FERMI 2 UFSAR

Revision 24

DTE Electric Company

November 2022

CHAPTER 1: INTRODUCTION AND GENERAL DESCRIPTION OF PLANT

1.1. INTRODUCTION

The original Final Safety Analysis Report (FSAR) was submitted in support of the Detroit Edison Company's (Edison) application for a license to operate a 3293-MWt (rated) nuclear power plant at the Enrico Fermi Atomic Power Plant site on the western shore of Lake Erie, at Lagoona Beach, Monroe County, Michigan. This Updated Final Safety Analysis Report (UFSAR) was prepared in response to 10 CFR 50.71(e).

The power plant is designated as Fermi 2. The Fermi 2 PSAR (CP Application) was filed in April 1969 and a construction permit CPPR-87 was issued in September 1972. The original FSAR was filed in April 1975. The plant received its license for fuel loading and low-power testing (5 percent power) on March 20, 1985, and its full-power operating license on July 15, 1985.

Fermi 2 uses a General Electric Company (GE) single-cycle, forced-circulation BWR of the BWR 4 Class, with a pressure-suppression Mark I containment. Fermi 2 is similar in design to these nuclear power plants: Browns Ferry Nuclear Plant Units 1, 2, and 3; Cooper Nuclear Station; Edwin I. Hatch Unit No. 1; and Brunswick Steam Electric Plant Units 1 and 2. The design power rating (emergency core cooling system [ECCS] design basis) for Fermi 2 is 3486 MWt, with a turbine-generator design gross electrical output at the generator terminals of 1235 MWe and a net electrical output of 1170 MWe.

On September 9, 1992, the NRC issued Amendment 87 to the Fermi 2 operating license authorizing a change in the thermal power limit from 3293 MWt to 3430 MWt, a 4.2 percent increase in the thermal power and a 5 percent increase in steam flow. This changed the net electrical capacity from 1093 MWe to 1139 MWe, or an increase of 46 MWe.

During RF05 the LP Steam Path was replaced by a GE designed LP Steam Path with a higher efficiency. This changed the designed net electrical capacity from 1139 MWe to 1150 MWe, or an increase of 11 MWe.

During RF07 the HP Steam Path was replaced by a GE designed HP Steam Path with a higher efficiency. However, the gross generator output will not exceed the present 1217 MWe.

During RF11, the Moisture Separator Reheaters (MSRs) were replaced. The gross generator output will not exceed MWe noted above.

The Fermi Power Uprate Program followed the GE Nuclear Energy generic guidelines and evaluations for BWR power plants.[1,2]

---

[1] GE Nuclear Energy, "Generic Guidelines for General Electric Boiling Water Reactor Power Uprate," Licensing Topical Report NEDC-31897P-1, Class III, (Proprietary), June 1991

[2] GE Nuclear Energy, "Generic Evaluations of General Electric Boiling Water Reactor Power Uprate," Licensing Topical Report NEDC-31984P, Volumes I and II, Class III, (Proprietary), July 1991.

On February 10, 2014, the NRC issued Amendment 196 to the Fermi 2 operating license authorizing a change in the thermal power limit from 3430 MWt to 3486 MWt, a 1.64 percent increase in thermal power and a 1.88 percent increase in steam flow. This changed the net electrical capacity from 1150 MWe to approximately 1170 MWe. This power uprate was performed in accordance with 10 CFR 50, Appendix K and reflects the improvement in feedwater flow measurement. The Fermi 2 Measurement Uncertainty Recapture (MUR) power uprate followed the GE generic guidelines and evaluations for BWR plants provided in GEH Topical Report NEDC-32938P-A, "Generic Guidelines and Evaluations for General Electric Boiling Water Reactor Thermal Power Optimization," Revision 2, May 2003.

Fermi 2 specific analyses and evaluations were performed, consistent with the generic guidelines, for systems and components that might be affected to ensure their capability to support the increase in power output and steam flow. Since data is described in detail in the UFSAR, revisions were made to this data to reflect the power uprates, as appropriate. The analyses and evaluations resulted in determinations that the systems and components were either not affected by power uprate or had sufficient design capacity to accommodate uprate conditions.

In addition to the above, the effect of the uprates on the environment was assessed to verify that operation of Fermi 2 at uprated power was environmentally acceptable with established NRC requirements and that consistency was maintained with Federal, State, and local regulations. As a result, no changes to the Environmental Protection Plan or to any of the non-NRC permits are required.

The Detroit Edison Company changed its name to DTE Electric Company as of January 1, 2013. The name change to DTE Electric Company was purely administrative in nature; the legal entity remained the same and the name change did not involve a transfer of control or of an interest in the license for Fermi 2. DTE Electric Company continues to be a wholly owned subsidiary of DTE Energy Company. For the purposes of the Fermi 2 UFSAR, except for UFSAR sections of historical context, all DTE Energy Company designations referenced throughout the UFSAR (e.g. DTE Electric, Edison, Detroit Edison, DECo, etc.) are synonymous.

DTE Electric submitted an application for renewal of the operating license for an additional 20 years on April 24, 2014 by letter NRC-14-0028. The application documented the technical and environmental reviews performed to support extension of the license to March 20, 2045. The NRC performed an in-depth review, including audits, an inspection, and multiple requests for additional information. The NRC issued the final Safety Evaluation Report on the License Renewal of Fermi 2 on July 12, 2016. The Safety Evaluation Report was re-issued as NUREG-2210 in October 2016. NUREG-1437, Supplement 56, the Generic Environmental Impact Statement for License Renewal of Nuclear Plants Regarding Fermi 2 Nuclear Power Plant, was published in September 2016.

Appendix A of the License Renewal Application (LRA) included a supplement to be inserted into the UFSAR following approval of the renewed license. That appendix, including changes submitted in response to NRC requests for additional information, is added to the UFSAR as Appendix B. The appendix addresses the aging management programs that will be implemented per the commitments in the License Renewal Application, a summary of how time limited aging analyses were addressed, and a list of commitments made in the

LRA. Changes to Appendix B may be made per the process for UFSAR revisions under the auspices of 10 CFR 50.59.

The renewed license was issued December 15, 2016.

1.2 GENERAL PLANT DESCRIPTION

1.2.1 General Design Criteria

The general architectural and engineering criteria for the design, construction, and operation of Fermi 2 are summarized in this subsection. For specific NRC General Design Criteria (GDC) conformance description, see Section 3.1.

The discussion of the GDC that follows is divided into three sections. First, the overall requirements criteria are presented for the plant and for the nuclear safety systems and engineered safety features (ESFs). Then the GDC are presented in two ways. First, the criteria are considered in a classification-by-classification approach. Second, the criteria are considered in a system-by-system or system group approach.

1.2.1.1 Overall Requirements Criteria

1.2.1.1.1 Plant Criteria

The plant is designed, fabricated, erected, and operated to generate electricity in a safe and reliable manner. Plant design conforms with applicable codes and regulations and complies with regulatory guides to the extent described in Appendix A.

The plant is also designed, fabricated, erected, and operated in such a way that the release of radioactive materials to the environment is less than the limits of 10 CFR 20 and 10 CFR 50, pertaining to the release of radioactive materials, during normal operation and abnormal events.

Components and structures are provided with appropriate safety factors and adequate strength and stiffness so that a hazardous release of radioactive material will not occur.

Careful consideration is given to all known environmental conditions associated with maintenance, testing, and postulated accidents, including LOCAs, that could result in unplanned releases of radioactive material from the plant. Pollution control equipment and specific design provisions are incorporated in the plant for the specific purpose of protecting public health and safety from the release of radioactive material under both normal and abnormal conditions.

1.2.1.1.2 Nuclear Safety Systems and Engineered Safety Features Criteria

Design margins for the nuclear safety systems and ESFs are conservative.

Nuclear safety systems are designed to respond to abnormal operational transients to limit fuel damage so that, should the freed fission products be released to the environs via the normal discharge paths for radioactive material, the limits of 10 CFR 20 and 10 CFR 50 will not be exceeded.

Nuclear safety systems and ESFs act to preclude damage to the nuclear system process barrier as a result of internal pressures caused by abnormal operational transients or accidents.

When positive and precise action is immediately required in response to accidents, such action is automatic, requiring no decision or manipulation of controls by plant operations personnel.

The reactor core and reactivity control systems are designed so that the control rod action is capable of making the core subcritical and maintaining it so, even when the rod of highest worth is fully withdrawn and unavailable for reinsertion.

Essential safety actions are carried out by equipment in sufficient redundance and independence so that a single failure of active components will not prevent the required actions.

Provision has been made for control of active components of nuclear safety systems and ESFs from the main control room.

Nuclear safety systems and ESFs are designed to permit demonstration of their compliance with functional performance requirements.

Nuclear safety systems and ESFs are designed to maintain operability under all plant-related and site-related events (e.g., earthquakes, tornadoes, floods, fires, etc.).

Features of the plant essential to the mitigation of accident consequences are designed for fabrication and erection to quality standards that reflect the importance of the safety function to be performed. A quality assurance program has been established and implemented.

1.2.1.2 Classification-by-Classification Approach

In this approach, three classifications are considered: (1) power generation; (2) safety; and (3) plant radiation zones. The corresponding GDC are discussed below.

1.2.1.2.1 Power Generation Classification Criteria

The GDC for the power generation classification are further subdivided into criteria for planned operations and for operational transients.

1.2.1.2.1.1 Planned Operations

Power generation design criteria for planned operations are as follows:

a. Fuel cladding is designed to retain integrity as a radioactive material barrier throughout the design power range. The fuel cladding accommodates, without loss of integrity, the pressures generated by fission gases released from fuel material throughout the design life of the fuel

b. Heat removal systems are provided in sufficient capacity and operational adequacy to remove heat generated in the reactor core for the full range of normal operational conditions from plant shutdown to design power. The capacity of such systems is adequate to prevent fuel cladding damage

c. Control equipment is provided to allow the reactor to respond to small load changes

d. Reactor power level is manually controllable

e. Control of the nuclear system is possible from a single location

f. Nuclear system process controls, including alarms, are arranged to allow the operator to rapidly assess the condition of the nuclear system and to locate process system malfunctions

g. Fuel handling and storage facilities are designed to maintain adequate subcriticality, shielding, and cooling for spent fuel

h. Interlocks or other automatic equipment are provided as backup to procedural controls to avoid conditions requiring unnecessary functioning of nuclear safety systems or ESFs

1.2.1.2.1.2 Operational Transients

Power generation design criteria for operational transients are as follows:

a. The fuel cladding, in conjunction with other plant systems, is designed to retain integrity throughout any abnormal operational transient

b. Heat removal systems are provided in sufficient capacity and operational adequacy to remove heat generated in the reactor core for any abnormal operational transient. The capacity of such systems is adequate to prevent fuel cladding damage

c. Control equipment is provided to allow the reactor to respond automatically to normal operational transients, such as major load changes, and to abnormal operational transients, including bringing the reactor to a hot-shutdown condition when appropriate

d. Backup heat removal systems are provided to remove decay heat generated in the core when the normal operational heat removal systems become inoperative. The capacity of such systems is adequate to prevent fuel cladding damage

e. Onsite standby electrical power sources are provided to allow removal of decay heat when normal offsite auxiliary power is not available.

1.2.1.2.2 Safety Classification Criteria

The design criteria for the safety classification are further subdivided into criteria for planned operations, operational transients, and accidents.

1.2.1.2.2.1 Planned Operations

Safety design criteria for planned operations are as follows:

a. The plant is designed, fabricated, erected, and operated in such a way that the normal release of radioactive materials to the environment is within the requirements of 10 CFR 20 and 10 CFR 50

b. The reactor core is designed so that its nuclear characteristics do not contribute to a divergent power transient

c. The nuclear system is designed such that there is no tendency for divergent oscillation of any operating characteristic, considering the interaction of the nuclear system with other appropriate plant systems

d. Gaseous, liquid, and solid waste disposal facilities are designed such that the discharge and offsite shipment of radioactive effluents are in accordance with applicable federal, state, and local regulations

e. The design provides a means by which plant operators are informed when limits on the release of radioactive material are approached

f. Sufficient indication is provided to allow determination that the reactor is operating within the range of conditions considered in the plant safety analysis

g. Radiation shielding and access control procedures are provided to allow a properly trained operating staff to control radiation doses within the limits of applicable regulations in any mode of normal plant operation

h. Procedures for fuel handling and design of fuel storage facilities prevent inadvertent criticality.

1.2.1.2.2.2 Operational Transients

Safety design criteria for operational transients are as follows:

a. The plant is designed, fabricated, erected, and will be operated in such a way that the release of radioactive materials to the environment is within the requirements of 10 CFR 20 and 10 CFR 50

b. Those portions of the nuclear system that form part of the nuclear system process barrier are designed to retain integrity as a radioactive-material barrier following abnormal operational transients

c. Nuclear safety systems act to ensure that no damage to the nuclear system process barrier results from internal pressures caused by abnormal operational transients

d. When positive and precise action is immediately required in response to abnormal operational transients, such action is automatic, requiring no decision or manipulation of controls by plant operations personnel

e. Essential safety actions are carried out by equipment of sufficient redundancy and independence that a single failure of any active component cannot prevent the required actions

f. Provision is made for control of the active components of nuclear safety systems from the main control room

g. Nuclear safety systems are designed to demonstrate their functional performance requirements

h. Nuclear safety systems are designed to maintain their function under all plant-related and site-related events (e.g., earthquakes, floods, tornadoes, and fires)

i. Standby electrical power sources have sufficient capacity to power all nuclear safety systems requiring electrical power

j. Onsite standby electrical power sources are provided to allow prompt reactor shutdown and removal of decay heat under circumstances where normal offsite auxiliary power is not available.

1.2.1.2.2.3 Accidents

Safety design criteria for accidents are as follows:

Fermi 2 has reanalyzed the DBA-LOCA, the control rod drop accident, and the fuel handling accidents in accordance with the methodology in Regulatory Guide 1.183. The release of radioactive materials to the environment is evaluated per the criteria of 10 CFR 50.67 for these accidents only. All other existing accidents are evaluated per the criteria in 10 CFR 100.

a. The plant is designed, fabricated, erected, and will be operated in such a way that the release of radioactive materials to the environment is within the requirements of 10 CFR 100 or 10 CFR 50.67, as applicable

b. Those portions of the nuclear system that form part of the nuclear system process barrier are designed to retain integrity as a radioactive material barrier following accidents. For accidents in which one breach in the nuclear system process barrier is postulated, such a breach does not propagate additional failures in the nuclear system process barrier

c. The ESFs act to ensure that no damage to the nuclear system process barrier results from internal pressures caused by an accident

d. When positive, precise action is immediately required in response to accidents, such action is automatic, requiring no decision or manipulation of controls by plant operating personnel

e. Essential safety actions are carried out by equipment of sufficient redundance and independence that a single failure of any active component cannot prevent the required actions

f. Provision is made for control of active components of the ESFs from the main control room

g. The ESFs are designed to permit demonstration of their functional performance requirements

h. The ESFs are designed to maintain their function under all plant-related and site-related events (e.g., earthquakes, floods, tornadoes, fires, etc.)

i. Onsite standby electrical power sources have sufficient capacity to power the nuclear safety systems and ESFs requiring electrical power during accident conditions

j. Features of the plant essential to the mitigation of accident consequences are designed to be fabricated and erected to quality standards that reflect the importance of the safety actions to be performed

k. The primary containment is designed to retain integrity as a radioactive material barrier during and following accidents that release radioactive material into the primary containment volume

l. The primary containment is designed to permit integrity and leaktightness testing at periodic intervals

m. A secondary barrier (containment) is provided that completely encloses both the primary containment and the fuel storage areas. The secondary barrier design incorporates systems and equipment for controlling the rate of release of radioactive materials from the barrier, and further includes a capability for filtering radioactive materials within the barrier. In the event of a design-basis tornado, the secondary containment barrier above the refueling floor will be breached. See Section 3.3 for additional discussion regarding tornado design

n. The secondary barrier is designed to act as a radioactive material barrier under the same conditions that require the primary containment to act as a radioactive material barrier

o. The secondary barrier is designed to act as a radioactive material barrier, if required, when the primary containment is open for expected operational purposes

p. The primary containment and secondary containment barrier constitute pollution control facilities which, in conjunction with other ESFs, limit radiological effects of accidents resulting in the release of radioactive material to the containment volumes to within the 10 CFR 100 limits or 10 CFR 50.67 limits, as applicable

q. Provisions are made for removing energy from within the primary containment, as necessary, to maintain the integrity of the containment system following accidents that release energy to the primary containment so as to ensure continuing air pollution control functional capability

r. Piping that penetrates the primary containment structure, and which could serve as a path for the uncontrolled release of radioactive material to the environs, is automatically isolated whenever such uncontrolled radioactive material release is threatened. Such isolation is accomplished in time to limit radiological effects to within the 10 CFR l00 limits or 10 CFR 50.67 limits, as applicable

s. The ECCS is provided to limit fuel cladding temperature to 2200 F as a result of a LOCA

t. The ECCS provides for continuity of core cooling over the complete range of postulated break sizes in the nuclear system process barrier in order to minimize the release of radioactive material and to ensure the continuous functional capability of the containment facilities

u. The ECCS is diverse, reliable, and redundant

v. Operation of the ECCS is initiated automatically when required, regardless of the availability of offsite power supplies and the normal generating system of the plant

w. The main control room is shielded against radiation so that occupancy under accident conditions is possible

x. For a special event such as loss of habitability of the main control room, it is possible to bring the reactor from power range operation to a hot-shutdown condition, from outside the main control room, as well as to bring the reactor to a cold-shutdown condition from the hot-shutdown condition

y. For a special event, such as inability to shut down the reactor with control rods, backup reactor shutdown capability is provided, independent of normal reactivity control provisions. This backup system has the capability to shut down the reactor from any normal operating condition and to maintain the shutdown condition.

1.2.1.2.3 Plant Radiation Zone Classification

Radiation zones are identified as a means of classifying the occupancy restrictions on various areas within the plant site boundary. The criteria for each zone are described in Section 12.1.

1.2.1.3 System-by-System Approach

In this approach, the following systems are considered: (1) nuclear system; (2) power conversion systems; (3) electrical power systems; (4) radwaste systems; (5) auxiliary systems; (6) shielding and access control system; (7) nuclear safety and ESFs; and (8) process control systems.

The design criteria are presented below for each one of these systems.

1.2.1.3.1 Nuclear System Criteria

Design criteria for the nuclear system are given below, divided in three groups: mechanical, thermal, and nuclear.

1.2.1.3.1.1 Mechanical

The fuel cladding is designed to retain integrity as a radioactive-material barrier throughout the design power range. The fuel cladding is designed to accommodate, without loss of integrity, the pressures generated by the fission gases released from the fuel material throughout the design life of the fuel.

The fuel cladding, in conjunction with other plant systems, is designed to retain integrity throughout any abnormal operational transient.

Those portions of the nuclear system that form part of the nuclear system process barrier are designed to retain integrity as a radioactive material barrier following operational transients and accidents. For accidents in which one breach in the nuclear system process barrier is postulated, such a breach does not cause additional breaches in the nuclear system process barrier.

1.2.1.3.1.2 Thermal

Heat removal systems are provided in sufficient capacity and operational adequacy to remove heat generated in the reactor core for the full range of normal operational conditions, from plant shutdown to design power, and for any abnormal operational transients. The capacity of such systems is adequate to prevent fuel cladding damage.

Heat removal systems are provided to remove decay heat generated in the core under circumstances wherein the normal operational heat removal systems become inoperative. The capacity of such systems is adequate to prevent fuel cladding damage. Following loss of operation of the normal heat removal systems, the reactor can be automatically shut down fast enough to permit decay heat removal systems to become effective.

1.2.1.3.1.3 Nuclear

The reactor core and the reactivity control system are designed such that the control rod action is capable of bringing the core subcritical, and maintaining it so, even when the rod of highest reactivity worth is fully withdrawn and unavailable for reinsertion.

The reactor core is designed so that its nuclear characteristics do not contribute to a divergent power transient.

The nuclear system is designed so that there is no tendency for divergent oscillation of any operating characteristic, considering the interaction of the nuclear system with other appropriate plant systems.

1.2.1.3.2 Power Conversion Systems Criteria

The power conversion systems are designed to meet the following criteria:

a. Produce electrical power from the steam coming from the reactor, condense the steam into water, and return the water to the reactor as heated feedwater, with the major portion of its gases and particulate impurities removed

b. Ensure that any fission products or radioactivity associated with the steam and condensate during normal operation are safely contained inside the system, or are released under controlled conditions.

1.2.1.3.3 Electrical Power Systems Criteria

The electrical power systems are designed to meet the following criteria:

a. Sufficient normal and standby auxiliary sources of electrical power are provided to attain prompt shutdown and continued maintenance of the plant in a safe condition under all credible circumstances

b. The power sources are adequate to accomplish all required ESF functions under postulated design-basis accident (DBA) conditions.

1.2.1.3.4 Radwaste Systems Criteria

The radwaste systems are designed to meet the following criteria:

a. The radwaste systems are designed to limit release of radioactive materials from the plant during normal operation to within the requirements of 10 CFR 20 and 10 CFR 50

b. Gaseous, liquid, and solid waste disposal systems are designed so that discharge of effluents and offsite shipments are in accordance with applicable regulations, including 10 CFR 50, 10 CFR 71, and 49 CFR 171 through 49 CFR 179, as appropriate.

The design provides a means by which plant operations personnel can be informed whenever operational limits on the release of radioactive material are approached.

1.2.1.3.5 Auxiliary Systems Criteria

Design criteria for each one of the auxiliary systems are presented below. The auxiliary systems considered are: (1) fuel handling and storage systems; (2) water systems; (3) process auxiliaries systems; (4) heating, ventilation, and air conditioning (HVAC) systems; and (5) other auxiliary systems.

1.2.1.3.5.1 Fuel Handling and Storage Facilities

Fuel handling and storage facilities are designed to prevent criticality and maintain adequate shielding and cooling for spent fuel.

1.2.1.3.5.2 Water Systems

The condenser circulating water system is designed to condense the steam discharged from the low-pressure turbines into the condenser.

The general service water (GSW) system is designed to remove heat from the reactor and turbine building closed cooling water (TBCCW) loops and selected equipment to maintain proper equipment temperatures during changing ambient conditions and plant operating modes.

The turbine building closed cooling water system (TBCCWS) is designed to transfer heat from the auxiliary equipment housed in the turbine building to the GSW system to maintain proper equipment temperatures, considering variations in the service water temperatures and plant operating conditions.

The reactor building closed cooling water system (RBCCWS) is designed to transfer heat from reactor auxiliary equipment to the GSW system to maintain proper equipment temperatures, considering variations in service water temperature and plant operating conditions.

The emergency equipment cooling water system (EECWS) provides a backup to the RBCCWS to cool essential equipment by transferring heat to the ultimate heat sink through the emergency equipment service water system (EESWS). It is designed to maintain this function in the event of seismic disturbance, loss of offsite power, or other site- or plant-related events.

The supplemental cooling chilled water system assists the RBCCW system in the RBCCW supplemental cooling mode of operation. RBCCW supplemental cooling is a loop within

RBCCW that provides water cooled by chilled water from SCCW to the EECW loops. The SCCW system and the RBCCW supplemental cooling loops are non-safety-related and are intended to operate during normal plant operation when GSW inlet temperatures are greater than 60°F (nominal).

The demineralized water makeup system is designed to provide water of the required purity in quantities sufficient for plant needs.

The potable water system is designed to provide drinking-quality water, according to state and local standards, in sufficient quantity for the use of plant personnel.

The sanitary wastewater system is designed to dispose of nonradioactive plant sewage liquid waste in accordance with state and local regulations.

The ultimate heat sink (residual heat removal [RHR] complex) is designed to provide cooling to the reactor system and essential auxiliaries under emergency conditions when the normal heat sinks are not available.

The condensate storage facilities are designed to provide retention of condensate to meet the requirements of plant systems, particularly primary system makeup to the condenser and water supply for selected ECCS. The facilities are designed with due regard for radioactive contamination of the condensate.

1.2.1.3.5.3 Process Auxiliary Systems

The compressed air system (instrument and service air) is designed to provide air of required quality at pressures and quantities sufficient to meet plant needs for various operating conditions.

The process sampling system is designed to enable the plant personnel to determine the composition and properties of process fluids in a safe and efficient manner.

The equipment and floor drain systems are designed to conduct drain fluids from general plant areas and equipment to the appropriate radwaste processing facilities.

1.2.1.3.5.4 Heating, Ventilation, and Air Conditioning Systems

The HVAC systems are designed to provide the required ambient environment for plant equipment, to provide a comfortable working environment for plant personnel, and to control airborne radioactivity.

1.2.1.3.5.5 Diesel Generator Auxiliaries

The onsite standby power system (diesel generator) auxiliaries are designed to provide the services required by the diesel generators. Each diesel generator is provided with its own auxiliaries, independent of all other units.

1.2.1.3.5.6 Other Auxiliary Systems

The fire protection system (FPS) is designed to adequately protect the plant from special hazards in accordance with national standards and insurance requirements.

The communications system is designed to provide contact between the main control room and various plant areas. Provisions are made for maintaining communications between essential areas in the event of loss of power.

The lighting systems are designed to provide adequate illumination for work in all plant areas. Provisions are made for emergency lighting in essential areas in the event of loss of power.

1.2.1.3.6 Shielding and Access Control Systems Criteria

The plant radiation shielding is designed to minimize the exposure of plant operating personnel and the general public to radiation due to the reactor, power conversion, auxiliary, and waste processing systems during normal operation, anticipated operational occurrences, postulated accident conditions, and maintenance. Radiation shielding is provided and access control patterns are established to limit radiation doses to the plant staff. The main control room and the technical support center are shielded against radiation so that occupancy is possible under accident conditions.

1.2.1.3.7 Nuclear Safety Systems and Engineered Safety Features Criteria

Design criteria for the nuclear safety systems and ESFs, in the system-by-system approach; have already been listed in various other paragraphs. They are as follows:

a. Design margins for the nuclear safety systems and ESFs are conservative

b. Nuclear safety systems are designed to respond to abnormal operational transients to limit fuel damage so that, should the freed fission products be released to the environs via the normal discharge paths for radioactive material, the limits of 10 CFR 20 and 10 CFR 50 will not be exceeded

c. Nuclear safety systems and ESFs act to preclude damage to the nuclear system process barrier as a result of internal pressures caused by abnormal operational transients or accidents

d. When positive and precise action is immediately required in response to accidents, such action is automatic, requiring no decision or manipulation of controls by plant operating personnel

e. The reactor core and reactivity control systems are designed so that the control rod action is capable of making the core subcritical and maintaining it so, even when the rod of highest reactivity worth is fully withdrawn and unavailable for reinsertion

f. Essential safety actions are carried out by equipment in sufficient redundancy and independence so that a single failure of active components will not prevent the required actions

g. Provision has been made for control of active components of nuclear safety systems and ESFs from the main control room

h. Nuclear safety systems and ESFs are designed to permit demonstration of their compliance with functional performance requirements

i. Nuclear safety systems and ESFs are designed to maintain operability under all plant-related and site-related events (e.g., earthquakes, tornadoes, floods, fires)

j. Features of the plant essential to the mitigation of accident consequences are designed for fabrication and erection to quality standards that reflect the importance of the safety function to be performed. A quality assurance program has been established and implemented

k. Onsite standby electrical power sources are provided to allow prompt reactor shutdown and removal of decay heat under circumstances where normal offsite auxiliary power is not available

l. The plant is designed, fabricated, erected, and will be operated in such a way that under accident conditions the release of radioactive materials to the environment is within the requirements of 10 CFR l00 or 10 CFR 50.67 as applicable

m. Those portions of the nuclear system that form part of the nuclear system process barrier are designed to retain integrity as a radioactive material barrier following accidents. For accidents in which one breach in the nuclear system process barrier is postulated, such a breach does not propagate additional failures in the nuclear system process barrier

n. Onsite standby electrical power sources have sufficient capacity to power the nuclear safety systems and ESFs requiring electrical power during accident conditions

o. The primary containment is designed to retain integrity as a radioactive material barrier during and following accidents that release radioactive material into the primary containment volume

p. The primary containment is designed to permit integrity and leaktightness testing at periodic intervals

q. A secondary barrier (containment) is provided that completely encloses both the primary containment and the fuel storage areas. The secondary barrier design includes a method for controlling the rate of release of radioactive materials from the barrier, and further includes a capability for filtering radioactive materials within the barrier. In the event of a design-basis tornado, the secondary containment barrier above the refueling floor will be breached. See Section 3.3 for additional discussion regarding tornado design

r. The secondary barrier is designed to act as a radioactive material barrier under the same conditions that require the primary containment to act as a radioactive material barrier

s. For a special event such as loss of habitability of the main control room, it is possible to bring the reactor from power range operation to a hot-shutdown condition from outside the main control room, as well as to bring the reactor to a cold-shutdown condition from the hot- shutdown condition

t. For a special event, such as inability to shut down the reactor with control rods, backup reactor shutdown capability is provided, independent of normal reactivity control provisions. This backup system has the capability to shut down the reactor from any normal operating condition and to maintain the shutdown condition.

1.2.1.3.8 Process Control Systems Criteria

Design criteria for the various process control systems are listed below. The systems under consideration are as follows: (l) nuclear systems; (2) power conversion systems; and (3) electrical power systems.

1.2.1.3.8.1 Nuclear System Process Control

Design criteria for nuclear system process control are as follows:

a. Control equipment is provided to allow the reactor to respond to load changes

b. It is possible to control the reactor power level manually

c. Control of the nuclear system is possible from a single location

d. Nuclear system process controls and alarms are arranged to allow the operator to assess the condition of the nuclear system rapidly and locate process system malfunctions

e. Interlocks, or other automatic equipment, are provided as a backup to plant procedural controls to avoid conditions requiring the actuation of nuclear safety systems or ESFs.

1.2.1.3.8.2 Power Conversion Systems Process Control

Design criteria for power conversion systems process control are as follows:

a. Control equipment is provided to control the reactor pressure throughout its operating range

b. The turbine is able to respond automatically to minor changes in load

c. Control equipment in the feedwater system maintains the water level in the reactor pressure vessel (RPV) at the optimum level required by steam separators

d. Control of the power conversion equipment is possible from one location

e. Interlocks or other automatic equipment are provided, in addition to procedural controls, to avoid conditions requiring unnecessary actuation of nuclear safety systems or ESFs.

1.2.1.3.8.3 Electrical Power System Process Control

Design criteria for electrical power system process control are as follows:

a. The electrical power system is designed as a split bus system, with either system being adequate to safely shut down the unit

b. Protective relaying is used to detect and isolate faulted equipment from the system with a minimum of disturbance in the event of equipment failure

c. Undervoltage relays are used on the emergency equipment buses to isolate them from the normal electrical system in the event of loss of offsite power, and to initiate starting the onsite standby power system diesel generators

d. The standby emergency power diesel generators are started by automatically initiated control relays. The generators are also loaded by a programmed control system to meet the existing emergency conditions

e. All 4160-V and 480-V electrically operated breakers are controllable from the main control room

f. Metering for essential generators, transformers, and circuits is monitored in the main control room.

1.2.2 Plant Description

Fermi 2 contains a GE BWR nuclear steam supply system (NSSS) that delivers at rated flow approximately 14,864,000 lb/hr of 991-psia steam to the turbine generator and auxiliary equipment, which produces (at rated steam flow) 1217 MWe of gross electrical output at the generator terminals. The main condenser circulating water is cooled by two wet-type, natural-draft, hyperbolic cooling towers. The plant is equipped with auxiliary systems for control of radioactive contamination, nuclear safety assurance, and operation of the NSSS and turbine generator. The plant is located southwest of Detroit, Michigan and is intended to supply electrical power to the Edison service area.

1.2.2.1 Location and Size of Site

The Fermi 2 site is located on the shore of the western end of Lake Erie, at Lagoona Beach in Frenchtown Township, Monroe County, Michigan. The site is approximately 6 miles northeast of Monroe, Michigan, 30 miles southwest of downtown Detroit, Michigan, and 25 miles northeast of Toledo, Ohio. Reactor centerline coordinates are latitude 41 57'48"N., and longitude 83 15'31"W. The site consists of approximately 1260 acres.

On the same site is Fermi 1, originally a fast breeder reactor, and later also a conventional oil-fired power plant. Both are decommissioned. Also on the site are four oil-fired combustion turbine peaking units rated at 62.4-MWe total capacity. In addition, there is the Independent Spent Fuel Storage Installation for dry storage of Fermi 2 spent fuel. Figures 1.2-1, 1.2-2, and 1.2-3 show the relationship of the site to the surrounding areas. Figure 1.2-4 shows the site boundary and general site location of Fermi 1 and Fermi 2. Figure 1.2-5 is the Fermi site plan.

Transportation facilities are readily available. Interstate Highways 75 and 275 are approximately 5 miles west of the site. More immediate access to the site is available from the Dixie Highway, which runs north and south approximately 2 miles west of the site. From the Dixie Highway, Enrico Fermi Drive (a paved private access road) enters the site on the western boundary where it serves as the main entrance. Rail service to the site is furnished by a spur line from the main line which is 4 miles west of the site.

1.2.2.2 Description of Plant Environs

1.2.2.2.1 General

The site is bounded on the north by Swan Creek, on the east by Lake Erie, on the south by Pointe Aux Peaux Road, and on the west by Toll Road. Entrance to the site is from the west by way of Enrico Fermi Drive, a private road owned by Edison, and from the south via Pointe Aux Peaux Road to Quarry Lake Road, also owned by Edison.

The northern and southern areas of the site are dominated by large lagoons. The western areas are dominated by several woodlots and a series of quarry lakes. Site elevation ranges from approximately 25 ft above the lake level on the western edge of the site to lake level on the eastern edge.

1.2.2.2.2 Population

The area within a 10-mile radius of the site has an estimated total population of 86,214 (1980 data). The only substantially populated community within this radius is the city of Monroe, Michigan, approximately 6 miles southwest, whose 1980 population was 22,995.

Downtown Detroit, Michigan, is located approximately 30 miles northeast of the Fermi site. Downtown Toledo, Ohio, is located about 25 miles southwest.

1.2.2.2.3 Land Use

Approximately 70 percent of Monroe County, in which the plant is located, is farmland. Most of the industrial activity in the county is concentrated in the city of Monroe. Within a 50-mile radius of the site are all, or portions of, eight counties in Michigan, nine counties in Ohio, and two counties in Ontario, Canada. A large number and variety of manufacturing industries are found in this area. However, according to 1974 data, more than 50 percent of the land within the 50-mile radius is farmland, except for the area in the six counties located around metropolitan Detroit and Toledo.

1.2.2.3 Design Bases Dependent On the Site Environs

1.2.2.3.1 Offgas System

A rooftop plant vent is provided for the discharge of gaseous effluent to the atmosphere. Gaseous releases will be in compliance with 10 CFR 20 and 10 CFR 50.

1.2.2.3.2 Liquid Waste Effluents

Liquid waste will be released so that concentrations at the point of discharge will be in compliance with 10 CFR 20 and 10 CFR 50.

1.2.2.3.3 Wind Loading Design

The primary containment, reactor systems, and structures that contain equipment necessary for safe shutdown are designed with a wind load consideration for a sustained high wind (90 mph) and a transient condition imposed by a postulated tornado (300-mph rotation, 60-mph translation, 3-psi external pressure drop at 1 psi/sec).

1.2.2.3.4 Seismic Design

The design of Category I structures is for a maximum horizontal ground acceleration of 0.15g. The maximum vertical ground acceleration is considered to occur simultaneously, and is equal to 0.67 times the horizontal ground acceleration. The combined stresses resulting from functional loadings and a safe-shutdown earthquake (SSE) having a horizontal ground acceleration of 0.15g will be such that a safe shutdown can be achieved.

1.2.2.3.5 Flooding

A comprehensive study has established a maximum stillwater elevation of 586.9 ft (New York Mean Tide, 1935) for the plant site, based on the probable maximum meteorological event (PMME).

The site grade is 583.0 ft (New York Mean Tide, 1935) along the periphery of the power block (reactor/auxiliary building, RHR complex, turbine house, radwaste building, service building, etc.). From this reference elevation, the site has been graded for proper drainage.

Fermi 2 Category I structures and components are conservatively flood protected (waterproofed) to an elevation of 588 ft.

The shoreline of that portion of the site occupied by the plant is protected from erosion resulting from wave action through the use of a specially constructed shore barrier.

1.2.2.3.6 Loss of Normal Heat Sink

The natural-draft cooling towers provide the normal heat sink for the once-through-type main unit condenser and auxiliary systems. Should this heat sink be lost, the reactor can be safely shut down and maintained using the mechanical-draft cooling towers and the RHR reservoir as a heat sink.

1.2.2.3.7 Environmental Radiation Monitoring Program

An environmental monitoring program has been under way at the Fermi site since 1958 when Fermi 1 was being constructed. The present program, which has been specific for Fermi 2 since 1978, is referenced in UFSAR Section 11.6.

1.2.2.4 General Arrangement of Structures and Equipment

The principal structures located on the plant site are the following:

a. The reactor building, which houses the drywell, the suppression pool, the NSSS, the ESFs, some auxiliary systems equipment, and the fuel storage and shipping area

b. The turbine building, which houses the power conversion equipment, the offgas system, and the plant auxiliaries

c. The auxiliary building, which houses the main control room, the computer facility, electrical equipment, and HVAC equipment

d. The radwaste building, which houses the radioactive waste treatment facilities for liquid and solid waste

e. The switchyard

f. The condensate storage tanks and fuel-oil storage tanks

g. The RHR complex, which houses the emergency diesel generators (EDGs), the RHR cooling towers, the RHR service water (RHRSW) reservoir, and the RHRSW, EESWS, and EDG service water pumps

h. Two natural-draft hyperbolic circulating water cooling towers, and corresponding intake conduits, intake structures, and discharge structures

i. The GSW house, and corresponding intake conduits, intake structures, and discharge structures

j. The circulating water pump house, and corresponding intake conduits, intake structures, and discharge structures

k. A reservoir pond

l. The auxiliary boiler house

m. The meteorological towers

n. The office service building and annex

o. The Fermi 1 plant complex

p. The nuclear operations center

q. Technical assistance center

r. Availability improvement center.

s. Hydrogen/Oxygen supply facility for hydrogen water chemistry

t. Nuclear training center

u. The Independent Spent Fuel Storage Installation (ISFSI) Equipment Storage Building

v. The Independent Spent Fuel Storage Installation (ISFSI) Pad

w. ISFSI Fabrication Pad

x. ISFSI Transfer Pad

y. ISFSI Cask Transfer Facility

z. FLEX Storage Facility #1

aa. FLEX Storage Facility #2

The arrangement of these structures on the plant site is shown in Figure 1.2-5. Figures 1.2-6 through 1.2-31 show the equipment arrangement in the principal buildings.

1.2.2.5 Nuclear System (Chapter 4)

The nuclear system includes a single-cycle, forced-circulation GE BWR that produces steam for direct use in the steam turbine. A heat balance showing the major parameters of the nuclear system for the rated power conditions is shown in Figure 1.2-32.

1.2.2.5.1 Reactor Core and Control Rods (Section 4.5)

Fuel for the reactor core consists of enriched uranium dioxide (UO_2) pellets sealed in Zircaloy-2 tubes. These tubes (or fuel rods) are assembled into individual fuel assemblies. Gross control of the core reactivity is achieved by cruciform-shaped, movable, bottom-entry control rods dispersed throughout the lattice of fuel assemblies. These rods are controlled by individual hydraulic systems.

Each fuel assembly has several fuel rods with gadolinia (Gd_2O_3) mixed in solid solution with the UO_2. Gadolinia is a burnable poison that diminishes the reactivity of the fresh fuel and is depleted as the fuel reaches the end of its first cycle.

A conservative limit of plastic strain is used for the design criterion for fuel rod cladding failure. The peak linear heat generation for steady-state operation is well below the damage limit, even late in life. Experience has shown that the control rods are not susceptible to distortion and have an average life expectancy many times greater than the residence time of a fuel loading.

1.2.2.5.2 Reactor Pressure Vessel and Internals (Section 4.5)

The RPV contains the following:

a. Core and supporting structures

b. Steam separators and dryers

c. Jet pumps

d. Control rod guide tubes

e. Distribution lines for the feedwater, core sprays, and standby liquid control

f. In-core instrumentation

g. Other components.

The main connections to the RPV include the steam lines, the coolant recirculation lines, feedwater lines, control rod drive (CRD) housings, and ECCS lines.

The RPV is designed and fabricated in accordance with applicable codes for a pressure of 1250 psig. The nominal rated operating pressure in the steam space above the separators is 1045 psia. The RPV is fabricated of carbon steel and is clad internally (except for the top head) with stainless steel.

The reactor core is cooled by demineralized water that enters the lower portion of the core and boils as it flows upward around the fuel rods. The steam leaving the core is dried by steam separators and dryers located in the upper portion of the RPV. The steam is then directed to the turbine through four 24-in.-diameter main steam lines. Each steam line is provided with three isolation valves in series, one inside the primary containment, and two outside the primary containment.

1.2.2.5.3 Reactor Recirculation System (Subsection 5.5.1)

The reactor recirculation system pumps reactor coolant through the core to remove energy generated in the fuel. This is accomplished by two recirculation loops external to the RPV but inside the primary containment. Each external loop has one motor-driven recirculation pump. Recirculation pump speed can be varied to allow control of reactor power level through the effects of coolant flow rate on moderator void content. The internal portion of the loop consists of the jet pumps, which contain no moving parts, but have high-velocity nozzles to provide a continuous internal circulation path for the core coolant flow. The jet pumps are located in the annular region between the core shroud and the vessel inner wall, and any recirculation line break would still allow core flooding to approximately two-thirds of the core height: the level of the top of the jet pumps.

1.2.2.5.4 Residual Heat Removal System (Subsection 5.5.7)

The RHR system consists of pumps, heat exchangers, and piping that fulfill the following functions:

a. Remove decay heat during and after plant shutdown

b. Remove heat from the primary containment following a LOCA.

1.2.2.5.5 Reactor Water Cleanup System (Subsection 5.5.8)

The reactor water cleanup (RWCU) system recirculates a portion of reactor coolant through a filter-demineralizer to remove particulate and dissolved impurities from the reactor coolant. It also removes excess coolant from the reactor system under controlled conditions.

1.2.2.6 Power Conversion System (Chapter 10)

The megawatt output of the generator is a function of the reactor steam power input to the turbine. Turbine control is achieved by an integrated speed and pressure control system. After the turbine has been brought to the synchronous speed of the power grid system and the generator breakers are closed to lock the machine into the system, the turbine is on pressure control. The turbine acts as a pressure-control device, maintaining the reactor pressure at its particular pressure setpoint level by varying control and/or bypass valve opening. The steam admitted to the turbine is controlled by a pressure regulator that senses the pressure just before the turbine inlet, thus controlling RPV pressure. Figure 1.2-33 shows the turbine-generator heat balance at rated flow.

Feedwater into the reactor is governed by a three-element control system that senses water level, main stream flow rate, and feedwater flow rate. Each of the signals combines in a three-element controller to control the speed of the two turbine-driven reactor feed pumps, thereby regulating feedwater requirements.

1.2.2.7 Electrical Power Systems (Chapter 8)

Power output from the unit is from a nominally rated 1350-MVA turbine generator. Generator output voltage is 22 kV. It is stepped up to 345 kV through two parallel main power transformers, then fed to the 345-kV switchyard and then to the system grid.

Offsite power available for the plant auxiliary system is from both the 345-kV switchyard, just west of the plant, and the 120-kV switchyard located at Fermi 1. Normal auxiliary power is provided from two system service transformers. One transformer is connected to the Fermi 2 345-kV switchyard, which is arranged in a nominal double breaker-double bus design. The remaining system service transformer is energized from the 120-kV switchyard through the 120/13.2-kV transformer 1 with an alternate through 120/13.8/13.8-kV transformer CTG II at the Fermi 1 site.

Onsite standby emergency power is provided from a four-diesel split-bus arrangement that is located in the RHR complex Category I structure near the reactor building. The diesel generators are sized to adequately carry the load necessary to shut down the reactor during a LOCA coincident with a complete loss of offsite power. Battery power is available for loads through two sets of 260/130-V dc Category I station batteries. The batteries furnish power to redundant essential loads. A highly reliable source of 48/24-V dc power is available for neutron monitoring and certain other instrumentation. In addition, a balance-of-plant (BOP) 260/130-V dc battery provides dc power for BOP loads. The batteries are sized to provide adequate power to those loads for a period of not less than 4 hr without battery charger availability. The chargers are full sized and capable of handling the load requirements, while still providing the required float charge for the battery.

1.2.2.8 Radwaste Systems (Chapter 11)

The radioactive waste disposal systems and the radiation monitoring systems (RMS) are designed so that liquid, solid, and gaseous effluents are considerably below those specified in 10 CFR 20.

1.2.2.9 Nuclear Safety Systems and Engineered Safety Features

1.2.2.9.1 Reactor Protection System (Section 7.2)

The reactor protection system (RPS) initiates a rapid, automatic shutdown (scram) of the reactor. It acts in time to prevent fuel cladding damage and any nuclear system process barrier damage following operational transients. The RPS overrides all operator actions and process controls and is based on a fail-safe design philosophy that allows appropriate protective action even if a single failure occurs.

1.2.2.9.2 Neutron Monitoring System (Subsection 7.6.l)

Those portions of the neutron monitoring system (NMS) that provide high neutron flux signals to the RPS qualify as a nuclear safety system. The intermediate range monitors (IRMs) and average power range monitors (APRMs), which monitor neutron flux via in-core detectors, signal the RPS to scram in time to prevent fuel cladding damage as a result of overpower transients.

1.2.2.9.3 Control Rod Drive System (Subsection 4.5.2)

When a scram is initiated by the RPS, the CRD system inserts the negative reactivity necessary to shut down the reactor. Each rod is individually controlled by a hydraulic control unit (HCU). When a scram signal is received, high-pressure water, stored in an accumulator in the HCU, forces its control rod into the core.

1.2.2.9.4 Nuclear System Pressure Relief System (Subsection 5.2.2)

A pressure relief system, consisting of safety/relief valves mounted on the main steam lines, prevents excessive pressure inside the nuclear system following either abnormal operational transients or accidents.

