in a control room toxic concentration meets the Regulatory Guide criterion for not considering such scenario to be a credible event (Reference 6).

The CCACS ensures that the toxic or noxious substances that might result from one of the above events do not prevent occupancy of the main control room.

Upon manual initiation of chlorine mode, the (100 percent recirculation) chlorine mode of operation of the air conditioning system commences; in this configuration, there is no makeup airflow and approximately 1200 cfm of the main control room airflow is passed through the recirculation air filter train for cleanup.

The safety of main control room operators is further ensured by the provision of self-contained breathing apparatus units in the main control room, as described in Subsection 6.4.2.5. Storage provisions for the breathing apparatus and procedures for use permit operators to don appropriate respirators upon detection of toxic gases or chlorine odors. The emergency plan includes instructions for immediate donning of breathing apparatus on detection of chlorine release, and the training of main control room personnel includes rehearsal and the procedures necessary for rapid utilization of the equipment.

A fire-detection system is provided throughout the control center. The system consists of ionization or photoelectric detectors for alarming the presence of smoke or for actuating the automatic gaseous fire-suppression systems where provided.

In the chlorine mode, introduction of smoke and/or noxious fumes from outside fires into the main control room is prevented; in the unlikely event of a UL Class A fire inside the main control room, the smoke purge system is used to remove the products of the fire from the main control room.

For smoke purging, the normal air conditioning system can be operated on a zero-recirculation basis, with a greatly increased outside air intake. As the zero-recirculation terminology implies, airflow in the control center areas is on a once-through basis.

In summary, the CCACS is highly flexible, providing modes of operation that ensure acceptable air quality.

6.4.3.5 Fire Protection

A description of the fire protection system for the main control room is identified in Subsection 9.5.1.

6.4.3.6 Personnel Protection

Self-contained breathing apparatus is provided for emergency use in the main control room. The apparatus is selected according to the guidelines of ANSI Z88.2 (Reference 4). A respiratory protective program meeting the requirements of Occupational Safety and Health Administration (OSHA) 1910.134 (Reference 5) has been established and will be maintained, thereby ensuring the effectiveness of the provisions for personnel protection.

6.4.3.7 Utilities and Sanitation

Several communications channels are maintained open under all conditions. Most of the communications systems are in routine use. Those systems not frequently used are subjected to periodic maintenance and testing to ensure their state of readiness. The provision of diverse and redundant systems ensures a reliable communications capability.

Lighting is provided in the main control room at all times. The installation of normal and emergency systems, with power-source redundancy, ensures that the main control room is adequately illuminated. The normal lighting system is proven operable during regular operating periods and will continue to operate under most accident conditions; in the event that the normal system is inoperative, the emergency system provides illumination.

Kitchen and sanitary facilities are proven operable under normal conditions and will continue to function under accident conditions.

6.4.4 Testing and Inspection

6.4.4.1 Radiation Monitoring System

Testing and inspection of the RMS ensure that each functional requirement of the system is met. The RMS is tested in conjunction with the CCACS to ensure that the monitors perform the desired functions.

The area and process radiation monitors are readily accessible for testing, inspection, and calibration. The testing of the monitors does not interfere with normal operation of the habitability systems for the main control room. Portable equipment such as air samplers, personnel dosimeters, and other radiation analysis equipment applicable to main control room habitability is tested and inspected periodically as required.

Specific details of the measures taken to ensure the operability of radiation monitoring equipment are given in Subsections 12.1.4, 12.2.4, and 12.3.4.

6.4.4.2 Control Center Air Conditioning System

The CCACS is subjected to those tests and inspections required to ensure its capability to perform its designed functions throughout the lifetime of the plant. As indicated in the preceding subsection, those portions of the system that interact directly with other systems are subjected to testing concurrent with the other systems.

The system and its components are tested in accordance with the codes and standards to which they are designed, and with the tests and inspections specified in Section 9.4, the Technical Specifications, and the Technical Requirements Manual. The compliance of the emergency makeup air and emergency recirculation filter trains and their components with Regulatory Guide 1.52 is described in Subsection A.1.52. Testing of the filter trains and their components involves

a. Predelivery and component qualification tests

b. Onsite preoperational acceptance tests

c. Operational surveillance tests

The quantity of air supplied for pressurization of the control center is determined by performing a duct traverse measurement at the installed test ports in the ductwork. The static pressure differential in the control center complex is measured to verify that a pressure of 1/4 ± 1/8-in. water gage is maintained by the CCACS operating in the emergency mode.

Should a component or material in the CCACS fail to meet the required level of performance, the component or material is replaced. Should the system fail to meet performance standards in any mode of operation, the component(s) adversely affecting the system performance is replaced. The modes of operation considered for the main control room are normal mode, recirculation mode (radiation emergency), chlorine mode (complete isolation), and purge mode (smoke removal with zero recirculation).

6.4.4.3 Main Control Room Fire Protection System

Fire protection for the main control room is ensured by fire extinguishers inside the main control room, fire-detection equipment, the smoke purge capability of the CCACS, and the isolation provisions of that system. Inspection and testing requirements are provided in Subsection 9.5.1.

6.4.4.4 Other Control Center Habitability Systems

Self-contained breathing apparatus is inspected to ensure that pressures are at least equal to those required to supply air for the minimum acceptable breathing period. If cylinder pressure is insufficient, the cylinder is recharged or replaced. Regulators in the air packs are periodically inspected to verify operability; units that do not function properly are repaired or replaced.

The communications and lighting systems are proven operable, in part, by normal use, with backup or emergency facilities tested periodically by individual tests or intentional disabling of the primary system.

Kitchen and sanitation facilities are known to be operable through normal use.

6.4.5 Instrumentation

The individual system design sections of the UFSAR contain descriptions of the instrumentation used for monitoring and actuating those portions of the systems vital to main control room habitability. Design details and logic of the instrumentation are discussed in Chapter 7.

CHAPTER 7: INSTRUMENTATION AND CONTROLS

7.1 INTRODUCTION

7.1.1 Identification and Classification of Safety-Related and Power Generation Systems

7.1.1.1 General

Depending on their function, instrumentation and control systems may be classified as either power generation systems or safety systems. In some cases, portions of a system may have a safety function while other portions of the same system may be classified as power generation. A complete description of the reasoning behind this system of classification can be found in Subsection 1.2.1.

The systems presented in this chapter have been classified under safety design-basis systems, power generation design-basis systems, reactor protection systems (RPS), engineered safety feature (ESF) systems (containment isolation, emergency core cooling system, etc.), safe shutdown systems, other safety and power generation systems, and control systems. Figure 7.1-1 lists the Fermi 2 safety-related instrumentation, control, and supporting systems. Instrumentation and control systems identical to those of nuclear power plants of similar design that have recently received construction permits or operating licenses are identified in Table 7.1-1.

7.1.1.2 Identification of Individual Systems

The RPS instrumentation and control initiates an automatic reactor shutdown (scram) if monitored system variables exceed preestablished limits. This action prevents fuel damage, limits system pressure, and thus restricts the release of radioactive material.

The primary containment and reactor vessel isolation control system (CRVICS) initiates closure of various automatic isolation valves in response to a limiting value of a system variable. The closure of isolation valves enables containment of radioactive materials either inside the reactor pressure vessel (RPV) or inside the primary containment. The system responds to various indications of pipe breaks or radioactive material release.

The emergency core cooling system (ECCS) instrumentation and control provides initiation and control of specific core cooling systems such as the high-pressure coolant injection (HPCI) system, the automatic depressurization system (ADS), the core spray system, and the low-pressure coolant injection (LPCI) system.

The neutron monitoring system (NMS) instrumentation and control uses in-core neutron detectors to monitor core neutron flux. The NMS provides signals to the RPS to shut down the reactor when an overpower condition is detected. High average neutron flux is used as the overpower indicator during power operation. Intermediate range detectors are used as overpower indicators during startup and shutdown. The NMS also provides power level indication during planned normal operation.

The refueling interlocks instrumentation and control serves as a backup to procedural core reactivity control during refueling operations.

The reactor manual control system (RMCS) instrumentation and control allows the operator to manipulate control rods and to determine their positions. Various interlocks are provided in the control circuitry to prevent multiple operator errors or equipment malfunctions from requiring the action of the RPS.

The RPV instrumentation monitors and transmits information concerning key RPV operating variables.

The recirculation flow control system (RFCS) instrumentation and control controls the reactor recirculation pumps and motor-generator sets to vary the coolant flow rate through the core. This system permits either manual or automatic control. The recirculation pump trip (RPT) function of the RFCS is designed to mitigate the effects of an anticipated transient without scram (ATWS) event.

The feedwater system instrumentation and control regulates the feedwater system flow rate so that proper RPV water level is maintained. The feedwater control system uses RPV water level, main steam flow, and feedwater flow signals to regulate feedwater flow. The system is arranged to permit single-element (level only), three-element (level, steam flow, feed flow), or manual operation.

Pressure-regulator and turbine-generator instrumentation and control work together to allow proper generator and reactor response to load-demand changes. The pressure regulator acts to keep nuclear system pressure essentially constant, so that pressure-induced core reactivity changes are controlled. To maintain constant pressure, the pressure regulator adjusts the turbine control valves or turbine bypass valves. The turbine-generator controls regulate turbine speed during startup. If the generator electrical load is lost, the turbine-generator speed-load controls initiate rapid closure of the turbine control valves (coincident with fast opening of the bypass valves) to prevent excessive turbine overspeed.

The process radiation monitor system (PRMS) instrumentation and control for process liquid and gas lines provides control of radioactive material released from the Fermi site. The main steam line radiation monitors detect gross release of fission products from the fuel and isolate the reactor water sample system, trip condenser mechanical vacuum pumps, and trip gland seal exhausters.

The area radiation monitor system (ARMS) instrumentation provides gamma-sensitive detectors throughout the plant. Outputs are recorded on multipoint recorders.

Reactor core isolation cooling (RCIC) system instrumentation and control causes the addition of makeup water to the RPV in the event that the reactor feedwater supply system is lost during plant operation.

Standby liquid control system (SLCS) instrumentation and control provides for manual initiation of a reactivity control system redundant to manual control rod movement which can shut the reactor down from rated power to the cold condition if withdrawn control rods cannot be inserted to achieve reactor shutdown. In addition, SLCS instrumentation and control provides for manual initiation of a pH control system following a LOCA in the event of fuel failure.

Reactor water cleanup (RWCU) system instrumentation and control provides for manual initiation of system equipment to maintain high water purity and reduce concentrations of fission products in the reactor water.

The leak detection system (LDS) instrumentation and control uses various temperature, pressure, and flow sensors to detect, annunciate, and isolate (in certain cases) water and steam leaks in selected reactor systems.

The residual heat removal (RHR) system instrumentation and control provides for manual initiation of cooling to remove the decay and sensible heat from the RPV so that the reactor can be refueled and serviced.

Radwaste system instrumentation and control supports manual processing and disposing of the radioactive process wastes generated during power operation.

The emergency diesel generator (EDG) instrumentation and controls automatically provide ac power to those devices necessary to effect a safe shutdown with subsequent reactor decay heat removal should normal offsite power not be available.

The alternate rod insertion (ARI) function of the control rod drive (CRD) system is designed to mitigate the potential consequences of an ATWS. The ARI equipment is redundant and diverse to the RPS and has its own detection and actuation logic.

The various instrumentation and control system designers and fabricators are identified in Table 7.1-2.

Emergency support facilities, which include an onsite technical support center (TSC), an onsite operational support center (OSC), an onsite emergency operations facility (EOF), an alternate (offsite) EOF, and the Integrated Plant Computer System (IPCS) for data handling and computational capabilities are provided to support operations in the event of an emergency.

7.1.1.3 Classification

7.1.1.3.1 Safety-Related Systems

Safety systems are those systems whose actions are necessary to protect the integrity of radioactive material barriers and/or prevent the release of radioactive material. These systems may be components, groups of components, or groups of systems. A complete list of these systems is shown in Figure 7.1-1.

7.1.1.3.2 Power Generation Systems

Power generation systems are systems whose actions are not required to protect the integrity of radioactive material barriers and/or prevent the release of radioactive material. The instrumentation and control portions of these systems may, by their actions, prevent the plant from exceeding preset limits that would cause action of the safety systems. A complete list of these systems is shown in Figure 7.1-1.

7.1.1.3.3 General Functional Requirements

Power generation systems and safety systems may have both a safety design basis and a power generation design basis, depending on their function. The safety design basis states in functional terms the unique design requirements that establish limits for the operation of the system. The general functional requirements portion of the safety design basis is those requirements that have been determined to be sufficient to ensure the adequacy and reliability of the system from a safety viewpoint. Many of these requirements have been introduced into various codes, criteria, and regulatory requirements.

7.1.1.3.4 Specific Regulatory Requirements

All systems have been examined with respect to specific regulatory requirements applicable to instrumentation and control. These regulatory requirements consist of all applicable codes including 10 CFR 50, Appendix A, General Design Criteria; 10 CFR 50, Appendix B, Quality Assurance Criteria; and regulatory guides.

As a result of this examination, it has been determined that two IEEE standards are applicable to the instrumentation and control associated with every safety-related system: IEEE 344-1971 and IEEE 323-1971. Compliance with the requirements of IEEE 323-1971 and IEEE 344-1971 for GE-supplied systems is discussed in NEDO-10698 and NEDO-10678, respectively, and Sections 3.11 and 3.10 of the UFSAR.

Fermi 2 complies with IEEE 336-1971, except as modified by the Edison Quality Assurance (QA) procedures.

The specific regulatory requirements applicable to each system's instrumentation and control are specified in appropriate subsections. The four most important safety systems have been reduced to the subsystem level and the applicable regulatory requirements are specified. This information is contained in Figures 7.1-2 through 7.1-5.

7.1.2 Identification of Safety and Power Generation Criteria

Design bases and criteria for instrumentation and control equipment design are based on the need to have the system perform its intended function while meeting requirements of applicable general design criteria, regulatory guides, and industry standards.

The plant instrumentation and control systems are listed by functional classification and regulatory classification in Figure 7.1-1.

Nominal instrument setpoints and ranges are shown in Chapter 7. Final instrument setpoints are provided in the Technical Specifications.

7.1.2.1 Design Bases

IEEE 279-1971 defines the design requirements with respect to the design bases of safety-related systems. Using the IEEE 279-1971 format, the following fulfills these requirements:

a. The generating station conditions that require protective action are
    1. Excessive radioactive releases to the atmosphere
    2. Excessive nuclear system stress
    3. Excessive containment stress.

b. The generating station variables that require monitoring to provide protective actions are listed in Tables 7.2-2, 7.2-3, 7.3-5 through 7.3-8, and 7.3-10

c. The minimum number of sensors and locations required to monitor safety-related variables is shown in Tables 7.2-2, 7.2-3, 7.3-5 through 7.3-8, and 7.3-10

d. Conservative operational limits for each safety-related variable are discussed in the Technical Specifications

e. The margin between operational limits and the level of determining the onset of unsafe conditions is discussed in the Technical Specifications

f. Levels requiring protective action are discussed in the Technical Specifications

g. Range of energy supply and environmental conditions of safety systems is shown in Section 8.3 and Tables 3.11-1 through 3.11-4, respectively

h. Malfunctions, accidents, and other unusual events that could cause damage to safety systems are discussed in Subsections 7.2.2.2.2.1 and 7.3.1.3

i. Minimum performance requirements are shown in Tables 7.2-2, 7.2-3, 7.3-5, 7.3-6, 7.3-8, and 7.3-10.

7.1.2.1.1 Reactor Protection System

7.1.2.1.1.1 Safety Design Bases

General Functional Requirements

The RPS is designed to meet the following functional requirements:

a. The RPS initiates a reactor scram with precision and reliability to prevent or limit fuel damage following abnormal operational transients

b. The RPS initiates a scram with precision and reliability to prevent damage to the nuclear system process barrier as a result of excessive internal pressure: that is, to prevent nuclear system pressure from exceeding the limit allowed by applicable industry codes

c. To limit the uncontrolled release of radioactive materials from the fuel or nuclear system process barrier, the RPS precisely and reliably initiates a reactor scram upon gross failure of either of these barriers

d. To detect conditions that threaten the fuel or nuclear system process barriers, RPS inputs are derived from variables that are true direct measures of operational conditions

e. The RPS responds correctly to the sensed variables over the expected range of magnitudes and rates of change

f. An adequate number of sensors are provided for monitoring essential variables that have spatial dependence

g. The following bases ensure that the RPS is designed with sufficient reliability

   1. If failure of a control or regulating system causes a plant condition that requires a reactor scram but also prevents action by necessary RPS

channels, the remaining portions of the RPS meet the requirements of Items a., b., and c. above

2. Loss of one power supply neither causes nor prevents a reactor scram
3. Once initiated, a RPS action goes to completion. Return to normal operation requires deliberate operator action
4. There is sufficient electrical and physical separation between redundant instrumentation and control equipment monitoring the same variable to prevent environmental factors, electrical transients, or physical events from impairing the ability of the system to respond correctly
5. Earthquake ground motions, as amplified by building and supporting structures, do not impair the ability of the RPS to initiate a reactor scram. See also Section 3.10
6. No single failure within the RPS prevents proper RPS action when required to satisfy the safety design bases Items a., b., and c. above
7. Any one intentional bypass, maintenance operation, calibration operation, or test to verify operational availability does not impair the ability of the RPS to respond correctly
8. The system is designed for a high probability that when the required number of sensors for any monitored variable exceeds the scram setpoint, the event results in an automatic scram and does not impair the ability of the system to respond correctly as other monitored variables exceed their scram trip points.
9. The operation of the Hydrogen Water Chemistry System is prevented from affecting RPS operation by the use of contact-to-coil separation.

h. The following bases reduce the probability that RPS operational reliability and precision will be degraded by operator error:

1. Access to trip settings, component calibration controls, test points, and other terminal points are under the control of plant operations supervisory personnel
2. Manual bypass of instrumentation and control equipment components is under the control of the main control room operator. If the ability to trip some essential part of the system has been bypassed, this fact is continuously indicated in the main control room.

i. The RPS and ESF equipment is physically identified as safety equipment in the plant as follows:

1. Equipment associated with the RPS, primary containment isolation system, and ESF equipment is identified so that two facts are apparent: first, that the equipment is part of the RPS, primary containment isolation system, or an ESF system; and second, that the equipment is associated with a particular grouping (or division) of enforced segregation
2. Panels and racks associated with these systems are labeled with marker plates that are conspicuous by means of color, shape, or color of engraving fill. The information on the marker plate includes both system and division identification
3. Junction and/or pull boxes enclosing wiring for the RPS and an ESF system have identification similar to and compatible with the panels and racks described above
4. Wiring and cables outside cabinets and panels are suitably color-coded to identify the division. Identification tags or markers for wiring conduits are conspicuously different from other similar tags and markers and shall include both system and division identity
5. Those trays or conduits that carry RPS or ESF system wiring are to be identified with conspicuous tags at entrance and exit points of each room through which they pass.

Specific Regulatory Requirements

The RPS is designed to meet the following functional requirements:

a. Industry Standards - In addition to the previous functional design requirements, the RPS complies with the requirements of IEEE 279-1971. A point-by-point comparison of IEEE 279-1968 is contained in Topical Report NEDO-10139. Section 7.2.2.2.2 of the UFSAR lists those topics where IEEE 279-1971 differs from IEEE-279-1968 and shows conformance to those differences. IEEE 323-1971, IEEE 338-1971, IEEE 379-1972, and IEEE 344-1971 also apply to the RPS

b. General Design Criteria of (GDC) l0 CFR 50 - GDC 13,20-24, and 29 of l0 CFR 50, Appendix A, have also been implemented in the design of the RPS

c. Regulatory Guides - Regulatory Guide 1.22, Periodic Testing of Protection System Actuation Function, applies with respect to periodic testing, and Regulatory Guide 1.53, Trial-Use Guide for the Application of the Single-Failure Criterion to Nuclear Power Generating Station Protection Systems, applies with respect to single-failure criteria.

7.1.2.1.1.2 Power Generation Design Basis

The RPS has no power generation objective. The setpoints, power sources, and instrumentation and control are arranged in such a manner as to preclude spurious scrams.

7.1.2.1.2 Containment and Reactor Vessel Isolation Control System

Safety Design Bases - General Functional Requirements

The following functional design bases are implemented in the containment and reactor vessel isolation control system (CRVICS):

a. The time required to close the main steam isolation valves (MSIVs) is short in order to minimize the loss of coolant from a main steam line break

b. The time required to close the MSIVs is not so short that inadvertent isolation of steam lines causes a more severe transient than the transient resulting from closure of the turbine stop valves coincident with failure of the turbine bypass system. This ensures that the MSIV closure speed is compatible with the ability of the RPS to protect the fuel and nuclear system process barrier

c. To ensure the timely isolation of main steam lines, at least one of the isolation valves in each of the main steam lines does not rely on continuity of any variety of electrical power to achieve closure

d. To provide the operator with means redundant to the automatic isolation functions to take action in the event of a failure of the nuclear system process barrier, it is possible for the main control room operator to manually initiate isolation of the RPV

e. To limit the release of radioactive materials to the environs, the containment, drywell, and reactor vessel isolation control system, with precision and reliability, initiates timely isolation of penetrations through the containment and drywell structure whenever the values of monitored variables exceed preselected operational limits

f. To provide assurance that important variables are monitored with precision, an adequate number of sensors are provided (Table 7.3-9)

g. To provide assurance that conditions indicating a failure of the nuclear system process barrier are detected with sufficient timeliness and precision, primary CRVICS inputs are derived, to the extent feasible and practical, from variables that are direct measures of operational conditions

h. The steam resulting from a design-basis LOCA flows to the pressure suppression pool to limit pressure in the containment

i. The power supplies for the containment, drywell, and reactor vessel isolation control system are arranged so that loss of one supply cannot prevent automatic isolation when required

j. The system is designed so that, once initiated, automatic isolation action goes to completion. Return to normal operation after isolation action requires deliberate operator action

k. Earthquake ground motions do not impair the ability of the containment, drywell, and reactor vessel isolation control system to initiate automatic isolation

l. Any one failure, maintenance operation, calibration operation, or test to verify operational availability does not impair the functional ability of the isolation control system to respond correctly to essential monitored variables, assuming no other active failure occurs

m. The system is designed for a high probability that, should any essential monitored variable exceed the isolation setpoint, the event results in automatic isolation and does not impair the ability of the system to respond correctly as other monitored variables exceed their trip points

n. There is sufficient electrical and physical wiring and piping separation between trip channels monitoring the same essential variables to prevent environmental factors, electrical faults, and physical events from impairing the ability of the system to respond correctly, in accordance with Paragraph 4.6 of IEEE 279-1971.