1.2.2.9.5 Reactor Core Isolation Cooling System (Subsection 5.5.6)

The reactor core isolation cooling (RCIC) system provides makeup water to the RPV when the vessel is isolated. The RCIC system uses a steam-driven turbine pump unit and operates automatically, with sufficient coolant flow in time to maintain adequate water levels in the RPV.

1.2.2.9.6 Primary Containment (Section 6.2)

The primary containment (Mark I containment) is a steel plate pressure vessel consisting of a light bulb-shaped drywell and a torus-shaped pressure suppression chamber. The primary containment is designed in accordance with the 1968 ASME Boiler and Pressure Vessel Code, Class B Vessel, including the 1969 summer addenda. The basic objective of the primary containment is to provide the capability, in the event of a postulated LOCA, of limiting the release of fission products within the values specified in 10 CFR 50.67 or 10 CFR 100.

1.2.2.9.7 Primary Containment and Reactor Isolation System (Subsection 6.2.4)

The containment isolation system consists of the isolation valves and controls required for the timely isolation of the containment in the event of incidents when the free release of containment contents cannot be permitted. The reactor isolation system consists of the isolation valves and controls required for the timely isolation of the RPV in the event of incidents when the fuel must be prevented from failing.

1.2.2.9.8 Secondary Containment (Section 6.2)

The reactor building, in conjunction with the reactor building heating and ventilation system and the standby gas treatment system (SGTS), constitutes the secondary containment. The primary purpose of the secondary containment is to minimize the ground-level release of airborne radioactive materials and provide means for a controlled release of the building atmosphere.

The reactor building is a cast-in-place reinforced-concrete structure enclosing the primary containment. The superstructure of the reactor building is composed of structural steel and steel siding.

1.2.2.9.9 Main Steam Line Isolation Valves (Subsection 5.5.5)

All pipelines that penetrate the primary containment, offering a potential release path for radioactive material, are provided with redundant isolation capabilities. The main steam lines, because of their large size and large mass flow rates, are given special isolation consideration. The automatic isolation valves in each main steam line, immediately inside and outside the primary containment, are powered by both pneumatic pressure and spring force. These valves fulfill the following objectives:

a. Prevent excessive damage to the fuel barrier by limiting the loss of reactor coolant from the RPV as a result of (1) a major leak in the steam piping outside the primary containment, or (2) a malfunction of the pressure control system causing excessive steam flow from the RPV

b. Limit the release of radioactive materials by closing the nuclear system process barrier in the event of a gross release of radioactive materials from the fuel to the reactor cooling water and steam

c. Limit the release of radioactive materials by closing the primary containment barrier in the event of a major leak from the nuclear system inside the primary containment.

A third, motor-operated, main steam isolation valve (MSIV) is provided in each main steam line to limit postulated leakage. See Subsection 6.2.6.

1.2.2.9.10 Main Steam Line Flow Restrictors (Subsection 5.5.4)

A venturi-type flow restrictor is installed in each steam line. These devices limit the loss of coolant from the RPV before the MSIVs are closed, in case of a main steam line break outside the primary containment.

1.2.2.9.11 Emergency Core Cooling System (Section 6.3)

A number of functions of the ECCS are provided to limit fuel cladding temperatures to minimize the release of radioactive material and to ensure the continued functional capability of the containment facility if a breach in the nuclear system process barrier results in a loss of reactor coolant. The four functions of the ECCS are presented in the following paragraphs.

1.2.2.9.11.1 High Pressure Coolant Injection System

The high pressure coolant injection (HPCI) system provides and maintains an adequate coolant inventory inside the RPV. This limits fuel cladding temperature, which may result from postulated small breaks in the nuclear system process barrier. A high-pressure system is needed for small breaks because the RPV depressurizes slowly, preventing low-pressure systems from injecting coolant. Also, the HPCI system reduces RPV pressure rapidly, permitting operation of the low-pressure systems. The HPCI system includes a turbine-driven pump powered by reactor steam. The system is designed to accomplish its function on a short-term basis, without reliance on plant auxiliary power supplies other than the dc power supply.

1.2.2.9.11.2 Automatic Depressurization System

The automatic depressurization system (ADS) rapidly reduces RPV pressure in a LOCA situation in which the HPCI system fails to maintain the RPV water level. The depressurization provided by the system enables the low-pressure ECCS to deliver cooling water to the RPV. The ADS uses some of the relief valves that are part of the nuclear system pressure relief system. The automatic relief valves are arranged to open on conditions indicating that a break in the nuclear system process barrier has occurred, and that the HPCI system is not delivering sufficient cooling water to the RPV to maintain the water level above a preselected value. The ADS will not be activated unless either the core spray or low pressure coolant injection (LPCI) system pumps are operating. This ensures that adequate cooling will be available so that boiling will not occur at the reduced pressure.

1.2.2.9.11.3 Core Spray System

The core spray system consists of two independent pump loops that deliver cooling water to independent spray spargers over the core. The system is actuated by conditions indicating that a breach exists in the nuclear system process barrier. Water is delivered to the core after RPV pressure is reduced. This system provides the capability of cooling the fuel by spraying water onto the core. Either of the core spray loops is capable of limiting fuel cladding temperature to less than 2200°F following a LOCA.

1.2.2.9.11.4 Residual Heat Removal - Low Pressure Coolant Injection Mode

The LPCI is an operating mode of the RHR system, but is discussed here because the LPCI mode acts as an ESF in conjunction with the other functions of the ECCS. The LPCI system uses the pump loops of the RHR system to inject cooling water at low pressure into an undamaged reactor recirculation loop. The LPCI is actuated by conditions indicating a breach in the nuclear system process barrier. Water is delivered to the core after RPV pressure is reduced. The LPCI operation, together with the core shroud and jet pump arrangement, provides the capability of core reflooding, following a LOCA, in time to prevent fuel cladding temperature from exceeding 2200°F.

1.2.2.9.12 Residual Heat Removal System - Containment Cooling Mode (Section 6.3)

The containment cooling subsystem is placed in operation to limit the temperature of the water in the suppression pool following a design-basis LOCA. In the containment cooling mode of operation, the RHR pumps take suction from the suppression pool and pump the water through the RHR system heat exchangers. Cooling takes place by transferring heat to the RHRSW system. The primary coolant is then discharged back to the suppression pool.

Another portion of the RHR system sprays water into the primary containment as an augmented means of removing energy from the containment following a LOCA. This capability is in excess of the required emergency heat removal capability and can be placed in service at the discretion of the operator.

1.2.2.9.13 Control Rod Velocity Limiter (Subsection 4.5.2.1)

A control rod velocity limiter is attached to each control rod to limit the velocity at which it can fall out of the core should it become detached from its CRD. This action limits the rate of reactivity insertion resulting from a control rod drop accident. The limiters contain no moving parts.

1.2.2.9.14 Control Rod Drive Housing Supports (Subsection 4.5.3)

The CRD housing supports are located underneath the RPV near the control rod housings. The supports limit the travel of a control rod should a control rod housing become ruptured. The supports prevent a nuclear excursion as a result of a housing failure and thus protect the fuel barrier.

1.2.2.9.15 Standby Gas Treatment System (Subsection 6.2.3)

The SGTS consists of two identical 100 percent equipment and filter trains for the plant. On detection of radioactivity or conditions that could lead to a release of radioactivity, the SGTS functions to minimize the release-related offsite dose rates by permitting the venting and purging of both the primary and secondary containment atmospheres under accident or abnormal conditions, and at the same time containing any airborne particulate or halogen contamination that might be present. Either train may be considered as an installed spare, with the other train being capable of passing the required amount of air. Either train alone is capable of exchanging the total reactor building air volume once in a 24-hr period.

Each equipment train contains an electric heater, a prefilter, a high-efficiency particulate filter (water and fire resistant), an iodine filter (fire resistant), a fan, and associated instrumentation.

The primary containment can be purged through the SGTS.

1.2.2.9.16 Onsite AC Power Supply (Subsection 8.3.1)

The onsite ac power supply provides sufficient power to those devices necessary to produce a safe shutdown with subsequent reactor decay heat removal should normal offsite power not be available. Power is derived from four EDGs housed in a Category I structure (RHR complex) located near the reactor building. The EDGs are installed in division pairs. Either division pair is capable of completely maintaining itself and the safety loads it supplies for 7 days. The entire standby power supply system is independent of offsite power.

1.2.2.9.17 DC Power Supply (Subsection 8.3.2)

The dc power supply provides power to those safety devices receiving their motive and/or control power from the station battery systems. The batteries are redundant and each has a battery charger capable of providing the full load capacity and maintaining the float charge on the battery.

1.2.2.9.18 Ultimate Heat Sink (Residual Heat Removal Complex) Section 6.3 and Subsection 9.2.5)

The RHR complex provides cooling for the RHR system, EESW, and EDGs. The RHR complex consists of mechanical-draft cooling towers, cooling water reservoirs, RHR, and emergency equipment cooling and EDG cooling service water pumps. The RHR complex also contains the EDGs. (See Figures 1.2-25 through 1.2-31.)

1.2.2.9.19 Main Steam Line Radiation Monitor System (Subsection 11.4.3.8.2.3)

The main steam line radiation monitor system consists of four gamma radiation channels located external to the main steam lines just outside the primary containment. The monitors are designed to detect a gross release of fission products from the fuel. On detection of high radiation, the trip signals generated by the monitors are used to isolate the reactor water sample system, trip condenser mechanical vacuum pumps, and trip glad seal exhausters.

1.2.2.9.20 Fuel Pool Ventilation Exhaust Radiation Monitor System (Subsection 11.4.3.8.2.11)

The fuel pool ventilation exhaust radiation monitor system consists of four radiation monitors arranged to monitor the activity level of the ventilation exhaust from the fuel pool area. On detection of high radiation, the SGTS is automatically started, the primary containment vent valves are closed, the reactor building vent system is isolated, the control center is isolated, and control center emergency recirculation is initiated.

1.2.2.9.21 Emergency Equipment Cooling Water System (Subsection 9.2.2)

Equipment required for a safe shutdown of the reactor is cooled by the EECWS, which is cross connected to the RBCCWS for normal operation. The EECW is isolated and is cooled by the ultimate heat sink (RHR complex) for emergency operation. The EECWS is designed to Category I requirements.

1.2.2.9.22 Combustible Gas Control (Subsections 6.2.5 and 9.3.6)

The NRC amended 10 CFR 50.44, “Standards for combustible gas control system in light-water-cooled power reactors” on October 16, 2003 to eliminate the requirements for hydrogen recombiners. The hydrogen recombiner Technical Specification requirements were subsequently removed by License Amendment 159, dated March 15, 2004. Regulatory Guide 1.7 was revised in March 2007 to reflect the amended 10 CFR 50.44. The Combustible Gas Control System (CGCS) has been retired in place with its electrical circuits de-energized and fluid process piping isolated from primary containment with redundant locked-closed isolation valves. Combustible gas control of the primary containment is provided by inerting the primary containment with nitrogen.

1.2.2.9.23 Instrumentation and Control Power Supply System Subsection 8.3.1)

The purpose of the instrumentation and control power supply system is to provide a reliable source of 120-V ac regulated power where necessary, for analog instrumentation, solenoid valves, and logic relaying for certain specific systems. These systems include: core spray, RHR, radwaste control, and NSSS process instrumentation.

1.2.2.9.24 Main Control Room Emergency Ventilation System (Section 6.4)

A main control room emergency ventilation system is provided to protect the main control room operators against radiation, smoke, or any noxious chemical release. It consists of an emergency makeup (pressurizing) and a control center recirculation filter train with 100 percent redundant active components.

1.2.2.9.25 Engineered Safety Features Ventilation Cooling System (Subsection 6.2.l.2)

All ESF equipment is provided with ventilation fans and/or cooling units to maintain design temperatures if the normal ventilation system is isolated. Redundant divisional ESF equipment is supplied with its own independent ventilation equipment powered by the corresponding division of the ESF bus.

1.2.2.10 Special Safety Systems

1.2.2.10.1 Standby Liquid Control System (Subsection 4.5.2.4)

Although not intended to provide prompt reactor shutdown, like the control rods, the standby liquid control system (SLCS) provides a redundant, independent, and different way to bring the nuclear fission reaction to subcriticality and maintain subcriticality as the reactor cools. The system permits an orderly and safe shutdown in the event that control rods cannot be inserted into the reactor core in sufficient number to accomplish shutdown in the normal manner. The system is sized to counteract the positive reactivity effect in decreasing power from rated power to the cold-shutdown condition.

The SLCS is also credited for injecting sodium pentaborate into the reactor coolant system after a design basis LOCA in order to control ECCS water pH to prevent iodine re-evolution. The SLCS can be manually initiated to provide this function.

1.2.2.10.2 Plant Equipment Outside the Main Control Room To Effect Reactor Shutdown (Section 7.5)

Instrumentation and controls necessary to meet the requirements of 10 CFR 50, Appendix A, Criterion 19, have been provided on a remote shutdown panel located outside the main control room. Details of the instruments and controls provided on the shutdown panels and the procedures required for carrying out a safe and orderly shutdown are described fully in Subsection 7.5.1.5.

Additionally, local shutdown panels are provided to meet the requirements of 10 CFR 50, Appendix R. These panels are provided in the event a fire causes a loss of control from the main control room. Details on achieving reactor shutdown in this event are provided in Subsection 7.5.2.5.

1.2.2.11 Nuclear System Process Control and Instrumentation

1.2.2.11.1 Reactor Manual Control System (Subsection 7.7.1.1)

The reactor manual control system (RMCS) provides the means by which control rods are positioned from the main control room for gross power control. The system operates valves in each HCU to change control rod position. Only one control rod can be manipulated at a time. The RMCS includes the logic that restricts control rod movement (rod block), under certain conditions, as a secondary control.

1.2.2.11.2 Recirculation Flow Control System (Subsection 7.7.1.2)

The recirculation flow control system (RFCS) controls the speed of the reactor recirculation pumps. Adjusting the pump speed changes the coolant flow rate through the core, thereby changing the core power level.

1.2.2.11.3 Neutron Monitoring System (Subsection 7.6.1.13)

The NMS is a system of in-core neutron detectors and out-of-core electronic monitoring equipment. The system provides indication of neutron flux, which can be correlated to thermal power level, for the entire range of flux conditions that can exist in the core. The source range monitors SRMs and the IRMs provide flux level indications during reactor startup and low power operation. The local power range monitors (LPRMs) and APRMs allow assessment of local and overall flux conditions during power range operation. Rod block monitors (RBMs) are provided to prevent rod withdrawal when reactor power should not be increased at the existing reactor coolant flow rate and also function to prevent local fuel damage. The flux mapping and calibration subsystem provides a means to calibrate individual monitors with traveling in-core probes.

1.2.2.11.4 Refueling Interlocks (Section 7.6.1.1 and Subsection 9.1.4)

A system of interlocks that restricts movement of refueling equipment and control rods when the reactor is in the refueling mode prevents an inadvertent criticality during refueling operations. The interlocks back up procedural controls that have the same objective. The interlocks affect the refueling bridge, refueling bridge hoists, fuel grapple, and control rods.

1.2.2.11.5 Reactor Pressure Vessel Instrumentation (Section 5.6)

In addition to instrumentation for the nuclear safety systems and ESFs, instrumentation is provided to monitor and transmit information that can be used to assess both the condition existing inside the RPV and the physical condition of the vessel itself. This instrumentation monitors RPV parameters such as pressure, water level, surface temperature, internal differential pressures, coolant flow rates, and top head flange leakage.

1.2.2.11.6 Integrated Plant Computer System (Subsection 7.6.1.9)

The Integrated Plant Computer System (IPCS) includes the following process monitoring functions:

a. Scan, Log and Alarm (SLA)

b. Man-Machine Interface (MMI)

c. Data Archival

d. Nuclear Steam Supply System (NSSS)

e. Balance of Plant (BOP)

f. Emergency Response

   1. Safety Parameter Display System (SPDS)

   2. Emergency Response Data System (ERDS)

g. Meteorological (MET)

h. Transient Recording and Analysis (TRA)

i. External System Interfaces

1.2.2.11.7 Reactor Coolant Pressure Boundary Leakage Detection System (Subsection 5.2.7)

The nuclear leak detection system consists of temperature, pressure, flow, and fission product sensors with associated instrumentation and alarms. This system detects and annunciates leakage in the following systems:

a. Main steam lines

b. Reactor water cleanup

c. Residual heat removal

d. Reactor core isolation cooling

e. High pressure coolant injection

f. Instrument lines.

Small leaks are generally detected by temperature and pressure changes, fillup rate of drain sumps, and fission product concentration inside the primary containment. Large leaks are also detected by changes in reactor water level and changes in process lines.

1.2.2.11.8 Emergency Core Cooling System Suction Piping Leakage Detection (Subsections 6.3.2.2.7and 7.6.1.8.12)

The ECCS leak detection system (LDS) uses the sump level and torus water level monitors to identify any failed line in the reactor building subbasement area and, thereby, prevents a loss of ECCS pump suction head.

1.2.2.11.9 Primary Containment Monitor System (Subsections 6.2.1.5 and 7.6.1.12)

The NRC amended 10 CFR 50.44, “Standards for combustible gas control system in light-water-cooled power reactors” on October 16, 2003 to eliminate the requirements for hydrogen recombiners. The hydrogen recombiner Technical Specification requirements were subsequently removed by License Amendment 159, dated March 15, 2004. Regulatory

Guide 1.7 was revised in March 2007 to reflect the amended 10 CFR 50.44. The Combustible Gas Control System (CGCS) has been retired in place with its electrical circuits de-energized and fluid process piping isolated from primary containment with redundant locked-closed isolation valves.

The primary containment monitor system (PCMS) is an advisory system only, which consists of measurements of hydrogen and oxygen concentration, particulate and gaseous radiation level, pressure, temperature, and water level in the drywell and suppression chamber. Hydrogen and oxygen monitors provide an operator with necessary information for the effective control of the nitrogen inerting system. The radiation monitor supplies information necessary for effective control of the SGTS as a primary containment atmospheric cleanup system and is a part of a redundant leak detection system, operating in conjunction with the drywell floor drain sump level indicating system. Hydrogen and radiation monitors also yield vital information regarding personnel access to the primary containment. The remaining instruments supply information on the overall conditions of the atmosphere in the drywell and suppression chamber and on water level and temperature in the suppression chamber.

1.2.2.11.10 Rodworth Minimizer Computer (Subsection 7.6.1.20)

The rodworth minimizer microcomputer system is a stand alone microcomputer-based system with an RWM operator display and a continuously operating self-test feature that enforces adherence to established startup, shutdown, and low power control rod procedures. The RWM prevents rod motion under low power conditions if the rod being moved is not moved in accordance with a preplanned pattern. The effect of the RWM is to limit the reactivity worth of the control rods by enforcing adherence to the preplanned rod pattern.

1.2.2.12 Power Conversion System Process Control and Instrumentation

1.2.2.12.1 Pressure Regulator and Turbine Generator Control (Subsection 10.4.4)

The pressure regulator maintains control of the turbine control and bypass valves to allow proper generator and reactor response to system load demand changes while also maintaining the nuclear system pressure essentially constant.

The turbine-generator speed-load controls act to maintain the turbine (generator frequency) at constant speed.

1.2.2.12.2 Feedwater Control System (Subsection 7.7.1.3)

A three-element controller is used to regulate the feedwater system so that the proper water level is maintained in the RPV. The control system uses main steam flow rate, RPV water level, and feedwater flow rate signals. The feedwater control signals are used to control the two turbine-driven feedwater pumps.

1.2.2.12.3 Turbine Generator Overspeed Trip System (Subsection 10.2.2)

The turbine generator overspeed trip system protects the turbine generator on overspeed. The system has overspeed trip mechanisms (four magnetic speed pickups and two overspeed trip rings), which will shut down the turbine, closing all valves (turbine high-pressure stop valves, control valves, low-pressure intercept valves, and low-pressure stop valves), on detection of the overspeed condition.

1.2.2.13 Electrical Power System Control and Instrumentation (Chapter 8)

The electrical power system is monitored by indicating and/or recording devices to account for the power generated at the plant, and to determine the auxiliary power usage required to achieve this level of generation. System requirements will govern the generator excitation level needed for the desired megavar output from the generator at the required terminal voltage. Wattmeters, ammeters, varmeters, etc., will be used to indicate electrical conditions. Selected inputs to the IPCS will record conditions for later comparison or record purposes.

1.2.2.14 Radiation Monitoring and Control (Chapters 11 and 12)

1.2.2.14.1 Process and Effluent Radiological Monitoring System (Section 11.4)

Radiation monitors are provided on various lines to monitor for either radioactive materials, released to the environs via process liquids and gases, or process system malfunctions. Subsection 11.4.1 provides the complete listing of all radiation monitoring systems.

1.2.2.14.2 Area Radiation Monitoring (Subsection 12.1.4)

The area radiation monitoring system (ARMS) provides indication in the relay room and recording and alarm in the main control room of abnormal radiation levels in plant work areas where radioactive material may be stored, handled, or inadvertently introduced. In addition, selected local areas have local alarm and/or indication, where necessary, to warn personnel of a substantial rapid increase in radiation levels.

1.2.2.14.3 Site Environs Radiation Monitoring (Section 11.6)

The site environs radiation monitoring program includes the use of passive dosimeters for direct radiation measurement and the orderly collection of samples for laboratory analyses. These analyses include airborne, aquatic, and terrestrial radiological measurements.

The program is designed to document: (1) background levels of direct radiation and concentrations of radionuclides that exist in aquatic and terrestrial ecosystems before and during plant operation; and (2) the concentrations of radionuclides that could be attributable to the operation of Fermi 2.

1.2.2.14.4 Liquid Radwaste Control (Section 11.2)

The liquid radwaste system is designed to segregate, collect, and process waste generated throughout the plant. Processing of the waste is normally sufficient to allow recycling of the wastewater. Ties exist among all of the liquid radwaste subsystems to provide backup processing in the event of failure of one subsystem.

1.2.2.14.5 Solid Radwaste Control (Section 11.5)

The solid radwaste system is designed to handle and package solid waste produced by the plant. The waste, depending on its radioactivity and type, will be packaged for offsite shipment in accordance with applicable regulations.

1.2.2.14.6 Gaseous Radwaste Control (Section 11.3)

The gaseous radwaste system processes and controls the release of gaseous radioactive wastes to the site environs so that the total radiation exposure to persons outside the controlled area does not exceed the limits of 10 CFR 20 and 10 CFR 50.

Continuous radiation monitors provide indications of radioactive release from the reactor by monitoring the offgas equipment trains. The offgas system radiation monitors are used to monitor and alarm on indication of high radioactivity.

1.2.2.15 Auxiliary Systems

1.2.2.15.1 New and Spent-Fuel Storage (Subsections 9.1.1 and 9.1.2)

New fuel may be stored in a dry vault in the reactor building subject to the restrictions discussed in Section 9.1.1.2.1. Irradiated (spent) fuel is stored underwater in the reactor building in the spent fuel pool or in dry storage casks at the Independent Spent Fuel Storage Installation.

1.2.2.15.2 Fuel Pool Cooling and Cleanup System (Subsection 9.1.3)

A fuel pool cooling and cleanup system (FPCCS) removes decay heat from spent fuel stored in the fuel pool and maintains a specified water temperature, purity, clarity, and level.

1.2.2.15.3 Nitrogen Inerting System (Containment) (Subsection 9.3.6)

The nitrogen inerting system is provided primarily to maintain a nitrogen atmosphere (inerted) inside the primary containment, and also to supply pressurized nitrogen for pneumatic service inside the primary containment and distribution throughout the plant.

1.2.2.15.4 Heating, Ventilation, and Air Conditioning Systems (Sections 6.4 and 9.4)

The objective of the plant HVAC systems is to provide a thermal environment and air quality to ensure personnel comfort, health, and safety and efficient equipment operation and integrity. In addition, the HVAC system for the main control room and the RHR ventilation systems and the fan-coil cooling units located in the reactor/auxiliary building have the further objective to operate under postulated accident conditions.

The HVAC systems provide individual air supply and exhaust systems as described in Section 9.4 for each system. Normally airflow will be routed from areas of lesser to areas of progressively greater potential contamination prior to being exhausted from the building. The ventilation arrangement will protect personnel and equipment from airborne contaminants and temperature extremes. The ventilation air exhaust from each ventilation system is located in such a manner as to minimize the possibility of the same air as was exhausted being drawn into a fresh air intake. Exhaust of potentially radioactive gases will be monitored. If the radioactivity in the exhaust systems exceeds a predetermined level, the ventilation system is shut down and the system intake and exhaust dampers are closed.

1.2.2.15.5 Normal Auxiliary AC Power (Section 8.3)

Normal auxiliary power is provided from two system service transformers. One transformer is connected to the Fermi 2 345-kV switchyard, which is arranged as a highly reliable double breaker-double bus design. The remaining system service transformer is energized from the 120-kV switchyard through the 120/13.2-kV transformer at the Fermi 1 site.

1.2.2.15.6 Reactor Building Closed Cooling Water System (Subsection 9.2.2)

The RBCCWS is a closed-loop system that provides parallel flow cooling to auxiliary equipment in the drywell and the reactor building. The closed loop provides a barrier between contaminated systems and the GSW discharged to the circulating water reservoir. Heat is removed from the closed loop by the GSW system.

1.2.2.15.6.1 RBCCW Supplemental Cooling (Subsection 9.2.2)

RBCCW is designed with two RBCCW supplemental cooling loops. These loops operate using separate pumps and heat exchangers using chilled water from the supplemental cooling chilled water system to cool the RBCCW supplied to the EECW loops during normal plant operation. RBCCW supplemental cooling operation is optional, intended for use when the GSW supply temperature exceeds approximately 60°F.

1.2.2.15.6.2 Supplemental Cooling Chilled Water (Subsection 9.2.9)

The supplemental cooling chilled water (SCCW) system is a chilled water closed loop system designed to cool the water that is supplied to EECW by the RBCCW supplemental cooling loops.

The SCCW system transfers the heat it has removed from the RBCCW via the supplemental RBCCW system to the GSW system via mechanical chillers. The chillers are designed to operate using GSW supply water at 60°F or greater.

1.2.2.15.7 Turbine Building Closed Cooling Water System (Subsection 9.2.7)

The TBCCWS is designed to cool the auxiliary plant equipment associated with the power conversion systems over the full range of normal plant operation.

1.2.2.15.8 Water Systems

1.2.2.15.8.1 Circulating Water System (Subsection 10.4.5)

The circulating water system is a closed-loop system designed to condense steam exhausting into the main condenser from the main turbine. The system consists of five circulating water pumps, two vertical natural-draft cooling towers, piping, and a cooling reservoir. The circulating water pumps are located in a circulating-water pump house adjacent to the reservoir.

1.2.2.15.8.2 General Service Water (Subsection 9.2.1)

The GSW system is designed to cool various non-safety-related plant auxiliary systems such as the RBCCW and the TBCCW during all normal plant operating modes. The GSW system also provides the source of makeup water for the plant FPS and serves as a source of makeup water for the RHR complex. The once-through GSW discharges into the station's circulating water system where its heat load is rejected in the two natural-draft cooling towers. The GSW thus serves as cooling tower makeup.

1.2.2.15.9 Compressed Air Systems (Subsection 9.3.1)

The service and instrument air systems provide a continuous supply of compressed air of suitable quality and pressure for instrument control and general plant use. The service air compressor and the instrument air compressors discharge into their respective air receivers. The air is then distributed throughout the plant. Instrument air is additionally filtered and dried prior to distribution throughout the plant.

1.2.2.15.10 Makeup Demineralized Water System(Subsection 9.2.3)

Potable water is demineralized by the makeup demineralizer system and is stored in the demineralized water storage tank.

1.2.2.15.11 Potable Water System (Subsection 9.2.4)

The potable water system provides the necessary supply of domestic water for the plant. The potable water is supplied by the Frenchtown Township Water Supply System to meet drinking water standards.

1.2.2.15.12 Plant Equipment and Floor Drainage(Subsection 9.3.3)

The equipment and floor drainage system is designed to collect liquid waste throughout the plant and discharge the radioactive waste to the radwaste system for processing. Separate drainage facilities are provided for nonradioactive waste.

The drainage system is also used to detect abnormal leakage in the ESF rooms.

1.2.2.15.13 Process Sampling Systems (Subsection 9.3.2)

The process sampling system provides process information that is required to monitor plant conditions and equipment performance. Representative liquid and gas samples are taken automatically and/or manually during normal plant operation for laboratory or on-line analyses.

1.2.2.15.14 Plant Communication Systems (Subsection 9.5.2)

Plant communications consist of a Hi-Comm system of loudspeakers and hand sets, two-way radio units on a unique wavelength, and main control room phones (hard-wired units) that use local phone jack connections at instrument panels and other selected areas.

1.2.2.15.15 Fire Protection System (Subsection 9.5.1 and Appendix 9A)

The FPS is designed to provide an adequate supply of water, CO_2, Halon, or chemicals to points throughout the plant area where fire protection may be required. Diversified fire alarm and fire suppression types are selected to suit the particular areas or hazards being protected. The water for the system is taken from Lake Erie, and constant pressure is provided by the FPS jockey pump. One electrically driven pump, one diesel-engine-driven pump, and the associated piping, valves, and hydrants are provided.

Chemical fire-fighting systems (portable extinguishers) are also provided as additions to, or in lieu of, the water fire-fighting system and the CO_2 and Halon flooding systems. The necessary instrumentation and controls are provided for the proper operation of the fire-fighting systems and for fire detection and annunciation.

1.2.2.15.16 Auxiliary Steam Boilers (Subsection 9.4.8)

The two auxiliary steam boilers are designed to provide low pressure steam for plant heating and to the radwaste evaporators. The boilers and their associated auxiliary equipment are located in the auxiliary boiler house. The boilers may be operated from the main control room.

Each boiler is designed to provide 50,000 lb/hr of l20-psia steam. Combined capacity of the two boilers will provide sufficient heating and radwaste evaporator steam during a shutdown for refueling.

1.2.2.15.17 Condensate Storage and Transfer System (Subsection 9.2.6)

The condensate storage and transfer system (CSTS) is designed to store and distribute condensate and demineralized water throughout the plant during normal and shutdown plant conditions. The condensate storage and return tanks are arranged to permit gravity feed to the condensate supply pumps and to the HPCI, RCIC, CRD, standby feedwater (SBFW), and core spray systems. During normal station operation, hotwell level is raised as necessary by vacuum dragging water to the hotwell from the CST or CRT. When the plant is shutdown, or when a greater flow is required, the normal, or if necessary the emergency, hotwell supply pumps will start and stop automatically depending on hotwell level.

The makeup demineralized storage tank feeds demineralized water transfer pumps, which supply water to the demineralized water service risers and the condensate storage tank.

1.2.2.15.18 Primary Containment Air Cooling and Handling System (Subsection 9.4.5)

The drywell cooling system's primary function is to maintain the temperature of the drywell atmosphere within design conditions. The system uses air-to-water cooling coils with water being supplied by the RBCCW system during normal operating conditions and by the EECW system during abnormal conditions. However, high drywell pressure will automatically close the EECW supply line outboard containment isolation valves.

1.2.2.16 Shielding (Section 12.1)

Shielding is designed so that the dose to personnel manning the main control room and the technical support center during the course of a postulated LOCA is less than 5 rem to the whole body, or its equivalent to any part of the body. For those Design Basis Accidents that are reanalyzed in accordance with Regulatory Guide 1.183, the shielding is shown to limit dose to the Control Room and TSC personnel to less than 5 rem TEDE. In addition, the shielding ensures that, during normal operation and plant shutdown for refueling and maintenance, the dose to personnel and the dose at the site boundary will be as low as reasonably achievable (ALARA) and within the limits specified in 10 CFR 20.

1.3 COMPARISON TABLES

This section highlights the principal design features of Fermi 2, and provides a comparison of its major features with other BWR facilities for which license applications had been made under 10 CFR 50 at the time of submittal of the original Fermi 2 FSAR.

The design of this facility was based on proven technology attained during the development, design, construction, and operation of BWRs of similar types. The data, performance characteristics, and other information presented herein are subject to revisions as the design of the referenced facilities evolves. However, the information presented is adequate for general comparison purposes and thus will not be subsequently revised.

1.3.1. Comparisons With Similar Facilities Designs

The similar facilities used for comparison are: (l) Brunswick Steam Electric Plant Units 1 and 2; (2) Browns Ferry Nuclear Plant Units 1, 2, and 3; (3) Cooper Nuclear Station; and (4) Edwin I. Hatch Unit No. 1. Of these facilities, Browns Ferry 1, 2, and 3 received operating permits on June 26, 1973, June 28, 1974, and July 2, 1976, respectively. Cooper received an operating permit on January 18, 1974. Hatch received an operating permit on August 6, 1974.

1.3.2. Nuclear System Design Characteristics

Table 1.3-1 summarizes the original design and operating characteristics of Fermi 2, as well as those of the similar facilities discussed in Subsection 1.3.1.

1.3.3. Power Conversion Systems Design Characteristics

Table 1.3-2 compares the original power conversion systems design characteristics of Fermi 2 with those of the similar facilities discussed in Subsection 1.3.1.

[a] Original design information provided for comparison purposes only. Not intended to be updated. For current Fermi 2 information, refer to main body of UFSAR.

1.4 IDENTIFICATION OF AGENTS AND CONTRACTORS

1.4.1 The Detroit Edison Company

The Detroit Edison Company changed its name to DTE Electric Company as of January 1, 2013. The name change to DTE Electric Company was purely administrative in nature; the legal entity remained the same and the name change did not involve a transfer of control or of an interest in the license for Fermi 2. DTE Electric Company continues to be a wholly owned subsidiary of DTE Energy Company. For the purposes of the Fermi 2 UFSAR, except for UFSAR sections of historical context, all DTE Energy Company designations referenced throughout the UFSAR (e.g. DTE Electric, Edison, Detroit Edison, DECo, etc.) are synonymous.

Edison is the sole owner of Fermi 2 and, as such, is responsible for the design, construction, and operation of the facility. Edison is the architect-engineer for Fermi 2.

Edison employed an engineering, design, and construction supervision staff. Many of the key engineering personnel had had previous nuclear experience, primarily on the design, construction, and operation of fast breeder reactor Fermi 1, and, subsequently, in the design and construction of Fermi 2.

Edison has extensive power plant design and development experience, having acted as architect-engineer on the majority of its own power generating facilities.

To ensure competence in all areas of Fermi 2 design and construction, Edison retained various principal agents and contractors.

1.4.2 Sargent & Lundy

Sargent & Lundy (S&L) was retained for the civil, structural, and architectural design of the reactor building and other areas of the plant where that firm's experience was especially appropriate. These include preparation of the specifications for the primary containment vessel, certain electrical design tools, and piping system analyses. By a separate contract, S&L was responsible for the design of the residual heat removal (RHR) complex.

Sargent & Lundy had specialized in consulting and design engineering for the generation, transmission, and distribution of electric power for three-quarters of a century. They had provided engineering services for l5 percent of the nation's investor-owned electric generating capacity. More than 650 turbine generator units with a total capacity of more than 70,000 MWe had been put in operation or were on order; of this total more than 21,800 MWe was nuclear generating capacity, the majority of which was of the water reactor type. Sargent & Lundy had been actively engaged in the nuclear power plant field since its inception.

1.4.3 Stone & Webster Engineering Corporation

Stone & Webster Michigan, Incorporated (S&W), a wholly-owned subsidiary of Stone & Webster, Incorporated, was retained and assigned responsibility for completion of certain engineering and design tasks commencing in January 1978. Some of the major tasks included design of the plant security system, high density fuel racks, pipe hanger design assistance, nonnuclear steam supply, integrated leak-rate testing, and review of seismic requirements. Stone

& Webster also provided assistance in the general areas of licensing requirements, advisory operations, and various electrical, mechanical, and instrument and control activities.

Stone & Webster is an engineering and construction firm serving the electric utility industry in the design and construction of all types of power stations. Stone & Webster had provided engineering services related to generating capacity in excess of 70,000,000 kW. Stone & Webster had been actively engaged in engineering and construction of nuclear power plants since 1954. Over 26,000,000 kW of generating capacity had been associated with S&W's nuclear engineering services.

1.4.4 General Electric Company

General Electric (GE) was contracted to design, fabricate, and deliver the single-cycle boiling water nuclear steam supply system (NSSS), fabricate the first core of nuclear fuel, and provide technical direction for installation and startup of this equipment. General Electric had been engaged in the development, design, construction, and operation of BWRs since l955. Thus, GE had substantial experience, knowledge, and capability to design, manufacture, and furnish technical advice for the installation and startup of the reactor.

GE was later contracted to design, fabricate and deliver a replacement for the LP Turbine Steam Path installed during RF05 and the HP Turbine System Path installed during RF07.

1.4.5 General Electric Company Turbine-Generator, Ltd.

General Electric Company (GEC) Turbine-Generator, Ltd. of Rugby, England, was responsible for the design, fabrication, and delivery of the turbine generator as well as for providing technical assistance for installation and startup of this equipment. General Electric Company Turbine-Generator, Ltd. had had a long history of fabrication and application of turbine generators in electrical power production facilities.

The LP Turbine Steam Path was replaced during RF05 with GE designed components. The major components replaced were the rotors, diaphragms, associated seals and steam flow guides, including the internal exhaust hood spray piping and nozzles.

The HP Turbine Steam Path was replaced during RF07 with GE designed components. The major components replaced were the rotor, diaphragms, associated seals, and coupling spacers. An inlet snout was added to provide the steam flow path into the first stage diaphragm nozzles.

1.4.6 Other Consultants

1.4.6.1 Dames & Moore

The independent consulting firm of Dames & Moore (D&M) was retained to do hydrology, geology, and seismology studies for Fermi 2. Having performed environmental studies for approximately 50 nuclear power plant sites, D&M was active in the field of environmental engineering related to nuclear power plant construction.

1.4.6.2 NUS Corporation

NUS Corporation was retained to provide software for startup and operation of Fermi 2, and to prepare the environmental report and other environmental and licensing consulting services.

Software for Fermi 2 included administrative documents to govern startup, system descriptions, and preoperational test procedures. NUS was also responsible for preparation of the plant operating manual. NUS also provided environmental consulting services in the areas of aquatic ecology, land and water use, thermal and chemical effects, alternatives, radiological effects, and miscellaneous licensing consulting services as required.

NUS had provided consulting services throughout the world for a wide range of utilities, industries, and governmental organization.

1.4.6.3 Ralph M. Parsons Company

Ralph M. Parsons Company of Michigan (Parsons) was engaged as the general contractor for Fermi 2 with responsibility for overall construction management of the entire facility, and with direct contractual responsibility for field fabrication of small diameter piping, and installation of the plant piping systems and mechanical equipment. Parsons was terminated as general contractor in November 1974.

Under a separate contract, Ralph M. Parsons of Los Angeles was engaged to help establish the initial Quality Assurance (QA) and Quality Control (QC) Organization at the site to work in conjunction with Edison to provide work surveillance, inspection, and documentation services which ensure conformance to the codes and standards applicable to nuclear construction and the design specifications. In addition, Ralph M. Parsons of Los Angeles provided support in seismic and pipe structure analyses and specific engineering assignments.

Parsons was one of the world's largest architectural, engineering, and construction firms. Its world headquarters were located in Los Angeles, California, with principal offices in several foreign countries. The company had demonstrated its total engineering and construction capability in a variety of foreign and domestic industrial, technical, and scientific projects completed for the petroleum refining, metallurgical processing, power generation, aerospace, chemical processing, shipbuilding, commercial transportation, and nuclear industries.

Projects included engineering and construction of rapid transit facilities, transportation systems, water and sewage treatment, desalination plant, petroleum and petrochemical plants, gas processing facilities, marine and port complex, automated shipyard, airports and air terminals, mining and metallurgical facilities, environmental process development, fast breeder nuclear reactor installation, nuclear power plant installation, and many others.

1.4.6.4 Daniel Construction Company

Daniel Construction Company was retained and assigned responsibility for site construction management commencing in November 1974. It maintained that responsibility throughout construction until systems and structures nearing completion were transferred to Edison. Commencing in January 1984, Daniel assisted the Fermi 2 Project Management Organization as needed and was responsible for the day-to-day management of Wismer & Becker, API, and Chicago Bridge and Iron Company. Daniel Construction Company, a division of Daniel International Corporation, of Greenville, S.C., had a wide variety of engineering and construction assignments being completed in many parts of the world. A recent survey of the nation's 400 largest contractors rates Daniel fourth in contract awards, twelfth in international contract awards, and thirty-second in design awards.

Daniel had acquired extensive construction and project management experience in major industrial complexes for the chemical, paper, rubber, textile, aluminum, and power generation industries. These construction services involved the ability to meet precise tolerances and specifications on erection, fabrication, and equipment installation, and required a thorough knowledge of heavy construction, mechanical, electrical, and instrumentation techniques and methods. This experience and the developed capabilities were applicable to the construction of nuclear power facilities.

The Daniel Construction Company Quality Assurance Program for ASME nuclear code construction was evaluated and accepted by an ASME survey team, and the certificate of authorization to perform code construction ("N" stamp) was awarded Daniel following the ASME team audit of field implementation and enforcement.

Daniel's experience included construction of nuclear and fossil fueled power plants. Daniel's first project of this nature was construction of the nuclear power Carolina-Virginia Tube Reactor at Parr, South Carolina. This facility operated several years as a prototype plant. Nuclear power plant construction projects included the following:

a. Joseph M. Farley Nuclear Plant, Unit No. 1 and Unit No. 2, 829-MW PWR each, for Alabama Power Company

b. Virgil Summer Nuclear Power Plant, a 920-MW nuclear power generating plant of the Westinghouse pressurized-water type, for South Carolina Electric and Gas Company

c. Shearon Harris Nuclear Power Plant for Carolina Power & Light Company.

1.4.6.5 EG&G, Inc.

EG&G was engaged to provide site meteorological programs. EG&G has performed a variety of marine, meteorological, biological, hydrological, and climatological analyses, instrumentation selection and application, and a full range of services including field installation, maintenance, data gathering and processing, diffusion modeling, and report preparation for many clients.

1.4.6.6 Bechtel Power Corporation

Bechtel Power Corporation was the general services contractor for the Fermi 2 power plant. Bechtel provided engineering, construction, maintenance, startup assistance, and plant operational support services as mutually agreed to by Edison and Bechtel. The work was performed on Quality Assurance Level 1 or non-quality-related systems within the plant. The governing quality assurance program, either Edison's or Bechtel's, was adhered to depending on the kind and nature of the work for which the services are rendered.

Bechtel had demonstrated its ability in successfully performing construction management, engineering, and other functions in accordance with quality assurance programs under the jurisdiction of the NRC over past years. As such, Bechtel was deemed fully qualified to perform any safety-related work that may be assigned to it by Edison.

1.4.6.7 L. K. Comstock

L. K. Comstock was responsible for furnishing labor, tools, equipment, and materials as required to complete the electrical installation at Fermi 2. Comstock's work included electrical installation at Fermi 2. Comstock's work also included receiving, storing, installing, connecting, and readying for service all electrical equipment as well as providing electrical QA/QC services and design engineering services.

Comstock had extensive experience in the nuclear power field and understood the QA requirements. It had provided construction services on the BWR units at Dresden and Quad Cities and had completed the electrical erection contracts at the Kewaunee, Prairie Island, Cook, and FitzPatrick nuclear projects.

1.4.6.8 Commonwealth Associates, Inc., of Gilbert Commonwealth

Commonwealth Associates, Inc., of Gilbert Commonwealth, was retained in 1981 to provide technical personnel to assist during the construction of Fermi 2 in the Field Engineering, Startup, Nuclear Production, and Quality Assurance Departments.

The personnel provided by Commonwealth had the expertise, gained from work at other utilities, required during Fermi 2 construction and the startup operations.

1.4.6.9 NUTECH Engineers

NUTECH was retained to provide technical assistance to Edison's Engineering Department, on an as-required basis. Subsequently, it provided services to the Nuclear Production Department as well as other areas.

Areas of service provided included (a) In-Service Inspection Program development, (b) In-Service Inspection staff augmentation, (c) Computer Program development, (d) Radiation Emergency Preparedness Program development, and (e) Plant Unique Analysis Program addressing hydrodynamic loads in the containment.

1.4.6.10 Wismer & Becker

Wismer & Becker was responsible for furnishing labor, materials, tools, equipment, and technical and professional services as necessary for the installation of piping and mechanical equipment at Fermi 2. Support provided included QA/QC work and pressure testing on piping systems and equipment as required by the applicable codes and specifications.

For over 30 years, Wismer & Becker had been involved in all phases of power plant construction. Previous nuclear experience from the Council Bluffs and Diablo Canyon nuclear power plants had proved that Wismer & Becker had a thorough understanding of ASME Code Section III work and QA requirements

1.5 REQUIREMENTS FOR FURTHER TECHNICAL INFORMATION

This section is included for historical purposes and will not be further updated. It includes a discussion of Advisory Committee on Reactor Safeguards (ACRS) and AEC staff concerns regarding BWRs, Fermi 2 in particular. These concerns were expressed prior to and during the Fermi 2 Construction Permit period and were required to be resolved prior to or during construction.

1.5.1 Resolved Concerns

The ACRS has voiced various concerns about the development of BWRs. Specific concerns resolved during the development of the BWR, and specific Fermi 2 ACRS concerns and the documents in which each specific concern is resolved, were presented in Appendix B of the original Fermi 2 FSAR.

Although some of the concerns expressed by the ACRS did not directly apply to Fermi 2, they were included in Appendix B as evidence of the refinements and degree of analysis included in the design of the Fermi 2 BWR.

Specific GE development programs to improve the safety and performance of the BWR, and the status as applicable to Fermi 2, are discussed in Subsection 1.5.2.

Additionally, the AEC staff enumerated a number of concerns during the Fermi 2 Construction Permit review that were documented in Appendix D to the original FSAR. Appendix D also included the status of the NRC review and resolution of these Fermi 2 specific items.

1.5.2 General Electric Development Programs

1.5.2.1 Instrumentation for Vibration and Loose Parts Detection

System has been abandoned.

1.5.2.2 Core Spray Distribution

Because of the slight changes in core dimensions and spray sparger geometry from plant to plant, a series of tests was conducted. The purpose of these tests was to ensure that the core spray flow distribution for the Fermi 2 header design would supply adequate cooling water from the core spray system to each fuel assembly within the reactor core in the event of a LOCA. The tests demonstrated that each fuel assembly receives adequate cooling water flow for required spray flow rates between rated flow and runout flow conditions. Details of this test program were very similar to those described in Amendment 30 (December 1967) to the Oyster Creek FSAR, NRC Docket No. 50-219.

1.5.2.3 Vibration Testing of Reactor Internals

The major reactor components within the reactor pressure vessel have been subjected to extensive testing and dynamic analysis to properly describe any flow-induced vibration incurred during normal reactor operation and anticipated operational transients. Extensive prototype testing on BWR 4 plants has been reported in GE Topical Report NEDO-24057. Testing provisions for Fermi 2 invoke this prototype test program as stipulated by Regulatory Guide

1.20, Revision 2. An approved preoperational test was conducted prior to fuel load for flow-induced vibration of reactor internals. Refer to Subsection 3.9.1 for details.

1.5.2.4 Pipe Whip Inside Containment

Dynamic restraint tests have been performed on the plastic design restraints to demonstrate the adequacy of the piping restraint concept. The concept provides clearances that allow for normal thermal movements of the pipe but limit motion in the event of a postulated rupture.

Edison has extensively analyzed the dynamic effects of pipe ruptures inside containment and has installed design provisions including pipe whip restraints to prevent damage caused by pipe whip. Refer to Section 3.6 for details.

1.5.2.5 Recirculation Pump-Motor Missiles

An analysis has been performed on the generation of missiles as a result of a recirculation line break. Based on GE analyses, postulated recirculation pump missiles, which may be generated during a design-basis LOCA overspeed condition, are safely contained within the pump casing. Analyses of pump missiles ejected from the open end of the broken pipe have also been performed. Piping restraints were added to prevent the potential missile exit points in the pipe from developing. Further details and references to GE topical reports are provided in Subsections 3.5.1.2 and 5.5.1.4.

1.5.2.6 Standby Gas Treatment System Filter Efficiency Test

A test program to demonstrate the efficiency of the new gasket-less carbon filter was successfully completed by Edison in 1974. NEDC-12431 (Reference 1) concluded that tests on the filter, simulating the Fermi 2 standby gas treatment system (SGTS) carbon filter, successfully demonstrated the ability of the filter to remove greater than 99.99 percent of the iodine processed through the filter. Thus, the Fermi 2 SGTS can be credited (with adequate conservatism) with an iodine removal efficiency of 95 percent. For additional information on this subject, refer to Subsection 6.2.3.

1.5.2.7 Hydrogen Flammability Tests

The NRC amended 10 CFR 50.44, “Standards for combustible gas control system in light-water-cooled power reactors” on October 16, 2003 to eliminate the requirements for hydrogen recombiners. The hydrogen recombiner Technical Specification requirements were subsequently removed by License Amendment 159, dated March 15, 2004. Regulatory Guide 1.7 was revised in March 2007 to reflect the amended 10 CFR 50.44. The Combustible Gas Control System (CGCS) has been retired in place with its electrical circuits de-energized and fluid process piping isolated from primary containment with redundant locked-closed isolation valves. Measures against hydrogen-oxygen combustion are provided by inerting of the primary containment atmosphere during plant operation. Refer to Subsections 6.2.5 and 9.3.6 for details.

1.5.2.8 Water Chemistry Program

Edison has participated extensively in water chemistry development programs and in the application of operating BWR water chemistry findings to the Fermi 2 plant. A water chemistry program with applicable Technical Requirements Manual and operating procedures has been developed in conformance with Regulatory Guide 1.56. General Electric Water Quality Document No. 22A2747 has served as a basis for this program. Refer to Subsections 9.3.2 and 10.4.6 for details.

1.5 REQUIREMENTS FOR FURTHER TECHNICAL INFORMATION

1.6 MATERIAL INCORPORATED BY REFERENCE

Table 1.6-1 lists topical reports that are incorporated in whole or in part by reference in this Updated Final Safety Analysis Report (UFSAR); these references are on file with the U.S. Nuclear Regulatory Commission (NRC).

UFSAR Figures that are derived from Edison controlled drawings contain a reference to the Edison drawing number. These figures will be regularly updated or have been removed. Drawings that are not expected to require revision fall into one or more of the following classes:

a. Figures that are typical (e.g., generic) sketches not showing design detail

b. Figures that will not change throughout the life of Fermi 2 (e.g., site geology, site geography, population distribution, and design criteria used during construction)

c. The portion of the drawing referenced from the UFSAR text that is not likely to change.

UFSAR Figures that are based on vendor drawings contain a reference to the vendor drawing number. These drawings may or may not be updated regularly or have been removed.

The Technical Requirements Manual (TRM) Volume 1 provides a central location for requirements relocated from the Fermi Operating License, Appendix A, Technical Specifications. The TRM Volume 1 (except for the Core Operating Limits Report) is incorporated by reference into the UFSAR.

SYMBOLS APPLICABLE TO SARGENT & LUNDY FIGURES

CHAPTER 2: SITE CHARACTERISTICS

2.1 GEOGRAPHY AND DEMOGRAPHY

Section 2.1 was prepared circa 1974 at the time of preparation of the original FSAR. It has not been updated in the area of geography and demography since it represents the area at the time the Construction Permit was issued. Minor changes were made in Subsection 2.1.3.5 in response to questions from the NRC in 1979.

2.1.1 Site Location

The Fermi 2 power plant is located at the Fermi site on the western shore of Lake Erie at Lagoona Beach, Frenchtown Township, Monroe County, Michigan (see Figures 2.1-1 through 2.1-3). The plant is approximately 8 miles east-northeast of Monroe, Michigan; 30 miles southwest of downtown Detroit, Michigan; and 25 miles northeast of downtown Toledo, Ohio.

The coordinates of the Fermi 2 reactor containment structure are latitude 41°57'48"N, and longitude 83°15'31"W. The Universal Transverse Mercator coordinates are 4,647,950 m north and 312,930 m east, Zone 17T.

2.1.2 Site Description

The Fermi site comprises approximately 1260 acres of land solely owned by The Detroit Edison Company (Edison). The site is bounded on the north by Swan Creek, on the east by Lake Erie, on the south by Pointe Aux Peaux Road, and on the west by Toll Road. Entrance to the site is from the west by way of Enrico Fermi Drive, a private road owned by Edison, and from the south via Pointe Aux Peaux Road to another private road also owned by Edison.

The northern and southern areas of the site are dominated by large lagoons. The western areas are dominated by several woodlots and quarry lakes. Site elevation ranges from the level of Lake Erie, on the eastern edge of the site, to approximately 25 ft above the lake level, on the western edge of the site.

An aerial photograph of the site taken May 5, 1983, is presented in Figure 2.1-4. A plot plan of the Fermi site showing the plant, its natural draft cooling towers, and other major structures is presented in Figure 2.1-5.

In accordance with 10 CFR l00, the exclusion area for Fermi 2 has been defined as that area within 915 m of the reactor containment structure. As indicated in Figure 2.1-5, this area encompasses a portion of adjoining Lake Erie.

2.1.2.1 Exclusion Area Control

The land portion of the exclusion area for Fermi 2 is entirely within the Fermi site. Consequently, Edison has the authority to determine all activities within the land portion of the exclusion area, including authority for the exclusion of personnel and property. No public roads, waterways, or railroads traverse the land portion of the exclusion area.

The Lake Erie shoreline of the plant site is unsuitable for beach activities. The limited beach area available is inaccessible to the public from the land side and is posted as private property. Few plant-unrelated activities are expected to take place on Lake Erie adjacent to the plant site. These will be primarily fishing from boats and pleasure craft; however, due to poor fishing and the shallow characteristics of the lake in this area, boating activities are not carried out in proximity to the shoreline. Past experience at the site has indicated the public has made little or no attempt to use the shoreline area or to approach the site from the lake. The emergency plans are described in Section 13.3.

2.1.2.2 Boundaries for Establishing Effluent Release Limits

The boundary used to establish Technical Specifications limits for the release of gaseous effluents from Fermi 2, in accordance with 10 CFR 20.106(a) and other related as-low-as-reasonably-achievable provisions, is based on the boundary of the Fermi site. The site boundaries for gaseous effluents and for liquid effluents shall be as shown in Figure 2.1-5. As shown in Figure 2.1-5, the closest on-land boundary line is approximately 915 m from the center line of the reactor building. This closest on-land boundary line corresponds to the maximum site boundary value of the meteorological dispersion parameter (c/Q) calculated for the baseline year 1974-1975.

Virtually all of the 1120-acre site is enclosed by a perimeter fence, restricting casual access to the property. Additionally, a fenced-in area surrounds the immediate plant area within the Fermi site, shown in Figure 2.1-5. Access to the plant area will be continually and actively controlled by Edison. Only those persons specifically authorized will have access to this area.

In those areas of the southern portion of the Fermi site outside the plant fenced-in area, the public will be permitted to use only those facilities specifically designated by Edison. Normal surveillance of these areas will be maintained by Edison, which, as sole owner of the entire Fermi site, has the authority to exclude personnel and property from the designated areas.

2.1.3 Population and Population Distribution

Figure 2.1-3 shows the locations of the municipalities and other cultural features surrounding the plant within 10 miles. Towns and cities in the region surrounding the plant within 50 miles are shown in Figure 2.1-2. These centers of population are listed in Table 2.1-1, along with their 1970 resident populations and their distances and directions from the plant.

2.1.3.1 Population Within 10 Miles

Within 10 miles of the plant, the estimated 1970 population was 63,963 persons; within 5 miles, it was 11,135 persons. The following communities, as identified by the 1970 Census of Population, and indicated in Figure 2.1-3, are within 10 miles of the plant:

	1973 Population	Distance (miles) and Direction from Plant
Stony Point	1,370	1 SSW
Estral Beach	419	2 NE
Woodland Beach	2,249	3 WSW
Detroit Beech	2,053	4 WSW
Monroe (closest point)	23,894	5.5 SW
South Monroe	3,012	6 SW
South Rockwood	1,477	8 N
Rockwood	3,119	9 N
Carleton	1,503	9 NW
Patterson Gardens	2,169	9 W

The City of Monroe and the villages of Estral Beach, South Rockwood, and Carleton are the only incorporated communities.

Estimates of the 1970 resident population within 5 miles of the plant were determined from house counts and 1970 census data. The house counts were determined from June 1970 aerial photographs obtained from the Southeast Michigan Council of Governments (SEMCOG) (Reference 1). House counts were converted to population by applying the ratios of persons to housing units obtained from 1970 census data (Reference 2). For the townships concerned (all in Monroe County), these ratios are

Berlin	3.53
Frenchtown	3.62
Ash	3.71

The resultant population data were assumed to be applicable, without adjustments, to April 1970.

Beyond the 5-mile radius, population estimates were based on 1970 census data (Reference 3) and the corresponding state map, account being taken of the population estimated to be within 5 miles of the plant. Use was made of data for the smallest applicable census unit (e.g., village, town, city, or township). From this state map, census units within each segment of the population wheel were identified, and their fractions within each segment determined. It was assumed that the population within each census unit was uniformly distributed.

Population projections for areas within 10 miles for the years 1980, 1990, 2000, 2010, and 2020 were based on corresponding projections for the individual counties concerned. There were no population projections available for census units smaller than counties. It was assumed that each component (or fraction) of a county had the same decennial rate of growth as that for the county as a whole.

Monroe and Wayne are the only counties with areas within 10 miles of the plant. Projections by SEMCOG were available for both counties for 1970, 1980, and 1990 (Reference 1). The

1970-1980 and 1980-1990 decennial rates of growth derived from these projections were applied to the 1970 census data to obtain the projected 1980 and 1990 populations. The projected 2000, 2010, and 2020 populations of the counties were derived by assuming their decennial rate of growth from 1990 to 2020 to be constant and equal to the average of the 1970-1980 and 1980-1990 rates of growth.

Figure 2.1-6 shows the estimated 1970 population distribution within 10 miles of the plant. Figures 2.1-7 through 2.1-11 show corresponding projected populations for the years 1980, 1990, 2000, 2010, and 2020. These projected population data are the unrounded mathematical results of the methods described above.

2.1.3.2 Population Between 10 and 50 Miles

The 1970 population and projections between 10 and 50 miles were determined in accordance with the method used for the area between 5 and 10 miles from the plant. For the areas within Canada, use was made of the June 1, 1971, Canadian census data (Reference 4) and corresponding provincial map. Using data from the previous Canadian census of June 1, 1966 (Reference 5), and assuming linearity, the 1971 Canadian census data were adjusted to April 1, 1970, so they would coincide with the 1970 U.S. census data.

For population projection purposes, counties between 10 and 50 miles of the plant were divided into four groups:

a. SEMCOG counties

b. Other Michigan counties

c. Ohio counties

d. Canadian counties.

The SEMCOG counties are Monroe, Wayne, Oakland, Macomb, Livingston, and Washtenaw. Wayne County was separated into two parts consisting of Detroit, and Wayne County minus Detroit. Projected populations for these counties for the years 1980-2020 were obtained as explained in Subsection 2.1.3.1 for Monroe and Wayne County projections at 5 to 10 miles. The projected 1980 and 1990 populations for Detroit were similarly derived; however, its population was assumed to remain unchanged (rather than to continue decreasing) from 1990 to 2020.

Other Michigan counties consist of Jackson and Lenawee. The projected populations for each of these counties were derived by assuming their decennial rates of growth from 1970 to 2020 to be constant and equal to the average of their 1960-1970 rates of growth, obtained from census data, and their 1970-1980 rates of growth, derived from 1970 census data and their 1978 population estimated by the State of Michigan (Reference 6).

The Ohio counties consist of Seneca, Sandusky, Ottawa, Lucas, Huron, Henry, Fulton, Erie, and Wood. The projected populations for each of these counties were derived by assuming their decennial rates of growth from 1970 to 2020 to be constant and equal to the 1970 to 1980 rates of growth obtained from 1970 to 1975 to 1980 to 1985 projections by the State of Ohio (Reference 7).

Official projections for Essex and Kent, the two Canadian counties, were not available. Projected 1980-2020 populations of these counties were based on their adjusted April 1, 1970, populations and were derived by assuming their decennial rates of growth from 1970 and 2020 to be constant and equal to their 1961-1971 rates of growth determined from Canadian census data.

Figure 2.1-6 shows the estimated 1970 population distribution between 10 and 50 miles from the plant. Figures 2.1-7 through 2.1-11 show corresponding projected populations for the years 1980, 1990, 2000, 2010, and 2020. These projected population data are the unrounded mathematical results of the methods described above.

2.1.3.3 Low-Population Zone

In accordance with criteria specified in 10 CFR 100, the outer boundary of the low-population zone (LPZ) for Fermi 2 will be 3 miles (4827 m) from the containment structure. The estimated resident population distribution within this distance for the years 1970 through 2020 is shown in Table 2.1-2. Population distribution for distances up to 50 miles from the plant is shown in Figures 2.1-6 through 2.1-11; a detailed map of the LPZ is shown in Figure 2.1-12.

The area within the LPZ does not contain either agricultural or industrial activities that would create a daily transient population of any magnitude. Therefore, other than the recreational activities that draw daily users, the daily population is relatively stable. As stated in Subsection 2.1.4.2.3, the population in the communities within the LPZ that have beach and boating facilities is predominantly permanent, and the facilities are for resident use. The schools, hospitals, institutions, and recreational areas are shown in Tables 2.1-3 through 2.1-5.

Sterling State Park and Point Mouillee State Game Area are approximately 5 miles from the Fermi 2 site and annually attract about 385,000 and 180,000 visitors, respectively, as shown in Table 2.1-5. Approximately 70 percent of use occurs between April and November.

2.1.3.4 Transient Population

2.1.3.4.1 Seasonal Agricultural and Horticultural Labor

Needs for seasonal agricultural and horticultural labor (including migrant workers) in Monroe County are listed in Table 2.1-6. Peak requirements, which occur in the month of October, are for a total of about 2335 seasonal workers, 34 percent of whom are expected to be migrant workers. Needs for such seasonal labor are at a minimum during the winter months, down to a total of about 230 workers, 12 percent of whom would be migrant workers. Following are 1972 data on migrant workers within 10 miles of Fermi 2 (Reference 8):

Employers	Number of Migrant Workers	Distance (miles) and Direction From Plant
Smith and Son	75	8 NW
J. F. Ilgenfritz	30	10 WSW

Employers	Number of Migrant Workers	Distance (miles) and Direction From Plant
Tracy Gaynier	12	11 SW
Don Wolmer	20	12 WSW
Walter Iott	20	12 WSW

2.1.3.4.2 Historical Attractions

There are two facilities in the City of Monroe that draw large numbers of visitors each year: the Custer Museum, 8 miles west-southwest of the plant; and the Monroe County Historical Museum, 8 miles west-southwest of the plant. In 1972, the former had approximately 12,000 visitors and the latter about 45,000 (Reference 9).

2.1.3.4.3 Commuters

Monroe and Wayne are the only two counties with areas within 10 miles of the plant site. Monroe County has an inflow of 1500 commuters and an outflow of 19,292 commuters, a net loss of 17,792 individuals per day. Wayne County, with an inflow of 139,305 and an outflow of 165,754 commuters, has a net loss of 26,449 individuals per day (Reference 10).

2.1.3.4.4 Seasonal Homes

Within 10 miles of the plant, according to the 1970 census data, there were 51 seasonal homes in Monroe County and 26 in Wayne County (Reference 11).

Many of the houses that had been used in the past as summer cottages are currently used as permanent homes.

2.1.3.5 Population Center

The nearest population center, as defined in 10 CFR 100, is the City of Monroe, which had a 1970 population of 23,894. Its nearest corporate boundary is approximately 5.5 miles southwest of Fermi 2.

The residential population distribution of the city and the surrounding jurisdiction (Frenchtown Township) shows this distance to be a valid, conservative figure for use as the population center distance. The concentrated residential section of the city is farther distant from the plant site, with the closest portion of the city along the northeastern boundary being predominantly open for industrial development (Reference 12).

Frenchtown Township in 1977 was composed of scattered, small residential clusters and a few small communities along the shore of Lake Erie (Reference 13). The 1975 total population was estimated to be 15,900 over a land area of 27,000 acres an average density of about 0.6 person/acre (Reference 13). Future land use and residential population distribution for the city and township were also examined to determine the potential influence of proposed growth on the population center distance. The Monroe land use plan did not propose further expansion on the northeast edge of the city. Some annexation had taken place on the west, but further annexation was not considered likely in 1979 (Reference 14).

The land area within the city boundary was slated to remain predominantly open or industrial. One small tract (approximately 39 acres) was proposed for potential residential development (Reference 12). The future growth of Monroe based on data available in 1979 would not create any densely populated residential land closer than 5.5 miles from Fermi 2.

Land use plans for Frenchtown Township indicated that future residential growth will take place in the vicinity of Fermi 2. Land use plans call for development of the corridor between Monroe and Fermi 2 and along the Lake Erie shore (Reference 13). A mixture of land uses was proposed; however, it was mainly recreational and low density (average of one dwelling unit per acre) and medium density (1 to 4 dwelling units per acre) residential. A 450-acre tract on the northeastern corner of the growth area had been rezoned from agricultural to residential use. This land, like most of the area, had severe soil limitations based on high water table, fair-to-poor bearing capacity, and moderate volume change. For this reason, the staff of the Monroe County Planning Commission had reservations about the residential rezoning of the site and suggested rezoning only for low density (Reference 15) (one dwelling unit per acre).

Based on the distribution and density of the proposed future land use, Frenchtown Township was not expected to form a contiguous extension of the population center of Monroe or develop into a separate densely populated center. From these facts it was apparent that the 5.5-mile population center distance would remain valid in the future.

2.1.3.6 Public Facilities and Institutions

A survey was conducted to locate public facilities and institutions, such as schools, hospitals, prisons, and parks, within 10 miles of the plant.

2.1.3.6.1 Schools

Schools within 10 miles of the plant are listed in Table 2.1-3 and indicated in Figure 2.1-13 (References 16 through 20). Closest to the plant is the Brest School at Woodland Beach (2.5 miles west-southwest) with a 1972 enrollment of 163. The Monroe County Community College, a 2-year college, is located 11 miles west-southwest of the plant and had a 1972 enrollment of 1676 students.

2.1.3.6.2 Hospitals

Data on hospitals and nursing facilities are contained in Table 2.1-4 (References 21 through 26). The closest facility to the plant is the Frenchtown Convalescent Center, 6 miles west, with 226 beds.

2.1.3.6.3 Prisons

The only jail within 10 miles of the plant is the Monroe County Jail, located in the City of Monroe. It has an average of 50 inmates per day (Reference 27).

2.1.3.6.4 Recreational Areas

Recreational areas within 10 miles of the plant are listed in Table 2.1-5 and indicated in Figure 2.1-14 (References 9 and 28 through 30). The recreational facilities closest to the plant are Stony Point Beach, about 2 miles south, and Estral Beach, 2 miles northeast. Swimming is reported to take place there. The largest facility in the area is Sterling State Park, 5 miles southwest of the plant.

2.1.4 Uses of Adjacent Lands and Waters

2.1.4.1 Agricultural Activities

Approximately 95 percent of the land area within 10 miles of Fermi 2 is within Monroe County, with the remaining 5 percent in Wayne County. About 71 percent of the land in Monroe County was used for farming; however, only 55 percent of the land within 10 miles of the plant consisted of farms. Farmland use within 10 miles of the plant in 1973 was as follows (Reference 31):

Crop	Percentage of Farmland
Soybeans	50
Corn	22
Wheat	7
Miscellaneous (vegetables, hay, oats, and grazing and pastureland)	7
Idle Cropland	14
Total	100

Data on the principal crops grown within 10 miles of the plant site in 1973 (Reference 31) were as follows:

Crop	Acreage	Annual Production (bushels)	Value
Soybeans	21,000	840,000	$2,940,000
Corn	9,500	902,500	$1,173,250
Wheat	3,150	126,000	$252,000

All soybeans and wheat were sold as cash crops. Approximately 75 percent of the corn was sold as a cash crop; the remaining 25 percent was used for feed.

The large livestock, poultry, and crop farms located within the environs of the Fermi site in 1973 are listed below:

Owner	Farm Type and Information	Distance (miles) and Direction From Plant
Ronald Welb	Poultry – 2,500 laying hens	5 NW
Del Chapman	Livestock – 1,500 sheep	7 N
Smith and Sons	Vegetables and greenhouse products	8 NW
Butler Farms	Livestock – 500 beef cattle	10 W
St. Mary's Farm	Livestock – 200 beef cattle	10 W
Clayton Dick	Poultry – 15,000 to 20,000 laying hens	16 WSW
Lennard and Sons	Potato farm - 2,000 acres	16 WSW

The Lennard and Sons farm was the largest potato farm in the State of Michigan, with a gross annual income of approximately $1.8 million. The Smith and Sons farm was one of the largest vegetable and greenhouse-product producers in the State of Michigan, with a gross annual income exceeding $500,000.

Table 2.1-7 contains data on the 29 dairy farms within l8 miles of the plant in 1971, and Figure 2.1-15 indicates their locations. Ten of these dairy farms were within 10 miles. The closest, owned by John Reiger and containing about 30 milking cows, was approximately 4 miles west of the plant. The only other dairy farm within 5 miles was that of Henry Noel. This dairy farm was approximately 5 miles northwest of the plant and had approximately 25 milking cows in 1973 (References 32, 33, and 34). The productive cows nearest the plant were located 3 miles north-northwest. Milk from these four cows was used for home consumption.

Livestock and dairy operations within 10 miles of the plant had been going out of business. Tax increases over the past years (an increase of $40 per acre in 1972) and attractive offers for farmland ($1000 to $1500 per acre) resulted in many farmers selling their grazing and pastureland and accepting employment with local industries (Reference 31). Agricultural statistics for Monroe County indicated that in 1964 there were approximately 3549 dairy cattle. In 1972 there were only 2100 dairy cattle. The County Agricultural Cooperative Extension Service was then discouraging new livestock and dairy operations within the county; however, it was assisting established farms to remain in operation. Crop farmers in the county were able to continue their operations due to the high productivity of the land, which compensated for the large tax increases (Reference 31).

In 1967, approximately 10 percent (approximately 37,700 acres) of the county's land was developed. However, agricultural land was being rapidly developed for nonagricultural purposes as the county became more urbanized. The comprehensive development plan of 1967 (Reference 35) for Monroe County called for the retention of agricultural land to serve as buffers between recommended major development corridors. Accordingly, this plan specified that the majority of land located west of U.S. Route 23 and U.S. Route 24, and west of Interstate 75 in the northeast quadrant of the county, be reserved primarily for agricultural use (Figure 2.1-16).

Economic projections showed that as the county grew and became more urbanized, some farmlands would be lost to urban development and farm employment would decrease. Farm employees would continue to be attracted to high-paying nonagricultural occupations, and farms would adopt additional labor-saving methods and machinery. It was estimated that by 1980 farm employment in the county would decrease to about 2 percent of the labor force as compared to 5.8 percent in 1960 (Reference 35).

The small portion of Wayne County within 10 miles of the plant was predominantly a residential area and had only a limited amount of agricultural activity: small crops of field corn, soybeans, hay, and some fresh market vegetables. There were no dairy farms in this area in 1973 (Reference 36).

Agricultural statistics of all counties within 50 miles of the plant site are presented in Tables 2.1-8 through 2.1-11 for the 1969 to 1971 time period (References 37 and 38).

2.1.4.2 Water Uses

The most prominent body of water in the environs of the Fermi site is Lake Erie. Rivers and streams entering Lake Erie within 10 miles of the site are shown in Figure 2.1-17. The five drainage basins within a 10-mile radius of the site are as follows (Reference 39):

Drainage Basin	Drainage Area (square miles)
Area between the Huron and Rouge Basins	120
Huron River	923
Stony and Swan Creeks	290
River Raisin	1,043
Southeast Monroe County	189

A detailed description of the hydrology of the region is presented in Section 2.4.

2.1.4.2.1 Potable Water Supplies

As shown in Figure 2.1-18, privately owned wells and four municipal water systems served the area within 10 miles of the Fermi site in the 1970 time period. The four municipal systems are those of Detroit, Monroe, Flat Rock, and Toledo (Ohio).

The Detroit system served most of Wayne County. In the area within 10 miles of the plant, this water system served portions of Brownstown Township, Rockwood, South Rockwood, the City of Carleton, and Berlin Township. The Flat Rock system served portions of Brownstown Township and Rockwood. The Monroe system, which has its intake on Lake Erie, served most of Frenchtown Township, the City of Monroe, and Monroe Township. The service area of the Toledo system included portions of La Salle and Erie Townships. Although these municipal water systems provided services in these areas, homeowners who had wells prior to the construction of the municipal water services were not obligated to use them. Consequently, about 15 percent of the homeowners in the service areas of these municipal systems were still obtaining their potable water from individually owned wells.

Owners of newly constructed dwellings in these service areas, however, were obligated to obtain their potable water from the municipal system.

Within 10 miles of the plant, homeowners outside the service areas of the municipal systems obtained their potable water from individually owned wells. These wells ranged in depth from 50 to 120 ft; however, well depths generally do not exceed 70 ft (Subsection 2.4.13.2). Throughout Monroe County there were approximately 6000 active wells in 1972, mostly in the western half of the county. The number of wells drilled from 1964 to 1972 in each of the townships wholly or partially within a 10-mile radius of the Fermi site was reported (Reference 40) to be as follows:

Frenchtown	336
Ash	216
Raisinville	324
Berlin	207
Monroe	115
Exeter	132
La Salle	288

Figure 2.1-19 shows the approximate number of wells in use in 1972 and their distribution within 10 miles of the currently unused quarry at the Fermi site (Reference 41).

The quality of well-water in Monroe County is generally poor. Efforts were being made for expanded use of municipal water services from the Detroit, Monroe, and Toledo systems. Plans in 1973 showed that Toledo would eventually serve not only La Salle and Erie Townships, but Bedford and Whiteford Townships as well (Reference 40). The Monroe system was planning a new treatment facility in the same region as the 1973 facility to increase the intake capacity to 4.5 billion gal per year, an increase of approximately 125 percent over the 1973 capacity. Future plans called for the servicing of the entire Frenchtown region, Raisinville, Dundee, and parts of London Township. No data on initial construction were available in 1972 (Reference 42). The Monroe water system has its intake on Lake Erie, in the Pointe Aux Peaux region, approximately 1 mile south of the Fermi site. The intake is 5260 ft long and 2.5 ft in diameter (Reference 43).

The 1973 plans for the Detroit water system showed that Ash Township was considering the use of Detroit water, while Exeter and London Townships were negotiating for service (Reference 40).

At one time, bottled water was being used as potable water by the communities along the Lake Erie shoreline because of the poor quality of the well-water. This condition has since been alleviated as a result of the services provided by the municipal water systems (Reference 40).

The following 1973 data on other municipal water systems in Monroe County (Reference 43) are provided for reference:

System	Source	Distance (miles) and Direction From Plant	Yearly Production (millions of gallons)	Area Served
Village of Dundee	River Raisin	19 W	70.8	Village of Dundee
Village of Petersburg	2 wells	21 WSW	53.0	Village of Petersburg

The Flat Rock water intake is located on the Huron River at a point about 10 miles north of the plant. Its average withdrawal is about 750,000 gal per day (Reference 44).

Data on municipal water intakes (including those of Toledo and Monroe) from Lake Erie are presented in Table 2.1-12 (1969-1972 data). The locations of the intakes for these municipal water systems are shown in Figure 2.1-20 (References 31, 45, and 46).

2.1.4.2.2 Agricultural Water Supplies

Within 10 miles of the plant in 1973, the Smith and Sons farm was the only agricultural user of surface water. The intake of this farm was on Swan Creek, at a point about 8 miles northwest of the plant. Water from this intake was used for irrigation and cattle watering. Within 50 miles of the plant, there were no known withdrawals of water from Lake Erie for agricultural irrigation or livestock watering. Previously existing withdrawals for agricultural purposes had been discontinued in this area. This was primarily a result of the residential development along the lakeshore (Reference 31).

2.1.4.2.3 Recreational Water Uses

Along the shoreline of Lake Erie in Monroe County there are numerous communities with beach and boating facilities.

Recreational activities at these places include swimming, water-skiing, motorboating, and sportfishing. The following are the principal recreational areas in the environs of the Fermi site:

Community	Distance (miles) and Direction From Plant
Pointe Aux Peaux	1 S
Stony Point	1 SSW
Estral Beach	2 NE
Woodland Beach	3 WSW
Detroit Beach	4 WSW
Avalon Beach	9 SW
Toledo Beach	11 SW
Luna Pier	15 SW

The majority of the homes in these communities were at one time used as summer cottages; however, most of them were being used as permanent homes in 1973. The water quality along the beaches of these communities was below that required by applicable standards for sports involving body contact with the water. Sterling State Park, located along the Lake

Erie shoreline 5 miles southwest of the plant site, was closed for swimming because of poor water quality. However, in spite of water quality and water-quality standards, water-sport activities continued to take place on the shoreline area in 1973 (Reference 40).

2.1.4.2.4 Fishing

Sportfishing activities in the general environs of the Fermi site are conducted off the shores of Lake Erie and along the shores of the River Raisin, and Stony and Swan Creeks. Lake Erie fish include carp, sheepshead, bullheads, suckers, channel catfish, white bass, yellow perch, and walleye. Fish in the River Raisin and Stony and Swan Creeks include panfish, suckers, catfish, perch, and bass (Reference 47).

There were approximately six commercial fishermen in 1973 who used the shores of Lake Erie in the Monroe County area. In 1971, the fish catch was approximately 172,736 lb, representing an estimated value of $24,343 (Reference 47). Commercial fishing in this area slackened over the 2-year period of 1972 and 1973 because of low availability of fish. However, as a result of improving conditions, it was predicted that commercial fishing would increase.

A summary of commercial fish landings taken from Lake Erie statistical districts in 1971 is presented in Table 2.1-13 for the Province of Ontario, and Table 2.1-14 for the State of Ohio (References 48 and 49). The respective districts are illustrated in Figure 2.1-21.

2.1.4.2.5 Industrial Water Use

Within 10 miles of the plant site, 1974 industrial users of Lake Erie water included the Fermi l Power Plant, the Monroe Power Plant, Union Camp Corporation, and Consolidated Packaging Corporation. The Fermi 1 plant, an oil-fired peaking unit located on the Fermi site, drew both potable and cooling water from Lake Erie. Potable water usage during 1971 and 1972 was 25 million gal per year and 19 million gal per year, respectively. It should be noted that the potable water system for Fermi 1 was the source of demineralized water for the construction of Fermi 2. Cooling water use averaged approximately 72 million gal per day when Fermi 1 was in operation. The Fermi 1 breeder reactor and oil-fired power plant have been permanently decommissioned. Four combustion turbine peakers are still in use on the site. The Monroe Power Plant, which is approximately 6 miles south-southwest of the Fermi site, obtains the major portion of its cooling water from Lake Erie at an intake located about 1300 ft from Lake Erie on the River Raisin. Monroe Unit 1 began operating in 1971, Unit 2 in 1972, Unit 3 in 1973, and Unit 4 in 1974. Each of these four units requires an average of 350,000 gpm for cooling purposes. Discharge is through a canal to Lake Erie. Their potable water supply is obtained from the City of Monroe (Reference 50).

The Union Camp Corporation (Reference 51) and the Consolidated Packaging Corporation (Reference 52), both located in the City of Monroe, have their Lake Erie intakes in the Sterling State Park region, which is approximately 5 miles southwest of the Fermi site. The water is piped approximately 3 miles overland to the corporate sites. After usage, it is discharged into the River Raisin at a point approximately 2 miles inland from Lake Erie. Both of these industries share the same pumping and discharging facilities. Their average daily withdrawals are approximately 3 million and 2.6 million gal, respectively. Both facilities obtain their potable water supplies from the Monroe municipal water system.

In Monroe, the Ford Motor Company has a large manufacturing plant (2700 employees) that has a water intake on the River Raisin at a point approximately 1.2 miles upriver from Lake Erie. From this intake, the Ford plant draws an average of approximately 12 million gal per day. This water is used for industrial purposes only. The potable water required for the plant is obtained from the City of Monroe at the rate of 200,000 gal per day (Reference 53).

COMMERCIAL FISHING STATISTICAL DISTRICTS IN LAKE ERIE

2.2 NEARBY INDUSTRIAL, TRANSPORTATION, AND MILITARY FACILITIES

Section 2.2 was prepared circa 1974 at the time of preparation of the original FSAR. It has not generally been updated in the area of nearby industrial, transportation, and military facilities since it represents the area at the time the Construction Permit was issued. However, changes have been made based on additions/modifications of facilities in the area.

2.2.1 Locations and Routes

2.2.1.1 Industrial Facilities

Industrial (and commercial) facilities within 5 miles of Fermi 2 are listed in Table 2.2-1, along with their products and number of employees (Reference 1).

The Fermi 1 breeder reactor, also on the Fermi site, is not operating and has been permanently shut down. The Fermi 1 plant is located on the site with Fermi 2. The Fermi 1 oil-fired plant has also been decommissioned, and it has been demolished. The 800,000-gal oil storage tank, which supplied the oil-fired boiler, has been abandoned. There is an additional nuclear power plant site within 30 miles of the Fermi site (Reference 2). This is Toledo Edison Company's Davis-Besse Nuclear Power Station, approximately 26 miles to the south-southeast.

There are three extractive industries within 10 miles of the site. The France Stone Company of Monroe, Michigan, is located 9.4 miles southwest of the Fermi site; the maximum quantity of explosives (mainly ammonium nitrate) stored at this quarry is between 25,000 and 35,000 lb (Reference 3). The Halloway Construction Company operates a quarry about 8 miles north of the site. A maximum of about 25,000 lb of explosives is stored at this quarry (Reference 4). Rockwood Stone, Inc., operates a quarry 3 miles north-northeast of the site. As reported to the NRC in July 1986, the maximum quantity of explosives located at this quarry is between 50,000 and 80,000 lb.

The Monroe Branch of the Austin Powder Company maintains a maximum storage of approximately 25,000 lb of dynamite at a site 6.7 miles west-southwest of the Fermi site. These explosives are used for agriculture and for highway construction, as well as for quarrying activities (Reference 5).

The Frenchtown Township water treatment facility is located approximately 2.5 miles south of the site. There are no explosives stored at this facility. The facility has a 1,000 gallon underground fuel oil storage tank for an onsite emergency generator. (Reference 5a).

2.2.1.2 Transportation Facilities

There are two major roads within 10 miles of the plant, Interstate 75 and U.S. Routes 24/25, shown in Figure 2.1-3. Their closest approach to the plant is 4.1 miles and 5.8 miles north-west of the plant site, respectively, with average 24-hr traffic flows of 27,300 and 9200 vehicles, respectively (Reference 6).

Within 10 miles of the plant, there are four Class I railroads. The Detroit and Toledo Shore Line Railroad, 4 miles northwest of the site, passes closest to and serves the Fermi site through the use of a single spur track. This company operates a freight service only between Detroit, Michigan, and Toledo, Ohio. At their closest approach to the plant, the other three lines (the Penn Central Railroad, the Chesapeake and Ohio Railroad, and the Detroit Toledo and Ironton Railroad) come to within 4 miles northwest, 7 miles west-northwest, and 9 miles northwest, respectively. The railroad yard in Monroe is the nearest yard to the plant. It is operated by the Penn Central Railroad and has a capacity of 230 cars (Reference 7).

Airports within 25 miles of the plant are listed in Table 2.2-2 and indicated in Figure 2.2-1. There are no major airports within 15 miles of the site. Three smaller airports are located about 9 miles from the site (Custer), 5 miles (Carl), and 2 miles (Marshall). The closest airport, Marshall Field, is 2 miles west of the plant. This is a small airfield with two sod runways, the longer being 1962 ft. This runway is oriented about northeast-southwest, approximately 30 degrees offset from the reactor site. Only light aircraft use this field. The weight of the heaviest aircraft using this field is about 3400 lb.

The closest major airports are Detroit Metropolitan and Willow Run, which are 19 miles north-northwest and 24 miles northwest of the plant, respectively (Reference 8). Figure 2.2-2 illustrates the approach patterns for Custer, Grosse Ile, and Detroit Metropolitan Airports. None of these approach patterns lie within 5 miles of the Fermi site.

There are three low level federal airways within 5 miles of the plant: V297, V96, and V10-188. The center line of airway V297 passes directly over the Fermi 2 plant and follows a southeast-northwest path. The center lines of airways V96 and V10-188 are 6.5 miles to the southeast and 4.0 miles north of the plant, respectively (Reference 8). (Airways are 4 miles wide.)

The shipping port nearest the plant is the Port of Monroe. Shipping traffic to this port is through an unobstructed channel, approximately 4.5 miles long, east-southeast of the site and extending from the head of navigation of River Raisin to the deep water in Lake Erie. As shown in Figure 2.2-3, the nearest approach of this channel to the Fermi site is approximately 6 miles south of the plant. Shipping traffic to the Port of Monroe is minimal in comparison to the traffic through the Detroit River. In 1964 there were only six commercial vessel trips inbound to the Port of Monroe, as compared to 10,999 upbound and 9693 downbound through the Detroit River (Reference 7). As shown in Figure 2.2-3, the Detroit River navigation channel connects to the West Outer Channel and the East Outer Channel in Lake Erie at a point approximately 7 miles northeast of the plant. The majority of the Detroit River traffic utilizes the East Outer Channel. Traffic on the West Outer Channel has a 5-mile nearest approach to the plant.

Oil and natural gas pipelines in the environs of the Fermi site are shown in Figure 2.2-4 and are described in Subsection 2.2.2.2.

2.2.1.3 Military Facilities

There are currently no military facilities within 10 miles of the plant. However, there are two restricted areas in Lake Erie, identified as Zone 1 and Zone 2. These zones are 20 miles and 27 miles from the plant, respectively, and are used as impact areas for small arms, ground artillery, and antiaircraft artillery from Camp Perry and from the test firing range at Erie

Industrial Park. Restrictions on weapon horizontal firing range and direction, as well as the nature of the projectiles, preclude a threat to the plant (Reference 9).

2.2.2 Descriptions

2.2.2.1 Industrial Facilities

The Fermi 1 power plant and the storage tank supporting the combustion turbine peakers of that plant are described in Subsection 2.2.1.1. The industrial facilities within 5 miles of the plant, including a description of their products and/or services and number of employees, are listed in Table 2.2-1.

The Frenchtown Township water treatment facility is a water processing plant for Frenchtown Township. The water treatment plant has the capacity to process 4,000,000 gallons of water per day. The chemicals used for water processing are not a hazard to Fermi 2 (Reference 5a).

2.2.2.2 Transportation Facilities

As shown in Figure 2.2-4, the natural gas distribution lines that pass nearest to the plant are those of the Michigan Gas Utilities Company. Their closest approaches are approximately 1.5 miles south and 2 miles west of the plant, with pipeline diameter sizes of 6 and 4 in., respectively. The natural gas transmission line of the Panhandle Eastern Pipeline Company passes approximately 10 miles northwest of the plant. There are currently no other gas pipelines within 10 miles of the plant.

The oil-products line of the Sinclair Pipeline Company, which passes 5 miles west of the plant, is the closest oil pipeline. Four other oil pipelines pass between 6 and 8 miles northwest of the plant. Of these, three are 6-in. to 12-in. oil products pipelines of the Pure Transportation Company, Sun Pipeline Company, and the Buckeye Pipeline Company; the fourth one is a 6-in. to 22-in.-diameter crude oil pipeline of the Buckeye Pipeline Company.

2.2.3 Evaluations

2.2.3.1 Cooling Water Intake Structure

The cooling water intake structure for Fermi 2 is a shoreline structure located adjacent to the existing Fermi 1 intake channel. This channel is protected by two rock jetties that extend into the lake. This intake provides cooling water and makeup water to the 5.5-acre pond, which is part of the closed-loop source of cooling water to operate the plant; the lake level at the mouth of the intake varies from 3 ft to 10 ft, depending on the status of the sandbar that continually forms at the end of the jetties and the prevailing level of Lake Erie. (Refer to Figure 2.4-9.)

Navigation by large ships and barges in the Western Basin does not normally approach within approximately 5 miles of the Fermi site. As a result of the very shallow water in the vicinity of the site, no large vessel could be expected to reach the site and damage the intake structure, even if this were attempted.

In addition, assuming that the intake structure is damaged sufficiently to prevent normal cooling water intake for an extended period of time, the 5.5-acre closed-cycle circulating water reservoir is of sufficient size to allow limited periods of normal plant operation with sufficient reserve to accomplish normal shutdown. If it were ascertained that the intake structure were to be inoperable for an extended period of time, reduction in load and shutdown would be initiated in a timely manner. In addition to the circulating water reservoir, the ultimate heat sink [residual heat removal (RHR) complex] provides cooling for 7 days in conformance with Regulatory Guide 1.27.

2.2.3.2 Industrial Facilities

The industrial facilities within 5 miles of the site (Table 2.2-1) do not present any potential danger to the safe operation of Fermi 2.

The Rockwood Stone, Inc., quarry located 3 miles from the site stores a maximum of 80,000 lb of ammonium nitrate fuel oil (ANFO) explosive in the delivery trailers on the quarry property at the ground surface level. ANFO has a TNT equivalence of 1.08. Edison has evaluated the effects on Fermi 2 of the explosion of this maximum inventory of explosives on the quarry site and of the explosion of a maximum shipment of 40,000 lb of the explosive at the closest approach to Fermi 2 (2 miles). Regulatory Guide 1.91 was used as a basis to evaluate overpressure effects. The U.S. Navy Design Manual Number 7.2, Foundations and Earth Structures, 1982, was used to estimate the ground motion effects due to blasting. It was concluded that the operation of the Rockwood Stone, Inc., quarry and the blast-induced overpressure, hydrostatic pressure, and ground motion effects due to accidental explosions do not pose a hazard to the Fermi 2 plant. The NRC Staff performed an independent evaluation of the blast-generated displacements, velocities, and accelerations of the ground using the empirical relationships in A. J. Hendron's paper titled Engineering of Rock Blasting on Civil Projects. Based on a review of Edison's analysis and on their independent evaluation, the NRC Staff concluded that the hazards due to blast-induced overpressure, ground motion, and hydrostatic pressure changes are insignificant with respect to Fermi 2 (Reference 10).

The Frenchtown Township water treatment plant is located approximately 2.5 miles south of the site. No chemicals with a potential to cause an explosion are used at this facility. Sodium hypochlorite is used for water treatment. This is not considered a hazard to Fermi 2 and it does not impact the chlorine release accident analysis as described in Section 6.4.

2.2.3.3 Offsite Transportation Facilities

As described in Subsections 2.2.1.2 and 2.2.2, no roads, railroads, or pipelines cross or pass close to the plant except for the site access road and railroad spur. No conceivable event associated with offsite highways, railroads, and pipelines in the area could be expected to influence normal operation of the plant.

The two principal shipping channels (described in Subsection 2.2.1.2) are 5 and 6 miles away from the Fermi 2 site. There is no potential for fire or explosion from any ship in one of these lanes to interfere with normal plant operation.

A 6-in.-diameter natural gas distribution pipeline passes 1.5 miles south of the plant. Potential explosions cannot endanger safe operation of the plant due to the size and distance of the line.

Table 2.2-2 and Figures 2.2-1 and 2.2-2 indicate the nearest airports to the Fermi site and the approach patterns for Custer, Grosse Ile, and Detroit Metropolitan airports.

The annual aircraft flights along the three low level federal airways V297, V96, and Vl0-l88, described in Subsection 2.2.1.2, are provided in Table 2.2-3, along with the aircraft types using these airways and an estimate of the probability of a crash at the Fermi site involving one of these aircraft. Also provided in Table 2.2-3 are estimates of the probabilities of crashes of private and corporate aircraft into the Fermi 2 spent fuel pool.

The Detroit Flight Service Center, which handles air traffic along 15 airways, including V297, V96, and V10-188, makes an average of about 34,000 radio contacts per year (References 11, 12, and 13). Between one-third and one-half of all flights along these airways make at least one radio contact with the Detroit Flight Service Center; thus a conservative estimate of the total flights per year along these 15 airways is about 100,000 or about 7000 per airway. About 40 percent of these flights are by commercial aircraft.

Aircraft crash data for the years 1970 through 1972 indicate that the probability of a crash during level or near-level flight is about 0.2 per million miles of operation for private and corporate aircraft (References 12, 14, and 15) and about 0.003 per million miles of operation for commercial air carriers (Reference 16).