Safety Design Bases - Specific Regulatory Requirements

The requirements of IEEE 279-1971 and IEEE 338-1971 are met by the CRVICS. See Section 3.10 for IEEE 344-1971 and Section 3.11 for IEEE 323-1971 conformance discussions.

7.1.2.1.3 Emergency Core Cooling System

Safety Design Bases - General Functional Requirements

The ECCS instrumentation and control is designed to meet the following functional safety design bases:

a. They automatically initiate and control the ECCS to prevent fuel cladding temperatures from reaching the NRC interim acceptance criterion

b. They respond to a need for emergency core cooling, regardless of the physical location of the malfunction or break that causes the need

c. The following safety design bases are specified to limit dependence on operator judgment in times of stress:

   1. The ECCS responds automatically so that no action is required of plant operators within 10 minutes after a LOCA

   2. The performance of the ECCS is indicated by main control room instrumentation.

d. Facilities for manual control of the ECCS are provided in the main control room.

Safety Design Bases - Specific Regulatory Requirements

The ECCS instrumentation and control is designed to meet the following specific regulatory requirements:

a. The instrumentation and control meets the requirements of IEEE 279-1971. The following safety design bases are specified to ensure reliability:

1. No single malfunction, maintenance, calibration, or test procedure prevents function of the ECCS, assuming no other active or passive failure occurs

2. No protective device automatically interrupts performance or availability of the ECCS unless continued operation would cause complete failure. Such protective devices indicate abnormal conditions for operator decision and action.

b. The instrumentation and control meets the requirements of IEEE 338-1971

c. The instrumentation and control meets the requirements of IEEE 323-1971 as discussed in Section 3.11

d. The instrumentation and control meets the requirements of IEEE 344-1971 as discussed in Section 3.10

e. The requirements of GDC 13, 35, 36, and 37 of 10 CFR 50, Appendix A, are met

f. The requirements of Regulatory Guide 1.22 are met.

7.1.2.1.4 Neutron Monitoring System

7.1.2.1.4.1 Source Range Monitor System

The source range monitor (SRM) system meets the following power generation design bases:

a. Neutrons generated by irradiated fuel and neutron detectors together provide a signal-to-noise ratio of at least 2:1 and a count rate of at least 3 counts per second with all control rods fully inserted prior to initial power operation

The minimum count rate may be reduced to ≥ 0.7 CPS provided the signal-to-noise ratio is ≥ 20 and is not applicable during certain refueling operations covered by Technical Specification 3.3.1.2 when the minimum count rate may not be able to be maintained.

b. The SRM system is able to

1. Indicate during the worst possible startup rod withdrawal conditions a measurable increase in output signal from at least one detecting channel before the reactor period is less than 20 sec

2. Indicate substantial increases in output signals with the maximum permitted number of SRM system channels out of service during normal reactor startup operations

3. Have channels on scale when the intermediate range monitor (IRM) system first indicates neutron flux during a reactor startup

4. Provide a measure of the time rate of change of the neutron flux (reactor period) for operational convenience

5. Generate interlock signals to block control rod withdrawal if the count rate exceeds a preset value or falls below a preset limit if the IRMs are not above the second range or if certain electronic failures occur.

7.1.2.1.4.2 Intermediate Range Monitor System

Safety Design Basis

The IRM system generates a trip signal that can be used to prevent fuel damage caused by abnormal operational transients that occur while operating in the intermediate power range. The independence and redundancy incorporated in the design of the IRM system are consistent with the safety design bases of the RPS. The IRM system is designed in accordance with the same federal codes, regulatory guides, and IEEE standards applied to the RPS.

Power Generation Design Bases

The IRM system generates a trip signal to block rod withdrawal if the IRM system reading exceeds a preset value or if the IRM system is not operating properly. The IRM system has overlapping neutron flux indications relative to the SRM system and power range monitoring subsystems.

7.1.2.1.4.3 Local Power Range Monitor System

Power Generation Design Bases

The local power range monitor (LPRM) system meets the power generation design bases and supplies the following:

a. Signals to the average power range monitor (APRM) system proportional to the local neutron flux at various locations within the reactor core

b. Signals to the rod block monitor (RBM) system to indicate changes in local relative neutron flux during the movement of control rods

c. Signals to alarm high or low local neutron flux

d. Signals proportional to the local neutron flux to operator display assemblies to be used for operator evaluation of power distribution, local heat flux, minimum critical power ratio, and fuel burnup rate

e. A sufficient number of LPRM signals to support the APRM safety design bases.

7.1.2.1.4.4 Average Power Range Monitor System

Safety Design Basis

During the worst permitted input LPRM system bypass conditions, the APRM system generates a trip signal in response to average neutron flux increases resulting from abnormal operational transients in time to prevent fuel damage. Each APRM also includes an OPRM

Upscale Function that generates a trip signal upon detection of thermal hydraulic induced power oscillations. The APRM system is designed in accordance with the requirements of the safety design bases of the RPS.

Power Generation Design Bases

The APRM system provides

a. A continuous indication of average reactor power from a few percent to 125 percent rated reactor power to the operator in the main control room

b. A continuous indication of average reactor power from a few percent to 125 percent rated reactor power to the Integrated Plant Computer System (IPCS)

c. Interlock signals for blocking further rod withdrawal to avoid an unnecessary scram actuation

d. A reference power level for the RBM system

7.1.2.1.4.5 Rod Block Monitor System

The power generation design bases for the RBM system meet the following power generation design bases:

a. Prevent local fuel damage that may result from a single rod withdrawal error

b. Provide a signal used by the operator to evaluate the change in the local relative power level during control rod movement

c. Prevent any single short or open of any single input to the RBM system from affecting any other inputs to the RBM system

d. Meet GDC 24 of 10 CFR 50, Appendix A.

7.1.2.1.4.6 Traversing In-Core Probe System

The traversing in-core probe (TIP) system meets the following power generation design bases:

a. Provides a signal proportional to the axial neutron flux distribution at selected small axial intervals over the regions of the core where LPRM system detector assemblies are located. This signal is of high precision to allow reliable calibration of LPRM system gains

b. Provides accurate indication of the position of the flux measurement which allows pointwise or continuous measurement of the axial neutron flux distribution.

7.1.2.1.5 Refueling Interlocks

Refueling interlocks meet the following safety design bases:

a. During fuel movements in or over the reactor core, all control rods are in their fully inserted positions

b. No more than one control rod can be withdrawn from its fully inserted position at any time when the reactor is in the refuel mode.

7.1.2.1.6 Reactor Manual Control System

Power Generation Design Basis

The RMCS provides the reactor operator with the means for controlling the power level and power distribution in the core. This is done by control rod positioning capability, which depends on electrical circuitry and switches. Position and power indicators provide surveillance of actions taken and the results of these actions.

Classification

This system is a power generation system, not essential for safety, and is classified in Chapter 3.

7.1.2.1.7 Reactor Vessel Power Generation Instrumentation

The power generation design bases for the RPV instrumentation consist of maintaining proper operating conditions. To maintain proper operating conditions, the RPV instrumentation is designed to provide the operator with sufficient indication of RPV temperature, reactor core flow rate, RPV water level, RPV pressure, and nuclear system leakage. These instruments augment existing information such that the operator can start up, operate, shut down, and service the reactor efficiently. Because the RPV instrumentation used for RPS, ESF, safe shutdown systems, and certain control systems is described and evaluated in other portions of this document, only those instruments not required for safety systems are described (Subsection 7.6.l.2).

7.1.2.1.8 Recirculation Flow Control System Safety Design Bases

The RFCS functions so that no abnormal operational transient resulting from a malfunction in the RFCS can result in damaging the fuel or exceeding nuclear system pressure limits.

Power Generation Design Bases

The RFCS is designed to allow manual recirculation flow adjustment, thereby enabling manual control of reactor power level.

7.1.2.1.9 Feedwater Control System

The feedwater control system meets the power generation design bases by regulating the feedwater flow to maintain adequate water level in the RPV according to the requirements of the steam separators, and to prevent uncovering of the reactor core over the entire power range of the reactor.

7.1.2.1.10 Pressure Regulator and Turbine-Generator Control

One of the main features of direct cycle BWRs is the direct passage of the nuclear steam supply system (NSSS) generated steam through the turbine. In this system the turbine is slaved to the reactor, in that all the steam generated by the reactor is normally accepted by the turbine. The operation of the reactor demands that the pressure regulator concept be applied to maintain a constant turbine inlet pressure with load-following ability handled by variation of the reactor recirculation flow or control rod position.

The turbine pressure regulator, in maintaining constant stop valve pressure, operates the steam bypass system such that up to 23.5 percent of nuclear boiler rated flow can be bypassed when operating below the maximum steam flow limit as well as during the startup and shutdown phases.

The pressure regulator and turbine-generator control system accomplishes the following control functions:

a. Controls turbine speed and turbine acceleration

b. Operates the steam bypass system to keep reactor pressure within limits, and avoids large power transients

c. Adjusts (manually) 52-in. manifold pressure to nullify a 30 psi drop over a reactor flow of 0 to 100 percent.

7.1.2.1.11 Process Radiation Monitor System

The process radiation monitor system is discussed in Section 11.4.

7.1.2.1.12 Area Radiation Monitor System

The area radiation monitor system is discussed in Section 12.1.

7.1.2.1.13 Offsite Environs Radiological Monitoring Programs

This material is discussed in the Offsite Dose Calculation Manual (ODCM).

7.1.2.1.14 Rad-Chem Radiation Monitoring Instruments

This material is discussed in Section 12.3.

7.1.2.1.15 Plant Computer Systems

7.1.2.1.15.1 Integrated Plant Computer System (IPCS)

The IPCS is a non-safety related computer system that combines various functions of legacy computer systems that it replaced. The IPCS provides the capability of monitoring, recording and displaying plant parameters via strategically located display devices.

The IPCS meets the following power generation design basees:

a. The IPCS is designed for use with, and has capacity for, the Fermi 2 plant alone.

b. The Scan, Log and Alarm (SLA) function provides continuous monitoring of plant parameters through on-line data acquisition equipment. Plant parameters are alarmed and logged based on pre-determined setpoints.

c. The IPCS supplies information to the operator via a man-machine interface (MMI) consisting of video displays and printers mounted within the operating panels.

d. Data archival of plant parameters is provided on both a short term (at process scan rates) and on a long term basis (at a reduced scan rate).

e. The Nuclear Steam Supply System (NSSS) function processes the heat balance data related to core operation into a condensed and usable form that assists in operating the core within prescribed limits.

   Reactor heat balance analysis is accomplished with both periodic and on-demand programs.

   The results from these calculations are displayed through alarms and on-demand and periodic computer printouts.

f. The Balance of Plant (BOP) function provides extended features beyond the NSSS function to other plant systems. The on-line data values required for monitoring BOP systems are obtained from BOP system sensors shared with other systems and from sensors installed specifically to provide input data for the computer. The IPCS is able to perform certain BOP calculations to aid with equipment operation and equipment operation documentation.

The on-line data-gathering and computation ability of the IPCS allows the display of on-line equipment performance indicators. These indicators provide a condensed summary of BOP equipment operational status.

g. The Emergency Response function is designed to gather data from selected plant parameters and data systems for use in the Safety Parameter Display System (SPDS) function and Emergency Response Data System (ERDS) function.

The SPDS function calculates and displays the value and status of the primary variables of the following systems:

1. Core Cooling
2. Fuel integrity
3. Reactivity
4. Reactor coolant system integrity
5. Containment integrity
6. Radioactivity effluent to the environment

The design basis of the SPDS function is to display to operating personnel a minimum set of parameters that define the status of the plant as necessary to assess plant safety status.

The ERDS function provides the NRC with SPDS data through a dedicated datalink.

h. The Meteorological (MET) function is designed to provide calculations using various meteorological parameters obtained from the Meteorological Data Acquisition System (MDAS). These calculations are used to support the requirements of Regulatory Guide 1.23 “Onsite Meteorological Programs”.

i. The Transient Recording and Analysis (TRA) function is designed to provide high-speed recording of select plant parameters that are of significant importance during plant transients. The analysis portion of the function provides statistical data reduction capabilities to aid operating personnel in understanding the event.

The IPCS interfaces with a wide variety of external systems through specialized data links for providing or obtaining process parameters. These systems include:

a. 3D-Monicore Computer System (3DM)

b. Power Range Neutron Monitor System (PRNM)

c. Rod Worth Minimizer System (RWM)

d. Radiological Dose Assessment Application (Raddose V)

e. Meteorological Data Acquisition System (MDAS)

7.1.2.1.15.2 3D-Monicore Computer System (3DM)

The 3DM computer is designed to determine periodically the three-dimensional power density distribution for the reactor core, and to provide printed logs that permit accurate assessment of core thermal performance.

The 3DM computer provides nearly continuous monitoring of the core margins to operating limits and appropriate alarms based on established core operating limits. This aids the operator in ensuring that the core is operating within acceptable limits at all times, especially during periods of power level changes.

7.1.2.1.16 Standby Gas Treatment System

Safety Design Basis - General Functional Requirements

The standby gas treatment system (SGTS) instrumentation and control meets the following safety design bases:

a. The instrumentation and control initiates the SGTS to provide filtration of air released from the reactor building following a fuel-handling accident or LOCA

b. The instrumentation and control limits the possibility of exfiltration from the reactor building to outdoors by maintaining negative pressure in the reactor building area

c. The SGTS responds automatically so that no initiating action is required of plant operators following a LOCA or fuel-handling accident

d. The responses of the SGTS are indicated on the main control panel

e. Facilities for the manual control of the SGTS are provided in the main control room

f. No single failure, maintenance, calibration, or test prevents operation of the SGTS

g. Any installed means of manually interrupting the availability of the SGTS is under the control of the operator or other supervisory personnel

h. Loss of interruptible instrument air and/or offsite electric power does not affect the normal function of the SGTS

i. The physical events accompanying a LOCA or fuel-handling accident could not prevent correct functioning of the instrumentation and controls

j. Seismic motions resulting from earthquake ground motion of the design-basis earthquake, missile, wind, and flood do not impair the operation of the instrumentation and control.

Safety Design Basis - Specific Regulatory Requirements

The requirements of IEEE 279-1971 and IEEE 344-1971 are met by the SGTS instrumentation and control. Additionally, GDC 13, 20-24, and 29 of 10 CFR 50, Appendix A, and Regulatory Guide 1.22 have been implemented in the design of this control system.

7.1.2.1.17 Control Center Atmospheric Control System

The control center atmospheric control is provided by the control center heating, ventilation, and air conditioning (HVAC) system, described in Subsection 9.4.1. The instrumentation and control for this system meets the following design bases.

Safety design bases include all the bases described under power generation design bases and the following:

a. The system controls are interlocked with the RMS to isolate the main control room and automatically route the outside makeup air for the control center HVAC system through the emergency and recirculation filter trains so that main control room habitability is maintained

b. The system operates in conjunction with ionization detection systems to annunciate in the main control room on detection of combustion products in the main control room ceiling space

c. The system has the capability to purge rooms manually with 100 percent outside air, or to route the outside air and recirculation air mixture of the control center HVAC system manually through odor, smoke, and halogen- removing filters that are normally bypassed

d. No single failure, maintenance, calibration, or test operation prevents the functioning of the control center HVAC instrumentation and control. A single active failure in the Halon fire protection system will cause closure of smoke/Halon dampers to the relay room, cable spreading room or computer room. Manual actions are required to reopen these dampers to reestablish airflow.

e. Any installed means of manually interrupting the availability of the control center HVAC system is under the control of the operator or other supervisory personnel

f. Loss of offsite electric power does not affect the normal functioning of instrumentation and controls

g. The physical events accompanying a LOCA or fuel-handling accident do not prevent correct functioning of the instrumentation and controls

h. Seismic motions resulting from earthquake ground motion, missile, wind, and flood do not impair the operation of the instrumentation and controls

i. The requirements of IEEE 279-1971, IEEE 323-1971, IEEE 338-1971, and IEEE 344-1971 are met by the control center HVAC system instrumentation and control. Additionally, GDC 13, 19, 20-24, and 29 of 10 CFR 50, Appendix A, and Regulatory Guide 1.22 have been implemented in the design of this control system.

j. The system has the following controls, interlocks, and overrides:

    1. The system can be manually selected to any of the four modes (i.e., normal, purge, chlorine or recirculation).

    2. The system will transfer to the purge or recirculation mode automatically upon receipt of the appropriate signals.

    3. The automatic purge mode will override the normal mode.

    4. The manual chlorine mode will override all modes except the automatic recirculation mode.

    5. The automatic recirculation mode will override all modes.

<u>Power Generation Design Bases</u>

The power generation design bases are

a. To control the temperature and humidity in the control center for operator comfort and electronic equipment stability. A small net positive pressure is maintained with respect to the outdoors and other areas of the plant on a year-round basis

b. To indicate temperature and status of operating equipment, such as supply and return air fans and the refrigeration unit, in the main control room

c. To annunciate on the control panel any operating transients that require operator's attention. This includes high temperature, loss of airflow from supply and return air fans, loss of refrigeration unit, high pressure drop across the supply air filters, and low positive pressure differential between the control center atmosphere and outdoors

d. To provide capability in the main control room to manually control and operate various components of the control center HVAC system

e. To provide a means to test instrumentation and controls and operation of redundant equipment to ensure availability at all times.

7.1.2.1.18 Emergency Equipment Cooling Water System

Safety Design Bases

General Functional Requirements - The instrumentation and control of the emergency equipment cooling water (EECW) system is designed to initiate and maintain operation of the EECW system automatically when normal operation of the reactor building closed cooling water (RBCCW) system is impaired (as indicated by a low differential header pressure), high drywell pressure is experienced, or upon loss of offsite ac power. The controls are provided

a. To open or close appropriate motor-controlled valves to retain essential cooling circuits and isolate those that are not required to be in service in an emergency

b. To start operation of the pumps of both loops to establish flow of the emergency equipment service water (EESW) system (the latter is used to remove heat from the EECW system heat exchangers)

c. To regulate the temperature of the EECW within the required range at the outlet of the EECW system heat exchanger

d. To maintain the demin level in the EECW makeup tank within the required range during normal plant operation.

Manual controls for initiating operation of the EECW system and its return to the standby state are also provided. The EECW makeup tanks are supplied with demineralized water during normal plant operation. The EECW system makeup tank is supplied via a crosstie line and a makeup pump from the EESW system to provide an alternate makeup supply for each division when the normal makeup supply to the tank is lost during and after the design basis accident. After EECW start, the EECW makeup tanks are replenished and pressurized by makeup pumps utilizing EESW water. The makeup pumps automatically start on makeup tank low pressure or low level, if the makeup tank isolation valve is open and normal makeup pump suction pressure is achieved. Instrumentation and controls are provided to automatically maintain EECW makeup tank pressure, and provide a source of safety-related water (EESW) during EECW system operation.

Specific Regulatory Requirements - The protection system functions contained in functions a. and b. above are required to comply with IEEE 279-1971, IEEE 308-1971, IEEE 323-1971, IEEE 336-1971, IEEE 338-1971 and IEEE 344-1971; GDC 18, GDC 20-24, and GDC 29 of 10 CFR 50, Appendix A and Appendix B; and Regulatory Guide 1.22. EECW system monitoring and control functions c. and d. are required to comply with the requirements of GDC 13.

Power Generation Design Basis

EECW may be manually initiated with the nonessential loads subsequently restored to facilitate RBCCW heat exchanger cleaning, to enhance drywell cooling during high lake water (GSW) temperature, for testing, or to provide RHR Reservoir freeze protection during extreme cold weather. A Loss of RBCCW while EECW is operating in this mode will not reinitiate EECW or re-isolate the nonessential loads. This action is not required, however, since this is not a condition requiring protective action as described in Section 7.1.2.1. The demineralized water level in the makeup tank is automatically maintained above a specified minimum amount during normal plant operation. Automatic makeup from EESW is provided for the condition when the normal demineralized water makeup supply is not available and the makeup tank is connected to the EECW loop (i.e., when the P4400F602A(B) valve is open).

7.1.2.1.19 Emergency Core Cooling System Auxiliary Systems

The ECCS auxiliary systems support operation of ECCS equipment. Instrumentation required for operation of this ECCS equipment, therefore, meets the redundancy and separation requirements of the ECCS equipment. The ECCS auxiliary systems consist of

a. Cooling water (EECW) system described in Subsection 7.1.2.1.18

b. Essential electric power systems described in Subsection 7.1.2.1.25

c. Area coolers for rooms and areas containing ECCS equipment (Section 9.4)

d. Leak detection in ECCS equipment rooms and areas, as described in Subsection 7.1.2.1.26.

Safety Design Basis

The EECW system is designed to be available for essential equipment as outlined in Subsection 7.1.2.1.18. The electric power available for the EECW system is also described in Subsection 7.1.2.1.25. Either the area coolers are designed for operation during emergency conditions, or the ECCS equipment is designed so that loss of the coolers does not jeopardize operation of the ECCS. Leak detection instrumentation monitors primarily for leaks of reactor water or steam. Leak detection instrumentation that automatically isolates ECCS equipment meets the redundancy/ separation requirements for those ECCSs. Subsection 7.1.2.1.26 describes the leak detection instrumentation design bases in more detail.

The EECW system is designed for the maximum expected heat load of ECCS emergency equipment that is used to provide equipment cooling and ventilation space cooling for the HPCI, RCIC, RHR, and core spray systems.

Power Generation Design Bases

The EECW and electrical power sources for the ECCS equipment are maintained in readiness so that they are available when needed. This includes maintaining a minimum level of condensate in the makeup tank. The room air ventilation system is also designed to filter and/or reroute air from rooms where airborne radiation may be present. The LDS initiates an alarm in the main control room in sufficient time for operating personnel to correct or isolate the leak. In some cases the LDS automatically isolates the leaking system.

7.1.2.1.20 Reactor Core Isolation Cooling System

Safety Design Basis - General Functional Requirements

The RCIC system is designed to meet the following general functional requirements:

a. The system is capable of maintaining sufficient coolant in the RPV in case of a loss of main feedwater flow

b. Provisions are made for automatic and remote manual operation of the system

c. To provide a high degree of assurance that the system operates when necessary, the power supply for the system is from immediately available energy sources of high reliability

d. To provide a high degree of assurance that the system operates when necessary, provision is made for periodic testing during reactor operation.

Safety Design Basis - Specific Regulatory Requirements

The RCIC system is considered a safety system rather than an ECCS because it is required for safe shutdown. The system is designed to meet the requirements, with exceptions as described in Subsection 7.4.2.2.2, of the federal codes, regulatory guides, and IEEE standards applied to the ESF systems.

7.1.2.1.21 Standby Liquid Control System

Safety Design Bases

General Functional Requirements - The major components of the SLCS consist of a storage tank, two positive displacement pumps, two explosive valves, and two check valves between the explosive valves and the reactor, as shown in Figure 7.4-3. The flow path is from the storage tank through the pumps, explosive valves, and check valves, and into the reactor to the bottom of the core plate. This system is capable of shutting the reactor down from full power to cold shutdown and maintaining the reactor in a subcritical state at atmospheric temperature and pressure conditions by pumping sodium pentaborate, a neutron absorber, into the reactor.

The sodium pentaborate also increases suppression pool pH to prevent iodine re-evolution following a LOCA in the event of fuel failure.

Dual components and dual circuits are used in portions of the system; however, this manually operated system is subject to single failure. Monitoring and testability have been provided for the components and circuits that are deemed most likely to fail. Redundant power sources supply power to this system.

The SLCS electrical components necessary for the injection of boron have been classified as QA Level 1M to indicate that they were not originally intended, procured, designed, or classified as safety related, but will be maintained and tested as a safety-related system.

Specific Regulatory Requirements - General Design Criterion 26 of 10 CFR 50, Appendix A, which requires the provision of an independent method of reactivity control, applies.

Power Generation Design Basis

The system is designed to shut the reactor down from full power to cold atmospheric conditions with sufficient margin to maintain the reactor subcritical at the cold condition in the event that manual control rod movement cannot be accomplished with the RMCS.

7.1.2.1.22 Primary Containment Monitoring System

The primary containment monitoring system consists of four instrumentation subsystems that collectively monitor the primary containment atmosphere for hydrogen concentration, oxygen concentration, gaseous radiation level, and temperature and pressure, and that monitor the pressure suppression pool water for temperature and level. The radiation monitor is principally provided to enhance the capability for detecting reactor water or steam leaks. The radiation monitor activates an alarm upon detecting radiation at or above a predetermined level. Monitoring of the other parameters is provided to secure information on transients resulting from a LOCA. The monitored parameters are indicated and recorded in the main control room.

The primary containment atmosphere monitoring system also serves to provide information on monitored parameters in the course of plant operations when conditions are normal. The four primary containment monitor subsystems are designated

a. Primary containment radiation monitor and the hydrogen/ oxygen monitor subsystem

b. Primary containment temperature monitor subsystem

c. Primary containment pressure monitor subsystem

d. Pressure suppression pool water level indicator subsystem.

The design bases and regulatory requirements for each of these subsystems are individually defined below.

7.1.2.1.22.1 Primary Containment Radiation Monitor and Hydrogen/ Oxygen Monitor Subsystems

Safety Design Bases

General Functional Requirements - The primary containment radiation monitor is designed to meet the following safety design bases:

a. Provide continuous radiation monitoring of the primary containment atmosphere during power operation, startup and hot shutdown of the reactor.

b. Provide particulate and halogen filters in the atmospheric sample flow line to collect integrated samples of these substances, on separate filters, for purposes of radiation analysis

c. Provides a high-radiation alarm with fully adjustable setpoints in the main control room.

d. Provide a diverse reactor coolant pressure boundary leak detection method using noble gas activity.

Specific Regulatory Requirements - The instrumentation and control of the primary containment radiation monitor subsystem is designed to conform to General Design Criterion 30 of 10 CFR 50, Appendix A and Regulatory Guide 1.45. The hydrogen/oxygen monitor subsystem is designed to meet Regulatory Guides 1.7 and 1.97, Category 3 and 2 requirements, respectively.

Power Generation Design Bases

The primary containment radiation monitor and hydrogen/oxygen monitor subsystems are designed to meet the following power generation design bases:

a. Provide indication in the main control room of the noble gas radioactivity and hydrogen/oxygen content of the primary containment atmosphere during normal operation

   The oxygen monitors provide verification of the status of the inerted atmosphere of containment and oxygen levels in the containment atmosphere following a significant beyond-design-basis accident for combustible gas control and accident management, including emergency planning.

   The hydrogen monitors provide diagnosis of the course of significant beyond-design-basis accidents for accident management, including emergency planning.

b. Provide means for obtaining radioactivity analysis of particulate and halogen content in the primary containment atmosphere

c. Provide an instrument failure (offscale low) alarm.

d. Provide high hydrogen and high oxygen alarms with fully adjustable setpoints in the main control room.

7.1.2.1.22.2 Primary Containment Temperature Monitor Subsystem

Safety Design Bases

General Functional Requirements - The primary containment temperature monitor subsystem is designed to meet the following safety design bases:

a. Provide continuous monitoring of the drywell atmosphere temperature with a distributed arrangement of temperature sensors to secure representative temperature data in the drywell region

b. Provide continuous monitoring of drywell cap atmospheric temperature with a sensor suitably located to secure representative temperature information in the cap region

c. Provide continuous measurement of drywell wall temperature with an arrangement of sensors distributed to obtain a representative determination of the wall temperature conditions in the drywell region

d. Provide continuous measurement of atmospheric temperature in the pressure suppression chamber

e. Provide continuous measurement of water temperature in the pressure suppression chamber.

Safety Design Bases

Specific Regulatory Requirements - The primary containment temperature monitor subsystem is designed to conform to GDC 13 of 10 CFR 50, Appendix A, and QA Criteria of 10 CFR 50, Appendix B, for nuclear power plants.

7.1.2.1.22.3 Primary Containment Pressure Monitor Subsystem

Safety Design Bases

General Functional Requirements - The primary containment pressure monitor subsystem is designed to meet the following safety design bases:

a. Provide continuous measurement of drywell atmospheric pressure

b. Provide continuous measurement of pressure suppression chamber atmospheric pressure.

Specific Regulatory Requirements - The primary containment pressure monitor subsystem is designed to meet GDC 13 of l0 CFR 50, Regulatory Guide 1.97, Appendix A, and QA Criteria of 10 CFR 50, Appendix B, for nuclear power plants.

Power Generation Design Basis

The primary containment pressure monitor subsystem provides a chart recorder in the main control room to continuously record and display the primary containment pressure monitored by this subsystem.

7.1.2.1.22.4 Pressure Suppression Pool Water Level Indicator Subsystem

Safety Design Bases

General Functional Requirements - The pressure suppression pool water level indicator subsystem is designed to provide measurement of water level in the pressure suppression chamber over the maximum practical range.

Specific Regulatory Requirements - The pressure suppression pool water level indicator system is designed to meet GDC 13 of 10 CFR 50, Regulatory Guide 1.97, Appendix A, and QA Criteria of 10 CFR 50, Appendix B, for nuclear power plants.

Power Generation Design Basis

The pressure suppression pool water level indicator subsystem is designed to provide a display in the main control room that indicates the water level in the pressure suppression chamber.

7.1.2.1.23 Radwaste Control System

7.1.2.1.23.1 Liquid Radwaste System

The safety design bases ensure that the liquid radwaste system instrumentation and control is designed to provide information to the liquid radwaste process operator. This information is needed to limit releases of radioactivity to the environment. Further discussion can be found in Subsection 7.7.1.6 and in Sections 11.2 and 11.4.

7.1.2.1.23.2 Gaseous Radwaste System

The safety design bases ensure that the gaseous radwaste system instrumentation and control system is designed to monitor and control the gaseous processing systems (offgas system and 2-minute holdup pipe system). It also detects, indicates, and alarms improper or abnormal conditions in the gaseous radwaste systems in time for corrective action. Further discussion can be found in Subsection 7.7.1.5 and in Sections 11.3 and 11.4.

7.1.2.1.24 Reactor Water Cleanup System

The purpose of the RWCU system is to provide continuous processing of the reactor water so that the purity is maintained within specified limits. The system also provides the means for removal of reactor water. For example, to maintain reactor water level during startup, it is necessary to dump water due to swell.

7.1.2.1.25 Power Systems

The power systems considered in this subsection include those electrical power sources used in, or associated with, shutting down the reactor and limiting the release of radioactive material following a design-basis event. The power systems include the standby ac system (Subsection 8.3.1), the plant dc system (Subsection 8.3.2), instrument ac power (Subsection 8.3.1), RPS power supplies (Subsection 8.3.1), and special power supplies for individual systems.

Electrical power supplies are available onsite as required to provide the electrical energy requirements of the ESF and safe- shutdown systems during all safety design-basis events and as long thereafter as required to satisfy safety requirements.

The design of the standby ac power system complies with accepted industrial standards for nuclear power plants and is compatible with the ESF system equipment design and arrangement.

Safety Design Bases

General Functional Requirements - The power systems are designed to meet the following general functional requirements:

a. Standby ac Power System

   1. General - The primary requirement of the standby ac power system is to maintain a high degree of reliability and timely availability of power sources for the ESF and safe-shutdown systems. This power is required to be made available promptly, within approximately 10 sec, and automatically on either a failure of preferred power sources at any time, or on a LOCA signal

      Before the diesel generator is connected to a bus, all offsite source breakers and bus load breakers, with the exception of certain selected breakers, are signaled to trip. The generator is then sequentially loaded to prevent overload or excessive voltage drop. Shutdown of the diesel generator is manual only, except for specific automatic trips to prevent equipment destruction

2. Load Assignment - Assignment of loads to emergency safety system buses is such that failure of a single standby power source does not prevent a safe shutdown of the reactor under conditions of a design- basis accident (DBA) concurrent with a design-basis event. "Design-basis event" is used here in the same sense as defined in IEEE 308-1971, i.e., any or all of a set of postulated environmental events for which the plant and ESF systems have been designed

   Automatic starting is required of all loads that may be required within 10 minutes after a LOCA. Automatically started loads may be stopped manually and other loads started manually as required by plant conditions.

   Automatically connected loads include the emergency core cooling pumps and valves, safety-related instrument power supply transformers, containment isolation valves (ac only), drywell cooling equipment, emergency lighting, standby gas treatment and control center heating, ventilation, and air- conditioning, main control room habitability, EECW system, ECCS room coolers, auxiliary building heating and ventilation, EDG auxiliary equipment, RHR complex ventilation equipment, and reactor building sumps

   Manually connectable loads are defined in Table 8.3-3.

b. Plant dc Power System - The primary requirement of the plant dc power system is to maintain highly reliable and continuously available sources of dc power for the control of a minimum complement of the ECCS and the ac power system equipment during operating conditions and during a DBA concurrent with a design-basis event

   Voltage variations are maintained within the demonstrated operating limits of each connected device with appropriate allowances for voltage drop in the cabling. Control battery terminal voltage range on a 130-V dc system is discussed in section 8.3.2.2.4

   The dc power sources for redundant ESF equipment must be arranged so as not to compromise the required independence or reduce redundancy below an acceptable level during a design-basis event (i.e., loss of one battery shall not disable any ESF function)

   The EDGs are equipped with sufficient protective devices to prevent destruction of the unit, e.g., overspeed trip, low oil pressure trip, generator differential relays, and crankcase overpressure. Other protective devices are used for protection when in test mode, but such devices alarm only when the unit is required to perform the designed safety function

c. Instrument ac Power - Power for process instrumentation associated with redundant ESF systems is to be provided by a standby source from the same division as the pump motors and ac valve motors for each system. This power is not classified as essential to nuclear safety, but is to be made available automatically when the bus to which it is connected is energized

The instrumentation power for the HPCI and RCIC systems is to be from a separate inverter that feeds from the same station battery that powers HPCI and RCIC controls, respectively.

d. Other Power Supplies

1. Reactor Protection System - Power supplies for the RPS are required to have sufficient stored energy to ride through switching transients within the switchyard or auxiliary power system. The safe failure characteristic of the RPS on loss of power exempts the RPS power supplies from being classified essential. However, redundancy is provided to avoid unnecessary plant shutdown on interruption of power to one RPS bus

2. Process Radiation Monitoring System - Certain aspects of the PRMS require 120-V ac power for purposes of recording and/or control. This power is provided from an instrument bus or an inverter power supply as appropriate.

Safety Design Bases

Specific Regulatory Requirements - The standby ac power and dc power systems are essential to safe shutdown of the reactor and/or for emergency core cooling, and therefore comply with all applicable AEC and IEEE standards for design, qualification, and testing. These include IEEE 279-1971, IEEE 308-1971, IEEE 323-1971, IEEE 338-1971, IEEE 344-l97l; GDC 1 through 5, 12, 18 and 19 of 10 CFR 50, Appendix A, and Regulatory Guides 1.6 and 1.9 (with exceptions as discussed in Subsection 8.3.1.2.2.2 and Appendix A.1.9).

7.1.2.1.26 Leak Detection System

7.1.2.1.26.1 Reactor Coolant Pressure Boundary Leakage Detection

Safety Design Bases

General Functional Requirements - The safety design basis for the LDS for setting leakage rate limits is that signals are provided to permit isolation of abnormal leakage before the results of this leakage become unacceptable.

The unacceptable results are a threat of significant compromise to the nuclear system process barrier and a leakage rate in excess of the coolant makeup capability to the reactor vessel.

Specific Regulatory Requirements - The part of leak detection that is related to isolation circuits is designed to meet requirements of the ESF systems and to conform to those federal codes, regulatory guides, and IEEE standards which apply to ESF systems.

Power Generation Design Basis

A means is provided to detect abnormal leakage from the nuclear system process barrier.

7.1.2.1.26.2 Emergency Core Cooling System Suction Line Detection

The ECCS suction line LDS is designed to provide information that would allow the manual closing of the valve in the broken line before the net positive suction head (NPSH) is lost to the redundant ECCS.

7.1.2.1.27 Reactor Shutdown Cooling System

Safety Design Bases

The instrumentation and control for the reactor shutdown cooling mode of the RHR system is designed to meet the following functional design bases:

a. Instrumentation and manual control are provided to enable the system to remove the residual heat (decay heat and sensible heat) from the RPV during normal shutdown

b. All facilities for manual control of the shutdown cooling system are provided in the main control room

c. Response of the shutdown cooling system is indicated by main control room instrumentation.

Power Generation Design Bases

The instrumentation and control for the reactor shutdown cooling system is designed to meet the following power generation design bases:

a. Provide cooling for the reactor during the shutdown operation when the vessel pressure is below the design pressure of the shutdown piping system

b. Cool the reactor water to a temperature which is practical for refueling and servicing operation.

7.1.2.1.28 Plant Cooling Systems

Two closed cooling water systems are used at Fermi 2 for removal of heat from equipment and space coolers. These are the RBCCW system and the turbine building closed cooling water (TBCCW) system, both described in Section 9.2. The EECW system, an ESF described in Subsection 7.3.4.2, forms an integral part of the RBCCW system.

7.1.2.1.28.1 Reactor Building Closed Cooling Water System Power Generation Design Bases

The instrumentation and control of the RBCCW system is designed in accordance with the following functional requirements:

a. It maintains the required flow of cooling water in the system and its two divisions during normal conditions and postulated abnormal conditions of the plant

b. On loss of offsite power, high drywell pressure, or on drop of differential pressure across the supply and return headers of either division beyond the preset limit, the EECW system will automatically isolate areas of the RBCCW system not essential for emergency cooling and to take over supplying the coolant flow that is required. A loss of RBCCW while EECW is operating for RBCCW heat exchanger cleaning, enhanced drywell cooling, testing, or RHR reservoir freeze protection will not reinitiate EECW or reisolate the nonessential loads. This action is not required, however, since this is not a condition requiring protective action as described in Section 7.1.2.1.

c. Restoration of the system to normal operation is by manual control.

7.1.2.1.28.2 Turbine Building Closed Cooling Water System Power Generation Design Bases

The instrumentation and control of the TBCCW system is designed in accordance with the following functional requirements.

a. It maintains the required flow of cooling water in this system during normal conditions of plant operation

b. It automatically becomes deactivated on loss of offsite power

c. Restoration of the system to normal operation after gain of power is by manual control.

7.1.2.1.29 Fuel Pool Cooling and Cleanup System

The fuel pool cooling and cleanup system (FPCCS) instrumentation and control is not required for power generation. Its function is to provide annunciation and control so that the FPCCS can maintain the spent fuel and equipment storage pools and the reactor water well below a desired temperature and at a degree of clarity necessary to refuel and service the reactor.

7.1.2.1.30 Post-LOCA Combustible Gas Control System

The NRC amended 10 CFR 50.44, “Standards for combustible gas control system in light-water-cooled power reactors” on October 16, 2003 to eliminate the requirements for hydrogen recombiners. The hydrogen recombiner Technical Specification requirements were subsequently removed by License Amendment 159, dated March 15, 2004. Regulatory Guide 1.7 was revised in March 2007 to reflect the amended 10 CFR 50.44. The Combustible Gas Control System (CGCS) has been retired in place with its electrical circuits de-energized and fluid process piping isolated from primary containment with redundant locked-closed isolation valves. Combustible gas control of the primary containment is provided by inerting the primary containment with nitrogen.

7.1.2.1.31 Control Air System

The instrumentation and control of the control air system is designed in accordance with the following functional requirements.

a. The control air system maintains the required quantity and quality of control air to both interruptible and noninterruptible control air users

b. On loss of control air pressure below a preset limit, the control air compressors are automatically started and the two divisions of the control air system are automatically isolated from all interruptible control air users and the station air system so that each control air compressor is supplying only its own essential division

c. It provides for manual actuation of the system from the main control room for testing of the system or for manual initiation of the system.

7.1.2.1.32 Alternate Rod Insertion

The safety design bases are as follows:

a. The sensors, transmitters, trip units, and associated logic for the ARI are Class 1E, redundant to the reactor protection system, and environmentally and seismically qualified to IEEE 323-1974 and IEEE 344-1975

b. The ARI sensors monitor reactor pressure and water level and trip the reactor if these variables reach their respective trip setpoints. The trip is accomplished by energizing the ARI valves, thereby venting the air supply holding the scram valves shut.

7.1.2.2 Independence of Redundant Safety-Related Systems

The criteria for the separation of safety-related mechanical and electrical equipment are discussed in Section 3.12 and Subsection 8.3.1. The independence of redundant safety-related systems satisfies the applicable requirements of IEEE 279-1971. The requirements of 10 CFR 50, Appendix B, are met as described in Chapter 17.

7.1.2.3 Physical Identification of Safety-Related Equipment

Equipment associated with the RPS, the ESF, the safe shutdown systems, and the auxiliary electrical equipment associated with these systems are identified so that it is apparent that

a. The equipment is part of the RPS, ESF, or safe shutdown system

b. The equipment item is associated with a particular grouping (or division) of enforced segregation.

The identification consists of marking panels and equipment racks with marker plates that are conspicuously different in color than those for other panels or racks. These markers include identification of the proper division of the equipment within the system.

The equipment identification number and the applicable segregation code, both numerical and color code, are applied to each piece of safety-related equipment either before or during that equipment's installation.

7.1.2.4 Conformance To IEEE-317

Qualification of the penetration assemblies and their associated electrical services is provided by compliance with IEEE 317-1972. Power cables are provided with reliable decoupling devices at their load centers to ensure fault interruption prior to any penetration damage. All cables having safety-related functions are separated from their redundant counterparts in different penetration assemblies.

7.1.2.5 Conformance To IEEE-323

IEEE 323-1971 applies to equipment purchased before November 15, 1974, and IEEE 323-1974 applies to equipment purchased on or after November 15, 1974.

Written procedures and responsibilities are developed for the design and qualification of all Class 1 electric equipment. This includes preparation of specifications, qualification procedures, and documentation for Class 1 equipment. Qualification testing or analysis is accomplished prior to release of the engineering design for production. Standards manuals are maintained containing specifications, practices, and procedures for implementing qualification requirements; and an auditable file of qualification documents is available for review.

7.1.2.6 Conformance To IEEE-336

The implementation of the Quality Assurance Procedures for construction activities ensures compliance with the requirements of IEEE 336-1971.

7.1.2.7 Conformance To IEEE-338 and Regulatory Guide 1.22

For a more detailed description of conformance, for all safety- related systems, see Subsections 7.2.2, 7.3.2, 7.4.2, and 7.6.2.