Aircraft crash probabilities provided in Table 2.2-3 are based on crash bands of 13 miles for V96, 8 miles for V10-188, and 2 miles for V297. The target area for the plant was conservatively assumed to be 0.015 square miles (References 17, 18, 19, 20, and 21). The conservatively estimated probability of a commercial aircraft crash into the Fermi 2 plant is 8.9×10^{-8} per year and for a private aircraft 8.9×10^{-6} per year.

The target area for the spent fuel pool was taken to be 0.0001 square miles. A conservatively estimated probability of a private aircraft crash into the spent fuel pool is 5.9×10^{-8} per year. The exterior walls of the Category I reactor/auxiliary building were analyzed for the crash of the largest private aircraft capable of using Marshall Field and were found able to withstand such a postulated event.

2.2.3.4 Onsite Storage of Fuels and Explosives

The site access rail spurs are not used for the transportation of explosives or fuel oil. Fuel oil is transported by truck to the fuel-oil storage tanks onsite. A winter blend of #2 and #1 fuel oil is required for operation of the 62.2 MWe combustion turbine peakers south of Fermi 1.

The 300,000-gal fuel-oil storage tank for the combustion turbine peaker units is located approximately 1/3 mile south from the plant and safety-related plant structures. The results of any event related to the transportation and storage of fuel oil at this tank would have no effect on the normal operation of Fermi 2 or endanger safety-related plant structures or equipment. The tank is surrounded by a conservatively sized clay-lined dike with a polyethylene geomembrane inner dike liner and is equipped with piping to a foam distribution manifold on the tank. In the event of a fire involving the tank, a foam-generating fire truck can be connected to a nearby hydrant (furnished for the purpose). The foam discharge lines from the truck can be connected to the tank manifold piping using the provided fire department connection, and foam distributed within the tank. Should the tank rupture, the tank contents will be contained within the dike, and any fire extinguished using conventional fire fighting methodologies as well as the manifold. The fuel storage facility has been designed in accordance with applicable fire codes.

A 20,000 gallon liquid hydrogen storage tank is located at the HWC gas supply facility. The gas supply facility is approximately 1100 feet northwest of the RHR Complex. The tank location has been chosen to ensure that the results of any event related to transportation or storage of hydrogen at this tank would have no effect on the safe operation of Fermi 2 or endanger safety-related plant structures or equipment. The gas supply facility has been designed in accordance with applicable fire codes and the nuclear industry guidelines for permanent HWC installations.

Other onsite fuel storage facilities are identified and evaluated in Subsection 9.5.1 and Appendix 9A.

The only storage of explosives in the vicinity of the unit will be in quantities sufficiently small and at such a distance that no postulated accident can endanger the safe operation of the unit.

2.2.3.5 Onsite Storage of Toxic Chemicals

Sodium hypochlorite and a small quantity of acids are stored onsite.

Sulfuric acid for circulating water is transported in accordance with all applicable regulations. Safety measures are taken near handling and storage facilities. Any spills during transfer operations will soak into the ground and be neutralized or will drain to a chemical sump for neutralization.

Sodium hypochlorite used to treat the circulating water is stored at the circulating water pumphouse in a tank located within a nominal 150 percent tank capacity retention dike and pad.

Sodium hypochlorite used to treat the GSW System is stored at the GSW pumphouse in a tank located within a nominal 150 percent tank capacity retention dike and pad.

2.2.3.6 Cooling Tower Collapse

The cooling towers are hyperbolic in design and any postulated failure of this tower would cause it to collapse inwardly. This failure would in no way endanger the safe shutdown of the unit.

2.3 METEOROLOGY

2.3.1. Regional Climatology

2.3.1.1. Data Sources

The regional climatology pertinent to the Fermi site was determined from data acquired by the National Weather Service and summarized by the Environmental Data Service. The 1971 through 1974 local climatological data were obtained for the Detroit Metropolitan Airport (Reference 1), Detroit City Airport (Reference 2), and for Toledo, Ohio (Reference 3). The climatological summary was obtained for the cities of Monroe (Reference 4) and Willis (Reference 5), Michigan. These data provided sufficient information to determine the climatological characteristics of the area surrounding the Fermi site.

Extreme wind data were obtained from studies by Thom (Reference 6). Severe storm and tornado data were obtained from monthly storm data (Reference 7), climatological data national summary (Reference 8), the tornadoes of western Canada (Reference 9), and tornado probabilities (Reference 10).

The data for meteorological extremes were obtained for Detroit Metropolitan Airport, Detroit City Airport, and for Toledo Express Airport from the local climatological data for each station. Extremes for Monroe and Willis, Michigan, were obtained from the climatological summary for each station.

Monthly storm data were used to determine the number of occurrences of hailstorms and ice storms.

Climatological data for restrictive dilution conditions were obtained from a variety of sources concerned with stagnating conditions in the United States (References 11 and 12).

2.3.1.2. General Climate

The Fermi site is located in the southeast lower climatic district of Michigan on the western shore of Lake Erie. The lake smooths out most climatic extremes, with the most pronounced lake effect occurring in the coldest part of the winter when there is an excess of cloudiness and very little sunshine. Prevailing winds are from the western sectors in winter. Periods of easterly winds (off Lake Erie) and local lake breezes modify temperatures during the summer months. The climate in the area alternates between semi-marine and continental (Reference 4).

The predominant wind in the area is from the southwest, averaging approximately 10 mph (Reference 1). The average afternoon (1:00 p.m.) relative humidity for the Fermi site area is 58 percent, and varies from 52 percent in May to 71 percent in December (Reference 1). The highest temperature recorded in the area was 105°F (Reference 2) and the lowest was -19°F (References 1 through 5).

Precipitation is well distributed throughout the year. The Fermi site area receives an average of 31.15 in. of precipitation per year, with 56 percent occurring between the months of May and October. Minimum amounts of precipitation generally occur during the winter months (December, January, and February) and average approximately 2.0 in. per month. Maximum amounts of precipitation generally occur during the summer months (June, July, and August) and average approximately 3.0 in. per month (References 1 through 3). The mean annual snowfall in the area is 33.7 in. (References 1 through 5).

2.3.1.3. Severe Weather

2.3.1.3.1. Extreme Winds

According to a compilation by Thom (Reference 6) for characterizing extreme winds, the extreme mile wind speed at 30 ft above the ground, which is predicted to occur once in 100 years, is approximately 90 mph. The approximate values for other recurrence intervals are listed in Table 2.3-1, with the extrapolated value of 117 mph for the 1000-year recurrence interval (Reference 6). The extreme mile wind speed is defined as being the 1-mile passage of wind with the highest speed for the day. Based on the gustiness factor of 1.3, the highest instantaneous gust expected in 100 years is 117 mph. The highest mile wind recorded at Detroit City Airport, based on the 1934 through 1965 period of record, was 77 mph from the northwest (Reference 2). Based on the 1956 through 1972 period of record, the highest mile wind recorded at Toledo, Ohio, was a 72-mph wind from the southwest (Reference 3).

The Category I structures of Fermi 2 are designed to withstand a 90 mph fastest mile sustained wind velocity, 30 ft above ground level. This wind velocity has a 100-year recurrence interval.

The relationships to determine the vertical velocity distribution of the wind are obtained from Page 1139 of ASCE Paper No. 3269 for coastal areas and are as follows:

for $V_{30} \leq 60$ mph

$$V_z = V_{30}\left(\frac{z}{30}\right)^{0.3}$$

for $V_{30} > 60$ mph

$$V_Z = V_{30}\left(\frac{z}{30}\right)^{x}$$

where

V_{30} = basic wind velocity (mph) at a height 30 ft above ground level (grade)

x = factor which varies from 0.3 when V_{30} = 60 mph to 0.143 when V_{30}= 130 mph (Reference 3)

V_z = wind velocity (mph) at a height (z) above grade

Z = distance above grade in ft

Thus, at heights between 100 and 150 ft above grade, the height of the upper portion of the reactor building, the wind velocity is calculated to be 123.5 mph. Gust factors have also been determined by the methods given on pages 1124 through 1198 in ASCE Paper No. 3269. For all Category I structures, the gust factor varies linearly from 1.1 at grade level to 1.0 at 400 ft. However, a gust factor of 1.1 was used for the full height of both the reactor/auxiliary building and the residual heat removal complex except for the blow-away siding design during the design tornado, where a factor of 1.0 was used.

2.3.1.3.2. Tornadoes

2.3.1.3.2.1. Frequency

During the period January 1951 through December 1974, a total of 51 tornadoes were reported within a 50-mile radius of the Fermi site (References 8 and 9). These 51 tornadoes occurred within the United States. This is an average of two tornadoes per year within this radius. There were no tornadoes reported within 50 miles of the site in Canada for the period 1951 through 1960 (Reference 9). Canadian tornado data were not available for the period 1961 to 1974. There was one tornado reported at Tecumseh, Ontario, on August 1, 1973. This tornado was not included in this analysis.

According to the statistical methods proposed by Thom (Reference 10), the probability of a tornado striking a point within a given area may be estimated as follows:

$$P = \frac{\bar{z}\bar{t}}{A}$$

where

P	=	mean probability per year
$\bar{z}$	=	geometric mean tornado path area
$\bar{t}$	=	mean number of tornadoes per year
A	=	area of concern

For the region surrounding the Fermi site, the geometric mean path length computed was approximately 2.15 miles, and the geometric mean path width computed was approximately 75 yd (References 7 and 10), yielding a mean path area ($\bar{z}$) of 0.092 square mile, based on the January 1951 through December 1974 period of record. The use of a 50-mile radius to compute A (excluding the water area of Lake St. Clair and Lake Erie and the land area in Canada) and a value of 2.125 for $\bar{t}$ yields a tornado probability of 4.075 x 10^{-5} per year, or a recurrence interval of 24,500 years.

It should be noted that the June 8, 1953, tornado in northern Ohio had a reported path length of 100 miles and a path width of 440 to 1760 yd. These data were not used in the computation of $\bar{z}$, as recommended by Thom (Reference 10), who states that tornadoes with reported paths longer than 100 miles and paths wider than 1000 yd are considered doubtful observations. However, including this tornado, this yields a probability of 4.7 x 10^{-5}, or a recurrence interval of 21,200 years.

During the period of record studied, three tornadoes occurred within 5.5 miles of the Fermi site, but it is difficult to determine which occurred closest to the site. These were (1) on June 28, 1973, a tornado was observed 3 miles south of Estral Beach; no data on path length or width were given; (2) on June 12, 1973, a tornado occurred 3 miles west of South Rockwood with a path length of 0.1 mile and width of 40 yd; and (3) another nearby tornado occurred on June 11, 1968, at Monroe, Michigan. The path length reported was "short" and no path width was given. No persons were reported killed or injured, and the damage was estimated at from $500 to $5000 (References 7 and 8).

Not included in the above tornado discussion were water spouts and funnel clouds sighted in the area that did not touch the ground. Only one water spout was sighted within 50 miles of the site during the period 1965 through 1974. This occurred on August 1, 1965, 13 miles southeast of Mt. Clemens; there was no damage reported.

2.3.1.3.2.2. Parameters

Category I structures housing the systems required for a safe shutdown of the plant in the event of a tornado are designed to withstand the effects of a tornado by providing either sufficiently strong structures or appropriate venting. The design parameters of the Fermi 2 design-basis tornado are

a. A rotational wind velocity of 300 mph

b. A translational wind velocity of 60 mph

c. An external pressure drop of 3 psi at the rate of 1 psi/sec.

2.3.1.3.3. Precipitation Extremes

Tables 2.3-2 through 2.3-6 list extremes of precipitation and other meteorological parameters for several stations that surround the Fermi site. The maximum amount of precipitation recorded for a 24-hr period was 4.39 in. at Toledo, Ohio, in July 1969. The maximum monthly snowfall measured in the region was 28.5 in. at Monroe, Michigan, in March 1954 (Reference 1 through Reference 5). A December 1 and 2, 1974, snowstorm deposited 19.3 in. of snow at the Detroit Metropolitan Airport.

The 100-year recurrence snowpack and 100-year recurrence daily snowfall were computed using data from the Detroit Metropolitan Airport for the years 1971-1974 inclusive (see Figures 2.3-1 and 2.3-2). Each of these had the data ranked according to the amount and number of occurrences in the 4-year period. From these ranked amounts, a cumulative distribution table was generated. This cumulative percentage was graphed as a function of amount and the curve visually extrapolated to the value occurring in 100 years.

Snowpack

Number of Occurrences	Maximum Snowpack (in.)	Cumulative Number of Occurrences	Cumulative Percentage
10	Trace	36	100.00
8	1	21	72.22
3	2	18	50.00
5	3	15	41.67
3	4	10	27.78
1	5	7	19.41
2	7	6	16.67
1	8	4	11.11
1	9	3	8.33
2	11	2	5.56

The average number of observations per year is nine for this calculation, so that 100 years would provide 900 samples. The 100-year recurrence percentage would therefore be 0.11 percent. Referring to the graph of the cumulative frequency of snowpack versus amount, the extrapolated 100-year recurrence value is 27.8 in.

Daily Snowfall

Number of Occurrences	Maximum Daily Snowfall (in.)	Cumulative Number of Occurrences	Cumulative Percentage
4	Trace	28	100.00
2	0.1	24	85.71
1	0.5	22	78.57
1	0.6	21	75.00
2	1.0	20	71.43
1	1.3	18	64.29
1	1.5	17	60.71
1	1.6	15	57.14
1	1.7	15	53.14
1	2.5	14	50.00
2	2.7	13	46.43
1	2.8	11	39.29
1	2.9	10	35.71
1	3.1	9	32.14
1	3.2	8	28.57
1	3.7	7	25.00
1	3.8	6	21.43
1	4.7	5	17.86
1	5.2	4	14.29
1	8.4	3	10.71
1	8.7	2	7.14
1	19.3	1	3.75

The average number of observations per year is seven for this calculation, so that 100 years would provide 700 samples. The 100-year recurrence percentage would therefore be 0.15 percent. Referring to the graph of the cumulative frequency of maximum daily snowfall versus amount, the extrapolated 100-year recurrence value is 28.2 in.

2.3.1.3.4. Hailstorms

A review of hailstorm data for the period of 1962 through 1974 is reported in storm data for Monroe County and the immediately surrounding counties of Lenawee, Washtenaw, Wayne, Lucas (Ohio), and Ottawa (Ohio). This review indicates that there were 93 days with hailstorms in this area. Generally, these hailstorms occurred with scattered thunderstorms which covered a wide area (i.e., northern Ohio or southern Michigan). One of the most severe storms in the area occurred on July 19, 1967, in Wayne and Monroe Counties. Hailstones varying in size from "small peas to larger than golf balls" were reported to have accumulated to depths of 6 to 7 in. in spots. Damage to both crops and property ranged from $5000 to $50,000 (Reference 7).

2.3.1.3.5. Ice Storms

A study of ice storm data for the 1962 through 1974 period for Monroe County and the immediately surrounding counties indicates that there were 26 storms in this region. The storms were rarely limited to a small area, but were widespread over the state. The greatest accumulation of ice in the region came from the January 26 and 27, 1967, storm, which deposited up to 3 in. of ice in northern Ohio (Reference 7).

2.3.1.3.6. Thunderstorms

Thunderstorms occur on an average of 35 days per year, approximately 80 percent occurring in the months of June, July, and August (References 1 through 3). Generally, these thunderstorms encompass a large area (on the order of several hundred square kilometers each) and are associated with strong winds, intense precipitation for short time intervals, and lightning. Lightning incidence is estimated at about 10 flashes per year per square kilometer.

Each thunderstorm produces an average of about 120 independent flashes to ground (an average of one every 20 sec. for an interval of about 40 minutes). Each thunderstorm (isolated) encompasses an area of about 400 km^2 (20 km on a side). With 35 days per year associated with thunderstorms, these estimates give

$$\frac{35\ \text{Storms}}{400\ \text{km}^2} \text{ x } 120\ \frac{\text{flashes}}{\text{storm}} = 10\,\frac{\text{flashes}}{\text{Km}^2} \text{ per year.}$$

2.3.1.3.7. Restrictive Dilution Conditions

The frequency of occurrence of low-level inversions or isothermal layers based at or below a 500-ft elevation in the site region is approximately 28 percent of the total hours on an annual basis, according to Hosler (Reference 11), who takes into account lake and ocean effects on inversion frequencies. Seasonally, the greatest frequencies of inversions based on percent of total hours are 30 percent during the summer and fall. The inversion frequencies are 25 percent in the spring and 20 percent in the winter. The majority of these inversions are nocturnal in nature.

The mean mixing depth is another restriction to atmospheric dilution. The mixing depth is the thickness of the atmospheric layer, measured from the surface upward, in which convective overturning is taking place, caused by the daytime heating at the surface. The mixing depth is usually at its shallowest during the early morning hours, just after sunrise, when the nocturnal inversion is being modified by solar heating at the surface. The mixing depth is at its greatest during the later part of the afternoon, 3:00 p.m. to 4:00 p.m., when the maximum surface temperature of the day is reached. The monthly mean daily mixing depths, based on Flint, Michigan, upper air data for the period January 1960 through December

1964, are presented in Table 2.3-7 (Reference 12). Shallow mixing depths have a greater frequency of occurrence during the fall and winter months.

Periods of high air pollution potential are usually related to a stagnating anticyclone, with the average wind speed less than or equal to 9.0 mph (4.0 m/sec), no precipitation, and a mixing depth of less than 1600 ft (Reference 14).

The greatest air pollution potential in the site region occurs during the months of August, September, and October, when the tendency is greatest for a quasi-stationary anticyclone to develop in the region (Reference 15).

According to Korshover (Reference 15), there were approximately 19 anticyclone stagnation cases, each 4 days or more, reported in the site region during the period 1936-1967.

2.3.1.3.8. Maximum Roof Loadings

The following data itemize the maximum snow and ice load in inches of water that the roofs of safety-related structures are capable of withstanding during plant operation. The operating- basis conditions are based on the service conditions allowable stresses or strengths. The design-basis conditions are based on the strength of the structure at yield stresses with a load factor of 1.0.

Safety-Related Structure	Operating-Basis Snow and Ice Load (psf)	Water Equivalent (in.)	Design-Basis Snow and Ice Load (psf)	Water Equivalent (in.)
Reactor / auxiliary building	30	5.8	87	16.7
RHR Complex	70	13.5	276	53.0*

*This depth exceeds parapet height

2.3.2. Local Meteorology

2.3.2.1. Data Sources

The original Fermi 2 FSAR was filed with 12 months (June 1, 1974, to May 31, 1975) of onsite data obtained from a 60-m tower equipped with sensors that meet the requirements of Regulatory Guide 1.23 (Reference 16). Data from previous site meteorological systems and offsite National Weather Service sources were included as appropriate.

Offsite wind, stability, precipitation, temperature, relative humidity, and fog data were based on meteorological observations from Detroit Metropolitan Airport and Toledo Express Airport, both first-order National Weather Service stations (References 1 and 3). Additional temperature and precipitation data were obtained from National Weather Service cooperative stations at Monroe and Willis, Michigan (References 4 and 5). The 1956 to 1959 period site wind, stability, and precipitation data were obtained and summarized by the University of Michigan from the Fermi 1 100-ft meteorological tower (Subsection 2.3.3.1.1) (References 17 and 18). Additional onsite data from a low-level 33-ft tower at Langton Road are presented in this section, based on data obtained and reduced by the University of Michigan for the period January 1, 1972, to December 31, 1972. These data include ambient temperature and relative humidity; however, the low-level wind data are only briefly discussed because of unfavorable (42 percent) data recovery.

Wind stability and fog data summaries for Detroit Metropolitan Airport and Toledo Express Airport were also obtained.

2.3.2.2. Normal and Extreme Values of Local Meteorological Parameters

The distribution of wind direction and speed is an important factor when considering transport conditions relevant to site diffusion climatology. The monthly, seasonal, and annual distributions of wind direction and speed from the 60-m tower at the Fermi site (June 1, 1974, to May 31, 1975) are presented in Figures 2.3-3 through 2.3-19. For comparative purposes, data from Detroit City Airport (81-ft level, 1951 to 1960) and Toledo Express Airport (20-ft level, 1950 to 1955) are presented in Figures 2.3-20 through 2.3-31; each month presented represents averaged data for the years reported. These data are summarized and presented in annual wind roses in Figure 2.3-32. Average wind directions for all locations show a predominance of winds from the southwest through west-southwest. Limited site data from the Langton Road Tower (33-ft level) for the January 1, 1972, to December 31, 1972, period indicate a predominance of winds from the south through west-southwest.

Atmospheric dilution is directly proportional to the wind speed, with other factors remaining constant. Table 2.3-8 presents the average wind speeds and frequencies of calms for the Fermi site, the Detroit Metropolitan Airport, and the Toledo Express Airport. A calm is defined as a wind speed of $\leq$1.0 mph for the Fermi site 60-m and 150-m tower data and $\leq$1.2 mph for data recorded at National Weather Service stations and the Fermi site 100-ft tower. The threshold of the anemometer was used as the determining value of calm conditions. The highest average speed of the four stations, summarized in Table 2.3-8, is at the Fermi site at the 60-m level. This can be attributed to the higher exposure height of the wind sensors at the Fermi site and the shoreline location of the site, since wind speeds during onshore wind flows may be greater, and a lake breeze situation can develop during periods when light winds or calms are recorded at inland meteorological stations. Variations in speed can also be attributed to differences in instrumentation, data reduction techniques, and periods of record.

2.3.2.2.1. Wind Direction Persistence

Wind direction persistence is important when considering potential effects from a contaminant release. Wind direction persistence is defined as a continuous flow from a given direction or range of directions. Figure 2.3-33 shows the probability of occurrence of a 22-1/2° sector wind flow persistence as a function of duration, based on data from the 60-m tower (June 1, 1974, to May 31, 1975) and offsite data from the Detroit Metropolitan Airport (1959 to 1962 data period) and the Toledo Express Airport (1959 to 1963 data period). The wind persistence summary from onsite data (60-m tower) is shown in Table 2.3-9 in increments of 1 hr.

Based on the onsite observation time (12 months), the 10-m level data indicate a 5 percent probability of continuous wind direction persistence of about 7 hr and a 1 percent probability of 11-hr duration. At the 60-m level, these same percentages are 7 hr and 13 hr, respectively.

The 5 and 1 percent probabilities of continuous wind direction persistences at the 60-m level were greater than those observed at the 10-m level, as should be expected. The Detroit Metropolitan Airport data at 58 ft indicate a 5 percent probability of continuous wind direction persistence periods greater than 9 hr and a 1 percent probability of continuous wind direction persistence periods greater than 15.5 hr. The Toledo Express Airport data at 20 ft indicate a 5 percent probability of continuous wind direction persistence for periods greater than about 16 hr.

The maximum wind persistence at the Fermi site within a 22-1/2° sector, recorded on the 60-m tower during the June 1, 1974, to May 31, 1975, period, was one period lasting for 32 hr at the 10-m level from the south, associated with an average speed of 21 mph. The maximum wind persistence at the Detroit Metropolitan Airport within a 22-1/2° sector, recorded during the 1959 to 1963 period, was a 37-hr wind from the east-southeast, associated with an average speed of 17 mph. The maximum wind persistence at the Toledo Express Airport within a 22-1/2° sector, recorded during the 1959 to 1963 period, was a 37-hr wind from the east-northeast associated with an average wind speed of 17.0 mph. Episodes of maximum wind persistence within a 22-1/2° sector for the Fermi site 10-m level (60-m tower) data, Detroit Metropolitan Airport, and the Toledo Express Airport are presented in Figure 2.3-34.

2.3.2.2.2. <u>Atmospheric Stability</u>

Stability is a measure of the degree of atmospheric turbulence. A low degree of wind turbulence can be expected for stable conditions, resulting in relatively suppressed diffusion conditions. Conversely, during periods of instability, a high degree of wind turbulence can be associated with relatively enhanced diffusion conditions.

The seasonal and annual frequencies of stability indices for the Detroit Metropolitan Airport, Toledo Express Airport, and the Fermi site 60-m tower are presented in Tables 2.3-10 and 2.3-11. The stability data for the two airports were classified according to the Pasquill-Turner approach (Reference 19). This method is an indirect approach and involves the utilization of factors such as cloud cover, solar insulation, time of day, and wind speed to classify data that are generally available at National Weather Service observation stations. The onsite stability data were determined for the 60-m tower for the June 1, 1974, to May 31, 1975, period. The stabilities were classified from $\Delta T_{(60\ m\text{-}10\ m)}$ data, using the procedure outlined in Regulatory Guide 1.23 (Reference 16). Examination of Tables 2.3-10 and 2.3-11 indicates the predominance of neutral conditions. The frequency of stable (E, F, and G) conditions for both Detroit Metropolitan Airport and Toledo Express Airport is similar to the frequency of inversions based on Fermi site $\Delta T_{(100\ ft\text{-}25\ ft)}$ data from the 100-ft tower on a seasonal and annual basis (Table 2.3-12). The onsite data from the 60-m tower show a larger spread in the stability data.

Onsite stability data for the 1956 to 1959 period were compiled on a seasonal and annual basis and summarized in reports by the University of Michigan (References 17 and 18). The data were based on a $\Delta T_{(100\ ft\text{-}25\ ft)}$ and were obtained from the 100-ft tower described in Subsection 2.3.3.1. The data were classified into the following three groups:

a. Strong vertical temperature gradients ($\Delta T_{(100\ ft\text{-}25\ ft)} < 0.98°C/100$ m or -5.4°F/1000 ft)

b. Weak vertical temperature gradients ($\Delta T_{(100\ ft\text{-}25\ ft)}$ >0.98°C/100 m or 5.4°F/1000 ft, and ≤0)

c. Inversions (temperature increases with height).

In addition, $\Delta T_{(300\ ft\text{-}20\ ft)}$ data are available from the WJBK-TV tower located in the northwest suburbs of Detroit, approximately 35 miles north of the Fermi site. Data from this tower were analyzed for the 1956 to 1959 period for inversion conditions only.

Fermi site $\Delta T_{(60\ m\text{-}10\ m)}$ data from the 60-m tower are presented on an hourly basis over the June 1, 1974, to May 31, 1975, period in Tables 2.3-13 and 2.3-14. Additional Fermi site $\Delta T_{(100\ ft\text{-}25\ ft)}$ data from the 100-ft tower are presented on a seasonal and annual basis in Table 2.3-12. WJBK-TV $\Delta T_{(300\ ft\text{-}20\ ft)}$ data for inversion conditions only are presented in Table 2.3-15 for comparative purposes. These two locations compare favorably as to frequency of occurrence of inversion conditions. Both have a maximum during the summer and a minimum during the spring. The diurnal distribution of frequency of inversions at the WJBK-TV tower compares well with that at the Fermi site using data from the 60-m tower. The maximum frequency of inversions occurs in the midmorning hours (5:00 a.m. to 8:00 a.m.), while the maximum frequency of unstable conditions occurs in the early afternoon hours (1:00 p.m. to 3:00 p.m.).

Table 2.3-16 shows the inversion persistence derived from the 60-m tower measurements over the June 1, 1974, to May 31, 1975, period.

The stability classes were determined from $\Delta T_{(60\ m\text{-}10\ m)}$ 60-m tower data using the classification scheme outlined in Regulatory Guide 1.23. For Table 2.3-16, an inversion was defined as the existence of a temperature difference between the 60-m level and the 10-m level of greater than -0.0°C (i.e., temperature change with height (°C/100 m) >-0.0).

Figure 2.3-35 presents the probability of inversion persistence for durations greater than 6 hr, based on the frequency of occurrence with respect to surface-based inversions only. These data are based on Fermi ΔT site data from the 100-ft tower for the 1956 to 1959 period and ΔT site data from the 60-m tower for the June 1, 1974, to May 31, 1975, period. Figure 2.3-35 shows a 5 percent probability of an inversion lasting longer than 25 hr and a 1 percent probability of an inversion lasting longer than 43 hr, using the 100-ft tower data. For the 60-m tower data, these same percentages produce inversions of 18 hr and 30 hr, respectively.

Joint frequency tables of wind directions and speed by stability class are presented in Appendix 2A of the original FSAR for onsite Fermi data from the 60-m tower from June 1, 1974, to May 31, 1975. Current data for the 10-m level and 60-m level are provided by the operational meteorological system (Subsection 2.3.3.2). Annual summaries of meteorological data are prepared as required by the Technical Specifications.

2.3.2.2.3. Distribution and Frequency of Precipitation

Distribution of precipitation as a function of wind direction is presented in Table 2.3-17 for the Fermi site, using data from 1956-1959 from the 100-ft tower and from June 1, 1974, to May 31, 1975, from the 60-m tower. The 100-ft tower data show that the highest frequency of precipitation occurs when associated with winds from the southwest through west-northwest. The average wind speeds (100-ft level) during precipitation are 11.0 mph for all directions. The frequency of precipitation during calm conditions is 0.2 percent of the total hours of precipitation (Reference 18). The 60-m tower data show a larger spread, which may be due to the smaller sample size (12 months). A wind rose showing the distribution of wind speed versus wind direction with respect to precipitation only is presented in Figure 2.3-36.

2.3.2.2.4. Natural Fog Occurrences

Fog is essentially a cloud that has developed on the ground. Therefore, the processes leading to fog formation are similar to those for cloud formation. In general, the conditions that promote water-vapor condensation in ground-level air may lead to fog conditions. Aside from the interrelated thermodynamics of the ambient air and the ground surface, a number of other factors may influence the formation of fog. These factors include the size, character, and number of condensation nuclei; the extent of cloud cover; the wind speed and direction; the time of day; and the atmospheric turbulence.

The surface air may generally be treated as a mixture of dry air and water vapor. The most frequent and effective cause of fog is the cooling of humid surface air to a point where vapor condensation occurs. The condensation generally takes place on larger and more active condensation nuclei, and may occur somewhat before the dewpoint temperature (saturation) is reached. However, as long as the moisture content is sufficiently below the saturation value, condensation does not occur and fog conditions do not exist.

According to Byers, there are three types of fog which predominate in the Great Lakes area (Reference 20). Spring and early summer conditions (warm atmosphere and cold lake) contribute to the formation of land and lake breeze fogs. In the fall, advection-radiation fogs form over the land. During the fall and winter, steam fogs form over the lakes.

In the formation of a land and lake breeze fog, warm moist air from the land is transported out over the cold lake and, if the winds are light, a dense surface fog may develop over the lake. The fog may then be carried out over the land by a lake breeze during the day and may recede at night during a land breeze flow. These fogs rarely penetrate very far inland (i.e., 2 or 3 miles).

An advection-radiation fog is formed by nighttime radiational cooling of air of high humidity that has been advected inland from the lake during the day. This advection of lake air with a high relative humidity makes possible the formation of fog with normal nocturnal cooling.

Steam fog will form when cold air with a low vapor pressure passes over warm water. Steam fog is generally shallow in depth (i.e., 50 ft to 100 ft thick). According to Rondy, the western end of Lake Erie will have 70 percent to 90 percent ice coverage out to 35 miles by January 15 during a normal winter. The extreme western shoreline, where the Fermi site is located, will have 100 percent coverage out to 5 miles from the shore by January 15 (Reference 21). Therefore, steam fog in the Fermi site area will occur mostly during the fall.

Fog occurs predominantly during the early morning hours when the moisture-bearing air is cooled to the lowest temperature and the vapor saturation of the air is most closely approached. This effect is illustrated in Figure 2.3-37 where the probability of fog occurrence at the Detroit Metropolitan Airport, for the December 1, 1958, to September 1, 1962, period, is plotted versus the hour of the day for the annual average. Over the year, the peak frequency of fog occurrence is about 32.1 percent of the total hours of fog and occurs between 5:00 a.m. and 7:00 a.m. There is a notably higher frequency of fog between the hours of 11:00 p.m. and 10:00 a.m. Fog (other than frontal fog) is normally expected to dissipate during the late morning hours, particularly on clear, sunny days. However, cloud cover can extend the period of fog well into the daytime hours.

The monthly percentage occurrences of fog based on Detroit Metropolitan Airport data are presented in Figure 2.3-38. As can be seen in Figure 2.3-38, the monthly distribution of fog at the Detroit Metropolitan Airport does not show the distribution of fog for a Great Lakes area station predicted by Byers. Great Lakes area fogs have peak occurrences in the spring, early summer, and fall. The Detroit Metropolitan Airport shows peaks in the fall and winter. The major cause of the difference between occurrences observed at the Detroit Metropolitan Airport and those predicted by Byers is the location of the airport with respect to Lake Erie. Detroit Metropolitan Airport is located approximately 20 miles from Lake Erie. Because of this, lake- land breeze-type fogs, which rarely penetrate more than 2 to 3 miles inland, will not be evident at the airport. Because the Toledo Express Airport is 20 miles from Lake Erie, these types of fogs will not be evident there either. However, in a location such as the Fermi site, the lake will have a greater effect on natural fog occurrences, and the types and frequencies of fog should be the same as outlined by Byers.

The presence of fog onsite (at the shoreline) is associated with, for the most part, calm wind conditions. The ability of the natural draft cooling tower plume to rise to considerable heights is a significant factor in reducing the potential of adverse ground-level environmental effects. For example, under calm wind conditions, a typical plume penetration height for the Fermi 2 cooling towers is about 1000 ft above the top of the towers. In addition, the major roadways in the vicinity of the site are Interstate 75 and U.S. 24/25, whose closest approaches are 5.1 and 5.8 miles to the northwest, respectively. Dixie Highway, Pointe Aux Peaux Road, and Toll Road are closer, but are not considered major highways (Reference 22).

2.3.2.2.5. Meteorological Parameters

The extremes and means of meteorological parameters have been tabulated in Tables 2.3-2 through 2.3-6 for the Detroit City Airport, Detroit Metropolitan Airport, Toledo Express Airport, and Monroe and Willis, Michigan.

Table 2.3-18 presents the average temperature and relative humidity by month during the January 1, 1972, through December 31, 1972, period at the Fermi site (Langton Road Tower), the Detroit City Airport, and the Toledo Express Airport, for comparative purposes. However, the average relative humidity values by month for Fermi site data seem somewhat high and may, to some extent, be attributed to instrumentation and calibration inaccuracies. (Prevailing winds for the period were from the south through west-southwest.)

Figures 2.3-39 and 2.3-40 show the means of the daily averages and extremes of ambient air temperature and relative humidity, respectively. Relative humidity data were derived from ambient air temperature and dewpoint temperature data collected at the 10-m level of the 60-m tower from June 1, 1974, through May 31, 1975.

A comparison of monthly average temperatures and monthly high and low temperatures between the Fermi site data and National Weather Service data nearby, for the June 1, 1974, through May 31, 1975, period, is shown in Table 2.3-19.

2.3.2.3. Potential Influence of the Plant and the Facilities on Local Meteorology

The physical structures of the plant, especially the large natural draft cooling towers, are expected to locally increase atmospheric turbulence. There is also a potential for somewhat decreased low-level wind speeds in the immediate vicinity of the physical structures of the plant due to a wind-shielding effect. A study has shown that a cooling tower has an extended downwind wake upward to at least one and one-half times the tower height and downwind approximately two to three times the tower diameter. This will occur for wind speeds greater than 5 to 8 mph. Analysis has shown that any increase in precipitation due to the natural draft system will be minimal. Maximum precipitation from drift is predicted to occur at a distance of 3 km (1.8 miles) both northeast and west-southwest of the cooling towers at a total rate of approximately 0.008 in. annually. The increase in surface relative humidity is insignificant. The greatest relative humidity increase (nearly 21 percent at 1500 m downwind) will occur on winter mornings at an approximate height of 470 m (1542 ft). This 21 percent increase is ample to cause a visible plume from the natural draft cooling tower to extend downwind approximately 1000 m during the winter. There will be no significant fogging problems offsite on an annual basis. The offsite ground-level visibility reduction (to <1000 m) is predicted to occur only about 1 hr per year (Reference 22).

The cited cooling tower studies were conducted specifically for the Fermi 2 cooling towers by the NUS Corporation. The parameters used and the results of these studies are presented in the Fermi 2 Environmental Report in Section 5.1. The models used are described in Section 6.1 and were filed with the NRC on August 30, 1974, as the reports listed below as supporting documents to Docket Nos. 50-500 and 50-501.

a. Langrangian Vapor Plume Model - Version 3 (LVPM-3), NUS-TM-S-184
b. FOG Model Description, NUS-TM-S-185
c. ICE Model Description, NUS-TM-S-186.

2.3.2.4. Topographic Description

2.3.2.4.1. General Description

The terrain in the region of the Fermi site is characterized by flat plains, with the relief varying from 0 to 100 ft. More than 80 percent of the area is gently sloping. However, the actual site area is relatively flat and characterized by marshlands. Figures 2.3-41 and 2.3-42 are topographic maps of the area within 5- and 50-mile radii, respectively. Figure 2.3-43 is a topographic cross section of the Fermi site area out to 5 miles from the plant site and Figure 2.3-44 is a topographic cross section of the Fermi site out to 50 miles.

2.3.2.4.2. Topographic Influences on Meteorological Diffusion Estimates

The major local topographic effect on site meteorology is the presence of Lake Erie and the resultant occurrences of lake and land breeze circulations. Lake and land breeze circulations are driven by horizontal pressure gradients across the shoreline. These pressure gradients are the result of the temperature variation between water and land. This temperature differential between water and land can be most readily explained by the turbulent mixing and transport of surface heat by wave action and currents in a lake. This turbulent mixing process within the lake effects a continuous downward transport of surface heat through the water, thus lowering the surface water temperature (and also lowering the temperature of the overlying air), in contrast with the strong surface heating of the air over the shoreline region. This contrast is also intensified because the lake water has a higher thermal capacity than that of the soil. The temperature differential across the shoreline is enhanced under clear skies and light geostrophic winds.

Because the land is heated faster than the lake, the air above the land becomes warmer than the air above the lake. The warmer air over the land begins to rise as it expands and becomes less dense. At an average height aloft of 700 m, a pressure gradient from the land to the lake is formed (Reference 23). Because of this pressure gradient, air begins to flow from the land toward the lake. This offshore flow aloft is known as the return flow. Typical return flows extend above 1500 m and have velocities that can exceed 5 m/sec.

Because air is advected from the land to over the lake aloft, a surface low is formed over the land and a surface high is formed over the water. With a surface pressure gradient thus formed, an onshore wind flow at the surface (the lake breeze) is started. To complete the circulation cell of the lake breeze, there is strong upward motion (with average updrafts of over 1 mph) over the land and subsiding air over the lake. Figure 2.3-45 is a schematic representation of the streamlines during a well-developed lake breeze cell (Reference 23). Although formation of the lake breeze circulation is usually perpendicular to the shoreline, Coriolis forces become significant as the system matures. During the later afternoon, the lake breeze can be expected to have a major component parallel to the shore (i.e., to the right of the original trajectory).

In the middle latitudes, lake breezes can occur during 30 to 60 percent of the days in the spring and summer months of the year. Lake breezes can also occur during the fall and winter seasons, although less frequently than during the spring and summer. Land breezes are the converse of lake breezes and may develop when lake temperatures are warmer than land temperatures, such as during the fall and early winter, or during the night in the summer. However, land breezes are generally weaker and less frequent than lake breezes. Once the lake becomes covered by ice, the temperature differential between lake and land becomes minimal, and the lake effect becomes nonexistent.

The front edge of the lake breeze flow has the basic characteristics of a cold front with cool, moist lake air behind the front advancing inland. This lake breeze front may advance 30 km or more inland (Reference 24).

During onshore wind flow, such as a lake breeze, cool air flowing off the lake is modified by thermal surface heating and by surface roughness effects as the air flows over the land. The air from the lake is modified significantly as it flows over the land, especially during the spring and early summer. The air is heated from below, resulting in an unstable vertical temperature gradient and hence enhanced diffusion conditions. Surface roughness effects over the land increase atmospheric turbulence (also resulting in enhanced diffusion conditions), although low-level wind speeds will decrease. The thermal and roughness effects occur at the shoreline and form a "boundary layer" which increases vertically with distance inland. Within this boundary layer is unstable air, with stable air and an intense elevated inversion (suppressed diffusion) above the boundary layer. During the late fall and winter seasons, especially when there is not as large a temperature differential between the lake and the land as during the spring and early summer, the boundary layer is more shallow and the surface-based inversion (suppressed diffusion), normally formed right at the lakeshore, penetrates further inland.

Offshore wind flows generally result in somewhat suppressed diffusion conditions. The warm air advected from over the land is cooled from below, resulting in a stable vertical temperature gradient (inversion) and less diffusion for the over-water flow than for an overland flow. There is also a decrease in wind turbulence, although wind speeds will increase as the air flows from the relatively rough land surface over the smooth water surface. In addition to lake land breezes near a shoreline, there are also downwash and upwash effects. The primary cause of a downwash or upwash condition is the difference in surface roughness between the land and the lake (Reference 24). The upwash situation occurs with the winds blowing off the lake. The air flows from the relatively frictionless lake surface over the rough land, and a reduction in low-level wind speed occurs. This reduction in wind speed enhances plume rise to the extent that the plume can more easily escape the dynamic downwash effects of the plant structure. Downwash effects occur primarily with an offshore wind. The low-level winds coming off the relatively rough land over the smooth lake increase in speed. This increase in wind speed enhances plume downwash toward the lake surface.

A qualitative study of the surface characteristics of lake breezes at and in the near vicinity of the Fermi 2 site has been reported in Reference 25. The preliminary results of this study confirm the aforementioned factors. During the summer months, about one-third of the days were determined to give rise to a lake breeze situation. The inland penetration of these airflows averaged about 4 miles with a mean temperature decrease at the site of about 2°F and a relative humidity increase at the site of about 10 percent. The mean wind speed change due to a lake breeze situation was small (1 to 2 mph) when the lake breeze was in a direction so as to enhance the wind speed. Under conditions when the lake breeze occurred in opposition to a gradient wind, some wind direction changes were found. However, the infrequency of these situations makes it doubtful that the lake breeze could significantly change the atmospheric dispersion of effluents on an annual basis.

Edison performed a short-term meteorological study, specifically for emergency planning application, during the lake breeze seasons of 1983 and 1984 to determine the effect of Lake Erie on plume transport characteristics at the Fermi 2 site.

2.3.3. Onsite Meteorological Programs

2.3.3.1. Preoperational Onsite Meteorological Program

2.3.3.1.1. Meteorological Facility Operations

Onsite data presented in this report were collected from three different locations within the site boundary: from a 60-m tower approximately 2400 ft southwest of the Fermi 2 reactor building (since June 1, 1974) (Data from the 60-m tower were used for the diffusion estimate modeling); from the Fermi 1 100-ft tower located approximately 500 ft south-southeast of the Fermi 1 turbine building (December 1, 1956, to November 30, 1959); and from a 10-m (33-ft) tower located near Langton Road (January 1, 1972, to December 31, 1972).

Data were also collected from a 150-m tower that was located approximately 2400 ft south of Fermi 2 on the Lake Erie shoreline. One year of data (June 1, 1974, to May 31, 1975) from the 150-m tower and the 60-m tower were compared (Reference 26). The results of that study show that the 60-m tower data are representative of the Fermi 2 onsite meteorological conditions. When the Fermi 2 preoperational meteorological program was completed May 31, 1976, the 150-m tower was decommissioned. At that time, the 60-m tower operations were also discontinued until approximately 18 months prior to Fermi 2 fuel load (Reference 27). Following this, meteorological data have been collected only from the 60-m tower; thus the 60-m tower data are presented in this section. The 60-m tower data were collected, developed, and analyzed according to Regulatory Guides 1.23 and 1.111, Revision 1 (Reference 26).

The bases for decommissioning the 150-m tower, which was approved by the NRC (Reference 27), were as follows:

a. The analysis of the meteorological data collected shows the 60-m tower data are, for most parameters including χ/Q values, a more conservative characterization of the Fermi 2 conditions
b. The inland location of the 60-m tower is more representative of the air layer into which the plant effluent will be released since the gaseous release point is approximately 250 m from the shoreline on the west side (inland) of the building complex
c. Gas turbine peaking units located north of the 150-m tower affect the temperature measurements at the 10-m and 60-m levels, and consequently ΔT values, when the winds are from the north-northwest sector. During these periods, the data have to be rejected, which can seriously jeopardize the 90 percent data-recovery requirement of Regulatory Guide 1.23
d. The Fermi 1 plant structures are located such that building wake may bias the wind data for the 150-m tower for northerly directions
e. The 60-m tower is less susceptible to the icing conditions and localized lake shoreline effects experienced at the 150-m tower
f. The 2 years of data collected on the 150-m tower compare favorably, indicating only minor variations between seasons that are considered to be within the expected statistical variations between years. Thus 1 year of data at either tower, since it can be assumed the 60-m tower correlations would be valid for any year period, can be considered representative of site meteorology.

Data and discussions for the 100-ft and Langton Road towers are presented to provide supplementary site information. Data reduction on the 100-ft tower covered only the period from 1956 to 1959 to obtain data for the Fermi 1 plant; therefore, neither the instruments, data collection methods, nor data-reduction methods meet Regulatory Guide 1.23 requirements. The 33-ft Langton Road tower was originally installed as a satellite to the 150-m tower and was not instrumented to meet Regulatory Guide 1.23 requirements. A brief description of the 100-ft and 33-ft towers is presented in the following paragraphs.

On the 100-ft tower, wind speed and direction were measured at the 24-ft (7 m) level, 56-ft (17 m) level, and the 100-ft (30 m) level. Temperature sensing elements were located at 5 ft (1.5 m), 25 ft (7.6 m), 57 ft (17 m), and 100 ft (30 m). A standard National Weather Service rain gage was located near the base of the tower. Specifically, the instrumentation of the 100-ft tower included

a. Wind instrumentation - three Bendix aerovanes
b. Temperature instrumentation - four ventilated and shielded iron-constantan thermojunctions
c. Precipitation instrumentation - one standard National Weather Service rain gage located at the base of the tower.

Data analyses are available from the above station for the December 1, 1956, to November 30, 1959, period and include only the 100-ft wind and temperature measurements ΔT(100 ft-25 ft).

The Langton Road tower (33 ft) was onsite in an open field, approximately 3500 ft west of the plant. This 10-m tower was maintained and operated by the University of Michigan. Wind data at Langton Road were collected at the 10-m level; temperature and relative humidity were recorded on a hygrothermograph housed in a conventional instrument shelter at a height of approximately 5 ft (1.5 m). Specifically, the instrumentation at the Langton Road tower included

a. Wind instrumentation - Gill propeller vane direction and speed sensors at the 10-m level
b. Temperature and humidity instrumentation - Belfort hygrothermograph housed in a conventional instrument shelter.