7.1.3 Protection System Inservice Testability

This section is provided to describe the analog transmitter/trip unit (AT/TU) system. The AT/TU system is a plant protection system testability feature generically applied to the reactor protection (trip) system, ESF systems, and the RCIC system.

The AT/TU system provides highly accurate continuous monitoring of process parameters, excellent setpoint stability, and convenient on-line testability.

For additional testability discussions, refer to Topical Report NEDO-21617-A, dated December 1978, Analog Transmitter/Trip Unit System for Engineered Safeguard Sensor Inputs (Reference 1).

7.1.3.1 General Description

The AT/TU system uses analog instrument channels to monitor important plant variables (e.g., reactor water level, reactor pressure, drywell pressure, and process flow). The analog transmitter converts the process variable sensed to a 4- to 20-mA linear signal. The signal is transmitted to electronic trip units located on the fourth floor of the auxiliary building. The trip units compare the transmitted signal with a fixed reference signal (setpoint). When the transmitted signal increases above or decreases below the setpoint, the trip unit activates an associated relay. The relay provides either open or closed contacts on activation.

The trip units consist of master trip assemblies, slave trip assemblies, and calibration units. The master trip unit is a plug-in printed circuit assembly designed to accept a 4- to 20-mA signal from a remote transmitter. The trip unit contains the circuitry necessary to condition the transmitter current, compare with the setpoint, provide trip output, and provide analog output signals. An alarm is generated by an inoperative or out-of- service trip unit. The master trip unit also contains a panel meter that displays transmitter current and is scaled in the units of the process variable being measured by the transmitter wired to the master trip unit. A switch position selection internal to the master trip unit allows for selection of either high trip point or low trip point. This allows the testing of trip circuitry for a particular channel with the trip circuitry either energized or deenergized during normal operation.

The slave trip unit is used in conjunction with a master trip unit when different setpoints from a common transmitter are desired. The slave trip unit receives its input signal from the analog output of a master trip unit. There is no direct connection to any 4- to 20-mA transmitter. No analog output signals are generated by the slave unit. Calibration of the slave unit is accomplished by commanding the master trip unit, which drives the slave unit under test into the calibration mode, and then performing the normal calibration procedure.

The calibration unit furnishes the means by which an in-place calibration check of the master and slave trip units can be performed. The calibration unit contains a stable current source and a transient current source. The stable current source is used to verify the calibration point of any given channel. The transient current source is used to provide step current input into a selected trip unit so that the response time of that channel can be determined.

During calibration, the trip action is displayed on the removable display assembly. The accuracy of the analog output of the master trip unit may also be checked during the calibration procedure with an external meter or recorder.

7.1.3.2 Analysis

For a discussion of conformance with regulatory guides and IEEE standards, see Reference 1.

UPDATED FINAL SAFETY ANALYSIS REPORT

FIGURE 7.1-5

HIGH PRESSURE ECCS - HPCI AND ADS NETWORK

7.2 REACTOR PROTECTION SYSTEM

7.2.1 Description

7.2.1.1 Reactor Protection System Instrumentation and Control System Description

7.2.1.1.1 System Identification

7.2.1.1.1.1 Identification

The reactor protection system (RPS) includes the motor-generator power supplies, sensors, relays, bypass circuitry, and switches that cause rapid insertion of control rods (scram) to shut down the reactor. It also includes outputs to the Integrated Plant Computer System (IPCS) and annunciators, although these latter two systems are not part of the RPS. Trip functions are summarized in Figure 7.2-1.

A completely redundant capability, the alternate rod insertion function of the control rod drive (CRD) system is provided to mitigate anticipated transient without scram (ATWS) events (see Subsection 7.6.1.18).

7.2.1.1.1.2 Classification

The RPS is classified as Safety Class 2, Category I, and Quality Group B.

7.2.1.1.1.3 Reference Design

The Fermi 2 RPS is similar, except for system size, to the Edwin I. Hatch, Unit 1 RPS. There are no differences other than those instrument panel locations within the plant and manual scram logic arrangement.

7.2.1.1.2 Power Sources

The RPS receives power from two high-inertia ac motor-generator sets (Figure 7.2-2). A flywheel provides high inertia sufficient to maintain voltage and frequency within 5 percent of rated values for at least 1 sec following a total loss of power to the drive motor.

Alternate power is available to reach the RPS buses. The 120-V ac supply bus A is available to RPS bus A, and the 120-V ac alternate supply bus B is available to RPS bus B.

The RPS power supplies have been modified to prevent the inadvertent application of out-of-tolerance voltage or frequency power to the RPS relay trip logic. The electrical protection assembly consists of a GE type TFJ-175A circuit breaker with an under-voltage release controlled by a protection logic circuit card. The protection logic disconnects the RPS logic from the RPS power supply whenever voltage or frequency exceeds normal tolerances.

The protection is redundant and includes each alternate power supply, as shown in Figure 7.2-2. The electrical protection assemblies (EPA) are packaged in enclosures that are mounted seismically on the outside wall of each RPS motor-generator set cubicle. Two assemblies are connected in electrical series between each source of RPS power and the respective RPS distribution panel. Controls for testing and operation are provided on each assembly along with status indication for the particular trip parameters. Following a trip, the breaker must be reset locally.

The EPA's are qualified to meet IEEE 344-1975 and IEEE 323-1974.

The EPA trip setpoints are within $\underline{+}$10 percent of nominal ac voltage and -5 percent of the nominal frequency of 60 Hz.

Each protection logic has an independent time delay adjustable from 0.3 to 3.6 sec to prevent spurious trips and the resulting scrams.

7.2.1.1.3 Equipment Design

7.2.1.1.3.1 Initiating Circuits

Neutron monitoring system (NMS) instrumentation is described in Section 7.6. Figure 7.2-3 clarifies the relationship between NMS channels, NMS logics, and the RPS logics. The NMS channels are part of the NMS. The NMS logics are part of the RPS. As shown in Figure 7.2-4, there are four NMS logics associated with each trip system of the RPS. Each RPS logic receives inputs from two NMS logics. Each NMS logic receives signals from one intermediate range monitor (IRM) channel and one average power range monitor (APRM) voter channel. The position of the mode switch determines which input signals effect the output signal from the logic. The NMS logics are arranged so that failure of any one logic cannot prevent the initiation of a high neutron flux scram. The RPS logic is a "one-out-of-two-taken-twice" system as discussed in Subsection 7.2.l.l.3.2.

Reactor pressure is measured at two locations. A pipe from each location is routed through the primary containment and terminates in the reactor building. Two panel-mounted pressure transmitters monitor the pressure in each pipe. Cables from these transmitters are routed to the main control room. One pair of the transmitters is physically separated from the other pair. Each transmitter provides a high-pressure signal to one channel. The transmitters are arranged so that two transmitters provide an input to trip system A and two transmitters provide an input to trip system B, as shown in Figure 7.2-5. The physical separation and the signal arrangement ensure that no single physical event can prevent a scram caused by nuclear system high pressure.

Reactor pressure vessel (RPV) low-water-level signals are initiated from differential pressure transmitters that sense the difference between the pressure due to a constant reference column of water and the pressure due to the actual water level in the vessel. A reference leg backfill system provides a continuous flow of water from the CRD charging header to the reactor water level reference legs. This flow prevents accumulation of non-condensable gases in the reference leg, and the associated erroneous high water level indication which could result from degassing in the reference leg upon system depressurization. The transmitters are arranged on two sets of taps in the same way as the nuclear system high pressure transmitters (Figure 7.2-5).

Two instrument lines attached to taps on the RPV, one above and one below the water level, are required for the differential pressure measurement for each transmitter. The two pairs of lines terminate outside the primary containment and inside the reactor building. They are physically separated from each other and tap off the RPV at widely separated points. Other systems sense pressure and level from these same pipes. The physical separation and signal arrangement ensure that no single physical event can prevent a scram due to RPV low water level.

Turbine stop valve closure inputs to the RPS come from valve stem position switches mounted on the four turbine stop valves. To provide the earliest positive indication of closure, each of the double-pole, double-throw switches opens before the valve is more than 10 percent closed. Either of the two channels associated with one stop valve can signal valve closure, as shown in Figure 7.2-6. The logic is arranged so that closure of three or more stop valves initiates a scram, when the reactor is operating above 29.5 percent of rated power.

Turbine control valve fast closure inputs to the RPS come directly from contacts of the relays that effect control valve fast closure. Operation of any two of these relays will initiate control valve fast closure. Fast closure of one control valve in each RPS logic will initiate a scram whenever the reactor is operating above 29.5 percent of rated power.

Position switches mounted on the eight main steam isolation valves (MSIVs) signal MSIV closure to the RPS. To provide the earliest positive indication of closure, each of the double-pole, double-throw switches is arranged to open before the valve is more than 10 percent closed. Either of the two channels associated with one isolation valve can signal valve closure. To facilitate the description of the logic arrangement, the position-sensing channels for each valve are identified and assigned to RPS logics as follows:

Valve Identification	Position-Sensing Channels	Trip Channel Relays	Assignments
Main steam line A, inboard valve	F022A (1) and (2)	A, B	A1, B1
Main steam line A, outboard valve	F028A (1) and (2)	A, B	A1, B1
Main steam line B, inboard valve	F022B (1) and (2)	E, D	A1, B2
Main steam line B, outboard valve	F028B (1) and (2)	E, D	A1, B2
Main steam line C, inboard valve	F022C (1) and (2)	C, F	A2, B1
Main steam line C, outboard valve	F028C (1) and (2)	C, F	A2, B1
Main steam line D, inboard valve	F022D (1) and (2)	G, H	A2, B2
Main steam line D, outboard valve	F028D (1) and (2)	G, H	A2, B2

Thus, each logic receives signals from the valves associated with two steam lines as shown in Figure 7.2-7. The arrangement of signals within each logic requires closing of at least one valve in each of the steam lines associated with that logic to cause a trip of that logic. For example, closure of the inboard valve of steam line A and the outboard valve of steam line C causes a trip of logic B1. This in turn causes trip system B to trip. No scram occurs because no trips occur in trip system A. In no case does closure of two valves or isolation of two steam lines cause a scram due to valve closure. Closure of one valve in any three steam lines causes a scram.

Wiring for the position-sensing channels from one position switch is physically separated in the same way that wiring to duplicate sensors on a common process tap is separated. The wiring for position-sensing channels feeding the different trip logics of one trip system is also separated.

The MSIV closure scram function is effective only if the reactor mode switch is in RUN.

The effects of the logic arrangement and separation provided for the MSIV closure scram are as follows:

a. Closure of one valve for test purposes with one steam line already isolated will not cause a scram resulting from valve closure

b. Automatic scram will occur on isolation of any three steam lines

c. No single failure can prevent an automatic scram required for fuel protection due to MSIV closure.

Four nonindicating level switches (one for each channel) provide scram discharge volume (SDV) high-water-level inputs to the four RPS channels. An additional level-indicating switch (trip unit), with transmitter, in each channel is redundant to the level switch in that channel. This arrangement provides diversity to ensure that no single event could prevent a scram caused by SDV high water level. With the scram setting listed in Table 7.2-1 and in the Technical Specifications, a scram is initiated when sufficient capacity remains in the SDV to accommodate a scram. Both the amount of water discharged and the volume of air trapped above the free surface during a scram have been considered in the selection of the trip setting.

Drywell pressure is monitored by four pressure transmitters as described in Subsection 7.3.2.2.8.f. The transmitters are physically separated and electrically connected to the RPS so that no single failure can prevent a scram caused by primary containment high pressure.

Main condenser low vacuum trip will be effected indirectly through main steam line isolation. A main condenser vacuum of approximately 7 PSIA will cause steam line isolation valve closure, which in turn causes reactor trip.

Four turbine first-stage pressure transmitters are provided to initiate the automatic bypass of the turbine control valve fast closure and turbine stop valve closure scrams when the first-stage pressure is below some preset fraction of rated pressure corresponding to 29.5 percent of rated power. The transmitters are arranged so that no single failure can prevent a turbine stop valve closure scram or turbine control valve fast closure scram.

Channel and logic relays are fast-response, high-reliability relays. Power relays for interrupting the scram pilot valve solenoids are magnetic contactors. The system response time, from the opening of a sensor contact up to and including the opening of the trip actuator contacts, is less than 50 msec. The time requirements for control rod movement are discussed in Subsection 4.5.2.

Sensing elements have enclosures to withstand conditions resulting from a steam or water line break long enough to perform satisfactorily. Environmental specifications for the instruments of the RPS are given in Table 3.11-1.

To gain access to those calibration and trip setting controls located outside the main control room, operations personnel must remove a cover plate, access plug, or sealing device before any trip setting can be adjusted.

Wiring for the RPS, outside of the enclosures in the main control room, is run in rigid metallic conduits used for no other wiring. The wires from duplicate sensors on a common process tap are run in separate conduits. Wires from sensors of different variables in the same RPS logic can be run in the same conduit.

The scram pilot valve solenoids are powered from eight actuator logic circuits, four circuits from trip system A and four from trip system B. The four circuits associated with any one trip system are run in separate conduits.

Electrical panels, junction boxes, and components of the RPS are prominently identified by nameplates. Circuits entering junction boxes or pull boxes are conspicuously marked inside the boxes. Wiring and cabling outside cabinets and panels are identified by color, tag, or other conspicuous means.

7.2.1.1.3.2 Logic

The basic arrangement of the RPS actuators and actuator logic is illustrated in Figure 7.2-8. The system is arranged as two separately powered trip systems. Each trip system has two automatic trip logics, as shown in Figure 7.2-9. Each logic used for automatic trip receives input signals from at least one channel for each monitored variable. At least four channels for each monitored variable are required, one for each of its four automatic trip logics.

Each automatic trip logic provides two inputs into each of the actuator logics of one trip system, as shown in Figure 7.2-8. Thus, either of the two automatic trip logics associated with one trip system can produce a trip-system trip. The logic is a "one-out-of-two" arrangement. To produce a scram, the actuator logics of both trip systems must be tripped. The overall logic of the RPS is termed "one-out-of-two taken twice."

7.2.1.1.3.3 Scram Bypasses

A number of manual and automatic scram bypasses are provided. These account for the varying protection requirements that depend on reactor conditions. They also allow for instrument service during reactor operations. All manual bypass switches are in the main control room under the direct control of the main control room operator. The bypass status of trip system components is continuously indicated in the main control room.

To properly reset the RPS at plant shutdown and during initial plant startup, a bypass is required for the MSIV closure scram trip. This bypass has been designed to be in effect when the mode switch is in the SHUTDOWN, REFUEL, or STARTUP position.

Hence, the bypass is necessary to provide for proper RPS reset action whenever the MSIVs are closed during very low power operation.

In the terms of the power generation design bases, the actual pressure scram setpoint is established from considerations of reducing reactor overpressure in the event of isolation at high power levels.

Since the high-pressure scram and reactor relief valves provide protection against overpressure, there would be no safety problem if the reactor were held at normal operating pressure and at a low power level with the MSIVs closed.

The scram initiated by placing the mode switch in SHUTDOWN is automatically bypassed after a short time delay. The bypass allows the CRD hydraulic system valve lineup to be restored to normal. An annunciator in the main control room indicates the bypassed condition. The turbine control valve fast closure scram and turbine stop valve closure scram are automatically bypassed if the turbine first-stage pressure is less then 29.5 percent of rated power. Closure of these valves from a low initial power level does not threaten the integrity of any radioactive material release barrier.

Turbine and generator trip bypass is effected by four pressure switches associated with the turbine first stage. Any one channel in a bypass state produces a main control room annunciation.

Bypasses for the NMS channels are described in Subsection 7.6.1.13.

The scram discharge high water level trip bypass is controlled by the manual operation of two keylocked switches, a bypass switch, and the mode switch. The mode switch must be in either the SHUTDOWN or the REFUEL position. Four bypass channels emanate from the four banks of the RPS mode switch and are each connected into the RPS logic. This bypass allows the operator to reset the RPS scram relays so that the system is restored to operation while the operator drains the scram discharge volume. In addition, actuating the bypass initiates a control rod block. Resetting the trip actuators opens the scram discharge volume vent and drain valves. An annunciator in the main control room indicates the bypass condition.

The RPS reset switch is used to momentarily bypass the seal-in contacts of the final actuators of the reactor shutdown systems. These seal-in contacts are located downstream from the protection channel outputs. The reset is effected in conjunction with auxiliary relays. If a single channel is tripped, the reset is accomplished immediately upon operation of the reset switch. On the other hand, if a reactor scram situation is present, manual reset is prohibited for a 10-sec period to permit the control rods to achieve their fully inserted position.

7.2.1.1.3.4 Interlocks

The scram discharge volume high-water-level trip bypass signal interlocks with the reactor manual control system (RMCS) to initiate a rod block. The interlock is performed using isolating relay contacts so that no failure in the control system can prevent a scram.

The RPV low water level, primary containment high pressure, and turbine stop valve position signals are shared with the primary containment and reactor vessel isolation-control system

(CRVICS). The sensors feed sensor relays in the RPS. Contacts from these relays interlock to the primary containment and reactor vessel isolation system.

7.2.1.1.3.5 Redundancy and Diversity

The RPS is divided into two divisions. Each division duplicates the function of the other to the extent that either may perform the required function regardless of the state of operation or failure of the other.

Functional diversity is provided by monitoring dependent RPV variables. Pressure, water level, and neutron flux are all interdependent and are separate inputs to the system. Also, MSIV closure, turbine stop valve closure, and turbine control valve fast closure are anticipatory of an RPV high pressure and are separate inputs to the system.

7.2.1.1.3.6 Actuated Devices

The actuator logic opens when a trip signal is received, and then deenergizes the scram valve pilot solenoids. There are two pilot solenoids per control rod. Both solenoids must deenergize to open the inlet and outlet scram valves to allow drive water to scram a control rod. One solenoid receives its signal from trip system A and the other from trip system B. The failure of one control rod to scram will not prevent a complete shutdown.

The individual control rods and their controls are not part of the RPS. Further information on the scram valves and control rods is contained in Subsection 4.5.2.

7.2.1.1.3.7 Separation

Four sensor channels monitor these various process variables listed in Subsection 7.2.1.1.3.1. Separation criteria for the sensors are given in Section 3.12. The sensor devices are separated in such a way that no single failure can prevent a scram. All protection system wiring outside the control system cabinets is run in rigid metal conduit. Six physically separated cabinet bays are provided for the four scram logics. Where two RPS channels of the same trip system enter the same bay they are separated by barriers.

The mode switch, scram discharge volume high-water-level trip bypass switch, scram reset switch, and manual scram switch are all mounted on one control panel. Each device is mounted in a can and has a sufficient number of barrier devices to maintain adequate separation. Conduit is provided from the cans to the logic cabinets.

The outputs from the logic cabinets to the scram valves are run in four conduits for trip system A and four conduits for trip system B. The four conduits match the four scram groups shown in Figure 7.2-2. The groups are selected so that the failure of one group to scram will not prevent a reactor shutdown.

7.2.1.1.3.8 Testability

The RPS can be tested during reactor operation by six separate tests. The first of these is the manual actuator test. By depressing the manual scram button for one trip channel, the manual actuators are deenergized, opening contacts in the actuator logics. After the first trip channel is reset, the remaining three manual trip channels are tested sequentially in a similar manner. The total test verifies the ability to deenergize all eight groups of scram pilot valve solenoids by using the manual scram pushbutton switches. In addition to main control room and sequence recorder indications, scram group indicator lights verify that the actuator contacts have opened.

The second test is the automatic actuator test. It is accomplished by operating the keylocked test switches one at a time for each automatic logic. The switch deenergizes the actuators for that logic and causes the associated actuator contacts to open. The test verifies the ability of each logic to deenergize the actuator logics associated with the parent trip system. In addition to annunciator and sequence recorder indications, the actuator and contact action can be verified by observing the physical position of these devices.

The third test includes calibration of the NMS by means of simulated inputs from calibration logic. Subsection 7.6.1.13 describes the calibration procedure.

The fourth test is the single rod scram test, which verifies capability of each rod to scram. It is accomplished by operating a toggle switch on the RPS test cabinet in the control center particular CRD. Timing traces can be made for each rod scrammed. Prior to the test, a physics review must be conducted to ensure that the rod pattern during scram testing will not create a rod of excessive reactivity worth.

The fifth test involves applying a test signal to each RPS channel in turn and observing that a logic trip results. The test signals can be applied to the process type sensing instruments (pressure and differential pressure) through calibration taps.

The sixth test involves applying a test signal to each RPS trip channel associated with the CRD Scram Discharge Volume High Water Level, Drywell High Pressure, Reactor High Pressure, Reactor Low Water Level, and NMS Trip and observing a trip relay contact closure using the RPS Test Box (RTB). The RTB lamp connected across the contacts of the trip relay during the functional test maintains circuit continuity and keeps the RPS Scram contactors energized while monitoring the status of the trip relay contacts (open/closed).

RPS response times are verified on a channel basis during preoperational testing and can be verified thereafter by similar tests with exception to the sensors. The neutron flux and radiation sensors, the primary sensor response time is included in the measurement of overall channel response time. This measured response time is added to an allowance for instrument line delay, as appropriate, for each application. This approach is consistent with the definition of response time, which is the maximum allowable time from when the variable being measured just exceeds the trip setpoint to the deenergizing of the control rod scram solenoids. The applicable test criterion is that the adjusted test-based value must not exceed the value used for the safety analysis.

During preoperational testing, and subsequently on a surveillance basis, the sensor response time was measured using a hydraulic ramp-test method similar to that described in Electric Power Research Institute Report No. NP-267, Sensor Response Time Verification. To the results of this measurement is added the delay for instrument line length as appropriate for each application. Also, the noise analysis method can be used for the sensor response verification.