The specifications for the above equipment are summarized in Table 2.3-20. Data have been collected and reduced from this station for the January 1, 1972, to December 31, 1972, period.

2.3.3.1.2. Preoperational 60-Meter Tower Meteorological Data System

All the preoperational meteorological data systems that have been used during the Fermi 2 program are described in this section. The data are available from the 150-m tower (Reference 26), but are not reported herein.

2.3.3.1.2.1. Instrumentation

A revised Fermi 2 site meteorological program was initiated in November 1973 that more adequately measured meteorological conditions at the Fermi site and met the requirements of Regulatory Guide 1.23. The revised program included the reinstrumentation of the 150-m tower on January 23, 1974, and the installation of a 60-m tower with identical instrumentation. The two-tower program monitored most meteorological conditions, with the 150-m tower measuring undisturbed onshore flow off Lake Erie, and the 60-m tower measuring the perturbed onshore flow characteristic of conditions that could affect gaseous effluent releases during overland flow conditions. Figure 2.3-46 is a map of the Fermi site area with the meteorological tower locations.

Instrumentation on the 60-m tower measured wind speed, wind direction, and temperature at the 10-m level and the 60-m level. In addition, dewpoint was measured at the 10-m level, and precipitation was measured at ground level.

The interface electronics and backup analog recorders were located at the base of the 60-m tower in an environmentally controlled instrument shelter. The primary recording was accomplished using a digital system with teletype printout in engineering units and a computer-compatible paper tape. A minicomputer, located in the instrument shelter at the base of the 150-m tower, provided continuous automatic sensor polling every 15 sec and printed out averages of the data collected from the last 15 minutes once every hour. During periods when data might be desired more often than once an hour, the operator could call for a printout at any desired time interval. The 60-m tower instrumentation was interconnected to the 150-m tower system by a 2500-ft data-transmission line. Thus, the tower was controlled by the minicomputer. The 2500-ft data-transmission line was protected at each end by optical isolators designed to withstand 10 kV. This minimized the interface effects of all but the closest lightning flashes.

The revised meteorological program instrumentation specifications are shown in Table 2.3-21. The revised site meteorological program was fully operational in May 1974. Onsite data from the preoperational test program were acquired and analyzed from the 60-m tower from June 1, 1974, to May 31, 1975, from the digital printouts and the computer-compatible paper tape. AST operational onsite program data were also selected and analyzed from the 60-m tower for the period January 1, 1995 through December 31, 1999.

2.3.3.1.2.2.Calibration

Analog. Every 6 months, all sensors, electronics, and recording equipment were calibrated. Additional onsite calibrations were performed during the service visits. Any necessary adjustments were made onsite and equipment that malfunctioned was either corrected onsite or replaced with similar spare equipment. After any adjustments or repairs, the calibration was repeated. Electronics calibrations were performed by simulating the output of each of the sensors with precision test equipment and monitoring the recorded values for each parameter. Wind speed sensors were replaced by a square wave frequency generator (with its output monitored by a frequency counter) that was adjusted to provide frequencies corresponding to known wind speeds. Wind direction sensors were replaced by a stable voltage source (with its output monitored by a digital voltmeter), which was adjusted to provide an output corresponding to known wind vane orientations. Temperature sensors were replaced with a stable decade resistance box, which was adjusted to provide accurate resistances corresponding to known temperatures. In all cases, the test instrument settings used were those for which the sensor manufacturer published calibration equivalents. Sensor calibrations are performed by the manufacturer. All results of both electronics and sensor calibrations are kept and filed onsite.

Digital. The complete instrumentation system was calibrated every 6 months. Electronics calibrations were virtually the same as were performed on the analog system. Dewpoint electronics calibrations were performed in the same manner as those for air temperature electronics. With the exception of precipitation, sensor calibrations were performed by the manufacturer. The precipitation sensor and electronics were calibrated by placing known weights in the emptied weighing bucket corresponding to a known amount of rainfall. All results of both electronics and sensor calibration were kept and filed onsite.

2.3.3.1.2.3.Service and Maintenance

Analog. Visits were made twice a week to the 150-m tower to change chart paper, fill inkwells and pens, and change ribbons. A visual inspection of the sensors was made to see if they had been damaged. Using the same precision test equipment used for calibration, all instrumentation was checked to ensure reliable operation.

Digital. Daily operational checks and service were performed by a resident technician. These checks included inspection of the data to determine that all sensors were functioning correctly and of the strip charts to ensure accurate recording. In addition, the technician marked the correct time to the nearest minute on the strip chart and verified the correct time of the digital system. Visual inspections of sensors were also performed to ensure that they had not been physically damaged.

2.3.3.1.3. Data Analysis Procedures

The data analysis procedures discussed in this subsection were those used for the data reported herein, which includes data from the 60-m tower, 100-ft tower, and Langton Road tower. The total preoperational meteorological program also included the 150-m tower from which data were collected and analyzed over the period from July 3, 1973, to May 31, 1975. However, approximately 170 m north of the 150-m tower, four peaking units were located that were operated during periods of high electrical demand. When the peaking units were in operation and the wind was from the north, it was occasionally noticed that significant increases in temperature at the 60-m and 150-m levels occurred. Because of this, it was deemed necessary to delete periods during which peaking unit operation influenced the determination of the lapse rate. This influence was apparent several times during the course of the annual data collection. Because of the problems associated with the 150-m tower's location, the 60-m tower was installed. An analysis of 1 year of simultaneous meteorological data from the 150-m tower and 60-m tower (Reference 26) showed that the 60-m tower data were representative of the onsite meteorology. Thus, after the Fermi 2 preoperational onsite meteorological data collection was completed, the 150-m tower was decommissioned. Future data will be collected using the 60-m tower only (Reference 26).

2.3.3.1.3.1.60-Meter Tower Data Reduction

The meteorological monitoring systems for the Fermi site are described in Subsection 2.3.3.1.2. The data acquisition system utilized two levels of instrumentation (10-m and 60-m) on the 60-m tower located approximately 2400 ft southwest of the Fermi 2 plant. The atmospheric stability conditions were determined from the temperature differences (ΔT) between the 10-m and 60-m temperature measurements, in accordance with the Pasquill Stability Criteria, Conditions A through G. Data from the 60-m tower were read by computer from paper tape to an IBM computer-compatible disk pack and magnetic tape for further use in modeling the site meteorological conditions and χ/Q calculations for various time periods. Strip charts were used only for backup. The strip- chart data, when needed, were read manually and the data put on IBM cards. Data from the charts were recovered by averaging the 15-minute period immediately preceding the hour. As long as 90 percent of the time span (13.5 minutes) was available for averaging, the data were deemed valid.

As a continuing operational verification of data validity, comparisons for all sensors at all levels on the tower between analog and digital averages were made on a random basis during the preoperational phase. The results of these comparisons for all parameters at the 10-m level and the air temperature at the 60-m level of the 60-m tower are shown in Table 2.3-22. For all checks the correlations are excellent. Differences can be attributed to strip-chart-reading error combined with the greater resolution of the digital system.

Precipitation at ground level was recorded onsite starting December 7, 1973. With the digital system operational, the strip charts were used only for backup, thus eliminating the strip-chart-reading task. Digital data were verified periodically against strip charts.

2.3.3.1.3.2. Langton Road Tower and 100-Ft Tower Data Reduction

Data from the 10-m Langton Road tower were recorded on strip charts and manually reduced. One 10-minute sample for each 1-hr available-data period was obtained for values of the wind direction range (i.e., the extremes of the direction trace peaks). Average values of wind direction and wind speed were obtained by visually estimating a median for the 1-hr sample of the analog traces. One reading was taken for each 1 hr of data available to obtain instantaneous values of temperature and relative humidity. The manually reduced data were transcribed on cards and were used as computer input for data analysis and summary.

Data from the 100-ft tower were also recorded on strip charts and manually reduced. Hourly averages of wind direction, wind speed, and temperature were obtained by estimating a median for the analog trace.

2.3.3.1.4. Meteorological Data Recovery

2.3.3.1.4.1. 60-Meter Tower Data Recovery

The meteorological data recovery rates for the 60-m tower data for the June 1, 1974 through May 31, 1975 period are listed in Table 2.3-23. The joint data recovery (ΔT, wind speed, wind direction) for the June 1, 1974, to May 31, 1975, period of 91.16 percent meets the 90 percent required by Regulatory Guide 1.23

The joint data recovery of wind speed and direction and ΔT for the January 1, 1995 through December 31, 1999 10-meter tower data that was utilized in the PAVAN model for accidental releases at offsite locations is 96.2 percent, also meeting the NRC 90 percent criterion.

For the calculations presented herein, only 10-m wind speed and direction, and temperature differences between 60-m and 10-m were used to calculate the short-term postulated accidental release diffusion estimates based on the 1995-1999 data. The 10-m and 60-m wind speeds were used to calculate the long-term mixed-mode annual average X/Q and D/Q values based on the June 1974 through May 1975 period.

2.3.3.1.4.2. Langton Tower and 100-Ft Tower Data Recovery

The meteorological data-recovery rates for the 33-ft Langton Tower data are listed in Table 2.3-24. Wind data for the January 1, 1972, to December 31, 1972, period have not been included in this report due to a low data-recovery rate. The recovery was 94 percent for the temperature and relative humidity data for the report period. The data-recovery rate for the 100-ft tower was 77 percent for temperature data, and 96 percent for the 100-ft- level wind data for the December 1, 1956, to November 30, 1959, period. Data-recovery information for other levels of the 100-ft tower are not readily available.

2.3.3.2. Operational Meteorological Monitoring System

The previously described preoperational meteorological program was upgraded for plant operation. The upgraded program is composed of two independent meteorological trains of instrumentation – a primary train and a secondary train – mounted on the 60-m tower. Both trains feed the data acquisition equipment of the Integrated Plant Computer System (IPCS) located in the Fermi 2 control center. The IPCS has the capability to share the meteorological data with other plant computers, display the data on IPCS terminals at various plant locations, and perform plume dispersion analysis in support of Emergency Plan activities. The NRC can also receive selected meteorological data through the Emergency Response Data System (ERDS). The operational meteorological monitoring system is described in further detail in the following subsections and is illustrated in Figure 2.3-47.

2.3.3.2.1. Instrumentation

Table 2.3-25 lists the meteorological parameters monitored, the sampling height(s), and the sensing technique for the primary and secondary systems.

To minimize data loss due to ice storms, external heaters are installed on all primary wind sensors. The heaters are thermostatically controlled and are of the slip-on/slip-off design for easy attachment. The wind sensor specifications are not affected by these heaters.

A windscreen is mounted around the precipitation gage to minimize the amount of windblown snow and debris deposited in the gage.

Electrical power is supplied to the primary and secondary systems by independent power supplies. One source of power is Fermi 2; the other is an offsite source. If one supply fails, the other automatically supplies the necessary power for both systems. Two precautions are taken to minimize lightning damage to the system. Two of the three legs are grounded and the signal cables are routed through a lightning protection panel. Each signal line is protected by transient protection diodes specifically designed to stay below the individual line voltage breakdown point.

2.3.3.2.2. Signal Conditioning

Inside the environmentally controlled instrument shelter, sensor signals are conditioned. Each sensor signal requires a single printed-circuit board to perform the necessary conversion, amplification, and scaling to provide a pair of analog outputs for each parameter. Zero and full-scale test switches are front-panel mounted on each printed-circuit board to facilitate parameter testing.

After conditioning through their respective printed-circuit boards, the 10-m horizontal wind direction and vertical wind speed signals pass into the Climatronics Standard Deviation Computer boards to compute the 15-minute average sigma theta and sigma phi.

The primary and secondary signal conditioner and standard deviation computer boards are completely independent of each other.

2.3.3.2.3. Data Transmission

The outputs of the instrument signal conditioning equipment is transmitted to the control center via two independent transmission lines. The one line incorporates a phone line between the shelter and the nuclear operations center, where information is microwaved to the Office Service Building. From the Office Service Building, the signals are transmitted to the control center. The second line uses a separate phone line from the shelter to the nuclear operations center, where the data are transmitted to the office service building via a phone line. From the office service building, the signals are transmitted to the control center. The two signals are electrically separated from one another from the 60-m tower to the control center. The instrumentation at the 60-m tower is electrically isolated from the equipment in the control center computer room.

2.3.3.2.4. Data Acquisition

The dual IPCS data acquisition multiplexors accept two trains of data from the Meteorological system primary and secondary data acquisition equipment. This data is provided to the IPCS computers to perform meteorological calculations, update the data archive, display the information on the man-machine interface, and output the data to communication devices. The IPCS provides redundant computers that provide a main (Master) and backup (Slave) capability. The redundant computers in conjunction with the two trains of data acquisition provide two independent paths of data. The IPCS system monitors available error signals to determine equipment status. If an instrument input malfunctions, if data are suspect, or an instrument input is manually removed from service, the IPCS will substitute the reading from the next level of redundancy as listed in Table 2.3-26 and indicate the substitution on the IPCS computers.

Meteorological data are available in five different formats: instantaneous values, 1-minute blocked averages, 15-minute rolling averages, 15-minute blocked averages, and 1-hour blocked averages.

In the event that a data path to IPCS is unavailable, a recorder is available on each train of instrumentation at the meteorological instrument building to archive the raw data.

2.3.4. Short-Term (Accident) Diffusion Estimates

2.3.4.1. Calculation of Offsite Atmospheric Diffusion Coefficients

2.3.4.1.1. Objective

To evaluate the dispersion potential of the atmosphere in the Fermi site area, calculations were made of concentrations of effluents normalized by the source strength of the power plant release. These atmospheric dilution factors were calculated using the meteorological data collected onsite from January 1, 1995 - December 31, 1999.

Short-term offsite transport was modeled using the PAVAN software (Reference 28), which is based on the NRC design-basis-accident methodology in Regulatory Guide 1.145

(Reference 31). PAVAN is a commercial software package applicable to nuclear safety-related analyses as well as non-safety related studies and evaluations. Its use is applicable for determining normalized offsite concentrations as required for the Exclusion Area Boundary (EAB) and the Low Population Zone (LPZ). These locations are defined in UFSAR Sections 2.1.2 and 2.1.3.3 as radial distances of 915 m and 4827 m, respectively, from the containment building.

Six different χ/Q values, corresponding to six different time periods following an accident, were calculated. The time periods postulated to follow an accident are those specified by the NRC in Regulatory Guide 1.145. These are 0-2 hr, 0-8 hr, 8-24 hr, 1-4 days, 4-30 days and the annual period.

2.3.4.1.2. Dispersion Equations

This section describes the governing atmospheric dispersion modeling equations and assumptions in accordance with Regulatory Guide 1.145.

Ground-levelχ/Q values were calculated for the 2 hours following the accident for the EAB and LPZ, and for the annual period for the LPZ. Calculations were based on the following equations:

$$\chi/Q = \frac{1}{\bar{U}_{10}(\pi\sigma_y\sigma_z + A/2)} \quad (2.3\text{-}1)$$

$$\chi/Q = \frac{1}{\bar{U}_{10}(3\pi\sigma_y\sigma_z)} \quad (2.3\text{-}2)$$

$$\chi/Q = \frac{1}{\bar{U}_{10}\pi\Sigma_y\sigma_z} \quad (2.3\text{-}3)$$

Where:

- χ/Q is relative concentration, in sec/m^3
- π is 3.14159
- $\bar{U}_{10}$ is wind speed at 10 meters above plant grade, in m/sec
- σ_y is lateral plume spread, in m, a function of atmospheric stability and distance
- σ_z is vertical plume spread, in m, a function of atmospheric stability and distance
- Σ_y is lateral plume spread with meander and building wake effects (in meters), a function of atmospheric stability, wind speed, and distance [for distances of 800 m or less, Σ_y=Mσ_y, where M is determined from Regulatory Guide 1.145 Figure 3; for distances greater than 800 m, Σ_y=(M-1)σ_{y800m}+σ_y
- A is the smallest vertical-plane cross-sectional area of the reactor building, in m^2 (other structures or a directional consideration may be justified when appropriate). Offsite χ/Qs are calculated assuming a minimum cross-sectional area, A, of the combined reactor/auxiliary building of 2300 m^2, as shown in Figure 2.3-48

Plume meander is only considered during neutral (D) or stable (E, F, or G) atmospheric stability conditions where the highest χ/Q values resulting from equations 2.3-1, 2.3-2 and

2.3-3 is selected. For all other conditions (stability classes A, B, or C), meander is not considered and the highest χ/Q value of equations 2.3-1 and 2.3-2 is selected.

The χ/Q values calculated at the EAB based on meteorological data representing a 1-hour average is assumed to apply for the entire 2-hour period.

2.3.4.1.3. Determination of Max Sector and Overall 5 Percent Site χ/Q Values

2.3.4.1.3.1. Maximum Sector χ/Q

To determine the maximum sector χ/Q value at the EAB, a cumulative frequency probability distribution (probabilities of a given χ/Q value being exceeded in that sector during the total time) is constructed for each of the 16 sectors using the χ/Q values calculated for each hour of data. This probability is then plotted versus the χ/Q values and a smooth curve is drawn to form an upper bound of the computed points. For each of the 16 curves, the χ/Q value that is exceeded 0.5 percent of the total hours is selected and designated as the sector χ/Q value. The highest of the 16 sector χ/Q values is the maximum sector χ/Q.

Determination of the LPZ maximum sector χ/Q is based on a logarithmic interpolation between the 2-hour sector χ/Q and the annual average χ/Q for the same sector. For each time period, the highest of these 16 sector χ/Q values is identified as the maximum sector χ/Q value. The maximum sector χ/Q values will, in most cases, occur in the same sector. If they do not occur in the same sector, all 16 sets of values will be used in dose assessment requiring time-integrated concentration considerations. The set that results in the highest time-integrated dose within a sector is considered the maximum sector χ/Q.

2.3.4.1.3.2. 5 Percent Overall Site χ/Q

The 5 percent overall site χ/Q value for the EAB and LPZ is determined by constructing an overall cumulative probability distribution for all directions. χ/Q versus the probability of being exceeded is then plotted and an upper bound curve is drawn. From this curve, the 2-hour χ/Q value that is exceeded 5 percent of the time is found. The 5 percent overall site χ/Q at the LPZ for intermediate time periods is determined by logarithmic interpolation of the maximum of the 16 annual average χ/Q values and the 5 percent 2-hour χ/Q values.

2.3.4.1.4. Wind Speed Categorization

The meteorological database was prepared for use in PAVAN by transforming the five years (i.e., 1995-1999) of hourly meteorological tower data observations into a joint wind speed-wind direction-stability class occurrence frequency distribution. Seven (7) wind speed categories were defined according to Regulatory Guide 1.23 (Reference 16) with the first category identified as "calm". The higher of the starting speeds of the wind vane and anemometer (i.e., 0.75 mph) was used as the threshold for calm winds, per Regulatory Guide 1.145, Section 1.1. A midpoint was also assumed between each of the Regulatory Guide 1.23 wind speed categories, Nos. 2-6, as to be inclusive of all wind speeds. The wind speed categories have therefore been defined as follows:

Category No.	Regulatory Guide 1.23 Speed Interval (mph)	PAVAN-Assumed Speed Interval (mph)
1 (Calm)	0 to < 1	0 to < 0.75
2	1 to 3	≥ 0.75 to < 3.5
3	4 to 7	≥ 3.5 to < 7.5
4	8 to 12	≥ 7.5 to < 12.5
5	13 to 18	≥ 12.5 to < 18.5
6	19 to 24	≥ 18.5 to < 24
7	>24	≥24

In the equations shown in Section 2.3.4.1.2, it should be noted that wind speed appears as a factor in the denominator. This causes difficulties in making calculations for periods of calm. The procedures used by PAVAN to assign a direction to each calm period according to the directional distribution for the lowest wind-speed class. This is done separately for the calms in each stability class.

2.3.4.1.5. Short-Term X/Q Modeling Results

Atmospheric diffusion estimates developed for use in evaluating accidents are summarized in Table 2.3-27 for the above-mentioned periods following the accident. This table includes estimates for the maximum sector and overall 5 percent site χ/Q.

2.3.4.2. Calculation of Onsite (Control Room) χ/Q Values

2.3.4.2.1. Objective

To evaluate the dispersion potential of the atmosphere in the Fermi site area, calculations were made of concentrations of effluents normalized by the source strength of the power plant release. These atmospheric dilution factors were calculated using the meteorological data collected onsite from January 1, 1995-December 31, 1999.

Short-term onsite transport was modeled using the ARCON96 software, which is a commercially available general code for assessing atmospheric relative concentrations in the presence building wakes that is based on the NRC design-basis-accident methodology in Regulatory Guide 1.194 (Reference 32). The code user documentation and calculation methodology is documented in Revision 1 of NUREG/CR-6331, “Atmospheric Relative Concentrations in Building Wakes” (Reference 33).

ARCON calculates relative concentrations for a specified source-to-receptor configuration with the user supplied hourly meteorological data. It then combines the hourly averages to estimate concentrations for periods ranging in duration from 2 hours to 30 days. Wind direction is considered as the averages are formed. As a result, the averages account for persistence in both diffusion conditions and wind direction. Cumulative frequency distributions are prepared from the average relative concentrations. Relative concentrations that are exceeded no more than five percent of the time (95^{th} percentile relative concentrations) are determined from the cumulative frequency distributions for each averaging period. Finally, the relative concentrations for five standard averaging periods (0-2 hr, 2-8 hr, 1-4 days and 4-30 days) are calculated from the 95^{th} percentile relative concentrations.

2.3.4.2.2. Dispersion Equations

This section describes the governing atmospheric dispersion modeling equations and assumptions (with noted exceptions) in accordance with Regulatory Guide 1.194.

The basic diffusion model implemented in the ARCON96 is a straight-line Gaussian model that assumes the release rate is constant for the entire period of release. This assumption is made to permit evaluation of potential effects of accidental releases without having to specify a complete release sequence.

$$\frac{\chi}{Q} = \frac{1}{\pi \sigma_y \sigma_z U} \exp\left[-0.5\left(\frac{y}{\sigma_y}\right)^2\right] \qquad (2.3\text{-}4)$$

where:

$\frac{\chi}{Q}$	is relative concentration, in sec/m^3
π	is 3.14159
U	is wind speed at 10 meters above plant grade, in m/sec.
σ_y	is lateral diffusion coefficient (m)
σ_z	is vertical diffusion coefficient (m), and
y	is distance from the center of the plume (m)

This equation represents a ground level release that is assumed to be continuous, constant, and of sufficient duration to establish a relative mean concentration. It also assumes that the material being released is reflected by the ground. Diffusion coefficients are typically determined from atmospheric stability and distance from the release point using empirical relationships. ARCON96 uses the same diffusion coefficient (σ_z and σ_y) parameterizations utilized in the NRC PAVAN code for calculating the short-term post-accident offsite atmospheric dispersion.

Calculation of the onsite χ/Q values associated with stack releases (i.e., SGTS, RBHVAC, and the TBHVAC), the “vent release” option was specified in conjunction with a zero-vent velocity. According to Regulatory Guide 1.194, the NRC specifies a ground release as the acceptable release mode for performing atmospheric dispersion calculations, consistent with this philosophy, the NRC does not accept the ARCON96 vent release calculation methodology. However, ARCON96 is coded to use the ground release equations when the vent exiting velocity is less than the wind-speed. Thus, in specifying a zero vent exiting velocity for cases where the vent release option was selected, the ground release equations were implemented and the intent of Regulatory Guide 1.194 was met. The purpose for specifying the zero-velocity vent release option was to allow for consideration of the 60-meter meteorological data in the calculation of the atmospheric relative concentration. Alternatively, the ground release option could have been specified with same inputs for the release and receptor elevations with the same result. In addition, in specifying the vent release, no credit was assumed for pre-dilution of the relative source term concentration inside the secondary containment or turbine building free air volumes or in the volumetric flows of the HVAC system associated with a particular vent location.

ARCON 96 includes the effects of low wind speed and building wake by replacing σ_z and σ_y above by composite wake diffusion coefficients of the following form:

$$\Sigma_y = \left(\sigma_y^2 + \Delta\sigma_{y1}^2 + \Delta\sigma_{y2}^2\right)^{1/2} \text{ and } \Sigma_z = \left(\sigma_z^2 + \Delta\sigma_{z1}^2 + \Delta\sigma_{z2}^2\right)^{1/2} \qquad (2.3\text{-}5)$$

where σ_Z and σ_y are the normal diffusion coefficients and $\Delta\sigma_{z1}$ and $\Delta\sigma_{y1}$ are the low wind speed corrections and $\Delta\sigma_{z2}$ and $\Delta\sigma_{y2}$ correct for building wake. The building wake correction is calculated based on a 2300 m^2 building area cross-section.

ARCON96 was run assuming the default surface roughness factor of 0.1 meters. This value is representative of a terrain having low-lying vegetation; i.e., farmland, wetland, etc.

2.3.4.2.3. Wind Speed Categorization

The meteorological database was prepared for use in ARCON96 by transforming the five years (i.e., 1995-1999) of hourly meteorological tower data observations into the format required by ARCON96. The required input consists of the Julian day, hour, 10-meter wind direction, 10-meter wind speed, stability class, 60-meter wind direction, and 60-meter wind speed for each of these years. ARCON96 requires the specification of the calm threshold. χ/Q values calculated using wind velocities below the calm threshold are automatically included in the statistical evaluation of a specific χ/Q regardless of the associated wind direction. Regulatory Guide 1.194 suggests a minimum calm threshold of 0.5 m/s; however, the ARCON96 performed in support of Alternate Source Term implementation were reviewed and approved with a calm threshold of 0.33 m/s. Based on NRC endorsement of the regulatory guide and endorsement of the original AST submittal, both values are acceptable.

2.3.4.2.4. Physical Orientation of Source-Receptor Combinations and Dual Inlet Credit

Consistent with Regulatory Guide 1.194, Position 3.4, the source-to-receptor distances used to calculate the atmospheric dispersion coefficients were calculated as the slant distance or direct line-of-site distances. Conservatively, the values of relative air concentrations used to evaluate vital area doses do not credit the additional distance incurred in circumventing intervening plant structures. However, such credit is permitted in accordance with the NRC methodology and was considered in evaluating the relative importance of postulated potential MSIV and secondary containment bypass leak release locations against the Turbine Building exhaust stack as a single representative release point.

2.3.4.2.4.1. DBA LOCA

Post LOCA atmospheric dispersion of ECCS and primary containment leakage was evaluated based on an assumed release via the SGTS stack to the control room north and south emergency air intakes. The TBHVAC stack was the assumed release point for Main Steam Line Leakage, also having the main control room north and south emergency air intakes as receptors. The table below identifies the horizontal and vertical separation distances between the postulated source and receptor locations. The RBHVAC stack and secondary containment wall were not assumed release locations evaluated in support of the LOCA analysis performed using the Alternate Source term. Nevertheless, their physical locations with respect to the control center emergency air intakes are included for historical purposes.

Source Release Location	Intake Separation Distance, meters [Horizontal/Vertical]	
	South Emergency/Normal*	North Emergency
SGTS Stack	39.4/24.9	17.2/35.8
TBHVAC Stack	69.1/10.7	111.1/21.6
RBHVAC Stack	11.6/24.9	48.8/35.8
Secondary Containment Wall	13.9/0	13.9/0

*Note that the vertical distance used to calculate the atmospheric dispersion coefficients for transport to the south emergency air intake for the LOCA analysis credits only the upper, missile-proof portion of the inlet plenum. The south emergency air intake also includes a safety-related sided enclosure that extends the intake down an additional 10.9 meters.

The Fermi 2 Control Center HVAC system is designed with dual emergency makeup air inlets located on the North and South sides of the Auxiliary Building. With the exception of the TBHVAC exhaust stack, the emergency air inlets have a separation distance that is sufficient to place them outside of a 90° wind direction window centered on the line-of-sight from any of the stack locations above to the opposite emergency air intakes. Thus, consistent with Regulatory Guide 1.194, Position 3.3.2, they are configured such that neither release point is capable of simultaneously impacting both air inlets. Furthermore, the Control Room Emergency Filtration System associated with CCHVAC is capable of automatically selecting the inlet with the lowest dose. However, the operators are procedurally instructed to take manual control of the inlet selection. On this basis, consistent with Regulatory Guides 6.4 and 1.194, Position 3.3.2.3, the χ/Q associated with the most favorable intake is assumed and divided by a factor of four. Fermi differs from the Regulatory Guide 1.194, Position 3.3.2.3 in that the factor of four is applied from the start of the accident rather than from the time the manual action is assumed to occur.

The TBHVAC stack is the assumed release point for the source term associated with Main Steam Isolation Valve leakage. This stack location does not have sufficient separation relative to the two inlets to allow dual inlet credit. The value of χ/Q calculated by ARCON96 is used directly (i.e., with no correction or reduction) to represent MSIV leakage transport to the control center with only credit for the ability of the operator to select the most favorable inlet. In this manner, the transport to the control center occurs instantaneously as the leakage occurs as if TBHVAC were in operation with no credit for any dilution in the TBHVAC airflow or the very large volume above the turbine deck. Each of the thirteen smoke vents on the Turbine Building roof and the external doors associated with the turbine and auxiliary buildings were also considered in selecting an appropriate release location. While the χ/Qs calculated for these locations were potentially larger than that associated with the TBHVAC stack value, the conservatism in the application of the stack value with no credit taken for mixing or deposition was considered adequately compensating.

2.3.4.2.4.2.Fuel Handling Accident

Fermi considers two types of fuel handling accidents, one that occurs 24 hours post-scram that involves a drop of recently irradiated fuel and credits only secondary containment and the operation of the SGTS for mitigation. The second type of fuel handling accident involving fuel that is no longer "recently irradiated," which occurs following a post-scram delay period sufficient such that credit for secondary containment and SGTS operation is not required.

Although not specifically required in Regulatory Guides 1.183 and 1.194, the FHA analyses submitted in support of Amendments 144 and 160, conservatively applied the 0-2 hr control room χ/Q values calculated by ARCON96 to the entire 30-day duration of accident.

Neither type of fuel handling accident assumes credit for the operation of the Control Room Emergency Filtration System. Consequently, the factor associated with the dual inlet configuration is not credited for reducing the value of χ/Q calculated by the ARCON96 software. Adequate separation is credited, however, to ensure that only the single most limiting air intake is specified.

The release and receptor locations used to evaluate the radiological consequences of the fuel handling accident differ from those associated with the DBA LOCA and depend on which of the two types of fuel handling accidents is to be evaluated.

2.3.4.2.4.2.1. 24-Hour Fuel Handling Accident Involving Recently Irradiated Fuel

This accident postulates an initial brief period of unfiltered release via the RBHVAC stack prior to secondary containment isolation and operation of the SGTS. ARCON96 was used to calculate the atmospheric dispersion coefficient representing transport from these stacks to each emergency air intake. The source-to-receptor distances are as specified in the table in Section 2.3.4.2.4.1 except the additional vertical distance of 10.9 meters associated with the full length of the south emergency air intake is credited.

2.3.4.2.4.2.2. Fuel Handling Accident Involving Fuel No Longer Considered Recently Irradiated

This accident assumes no credit for secondary containment isolation or operation of the SGTS. Consequently, the most likely release path would be via the RBHVAC stack as a consequence of continued RBHVAC operation. Several source-to-receptor locations were considered in establishing the limiting plant configuration, these included the SGTS and RBHVAC stacks as well as the reactor building railroad bay and first floor personnel air-lock (via the Outage Building front) doors.

While RBHVAC was identified and the most credible release point, the outage building front doors were conservatively selected as a bounding release location. Due to the location of the outage doors on the south side of the reactor building, the corresponding limiting receptor location is the south emergency air intake. The horizontal and vertical distances between these source and receptor locations are 29.3 m and 18.6 m for an overall slant distance of 34.7 m. The overall slant distance was input to ARCON96 in evaluating the associated atmospheric dispersion as a ground release.

This source-to-receptor pathway presumes the source term is removed from the building and is transported to the control room via the normal/emergency makeup air intakes. Thus, the control room envelope is effectively assumed to be intact and any maintenance that involves breaches of the control room envelope must include the controls necessary to preserve this assumption.

2.3.4.2.4.3. Control Rod Drop Accident

This accident considers two release paths: delayed release from the main condenser and a forced release from the offgas system due to the continued operation of the steam-jet air ejectors. The main condenser activity is released to the environment via the TBHVAC stack and is modeled as a zero-velocity vent release. The steam-jet air ejector activity is released to the environment through the RBHVAC stack and is also modeled as a zero-velocity vent release. ARCON96 was used to calculate the atmospheric dispersion coefficients representing transport from these stacks to each emergency air intake. The source-to-receptor distances are as specified in the table in Section 2.3.4.2.4.1. The analysis assumes no credit for the operation of the Control Room Emergency Filtration System. Consequently, the factor associated with the dual inlet configuration is not credited for reducing the value of χ/Q calculated by the ARCON96 software. Although the χ/Q values are calculated for both emergency air intakes, the analysis conservatively uses the values associated with the south emergency air intake.

2.3.4.2.5. Short-Term Onsite χ/Q Modeling Results

Atmospheric diffusion estimates developed for use in evaluating accidents are summarized in Table 2.3-28.

2.3.5. Long-Term Diffusion and Deposition Calculations

To evaluate the long-term dispersion potential of the atmosphere in the Fermi site area, calculations were made of effluent concentrations normalized by source strength of the power plant release and relative deposition rate. These atmospheric dilution and deposition factors were calculated using meteorological data collected onsite at the 60-m tower over the period June 1, 1974, to May 31, 1975. The long-term calculations are based on the straight line trajectory airflow model where a mixed-mode release, depending on wind speed, is assumed as described in Regulatory Guide 1.111, Revision 1 (Reference 30).

The models used to evaluate the long-term (annual) estimates of χ/Q and D/Q are described in Annex B of Appendix 11A. The analyses reported herein were performed for three separate sources at the Fermi 2 site: the containment building vent, the turbine building vent, and the radwaste building vent. Since the calculations were performed assuming a mixed-mode release based on wind speed, the release characteristics of each source are given in Table 2.3-28.

It should be noted that the results of the calculations performed for χ/Q (undecayed and undepleted, and decayed and depleted for radioiodines) and D/Q for radioiodines and particulates are presented in Appendix 2A.

2.3.5.1. Undecayed and Undepleted χ/Q Estimates

Values of χ/Q assuming no decay or depletion were calculated for the three air effluent releases using the mixed-mode techniques referenced in Annex B to Appendix 11A and

Regulatory Guide 1.111, Revision 1, July 1977. The calculations were performed for all 22-1/2° sectors at distances of

a. 0.4 to 1.6 km in 0.4-km increments
b. 1.6 to 16 km in 0.8-km increments
c. 16 to 80 km in 8-km increments.

These values of undecayed and undepleted χ/Q in units of seconds per cubic meter are presented in "wheel diagrams" for each source in Figures 2.3-52 through 2.3-54. Note that each figure provides values for the three distances for each release point. The numerical χ/Q values are presented by distance and sector in Appendix 2A.

2.3.5.2. Decayed and Depleted χ/Q Estimates

Values of χ/Q, assuming a radioactive effluent with a half-life of 8 days and using the plume depletion effect curves in Regulatory Guide 1.111, Revision 1, July 1977, in conjunction with the mixed-mode techniques, were calculated for the distances noted in Subsection 2.3.5.1.

These values of decayed and depleted χ/Q in units of seconds per cubic meter are presented for each of the three sources in Figures 2.3-55 through 2.3-57. The numerical values are presented by distance and sector in Appendix 2A.

2.3.5.3. Relative Deposition Estimates

Values of relative deposition (D/Q) per unit area were calculated for the three sources also using the mixed-mode techniques. The relative deposition-rate curves in Figures 6 through 9 of Regulatory Guide 1.111, Revision 1, July 1977, were used for the same distances as described above.

These values of relative deposition per unit area (square meters) are presented for each of the three sources in Figures 2.3-58 through 2.3-60. The numerical values are presented by distance and sector in Appendix 2A.

[a] Length of record, years, based on January data. Other months may be for more or fewer years if there have been breaks in the record.
[b] Climatological standard normals (1931-1960)
[c] Less than one half.
[d] Also on earlier dates, months, or years.
[e] Trace, an amount too small to measure.
[f] at Alaskan stations.
[g] Figures instead of letters in a direction column indicate direction in tens of degrees from true North; i.e., 09 - East, 18 - South, 27 - West, 36 - North, and 00 - Calm. Resultant wind is the vector sum of wind directions and speeds divided by the number of observations. If figures appear in the direction column under "Fastest Mile" the corresponding speeds are fastest observed 1-minute values.
[h] For period May 1966 through current year.
[i] To eight compass points only.

Below zero temperatures are preceded by a minus sign.

The prevailing direction for wind in the Normals, Means, and Extremes table is from records through 1963.

Unless otherwise indicated, dimensional units used in this bulletin are: temperature in ºF; precipitation, including snowfall in in.; wind movement in mph; and relative humidity in percent. Heating degree day totals are the sums of negative departures of average daily temperatures from 65ºF. Sleet was included in snowfall totals beginning with July 1948. The term "Ice Pellets" includes solid grains of ice (sleet) and particles consisting of snow pellets encased in a thin layer of ice. Heavy fog reduces visibility to 1/4 mile or less.

Sky cover is expressed in a range of 0 for no clouds or obscuring phenomena to 10 for complete sky cover. The number of clear days is based on averaqe cloudiness 0-3, partly cloudy days 4-7, and cloudy days 8-10 tenths.

Solar radiation data are the averages of direct and diffuse radiation on a horizontal surface. The langley denotes 1 g/cal/cm^2.

[a] Length of record, years, based on January data. Other months may be for more or fewer years if there have been breaks in the record.
[b] Climatological standard normals (1931-1960).
[c] Less than one half.
[d] Also on earlier dates, months, or years.
[e] Trace, an amount too small to measure.
[f] at Alaskan stations.
[g] Figures instead of letters in a direction column indicate direction in tens of degrees from true North; i.e., 09 - East, 18 - South, 27 - West, 36 - North, and 00 - Calm. Resultant wind is the vector sum of wind directions and speeds divided by the number of observations. If figures appear in the direction column under "Fastest Mile" the corresponding speeds are fastest observed 1-minute values.
[h] Data accumulated through 1965.
[i] To eight compass points only.

Means and extremes above are from existing and comparable exposures. Annual extremes have been exceeded at other sites in the locality as follows: Lowest temperature -24 in December 1872; maximum monthly precipitation 8.76 in July 1878; minimum monthly precipitation 0.04 in February 1887; maximum precipitation in 24 hours 4.75 in July 1925; maximum monthly snowfall 38.4 in February 1908; maximum snowfall in 24 hours 24.5 in April 1886; fastest mile of wind 95 from Northwest in June 1890.
Below zero temperatures are preceded by a minus sign.
The prevailing direction for wind in the Normals, Means, and Extremes table is from records through 1963.
Unless otherwise indicated, dimensional units used in this bulletin are: temperature in ºF; precipitation, including snowfall, in in.; wind movement in mph; and relative humidity in percent. Heating degree day totals are the sums of negative departures of average daily temperatures from 65ºF.Cooling degree day totals are the sums of positive departures of average daily temperatures from from 65°F. Sleet was included in snowfall totals beginning with July 1948. The term "Ice Pellets" includes solid grains of ice (sleet) and particles consisting of snow pellets encased in a thin layer of ice. Heavy fog reduces visibility to 1/4 mile or less.
Sky cover is expressed in a range of 0 for no clouds or obscuring phenomena to 10 for complete sky cover. The number of clear days is based on average cloudiness 0-3, partly cloudy days 4-7, and cloudy days 8-10 tenths.
Solar radiation data are the averages of direct and diffuse radiation on a horizontal surface. The langley denotes 1 g/cal/cm^2.

[a] Length of record, years, based on January data. Other months may be for more or fewer years if there have been breaks in the record.

[b] Climatological standard normals (1931-1960).

[c] Less than one half.

[d] Also on earlier dates, months, or years.

[e] Trace, an amount too small to measure.

[f] at Alaskan stations.

[g] Figures instead of letters in a direction column indicate direction in tens of degrees from true North; i.e., 09 - East, 18 - South, 27 - West, 36. - North, and 00 - Calm. Resultant wind is the vector sum of wind directions and speeds divided by the number of observations. If figures appear in the direction column under "Fastest Mile" the corresponding speeds are fastest observed 1-minute values.

[h] To eight compass points only.

Means and extremes above are from existing and comparable exposures. Annual extremes have been exceeded at other sites in the locality as follows: Highest temperature 105° in July 1936; maximum monthly precipitation 8.49 in October 1881; minimum monthly precipitation 0.04 in November 1904; maximum precipitation in 24 hr 5.98 in September 1818; maximum monthly snowfall 26.2 in January 1918; maximum snowfall in 24 hr 19.0 in February 1900; fastest mile 87 in March 1948.

Below zero temperatures are preceded by a minus sign.

The prevailing direction for wind in the Normals, Means, and Extremes table is from records through 1963.

Unless otherwise indicated, dimensional units used in this bulletin are: temperature in ºF; precipitation, including snowfall, in in.; wind movement in mph; and relative humidity in percent. Heating degree day totals are the sums of negative departures of average daily temperatures from 65ºF.Cooling degree day totals are the sums of positive departures of daily temperatures from 65°F. Sleet was included in snowfall totals beginning with July 1948. The term "Ice Pellets" includes solid grains of ice (sleet) and particles consisting of snow pellets encased in a thin layer of ice. Heavy fog reduces visibility to 1/4 mile or less.

Sky cover is expressed in a range of 0 for no clouds or obscuring phenomena to 10 for complete sky cover. The number of clear days is based on average cloudiness 0-3, partly cloudy days 4-7, and cloudy days 8-10 tenths.

Solar radiation data are the averages of direct and diffuse radiation on a horizontal surface. The langley denotes 1 $g/cal/cm^2$.

TABLE 2.3-20 METEOROLOGICAL SYSTEM EQUIPMENT SPECIFICATIONS (33-FT TOWER)

Instrument	Manufacturer	Model	Level	Specifications
Wind speed and direction	Gill	Model 35001 propeller vane	33 ft (10 m)	Wind Direction Range: 360°, mechanical 342°, electrical Wind Speed Range: variable 0-15 mph, 0-30 mph, 0-50 mph Threshold: Vane - 0.3-0.5 mph Propeller - 0.4-0.7 mph
Temperature and relative humidity	Belfort	Model 5-592 hygrothermograph	Shelter (Base approximately 4-1/2 ft above ground level)	Accuracy: Temperature: +1°F between -20°F to +100°F Humidity: ±3% RH between 20% and 95%, ±5% at extremes

TABLE 2.3-21 60-M TOWER ANALOG/DIGITAL METEOROLOGICAL SYSTEM INSTRUMENTATION (PREOPERATIONAL PROGRAM)

WIND SPEED SENSORS: All Levels

Sensor: Climet Instruments model #WS-011-1. Wind speed transmitter and cup assembly.

Distance constant:	5 ft maximum
Threshold wind:	0.6 mph
Accuracy:	± 0.1% or 0.15 mph, whichever is greater

Electronics: Analog signal conditioner constructed by EG&G, Albuquerque..

Accuracy:	± 0.1% full scale

Recorder: Digital representation of Datel Systems, Inc. model #ADC-E 3-digit (BCD) analog to digital converter.

OVERALL SYSTEM ACCURACY:	± 1% or 0.15 mph

Recorder: (Backup) Esterline Angus Model #EAL1102S dual analog recorder

Accuracy:	± 0.25% full scale
OVERALL SYSTEM ACCURACY:	± 1.04% or 0.38 mph, whichever is greater

WIND DIRECTION SENSORS: All Levels

Sensor: Climet Instruments model #WD-012-03 wind direction transmitter and wind vane assembly.

Distance constant:	1 m maximum
Damping ratio:	0.4 standard
Threshold:	0.75 mph
Accuracy:	± 3°

Electronics: Analog signal conditioner constructed by EG&G, Albuquerque

Accuracy:	± 0.10% full scale

Recorder: Digital representation of Datel Systems, Inc. model #ADC-E 3-digit (BCD) analog to digital converter.

Accuracy:	± ½ LSB

TABLE 2.3-21 60-M TOWER ANALOG/DIGITAL METEOROLOGICAL SYSTEM INSTRUMENTATION (PREOPERATIONAL PROGRAM)

Recorder: (Backup) Esterline Angus Model #EAL1102S dual analog recorder.

Accuracy:	± 0.25% full scale
OVERALL SYSTEM ACCURACY:	± 3.2°

TEMPERATURE SENSORS: All Levels

Sensors: Rosemount Engineering model #171BM platinum resistance thermometer.

Linearity:	0.01% full scale
Stability:	0.01°C per year
Aspiration rate:	24 ft/sec flow over sensor

Electronics: Analog signal conditioner constructed by EG&G, Albuquerque.

Accuracy:	± 0.10% full scale

Recorder: Digital representation of Datel Systems, Inc. model #ADC-E 3-digit (BCD) analog to digital converter.

Accuracy:	± ½ LSB

Recorder: (Backup) Esterline Angus Model #EAL1102S dual analog recorder.

Accuracy:	± 0.25% full scale
OVERALL SYSTEM ABSOLUTE ACCURACY:	± 0.2°C
OVERALL SYSTEM DIFFERENCE ACCURACY:	± 0.1°C

DEWPOINT SENSOR:

Sensor: Environmental Equipment Division of EG&G, model #110S-M dewpoint measuring set.

Range:	-80°F to +120°F
Accuracy:	± 0.5°F maximum

Electronics: Analog signal conditioner constructed by EG&G, Albuquerque.

Accuracy:	± 0.1% full scale

TABLE 2.3-21 60-M TOWER ANALOG/DIGITAL METEOROLOGICAL SYSTEM INSTRUMENTATION (PREOPERATIONAL PROGRAM)

Recorder: Digital representation of Datel Systems, Inc. model #ADC-E 3-digit (BCD) analog to digital converter.

Recorder: (Backup) Esterline Angus Model #EAL1102S dual analog recorder

Accuracy:	± 0.25% full scale
OVERALL SYSTEM ACCURACY:	± 0.35°C

PRECIPITATION SENSOR:

Sensor: Fisher & Porter Company model #35-1559 EA10, precipitation gage recorder.

Range:	0 to 19.5 in. precipitation
Accuracy:	± 0.015 in. of range span
Sensitivity:	0.025 in. response
OVERALL SYSTEM ACCURACY:	± 0.1 in.