The periodic response time testing for the reactor vessel steam dome pressure-high and the reactor vessel low water level-L3 have been eliminated. The BWROG Report NEDO-32291A and Supplement 1 provide the required analyses as briefly described in 7.2.1.1.3.8.1.

The response time of the trip comparators and trip delays is determined using the transient current source test method described in NEDO 21617-A, Analog Transmitters/Trip Unit System for Engineered Safeguard Sensor Trip Inputs. This test is performed as part of the preoperational test.

The balance of the RPS channel logic response time is tested using accepted methods that are documented in existing preoperational test procedures.

The reactor protection system instrumentation response times are shown in Technical Requirements Manual Volume I Table 3.3.1.1-1, which is referenced in UFSAR Table 7.2-4. Response time testing is required by the Technical Specifications. Technical Specification Table 3.3.1-2 was deleted from the Technical Specifications and added to the UFSAR as Table 7.2-4 (TRM Table 3.3.1.1-1) in agreement with NRC Generic Letter 93-08 and Amendment Number 100 to the Technical Specifications. The response times information of UFSAR Table 7.2-4 was then relocated to the Technical Requirements Manual Volume I.

7.2.1.1.3.8.1 Elimination of Response Time Testing

The elimination of selected response time testing requirements are supported by the analyses performed by the Boiling Water Reactor Owner's Group (BWROG) report. The BWROG report demonstrated that other periodic tests required by Technical Specifications (TS), such as channel calibrations, channel checks, channel functional tests, and logic system functional tests provide adequate assurance that instrument response times are within acceptable limits. The evaluation is documented in NEDO-32291A and Supplement 1, "System Analyses for Elimination of Selected Response Time Testing Requirements." The analyses assert that the response time tests are of little safety significance and result in unnecessary personnel radiation exposure, reduced availability of systems during plant shutdown, increased potential for inadvertent actuations of safety systems, and a significant burden to utility resources.

The basis for eliminating response time testing is consistent with Regulatory Guide 1.118 (Revision 2) which endorses IEEE 338-1977 which states:

> "Response time testing of all safety equipment, per se, is not required if, in lieu of response time testing, the response time of safety system equipment is verified by functional testing, calibration checks or other tests, or both. This is acceptable if it can be demonstrated that changes in response time beyond acceptable limits are accompanied by changes in performance characteristics which are detectable during routine periodic tests."

NEDO-32291A and Supplement 1 identify the potential failure modes of components in the affected instrumentation loops which could potentially impact the instrument loop response time. In addition, industry operating experience was reviewed to identify failures that affect response times and how they were detected. The failure modes identified were then evaluated to determine if the effect on response time would be detected by other testing requirements contained in TS. The results of this analysis demonstrate that other TS testing requirements (channel calibrations, channel checks, channel functional tests, and logic system functional tests) are sufficient to identify failure modes or degradations in instrument response times and assure operation of the analyzed instrument loops within acceptable limits. Furthermore, there were no failure modes identified that can be detected by response time testing that cannot also be detected by other TS-required tests.

A BWROG survey has concluded that instrument response time delays of 5 seconds can be reasonably detected by instrument technicians. A safety evaluation has confirmed that a 5-second increase in the response time of individual specific functions has a very low safety significance. This realistic bases evaluation showed that significant margin exists in the licensing analysis.

Within the trip function, redundancy exists in most safety trip functions (e.g., neutron flux, water level, drywell pressure). Also for most of these instruments, the response times are insignificant compared to the system actuation times.

NEDO-32291A and Supplement 1 are applicable to Fermi 2 and the affected components are evaluated in NEDO-32291A and Supplement 1. The vendors do not require periodic response time testing for these components. Fermi is in compliance with the guidelines of Supplement 1 to NRC Bulletin 90-01.

The recommendations from EPRI NP-7243 "Investigation of Response Time Testing Requirements" are:

1. The response time testing is required after replacing or refurbishing the transmitter (e.g., sensor cell, or variable damping) prior to returning the transmitters to service.
2. The transmitters that utilize capillary tubes are not used in any application that requires response time testing.

Furthermore, the technicians are in direct communication to verify that the response of the transmitter to the step input change or fast ramp is prompt, and in all cases less than five seconds. During this excursion, the transmitter/instrument loop is monitored for sluggishness or erratic operation that would be indicative of degraded transmitter/instrument loop performance.

The sensor response time may be assumed to be the design sensor response time. This will allow Fermi 2 to use manufacturer response time data and eliminate the requirement for a separate measurement of the sensor response time. Prior to return to service of a new transmitter or following refurbishment of a transmitter (e.g., sensor cell or variable damping components), a hydraulic response time test will be performed to determine an initial sensor-specific response time value.

7.2.1.1.4 Environmental Considerations

Electrical modules for the RPS are located in the primary containment, in the reactor building, and in the turbine building. The environmental conditions for these areas are shown in Tables 3.11-1 and 3.11-4.

Cabling for the RPS will be run in conduit or in an enclosed ferromagnetic cable tray. Separation will be in accordance with Section 3.12 and Subsection 8.3.1.

7.2.1.1.5 Operational Considerations

7.2.1.1.5.1 Normal

During normal operation, all sensor and trip contacts essential to safety are closed; channels, logics, and actuators are energized. In contrast, however, trip contact bypass channels consist of normally open contact networks that close to bypass.

7.2.1.1.5.2 Scram Functions

The following paragraphs discuss the functional considerations for the variables or conditions monitored by the RPS. Table 7.2-1 lists the preliminary specifications for instruments that provide signals for the system. Figure 7.2-1 summarizes the locations from which the RPS may receive a signal that causes a scram.

There are two pilot scram valves and two scram valves for each control rod, arranged as shown in Figure 7.2-2. Each pilot scram valve is solenoid operated, with the solenoids normally energized. The pilot scram valves control the air supply to the scram valves for each control rod. When either pilot scram valve is energized, air pressure holds the scram valves closed. The scram valves control the supply and discharge paths for CRD water. As shown in Figure 7.2-2, one of the scram pilot valves for each control rod is controlled by actuator logics A, and the other valve is controlled by actuator logics B. There are two dc solenoid-operated backup scram valves that provide a second means of controlling the air supply to the scram valves for all control rods. The dc solenoid for each backup scram valve is normally deenergized. The backup scram valves are energized (initiate scram) when trip systems A and B are both tripped.

The functional arrangement of sensors and channels that constitute a single logic is shown in Figure 7.2-2. A simplified logic schematic is included in Figure 7.2-9. When a channel sensor contact opens, its sensor relay deenergizes, causing contacts in the logic to open. The opening of contacts in the logic deenergizes its actuators. When deenergized, the actuators open contacts in all of the actuator logics for that trip system. This action results in deenergizing the scram pilot valve solenoids associated with that trip system (one scram pilot valve solenoid for each control rod). However, the other scram pilot valve solenoid for each rod must also be deenergized before the rods can be scrammed.

If a trip also occurs in any of the logics of the other trip system, the remaining scram pilot valve solenoid for each rod is deenergized. This permits the air to vent from the scram valves and allows CRD drive water to act on the CRD piston. Thus, all control rods are scrammed. The water displaced by the movement of each rod piston is vented into a scram discharge volume. When the solenoid for each backup scram valve is energized, the backup scram valves vent the air supply for the scram valve. This action initiates insertion of any errant control rods regardless of the action of the scram pilot valves (Figure 7.2-2).

A scram can be initiated manually. There are two sets of manual scram pushbuttons located on the surface of the main operating panel. The first set associated with logics A1 and B1 is located directly above the control rod pushbutton matrix on the "A" surface of the reactor control panel as shown on Figure 7.5-1. A second set of pushbuttons associated with logics A2 and B2 is located on the "B" surface of the reactor control panel as shown in Figure 7.5-1.

These pushbuttons are approximately 21 in. apart and 12 in. from the first set of the manual scram pushbuttons. Each of the four manual scram pushbuttons is individually canned and the control wiring is run in conduit within the control panel. To cause a manual scram, at least one button in each trip system must be depressed.

The manual scram pushbuttons in the first set are close enough to permit one hand motion to initiate the scram. By operating the manual scram button for one logic at a time and then resetting that logic, each actuator logic can be tested for manual scram capability. The reactor operator also can scram the reactor by interrupting power to the reactor protection system or by placing the mode switch in its shutdown position.

To restore the RPS to normal operation following any single trip system trip or scram, the actuators must be reset manually. The actuators can be reset only after a 10-sec delay, and only if the conditions that caused the scram have been cleared. The actuators are reset by operating switches in the main control room. Figure 7.2-2 shows the functional arrangement of reset contacts for trip system A.

When an RPS sensor trips, it lights a printed red annunciator window, common to all the channels for that variable, which indicates the out-of-limit variable. This window is located on the reactor control panel in the main control room. Each trip system lights a red annunciator window which indicates which trip system has tripped. An RPS channel trip also sounds a buzzer or horn that can be silenced by the operator. The annunciator window lights latch in until the initiating contact is reset. Reset is not possible until the condition causing the trip has been cleared. A sequence-of-events recorder identifies each tripped channel; however, the physical position of the RPS relays may also be used to identify the individual sensor that tripped in a group of sensors monitoring the same variable. The location of alarm windows permits the operator to quickly identify the cause of RPS trips and to evaluate the threat to the fuel or nuclear system process barrier.

All RPS trip events are recorded on a sequence-of-events recorder that includes nuclear steam supply system (NSSS) inputs. This record permits analysis of operational transient events that occur too rapidly for operator recognition.

The sequence-of-events recorder provides the time and alarm type of each event and can resolve the order of occurrence down to 1 msec. A lesser time difference causes the events to be treated as simultaneous.

Use of the events recorder is not required for plant safety. The printout of trips is particularly useful in routinely verifying the correct operation of pressure, level, and valve position switches as trip points are passed during startup, shutdown, and maintenance operations.

Reactor protection system inputs to annunciators, recorders, and the computer are arranged so that no malfunction of the annunciating, recording, or computing equipment can functionally disable the RPS. Direct signals from RPS sensors are not used as inputs to annunciating or data-logging equipment. Relay contact isolation is provided between the primary signal and the information output.

7.2.1.1.5.3 Operation Information

Indicators

Indicators are installed in the manual scram switches to indicate a trip system manual trip. Scram group indicators extinguish when an actuator logic opens. Process indicators for all RPS trip variables are available in the main control room.

Annunciators

Each RPS input is provided to the annunciator system through isolated relay contacts. Manual and automatic trip system trips also signal the annunciator system.

7.2.1.1.5.4 Setpoints

Nominal values for trip system setpoints are summarized in Table 7.2-1.

In response to the NRC letter from J. F. Stolz to W. H. Jens dated April 12, 1977, that defined specific requirements for instrument trip setpoint values, Edison has instituted a formal program with the cooperation of GE to develop the required technical data. The referenced setpoint data are presently included in the Technical Specifications.

Neutron Monitoring System Trip

To protect the fuel against high heat generation rates, neutron flux is monitored and used to initiate a reactor scram. The NMS setpoints and their bases are discussed in Subsection 7.6.1.13.

Nuclear System High Pressure

High pressure within the nuclear system threatens to rupture the nuclear system process barrier. A nuclear system pressure increase during reactor operation compresses the steam voids and results in a positive reactivity insertion. This causes increased core heat generation that could lead to fuel failure and system overpressurization. A scram counteracts a pressure increase by quickly reducing core fission heat generation. The nuclear system high-pressure scram setting is chosen slightly above the RPV maximum normal operating pressure to permit normal operation without spurious scram, yet provides a wide margin to the maximum allowable nuclear system pressure. The location of the pressure measurement, as compared to the location of highest nuclear system pressure during transients, has also been considered in the selection of the high-pressure scram setting. The nuclear system high-pressure scram setting also protects the core from exceeding thermal-hydraulic limits due to pressure increases during events that occur when the reactor is operating below rated power and flow.

Reactor Vessel Low Water Level

Low water level in the RPV indicates that the fuel is in danger of being inadequately cooled. Decreasing the water level while the reactor is operating at power decreases the reactor coolant inlet subcooling. The effect is the same as raising feedwater temperature. Should water level decrease too far, fuel damage could result. A reactor scram protects the fuel by reducing the fission heat generation within the core. The RPV low-water-level scram setting has been selected to prevent fuel damage following abnormal operational transients. These transients are caused by either single equipment malfunctions or single operator errors, and result in a decreasing RPV water level. The scram setting is far enough below normal operational levels to avoid spurious scrams. The setting is high enough above the top of the active fuel to ensure that enough water is available to account for evaporation loss and displacement of coolant following the most severe abnormal operational transient involving a level decrease. The selected scram setting was used in developing thermal-hydraulic limits. The limits set operational limits on the thermal power level for various coolant flow rates.

Turbine Stop Valve Closure

Closure of the turbine stop valve with the reactor at power can result in a significant addition of positive reactivity to the core as the nuclear system pressure rise causes steam voids to collapse. The turbine stop valve closure scram initiates a scram earlier than does either the NMS or nuclear system high pressure. It provides a satisfactory margin below core thermal-hydraulic limits for this category of abnormal operational transients. The scram counteracts the addition of positive reactivity resulting from increasing pressure by inserting negative reactivity with control rods. Although the nuclear system high-pressure scram, in conjunction with the pressure relief system, is adequate to preclude overpressurizing the nuclear system, the turbine stop valve closure scram provides additional margin to the nuclear system pressure limit. The turbine stop valve closure scram setting provides the earliest positive indication of valve closure.

Turbine Control Valve Fast Closure

With the reactor and turbine generator at power, fast closure of the turbine control valves can result in a significant addition of positive reactivity to the core as nuclear system pressure rises. The turbine control valve fast closure scram initiates a scram earlier than either the NMS or nuclear system high pressure. It provides a satisfactory margin to core thermal-hydraulic limits for this category of abnormal operational transients. The scram counteracts the addition of positive reactivity resulting from increasing pressure by inserting negative reactivity with control rods. Although the nuclear system high-pressure scram, in conjunction with the pressure relief system, is adequate to preclude overpressurizing the nuclear system, the turbine control valve fast closure scram provides additional margin to the nuclear system pressure limit. The turbine control valve fast closure scram setting is selected to provide timely indication of control valve fast closure.

Main Steam Line Isolation

The MSIV closure scram protects the reactor on loss of the heat sink. The MSIV closure initiates scram earlier than the NMS or nuclear system high pressure. Automatic closure of the MSIVs is initiated when conditions indicate a steam line break. The main steam line isolation scram setting is selected to give the earliest positive indication of isolation valve closure. The logic allows functional testing of main steam line trip channels with one steam line isolated.

Scram Discharge Volume High Water Level

Water displaced by the CRD pistons during a scram goes to the scram discharge volume. If the scram discharge volume fills with the water so that insufficient capacity remains for the water displaced during a scram, control rod movement would be hindered during a scram. To prevent this situation, the reactor is scrammed when the water level in the discharge volume is filling up, yet is low enough to ensure that the remaining capacity in the volume can accommodate a scram.

Primary Containment High Pressure

High pressure inside the primary containment may indicate a break in the nuclear system process barrier. It is prudent to scram the reactor in such a situation, to minimize the possibility of fuel damage and to reduce energy transfer from the core to the coolant. The drywell high-pressure scram setting is selected to be as low as possible without inducing spurious scrams.

Manual Scram

Pushbuttons are located in the main control room to enable the operator to shut down the reactor by initiating a scram.

Mode Switch in SHUTDOWN

When the mode switch is in SHUTDOWN, the reactor is to be shut down with all control rods inserted. This scram is not considered a protective function because it is not required to protect the fuel or nuclear system process barrier, and it bears no relationship to minimizing the release of radioactive material from any barrier. The scram signal is removed after a short delay, permitting a scram reset that restores the normal valve lineup in the CRD hydraulic system.

7.2.1.1.5.5 Mode Switch

A conveniently located, multiposition, keylock mode switch is provided to select the necessary scram functions for various plant conditions. The mode switch selects the appropriate sensors for scram functions and provides appropriate bypasses. The switch also interlocks such functions as control rod blocks and refueling equipment restrictions, which are not considered here as part of the RPS. The switch is designed to provide separation between the two trip systems. The mode switch positions and their related scram functions are

a. SHUTDOWN - Initiates a reactor scram; bypasses main steam line isolation scram

b. REFUEL - Selects NMS scram for low neutron flux level operation; bypasses main steam line isolation scram

c. STARTUP - Selects NMS scram for low neutron flux level operation; bypasses main steam line isolation scram

d. RUN - Selects NMS scram for power range operation.

7.2.1.2 Design-Basis Information

The design-basis information required by Section 3 of IEEE 279-1971 is provided in Subsection 7.1.2.1.1.

7.2.2 Analysis

7.2.2.1 General

Presented below are analyses to demonstrate how the various general functional requirements and the specific regulatory requirements listed under the RPS design bases described in Subsection 7.1.2.1.1.1 are satisfied. Considerations of loss of instrument air and loss of cooling water to vital equipment are discussed in Chapter 15.

7.2.2.2 Reactor Protection System

7.2.2.2.1 Conformance With General Functional Requirements

The RPS is designed to provide timely protection against the onset and consequences of conditions that threaten the integrity of the fuel barrier and the nuclear system process barrier. Chapter 15 identifies and evaluates events that jeopardize the fuel barrier and nuclear system process barrier. The methods of assessing barrier damage and radioactive material releases, along with the methods by which abnormal events are sought and identified, are presented in that chapter.

Design procedure has been to select tentative scram trip setting such that spurious scrams and operating inconvenience are avoided. It is then verified by analysis that the reactor fuel and nuclear system process barriers are protected. In all cases, the specific scram trip point selected is a value that prevents damage to the fuel or nuclear system process barriers, taking into consideration previous operating experience.

The scrams initiated by NMS variables, nuclear system high pressure, turbine stop valve closure, turbine control valve fast closure, and RPV low water level, prevent fuel damage following abnormal operational transients. Specifically, these scram functions initiate a scram in time to prevent the core from exceeding the thermal-hydraulic safety limit during abnormal operational transients. Chapter 15 identifies and evaluates the threats to fuel integrity posed by abnormal operational events. In no case does the core exceed the thermal-hydraulic safety limit.

The scram initiated by nuclear system high pressure, in conjunction with the pressure relief system, is sufficient to prevent damage to the nuclear system process barrier as a result of internal pressure. For turbine-generator trips, the stop valve closure scram and turbine control valve fast closure scram provide a greater margin to the nuclear system pressure safety limit than does the high pressure scram. Chapter 15 identifies and evaluates accidents and abnormal operational events that result in nuclear system pressure increases. In no case does pressure exceed the nuclear system safety limit.

The scrams initiated by the main steam line MSIV closure, and RPV low water level satisfactorily limit the radiological consequences of gross failure of the fuel or nuclear system process barriers. Chapter 15 evaluates gross failures of the fuel and nuclear system process barriers. In no case does the release of radioactive material to the environs result in exposures that exceed the guideline values of applicable published regulations.

Neutron flux is the only essential variable of significant spatial dependence that provides inputs to the RPS. The basis for the number and locations of neutron flux detectors is discussed in Subsection 7.6.1.13. The other requirements are fulfilled through the combination of logic arrangement, channel redundancy, wiring scheme, physical isolation, power supply redundancy, and component environmental capabilities.

The RPS uses "one-out-of-two-taken-twice" logic. Theoretically, its reliability is slightly higher than a "two-out-of-three" system and slightly lower than a "one-out-of-two" system. The differences can be neglected in a practical sense, however, because they are slight. The dual trip system is advantageous because it can be thoroughly tested during reactor operation without causing a scram. This capability for a thorough testing program significantly increases reliability.

The use of a different channel for each logic input allows the system to sustain any channel failure without preventing other sensors that monitor the same variable from initiating a scram. Any maintenance operation, calibration operation, or test results in only a single trip system trip. This leaves at least two channels per monitored variable capable of initiating a scram. The resistance to spurious scrams contributes to plant safety because reduced cycling of the reactor through its operating modes decreases the probability of error or failure.

When an essential monitored variable exceeds its scram trip point, it is sensed by at least two independent sensors in each trip system. Only one channel must trip in each trip system to initiate a scram. Thus, the arrangement of two channels per trip system ensures that a scram will occur as a monitored variable exceeds its scram setting.

Each control rod is controlled as an individual unit. A failure of the controls for one rod would not affect other rods. The backup scram valves provide a second method of venting the air pressure from the scram valves, even if either scram pilot valve solenoid for any control rod fails to deenergize when a scram is required.

Sensors, channels, and logics of the RPS are not used for control of process systems. Therefore, failure in the instrumentation and control of process systems cannot induce failure of any portion of the protection system.

Failure of either RPS motor-generator set would result, at worst, in a single trip system trip. Alternative power is available to the RPS buses. A complete, sustained loss of electrical power to both buses would result in a scram, delayed by the motor-generator set flywheel inertia.

The environment in which the instruments and equipment of the RPS must operate was considered in setting the environmental specifications given in Tables 3.11-1, 3.11-3, and 3.11-4. The specifications for the instruments located in the reactor or turbine buildings are based on the worst expected ambient conditions.

Design of the system to comply with safety class requirements and the fail-safe characteristics of the system ensure safe shutdown of the reactor during earthquake ground motion. The system fails in a direction that causes a reactor scram only when subjected to extremes of vibration and shock.

To ensure that the RPS remains functional, the number of operable channels for the essential monitored variables is maintained at or above the minimum given in Tables 7.2-2 and 7.2-3. The minimum applies to any untripped trip system; a tripped trip system may have any number of inoperative channels. Because reactor protection requirements vary with the mode in which the reactor operates, the tables show different functional requirements for the

RUN and STARTUP modes. These are the only modes in which more than one control rod can be withdrawn from the fully inserted position.