[a] Joint recovery between 10-m wind speed, 10-m wind direction, 10-m temperature, 60-m temperature.

TABLE 2.3-24 METEOROLOGICAL DATA RECOVERY (PERCENT) FOR 33-FT TOWER

(January 1, 1972 – December 31, 1972)

	Temperature Data	Relative Humidity Data
Spring (March, April, May)	94	93
Summer (June, July, August)	96	96
Fall (September, October, November)	96	96
Winter (December, January, February)	90	90
ANNUAL	94	94

TABLE 2.3-25 METEOROLOGICAL MONITORING NETWORK (OPERATIONAL PROGRAM)

Parameter	Sampling Height (m)	Sensing Technique
Primary Monitoring System		
Wind speed	10 and 60	Cups/light chopper
Wind direction	10 and 60	Vane/potentiometer
Vertical wind speed	10	Propeller
Differential temperature	10 to 60	Matched thermistors
Ambient temperature	10	Thermistor
Dewpoint	10	Lithium Chloride Type
Precipitation	1.5	Tipping bucket
Secondary Monitoring System		
Wind speed	10 and 60	Cups/light chopper
Wind direction	10 and 60	Vane/potentiometer
Vertical wind speed	10	Propeller/light chopper
Differential temperature	10 to 60	Matched thermistors
Ambient temperature	10	Thermistor

TABLE 2.3-26 METHOD FOR SUBSTITUTING REDUNDANT PARAMETERS FOR THE CRITICAL METEOROLOGICAL MEASUREMENTS

Level of Redundancy	10-Meter Level Wind Speed	10-Meter Level Wind Direction	Stability Indicator
0	Primary WS10	Primary WD10	Primary delta T
1	Secondary WS10	Secondary WD10	Secondary delta T
2			Primary sigma theta
3			Secondary sigma theta

TABLE 2.3-27 SUMMARY OF MAXIMUM SECTOR AND 5 PERCENT OVERALL SITE LIMIT χ/Q VALUES AT THE EAB AND LPZ FOR REGULATORY POST-ACCIDENT TIME PERIODS

EAB* (915 m)		LPZ* (4827 m)						
0-2 Hours		0-2 Hours		0-8 Hours	8-24 Hours	1-4 Days	4-30 Days	Annual Average
Max Sector	Site Limit	Max Sector	Site Limit	Max Sector	Max Sector	Max Sector	Max Sector	Max Sector
2.09 E-04	1.54 E-04	4.86 E-05	2.98 E-05	2.17 E-05	1.45 E-05	6.02 E-06	1.71 E-06	3.66 E-07
(ESE)		(ESE)		(ESE)	(ESE)	(ESE)	(ESE)	(ESE)

* For the EAB and LPZ, the 0-2 hour maximum sector χ/Q value is based on the highest sector-specific 0.5% χ/Q sector value; and the 0-2 hour site limit is based on the 5 percent overall site χ/Q value. In accordance with Regulatory Guide 1.145, the higher of these is selected as the controlling 0-2 hour χ/Q. Also, for the LPZ, per Regulatory Guide 1.145, logarithmic interpolation between the controlling 0-2 hour value and the maximum annual average χ/Q in any sector is performed to derive the approximate LPZ χ/Q value for each of the post-accident time periods.

TABLE 2.3-28 SUMMARY OF χ/Q (s/m^3) VALUES AT THE CONTROL CENTER COMPLEX FOR REGULATORY POST-ACCIDENT TIME PERIODS

Accident (source-to-receptor)	Time Interval				
LOCA					
	0-2 Hours	2-8 Hours	8-24 Hours	1-4 Days	4-30 Days
SGTS and ECCS leakage (SGTS stack-to-South control center intake)	6.18E-4	4.53E-4	1.88E-4	1.26E-4	8.70E-5
MSIV Leakage (TBHVAC Stack-to-North control center intake)	4.75E-4	3.78E-4	1.45E-4	9.80E-5	7.19E-5
Fuel Handling Accident					
	0-2 Hours	2-8 Hours	8-24 Hours	1-4 Days	4-30 Days
24-hr Drop of Recently Irradiated Fuel (SGTS-to-North Emergency Intake)	4.03E-3* 3.65E-3	The two-hour value is conservatively applied for the duration of accident.			
Fuel No Longer Recently Irradiated without SGTS (Outage Building-to-South Emergency Intake)	4.25E-3	The two-hour value is conservatively applied for the duration of accident.			
Control Rod Drop Accident					
	0-2 Hours	2-8 Hours	8-24 Hours	1-4 Days	4-30 Days
Condenser Release (TBHVAC stack-to-South Emergency Intake**)	1.17E-3	9.09E-4	3.41E-4	2.29E-4	1.73E-4
SJAE Release (RBHVAC stack-to-South Emergency Intake**)	7.33E-3	5.59E-3	2.35E-3	1.66E-3	1.26E-3

* This value applies during the initial unfiltered release via RBHVAC.
** CREF and dual inlet configuration not credited for control rod drop accident analyses.

2.4. HYDROLOGIC ENGINEERING

2.4.1. Hydrologic Description

2.4.1.1. Site and Facilities

The Fermi site is located adjacent to the western shore of Lake Erie (Figure 2.4-1). Prior to construction of Fermi 2, the site area was a lagoon separated from Lake Erie by a barrier beach, known as Lagoona Beach, which formed the eastern site boundary. The Fermi 2 preconstruction topography is shown in Figure 2.4-2. The lagoon was connected to Lake Erie by Swan Creek, a perennial stream that discharges into Lake Erie about 1 mile north of the Fermi plant site. The site for Fermi 2 was prepared by excavating soft soils and rock, and constructing rock fill to a nominal plant grade elevation of 583 ft. All elevations refer to New York Mean Tide, 1935. The topography of the developed site as of December 10, 1972, is shown in Figure 2.4-3.

Category I structures housing safety-related equipment consist of the reactor/auxiliary building and the residual heat removal (RHR) complex. These structures are indicated in Figure 2.1-5. The plant site is not susceptible to flooding caused by surface runoff because of the shoreline location and the distance of the site from major streams. Plant grade is raised approximately 11 ft above the surrounding area to further minimize the possibility of flooding. Flooding of the site is conceivable only as the result of an extremely severe storm with a storm-generated rise in the level of Lake Erie. Protection of safety-related structures and equipment against this type of flooding is provided through the location, arrangement, and design of the structures with respect to the shoreline and possible storm-generated waves.

After the excavation of topsoil, peat, and soft clay, construction of the plant site to grade Elevation 583 ft (nominal) was accomplished using the following fill materials:

a. Crushed rock (1-1/2-in. maximum) within 10 ft from the building walls (water has been observed to run off rather than drain through this evenly graded crushed rock)

b. Crushed rock (6-in. maximum) inside the perimeter road (surrounding the plant main structures), except adjacent to buildings (this permits water to drain quite well)

c. Quarry run rock for most fill areas outside the perimeter road (surrounding the plant main structures) (providing good drainage for water under almost all circumstances)

d. Topsoil for grass was placed on a layer of 1-ft-deep crushed-rock fill, 1-1/2-in. maximum, to avoid being washed down.

Roof water that is collected through drainage systems from all structures and catch basins inside the perimeter road is collected and routed to the station storm-water drain system to prevent ponding of water adjacent to structures. Water in the plant storm-water drain system is then discharged into the overflow canal. In grassy areas outside the perimeter road, and in gravel areas, catch basins discharge water into the quarry run fill. In paved areas, the catch basins are usually tied to the storm-water drain system. The plant circulating water is treated within the closed loop circulating water system, which includes the 5.5-acre circulating water reservoir.

2.4.1.2. Hydrosphere

2.4.1.2.1. Regional Conditions

The region of the Fermi site is located within the western part of the Lake Erie drainage basin. The divide between the Lake Michigan and the Lake Erie watersheds lies about 50 miles west of the site. Perennial streams in the region generally flow in a southeasterly direction and discharge into Lake Erie. Tributaries of these streams are intermittent and form a dendritic drainage pattern.

The average precipitation in the region ranges from 30 in. to 36 in./yr (Subsection 2.3.1.2). Average annual runoff ranges from 10 to 16 in. Infiltration is highest in the western part of the region in areas where permeable soils occur in end moraines and beach lacustrine deposits. High runoff coefficients are characteristic of the relatively impermeable lacustrine soils in the eastern part of the region.

2.4.1.2.2. Swan Creek

The Fermi site is in the Swan Creek drainage basin. The watershed is an area of 109 square miles, elongated in shape from northwest to southeast (Figure 2.4-4). The basin is about 25 miles long with a maximum topographic relief of about 130 ft. The drainage area topography is flat to gently undulating and varies from about 700 ft elevation in the upper watershed to about 570 ft elevation at Lake Erie.

Land in the basin is mixed in use for residential, commercial, industrial, and agricultural purposes. The surface soils are primarily lacustrine clay with some lacustrine sand ridges at the head of the watershed. The infiltration capacity of the basin soils is low. Surface drainage is poor and drainage ditch improvements are common in the upper part of the basin. Stream channel flow is retarded by typical vegetative cover of deciduous trees and brush undergrowth. There are no flow-control structures on Swan Creek. Stream level near the site is controlled by the level of Lake Erie.

Gages were placed along Swan Creek in 1971 and the collected data indicate that runoff is greatest during the spring and early summer (Reference 1). Data on the adjacent River Raisin and Huron River also indicate that runoff is highest during spring and summer. However, Swan Creek stream flow is normally too low for water supply use.

2.4.1.2.3. Lake Erie

2.4.1.2.3.1. Lake Characteristics

Lake Erie is approximately 240 miles long and has a mean width of 40 miles. The lake is divided into three principal subbasins: (1) a small, shallow basin at the west end which borders the site and is partially restricted by a chain of barrier beaches and islands; (2) a flat, unrestricted, and rather shallow basin in the center; and (3) a small, relatively deep eastern basin. The average depth of the lake is 61 ft and the maximum depth is 210 ft. The longitudinal axis of the lake trends northeast-southwest, a direction coincident with strong and persistent winds that predominate under normal meteorological conditions. Wind stresses acting upon the lake surface over a sustained period can have a considerable effect on the level of the lake.

The most significant lake level variations are observed mainly at the western and eastern ends of the lake and are caused by transport of water as a result of sustained wind actions. Historical records show that in about 96 percent of all extreme cases, high water occurred at the eastern end of the lake and low water occurred at the western end. This is a result of the predominantly westerly winds causing the lake to set up at the eastern end.

The lake bottom in the vicinity of the site slopes very gently toward the east, reaching a depth of approximately 12 ft about 1/2 mile offshore. The soil deposits below the west end of the lake consist primarily of sand with intermittent layers of gravel and/or clay.

Two primary current patterns exist in the Lagoona Beach embayment. Winds moving from the northwest clockwise through northeast result in a general southwestward airflow over the entire embayment. This airflow creates the pattern of water movement shown in Figure 2.4-5. When the winds are from east-southeast clockwise through west, northward longshore currents are found to exist with a pronounced clockwise eddy formed south of the Point Mouillee marshes. This current pattern is shown in Figure 2.4-6.

When onshore winds from east clockwise through east-southeast and offshore winds from west-northwest clockwise through northwest occur, phase systems of current flow develop that produce variable patterns. The longshore currents shift from one primary current pattern to the other, reflecting changes in the local wind system. These phase changes are generally of short duration. Under ice cover, variations occur in the southward current flow and result in divergence of the currents immediately south of the existing plant intake and convergence north and east of Pointe Aux Peaux as shown in Figure 2.4-7.

2.4.1.2.3.2. Water Use

The use of potable and agricultural surface water within 10 miles of the plant site is presented in Subsection 2.1.4.2. Surface-water users withdrawing water from intakes in Lake Erie are the only surface-water users subject to the effects of accidental or normal releases of contaminants from the plant into the hydrosphere. The existing intakes along the western shore of Lake Erie have been examined to ensure that the dilution capacity of Lake Erie is sufficient to preclude adverse effects on users from releases of contaminants (Subsection 2.4.12). It is expected that future intakes will be located in the same approximate area and likewise will not be exposed to adverse effects of contaminants.

Municipalities with Lake Erie intakes, listed in Table 2.1-12, are located as shown in Figure 2.1-20. The municipal water intake nearest to the plant is the Monroe intake near Pointe Aux Peaux, approximately 2 miles southeast of the site, as shown in Figure 2.4-1. The Toledo intake is located about 18.6 miles due south of the plant site. The 1972 annual withdrawals at the Monroe and Toledo intakes were 2000 x 10^6 gal and 29,200 x 10^6 gal, respectively.

2.4.1.2.4. Ground Water

Regional ground water features are discussed in Subsection 2.4.13.1.1. Ground water in the site area occurs in a dolomite aquifer, underlying a mantle of relatively impermeable glacial deposits and recent sediments. This mantle ranges up to 40 ft in thickness. Water wells are of low yield and the water is highly mineralized. The aquifer characteristics and ground water uses are described in more detail in Subsection 2.4.13.2.

2.4.2. Floods

2.4.2.1. Flood History

2.4.2.1.1. Maximum Mean Monthly Lake Levels

Based upon data collected by the U.S. Lake Survey, Detroit, Michigan (Reference 2), the highest observed monthly mean water level during the period of record from 1860 to 1973 was +4.9 ft above Low Water Datum. This level occurred during June 1973, at Monroe, Michigan. During 1973, the monthly mean water level varied between +3.0 and +4.9 ft above Low Water Datum, a vertical variation of 1.9 ft (Figure 2.4-9). In 2019, it was identified that the maximum mean monthly lake level had exceeded +4.9 ft above the Low Water Datum. This condition persisted for several months in 2019 and recurred during 2020. To address the potential for maximum mean monthly lake levels to exceed the historical observations in Reference 2 and Figure 2.4-9, additional analyses were performed to consider the impact to the site from maximum mean monthly lake levels up to +6.4 ft above Low Water Datum. See Sections 2.4.2.1.6 and 2.4.2.2.6 for additional information.

2.4.2.1.2. Maximum Wind Tide

Lake gaging records at Monroe have been collected for the periods from 1932 to 1939 and from 1952 to the present. Data from gages at Gibraltar and Toledo have been in existence since 1897 and have been correlated with records from the Monroe gage. Based on this relationship, the calculated maximum wind tide at Monroe was +4.5 ft on January 30, 1939. In an earlier report covering the period 1886 to 1896, a maximum wind tide of +5.5 ft was reported at Monroe. The description of the easterly gales that produced this wind tide suggests that they were more intense than those reported during the past 77 years. Therefore, it is reasonable to accept +5.5 ft (Elevation 576.0 ft) as the maximum wind tide occurrence since 1886.

2.4.2.1.3. Seiche History

Seiche history is discussed in Subsection 2.4.5.2.

2.4.2.1.4. Swan Creek

Complete flood data are not available for Swan Creek as gages were not installed until 1971. Long-term information exists from gages on adjacent drainage basins. On the River Raisin near Monroe, the largest flood (record begins in 1938) occurred on March 29, 1950, and the second largest on April 6, 1947. On the Huron River at Ann Arbor, the largest flood (record begins in 1918) occurred on April 5, 1947. Maximum annual floods occur principally in April and May. Discharge frequencies at the mouth of Swan Creek, estimated using standard methods (References 3 and 4), are shown in Table 2.4-1.

The estimated 100-year frequency discharge of 9300 cfs on Swan Creek is significantly less than the probable maximum flood (PMF) flow of 89,000 cfs (Subsection 2.4.3.4). In

Subsection 2.4.3.5, it is demonstrated that the PMF flow on Swan Creek could not cause flooding at plant grade Elevation 583.0 ft. Therefore, water levels for the estimated discharges in Table 2.4-1 are not pertinent to site flood considerations.

2.4.2.1.5. Recent Storms

2.4.2.1.5.1. April 1966 Storm and Flood Analysis

On April 27, 1966, a persistent storm system moved into the Lake Erie drainage basin. During the month of the storm, the mean lake level at Toledo, Ohio, was 1.7 ft above the Low Water Datum of 570.5 ft. The maximum surge on Lake Erie occurred at Toledo while proportionately smaller surges were measured at distances from Toledo. The water level at Toledo reached 577.50 ft, which was 7.0 ft above the datum. The surge was driven by steady northeast winds with a directional duration of about 48 hr. At the time of peak surge, 1000 hr on the 27th, the maximum wind velocity measured at the Detroit River Light Station was 38 knots. However, a maximum wind velocity of 42 knots from the east-northeast was measured at 1300 hr, by which time the surge elevation had dropped to 575.93 ft.

Wave heights ranging from 6 to 7 ft were reported at the Toledo Harbor Light Station. To supplement the available wave data, a wave hindcast analysis was performed for the Fermi site. As discussed above, the times of peak surge and of peak wind velocity do not coincide, and this was considered in the hindcast analysis. The critical wind speed measured at the Detroit River Light Station was 38 knots from the northeast. This wind speed was increased by a factor of 1.30 to obtain a velocity representative of open-water conditions. The fetch aligned with the wind direction was 51,650 ft long and had associated with it a depth of approximately 13 ft at high water. A significant wave height and period of 3.8 ft and 3.2 sec, and a maximum wave height and period of 6.8 ft and 3.8 sec, would have been generated during this storm. Because the shoreline north of the Fermi site is oriented northeast, the waves that approached the site would have been attenuated by refraction and by the available depth of water over the sloping lake bottom. A conservative approximation of the lake bottom slope in this area is 1:100. Using this slope and the maximum wave period, the maximum supported wave height reaching the beach at the highest water level would have been about 1.3 ft. Waves larger than this would have broken too far seaward of the beach berm to have affected the site. The maximum runup elevation that would have been reached during this storm is 579.6 ft. This elevation is considerably less than the plant grade at the Fermi site of 583.0 ft and the probable maximum meteorological event (PMME) water level of 586.9 ft (Subsection 2.4.5).

2.4.2.1.5.2. November 1972 Storm and Flood Analysis

On November 13, 1972, a sudden storm moved into the Lake Erie drainage basin. The storm produced widespread flooding after the storm winds shifted from south to northeast, resulting in local evacuation within the low-lying areas along the western and southwestern shores. The total effect of the storm was that of a wind tide plus the abnormally high water level of Lake Erie, which existed at the time. In November, the mean lake level at Toledo was 3.6 ft above the Low Water Datum of 570.5 ft. The maximum surge on Lake Erie occurred at Toledo, while proportionately smaller surges were measured at distances from Toledo. The water level at Toledo reached 577.9 ft, which is 7.4 ft above the datum, while the maximum level at the Fermi site was 576.8 ft, which is 6.3 ft above the datum. Marblehead and Cleveland, Ohio, experienced maximum surges to Elevations 577.0 and 576.2 ft, respectively. The surge was driven by northeast winds with a directional duration of approximately 24 hr and a maximum velocity of about 40 knots over the central portion of the lake.

For most of November 12, 1972, winds were light and out of the southwest. Very late on the 12th and throughout the 13th, winds shifted gradually to northwest, then to northeast. By midday on November 13, the northeast winds were established and the velocity increased to 20 knots. The water level began rising at the Fermi site at 0800 hr on November 13. The maximum wind speed at Toledo was 25 knots and was reached early on November 14. By midday on the 14th, when the wind direction was changing to north, the water level at the Fermi site had reached its maximum elevation, 576.8 ft. The water level dropped rapidly, reaching a minimum level of elevation at 1800 hr on the 14th. Wind direction remained northerly throughout the 15th and velocity varied from 5 to 14 knots. Secondary and tertiary seiches were experienced on the 15th, but decayed rapidly from bottom friction. The troughs of these seiches resulted in lake elevations of 573.5 and 573.3 ft at the Fermi site. By November 16, the water level had stabilized at approximately Elevation 574.3 ft.

Waves during this storm were not measured at the site. Sufficient data describing the storm are available to hindcast the probable wave attack at the site. Waves were estimated at the Detroit River Light Station as ranging between 5 and 8 ft. Wind speed reached a maximum of 35 knots from the northeast at the Detroit River Light Station while Toledo Express Airport reported a maximum of 25 knots from direction N50°E. Applying a factor of 1.3 to the Detroit River Light Station yields an over-water wind velocity of 45.5 knots. The fetch aligned with the wind direction was approximately 51,000 ft long and had associated with it a depth of approximately 20 ft at high water. A significant wave height and period of 4.2 ft and 3.3 sec, and a maximum wave height and period of 7.6 ft and 4.0 sec, would have been generated during this storm.

The waves that approached the Fermi site would have been limited in height by the available depth of water over the gradually sloping lake bottom. Figure 2.4-10 shows the bathymetry offshore of the site.

A conservative approximation of the lake bottom slope in this area is 1:100. Using this slope and the maximum wave period, the maximum supported wave height reaching the beach at highest water level would have been 1.7 ft. Waves larger than this would have broken too far seaward of the beach berm to have affected the site.

The maximum runup elevation which would have been reached during this storm is 579.6 ft. This elevation is considerably less than the plant grade at the Fermi site of 583.0 ft and the PMME water level of 586.9 ft.

2.4.2.1.5.3. <u>April 1973 Storm and Flood Analysis</u>

Another storm moved into the Lake Erie Basin on April 9, 1973. Although this storm was less intense than the November 1972 storm, its total impact was nearly equal to the November storm because of the extremely high static lake level at the time.

In April 1973, the mean lake level at Toledo was measured by the U.S. Lake Survey as +4.76 ft above the Low Water Datum of 570.5 ft. The maximum surge associated with this spring storm was measured as +3.3 ft at Toledo, which brought the total stillwater level to 578.6 ft. This is 0.7 ft higher than the level reached by the November l972 storm.

On April 8, 1973, wind speeds ranged from 15 to 20 knots, blowing steadily from the northeast. On the morning of the 9th, the wind speed increased, reaching a maximum value of 35 knots and shifting gradually to the east-northeast by 1430 hr. The water level began rising at Toledo, Ohio, at 0100 hr on April 9 and reached maximum Elevation 578.57 ft at 1600 hr on the 9th. The water level dropped rapidly, reaching minimum level Elevation 573.2 ft at 0100 hr on the l0th.

Secondary and tertiary seiches were experienced on the 10th, but decayed rapidly from bottom friction. By April 11, the water level had stabilized at approximate Elevation 574.6 ft. At the height of the storm, an 8-ft wave height was reported at the Detroit River Light Station.

To supplement the available wave data, a wave hindcast analysis was performed for the Fermi site. The maximum wind speed measured at the Detroit River Light Station was 35 knots from direction N67.5°E. This wind speed was increased by a factor of 1.30 to obtain an over-water velocity. The fetch aligned with the wind direction was 66,900 ft long and had associated with it a depth of approximately 20 ft at high water. A significant wave height and period of 4.8 ft and 3.6 sec, and a maximum wave height and period of 8.6 ft and 4.3 sec, would have been generated during this storm.

The waves that approached the Fermi site would have been limited in height by the available depth of water over the gradually sloping lake bottom. A conservative approximation of the slope of the lake bottom is 1:100. Using this slope and the maximum wave period, the maximum supported wave height reaching the beach at highest water level would have been 2.0 ft. Waves larger than this would have broken too far seaward of the beach berm to have affected the site. The maximum runup elevation that would have been reached during this storm is 581.7 ft. This elevation is less than the plant grade at the Fermi site of 583.0 ft and the PMME water level of 586.9 ft.

2.4.2.1.5.4. June 1973 Storm and Flood Analysis

High static lake levels continued through 1973. During June the mean lake level measured at Toledo by the U.S. Lake Survey was approximately 4.9 ft above the Low Water Datum of 570.5 ft. The earlier April 1973 storm occurred at a time when the lake was approximately 4.8 ft above the Low Water Datum. The maximum instantaneous surge associated with this June storm was measured at +3.4 ft at Toledo, which brought the total stillwater level to 578.7 ft. This was 0.1 ft above the April 1973 storm and 0.8 ft higher than the November 1972 storm.

At the Fermi site, maximum stillwater levels recorded by the U.S. Lake Survey reached a peak hourly reading of 577.75 (Low Water Datum) at 0200 hr on June 17, 1973. The Fermi water-level recorder does not record instantaneous water levels; however, interpolation from stations at Toledo, Ohio, and Gibraltar, Michigan, yields an instantaneous high of approximately 578.6 ft. Detroit area newspapers reported a maximum flood stage of 578.4 ft.

Wind speeds with an easterly component at the west end of Lake Erie between June 17 and June 18 were generally light to moderate. The Toledo Express Airport recorded fastest 1-minute velocities of only 9.6 knots, while the Detroit River Light Station recorded velocities between 10 and 15 knots. In addition, the Canadian government reported easterly gusts to 34 knots with an average of 20.9 knots at their Southeast Shoal lighthouse near Pt. Pelee, Ontario. The duration of these easterly winds was about 25 hr with peak velocities reached in the first 6 hr.

Winds at the east end of the lake, at Buffalo, were only slightly higher but maintained an easterly component for approximately 34 hr. It was this long-duration, moderate-wind regime at the east end of Lake Erie that was primarily responsible for the flooding at the west end. Buffalo reported east winds 12 hr before Toledo. The east winds from Buffalo were met by westerly winds from Toledo, which resulted in a temporary water buildup (to Elevation 576.3 ft 4 in.) at Cleveland. When the Toledo winds finally switched from west to east, the light to moderate velocities were enough to push the surge into the western end of the lake.

Wave heights, which were estimated during the storm at the Detroit River Light Station, ranged from 2 to 5 ft. To supplement available data, a wave hindcast analysis was performed at the Fermi site. Assuming a maximum steady-state wind velocity of 21 knots blowing from the east (N90°E), and applying a factor of 1.3, an over-water wind velocity of 27.3 knots is obtained. The maximum fetch aligned with the wind direction was 199,500 ft and had associated with it a depth of approximately 25 ft at high water. A significant wave height and period of 3.9 ft and 3.2 sec, and maximum wave height and period of 7.0 ft and 3.8 sec, would have been generated during this storm.

The waves that approached the Fermi site would have been limited in height by the available depth of water over the gradually sloping lake bottom. A conservative approximation of the slope of the lake bottom is 1:100. Using this slope and the maximum wave period, the maximum supported wave height reaching the beach at highest water level would have been 1.3 ft. Waves higher than this would have broken too far seaward of the beach berm to have affected the site. The maximum runup elevation that would have been reached during this storm is 581.0 ft. This elevation is less than the plant grade at the Fermi site of 583.0 ft and the PMME water level of 586.9 ft.

2.4.2.1.5.5. <u>April 1974 Storm and Flood Analysis</u>

In 1974 the highest water level measured by the U.S. Lake Survey at Toledo occurred on April 8 at 12 noon. The maximum reading was the result of sustained high static lake levels and an early spring storm.

In March and April the mean lake level at Toledo was approximately 4.4 ft above the Low Water Datum of 570.5. The maximum surge associated with the storm that moved through the area on April 7 and 8 was measured at +3.6 ft, which brought the total stillwater level to 578.5 ft. This was 0.2 ft below the June 1973 storm and 0.1 ft below the spring storm of April 1973.

At the Fermi site, the maximum stillwater level recorded by the U.S. Lake Survey was at Elevation 577.6 ft, which occurred at 12 noon on April 8.

Fastest 1-minute wind speeds measured at the Toledo Express Airport had a northeasterly direction and obtained a maximum of 26 knots with an average of 16.3 knots. At the Detroit River Light Station, a maximum wind velocity of 28 knots from the northeast and an estimated wave height of 4 to 5 ft were recorded at l030 hr on April 8. At 1630 hr on April 8, the light station recorded an east-northeast wind at 25 knots and a wave height of 5 to 6 ft. At this time water levels were already dropping at both Toledo and the Fermi site.

To supplement the available wave data, a wave hindcast analysis was performed for the Fermi site. Assuming a maximum steady-state wind velocity of 28 knots from direction N67.5°E and applying a factor of 1.3, an over-water wind velocity of 36.4 knots is obtained. The maximum fetch aligned with the wind direction was 66,900 ft long and had associated with it a depth of approximately 20 ft at high water. A significant wave height and period of 3.8 ft and 3.2 sec, and a maximum wave height and period of 6.8 ft and 3.7 sec, would have been generated during this storm.

The waves that approached the Fermi site would have been limited in height by the available depth of water over the gradually sloping lake bottom. A conservative approximation of the slope of the lake bottom is 1:100. Using this slope and the maximum wave period, the maximum supported wave height would have been 1.6 ft. Waves larger than this would have broken too far seaward of the beach berm to have affected the site. The maximum runup elevation that would have been reached during this storm is 581.3 ft. This elevation is less than the plant grade at the Fermi site of 583.0 ft and the PMME water level of 586.9 ft.

2.4.2.1.6. 2019 and 2020 Lake Level Observations

In July 2019, it was identified that a Lake Erie water level reading in the main control room was above the design input water level assumed in the Fermi 2 design basis flood event. Although this reading was instantaneous and localized, subsequent investigation identified that the average monthly lake level had also exceeded the design input water level of +4.9 ft (corresponding to El. 575.3 ft NYMT-1935) assumed in the Fermi 2 design basis flood event. Using these higher lake levels and factoring in the wind-driven storm surge of 11.4 ft of wave runup height from Section 2.4.5.3, the resultant site stillwater elevation was greater than the existing design stillwater maximum of +16.4 ft (corresponding to El. 586.9 ft NYMT-1935) in Section 2.4.5.3 but lower than the flood design criteria of the Reactor/Auxiliary Building (El. 588.0 ft) and RHR Complex (El. 590.0 ft). This condition persisted for several months in 2019 and recurred in June 2020. To address these (and potential future) higher observed lake levels, a supplemental analysis of the site stillwater flood elevation was performed using the Bretschneider method (Reference 30) for determining storm surge. Using the Bretschneider method, a wind-driven storm surge of 10.1 ft was calculated. This supplemental analysis therefore establishes that the site stillwater elevation of +16.4 ft (corresponding to El. 586.9 ft NYMT-1935) remains the design basis flood event limit even assuming maximum monthly mean lake levels up to +6.4 ft (corresponding to El. 576.8 ft NYMT-1935).

2.4.2.2. Flood Design Consideration

2.4.2.2.1. Conditions Considered

The following basic types of hypothetical flooding conditions were considered in the design:

a. The PMF of 89,000 cfs on Swan Creek coincides with the mean monthly maximum water level of 575.3 ft in Lake Erie. In the discussion of backwater computations (Subsection 2.4.3.5), the resulting PMF flow elevation of 577.3 ft would provide a safety margin of 5.7 ft. Even by the use of a conservative slope/area computation (Subsection 2.4.3.5), the PMF elevation would be less than 582 ft, or 1 ft below plant grade at 583 ft and 1.5 ft below the elevation of plant door sills

b. Historically, the maximum probable wind tide of 11.6 ft coincides with a maximum monthly mean lake level of 575.3 ft. The resulting stillwater flood elevation at the plant site area in this case is 586.9 ft, or 3.90 ft above the plant grade elevation (Subsection 2.4.5.3). In those infrequent instances where the maximum monthly mean lake level exceeds historical averages in Reference 2 and Figure 2.4-9, a supplemental analysis described in Sections 2.4.2.1.6 and 2.4.2.2.6 has determined that the resulting stillwater flood elevation would not exceed +16.4 (corresponding to El. 586.9 ft NYMT-1935) as long as maximum monthly mean lake levels remain at or below +6.4 ft (corresponding to El. 576.8 ft NYMT-1935). This ensures that the storm surge continues to bound the high water level of a PMP and PMF event

c. Local probable maximum precipitation (PMP) runoff on the plant site coincident with runoff from the 2-square mile area above the plant site, assuming blockage of plant drainage, would result in no adverse effects on the safety-related (Category I) facilities. The estimated PMF of 25,300 cfs with a corresponding elevation of less than 582 ft, and the 15-minute PMP of 4.9 in. over the plant site with a grade elevation of 583 ft and door sills at 583.5 ft would not result in adverse plant site flooding, as further discussed in Subsection 2.4.2.3. The temporary local water buildup due to the failure of the plant drainage system will flow into the lower land and swamps at the northern end of the plant area and eventually discharge into Lake Erie through estuaries. The local temporary water buildup elevation will be substantially lower than the flood elevation due to the maximum wind tide, as described in item b. above

d. The potential dam failure effect is not applicable, as described in Subsection 2.4.4

e. The water level at the site is controlled by Lake Erie. The PMF flow from Swan Creek has no significant effect on the design water level at the site. The maximum lake stillwater level due to storm surge is Elevation 586.9 ft (Subsection 2.4.5.3). Plant grade is at Elevation 583.0 ft. At plant grade elevation, the lake water would extend approximately 2.5 miles inland from the plant site (Figure 2.4-11) and even further inland at maximum stillwater level.

The case (item b) above is clearly the most critical condition and is defined as the PMME.

2.4.2.2.2. Reactor/Auxiliary Building Flood Criteria

The Category I reactor/auxiliary building, which houses safety-related systems and components, is designed against flooding to Elevation 588.0 ft, or 1.1 ft above the PMME stillwater flood elevation of 586.9 ft. All doors and penetrations through the outside walls below the design flood elevation are of watertight design. All safety-related systems and equipment located inside this Category I structure are protected from the PMME flood. The reactor/auxiliary building is also designed to withstand wave action associated with this flooding. Maximum wave effects and forces are discussed in Subsection 2.4.5.4.

All interior floor drain systems inside the reactor/auxiliary building are not connected to the yard storm drainage system and, therefore, no potential water backflow into the structure is anticipated during the design flood condition. Shore protection is not required to preclude flooding of this structure.

The reactor/auxiliary building has only a few essential penetrations in the exterior walls. All of these penetrations below Elevation 588 ft are watertight.

The presence of the turbine building prevents waves and wave runup above the sill elevations on the east wall of the reactor/ auxiliary building, thereby preventing flooding of the buildings. The south wall of the reactor/auxiliary building has two large openings, two rail pockets with waterproofed seals and several waterproofed pipe-sleeved openings. These large openings are in an air-locked rail-car door and an air-locked personnel door. Both of these doors, however, will be air-locked and completely waterproofed to preclude wave runup flooding.

The reactor/auxiliary building roof is designed for a live load of 30 lb/ft^2. This load is equivalent to approximately 6 in. of water, or its equivalent in snow, or snow and ice load combined. Roof drains are designed for a rainfall of 4 in./hr. The reactor building roof water drains through openings in the parapet wall into scuppers and then down through conductors to the auxiliary building roof. Roof drains in the auxiliary building roof carry the runoff into the buried site drainage system by first passing through the turbine building roof drainage system.

2.4.2.2.3. Residual Heat Removal Complex Flood Criteria

The RHR complex is watertight to Elevation 590.0 ft. The north, south, and west walls have no openings. The east wall has approximately 30 waterproofed pipe-sleeved openings. The east wall also has four sets of double 3 ft by 7 ft doors for access to the building. These doors are normally closed and locked, and have their thresholds at Elevation 590.0 ft and extend to Elevation 597.0 ft. They are of steel construction and are shielded behind reinforced-concrete missile walls. The east wall also has eight 4” diameter openings with water tight seals located within each of the two RHR cable vaults at elevations above 590’-6”.

Waves reaching the east wall of the RHR complex across the flooded site would be diminished considerably by the stairs, the missile wall, and the landing at Elevation 590.0 ft in front of the doors. The insignificant amount of runup above the flooded elevation of 586.9

ft, or generated by the reduced waves, may find its way through the door threshold and door jambs, at Elevation 590.0 ft, and be diverted into the floor drain system in the building. The structure is also designed to withstand the wave action associated with this flooding. Shore protection is not required to preclude flooding of this structure.

The roofs of the RHR complex are provided with an adequate number of drainage pipes to pass runoff resulting from the PMP. The PMP was obtained from U.S. Weather Bureau (National Oceanic and Atmospheric Administration) information (Reference 5). Further, the storm-drainage provisions surrounding the RHR complex are designed to pass the discharge from the drain pipes as well as the runoff from surrounding areas. The plant area drainage system is designed so that there is no possibility of ponding near the RHR complex. The roofs of the RHR complex are designed for a postulated maximum ice and snow load of 70 lb/ft^2. This load is based on the simultaneous accumulation of the most severe postulated ice resulting from the mechanical draft cooling towers drift loss (21 lb/ft^2) plus the seasonal snowpack (30 lb/ ft^2), and on an additional ice load (19 lb/ft^2).

The mechanical draft cooling tower drift loss is based on an assumed drift loss of 0.015 percent, with the fans operating at full speed. For evaluating the ice loading on the RHR complex roof, a conservative value of 0.1 percent for drift loss was used at full speed. Under freezing conditions, the fans operate at half speed or are completely shut off. The total water loss under these conditions is less than 390 gal/hr. Based on the above, it is estimated that, with two towers operating for 30 days with no wind drift, and with the temperature below freezing, the maximum ice accumulation is less than 4-1/2 in. This amount of ice is equivalent to about 21 lb/ft^2 live load.

The seasonal snowpack load is based on results of reported research (Reference 6). According to this reference, the seasonal snowpack load is 30 lb/ft^2.

2.4.2.2.4. Category I Yard Structures Flood Design Criteria

The Category I piping and electrical ducts between the RHR complex and the reactor building are below the site flood elevation of 586.9 ft during the PMME. The RHR supply, RHR return, and emergency equipment service water pipelines to both divisions will continue to function during the flood.

There are two sets of Category I ductbanks between the RHR complex and the Reactor/Auxiliary building, with a Division I and Division II ductbank in each set. In each case, the buried cable ducts between the RHR complex and the Reactor/Auxiliary building provide adequate cable separation to maintain independence of redundant circuits.

The first set of ductbanks was installed during plant construction. The physical separation of the two redundant, below-grade circuits is 30 ft at the point the cable ducts leave the southeast corner of the reactor building. The ducts make a sweeping bend with a minimum separation of 20 ft between them. After the bend, the ducts parallel the reactor building in a westerly direction, with 24-ft separation. This separation is constant until the ducts pass under the rail-car air lock, where the separation widens until the ducts enter (still below grade) the RHR complex.

Each circuit is separately housed in a cast-in-place, rectangular reinforced-concrete duct. The duct is covered by successive layers of compacted rock fill placed up to the finished site grade of 583.0 ft. The duct runs vary in elevation from 573.0 ft minimum to 580.0 ft maximum. Since maximum ground water elevation is 576.0 ft, the cables are not specifically designed for continuous underwater service. For low voltage power, control and instrumentation cables, there is no long term mechanism for water related insulation degradation due to lack of voltage stressor or a credible common mode failure mechanism. Therefore, low voltage cables perform their design functions while their external surface remains continuously wetted due to surrounding water. 4160-V essential power circuits are not routed within these ductbanks.

The second set of ductbanks, associated manholes, and cable vaults is installed above the maximum ground water elevation of 576.0 ft with ducts sloped to the manholes, such that circuits contained are not subject to continuous wetting. These are also cast-in-place, rectangular reinforced concrete ductbanks, but are located with the ductbank top approximately six inches below the surface and manhole covers at grade level. The ductbanks rise above grade and enter above ground cable vaults at the RHR complex and also rise above grade at the entrance to the Reactor/Auxiliary building cable vaults. 4160-V essential power circuits are routed within these ductbanks.

The minimum elevation for cable termination in either the RHR complex or reactor building is 588.7 ft, which is above the site maximum probable stillwater elevation of 586.9 ft.

2.4.2.2.5. Site Drainage Flood Design Criteria

The storm drainage system is not used to protect Category I structures from local PMP flooding, as further discussed in Subsection 2.4.2.3. Inlet manholes in the immediate plant vicinity are located at the low points of relatively flat roadside and railroad track areas, and in local area depressions. The storm-drainage conduit discharges westward into the existing overflow canal for Fermi 1 and eventually into Lake Erie through estuaries. The storm-drainage system is designed as a gravity system with a minimum velocity of 3 fps flowing full for a rainfall intensity of 4 in./hr. Runoff coefficients used are 1.0 for roofs and paved areas and 0.5 for gravel and grassed areas. The closed storm-drainage system provides the normal means of drainage for the plant site and building roofs.

The sedimentation potential of the site drainage system for anticipated rainfall conditions is negligible since the site consists principally of firmly compacted crushed-rock fill and grassed areas, and the slopes of the ditches feeding the inlet of manholes are relatively flat. The resulting velocity of the drainage flow is nonscouring. Riprap or paving is provided for protection of outlet ends at all discharge points of the storm sewer system.

2.4.2.2.6. Bretschneider Methodology for Determination of Storm Surge

It has been observed that more recent maximum monthly mean lake levels may exceed historical data from Reference 2 and Figure 2.4-9. The site stillwater flood elevation in Section 2.4.5.3 of +16.4 ft (corresponding to El. 586.9 ft NYMT-1935) was originally established using the historical data from Reference 2 and Figure 2.4-9 for the initial lake level and combined with the Platzman method of determining wind tide/storm surge. To address the more recent lake levels which may exceed historical data, a new methodology was utilized. The Bretschneider method (Reference 30) of determining storm surge was identified as an NRC-approved methodology (Reference 31) for this application and shown to be acceptable for this analysis. Using the Bretschneider method and starting from higher lake levels, the overall amount of storm surge is calculated to be +10.1 ft. Therefore, with this methodology, the site stillwater elevation of +16.4 ft (corresponding to El. 586.9 ft NYMT-1935 in Section 2.4.5.3 remains the design basis flood event limit even assuming maximum monthly mean lake levels up to +6.4 ft (corresponding to El. 576.8 ft NYMT-1935).

In addition to establishing use of the Bretschneider method for determining storm surge, the effects of lake levels higher than the historical data from Reference 2 and Figure 2.4-9 was assessed in supplemental evaluations for various site flooding considerations. The supplemental evaluations were either found to be bounded by their existing analyses, given the resulting same stillwater flood level, or were determined to not result in site flood protection criteria being exceeded.

2.4.2.3. Effects of Local Intense Precipitation

Flooding due to a local PMP on the adjacent 2-square mile drainage area west of the plant site, as shown in Figure 2.4-4, was examined. The local PMP shown in Table 2.4-2 was determined by use of Reference 5. The hourly distribution of the maximum 6-hr rainfall was determined by procedures presented in Reference 7. The shorter 15-minute-duration PMP was extrapolated by use of similar procedures. Due to its small area, the rational formula with a runoff coefficient of 1.0 and concentration time of 15 minutes was applied to compute the peak discharge (Reference 8). The maximum PMP intensity of 15 minutes is assumed to be 4.9 in., as shown in Table 2.4-2. The calculated peak discharge due to the local PMP is 25,000 cfs, which is 10,000 cfs greater than indicated by the PMF peak envelope curve for the Great Lakes region. The Great Lakes PMF peak discharge envelope curve indicates a maximum flow of 15,000 cfs, which represents a more severe flood than would result from the relatively flat 2-square mile local area if determined by the unit hydrograph PMP calculation procedure.

The calculated peak discharge due to the local PMP is 25,000 cfs. Assuming, conservatively, that the peak discharge would pass the plant site only along the axis of the overflow canal (Figure 2.1-5), a hypothetical cross section approximately 1 mile in length and normal to the axis of the overflow canal was constructed to intersect the southernmost chimney on the plant site and the intersection of Langton and Leroux roads to the west of the site (Figure 2.4-3).

Using the slope/area method and conservative values of slope and roughness coefficient, 0.001 ft/ft and 0.07, respectively, a flow of 31,500 cfs was determined as passing through the cross section with a maximum water surface elevation of 582 ft (New York Mean Tide, 1935). The peak flow due to a local PMP, 25,000 cfs, would pass through the cross section at an even lower water surface elevation. In this analysis, channel or cross-section bottom was assumed to be at maximum monthly mean lake level. And, as stated earlier, all flow due to a local PMP was assumed to pass through the hypothetical cross section. Under actual conditions, a peak flow due to the local PMP would flow both south of the plant site and to Lake Erie, as well as through the hypothetical cross section. Water surface elevations due to a local PMP would therefore be lower in actuality than those determined in our analysis.

At a hypothetical water surface elevation of less than 582 ft (New York Mean Tide, 1935), as determined in the above analysis, the maximum water elevation at peak flow due to a local

PMP would be more than 1 ft below plant grade (583 ft, New York Mean Tide, 1935) and would not pose a threat to safety-related structures onsite.

With respect to that portion of a local PMP falling on the plant site itself, including roof structures, runoff overflowing the roof parapets and from the downspouts, assuming that the site drainage system was completely blocked, would flow overland under conditions of site gradient (Figure 2.1-5) to lower elevations surrounding the site and then to Lake Erie itself.

All door sills on safety-related structures are at least 6 in. above plant grade. Because there are no downspouts or scuppers located near doors on safety-related structures, ponded water under local PMP conditions, with the event of a blocked site drainage system, should drain overland, as described above, prior to reaching the base of door sills on safety-related structures.

The local PMP is shown in Table 2.4-2, and the description of the runoff model is given in Subsection 2.4.3.3.

The drainage system in the plant site area is designed with inlet manholes located at the low points of relatively flat roadside and railroad ditches and in local area depressions. The storm-drainage system is not used to protect Category I structures from local PMP flooding, as described in Subsection 2.4.2.2.

2.4.3. Probable Maximum Flood on Swan Creek

The PMF is an estimated flood that may be expected from the most severe combination of critical meteorologic and hydrologic conditions that are reasonably possible in the region (References 5 and 7). The PMF on Swan Creek was estimated as the maximum flood runoff resulting from a PMP occurring on the entire drainage basin of 109 square miles, as shown in Figure 2.4-4.

2.4.3.1. Probable Maximum Precipitation

The estimation of a PMP includes both time and areal distributions. Due to its small drainage area (109 square miles), the PMP is assumed uniformly distributed throughout the entire Swan Creek watershed. The time distribution of a PMP is obtained as follows. The PMP for various durations shown in Table 2.4-3 was obtained from the all-season PMP (Reference 5). Its 2-hr time distribution for the maximum 6-hr rainfall and time sequence were based on procedures presented in Reference 7. Table 2.4-3 shows the synthesized PMP for the Swan Creek watershed.

2.4.3.2. Precipitation Losses

An estimate of precipitation losses was obtained using data from References 9 and 10 and studies of other similar areas. Surface soils in the Swan Creek drainage area are largely comprised of lacustrine clays, which have low infiltration capacity (Reference 11). The land use is estimated as follows: 30 percent small grain, 30 percent forage and pasture, 25 percent row crops, and 15 percent wooded land and buildings. Considering the Swan Creek type ground cover and soil surface as compared to similar type areas in other locations where studies have been made, minimum loss rates are higher in the summer months than in the winter months. These minimum losses can be characterized as follows.

a. Winter initial losses vary from 0.0 to 0.2 in., and winter infiltration losses vary from 0.01 to 0.02 in./ hr

b. Summer initial losses vary from 0.5 to 1.2 in., and minimum summer infiltration rates are approximately 0.05 in./hr.