In case of a LOCA, reactor shutdown occurs immediately following the accident, as one or more process variables exceed their specified setpoint. Operation verification that shutdown has occurred may be made by observing one or more of the following indications:

a. Control rod status lamps indicating each rod fully inserted

b. Control rod scram pilot valve status lamps indicating open valves

c. Neutron monitoring power range channels and recorders downscale

d. Annunciators for RPS variables and trip logic in the tripped state

e. Sequence-of-events recorder log of trips

f. IPCS control rod position log.

7.2.2.2.2 Conformance To Specific Regulatory Requirements

7.2.2.2.2.1 Industry Standards

IEEE 279-1971

IEEE 279-1971 is satisfied as follows (except for manual scram, which is addressed below):

NEDO-10139, "Compliance of Protection Systems to Industry Criteria: General Electric BWR Nuclear Steam Supply System," demonstrates compliance of the RPS with IEEE 279-1968. The following paragraphs address the differences between IEEE 279-1968 and IEEE 279-1971 standards:

a. Paragraph 4.7 - Control and Protection System Interaction. The RPS interlocks to control systems only through isolation devices such that no failure or combination of failures in the control system will have any effect on the RPS

b. Paragraph 4.22 - Identification of Protection System. Each system cabinet is marked with the words "Reactor Protection System" and the particular redundant portion is listed on a distinctively colored marker plate. Cabling outside the cabinets is identified by color coding (as discussed in Subsection 8.3.1).

Exact design comparisons with the testability requirements of IEEE 279-1971 4.9, 4.10, and 4.11 are given in NEDO-10139:

a.	Scram discharge volume	Pages 2-26, 2-27
b.	Main steam line isolation valve	Page 2-39
c.	Turbine stop valve	Pages 2-56, 2-57
d.	Turbine control valve	Pages 2-69, 2-70

e.	Reactor water level	Page 2-99
f.	Deleted	
g.	Neutron monitoring system	Page 2-125 (Plus NEDC-32410P-A, Pages 4-5, 4-6)
h.	Drywell pressure	Page 2-138
i.	Reactor pressure	Page 2-146
j.	Mode switch	Pages 2-164, 2-165
k.	Discharge volume bypass	Pages 2-170, 2-171
l.	Main steam line valve bypass	Page 2-178
m.	Turbine trip bypass	Page 2-186

The RPS manual scram function satisfies IEEE 279-1971 as follows:

a. Paragraph 4.2 - Single Failure Criterion

RPS manual controls comply with the single failure criterion. Four manual scram pushbuttons are arranged into two groups on one main control room Bench Board and the switches are provided with physical and electrical separation.

b. Paragraph 4.3 - Quality of Components and Modules

The RPS manual switches are selected to be of high quality and reliability.

c. Paragraph 4.4 - Equipment Qualification

Manual switches and trip logic components are certified by the vendor that they perform in accordance with the requirements listed on the purchase specification as well as in the intended application. This certification, in conjunction with the existing field experience with these components in this application, serves to qualify these components.

d. Paragraph 4.5 - Channel Integrity

The manual switches and components are specified to operate under normal and abnormal conditions of environment, energy supply, malfunctions, and accidents.

e. Paragraph 4.6 - Channel Independence

The manual scram pushbutton is a channel component. The trip channels are physically separated and electrically isolated to comply with this design requirement.

f. <u>Paragraph 4.7 - Control and Protection System Interaction</u>

The manual scram pushbutton has no control interaction.

g. <u>Paragraph 4.8 - Derivation of System Inputs</u>

Not applicable.

h. <u>Paragraph 4.9 - Capability for Sensor Checks</u>

Not applicable.

i. <u>Paragraph 4.10 - Capability for Test and Calibration</u>

A manual scram switch permits each individual trip logic, trip actuator, and trip actuator logic to be tested on a periodic basis.

j. <u>Paragraph 4.11 - Channel Bypass or Removal from Operation</u>

Since actuation of one manual scram pushbutton places its RPS trip system in a tripped condition, it is in compliance with this design requirement.

k. <u>Paragraph 4.12 - Operating Bypasses</u>

Not applicable.

l. <u>Paragraph 4.13 - Indication of Bypasses</u>

Not applicable.

m. <u>Paragraph 4.14 - Access to Means for Bypassing</u>

Not applicable.

n. <u>Paragraph 4.15 - Multiple Set Points</u>

Not applicable.

o. <u>Paragraph 4.16 - Completion of Protective Action Once It Is Initiated</u>

Once the manual scram push buttons are depressed, it is only necessary to maintain them in that condition until the scram contactors have de-energized and open their seal-in contacts. At this point, the trip actuator logic proceeds to initiate reactor scram regardless of the state of the manual scram push buttons.

p. <u>Paragraph 4.17 - Manual Actuation</u>

Four manual scram pushbutton controls are provided on one main control room Bench Board to permit manual initiation of reactor scram at the system level. The four manual scram pushbuttons (one in each of the four RPS trip logics) comply with this design requirement. The logic for the manual scram is one-out-of-two twice. No single failure in the manual or automatic portions of the RPS can prevent either a manual or automatic scram.

q. <u>Paragraph 4.18 - Access to Set Point Adjustments, Calibration, and Test Points</u>

Not applicable.

r. Paragraph 4.19 - Identification of Protective Actions

When any manual scram pushbutton is depressed, a control room annunciation is initiated and an IPCS alarm record is produced to identify the tripped RPS trip logic.

s. Paragraph 4.20 - Information Readout

The manual scram function complies with this requirement.

t. Paragraph 4.21 - System Repair

The manual scram function complies with this requirement.

The RPS is fail-safe and its power supplies are thus unnecessary for scram. A total loss of power causes a scram. A loss of one power source causes a trip system trip. IEEE 308-1971 does not apply to the RPS.

IEEE 323-1971

"General Guide for Qualifying Class I Electric Equipment" is satisfied by complete qualification testing and certification of all essential components. Records covering all essential components are maintained. For a complete summary of how the RPS complies with IEEE 323-1971, refer to NEDO-10698. See also Section 3.11.

IEEE 336-1971

"Installation, Inspection, and Testing Requirements for Instrumentation and Electric Equipment During Construction of Nuclear Power Generating Stations" is satisfied except as modified by the Edison Quality Assurance Procedures.

IEEE 338-1971

"Periodic Testing of Protection Systems" is complied with by being able to test the RPS from sensors to final actuators at any time during plant operation. The test must be performed in overlapping portions.

IEEE 344-1971

Conformance to IEEE 344-1971 is described in Section 3.10.

IEEE 379-1972

"Trial-Use Guide for the Application of the Single-Failure Criterion to Nuclear Power Generating Station Protection Systems" is judged to be satisfied by the RPS design criteria described in NEDO-10139.

7.2.2.2.2.2 Conformance To Regulatory Guides and 10 CFR 50

The RPS is designed so that it may be tested during plant operation from sensor device to final actuator device in compliance with Regulatory Guide 1.22. The test must be performed in overlapping portions so that an actual reactor scram does not occur as a result of the testing.

The RPS is judged to comply with Regulatory Guide 1.53 since all of the additional provisions of Regulatory Guide 1.53 as applied to IEEE 379 are met or exceeded by the actual design.

10 CFR 50, Appendix B

"Quality Assurance Criteria for Nuclear Power Plants." A Quality Assurance program has been established that includes quality control at the component vendor, at the nuclear steam supplier, at various stages of construction, and during installation at the nuclear power plant site. System design is continually checked for conformance to the applicable industry criteria. Periodic testing ensures that the system is available and adequate to perform its intended purpose. Quality assurance records are maintained by the nuclear steam supplier and Edison. For a complete description of the Quality Assurance Program, see Chapter 17.

General Design Criteria of 10 CFR 50, Appendix A

a. Criterion 13 - Each RPS input is monitored and annunciated

b. Criterion l9 - Instrumentation and control is provided in the main control room. The reactor can also be shut down from outside the main control room by opening breakers

c. Criterion 20 - The RPS constantly monitors the appropriate plant variables to maintain the fuel barrier and primary coolant pressure boundary. It automatically initiates a scram when the variables exceed the established setpoints

d. Criterion 2l - The RPS is designed with four independent and separated output channels. No single failure or operator action can prevent a scram. The system can be tested during plant operation to ensure its availability

e. Criterion 22 - The redundant portions of the RPS are separated such that no single failure or credible natural disaster can prevent a scram. Functional diversity is used by measuring flux, pressure, and level (all dependent variables) in the reactor vessel

f. Criterion 23 - The RPS is fail-safe. A loss of electrical power or air supply will not prevent a scram. Postulated adverse environments will not prevent a scram

g. Criterion 24 - The RPS has no control function

h. Criterion 29 - The RPS is highly reliable so that it is able to scram in the event of anticipated operational occurrences.

7.2.2.2.2.3 Instrument Ranges and Setpoints

The design criteria used in selecting instrument span and trip setpoints for safety-related applications consider the following factors:

a. The selection of instrument range is based on knowledge of the expected variation of the process variable being monitored. In all cases, the range selected is greater than the expected variable excursions

b. The accuracy of each trip setpoint is better than or equal to the accuracy assumed in the accident analysis performed for the Fermi 2 plant design

c. Trip setpoints are normally located in the portion of the instrument range of greatest accuracy. In all cases, the setpoint is located in the portion of the instrument's range that is consistent with the required accuracy

d. All of the safety-related trip setpoints are chosen to allow for the normal expected instrument setpoint drift without exceeding associated Technical Specifications

e. All setpoints are verified on a prescribed schedule as outlined in the Technical Specifications.

TABLE 7.2-1 REACTOR PROTECTION SYSTEM INSTRUMENTATION SPECIFICATIONS

Scram Function	Instrument	Trip Setting[a]
Nuclear system high pressure	Pressure transmitter	1080 psig
Primary containment high pressure	Pressure transmitter	1.68 psig
RPV low water level	Level transmitter	173.4 in. above top of active fuel
Scram discharge volume high water level	Level switch/ transmitter	50 gal
Turbine stop valve closure	Position switch	Before 10 percent valve closure
Turbine control valve fast closure	Valve fast closure initiation logic	Start of control valve fast closure
Main steam line isolation valve closure	Position switch	Before 10 percent valve closure
Neutron monitoring system scram	Neutron detector	(IRM) 120/125 divisions of FS APRM) Refer to UFSAR Table 7.6-9 for APRM system trip setpoints.

[a] Nominal values given for information. See Technical Specifications for actual operational settings.

TABLE 7.2-2 CHANNELS REQUIRED FOR FUNCTIONAL PERFORMANCE OF REACTOR PROTECTION SYSTEM: STARTUP MODE

This table shows the normal and minimum number of channels required for the functional performance of the RPS in the STARTUP mode. The "Normal" column lists the normal number of channels per trip system. The "Minimum" column lists the minimum number of channels per untripped trip system required to maintain functional performance.

Channel Description	Normal	Minimum[a,b]
Neutron monitoring system (APRM)[c]	2	2
Neutron monitoring system (IRM)	2	2
Nuclear system high pressure	2	2
Primary containment high pressure	2	2
RPV low water level	2	2
Scram discharge volume high water level	2	2
Manual scram	2	2
Each main steam line isolation valve position	0 (bypassed)	0

[a] During testing of sensors, the channel should be tripped when the initial state of the sensor is not essential to the test.

[b] Nominal values given for information. See Technical Specifications for operational requirements.

[c] Number of channels refers to final two-out-of-four voter channels for APRM. See Technical Specifications for more specific requirements related to APRM channels.

TABLE 7.2-3 CHANNELS REQUIRED FOR FUNCTIONAL PERFORMANCE OF REACTOR PROTECTION SYSTEM: RUN MODE

This table shows the normal and minimum number of channels required for the functional performance of the RPS in the RUN Mode. The "Normal" column lists the normal number of channels per trip system. The "Minimum" column lists the minimum number of channels per untripped trip system required to maintain functional performance.

Channel Description	Normal	Minimum[a,b]
Neutron monitoring system (APRM)[c]	2	2
Nuclear system high pressure	2	2
Primary containment high pressure	2	2
RPV low water level	2	2
Scram discharge volume high water level	2	2
Manual scram	2	2
Each main steam line isolation valve position	4	4
Each turbine stop valve position	4	4
Turbine control valve fast closure	2	2
Turbine first-stage pressure (bypass channel)	2	2

[a] During testing of sensors, a channel may be placed in an inoperable status for up to 6 hr for required surveillance without placing the trip system in the tripped condition, provided that at least one operable channel in the same trip system is monitoring that parameter.

[b] Nominal values given for information. See Technical Specifications for operational requirements.

[c] Number of channels refers to final two-out-of-four voter channels for APRM including the OPRM function. OPRM/APRM functions are independently voted in the two-out-of-four voters. See Technical Specifications for more specific requirements related to APRM channels.

TABLE 7.2-4 (TRM TABLE 3.3.1.1-1) REACTOR PROTECTION SYSTEM RESPONSE TIMES

The Reactor Protection System Response Times are listed in Technical Requirements Manual (TRM) Volume I Table 3.3.1.1-1. TRM Volume I is incorporated by reference into the UFSAR.

7.3 ENGINEERED SAFETY FEATURE SYSTEMS

Included in this section are descriptions and analyses of the instrumentation and controls for the following engineered safety feature (ESF) systems:

a. Emergency core cooling system (ECCS)

b. Primary containment and reactor vessel isolation control system

c. Emergency core cooling auxiliary system

d. Emergency equipment cooling water system

e. Main control room atmospheric control system

f. Standby gas treatment system

g. Standby power system

h. Deleted

The format of this section departs from the Regulatory Guide 1.70, Revision 2, Standard Format Guide in that the description and analysis are grouped together under each system heading rather than by descriptions and by analyses.

The main steam isolation valve leakage control system is discussed in Subsection 6.2.6.

7.3.1 Emergency Core Cooling System

7.3.1.1 Design-Basis Information

The design-basis information for the ECCS, required by Section 3 of IEEE 279-1971, is provided in Subsection 7.1.2.1.3.

7.3.1.2 System Description

The ECCS includes the following subsystems:

a. High-pressure coolant injection system (HPCI)

b. Automatic depressurization system (ADS)

c. Core spray system

d. Low-pressure coolant injection (LPCI) mode of the residual heat removal (RHR) system.

The purpose of ECCS instrumentation and control is to initiate appropriate responses from the ECCS to ensure that the fuel is adequately cooled in the event of a design-basis LOCA. The cooling provided by the system restricts the release of radioactive materials from the fuel by preventing or limiting the extent of fuel damage following situations in which reactor coolant is lost.

The equipment involved in the control of these systems includes automatic injection valves, steam turbine pump controls, electric pump controls, relief valve controls, and the switches, contacts, and relays that make up sensory logic channels. Testable check valves and certain automatic isolation valves are not included in this description since they are pertinent to the containment and reactor vessel isolation control system (CRVICS).

Power Sources

The instrumentation and control of the ECCS is powered by the 130-V dc and 120-V ac systems, and by the standby power system when required. The redundancy and separation of these power supply systems are consistent with the redundancy and separation of the ECCS instrumentation and control. Both of these power supply systems are described in detail in Chapter 8.

7.3.1.2.1 High Pressure Coolant Injection System Instrumentation and Control

When actuated, the HPCI system pumps water from either the condensate storage tank or the suppression chamber to the reactor pressure vessel (RPV) via the "A" feedwater pipeline. The HPCI system includes one turbine-driven pump, one dc motor-driven auxiliary oil pump, one barometric condenser dc condensate pump, one barometric condenser dc vacuum pump, other auxiliaries, automatic valves, control devices for this equipment, sensors, trip channels, and logic circuitry. The arrangement of equipment and control devices is shown in Figure 7.3-1.

Pressure and level transmitters used in the HPCI system are located on racks in the reactor building. The only operating component for the HPCI system that is located inside the primary containment is one of the two isolation valves in the HPCI turbine steam supply isolation valves. The rest of the HPCI system instrumentation and control components are located outside the primary containment. Cables connect the sensors to control circuitry in the main control room. The system is arranged to allow a full-flow functional test of the system during normal reactor power operation. The system will automatically return from the full-flow test mode to accident response operation.

The controls automatically initiate the HPCI system on receipt of either an RPV low water level signal or a primary containment high-pressure signal, and bring the system to its design flow rate, given in Section 6.3, within 60 sec. The controls then function to provide design makeup water flow to the RPV until the water level in the RPV reaches an upper limit. At this time the HPCI system shuts down until further need is indicated. The HPCI system would automatically restart on low water level and operate indefinitely without manual intervention. The controls are arranged to allow manual startup, operation, and shutdown from the main control room.

7.3.1.2.1.1 Initiating Circuits

The RPV low water level is monitored by four level transmitters that sense the differences between the pressure of a constant reference column of water and the pressure due to the actual height of water in the vessel. Two pipelines, attached to taps above and below the normal water level on the RPV, are required for the level transmitters. The lines are physically separated from each other and tap off the RPV at widely separated points. These same lines are also used for pressure and water level instruments for other systems.

A backfill system is installed on each level instrument reference leg. The system provides a metered flow of water from the control rod drive system to each leg. The flow is low enough to not affect the performance of the instrumentation. The backfill is designed to prevent the accumulation of dissolved noncondensable gases in the reference legs.

The level transmitters and primary containment high-pressure transmitters for the HPCI are arranged in pairs, with the transmitter contacts in a "one-out- of-two taken twice" electrical arrangement. This arrangement ensures that no single event can prevent HPCI initiation from RPV low water level or drywell high pressure. Cables from the level transmitters lead to the trip unit racks located in the fourth floor of the reactor building for logic and sequencing action.

The primary containment high-pressure initiation signal for the HPCI system uses output from the same trip unit that serves the RHR and core spray systems, as described in Subsection 7.3.1.2.3.

The HPCI system turbine is functionally controlled as shown in Figure 7.3-2. A speed governor limits the turbine speed to its maximum operating level. A control governor receives a pump flow signal and adjusts the turbine steam control valve so that design HPCI pump discharge flow rate is obtained. Manual control of the governor is possible in the test mode, but the governor automatically returns to automatic control on receipt of a HPCI initiation signal.

Figure 7.3-2 shows the various modes of turbine control. The flow signal used for automatic control of the turbine is derived from a differential pressure measurement across a flow element in the HPCI pump discharge line. The governor controls the pressure applied to the hydraulic operator of the turbine control valve, which in turn controls the steam flow to the turbine. Hydraulic pressure is supplied for both the turbine control valve and the turbine stop valve by the dc-powered oil pump during startup, and then by the shaft-driven hydraulic oil pump when the turbine reaches a certain speed.

On receipt of an initiation signal, the auxiliary oil pump starts, providing hydraulic pressure for the turbine stop valve and turbine control valve hydraulic operator. Since there is no flow at first in the HPCI system, the flow signal runs the control governor to the high speed stop. As hydraulic oil pressure is developed, the turbine stop valve and the turbine control valve open simultaneously, and the turbine accelerates toward the speed setting of either the control governor or the speed governor, whichever is lower. As HPCI flow increases, the flow signal adjusts the control governor setting so that rated flow is maintained. The turbine is automatically or manually shut down by tripping the turbine stop valve closed if any of the following signals are detected:

a. Turbine overspeed (automatic)

b. High turbine exhaust pressure (automatic)

c. Low pump suction pressure (automatic)

d. RPV high water level (automatic)

e. HPCI isolation signal (automatic)

f. Manual pushbutton

g. HPCI steam supply pressure low (automatic).

Turbine overspeed indicates a malfunction of the turbine control mechanism. High turbine exhaust pressure indicates a condition that threatens the physical integrity of the exhaust line. Low pump suction pressure warns that cavitation and lack of cooling can cause damage to the pump, which could place it out of service. A turbine trip is initiated for these conditions so that if the causes of the abnormal conditions can be found and corrected, the system can be quickly restored to service. The trip settings are selected far enough above or below normal values so that a spurious turbine trip is unlikely, but not too close to values that could cause damage before the turbine is shut down.

Turbine overspeed is detected by a standard turbine overspeed detection device. Two pressure transmitters are used to detect high turbine exhaust pressure; either transmitter can initiate turbine shutdown. One pressure switch is used to detect low HPCI pump suction pressure.

High water level in the RPV indicates that the HPCI system has performed satisfactorily in providing makeup water to the RPV. Further increase in level could result in HPCI turbine damage caused by gross carryover of moisture. The RPV high-water-level setting, which trips the turbine, is near the top of the steam separators and is sufficient to prevent gross moisture carryover to the turbine. Two level transmitters that sense differential pressure are arranged so that both transmitters are required to trip simultaneously to initiate a turbine shutdown.

UFSAR Section 7.5.1.4.2.1 describes that the wide-range water level system is uncompensated for variation in reactor water density and is calibrated to be most accurate at operational pressure and temperature conditions. At low reactor coolant temperatures and pressures, the higher water density causes the wide-range instruments to read higher than both the narrow-range instruments and the actual water level. Below approximately 550 psig, this phenomenon results in a wide-range level above the RPV high water level setting (Level 8) when the actual water level is normal (Reference 5). With wide-range level above Level 8, HPCI automatic initiation on the primary containment high-pressure signal and HPCI manual initiation are both inhibited by the Level 8 trip signal. HPCI automatic initiation on RPV low water level (Level 2) remains available since the Level 8 signal is automatically reset by the occurrence of a Level 2 actuation signal. For accidents occurring below 600 psig for which HPCI may be effective, analysis (Reference 5) has shown that HPCI automatic initiation at Level 2 is sufficient to perform the intended safety function and that the analyses of record from normal reactor pressure are bounding. Amendment 206 (Reference 6) revised the Technical Specifications to indicate that the HPCI functions of automatic initiation on primary containment high-pressure and manual initiation are not required to be operable below a reactor pressure of 550 psig.

The control scheme for the turbine auxiliary oil pump is shown in Figure 7.3-2. The controls are arranged for automatic manual control. On receipt of an HPCI initiation signal, the auxiliary oil pump starts and provides hydraulic pressure to open the turbine stop valve and the turbine control valve. As the turbine gains speed, the shaft-driven oil pump begins to supply hydraulic pressure. Should the shaft-driven oil pump malfunction, causing oil pressure to drop, the auxiliary oil pump restarts.

Operation of the barometric condenser components, which consist of the barometric condenser condensate pump (dc), the barometric condenser vacuum pump (dc), and the barometric condenser water level instrumentation, prevents outleakage from the turbine shaft seals. Operation of this equipment is automatic, as shown in Figure 7.3-2, and failure does not prevent the HPCI system from providing water to the RPV.

7.3.1.2.1.2 Logic and Sequencing

The RPV low water level and primary containment (drywell) high pressure are the two functions that can automatically start the HPCI system, as indicated in Figure 7.3-2 Sheet 1. The RPV low water level is an indication that reactor coolant is being lost and that the fuel is in danger of being overheated. Primary containment high pressure is an indication that a breach of the nuclear system process barrier has occurred inside the drywell.

The logic scheme used for the initiating functions is a "one-out-of-two taken twice" arrangement for both RPV low water level and high drywell pressure. Either one can initiate HPCI. The logic is powered from reliable dc buses. Level transmitters and drywell pressure transmitters are shared with core spray initiation.

Instrument settings for the HPCI system instrumentation and control are listed in Table 7.3-1. The RPV low water level (L2) setting for HPCI initiation is selected high enough above the active fuel to start the HPCI in time to prevent fuel clad failure and to prevent an unacceptable fraction of the core from reaching the temperature at which fuel fragmentation occurs (Section 6.3). The water level setting is far enough below normal levels that spurious HPCI system startups are avoided. The primary containment high-pressure setting is selected to be as low as possible without inducing spurious HPCI system startup.

To prevent the turbine pump from being damaged by overheating at reduced HPCI pump discharge flow, a pump discharge bypass is provided to route the water discharged from the pump to the suppression chamber. The bypass is controlled by an automatic, dc motor-operated valve whose control scheme is shown in Figure 7.3-2. At high HPCI flow, the valve is closed; at low flow, the valve is opened. Flow switches that measure the pressure difference across a flow element in the HPCI pump discharge line provide the signals used for flow indication.

The HPCI initially uses the condensate storage tank as the source of coolant to provide high-grade water to the reactor. A single failure of the condensate low-level switches or suppression pool high-level switches could cause a switchover of HPCI source water from the condensate storage tank to the suppression pool. A premature switchover has no adverse safety impact. The transfer to the suppression pool feature is to ensure an adequate long-term quantity of coolant or to control the pool level. The long-term source of water for the HPCI system is the suppression pool; thus a failure causes switchover to the desired suction source.

7.3.1.2.1.3 Bypasses and Interlocks

To prevent the HPCI steam supply line from filling up with water and cooling, a condensate drain pot, steam line drain, and appropriate valves are provided in a drain line arrangement just upstream of the turbine supply valve. The control scheme is shown in Figure 7.3-2. The controls position valves so that during normal operation, steam line drainage is routed to the main condenser. On receipt of an HPCI initiation signal, the drainage path is isolated. The water level in the steam line drain condensate pot is controlled by a level switch and a pilot air-operated solenoid valve that energizes to allow condensate to flow out of the pot.

During test operation, the HPCI pump discharge is routed to the condensate storage tank. Two valves, a dc motor operated valve (E4150F008) and an air operated valve (E41F011), are installed in the pump discharge to the condensate storage tank line. The piping arrangement is shown in Figure 7.3-1. The control scheme for the two valves is shown in Figure 7.3-2. On receipt of an HPCI system initiation signal, the two valves close and remain closed. The valves are interlocked to close if either of the suppression chamber suction valves are fully open. Valve E41F011 functions as a throttle valve while operating in the test mode. It is a fail-close globe valve with flow over the seat, capable of fast closure. It is credited for closure against pump shut off head. Valve E4150F008 is a slower motor operated valve which provides redundant isolation of the test line. If manual transfer from the test mode to vessel injection is desired, operator action is needed to close E41F011 prior to opening the HPCI injection valve. Numerous indications pertinent to the operation and condition of the HPCI system are available to the main control room operator. Figures 7.3-1 and 7.3-2 show the various indications provided.

7.3.1.2.1.4 Redundancy and Diversity

The HPCI system is actuated either by RPV low water level or by primary containment high pressure. Both of these conditions could result from a LOCA. The redundancy of the HPCI system initiating circuits is consistent with the design of the HPCI system. A single failure does not prevent activation.

7.3.1.2.1.5 Actuated Devices

All automatic valves in the HPCI system are equipped with remote manual test capability so that the entire system can be operated from the main control room. Motor-operated valves are provided with appropriate limit switches to turn off the motors when the fully open or fully closed positions are reached. Valves that are automatically closed upon isolation signals are equipped with manual reset devices so that they cannot be reopened without operator action. All essential components of the HPCI system controls operate independently of offsite ac power.

To ensure that the HPCI system can be brought to the design flow rate within 60 sec from the receipt of the initiation signal, the following operating times for essential HPCI system valves are provided by the valve operation mechanisms.

a. HPCI turbine steam supply valve - 50 sec

b. HPCI pump discharge valves - 40/50 sec

c. HPCI pump minimum flow bypass valve - 22.5 sec.

The operating time is the time required for the valve to travel from the fully closed to the fully open position, or vice versa. A HPCI steam supply line inboard isolation valve and the bypass valve around the HPCI outboard isolation valve are provided; they are intended to isolate the HPCI steam line in the event of a break in that line. A normally closed dc motor-operated isolation valve is located in the turbine steam supply line just upstream of the turbine stop valve. The piping and logic scheme for this valve is shown in Figures 7.3-1 and 7.3-2. On receipt of a HPCI system initiation signal, this valve opens and remains open until closed by operator action from the main control room.

Two isolation valves are provided in the steam supply line to the turbine. The valve inside the drywell is a Division I ac-powered valve that is normally open. The valve outside the drywell is a Division II dc-powered valve and is normally closed. A small bypass valve provides a warmup path around the closed valve to keep the turbine steam line free of water. The HPCI steam supply outboard isolation valve is signaled open on a HPCI initiation, and the HPCI steam supply inboard, and outboard isolation valves, and the bypass valve around the HPCI steam supply outboard isolation valve close automatically on a HPCI system isolation. The isolation signal takes precedence over the initiation signal. The control diagram is shown in Figure 7.3-2.

The primary element instrumentation for HPCI system isolation consists of the following:

a. Inside valve E41-F002

    1. Ambient temperature sensor - emergency area cooler high temperature. Isolation started as soon as activated

    2. Differential pressure transmitter - HPCI steam line high flow; a time delay has been added to this isolation to prevent spurious trips that could result from pressure spikes associated with pump startup

    3. Pressure transmitters - HPCI turbine exhaust diaphragm high pressure

    4. Pressure transmitters - HPCI steam supply pressure low.

b. Outside valve E41-F003 - Instrumentation similar to that described for the inside valve causes the outside valve to isolate if the conditions warrant isolation. Both valves can be individually actuated by manual pushbutton switches

    Three pump suction valves are provided in the HPCI system. One valve allows pump suction from the condensate storage tank while the other two series valves allow water to be taken from the suppression chamber. The condensate storage tank is the preferred source. All three valves are operated by dc motors. The control arrangement is shown in Figure 7.3-2

    On receipt of a HPCI system initiation signal, the condensate storage tank suction valve receives an open signal. If the water level in the condensate storage tank falls below a preselected level, the suppression chamber suction valves automatically open and the condensate storage tank suction valve automatically closes. Two level transmitters detect the condensate storage tank low-water-level condition. Either transmitter causes the suppression chamber suction valves to open and the condensate storage tank suction valve to close. The suppression chamber suction valves also automatically open if a high water level is detected in the chamber. Two level transmitters monitor the water level. Either transmitter can initiate opening of the suppression chamber suction valves. If open, the suppression chamber suction valves automatically close on receipt of the signals that initiate HPCI steam line isolation

    Two dc motor-operated HPCI pump discharge valves in the pump discharge pipeline are provided. The control schemes for these two valves are shown in

Figure 7.3-2. Both valves are arranged to open on receipt of either one of the HPCI system initiation signals. One of the pump discharge valves closes automatically on receipt of a turbine trip signal. The other valve remains open after HPCI system initiation until closed by the operator in the main control room.

7.3.1.2.1.6 Separation

General

Separation within the ECCS is such that no single failure can prevent core cooling. Instrumentation and control equipment and wiring are segregated into separate divisions designated Divisions I and II. Separate requirements are also maintained for the control and motive power for the ECCS. System separation is as follows:

Division I	Division II
Core spray pump A and pump C	Core spray pump B and pump D
Automatic depressurization	HPCI
RHR A and C	RHR B and D

Systems shown opposite each other are redundant. In addition, should HPCI fail to reduce RPV pressure through coolant makeup injection, the ADS will depressurize the RPV to allow LPCI and Core Spray to provide adequate core cooling. Control logic for all Division I systems is the 260/130-V dc Division I battery and for Division II systems is the 260/130-V dc Division II battery.

Specific

The HPCI system is a Division II system except for the HPCI main pump test line isolation valve E41F011, in which its motive force is fed from the interruptible air supply (note: the solenoid valves for E41F011 remain in Division II logic), and inside isolation valve E4150-F002, which is Division I ac powered. The E4150-F002 valve is controlled by logic operated from Division I 260/130-V dc battery so that no single failure can prevent the automatic closure of at least one valve of the pair of isolation valves. To maintain the required separation, HPCI system logic relays, instruments, and manual controls are mounted so that separation from Division I is maintained. Logic relays, instruments, and manual controls for outboard steam line isolation valve E41-F003 and bypass valve E41-F600 are separated from Division I equipment.

7.3.1.2.1.7 Testability

Instrumentation and control of the ECCS is designed to be completely testable during reactor operation. Specific test schedules for this and subsequent systems in this section (Section 7.3) are given in the Technical Specifications. Systems providing core cooling water are arranged with bypass valves so that pumps may be operated at design flow.

Instrumentation and control is designed to establish that the following functions are met:

a. Each instrument channel functions independently of all others

b. Sensing devices respond to process variables and provide channel trips at correct values

c. Sensors and associated instrument channels respond to both steady-state and transient changes in the process variable within specified accuracy and time limitations, and provide channel trips at correct values even when affected by process variations that may extend grossly beyond the expected trip setpoint

d. Paralleled circuit elements can perform their intended functions independently

e. Series circuit elements are free from shorts that can abrogate their function

f. Redundant instrument or logic channels are free from interconnecting shorts that could violate independence if a single malfunction should occur

g. No element of the system is omitted from the test if it could impair system operability in any way. (If the test is done in parts, then the parts must overlap sufficiently to ensure operability of the entire system)

h. Each monitoring alarm or indication function is operable.

The emergency core cooling system response times are shown in Technical Requirements Manual Volume I Table 3.3.5.1-1, which is referenced in UFSAR Table 7.3-11. Response time testing is required by the Technical Specifications. Technical Specification Table 3.3.3-3 was deleted from the Technical Specifications and added to the UFSAR as Table 7.3-11 (TRM Table 3.3.5.1-1) in agreement with NRC Generic Letter 93-08 and Amendment Number 100 to the Technical Specifications. The response times information of the UFSAR Table 7.3-11 was then relocated to the Technical Requirements Manual Volume I.

The periodic response time testing for the ECCS instrument channels has been eliminated. The BWROG Report NEDO-32291A provides the required analyses as briefly described in 7.2.1.1.3.8.1.

Specific

The HPCI system is provided with test jacks in each logic. The low reactor level or high drywell pressure "one-out-of-two taken twice" circuit can be tested completely by actuating only one instrument channel at a time. Insertion of the test plug at the logic relay panel actuates an annunciator in the main control room, indicating that the HPCI system is in test status.

7.3.1.2.1.8 Environmental Considerations

The control mechanism for the inboard isolation valve on the HPCI system turbine steam line is the only HPCI system control component located inside the primary containment that must remain functional in the environment resulting from a LOCA. The environmental capabilities of this valve are discussed in Subsection 7.3.2.2.9. The HPCI system instrumentation and control equipment located outside the primary containment is selected in consideration of the normal and accident environments in which it must operate. These conditions are listed in Table 3.11-3.

7.3.1.2.1.9 Operational Considerations

The HPCI system is not required for normal operations. Under the abnormal or accident conditions when it is required, initiation and control are provided automatically for at least 10 minutes. The automatic depressurization system (ADS) can also depressurize the reactor vessel to a point when the low pressure ECCS systems can be initiated to inject water into RPV. With the incorporation of the high drywell pressure signal bypass timer into the ADS automatic initiation logic, as discussed in Subsection 7.3.1.2.2.2, no operator actions are required to actuate ADS after any LOCA. When the bypass timer times out, the high drywell pressure initiation permissive signal is bypassed, and the ADS will be automatically initiated based on reactor vessel low water level signal alone. This is true even when the main steam line isolation valves (MSIV) line breaks outside the drywell and the break becomes isolated due to MSIV closure.

7.3.1.2.2 Automatic Depressurization System Instrumentation and Control

Automatically controlled relief valves are installed on the main steam lines inside the primary containment. The valves are dual purpose in that they relieve pressure either by normal mechanical action or by automatic action of an electric-pneumatic control system. Actuation is initiated on receipt of a signal indicating high drywell pressure, low RPV water level, and core spray and/or RHR pumps running. A time delay allows the operator to delay actuation if the HPCI system is in operation. The relief by normal mechanical action is intended to prevent overpressurization of the nuclear steam supply system (NSSS). If the HPCI system is not available during a small-break LOCA, the depressurization by automatic action of the ADS is intended to reduce NSSS pressure so that the core spray system or LPCI system can inject water into the RPV.

The automatic instrumentation and control equipment for the relief valves is described in this subsection. The instrumentation and control for one of the relief valves is discussed. Other relief valves equipped for automatic depressurization are identical.

The control system consists of pressure and water level sensors arranged in trip systems that control a solenoid-operated pilot air valve. The solenoid-operated pilot valve controls the pneumatic pressure applied to a bellows-actuator that operates the relief valve directly. An accumulator is included with the control equipment to store pneumatic energy for relief valve operation. The accumulator is sized to provide pneumatic pressure for five actuations of the pilot valve during interruptions if the pneumatic supply to the accumulator is switched from the normal to the emergency backup supply source.

Cables from the sensors lead to the trip unit racks located in the reactor building, where the logic arrangements are formed in cabinets. The electrical control circuitry is powered by dc power from the plant batteries. The power supplies for the redundant control circuits are selected and arranged to maintain tripping ability in the event of an electrical power circuit failure. Electrical elements in the control system energize to open the relief valve.

7.3.1.2.2.1 Initiating Circuits

The pressure and level transmitters used to initiate one ADS logic are separated from those used to initiate the redundant logic on the same ADS valve. Reactor pressure vessel low water level is detected by six transmitters that measure differential pressure. Primary containment high pressure is detected by four pressure transmitters. The primary containment high pressure signals are arranged to seal into the control circuitry. These signals must be manually reset to clear.

A timer is used in each ADS logic. The time delay setting before actuation of the ADS is long enough that the HPCI system has time to operate, yet not so long that the LPCI and core spray systems are unable to adequately cool the fuel if the HPCI system cannot. An alarm in the main control room is activated when either of the timers is timing. Resetting the ADS initiating signals recycles the timer. A display of the time remaining before the ADS actuates is available to the operator in the main control room.

7.3.1.2.2.2 Logic and Sequencing

The two initiating signals used for ADS are RPV low water level (level 1) and drywell high pressure. Simultaneous occurrences of RPV low water level and drywell high pressure conditions initiate a nominal 105 second time delay. After that time delay, ADS safety relief valves will operate if a sufficient number of low pressure ECCS pumps (RHR and/or core spray) are available for adequate core cooling. RPV low water level (level 1) signal also initiates a bypass timer which is set for a nominal 7 minutes. This time delay is provided to bypass the drywell high pressure permissive. If for some reason the drywell high pressure is not detected, the RPV low water level signal alone will actuate the ADS safety relief valves. The 7 minute bypass time delay, plus the original 105 second time delay and the permissive from appropriate ECCS pump discharge pressure will provide for ADS actuation. The instrument trip settings are given in Table 7.3-2.

Figure 7.3-6 shows the logic for ADS actuation, with the High Drywell Pressure Bypass Timer started on level 1. A nominal bypass timer time delay setpoint of 7 minutes was established for Fermi 2 from the unique analyses performed by General Electric, which is consistent with the analysis presented in NEDO-24708A (Figure Group 3.5.2.1-33). The results of these analyses demonstrate that adequate core cooling is ensured for isolation events, even with the ADS blowdown delayed after level 1 for an analytical time of 10 minutes. A subsequent confirmatory analysis established the adequacy of the bypass timer setpoint including increases in reactor rated thermal power to 3486 MWth (refer to Subsection 6.3.2.2 for analytical values).

Starting the bypass timer at level 1 allows the operator enough time to control the system manually and still ensure automatic depressurization in time to prevent excessive fuel heat-up, even under the worst-case conditions described above.

Primary containment high pressure indicates a breach in the nuclear system process barrier inside the drywell. For each logic train, a permissive signal indicating LPCI or core spray pump discharge pressure is also required. Discharge pressure on either of the two LPCI pumps or two of the core spray pumps (one discharge pressure sensor per pump) in the same division is sufficient to give the permissive signal. This signal prevents initiation of the ADS until the low-pressure ECCS is operating.

After receipt of the initiation signals and after a delay provided by timers, each of the solenoid pilot air valves is energized. This allows pneumatic pressure from the accumulator to act on the air cylinder operator. The air cylinder operator holds the relief valve open. Lights in the main control room indicate when the SRV is opened.

Manual reset switches are provided for the ADS initiation signal and primary containment high-pressure signals. By resetting these signals manually, the delay times are recycled. The operator can use the reset pushbuttons to delay or prevent automatic opening of the relief valves if such delay or prevention is prudent.

A manual inhibit switch is also provided for each ADS trip system. These switches allow the operator to inhibit ADS operation without repeatedly pressing the reset pushbuttons. Operation of the manual inhibit switch will activate a white indicating light and an annunciator to alert the operator of the inhibit action. Enabling the inhibit function will not terminate an ADS logic actuation after the 105 second time delay has elapsed. At this point, only the reset pushbutton can be used to affect the ADS operation. Refer to Subsection 6.3.2.17 for criteria in using the reset pushbutton switch.

Control switches are available in the main control room for each SRV associated with the ADS. The OPEN position is for manual SRV operation.

Two divisional ADS logic systems are provided: ADS "A,C" logic and ADS "B,D" logic (Figure 7.3-4). Division I sensors for low reactor water level and high drywell pressure initiate ADS "A,C" logic, Division II sensors initiate ADS "B,D" logic. Either ADS "A,C" logic or "B,D" logic actuates the solenoid pilot valve on each ADS valve.

The RPV low water level initiation setting for the ADS is selected to depressurize the RPV in time to allow adequate cooling of the fuel by the LPCI system or core spray system following a LOCA in which the HPCI system fails to perform its function adequately. The primary containment high-pressure setting is selected as low as possible without inducing spurious initiation of the ADS. This provides timely depressurization of the RPV if the HPCI system fails to start or fails after it successfully starts following a LOCA. Since the ADS is a backup for HPCI, different drywell pressure-sensing transmitters are used for ADS and HPCI.

The low-pressure pump discharge pressure setting used as a permissive for depressurization is selected to ensure that at least one of the four LPCI pumps or one of the core spray loops has received electrical power, has started, and is capable of delivering water into the RPV. The setting is high enough to ensure that the pump will deliver at near rated flow without being so low as to provide an erroneous signal indicating that the pump is actually running.

7.3.1.2.2.3 Bypasses and Interlocks

It is possible for the operator to manually delay the depressurizing action by depressing the timer reset pushbutton. The operator may also interrupt the depressurization at any time by the same action.

A manual switch is also provided to allow the operator to inhibit ADS operation (prior to its automatic initiation) instead of successively pressing the reset pushbuttons to reset the ADS timer.

The operator would make these decisions based on an assessment of other plant conditions.

7.3.1.2.2.4 Redundancy and Diversity

The ADS is initiated by a combination of high drywell pressure and low RPV water level. The initiating circuits for each of these parameters are redundant, as verified by the circuit description in this section.

7.3.1.2.2.5 Actuated Devices

All relief valves in the ADS are equipped with remote manual switches so that the ADS valves can be manually as well as automatically operated. The valves also relieve pressure by built-in mechanical action.

7.3.1.2.2.6 Separation

General

Refer to Subsection 7.3.1.2.1.6.

Specific

The ADS is a Division I system, but also makes use of Division II power and pneumatic supply. The "A,C" sensing and control logic is connected to the Section 1 half of the 260/130-V dc Division I battery. The "B,D" control logic is fed from the Section 2 half of the 260/130-V dc Division I battery, with automatic transfer to the Section 1 half. The "B,D" sensing and interposing relay circuitry (to the "B,D" control logic) is fed from the Division II battery.

Each valve is normally fed from the Section 1 half of the Division I battery, but each has a power monitor to automatically transfer to the Section 2 half of Division I battery on a power failure.

7.3.1.2.2.7 Testability

Refer to Subsection 7.3.1.2.1.7.