The Swan Creek losses adopted are initial losses of 0.5 in. and an infiltration rate of 0.02 in./hr during the probable maximum storm. This is assumed as occurring during a wet period with the most favorable antecedent conditions when the moisture capacity of the topsoil would be essentially satisfied. The adopted minimum losses for the Swan Creek area assuming the most favorable (to high runoff) antecedent (ground and rainfall) conditions are based on a conservative estimate for these conditions. The Swan Creek rainfall-excess relationships were determined by use of the minimum conservative losses during the PMP storm as shown in Table 2.4-4. The estimated precipitation losses and runoff are shown in Table 2.4-4.

2.4.3.3. Runoff Model

Because Swan Creek was ungaged prior to 1971, a synthetic unit hydrograph was developed for the 109-square mile basin, as shown in Figure 2.4-4, by using Snyder's method (Reference 12). The runoff was determined at the mouth of Swan Creek north of the site.

Figure 2.4-12 shows the synthetically derived unit hydrograph of 2-hr duration for the Swan Creek watershed. The hydrograph ordinates are shown in Table 2.4-4. Coefficients used in the derivation of the synthetic unit hydrograph are as follows: L = 25.4 miles, L_{ca} = 16.7 miles, C_t = 2.0, W_{50} = 16 hr, and W_{75} = 9 hr. The terms L and L_{ca} are distances measured on the U.S. Geological Survey (USGS) 7.5-minute topographical map for the site area. Time in hours, from start of rise to peak rate, or t_p, was determined using the formula

$$t_p = c_t(L * L_{ca})^{0.3}$$

The value of t_p was determined to be 12.3 hr using a basin parameter C_t of 2.0. Comparison of synthetic unit hydrograph values for Swan Creek with values for nearby stations with similar runoff characteristics as obtained from U.S. Army Corps of Engineers unpublished unit hydrographs is given in Table 2.4-5.

Table 2.4-5 illustrates the conservatism of the coefficients selected for the Swan Creek watershed. For example, a curve enveloping the q_p values would yield a unit hydrograph peak of about 3100 cfs for the 109 square miles as compared to the 4000 cfs peak adopted. The utilization of the extreme coefficient value was intended to include the possible nonlinear runoff response of Swan Creek due to high rainfall intensities.

2.4.3.4. Probable Maximum Flood Flow

The PMF for the 109-square mile watershed of Swan Creek was determined by appropriate application of the preceding analysis described in Subsections 2.4.3.1, 2.4.3.2, and 2.4.3.3. Base flow was assumed to be 100 cfs. The computed PMF hydrograph components are shown in Table 2.4-4.

The calculated basin-wide peak flow in Swan Creek due to the synthesized PMP is 89,000 cfs at the mouth of Swan Creek, as shown in Figure 2.4-13.

There are no dams or other regulating hydraulic structures on Swan Creek that could affect the hydrograph. The exact PMF stream course response cannot be assessed since Swan Creek has not been gaged for a sufficient period of time.

2.4.3.5. Water-Level Determinations

The water level at the site is controlled by Lake Erie. The PMF flow from Swan Creek has no significant effect on the design water level at the site. The maximum lake stillwater level due to storm surge is Elevation 586.9 ft (Subsection 2.4.2.2.1). Plant grade is at Elevation 583.0 ft. At plant grade elevation, the lake water would extend approximately 2.5 miles inland from the plant site (Figure 2.4-11) and even further inland at maximum stillwater level.

To estimate the maximum floodwater level, a section through the east end of the plant site and normal to Swan Creek was selected to compute backwater effects due to the PMF flow on Swan Creek. This section is 3.5 miles wide and is bounded by Port Sunlight Road to the north and Pointe Aux Peaux Road to the south (Figure 2.4-1). Neither of the roads was constructed as a flood-protection levee. In the vicinity of the control section, the land is flat, approximately at Elevation 572.5 ft (Figure 2.4-11).

The backwater calculations were done with the assumptions that the selected section has a water level at Elevation 575.3 ft, mean monthly maximum lake level, and the main plant structures are located 1500 ft west of this section. By applying the Manning formula (Reference 13) on a rectangular channel with a width of 3.5 miles and a bottom elevation of 572.5 ft, with a Manning's roughness coefficient of 0.07, the estimated rise of water level during a peak flood flow of 89,000 cfs is less than 2.0 ft. Therefore, the maximum flood level at the plant site due to the PMF flow from Swan Creek at the mean monthly maximum lake level is at approximately Elevation 577.3 ft, which provides a safety margin of more than 5.7 ft below the established plant grade of Elevation 583.0 ft.

The same procedures were applied using a higher peak flood flow of 115,000 cfs, resulting in an estimated maximum flood level at the plant site at Elevation 579.1 ft, which is 3.9 ft below the plant grade. Therefore, the PMF flow from Swan Creek has no flooding potential with respect to the plant site.

Additional computations, utilizing the slope/area method at a hypothetical cross section through Swan Creek above the plant site (Figure 2.4-4) determined that a flow of 106,000 cfs in Swan Creek would represent a maximum water surface elevation at the cross section of 582 ft (New York Mean Tide, 1935). The PMF of 89,000 cfs on Swan Creek (Subsection 2.4.3.4) should not cause flooding affecting safety-related structures at plant grade Elevation 583 ft (New York Mean Tide, 1935).

In the above computations by the slope/area method, a hypothetical cross section normal to Swan Creek and approximately 1.8 miles in length was chosen. Channel base or the bottom of the cross section was assumed to be at the elevation of the maximum monthly mean lake level. A slope of 0.001 ft/ft and a roughness coefficient of 0.07 were used in the computations.

2.4.3.6. Coincident Wind Wave Activity

A flood on Swan Creek would result in a landward extension of the lake. Therefore, wind activity determined for the lake would apply to the stream flood condition. Wave activity in Lake Erie is described in Subsection 2.4.5.4.

2.4.4. Potential Dam Failures (Seismically Induced)

There are no regulatory structures on Swan Creek. Nor are there dams on other streams or rivers in southeastern Michigan that should failure result because of seismic or other disturbances would affect water levels in Lake Erie along the plant shoreline.

2.4.5. Probable Maximum Surge and Seiche Flooding

2.4.5.1. Probable Maximum Winds and Associated Meteorological Parameters

Extensive studies have been made regarding the effects of wind setup on Lake Erie. Data developed by Platzman (Reference 14), which relate lake levels at Toledo and Buffalo to various wind conditions, were used to establish the wind setup for the site.

The Platzman one-dimensional wind setup model has been verified using four storms producing peak setup at Toledo (Reference 15). The model, valid for setup along the longitudinal axis of Lake Erie, has been shown to consistently calculate peak longitudinal setup greater than the measured peak longitudinal setup at Toledo when using the wind stress and bottom friction coefficients proposed by Platzman. Verification of this model is valid for input winds measured at the Ashtabula Coast Guard Station. The verification for one storm, and possibly a second, indicates that cross-lake wind setup can, at times, be significant and should be considered.

The conservatism of the model in predicting the longitudinal setup increases with increasing wind speed. For a maximum 3-hr average wind speed of 74 knots, the model is estimated to compute a longitudinal wind setup at Toledo 2 ft above the value which would be measured. Whereas an allowance should be made for the possibility of cross-lake setup occurring simultaneously with longitudinal setup at Toledo, an allowance is not required at the Fermi site near Monroe since Monroe is in the vicinity of the nodal point for cross-lake setup. The nodal point is the location where the change in stillwater level due to cross-lake setup is zero.

To establish meteorological conditions appropriate for calculation of the maximum probable wind setup for the site, winds with an easterly or northeasterly component that would be sustained for 6 to 9 hr were examined. The National Weather Records Center in Asheville, North Carolina, was commissioned to examine 25 years of wind records for eight stations in the vicinity of Lake Erie. The eight stations were Toledo, Windsor (Ontario), Sandusky, Cleveland, London (Ontario), Youngstown, Erie, and Buffalo. The National Weather Records Center tabulated (Reference 16) the speed, direction, and date of the fastest 1-minute wind having an easterly component.

The maximum, easterly 1-minute wind speeds observed for the 25-year period at the eastern four stations (London, Youngstown, Erie, and Buffalo) were 65, 37, 60, and 44 mph, respectively. The companion maximum, easterly 1-minute wind speeds observed at the western four stations (Toledo, Windsor, Sandusky, and Cleveland) were 40, 45, 35, and 35 mph respectively. Comprehensive analysis of these and other data (Reference 17) led to the conclusions that:

a. Maximum easterly wind speeds are substantially less than maximum westerly wind speeds

b. Maximum easterly wind speeds over the western portion of Lake Erie are somewhat less than maximum easterly wind speeds over the eastern portion of Lake Erie.

On this basis, a maximum, 1-minute easterly wind speed of 45 mph was selected as representative for the 25-year period of record for the site. This 1-minute value was converted to the probable maximum easterly wind as follows:

a. Overland wind speed was converted to over-water wind speed by multiplying the land value by 1.33. The maximum easterly wind speed over water is thus calculated as 60 mph. This wind speed is assumed to have a probability of once in 25 years

b. The maximum 1-minute easterly wind speed with a probability of once in 1000 years was calculated, using the method of Thom (Reference 18), to be 86 mph

c. A maximum 10-minute wind speed of 74 mph was calculated (Reference 19) by multiplying the maximum 1-minute easterly wind speed by 0.86

d. The 1000-year maximum easterly wind was taken as the maximum 10-minute wind speed of 74 mph.

The PMME data used to calculate the probable maximum wind tide at the Fermi site were obtained from the table of probable maximum wind estimates (over-water wind speeds) supplied by the AEC. The PMME wind speeds over the lake varied with time and distance along the lake axis. The peak 10-minute wind speed was 100 mph. Since the model used to calculate the probable maximum wind tide (Reference 14) is one dimensional, the PMME winds were directed along the axis of Lake Erie (N67.5°E). The PMME had a translational velocity of 20 mph moving from east to west, and duration of 60 hr.

2.4.5.2. Surge and Seiche History

2.4.5.2.1. Maximum Monthly Mean Lake Level

Historical maximum monthly mean water levels are discussed in Subsection 2.4.2.1.1.

2.4.5.2.2. Maximum Wind Tide

Historical maximum wind tides are discussed in Subsection 2.4.2.1.2.

2.4.5.2.3. Seiches

Seiches are periodic oscillations of the lake water level that are caused by changes in wind stress or barometric pressure acting upon the water surface. As the wind stress diminishes, the adverse gradient of the surface water cannot be maintained and an inertial surge of water occurs. Seiches also may result from very rapid changes in barometric pressure, usually associated with squall lines. However, sudden barometric disturbances are very infrequent on Lake Erie.

Analysis of gage records of Lake Erie indicates that the average period of oscillation for a seiche traveling between Toledo, Ohio, and Buffalo, New York, is approximately 14 to 15 hr. As a result of the greater depth of water at the east end of the lake and the generally higher wind speeds associated with the prevailing westerly winds, the maximum amplitudes of a seiche on Lake Erie occur at Buffalo.

Gages at Buffalo and Toledo indicate that the amplitude of the oscillations of a seiche decays rapidly with each subsequent oscillation. The rise in water level induced by the initial wind setup is greater than any subsequent rise associated with the seiche.

In addition to the general seiche that occurs over the entire lake surface, a local seiche may occur between the west end of Lake Erie and Point Pelee. Local seiches with amplitudes of up to 0.8 ft have been detected from gage records at Toledo and Monroe (Reference 20). These seiches can occur when the water body is in a state of equilibrium or constant stillwater level.

The stillwater level of Lake Erie near the Fermi site constantly changes in elevation, with respect to the rest of the lake during the PMME. This difference in water levels effectively damps out any seiche activity near the site. It is unlikely, therefore, that any seiche will occur simultaneously with the PMME. Consequently, for design purposes, no rise in water elevation from a seiche is considered.

2.4.5.3. Surge and Seiche Sources

The maximum PMME wind tide of 11.4 ft was calculated for the Fermi site with the PMME wind speeds as input to the verified Platzman one-dimensional wind setup model of Lake Erie (Reference 15). As an additional conservatism, the previously accepted wind tide of 11.6 ft was used for design purposes. This value does not include an allowance for cross-lake setup as none is required. Monroe is in the vicinity of the nodal point for cross-lake setup, where the change in stillwater level due to cross-lake setup is zero.

A total stillwater elevation of +16.4 ft (586.9 ft) was selected as the design maximum. This was based on the PMME defined by the AEC with a storm path along the axis of Lake Erie (N67.5°E). Elevation +16.4 ft results from a calculated wind tide of +11.6 ft superimposed on a maximum monthly mean lake level of +4.8 ft. This storm surge would occur at the Fermi site approximately 9 hr after the maximum wind reaches the shore. The storm surge hydrograph resulting from the PMME is shown in Figure 2.4-14.

No rise in water elevation resulting from a seiche was used in the design (Subsection 2.4.5.2.3).

2.4.5.4. Wave Action

2.4.5.4.1. Wind-Generated Waves

Wave characteristics are dependent upon wind speed, wind duration, water depth, and fetch length. Generated waves were calculated coincidental with the maximum storm surge hydrograph to determine the maximum flood elevations at the site. Fetch lengths were measured to the site from the axis of the lake (N67.5°E), from N78.75°E, and from due east (Figure 2.4-15). These fetches, hereafter referred to as degrees clockwise from north, have fetch lengths ranging from 11 to 33 nautical miles. Average lake depths range from 32 to 42 ft during probable maximum stillwater levels.

Using the AEC definition of probable maximum winds, component wind velocity profiles were plotted for fetch directions 67.5°, 78.75°, and 90.0° (Figure 2.4-16). Component wind velocities for fetch directions 78.75° and 90.0° were based on the wind velocity profile from 67.5°, the path of the storm.

The shallow water depths over the fetch approaching the Fermi site preclude deep-water wave activity; only shallow-water waves are generated during the PMME. The shallow-water wave generation curves of Bretschneider (Reference 21) were used to calculate significant wave heights and periods (Figure 2.4-14). The generated wave height and period profiles have a phase shift in time of +1.5 hr over the wind profiles to allow for the generation and travel of waves to the site.

The significant wave height is the normal available parameter from statistical analysis of synoptic weather charts. Approximate relations of the significant wave heights to other parameters of the normal wave spectra in nature have been defined. Assuming that the most probable maximum wave height, H_m, is given by the deep water simplified theoretical solution of Equation 2.4-1, then the ratio of H_m to H_s is 1.8 to 1.

$$H_m = 0.707 H_s \sqrt{\log_e N} \qquad (2.4\text{-}1)$$

where

N = number of waves during a period of steady-state conditions

H_s = significant wave height

This value is conservative, as the wave spectrum curve is flatter for shallow-water conditions near the Fermi site than for deep-water conditions applicable to the solution. Curves of H_m are presented in Figure 2.4-16.

2.4.5.4.2. Design Waves

2.4.5.4.2.1. Selection Bases

Selection of design waves depends on the wave climate at the site, the structures being considered, and the available water depths fronting the structures. Generated wave conditions during the PMME occurrence, offshore of the site location (Figure 2.4-16), are propagated shoreward to the various plant structures. In selecting design waves for various structures, the possible range of wave periods, heights, and approach directions during various times of the storm are considered to occur at critical conditions.

2.4.5.4.2.2. Incident Wave at Shoreline

The maximum stillwater level and the maximum offshore generated wave height do not occur simultaneously. Therefore, various stillwater levels are considered in selecting the critical wave conditions. The maximum generated wave height, significant wave height, and wave period (offshore of the plant site) are 21.9 ft, 12.2 ft, and 9.0 sec, respectively. These occur during the stillwater level of 582.8 ft, 1.50 hr after the maximum winds have crossed the shoreline (Figure 2.4-14). During the maximum stillwater level of 586.9 ft and 9 hr after the maximum winds have crossed the shoreline, the maximum wave height, significant wave height, and wave period are 14.0 ft, 7.8 ft, and 7.7 sec, respectively.

Design waves were generated offshore of the site location from approach directions 67.5° (path of PMME), 78.75°, and 90.0°. There should be no significant wave action south of 110° (i.e., normal to the shoreline) during the occurrence of the PMME, as this direction is a 42.5° departure from the wind direction. Waves north of 67.5° also are insignificant because of diminishing fetch length, shallow water depths, and change of direction through wave refraction. An 8-sec wave period generated from 67.5° would approach the plant site shoreline from due east because of refraction effects (Figure 2.4-10). A shorter wave period would not be affected by refraction as much as the 8-sec wave period.

As waves approach the shoreline, they start breaking in water depths approximately equal to their wave heights. Figure 2.4-14 shows breaking wave heights for shoreline toe elevations of 569 ft, 572 ft, and 575 ft. The upper breaking wave height limit considers the effects of wave setup. With continuous heavy wave action breaking against the shoreline, it is possible that the return flow of water lakeward will be slower, thus causing a pileup of water (wave setup) along the shoreline. The possibility of this wave setup was assumed to raise the stillwater level by an amount equal to one-tenth the breaking wave height. With this increase in stillwater level, a slightly higher wave could be supported before breaking.

In selecting the proper design wave that can attack the shoreline, Figure 2.4-14 is used. Design H_s and H_m curves were plotted from the maximum values of Figure 2.4-16. For a particular shoreline or shore barrier toe elevation, the breaking wave height is the controlling factor if it is less than the unbroken wave height during a given stillwater level. In Figure 2.4-14, which includes the storm surge hydrograph, the stillwater level is read off the right-hand ordinate while the wave parameters, H_m, H_s, and H_b, are read off the left-hand ordinate. In using either the significant wave height curve (H_s) or the maximum wave height curve (H_m), the breaking wave height curve (H_b) controls until it intersects (progressing positively from left to right along the TIME axis) the H_m or H_s curve. Thereafter, the unbroken wave height controls.

When using significant wave conditions and a toe elevation of 575.0 ft, the following applies:

a. For a time of +3 hr after the maximum winds reach shore, the design wave is a breaking wave of 7.9 ft to 8.6 ft, with a period of 8.8 sec, during a stillwater elevation of 584.0 ft

b. For a time of +9 hr, the design wave is a significant wave of 7.8 ft

c. The maximum design wave is a wave of 10.2 ft with a period of 8.4 sec and occurs during a stillwater elevation of 585.6 ft at a time of +5.1 hr.

2.4.5.4.2.3. Transmitted Wave

During the occurrence of the PMME, plant grade Elevation 583.0 ft is flooded for approximately 17 hr. Therefore, incident waves attacking the shoreline can be transmitted inland across the flooded plant grade. These transmitted wave heights depend on the available water depth above plant grade, the incident wave characteristics attacking the shoreline, the configuration of the shore barrier, and the location and configuration of other obstacles.

A rock shore barrier has been constructed in front of Fermi 2 along the shore between Plant Coordinate System Grid N6800 and N7800. The rock shore barrier crest elevation is 583 ft nominal; the toe elevation will be 572 ft nominal. For design wave considerations, a design toe elevation of 569.0 ft was used to allow for 3 ft of scour at the toe.

Transmitted wave heights (Reference 20) over the shore barrier are shown in Figure 2.4-17 for maximum and significant incident wave heights at the shore barrier. The incident water depth at the shore barrier toe and the inland depth of water above a plant grade elevation of 583.0 ft are also indicated in Figure 2.4-17.

Using this inland depth of water caused by flooding of plant grade, a curve indicating the maximum wave height that can be supported over the flooded plant grade, without breaking, is presented in Figure 2.4-17. During the maximum flooding of plant grade, the maximum supported wave height is less than the transmitted wave heights. Therefore, the maximum supported wave height is the controlling factor for plant structures located more than a few hundred feet inland from the shoreline. The maximum inland supported wave heights for plant grade Elevation 583.0 and 580.0 ft are 3.0 and 5.4 ft, respectively. The actual site grade at a given location may vary from the reference elevation of 583.0 ft. However, the resultant difference in the hydrostatic pressure due to the difference of supported wave heights would be insignificant.

Waves that are transmitted over the shore barrier will attack the office service and radwaste buildings of Fermi 2. These buildings are not Category I structures and, therefore, could be damaged during the storm without causing a safety concern to the public.

Small waves can reach the Category I structures by traveling around the northerly and southerly ends of the shore barrier. Waves traveling around the ends of the shore barrier undergo several effects, including the following:

a. Breaking caused by the shallow depths of the flooded plant grade

b. Diffraction around the ends of the other plant structures

c. Reflection off plant structures before reaching the Category I structures

d. Reduction caused by plant grade bottom friction and side friction of obstructing structures.

The significant wave period of 7.7 sec will approach the plant sites from due east, while lower period waves can approach the northerly end of the shore barrier from 65° (N65°E), and possibly approach the southerly end from 110° (E20°S). Waves approaching the north end of the shore barrier will be reduced to the maximum inland support wave heights of 3.0 and 5.4 ft for plant grade Elevations 583.0 and 580.0 ft, respectively, in approaching

Category I structures. Waves approaching the southerly end of the shore barrier will be reduced in height approaching Category I structures as a result of the maximum inland supported wave height and the protection provided by the office service and turbine buildings. Neglecting any reduction effects from protection provided by the office service and turbine buildings, waves approaching Category I structures from the south will be reduced to the maximum inland supported wave height of 3.0 ft for the plant grade elevation of 583.0 ft.

2.4.5.4.2.4. Wave Stability

In selecting the proper design wave for wave runup and wave forces against Category I structures, the wave period spectra must be considered since the significant wave period might not control. In calculating minimum wave periods, Equation 2.4-2 was used to determine the limiting wave steepness in shallow water (Reference 22).

$$H/L = 1/7 \tanh\left[\frac{2\pi d}{L}\right] \qquad (2.4\text{-}2)$$

As mentioned in Subsection 2.4.5.4.2.3, waves attacking Category I structures are controlled by the available water depth over the flooded plant grade elevations. For plant grades with very flat slopes, the maximum supported wave height is approximately 0.78 times the water depth. The plant grade of Fermi 2 is Elevation 583 ft 0 in., and therefore a maximum wave height of 3.0 ft can be supported. Where the plant grade elevation is 580 ft 0 in., a maximum wave height of 5.4 ft can be supported. With the plant grade elevation changing from 580.0 ft to 583.0 ft in the vicinity of Grid N8000, it would be possible for either the 3.0-ft or the 5.4-ft wave to strike the north or east sides of Category I structures. Minimum wave periods calculated for wave heights of 3.0 ft and 5.4 ft are 3.4 sec and 4.5 sec, respectively. The maximum wave period of about 9 sec (Reference 22) is for a significant wave height of 7.8 ft and a significant wave period of 7.7 sec.

2.4.5.5. Resonance

Resonance generated by waves can be a problem in enclosed bays or harbors when the natural period of oscillation of the bay is equal to the period of the incident waves. However, the Fermi site is not located in an enclosed embayment. The full exposure of the site to Lake Erie during PMME conditions, plus the flat slopes surrounding the site area, result in a natural period of oscillation of the flooded area that is much greater than that of the incident shallow-water storm waves. Consequently, resonance is not a problem at the site during the PMME occurrence.

2.4.5.6. Runup

2.4.5.6.1. Flood Levels

Refer to Subsection 2.4.2.2 for a discussion of flood levels.

2.4.5.6.2. Maximum Runup Elevations

Maximum runup elevations on the exposed north faces of the reactor/auxiliary building and the RHR complex are 593.0 and 598.0 ft for the 3.0-ft and 5.4-ft waves, respectively. The maximum runup elevation on the exposed south faces of the reactor/ auxiliary building and the RHR complex, the exposed east face of the RHR complex, and the west face of the reactor/auxiliary building is 593.0 ft for the 3.0-ft wave. This wave could possibly reach the west face of the reactor/auxiliary building by reflection from the east face of the RHR complex. The east face of the reactor/auxiliary building is not exposed to waves and wave runup. The west face of the RHR complex is landward of the storm direction and not subject to waves and wave runup. As previously stated, no shore protection is required to preclude flooding of these structures.

2.4.5.6.3. Wave Forces

Maximum wave pressures and forces against Fermi 2 Category I structures can result from a 3.0-ft or possibly a 5.4-ft wave striking the north or east faces of Category I structures. These wave heights are the maximum supported wave heights for plant grade Elevations 583.0 and 580.0 ft. Wave pressures and thrusts against smooth vertical walls have been calculated from nonbreaking, broken, and breaking wave conditions. The wave periods have been varied from the minimum wave period to the maximum wave period. The instantaneous impact forces produced by waves breaking against a structure result in intense shock pressure with a duration in the range of 1/100 to 1/1000 sec. The intense pressures occur when a thin cushion is entrapped by waves breaking on a structure.

The breaking wave conditions are calculated from Minikin's formula. In adapting Minikin's formula, unrealistic results are predicted for very flat slopes (slopes fronting a vertical wall). Therefore, when the actual slope is flatter than 20:1 or even 10:1 (horizontal to vertical), pressures derived from a 20:1 or 10:1 slope should be used. Pressures and thrusts from breaking wave conditions were calculated for both slope conditions. Porous fill material, which can become completely saturated during flooded conditions, is placed from the top of slab elevation of the Category I structure to the plant grade elevation. Therefore, hydrostatic pressures against Category I structures are considered to the depth of the upper surface of the slab of both buildings.

Wave pressure and thrust results for the reactor/auxiliary building and the RHR complex are presented in Figures 2.4-18 and 2.4-19. Wave pressure distribution diagrams are presented in Figures 2.4-20 and 2.4-21. The critical static pressure and thrust occur under the broken wave conditions, whereas the critical dynamic pressure and thrust occur under the breaking wave conditions for an assumed slope of 20:1 and the minimum wave periods of 3.4 to 4.5 sec. All Fermi 2 Category I structures are designed to withstand these forces.

2.4.5.7. Protective Structures

The importance of the shore barrier in providing protection for Category I structures during the PMME has been greatly reduced from the originally approved concept for the following reasons:

a. Category I structures are not susceptible to flooding from storm surge and wave runup

b. Category I structures are largely protected by other plant facilities

c. Category I structures are not subject to damage from transmitted waves behind the barrier

d. Category I structures are not endangered by wave forces from 3.0-ft to 5.4-ft waves

e. Damage to the shore barrier will not enable waves larger than 5.4 ft to break against Category I structures since these structures are located a minimum distance of 800 ft inland from the shoreline. Safety-related structures that are located this distance away would remain safe during the extreme high stillwater levels of the PMME.

The shore barrier design and location are shown in Figure 2.4-22. The parameters used in the shore barrier design are discussed in detail in this section. The shore barrier ends are to be constructed on a side slope of 3:1 (horizontal to vertical) as compared to the design slope of 2:1 used for the shore barrier. The ends of the shore barrier rubble-mound structures are of the same design as determined for the 2:1 slope. Criteria for construction of the multilayered barrier are shown in Figure
2.4-22. The ends have been flattened to a 3:1 slope to ensure that they can withstand conditions more severe than the design conditions.

A shore-barrier-slope-stability analysis was performed to deter-mine the factor of safety against sliding of the shore barrier, and it was concluded that the shore barrier has a sufficient factor of safety with regard to a sliding failure occurring at any soil layer. A report of this analysis was submitted to the NRC in July 1981.

The shore barrier, which allows for the possibility of 6 to 8 percent stone displacement during the PMME, extends from Grid N6800 to N7800 and preserves the integrity of the plant site fill placed to Elevation 583.0 ft.

The shore barrier, including the ends, consists of a rubble-mound structure using an armor cover of stone. A toe elevation of 572.0 ft, a crest elevation of 583.0 ft, and a lakeward-side slope of 2:1 (horizontal to vertical) were considered in its design. The design wave was based on the probable maximum storm event and a design shore barrier toe elevation of 569 ft, allowing for 3 ft of scour. Hudson's stability equation was used for determining the weights of armor units (Reference 21). Stability coefficients (K_D) listed in Reference 21 were used for significant wave conditions and are conservative values based on zero damage criteria for model studies. By allowing for some shore barrier damage (displacement of armor stones), a higher stability coefficient was used.

An armor cover was calculated using rough angular stone (density 165 lb/ft^3) placed on a 2:1 slope. Using a design toe elevation of 569.0 ft, the maximum significant breaking wave height (Figure 2.4-14) is found to be 12.2 ft during the probable maximum storm event. The possibility of some stone displacement (6 percent to 8 percent) was allowed for, with any displaced stones being replaced after the storm passed. A stability coefficient of 5.0 was used for two layers of stone placed randomly. This results in an armor layer 7.5 ft thick using 3.3-ton to 5-ton stone, as shown in Figure 2.4-22. The secondary layer is 3.5 ft thick with 600-lb to 1000-lb stone, while the filter layer is 1.5 ft thick, consisting of 30-lb to 50-lb stone. Below the filter layer is 1 ft of crushed rock (20 lb and under).

Where the plant grade elevation slopes from 580.0 to 583.0 ft, to the north of the Fermi 2 location, the slope is protected against the possibility of breaking 5.4-ft waves during the maximum stillwater level. Protection of the slope is achieved by lining it with suitable rock.

The NRC evaluated the as-built condition of the shore barrier and concluded that it met the requirements of General Design Criterion (GDC) 2 and was, therefore, acceptable on the basis that the inspection and maintenance program required by the Technical Requirements Manual provided reasonable assurance that the shore barrier would not be allowed to deteriorate significantly from its as-built configuration. The Technical Specifications require that the shore barrier be inspected on an annual basis and after major storms and seismic events exceeding operating-basis earthquake (OBE) intensity and be promptly restored to its prior condition in the event of any significant damage.

2.4.6. Probable Maximum Tsunami Flooding

The Fermi site is located in an area of the United States designated as having potentially minor seismic activity. Any tsunami activity in Lake Erie could only be generated by local seismic disturbances. Based on the history of the area, local seismic disturbances would result only in minor excitations in the lake. No tsunami has been recorded in Lake Erie; the only remotely similar phenomena observed have been low-amplitude seiches resulting from sudden barometric pressure differences. The low-amplitude seiches that could occur would be of negligible concern to the site.

2.4.7. Ice Flooding

Ice flooding is not a design basis at the Fermi site. The grade elevation of the plant site is at least 10 ft above the normal winter level of Lake Erie, and the emergency supply of water for cooling is not dependent upon natural bodies of water or the operation of intakes located where ice flooding could occur.

2.4.8. Cooling Water Canals and Reservoirs

2.4.8.1. Canals

A discharge canal is provided between the natural draft cooling towers and the circulating water reservoir. The canal is not part of a Category I system and is not safety related or necessary for the safe shutdown of the reactor.

2.4.8.2. Reservoirs

An open pond reservoir is provided as a collection basin from the natural draft cooling tower discharge to the circulating water pump house. The reservoir is not part of a Category I system and is not safety related or necessary for the safe shutdown of the reactor.

In addition, a reservoir is provided in the RHR complex. This is a Category I reservoir that is part of a closed cycle system that is not dependent upon natural bodies of water for makeup. The design basis for this complex in relation to water levels is described in Section 3.4.

2.4.9. Channel Diversions

The plant does not use water from channels; therefore, this subsection is not applicable.

2.4.10. Flooding Protection Requirements

All safety-related plant features are designed to withstand combinations of flood conditions and wave runup as discussed in Subsections 2.4.2.2 and 2.4.5.4. Protection of safety-related structures and components, including the effects of floods and waves, is discussed in Section 3.4 and Subsection 2.4.5.7.

2.4.11. Low Water Consideration

2.4.11.1. Low Flow in Rivers and Streams

Plant water sources are not related to the flow of rivers and streams in the area, except to the minor extent that these flows affect the general water level of Lake Erie.

2.4.11.2. Low Water Resulting From Surges, Seiches, or Tsunamis

2.4.11.2.1. Minimum Monthly Mean Lake Level

A summary of the historical minimum monthly mean lake levels was recorded by the U.S. Lake Survey during the period 1860 to 1973 and is presented in Figure 2.4-9. The minimum historic monthly mean lake level was reduced by approximately 40 percent of the recorded range of low water conditions (0.9) to give a minimum monthly mean design lake level of -1.5 ft below Low Water Datum.

2.4.11.2.2. Wind Setdown

Using the computer model prepared by Platzman (Reference 14 and Subsection 2.4.5.1), values were obtained for winds of varying speed from a westerly direction. Calculations based upon U.S. Weather Bureau data at Asheville, North Carolina, indicate that westerly winds of 70 mph sustained over a period of 6 hr would have a recurrence interval of one in 250 years. Using these values, the decrease in water level resulting from wind setdown at the site would be -9.2 ft (Elevation 561.3 ft).

Based upon probable maximum estimates of westerly winds furnished by the AEC, maximum wind setdown of the lake water level was calculated by Platzman's method (Reference 14) as -11.2 ft. The selected design wind setdown is -11.6 ft (Elevation 558.9 ft). This is identical to the calculated design PMME storm surge except with a minus instead of a plus sign.

2.4.11.2.3. Local Seiches and Tsunamis

For the same reasons as given in Subsections 2.4.5.2.3 and 2.4.6, no decrease in water level is assumed to occur from seiche and tsunami activity.

2.4.11.2.4. Design Level

Assuming that the effect of wind setdown occurs simultaneously with extreme minimum monthly lake levels, the resulting design stillwater level is Elevation -13.1 ft (Low Water Datum), or Elevation 557.4 ft.

The cooling water supply for safety-related systems is provided by the RHR complex, which contains its own water reservoir and is independent of ground water or lake-water level conditions. See Subsection 9.2.5 for a discussion of the RHR service water system.

2.4.11.3. Historical Low Water

The lowest observed monthly mean lake level during the period of record (1860 to 1973) was during February 1936, when Elevation -1.2 ft (Low Water Datum) was recorded. Low lake levels are generally recorded during the month of February. The most extreme setdown on record (1897 to present) was -7.1 ft on March 22, 1955. This level was calculated from gage records obtained at Gibraltar and Toledo.

If coincident occurrence of the minimum historical lake level and setdown is assumed (-8.3 ft), a minimum probable low water elevation of 562.2 ft is obtained. The conservatism of the design values is realized by comparing these figures with the respective -1.5-ft and -11.6-ft values that were combined for the design level elevation of -13.1 ft.

2.4.11.4. Future Control

There is no future control anticipated for Lake Erie (Reference 23). Drainage improvements on Swan Creek have been made, but no additional controls are planned (Reference 24).

2.4.11.5. Plant Requirements

As described in Subsection 9.2.5, the cooling water supply for safety-related systems is provided by the RHR service water system, which contains its own water reservoir and is independent of ground- or lake-water supplies.

The main plant cooling water supply is provided by the circulating water pond (Subsection 10.4.5) and requires only makeup water from Lake Erie.

2.4.11.6. Heat Sink Dependability Requirements

The RHR complex contains the ultimate heat sink for Fermi 2, which is the RHR service water system. The RHR complex includes a man-made structure with a self-contained reservoir and is discussed in Subsection 9.2.5. This service water complex is independent of local water-level conditions.

2.4.12. Environmental Acceptance of Effluents

Discharge of liquid radwaste effluents is through a decant line into Lake Erie. The release point is indicated in Figure 2.1-5. Liquid effluent accidentally released at the surface from the plant eventually flows either eastward into Lake Erie or into the north lagoon after percolation downward through the crushed-rock fill. The configuration of the surface-area drainage pattern does not permit flow westward toward inland areas. Since the lagoon drains into the lake via Swan Creek, liquid surficial discharges would ultimately reach and be diluted by waters of Lake Erie. Any percolation into ground water ultimately reaches Lake Erie (Subsection 2.4.13). The locations and users of surface and ground water pertinent to effluent releases from the plant are provided in Subsections 2.4.1.2 and 2.4.13. The effects of plant effluent releases to Lake Erie were examined by calculating dilution factors at the Monroe intake and the Toledo intake.

Studies of the currents and dilution capacity of Lake Erie were made by Ayers (Reference 25) who found that except under ice-cover conditions there are two primary current patterns, northward and southward, with a velocity range from 0.1 to 0.3 mph. During ice-cover periods, the current is predominantly southerly with a velocity of less than 0.1 mph. The probable percentages of occurrence of the current patterns are 30 percent, southerly; 50 percent, northerly; and 20 percent, phase system. The duration of ice-cover ranges from 1 to 4 months.

Based on Ayers' measurements, dilution factors for the Monroe intake and the Toledo intake were estimated and are summarized in Table 2.4-6. The dilution factors were determined using the plant blowdown discharge line into Lake Erie as the effluent release point.

The annual average dilution factor was calculated on the basis of 40 percent (southerly) and 60 percent (northerly) current directions, with an ice-cover duration of 2 months occurring during southerly current conditions. Current velocities used in the calculations are 0.394 fps under ice-free conditions and 0.117 fps under ice-cover conditions. The worst condition for dilution factors is based on a southerly current under ice-cover conditions with a current velocity of 0.04 fps.

The subsurface diffusion of accidental releases of liquid radioactive effluents is considered in Subsection 2.4.13.

2.4.13. Ground Water

2.4.13.1. Description and Onsite Use

Ground water is not used as a source of water supply for the plant. Ground water features are subsequently described.

2.4.13.1.1. Regional Ground Water Features

The project area is located in the eastern lake section of the central lowlands physiographic province (Figure 2.5-1). Bedrock formations dip northwest into the Michigan Basin. They are generally covered by glacial drift deposits that vary considerably in thickness and composition. The bedrock topography at the base of the drift is irregular as a result of erosion and differential scouring by Pleistocene glaciation.

The drift deposits range from nearly impervious till to coarse channel deposits of gravel and boulders. To the northwest of the site, drift deposits occur that are sufficiently thick and permeable enough to allow development of ground water. To the south, soluble limestone and dolomite formations compose the principal aquifers. The distribution of these regional aquifers, as described by the USGS (Reference 26), is shown in Figure 2.4-23. Regional aquifers capable of furnishing public ground water supplies do not exist near the site because the bedrock formations are not highly pervious and contain poor quality water. The drift is thin and consists of nearly impervious till. Ground water conditions in Monroe County are described by Sherzer (Reference 27) and by Mozola (Reference 11).

Bordering Lake Erie and surrounding the site area are soils associated with former higher stages of Lake Erie. The soils are thin, generally organic, and do not serve as aquifers. The soil units are described in Subsection 2.5.1.1.2. Geologic units in the site region, principally the bedrock formations, are described in detail in Subsection 2.5.1.1.

2.4.13.1.2. Local Ground Water Features

In the site area, geologic units consist of bedrock formations that are overlain by thin and nearly impervious till and lacustrine deposits (Subsection 2.5.1.2). At the site, the lacustrine and till units have been partially excavated and replaced with crushed-rock fill (Subsection 2.4.1.1).

The till and lacustrine deposits are too thin and impervious to serve as aquifers. They are about 14 ft thick at the site. Descriptions of these deposits are given in Subsection 2.5.1.2.7.

The test borings explored the bedrock formations beneath the site to depths of 324.7 ft, penetrating the Bass Islands Group and part of the Salina Group. The formations dip slightly to the northwest (Subsection 2.5.1.2.3.2). The uppermost bedrock formation at the site is the Bass Islands Group; the upper surface of the Bass Islands is erosional and somewhat irregular. It is covered with till and lacustrine deposits less than 20 ft thick. At the site, the upper surface of the Bass Islands is about 550 ft elevation (Subsection 2.5.1.2.2) and exists to a depth of about l00 ft (Figure 2.5-15). It is directly below glacial drift in a 7-mile-wide band bordering Lake Erie (Figure 2.5-5). The Bass Islands Group consists of thin-bedded, fractured, locally vuggy, gray-brown dolomite, with carbonaceous shale partings. The formation is described in greater detail in Subsection 2.5.1.2.2. The Bass Islands Group comprises a confined aquifer at the site. During the exploration borings program, there was artesian flow from a number of borings penetrating the Bass Islands Group (Figures 2.5-24 through 2.5-56). Ground water in the Bass Islands Group is confined by the overlying till and lacustrine deposits. During construction dewatering, the ground water is drawn down below the confining layer.

Below the Bass Islands Group are fractured limestone and dolomite formations of the Salina Group. The Salina Group formations appear to comprise aquifers even in the argillaceous beds because test borings at the plant site encountered artesian flows from them.

Water quality was sampled at various zones. The water is highly mineralized. Sulfate content was similar in all formations. Results of the chemical analyses of the zones tested are shown in Table 2.5-16 and discussed in Subsection 2.5.1.2.4.

The aquifers receive recharge by infiltration of precipitation on higher ground areas west of the site as indicated by a mapping of the regional ground water level, shown in Figure 2.4-24. Because the ground water surface approximates the shape of the land surface, water apparently can percolate through the till. The map was prepared from water levels measured in wells completed within the Bass Islands dolomite. These well locations are shown in

Figure 2.4-25. Water-level measurement data for the wells are presented in Table 2.4-7. The slope of the water level toward Lake Erie indicates that the lake comprises the ultimate sink for ground water flow.

The permeability data developed from pressure tests of borings at the Fermi site are described in Subsection 2.5.4.6. Of 29 tests in four borings, permeability varied from 210 to 2220 ft/yr. The average was 763 ft/yr. Because permeability is developed in rock joints and fractures, it can vary considerably from place to place.

Ground water is not a water supply source for the plant or any of its supporting facilities.

2.4.13.2. Sources

All municipal supplies within 25 miles of the site are from streams or lakes (Reference 28). In areas not served by municipal water systems, water supplies for domestic use are generally obtained from private wells. There are no industrial or municipal water wells in the site area (Reference 7). The network of private wells presently in use forms the source of water for domestic and livestock purposes in farms and homes west and north of the site, and for residences in the Stony Point area to the south, where the largest concentration of wells in the area occurs. The distribution of private water wells surrounding the site area is shown in Figure 2.4-26. This figure shows that there are about 4000 wells within 10 miles of the site. A survey of available drillers' records on approximately 400 wells in the site vicinity, filed at the Michigan Department of Natural Resources, shows that well depths generally do not exceed 70 ft. The wells are 4 to 6 in. in diameter, drilled into dolomite bedrock, and cased only through overburden soils into bedrock. Casings are uncemented, and the remainder of the hole below the casings is left open. Pumps are submersible or centrifugal (suction) type, having a capacity of about 10 gpm or less. The pumpage of water per well is probably on the order of 200 to 400 gal per day, typical of residential use. A certain amount of seasonal variation in water use can be expected because in summer months lawns and gardens are irrigated.

There has been virtually no long-term ground water level decline in the site area. The largest concentration of wells is in Stony Point. Pumping there may have lowered the water levels by 5 to 10 ft, on the basis of water levels reported on numerous drillers' logs since the 1940s. The radius of influence of pumping from these wells cannot be detected more than 1 mile away from Stony Point, on the basis of water-level data. Pumping from an onsite rock quarry operation in 1969-1972 caused a temporary lowering of water level. Pumping was terminated in June 1972 and the abandoned quarry was allowed to fill with ground water. The piezometric surface in the vicinity of the quarry returned to its normal level by the summer of 1973. The ground water level was monitored during the quarry dewatering and the data are shown in Table 2.4-7. Water level in the quarry is now approximately at land surface.

At the site, the confining layers have been stripped to permit the excavation for subgrade structures constructed in the aquifer. Backfill around the completed structures will not permit percolation into the aquifer at the site (Subsection 2.4.1.1).

The water use trend in the area is from ground water to surface water. The low transmissibility of the formation will not permit large-yielding water wells. Undesirable water quality is typical. As described in Subsection 2.5.1.2.9 and noted on boring logs, the ground water is high in sulfate content and hydrogen sulfide. Many neighboring communities, for example Woodland Beach and Berlin Township, have recently abandoned individual water wells in favor of a surface-water treatment-distribution system. Because surface water is available from nearby municipal systems for the communities in the area, the trend of increasing surface-water use and decreasing ground water use can be expected to continue in dense population areas. Isolated homesites, as on farms, will probably continue to use ground water.

Because of the trend toward decreasing use of ground water, it is improbable that any significant change in ground water gradient will occur from well pumping. The gradient is radially out from the deep foundations of Fermi 2. There are no domestic wells downgradient from the site. If, for any reason, a reversal of ground water gradient from the site to the water wells were to occur, it would have to be for some reason other than pumping from the wells. This is true because, in order to create a gradient from the site to the water wells, the water level at the wells would have to be drawn down below their depth. It is therefore considered highly improbable that there will be any ground water condition in the future resulting in gradient reversal from the site toward the water wells.

The regional lakeward gradient is shown on the contour map of Figure 2.4-25. Water-level data used to prepare the map are shown in Table 2.4-7. Water levels at the site were depressed as a result of dewatering for Fermi 2 quarry operation. Prior to construction of Fermi 2, water flowed naturally from many of the borings in the area, as indicated on the boring logs in Figures 2.5-24 through 2.5-56. On the basis of the above-grade static level implied by these flows and water levels in wells in peripheral areas, it is suggested that ground water level at the site is normally above 575 ft.

Water levels in wells fluctuate seasonally, generally highest in spring and lowest in fall. Seasonal fluctuations are not related to Lake Erie fluctuations, although seasonal peaks are somewhat coincidental. The Lake Erie fluctuations are of lower magnitude (Subsection 2.4.2) than ground water fluctuations. It is suggested that the fluctuations coincide because both water bodies respond to the same influences of recharge and evapotranspiration. Water-level fluctuations in the site vicinity since 1970 are provided by the data in Table 2.4-7.

The nearest government agency observation well is approximately 20 miles to the west, in the Dundee area. It is monitored by the USGS. Because the well is completed in glacial drift, water-level fluctuations in the well cannot be considered representative of water-level fluctuations that would occur in the bedrock formation wells in the site area.

Flow rates within the aquifer are highly variable, owing to the fractured and jointed nature of the bedrock. The width, density, and directional pattern of openings can vary from place to place, as indicated by exposures of rock in excavations of the Fermi 2 site and in the onsite rock quarry to the south. An average velocity of flow in the bedrock aquifer is derived on the following basis:

Porosity, n = 0.01, conservatively assumed (Reference 29)

Permeability, k = 2 ft/day, from tests in borings

Hydraulic gradient, $I = \frac{3 \text{ ft}}{2{,}500 \text{ ft}} = 0.0012,$ determined between wells 17M2 and 17Q1 (12/31/1973)

Velocity, V = kI/n = 0.24 ft/day

It is noted that the natural water-level gradient at the site is not available owing to construction dewatering at Fermi 2.