Specific

The ADS has two trip systems; either one can initiate automatic depressurization. Each trip system has two trip logics, both of which must trip to initiate depressurization. Four test jacks are provided, one in each trip logic. To prevent spurious actuation of the ADS during testing, only one trip logic is actuated at a time. An alarm is provided if a test plug is inserted on both trip logics. Operation of the test plug switch along with actuation of the ADS reactor level interlock and the ac interlock (RHR or core spray pumps running) closes one of the two series relay contacts in the valve-solenoid circuit. This causes a light to turn on, indicating proper trip logic operation. When the test is performed, continuity of the solenoid circuit is verified. Testing of the other trip logic and trip system is accomplished in a similar manner. Annunciation is provided in the main control room whenever a test plug is inserted to indicate ADS in test status.

7.3.1.2.2.8 Environmental Considerations

The signal cables, solenoid valves, pressure switches for indication, and SRV operators are the only instrumentation and control equipment for the ADS located inside the primary containment. They remain functional in the environment resulting from a LOCA. These items operate in the most severe environment resulting from a design-basis LOCA (Section 3.11). Gamma and neutron radiation is also considered in the selection of these items. Equipment located outside the drywell also operates in its normal and accident environments.

7.3.1.2.2.9 Operational Considerations

The instrumentation and control of the ADS is not required for normal plant operations. When automatic depressurization is required, it is initiated automatically by the circuits described in this section. No operator action is required for at least 10 minutes following initiation of the system.

A temperature element is installed on the SRV discharge piping several feet from the valve body. The temperature element is connected to a multipoint recorder in the main control room so that a means of detecting SRV leakage during plant operation is provided. When the temperature in any SRV discharge line exceeds a preset value, an alarm is sounded in the main control room. The alarm setting is enough above normal rated power temperatures to avoid spurious alarms, yet low enough to give early indication of SRV leakage.

7.3.1.2.3 Core Spray System Instrumentation and Control

The core spray system consists of two independent spray loops, as illustrated in Figure 7.3-7. The core spray system is capable of supplying sufficient cooling water to the RPV to adequately cool the core following a design-basis LOCA. The two spray loops are physically and electrically separated so that no single physical event makes both loops inoperable. Each loop includes two ac pumps, appropriate valves, and the piping to route water from the suppression chamber to the RPV.

The instrumentation and control for the core spray system includes the sensors, relays wiring, and valve-operating mechanisms used to start, operate, and test the system. Except for the testable check valve in each spray loop, which is inside the primary containment, the sensors and valve closing mechanisms for the core spray system are located in the reactor building.

Cables from the sensors are routed to the trip unit racks located in the auxiliary building, where the control circuitry is assembled in electrical panels. Each core spray pump is powered from a different ac bus which is capable of receiving standby power. The power supply for automatic valves in each loop is the same as that used for the core spray pump in that loop. Control power for each of the core spray loops comes from separate dc buses.

The electrical equipment for one core spray loop is located in a separate cabinet from that used for the electrical equipment for the other loop.

7.3.1.2.3.1 Initiating Circuits

Primary containment pressure is monitored by four pressure transmitters mounted on instrument racks outside the drywell, but inside the reactor building. Cables are routed from the transmitters to the relay logic cabinets. Each drywell high-pressure trip channel provides an input into the trip logic shown in Figure 7.3-8. Pipes that terminate in the reactor building allow the transmitters to communicate with the drywell interior.

Four drywell pressure transmitters are electrically connected to a "one-out-of-two taken twice" circuit as well as four water-level transmitters to both loops, so that no single event can prevent the initiation of the core spray system due to primary containment high pressure. Contacts from the primary containment high-pressure signal relays are also used in the HPCI, LPCI/RHR, and core spray systems.

Contacts from the RPV low water level (Level 1), initiation signal relays are used in the ADS, core spray, LPCI, and primary CRVICS systems.

7.3.1.2.3.2 Logic and Sequencing

The control scheme for the core spray system is illustrated in Figure 7.3-8. Trip settings are given in Table 7.3-3. The overall operation of the system following the receipt of an initiating signal is as follows:

a. Test bypass valves are closed and interlocked to prevent opening

b. If normal ac power is available, the core spray pumps in both spray loops start 5 sec after receiving the initiation signal

c. If normal ac power is not available, the core spray pumps in both spray loops start 5 sec after standby power becomes available to that particular pump

d. When the RPV pressure drops to a preselected value, valves open in the pump discharge lines, allowing water to be sprayed over the core.

The RPV low water level indicates that the core is in danger of being overheated due to loss of coolant. Drywell high pressure indicates that a breach of the nuclear system process barrier has occurred inside the drywell. The considerations used in establishing the RPV low water level and primary containment high-pressure settings and the instruments that provide the initiating signals are the same as those used for the HPCI system.

To prevent pump overheating at reduced core spray pump flow, a pump discharge bypass is provided from each loop. The bypass routes the discharge from both pumps in a loop back to the suppression chamber. The bypass is controlled by an automatic motor-operated valve whose control scheme is shown in Figure 7.3-8. At core spray high loop flow, the bypass valve is closed; at low flow, the bypass valve is opened. A flow switch measures the flow in each of the two loops.

7.3.1.2.3.3 Bypasses and Interlocks

During test operation, each core spray loop discharge can be routed to the suppression pool. Motor-operated valves are installed in the test lines. On receipt of a core spray initiation signal, the bypass valve closes and remains closed. The piping arrangement is shown in Figure 7.3-7; the control scheme for the two valves is shown in Figure 7.3-8.

7.3.1.2.3.4 Redundancy and Diversity

The core spray system is completely redundant with two independent spray loops. Initiation of the system is described in Subsection 7.3.1.2.3.1.

7.3.1.2.3.5 Actuated Devices

The control arrangements for the core spray pumps are shown in Figure 7.3-8. The circuitry provides for the detection of power available so that all pumps are automatically started. Each of the four pumps can be controlled by a main control room remote switch, or by the automatic control system. A pressure transducer on the discharge line from each core spray pump provides a signal in the main control room to indicate the successful startup of a pump. If a core spray initiation signal is received when normal ac power is not available, all core spray pumps start 5 sec after restoration of the particular bus voltage from which the pump motor receives power, and avoids overloading the source of standby power. The core spray pump motors are provided with overload protection. Overload relays are applied to maintain power as long as possible without immediate damage to the motors or emergency power system. Valve motors are protected by overload alarms and trips.

Flow measuring instrumentation is provided in each of the two core spray loop discharge lines. The instrumentation provides flow indication in the main control room.

Except where specified otherwise, the remainder of this description of the core spray system refers to one spray loop. The second core spray loop is identical. The control arrangements for the various automatic valves in the core spray system are indicated in Figure 7.3-8.

Each of the valves is equipped with limit switches to turn off the valve motor when the valve reaches the limits of movement. Appropriate interlocks prevent the incorrect positioning of the valves by manual action after the system has been automatically actuated. All motor-operated valves are equipped with limit switches that provide main control room indication of valve position. Each automatic valve can be operated from the main control room.

On receipt of an initiation signal, the test bypass valve is interlocked shut. Having received the initiation signal, the core spray pump discharge valves are automatically opened when NSSS pressure drops to a preselected value. The setting is selected low enough so that the low-pressure portions of the core spray system are not overpressurized, yet high enough to open the valves in time to provide adequate cooling for the fuel. Four pressure transmitters are used to monitor nuclear system pressure. The transmitters can initiate opening of the discharge valves on a "one-out-of-two taken twice" basis. The signal received on automatic core spray initiation overrides all other signals. The full-stroke operating times of the motor-operated pump discharge valves are selected to be rapid enough to ensure proper delivery of water to the RPV in a design-basis accident (DBA). The full stroke operation times are as follows:

a. Test bypass valve - 108 sec

b. Pump suction valve - 80 sec

c. Outboard pump discharge isolation valves - 13 sec

d. Inboard pump discharge isolation valves - 12 sec

7.3.1.2.3.6 Separation

General

Refer to Subsection 7.3.1.2.1.6.

Specific

The core spray system consists of independent Division I and II systems. Pumps A and C are in Division I and pumps B and D are in Division II. Two separate logics located in separate panels are used. Logic for the "A" loop is operated by the 260/130-V dc Division I battery and logic for the "B" loop is operated by the 260/130-V dc Division II battery.

7.3.1.2.3.7 Testability

General

Refer to Subsections 7.1.3.1 and 7.3.1.2.1.7.

Specific

The core spray system is provided with a test jack in both "A" and "B" logics. The low reactor level or high drywell pressure "one-out-of-two taken twice" circuit can be completely tested by only actuating one instrument channel at a time. Insertion of the test plug at either logic relay panel actuates an annunciator in the main control room, which indicates that the core spray system is in test status.

7.3.1.2.3.8 Environmental Considerations

The only control components pertinent to core spray system operation that are located inside the primary containment are those controlling the testable check valve on each of the two injection lines. Other equipment, located outside the drywell, is selected in consideration of the normal and accident environments in which it must operate (Table 3.11-3).

7.3.1.2.3.9 Operational Considerations

The core spray system is not required for normal operations. When it is required for accident conditions, it is initiated automatically by the circuitry described in this section. No operator action is required for at least 10 minutes following initiation. After this time, manual operation may be assumed by the operator.

Core spray system pressure between the two pump discharge valves is monitored by a pressure switch to permit detection of leakage from the nuclear system into the core spray system outside the primary containment. A detection system is provided to continuously confirm the integrity of the core spray piping between the inside of the RPV and the core shroud. A differential pressure switch measures the pressure difference between the bottom of the core and the inside of the core spray sparger pipe just outside the RPV. If the core spray sparger piping is sound, this pressure difference will be the pressure drop across the core. If integrity is lost, this pressure drop will include the core pressure drop and the steam separator pressure drop. An increase in the normal pressure drop initiates an alarm in the main control room. Pressure in the core spray pump suction line is monitored by a locally mounted pressure indicator to permit determination of suction head and pump performance.

7.3.1.2.4 Low-Pressure Coolant Injection Instrumentation and Control

Low-pressure coolant injection is an operating mode of the RHR system. The LPCI system is designed to provide water to the RPV following the design-basis LOCA.

Figure 5.5-13 shows the entire RHR system, including the equipment used for LPCI operation.

The instrumentation for LPCI system operation controls other valves in the RHR system. This ensures that the water pumped from the suppression chamber by the main system pumps is routed directly to the reactor. These interlocking features are described in this subsection.

Operation of the LPCI system uses four pumps and two loops, although only three out of four pumps are needed for LPCI cooling. Each loop injects into the reactor through the recirculation pump loop. Figure 5.5-13 shows the location of instruments, control equipment, and LPCI system components. Except for the LPCI system testable check valves, the components pertinent to LPCI system operation are located outside the primary containment.

Power for the LPCI system pumps is supplied from ac buses that can receive standby ac power. Each pump is powered from a separate bus. Motive power for the automatic valves comes from one of the lines that powers the pumps for that loop. Control power for the LPCI components comes from the dc buses.

The LPCI is arranged for automatic and remote manual operation from the main control room. Manual operation allows the operator to act independently of the automatic controls in the event of a LOCA.

7.3.1.2.4.1 Initiating Circuits

The two automatic initiation functions provided for the LPCI systems are RPV low water level and primary containment (drywell) high pressure. Either of these functions initiates the LPCI system.

The low level initiation signal for the LPCI system is a "one-out-of-two taken twice" circuit arrangement using relay contacts from the core spray system. It is used in conjunction with the primary containment high-pressure initiation signal. The high-pressure initiation signal uses pressure transmitters such as those described for the core spray system in Subsection 7.3.1.2.3. A discussion of the LPCI mode loop selection logic is provided in Subsection 6.3.2. Additional information can be found in Subsection 7.3.1.2.4.10.

7.3.1.2.4.2 Logic and Sequencing

The overall LPCI system operating sequence following the receipt of an initiation signal is as follows:

a. All four main system pumps start with no delay, taking suction from the suppression chamber. The valves in the suction paths from the suppression chamber are kept open so that no automatic action is required to line up suction, except when the system is lined up in shutdown cooling. For the loop in shutdown cooling, the suction path requires manual action to realign, and the operating pump(s) need to be reset after trip.

b. Valves used for other RHR operating modes (containment spray, RHR, etc.) are automatically positioned so that the water pumped from the suppression chamber is routed correctly

c. When nuclear system pressure has dropped to a value at which the LPCI system pumps are capable of injecting water into the vessel, the LPCI system injection valves automatically open. If a shutdown cooling isolation has occurred, then the logic needs to be manually reset to permit the LPCI system injection valves, F015A/B to open.

d. The LPCI loops then deliver water to the RPV until vessel water level is adequate to provide core cooling. Cooling water level is ensured since the pump is sealed in. The LPCI cannot be canceled for 5 minutes.

In the descriptions of the LPCI system instrumentation and control that follow, Figure 5.5-13 can be used to determine the physical location of sensors. Figure 7.3-9 can be used to determine the functional use of each sensor in the control circuitry for LPCI system components. Instrument characteristics and settings are given in Table 7.3-4. Actuation logic is shown in Figures 7.3-9 Sheets 1 and 2.

Additional information that provides a more detailed description of the differential pressure sensors used in the LPCI loop selection logic and additional clarification of the loop selection logic can be found in Subsection 7.3.1.2.4.10.

7.3.1.2.4.3 Bypasses and Interlocks

When an RHR loop is operating in the SDC mode, the loop is designed to isolate automatically on low reactor water level (i.e., Level 3) or high reactor pressure. If the system isolates on decreasing level before LPCI initiates (since Level 3 is higher than Level 1), the common SDC suction (E11F008 and 9) valves and the LPCI injection valves (E11F015A and B) in both divisions close, and pumps in the loop that is operating in the SDC mode trip on loss of suction path. The LPCI loop pumps that are lined up in standby mode are not affected. Under these circumstances, if LPCI injection is necessary, operator action would be necessary to align RHR to the LPCI mode. The LPCI injection valves' logic would have to be reset for both the loop in SDC and the loop in LPCI standby mode using the divisional push buttons in the control room. In the loop that was in SDC, the pump control logic would have to be reset before the pump could be started. The torus suction valves for the loop that was in SDC would have to be opened. All of these actions would be performed at the control room panels for the associated RHR loops.

As shown on Sheet 2 of Figure 7.3-9, there are three time-delay interlocks in the loop selection logic:

a. A 0.5-sec delay to determine if either recirculation loop is shut down (in which case, the other loop is also shut down)

b. A 2.0-sec delay to allow momentum effects to settle and system parameters to stabilize

c. A 0.5-sec delay while loop selection logic is being cycled.

Once the specific recirculation loop is selected for injection and the reactor pressure is below the RHR overpressure interlock setpoint, the RHR outboard and inboard valve circuits for that loop receive an OPEN permissive and a CLOSE block. The signal to the outboard valve is locked in for 5 minutes; this time is considered sufficient for the system to reflood the core to at least two-thirds of its height. Expiration of the 5-minute lock-in period does not initiate valve closure, but does give the operator the facility to throttle the flow.

The other loop, the loop not selected for LPCI injection, receives a CLOSE signal for 10 minutes when the loop selection is made. If the LPCI initiation signal remains, there is no capability in the logic to manually bypass the 10- and 5-minute delays in the loop selection logic. Once the loop is selected, the operator cannot change loops for 10 minutes.

To protect the main system pumps from overheating at low flow rates, a minimum flow bypass line is provided that routes water from the pump discharge to the suppression chamber. A motor- operated valve controls the flow in each bypass line. The minimum-flow bypass valve automatically opens on sensing low flow in the discharge line, and automatically closes when flow is above the low flow setting. Figure 5.5-13 shows the location of the flow sensors. The OPEN circuit contains a 25-sec delay permissive; this prevents loss of reactor vessel inventory to the suppression pool during shutdown cooling mode initiation.

The valves that divert water for containment cooling (F016, F021, F024, F027, F028) are signaled closed on receipt of an LPCI system initiation signal. These valves cannot be opened by manual action unless two conditions exist: the accident initiation signal indicating the need for containment cooling is present; and the RPV water level inside the core shroud is above the level equivalent to two-thirds the core height, which indicates that the pumps are not needed for the LPCI function.

Two differential-pressure transmitters are used to monitor water level inside the core shroud. Each is separately piped to the RPV. A keylock switch in the main control room allows manual override of the two-thirds core height and accident initiation signal permissives for the containment cooling valves.

The RHR heat exchanger bypass valve, F048, receives an OPEN and block CLOSE permissive from the LPCI initiation signal so maximum flow is available for injection. After 3 minutes, this permissive is blocked and the operator can manually close, throttle, or leave the valve in the open position.

7.3.1.2.4.4 Redundancy and Diversity

The LPCI system is redundant in that two separate loops are provided with pumps A and C feeding into loop A, and pumps B and D feeding into loop B. Loops A and B are tied together by means of a cross-header with a locked-open valve in the header. Initiation of the system is described in Subsection 7.3.1.2.4.

7.3.1.2.4.5 Actuated Devices

The functional control arrangement for the LPCI system pumps is shown in Figure 7.3-9. If ac power is available, all four LPCI system pumps start with no delay. Otherwise, they start as soon as the emergency power is available. The operator can manually control the pumps from the main control room. This permits him to use the pumps for other purposes such as containment cooling.

Two pressure-indicating transmitters are installed in each pump discharge line to verify that pumps are operating following an initiation signal. The pressure signal is used in the ADS to verify availability of low-pressure core cooling. The pressure transmitters are located upstream of the pump discharge check valves to prevent the operating pump discharge pressure from concealing a pump failure.

The main system pump motors are provided with overload protection. The overload relays maintain power on the motor as long as possible without harming the motor or jeopardizing the emergency power system.

All automatic valves used in the LPCI function are equipped with remote-manual test capability. The entire system can be operated from the main control room. Motor-operated valves have limit switches to turn off the motors when the fully open positions are reached. Torque switches are also provided to control valve motor forces when valves are closing. Thermal overload devices are used to trip motor-operated valves. Valves that have vessel and containment isolation requirements are described in Subsection 7.3.2.

The LPCI system pump suction valves from the suppression pool are normally open. To reposition the valves, a keylock switch must be turned in the main control room. On receipt of an LPCI initiation signal, certain reactor shutdown cooling system valves and the RHR test line valves are signaled to close, although they are normally closed, to ensure that the LPCI system pump discharge is correctly routed. Included in this set of valves are the valves that, if not closed, would permit the main system pumps to take suction from the reactor recirculation loops, a lineup used during normal shutdown cooling system operation.

A timer similar to that used in the LPCI system pump control circuitry cancels the LPCI open signal to the heat exchanger bypass valves after a 3-minute delay, which is time enough to permit satisfactory start of the LPCI system. The signal cancellation allows the operator to control the flow through the heat exchangers for other postaccident purposes. Canceling the open signal does not cause the bypass valves to close.

7.3.1.2.4.6 Separation

General

Refer to Subsection 7.3.1.2.1.6.

Specific

The LPCI system is a Division I and II system. Pumps A and C are in Division I, and pumps B and D are in Division II. Two separate logics located in separate panels are used. Logic for loop A (pumps A and C) is operated by the 260/130-V dc Division I battery and logic for loop B is operated by the 260/130-V dc Division II battery.

7.3.1.2.4.7 Testability

General

Refer to Subsection 7.3.1.2.1.7.

Specific

The LPCI system is provided with test jacks in each logic. The low reactor level or high drywell pressure "one-out-of-two taken twice" circuit can be completely tested by actuating only one instrument channel at a time. The other test jacks are used in the logic to facilitate testing as required. Insertion of the test plug in any jack actuates an annunciator in the main control room, indicating that LPCI is in test status.

7.3.1.2.4.8 Environmental Considerations

The only control components pertinent to LPCI system operation that are located inside the primary containment are those controlling the testable check valves on the injection lines. Other equipment, located outside the drywell, is selected in consideration of the normal and accident environments in which it must operate, as described in Table 3.11-3.

7.3.1.2.4.9 Operational Considerations

The LPCI system is a mode of the RHR system. The pumps, valves, piping, and other equipment used for the LPCI system are used for other modes of the RHR system. The LPCI mode is not required for normal operation.

7.3.1.2.4.10 Low-Pressure Coolant Injection Loop Selection Logic

Because the LPCI system injects water into the reactor through the discharge piping of one of the recirculation loops, it is necessary to make certain that the water is not injected into a broken recirculation loop. To satisfy this requirement, a break-detection system is provided to select the recirculation loop that is broken. This system then provides a signal that causes the LPCI water to be injected through the unbroken loop.

The location of the break in the recirculation system is determined by comparing the pressure of the two recirculation loops. The broken loop will indicate a lower pressure than the unbroken loop. The loop with the higher pressure is then used for LPCI injection or, if both pressures are the same, loop B is selected for injection. A diagram showing the relative physical location of the loop selection differential measurement can be found in Figure 5.5-2.

This logic system for break detection or loop selection is shown in Figure 7.3-9 and the details follow:

a. The entire LPCI system is activated by either high drywell pressure or reactor low water level. Each of these signals is of the one-out-of-two-twice type

b. The recirculation pump differential switches set up the network logic in the optimum arrangement depending on whether one pump or two pumps are operating. If only one pump is operating, the pressure difference due to the pump flow tends to mask the pressure difference due to the break. To avoid this, the loop selection time is delayed (0.5 sec) to determine if either recirculation pump is shut down and to allow proper selection of the unbroken loop. If only one pump is operating, the pump is tripped by the logic circuit

c. The reactor-vessel-pressure permissive delays the one- pump-operating side of the logic network until the reactor pressure has dropped to less than about 900 psig. The delay is added to provide time for the recirculation pump coastdown

d. After satisfaction of the reactor-pressure permissive mentioned above or if both recirculation pumps have indicated ΔP greater than the setpoint, the logic network is delayed about 2 sec to allow momentum effects to settle and system parameters to stabilize