2.4.13.3. Accident Effects

Ground water conditions of the site (Subsection 2.4.13.1) consist of a bedrock aquifer confined under artesian pressure beneath a cap of relatively impervious glacial deposits. Under natural conditions, the ground water gradient is radially out from the deep foundations of Fermi 2.

In the unlikely event of an earthquake, minor cracking in the walls of at least the subgrade portion of the radwaste building structure could occur. The radwaste liquid storage tanks could also undergo stress cracking and leaking to allow fluid flow between the interior of the structure and the surrounding earth. Initially, liquid would be retained within the structure and diluted by inflowing ground water from the dolomite aquifer in contact with the structure. There would be a slow inflow of ground water and the water level inside the structure would rise until it attained the elevation of the piezometric level of the aquifer, approximately Elevation 575.0 ft. At this time, the radioactive material will have been diluted 10:1 or greater.

The time required to fill the structure would be on the order of 3 to 4 weeks. This length of time is determined on the basis of the following information:

a. During construction dewatering of the reactor building basement, pumping was stopped overnight and on weekends. The excavation became flooded up to 3 ft as a result of inflowing ground water. On one such occasion, the water-level rise in the excavation was measured. The rate of rise was 0.0281 ft/hr

b. It is assumed that this same rate of rise could occur in the radwaste building excavation, but adjusted to account for the space occupied by masonry and equipment, which is approximately one-third of the total floor area. The adjusted rate of rise is somewhat higher, almost 0.042 ft/hr

c. The rate of rise decreases continuously as the water level in the structure approaches ground water level. The assumption of a steady rate of water level rise of 0.042 ft/hr is therefore conservative.

During the 3- to 4-week period during which water is rising in the structure, equipment can be mobilized for pumping, storage, processing, and disposal of radioactive material.

If the structure is allowed to fill completely, diluted material would move into and through the aquifer at the same rate of flow and direction of movement as the existing ground water in the aquifer. The direction of movement to the perimeter of the owner controlled area would be east at a rate of 0.24 ft/day (Subsection 2.4.13.2) and would eventually discharge into Lake Erie.

The length of time required to travel the 460-ft distance from the structure to the Lake Erie shoreline is 1920 days. By this time, the specific activity of the radioactive material will have been below the limits set forth in 10 CFR 20. (For details of this accident analysis, see Subsection 15.7.3.)

For a discussion of flood protection of the onsite storage building, see Subsection 11.7.2.2.5.

2.4.13.4. Monitoring and Safeguard Requirements

It was demonstrated in Subsection 2.4.13.2 that no water wells are located downgradient from the site. As part of the operational radiological environmental monitoring program, Edison will measure the water level monthly in existing observation wells. The comparison of the data will show flow reversal if it occurs. Should a reversal in flow occur, grab samples would be taken and analyzed for gross beta and gamma isotopes if a path is available from the plant to the ground water. Results would be reported in accordance with the requirements of the Technical Specifications 5.6.2 and 5.6.3.

Under accident conditions, postulated in Subsection 2.4.13.3, monitoring wells will be drilled between the affected structures and the Lake Erie shoreline to monitor subsurface travel and dispersion of radioactive material. Exploratory drilling experience at the Fermi site indicates that truck-mounted drilling rigs are available from Detroit and Toledo and that an observation well could be drilled within several days.

2.4.13.5. Design Bases for Subsurface Hydrostatic Loadings

As described in Subsection 2.4.13.2, the natural ground water level at the site is on the order of 575 ft. As a conservative value for computing normal subsurface hydrostatic loadings, the ground water level is assumed to be 576.0 ft.

Because of the ground-level conditions, construction dewatering is necessary during all major building excavations. In the Fermi 2 construction, dewatering was done by sump pumps placed in the excavations. At the reactor building, grout curtains were installed to minimize ground water inflow and to prevent seepage that would cause falling rock from the walls of the excavations. The Fermi 2 reactor building excavation is 204 by 154 ft, with floor elevations of 540.0 and 551.0 ft.

Bedrock beneath the structure is dolomite, and was pressure grouted for added strength. The dewatering does not affect the structural integrity of the rock. All major safety-related structures have their foundations on bedrock and not within the overburden soils or drift (Subsection 2.5.4.11).

Water supply wells will not be used at the facility.

2.4.14. Technical Specifications and Emergency Operation Requirements

Fermi 2, together with its associated safety-related facilities, is designed to function in a safe manner despite the occurrence of any of the adverse hydrologic events previously discussed. These events have been postulated to occur in appropriate combinations, and such provisions for the safe operation of the plant have been incorporated into the design.

2.4.14.1. Flooding

The probable maximum water levels in Swan Creek resulting from precipitation or flood are discussed in Subsection 2.4.3. These levels are less than those anticipated from the probable maximum surge on Lake Erie.

2.4.14.2. Dam Failures

Potential dam failures are discussed in Subsection 2.4.4. It has been found that there are no regulatory structures on Swan Creek. In addition, there are no dams on other streams and rivers in southeastern Michigan, the failure of which would affect water levels in Lake Erie along the plant shoreline.

2.4.14.3. Surge and Seiche Flooding

The PMME is caused by storm surge. This event, discussed in Subsection 2.4.5, causes a stillwater level at the site of 586.9 ft, or 3.9 ft above plant grade elevation. As described, the Category I structures are designed for the PMME flood level plus runup from small waves generated on the flooded site. The openings in the structures are watertight and designed for the high-water levels.

The water levels associated with the seiche, discussed in Subsection 2.4.5, have been found to be less than the storm surge.

2.4.14.4. Tsunami

Tsunami is discussed in Subsection 2.4.6. Water levels associated with this event have been found to be less than for the storm surge.

2.4.14.5. Ice Flooding

Ice flooding is discussed in Subsection 2.4.7.

TABLE 2.4-7 WATER WELL DATA[a]

Map Reference Number	Well Number	Depth (ft)	Elevation of Water Level (ft)	Date

[a] Shown in Figure 2.4-25.

[b] Not shown in Figure 2.4-25.

[c] Monitor wells are underlined.

Explanation of well numbering system:

The well locations are identifiable by the well number. The well numbering system, which is commonly used by water resource agencies, including the U.S. Geological Survey, designates the location of the well within a 40-acre parcel of land. The standard one-square-mile section is subdivided into 40-acre parcels as follows:

D	C	B	A
E	F	G	H
M	L	K	J
N	P	Q	R

As an example, suppose a given well is located as follows:

a. Township 7 South

b. Range 10 East

c. Section 32

d. northeast corner.

That well would be given the number, 7S/10E-32A1.

The number 1 following the letter A indicates that this is the first well inventoried in the 40-acre parcel lettered A.

All the wells within the immediate vicinity of the site are shown in Figure 2.4-25. These wells are identified and located by the last two digits of the previously described well numbering system and listed under the heading, "MAP Reference Number."

2.5. GEOLOGY AND SEISMOLOGY

The Fermi site is located on the shore of the western end of Lake Erie at Lagoona Beach, Frenchtown Township, Monroe County, Michigan. Geologic and seismic studies of the Fermi site were conducted for Fermi 2 in 1968 and 1969. Detailed foundation studies were performed for the Fermi 2 reactor/auxiliary building in 1969, and rock foundation grouting for these structures was performed in 1970. Detailed foundation studies were performed in 1972 for the Fermi 2 residual heat removal (RHR) complex. Foundation grouting for the RHR complex has been completed. The geologic, seismic, and foundation studies for Fermi 2 were conducted by Dames & Moore (D&M) with the results of a few of the studies presented in the Fermi 2 PSAR. The location of Fermi 2 is shown in Figure 2.4-1. The topography of the site with the location of the principal plant facilities is shown in Figure 2.4-3.

The site is located within the Central Stable Region tectonic province of the North American continent. Some regional faulting and seismic activity is known, but the region is characteristically one of relative stability. There are no known faults within 25 miles of the site and there are no capable faults within 200 miles of the site.

Approximately 3100 ft of Paleozoic sedimentary rocks overlie the Precambrian basement in the area. Overlying the Paleozoic sedimentary rock strata are Pleistocene soils of glacial origin that are less than 20 ft thick at the site. The site is located on the southeast side of the Michigan Basin. The sedimentary rock strata generally dip to the northwest toward the center of the Michigan Basin. The bedrock immediately underlying the site consists of dolomites of the Bass Islands Group of the Silurian System. The Bass Islands Group is competent dolomite with thin shale beds and is variably fractured and contains some vuggy zones. No geologic conditions are known that could have an adverse effect on the safety of plant facilities.

All major Fermi 2 Category I structures are supported in the Bass Islands dolomite. Foundation pressure grouting of the bedrock was performed to improve subsurface conditions. A test blasting program was conducted, and blast monitoring was provided during construction. Criteria for foundation treatment and design were formulated, based on foundation studies performed at the locations of Category I and other major structures.

All Category I structures are designed to respond to peak horizontal ground accelerations of the rock surface at foundation levels of 8 and 15 percent of gravity for the operating-basis earthquake (OBE) and safe-shutdown earthquake (SSE), respectively. Site-related response spectra were used to analyze the response of structures to earthquake ground motion.

The results of the geologic and seismic studies for Fermi 2 are summarized in Subsections 2.5.1 through 2.5.3. The stability of subsurface materials at the locations of Fermi 2 Category I and major structures is summarized in Subsection 2.5.4.

2.5.1. Basic Geologic and Seismic Information

Basic geologic and seismic data were obtained by D&M for the Fermi site from 1968 through 1972 in three major programs:

a. Geologic and seismic studies in 1968 for the Fermi 2 site

b. Foundation studies in 1969 for the reactor/auxiliary building

c. Foundation studies in 1972 for the RHR complex.

The general scope of these studies is outlined in the following paragraphs.

The geologic and seismic program of investigation conducted in 1968 at the Fermi site for Fermi 2 (Reference 1) included the following:

a. A thorough review of pertinent geologic literature (published and unpublished) and interviews with university and state geologists

b. A geologic reconnaissance of the site and surrounding area, and a review of maps and aerial photographs

c. Field explorations that were performed to evaluate the geologic and seismologic characteristics of the site, consisting of the following:

    1. Geologic test boring program
    2. Geologic inspection of the site and surrounding area
    3. Geophysical refraction survey
    4. Blast monitoring observations
    5. Micromotion measurements
    6. Borehole geophysical measurements
    7. Ground water observations

d. A laboratory soil- and rock-testing program for Fermi 2 was conducted.

In 1969, a comprehensive foundation investigation was performed at the Fermi 2 reactor/auxiliary building and adjacent structures (Reference 2). The field explorations consisted of the following:

a. Test boring program

b. Water pressure testing in selected borings

c. Ground water observations

d. Ground water sampling.

Laboratory testing during this investigation consisted of density and unconfined compression tests on selected rock cores and chemical analyses of ground water.

In 1972, a comprehensive foundation investigation was performed at the location of the Fermi 2 RHR complex (Reference 3). The field exploration program consisted of the following:

a. Test boring program

b. Water pressure testing

c. Piezometer installation

d. Geologic reconnaissance.

Laboratory testing for this investigation consisted of pulsating load triaxial tests, unconfined compression tests, consolidation tests, moisture-density tests on soil samples, and unconfined compression tests on rock cores.

Supplementary seismic evaluations were completed for the Fermi 2 site in October 1982 by Weston Geophysical Corporation. These evaluations led to the establishment of facility site specific response spectra that were subsequently used to validate the satisfactory nature of the original facility design-basis earthquake provisions. The site-specific earthquake was characterized in terms of Richter magnitude (from 4.9 to 5.9) and epicentral distance (25 km). Site-specific response spectra were developed from real-time histories for the appropriate magnitude and distance, and foundation conditions similar to the Fermi site. (Weston Geophysical Corporation, Draft Site Specific Response Spectra for Enrico Fermi 2; October 1982.)

2.5.1.1. Regional Geology

2.5.1.1.1. Physiography

The Fermi site is located in the northern portion of the midwestern United States in the Central Lowlands Physiographic Province. This physiographic province has been subdivided into eight physiographic sections. Michigan is located in the Eastern Lake Section (Figure 2.5-1).

The Eastern Lake Section is characterized by glacial landforms (including end moraines, ground moraines, outwash plains, kames, eskers, and drumlins) and by beach and lacustrine deposits formed during the fluctuations of the Great Lakes. The glacial deposits overlie maturely dissected bedrock cuestas and broad areas of relatively flat-lying bedrock. The bedrock is exposed locally. The bedrock surface was dissected prior to being covered with glacial drift. The rock surface tends to be gently rolling with well-developed valley systems.

The Fermi site is located on a lake plain formed during the high-water stages of Lake Erie. There is little topographic relief on the lake plain, which results in poor surface drainage. It has been dissected by eastward-flowing creeks and rivers. The relief on the lake plain within the vicinity of the project area is approximately 25 ft.

2.5.1.1.2. Stratigraphy

2.5.1.1.2.1. Soil Units

The soil units in the region include Pleistocene-aged deposits consisting of alluvium, lacustrine materials, peats, tills, outwash, glaciofluvial materials, glaciolacustrine materials, and residual soil. Figure 2.5-2 shows the distribution of surface Pleistocene glacial deposits of the southern peninsula of Michigan and portions of surrounding states. The site area is located in a glaciolacustrine section on the western edge of Lake Erie. The distribution of surface soil units within eastern Monroe County is shown in Figure 2.5-3. The soil deposits in Monroe County range in thickness from 0 to over 150 ft (Reference 4).

2.5.1.1.2.2. Rock Units

The distribution of the rock units that form the bedrock surface within the region is shown in Figure 2.5-4 and the stratigraphic sequence of the various-aged rock units is shown in the legend. The rock units in the Michigan Basin consist of sedimentary strata of Jurassic, Pennsylvanian, Mississippian, Devonian, Silurian, Ordovician, and Cambrian ages, as well as an igneous and/or metamorphic complex of Precambrian-aged rocks.

The sedimentary sequence in the Monroe County area includes Devonian- through Cambrian-aged strata. The local distribution of these strata is shown in Figure 2.5-5. These strata consist of 2500 to 3500 ft of limestones, dolomites, sandstones, and shales. The Precambrian basement in southeastern Michigan consists of crystalline rocks of igneous and metamorphic origin (Reference 4) and occurs at a depth of about 3100 ft.

2.5.1.1.3. Structural Geology

The Fermi site is located within the Central Stable Region tectonic province of the North American continent. This tectonic province is characterized by a thick sequence of sedimentary strata overlying the Precambrian basement. The Precambrian basement is exposed in Wisconsin, Minnesota, and the upper peninsula of Michigan. During Paleozoic and early Mesozoic time, the area was subjected to a series of vertical crustal movements that formed broad basins and arches. The arches and basins have been modified by local folding and faulting. Major geologic structures are shown in Figures 2.5-6 and 2.5-7. The relation between structures and gravimetric and magnetic anomalies is discussed in Subsection 2.5.1.1.5.2.

2.5.1.1.3.1. Folding

The distribution of major folds in the region is shown in Figure 2.5-6 and the characteristics of these folds are presented in Table 2.5-1. The Fermi site is located on the southeast side of the Michigan Basin, which corresponds to the northwest flank of the northeast-trending Findlay Arch. Ells (Reference 5) has proposed the name "Washtenaw Anticlinorium" to describe a broad northwesterly plunging structure in southeast Michigan that is composed of several smaller folds. This broad structural feature covers about 4500 square miles within Michigan and continues into Ohio, Ontario, and Lake Erie. Local structures within this broad structurally high region include the Howell Anticline, the Freedom Anticline, and the Lucas Monocline. The northwest-trending Howell Anticline is located north and northwest of the project area. The northwest-trending Freedom Anticline is located west of the project area, and the north-to-northwest-trending Lucas Monocline lies southeast of the project area and along the projected trend of the Bowling Green Fault.

The direction and amount of regional dip of the strata in south-eastern Michigan are variable. In the vicinity of the site, the strata dip northwest toward the Michigan Basin at 0.5° or less (Reference 4).

The Howell Anticline approaches to within about 25 miles north of the site and extends approximately 80 miles to the northwest. The northwest-southeast-trending fold is located on the southeast flank of the Michigan Basin and has a maximum structural relief, in the early Paleozoic rocks, of about 1000 ft (Reference 22 in Reference 5). The relief is less pronounced in the younger strata. It has been suggested that faulting is associated with the Howell Anticline (References 5, 6, and 7) as discussed in Subsection 2.5.1.1.3.2.

The Lucas Monocline is a north-to-northwest-trending series of folds in southeastern Michigan located approximately 30 miles southwest of the site. It has been inferred by Ells (Reference 5) that the Lucas Monocline may connect with or be associated with the Bowling Green Fault, which is mapped in northwest Ohio (References 6 and 8). Other researchers (Reference 9) have inferred that the Lucas Monocline is actually a fault structure. The folds bend northwestward in southern Michigan where they join the Freedom Anticline. The early Paleozoic rocks in this folded area have a maximum structural relief on the order of 500 ft.

The Chatham Sag (References 5 and 10) is a broad, gentle northwest-trending syncline that has been mapped as far south as the north shore of Lake Erie. The axis of the syncline lies about 50 miles northeast of the site. The Chatham Sag crosses the Findlay-Algonquin Arch System and is virtually unrecognizable in the early Paleozoic strata. A system of small faults, the most prominent of which is the Electric Fault, is associated with this structure.

Several small earthquakes have occurred near the juncture of the Findlay, Cincinnati, and Kankakee Arches. These earthquakes cannot be associated with any known structures, but are believed to have occurred along a zone of structural weakness that separates the three arches.

A portion of the U.S. Geological Survey (USGS) tectonic map of the United States is shown in Figure 2.5-8. This map shows the detail of some of the structural features in the Michigan Basin area.

2.5.1.1.3.2. Faulting

The distribution of major faults in the region is shown in Figure 2.5-7, and their characteristics are presented in Table 2.5-2. The Bowling Green, Electric, Tekonsha Trend, and Albion-Scipio Trend faults are the four major faults within 100 miles of the project area.

The Bowling Green Fault is located approximately 35 miles southwest of the site. It has been inferred by some workers (Reference 9) that faulting extends northward into southeast Michigan. Some (Reference 5) have inferred that major faulting is not present in this area in Michigan and have interpreted the structure to be a result of folding. Others (Reference 11) believe no major faulting to be affiliated with the structure at all, and interpret it as being a monocline.

Since the very existence of the fault is in question, no clear-cut evidence is available that would either indicate age of last movement or definition of the fault. For purposes of conservatism, the Bowling Green structure is assumed to be a fault. The fault is not believed to extend into Michigan (Reference 12). The evidence available for faulting is described as follows (Reference 7):

> A drop by faulting of more than 200 feet in the top of the Trenton Limestone is indicated between well locations in the vicinity of Findlay, Cygnet, and Bowling Green, Ohio. The fault which is down-thrown on the west extends northward and connects with the Lucas County (Ohio) - Monroe County (Michigan) monocline.

Thus, the only evidence of the age of last faulting is Middle Ordovician (based upon evidence in the Trenton Limestone).

Evidence of faulting along the west flank of the Howell Anticline has been presented (References 7 and 13) and it has been suggested that total vertical displacement may be as much as 1000 ft (Reference 13). The type of faulting, amount of displacement, and orientation have not been absolutely determined. More recent work (Reference 5) has revealed that faults of major displacement are not believed to exist in connection with the immediate west flank of the Howell Anticline and it is shown that, although minor faulting may have occurred along the west flank or across the structure, it is not of the magnitude generally described by earlier investigators. Developments of the Howell Anticline associated with major faulting may have begun as early as Late Ordovician and continued throughout most of the Paleozoic. If the presence of Jurassic-aged rock in the Michigan Basin is considered, developments may have taken place as late as Cretaceous time. The age of last faulting within the State of Michigan, however, appears to be Paleozoic (Reference 14).

A system of faults located 45 miles northeast of the site is associated with the Chatham Sag. The Electric Fault in this fault system has a reported maximum vertical displacement of 300 ft (Reference l5). Maximum displacements of less than 100 ft have been reported for other faults in this system (Reference 15).

Faulting has been postulated along the Tekonsha oil field structure, and several small seismic events have been tentatively correlated to these. The structure trends northwest-southeast for an inferred length of 60 miles. Only limited, minor structural indications of this fault have been recorded.

The age of the faulting in the southeastern portion of the Michigan Basin is assumed to be Ordovician, although some evidence exists of minor movement in post-Ordovician time (Ells, personal communication).

The Keweenawan-Lake Owen Fault System lies northwest of the Michigan Basin, approximately 430 miles northwest of the site. It has a northeast trend on the Keweenawan Peninsula in Lake Superior. Vertical displacements on this fault system of a few thousand feet to more than 9000 ft are known (Reference l6). This fault system is not associated with the Michigan Basin.

The Rough Creek-Kentucky River Fault System in southern Illinois and central Kentucky is approximately 350 miles south of the site.

2.5.1.1.3.3. Pop-up and Affiliated Structural Features

Pop-up features in bedrock have been identified in various parts of western New York State, and in Canada. The existence of several of these features has been documented (Reference 17) in various parts of the North American continent and their existence has been attributed to the release of postglacial horizontal compressive stresses. In addition to occurring in regions where activities of Man have been limited, these and affiliated phenomena have been seen in man-made structures such as excavations into bedrock.

Actual pop-ups have not been noted in southeastern Michigan or adjacent portions of Ohio, Indiana, or Canada, but surficial folding of Devonian shales has been observed in northwestern Ohio.

Although pop-ups have not been specifically documented in the site region, pop-ups or "heave" are fairly common occurrences in quarries in a wide range of localities due to a reduction of lithostatic load.

The small mound-like features noted during the mapping of excavation at the site are believed to be of organic origin. During the excavation process, no rockbursts, pop-ups, or heaves were seen. This can be attributed to a lack of compressive stresses as described in Reference 17 and insufficient depth of excavation to reduce lithostatic loading sufficiently to cause such features to occur.

2.5.1.1.4. Ground Water

In the region surrounding the site, ground water aquifers are present in two types of material: glacial outwash deposits and Paleozoic bedrock. An expanded discussion of regional ground water conditions is found in Subsection 2.4.13.

2.5.1.1.5. Geologic History

2.5.1.1.5.1. General

The study of geologic history provides an insight as to the tectonic stability of a region and a better understanding of stratigraphic relationships between various soil and rock units. It also furnishes correlative data that assist in the interpretation of events in adjacent regions.

An accurate interpretation of geologic history is the result of years of cumulative effort. It is based on numerous examinations of soil and rock units in exposures, and from borings with regard to lithology and fossil content.

The generalized stratigraphic succession and the distribution of the bedrock units in Michigan are presented in Figure 2.5-4. They are composite in nature. The entire series of stratigraphic units is not likely to be encountered at any given locality; however, it is a graphic illustration of the changing geologic history. Individual time units are discussed in the following paragraphs, and the tectonic and structural features mentioned are shown in Figures 2.5-6 and 2.5-7.

2.5.1.1.5.2. Precambrian

The basement rocks of Michigan are Precambrian in age. They include granite, felsic and mafic gneiss, volcanics, metavolcanics, metasediments, mafic volcanics, and mafic intrusives (Reference 18). Radiometric dates range from approximately 600 to 3500 million years (Reference 19). These rocks represent a complex series of geologic events that include sedimentation, uplift and erosion, subsidence and deposition, mountain building, volcanism, and igneous intrusions followed by erosion, which have produced an irregular surface upon which the overlying Paleozoic sediments have been unconformably deposited.

The regional Bouguer gravity map (Figure 2.5-9) and the regional magnetic map (Figure 2.5-10) of the Southern Peninsula of Michigan substantiate the conclusion that the basement rocks are both structurally and lithologically complex. The Mid-Michigan Anomaly, the dominant feature of the gravity map and to a lesser degree of the magnetic map, has been interpreted by Hinze (Reference 20) as originating from the mafic rocks of Keweenawan age similar to those that outcrop in the Lake Superior region. This feature consists of a positive gravity anomaly and a correlative magnetic high. Pirtle (Reference 21) states, "...it is believed that the principal folds now existing in the later sediments are controlled by trends of folding or lines of structural weakness which existed in the basement rocks." This opinion is still the prevalent one shared by most workers (Reference 20). The most obvious example of this correlation is the alignment of the Washtenaw Anticlinorium with the Mid-Michigan Anomaly in Washtenaw and Livingston Counties.

2.5.1.1.5.3. Cambrian

At the beginning of the Cambrian Period, a mountainous belt extended across most of the Upper Peninsula of Michigan. Erosion of topographic highs dominated while clastic sediments accumulated in the surrounding lowlands.

Paleozoic deposition in southern Michigan began when Late Cambrian seas spread across the interior of the continent, depositing clean sandstones, dolomites, and limestones characteristic of shallow, clear seas with bordering land masses of low relief.

The accumulation of sediments in the Michigan Basin originated with Late Cambrian subsidence. During this period of geologic history, the Michigan and Illinois Basins were not separated. This early, undifferentiated basin is known as the Eastern Interior Basin.

2.5.1.1.5.4. Ordovician

The Ordovician was the period during which Paleozoic seas became fully established in Michigan.

The variable nature of the rocks in southern Michigan, as revealed by deep-boring data, suggests fluctuating marine conditions. Deposition of Lower Ordovician dolomite and sandstone indicates that seas were present in the Lower Peninsula while absent in the Upper Peninsula. Two regressions of the sea during the Ordovician are indicated by unconformities within the sedimentary sequence of southern Michigan, one at the top of the Prairie du Chien Group during the Early Ordovician and the other at the top of the Eden Group during the Late Ordovician.

2.5.1.1.5.5. Silurian

Seas persisted in Michigan from Ordovician into Silurian time. Apparently, the entire state was occupied by offshore waters so that the Silurian marine deposits in Michigan are mainly chemical precipitates formed in clear seas. Locally, shallow banks supported reefs. It is believed that coral reef formations along the margins of the Michigan Basin effectively isolated the basin area from the main marine body and formed an evaporation basin. Great accumulations of Silurian salt, anhydrite, and gypsum were formed.

The Silurian was a time of accelerated downwarping of the Michigan Basin. Slight expressions of the Findlay and Kankakee Arches are seen in the Upper Silurian sediments in the southeast and southwest corners of Michigan, respectively.

Near the close of the Silurian Period, the seas withdrew from the Michigan Basin.

2.5.1.1.5.6. Devonian

During Early Devonian time, the southeastern portion of the Michigan Basin was subjected to erosion and/or nondeposition. To the north and northwest, however, marine sedimentation continued.

By Middle Devonian time, the Michigan Basin was fully occupied by the sea, which deposited limestones and, finally, shales in a relatively shallow-water environment.

2.5.1.1.5.7. Mississippian

Marine waters that existed since Middle Devonian time continued into Early Mississippian time. Alternating shales, siltstones, and sandstones are representative of sediments of Mississippian age.

Tilting of the Michigan Basin area is believed to have occurred in Early Mississippian time, resulting in a marked expression of the Findlay Arch and possibly the northeast-southwest trending folds in the central portion of the Michigan Basin. Toward the close of Early Mississippian time, a major regression of the sea maintained much of southern Michigan as a near-shore and beach environment.

Middle Mississippian rocks are absent, which indicates that either there was no deposition due to a complete withdrawal of the sea from Michigan, or there was deposition and subsequent erosion.

Upper Mississippian deposits indicate a transgression of the sea. Some evaporite deposits similar to those found in Silurian sediments are present. Near the close of the period, the seas freshened and limestone was deposited.

In latest Mississippian time, the Michigan Basin was subjected to uplifting and folding that involved the Precambrian basement features. This activity produced many of the structures in Paleozoic rocks of the Michigan Basin in which gas and oil later accumulated (References 19 and 22).

2.5.1.1.5.8. Pennsylvanian

The pattern of alternating sedimentation established during the Mississippian Period continued into Pennsylvanian time and reached its peak with a characteristic cyclical sedimentation of alternating marine, brackish-water, and terrestrial deposits. Organic accumulation in the brackish-water swamps formed widespread coal beds.

From Pennsylvanian time to the Pleistocene Epoch, the area remained above sea level.

Erosion prevailed in post-Pennsylvanian time with the exception of some terrestrial sandstone and shale deposition during the Jurassic Period. The entire Mesozoic Era was relatively inactive, although broad uplift and some erosion did occur. Minor fault activity is believed to have taken place along the Keweenawan Fault System into Cretaceous time.

Geologic evidence suggests that southern Michigan existed as a low stable land mass for over 200,000,000 years, while the Appalachian Mountains, Rocky Mountains, and other structural features in North America were being formed or were undergoing additional movements.

2.5.1.1.5.9. Jurassic

The geologic record is almost completely missing from the end of Pennsylvanian time until the Pleistocene. The only rocks representing this long span of time are some sedimentary strata that for many years were referred to simply as "red beds." Their age was long uncertain but was thought to be Pennsylvanian. Early maps showed them as such. In recent years, fossilized microscopic plant spores have been found in well samples from the red beds. They have been identified as being Late Jurassic in age (Reference 19). Surface exposures of the rocks have not been found, and their presence beneath the glacial drift has been demonstrated only by well samples. The Jurassic red beds are normally about 100 ft thick, but in places attain thicknesses of 300 to 400 ft (References 19 and 22). The rock consists mainly of sandstone, shale, and clay, with minor beds of limestone and gypsum.

2.5.1.1.5.10. Pleistocene

Glaciation began during Pleistocene time some 1,000,000 years ago. In general, four distinct glacial advances are recognized throughout North America during this division of geologic history. From oldest to youngest, these are known as the Nebraskan, Kansan, Illinoian, and Wisconsinan glacial stages. There is positive evidence in Michigan for only the Wisconsinan glacial advance. However, Illinoian and Kansan glacial deposits are found to the south of Michigan in Ohio and Indiana. Therefore, it is reasonable to assume that Michigan was overridden by at least these two earlier advances as well (Reference 19).

The Wisconsinan glacial deposits blanket large portions of Michigan (Figure 2.5-2). These deposits represent a complex series of ice lobes that advanced and retreated a number of times. The ice sheets modified the Great Lakes basin and are responsible for almost all of the present-day surface topography.

2.5.1.2. Site Geology

2.5.1.2.1. Physiography

The site area (Figure 2.4-3) is located on a featureless lacustrine plain (Figure 2.4-1) along the western shore of Lake Erie. The plain was formed during the high-water stages of Lake Erie. It is essentially flat lying and generally poorly drained, but it has been slightly dissected along Swan Creek, which flows into Lake Erie at the northern edge of the Fermi site. The plain slopes gently to the east. The average elevation of the lacustrine plain is about 660 ft above mean sea level, or approximately 90 ft above mean lake level. The relief within the site boundaries is approximately 9 ft.

2.5.1.2.2. Stratigraphy

2.5.1.2.2.1. Soil Units

Local sand deposits are encountered in an old channel of Swan Creek at the north end of the site, and in the barrier beach, which forms the shoreline of Lake Erie at the site. Other sand deposits are encountered offshore. The maximum thickness of sand encountered in the lake is 25 ft. More recent surficial deposits of silt, peat, and clay are encountered in the lower, swampy areas at the site. A compact, relatively impermeable till mantles the rock throughout the site area. Occasional boulders, up to 3 ft in diameter, are encountered near the bedrock surface. The till is approximately l4 ft thick and is overlain by about 7 ft of impermeable stratified lacustrine clay.

Approximately 5 ft of lacustrine peaty silts and clay had been removed from the site area at the time of the Fermi 2 foundation investigation. The surface of glacial till was exposed at an average elevation of 566 ft, which is approximately 6 ft below the water surface of adjacent Lake Erie. The till consists of nearly impermeable silty to sandy clays with varying amounts of gravel and cobbles.

The thickness of the till deposit on top of bedrock within the immediate Fermi 2 plant area, as determined from the borings, ranges from a minimum of 8 ft to a maximum of 15.5 ft, and has an average thickness of approximately 14 ft. Wider variations may be present since both the upper and lower surfaces of the till are erosional surfaces.

2.5.1.2.2.2. Rock Units

The bedrock strata in the site area range in age from Silurian to Precambrian as shown in Figure 2.5-11. The bedrock surface is shown in Figure 2.5-12. A total of 40 test borings were drilled at the site for Fermi 2 detailed foundation studies. The locations of these borings are shown in Figures 2.5-13 and 2.5-14. The deepest boring at the site extended 109 ft into the Unit C bed of the Salina Group. Relationships between the units encountered during the drilling program are shown in the subsurface sections, Figures 2.5-15 through 2.5-20.

The description of the stratigraphic units below Unit C of the Salina Group is based on published reports. The estimated thicknesses of these deeper units are based on logs of boreholes drilled in the general area and on interpretation of structural geologic maps of the general area.

Bass Islands Group - Dolomite of the Bass Islands Group forms the uppermost bedrock stratum at the site and overlies the Salina Group. In the borings at Fermi 2, the Bass Islands dolomite is a gray-brown, thinly bedded rock of dense, finely crystalline character. Black shale partings about 1/8 in. in thickness are interspersed throughout the dolomite at spacings of about 4 in. Both the dolomite bedding and the shale partings are essentially horizontal. Occasional soft gray clay seams between 1/4 in. and 8 in. in thickness occur at random in the dolomite and are usually associated with fractured zones and vugs. Two marker beds in the Bass Islands Group were penetrated by the borings and have been correlated throughout the site. The upper marker bed is an oolitic dolomite ranging from 1.8 to 3.5 ft in thickness. The lower marker bed is a soft black shale. Recovered thickness of the shale among the several borings ranges from 0.2 to 1.2 ft; however, its in-place thickness is greater than the amounts recovered.

Fractures are present to a variable degree in the Bass Islands Group; joints are relatively tight and discontinuous, and usually display only very minor solution activity. The dominant trends of joints are N45°-60°W and N40°-50°E and are nearly vertical in dip (Reference 23). Where the rock is densely fractured, intervals have closely spaced joints that form fragmented zones. Fractures are oriented from 0° (horizontal) to 90° (vertical), and the thickness and depths of these zones are variable throughout the site. The fragmented zones range in thickness from a few inches to as much as 4.5 ft, and average about 1 ft.

Small vugs are present throughout the Bass Islands Group. They range from barely visible to 2 in. in maximum dimension. The amount of open space created by vugs ranges from about 0 to 30 percent of the total rock mass, with an average of 5 percent to 10 percent. Numerous vugs are also present which are lined with crystals of the mineral celestite. Fractures connect some of the vuggy zones, which increases the permeability to the rock mass.

The thickness of the Bass Islands Group, where fully penetrated by the borings, increases from 13.5 ft at boring 20 where part has been removed by erosion, to 101 ft at boring 201 (Figures 2.5-13 and 2.5-14).

Salina Group - The Salina Group at the site is subdivided into five beds referred to as:

a. Unit G, shales and argillaceous dolomite

b. Unit E, argillaceous dolomite

c. Unit C, dolomite

d. Unit A-2, dolomite

e. Unit A-1, dolomite.

Borings at the site encountered only the lower portion of the Bass Islands Group and extended as deep as Unit C of the Salina. Beds of the Salina Group in the site area consist of alternating layers of dark gray dolomite and shale. The maximum thickness of Salina Group strata penetrated during drilling was 224 ft in boring 79. None of the borings passed through the Salina Group into lower strata. Some brecciation was noted at the Bass Islands-Salina contact.

No salt beds were encountered in the vicinity of the site. Figure 2.5-21 is an isopach map of the Salina salt beds in southeastern Michigan. Salt present in Wayne County thins to the south and is absent in Monroe County. The only salt underlying the site is an insignificant quantity in the form of very small salt crystals (1/16-in. in diameter) disseminated through several feet of a dense dolomite in the Unit G, E, and C formations.

The shale intervals of the Salina Group, as observed in recovered core, range from soft to hard and from 0.01 ft to 2.2 ft in thickness. Gray clay seams in the sequence are soft and occur predominantly in fractured and vuggy zones, and are responsible for the lower percentages of core recovery. The vugs are sedimentary features caused by decay of fossil matter or other depositional and consolidation features and do not indicate karst conditions at the site. Little of this material was recovered during drilling, but the maximum clay thicknesses are believed not to exceed 1 ft.

Unit G - Unit G directly overlies Unit E and consists of gray, hard and soft shales, dolomitic shales, and argillaceous dolomites with occasional traces of anhydrite. Unit G was observed to be about 60 ft thick at the site.

Unit E - Unit E, which directly overlies Unit C, consists of gray to brownish-gray, vuggy, shaly dolomite, dolomitic limestone, and limestone breccias. All vugs encountered in the borings were less than 2 in. in diameter. Due to the vugged zones, the unit is highly permeable and shows minor artesian ground water flow. Unit E is uniformly about 60 ft thick in the vicinity of the site.

Unit C - Unit C directly overlies the A-2 dolomite unit and consists of a buff to gray, hard, thin- to medium-bedded dolomite with thin seams of shaly dolomite and anhydrite. Generally, anhydrite layers were less than 6 in. in thickness and the thickest layer encountered was a 6-ft layer in boring 209 at approximate Elevation 295 ft. The base of Unit C was not penetrated in the borings drilled for this study. Unit C is estimated to be about 140 ft thick at the site.

Units A-2 and A-1 - The A-2 and A-1 units are buff-white to brownish-gray, very finely to finely crystalline dolomite. Stylolites, argillaceous thin layers, and partings are present. Although the test borings at the site did not go as deep as the A units, the units are considered to be present below the site.

Niagaran Group - The Niagaran Group consists of buff, gray, and light brown, fossiliferous, finely to coarsely crystalline dolomite. This group is stratigraphically equivalent to the Clinton and Guelph-Lockport Groups of southeastern Ontario, and has an estimated thickness of 425 ft near the site (Reference 24).

Cataract Group - This group is a buff to gray, fossiliferous dolomite with thin layers and partings of green to gray shale. Traces of pyrite and glauconite are present. Estimated thickness near the site, based on Michigan well logs, is 100 ft.

Richmond Group - The Richmond Group contains approximately 625 ft of shale and dolomite, based on Monroe County well logs. The shale is gray to green with some brick-red units throughout the section. Dolomite occurs as stringers within the shale and as gray to buff, fossiliferous beds containing red and gray shale seams.

Trenton-Black River Group - The Trenton Group is generally undivided in subsurface from the underlying Black River Group. These rocks consist of gray-brown to buff, fossiliferous dolomite and dolomitic limestone with noticeable oil stains and gas shows. Estimated thickness near the site is 825 to 850 ft. Several thin layers of metabentonitic clay occur within a 1-ft zone at the bottom of the Trenton Group. These layers have been noticed in drillers' logs of Monroe County and are discussed by Hussey (Reference 25). The Trenton-Black River Group unconformably overlies the St. Croixan Series at the site due to the local absence of Lower Ordovician deposits (Reference 16).

St. Croixan Series - The St. Croixan Series comprises dolomite, sandstone, and minor amounts of shale in approximately 475 ft of section. The dolomite is buff, white to gray, slightly glauconitic, finely crystalline, and occasionally shaly. The dolomite occurs in the upper section of the series and is underlain by buff, white to gray, fine- to coarse-grained sandstone. Gray shale layers occur throughout the sandstone as partings or more uncommonly as beds several feet in thickness.

Precambrian - The Precambrian basement is a metamorphic-igneous complex composed of granite and granitic gneiss (Reference l8). Estimated depth near the site to the Precambrian rock is about 3100 ft.

2.5.1.2.3. Structural Geology

The borings have not disclosed faulting at the site. Differential elevations in the bedrock strata were investigated and are interpreted as a shallow synclinal fold. The axis of the fold trends approximately N60°W and passes through the Fermi 2 area, as shown in Figures 2.5-22 and 2.5-23. The strata dip toward the axis of the fold at about 4° and 1.5° to the north and south sides, respectively. The axis of the synclinal fold plunges to the northwest at about 1.5°.

Several marker beds were used to trace the folding and to determine the configuration and continuity of the rock structures. The primary marker bed used was the lower oolitic horizon in the Bass Islands dolomite. Other marker beds were a thin continuous shale seam within the Bass Islands Group, and the contact between the Bass Islands Group and the Salina Group.

Small local folds of the shale, encountered at the site area, are quite common in southeastern Michigan and are not necessarily related to regional tectonic trends. Many have been detected through oil and gas exploration in Monroe and Wayne Counties.

2.5.1.2.3.1. Jointing

The Bass Islands dolomite is highly jointed. The vertical joints range from open to closed. Some are filled with gypsum, anhydrite, or selenite. The nature of this jointing has been observed in excavations for Fermi 2 and in a quarry located less than 1 mile west of Fermi 2. This quarry has been allowed to fill with water, and excavations for Fermi 2 have been filled so that observation of these joints has been obliterated. Nevertheless, mapping of the joints has been accomplished in the excavation for the reactor/auxiliary buildings (Reference 24) and more recently in the excavation for the RHR complex. Mapping of the excavation for the reactor/auxiliary building indicated trends of N45°-60°W and N60°-50°E. The RHR complex excavation exhibits joint trends of N21°-35°W and N54°-72°E. Quantity and degree of openness of jointing tends to decrease with depth in all excavations encountered at the site.

2.5.1.2.3.2. Folding

The regional structure at the site indicates a northwest dip of less than 0.5°. Local warpings superimposed on the regional dip are known to be present. Contour maps drawn using the base of an oolitic horizon marker bed within the Bass Islands Group indicate a shallow synclinal fold (Figures 2.5-22 and 2.5-23). The axis of the fold trends approximately N60°W and passes through the Fermi 2 area, as shown in Figures 2.5-22 and 2.5-23. The fold is asymmetrical and the strata on the northeast side dip southwest at about 4°. The strata on the southwest side dip northeast at about 1.5°. The axis of the syncline plunges northwest at about 1.5°. A small anticlinal feature superimposed on this shallow synclinal fold is indicated on Figure 2.5-23 on the basis of boring data. During the course of mapping of the excavation, this feature was also observed. It was noted that, in general, foundation surface bedding planes are higher in the east-central region of the excavation and gently dip to the south, west, and north, implying a slight doming of the bedding planes in this region of the excavation.

2.5.1.2.3.3. Faulting

There are no reported faults within 25 miles of the site. All reported regional faults are tabulated in Table 2.5-2 and are shown in Figure 2.5-7.

2.5.1.2.4. Ground Water

The surficial deposits at the site consist of low-permeability glacial till, lacustrine clay, and peat. Some fine sand is present along the shoreline of Lake Erie. The surficial deposits locally act as a confining layer above the Paleozoic bedrock aquifer, and a slight artesian pressure exists at the site. More detailed information on ground water conditions at the site is found in Subsections 2.4.13 and 2.5.4.6.

The rate of flow of artesian ground water was noted at varying depths during the 1968 and 1969 boring operations for Fermi 2 Category I structures and is shown in Table 2.5-3. Similarly, any noticeable odor of hydrogen sulfide gas was noted. These observations are presented on the boring logs. Chemical analyses of ground water were made and the results are given in Subsection 2.5.4.6.

2.5.1.2.5. Geologic History

The geologic history of the region is discussed in Subsection 2.5.1 and includes the history as represented by the geologic units from the Precambrian to the Pleistocene. At the site, the borings penetrated only the Middle and Early Silurian rocks (Niagaran and Cayugan Series) indicated on the site stratigraphic column, Figure 2.5-11. The presence of Precambrian, Cambrian, and Ordovician rocks underlying the Silurian sequence shown on the legend of the regional geologic map, Figure 2.5-4, has been proven by borings in areas adjacent to the site, and these rocks are probably present at the site. Those portions of the regional geologic history that are applicable to the site are the Precambrian, Cambrian, Ordovician, Silurian, and Pleistocene.

2.5.1.2.6. Hydrocarbon Production and Subsurface Gas Storage Potential

Neither hydrocarbon production nor subsurface gas storage is believed to have great potential within the site vicinity.

2.5.1.2.6.1. Hydrocarbon Production Potential

As mentioned in Subsection 2.5.1.2.2.2, oil stains and gas shows have been noted in the Trenton-Black River Group of Middle Ordovician age.

The Trenton-Black River Group does hold distinct possibilities for future hydrocarbon production. Virtually all Ordovician hydrocarbons have come from the eight-county area which includes Monroe and surrounding counties. Of this production, the AlbionScipio Trend, which crosses Calhoun, Hillsdale, and Jackson Counties, accounts for nearly 74 percent of the productive drilled acreage and most of the cumulative Ordovician hydrocarbons (Reference 26).

The eight-county area has been analyzed for hydrocarbon yield per square mile and has been thought to have been adequately drilled to assess its future potential.

Ells (Reference 26) says:

> For the purpose of estimating the amount of undiscovered hydrocarbons in the Middle Ordovician Trenton-Black River rocks, it is assumed that the eight-county area has been completely explored, that no additional fields will be found and that the total production from this area amounted to 92,694,457 bbl.

From this standpoint, although the majority of Ordovician oil is presently obtained from this eight-county area and primarily from the Albion-Scipio Trend, significant future hydrocarbon development is unlikely and the remainder of the Michigan Basin holds more promise for increased future development.

2.5.1.2.6.2. Subsurface Gas Storage Potential

Subsurface storage of gas has been successfully carried out in the State of Michigan and has been largely restricted to converted gas fields.

The nearest such field that has been used for subsurface storage of gas is the Northville Field in Wayne County. Other fields affiliated with subsurface gas storage are found in St. Clair and Macomb Counties at some distance from the site.

Monroe, Lenawee, and Washtenaw Counties and most of Wayne County are not considered prime candidates for gas storage. Increased gas storage is far more likely in regions of converted gas fields (Reference 27). This would preclude any great potential for subsurface storage of gas in isolated anticlinal structures as may occur in the site region.

2.5.1.2.7. Engineering Geology

Geologic conditions at the site are considered satisfactory for the support of the foundations of the Fermi 2 facilities. The foundations for all Category I structures are established into the Bass Islands dolomite beneath the glacial till and lacustrine deposits.

Fracturing is present to a variable degree in the Bass Islands Group. It ranges from sparse to dense. In the former case, the fractures occur as singular, isolated structures of different lengths and orientations. Other intervals are characterized by closely spaced fractures that form fragmented zones. The fragmented zones range in thickness from a few inches to as much as 4.5 ft. They average about 1 ft in thickness. The thicknesses and depths of these zones are variable. Occasionally they occur at similar elevations, but the extent of lateral continuity is difficult to ascertain.

Vuggy zones are present throughout the Bass Islands Group and range from barely visible size to 2 in. in maximum dimension. The amount of open space created by vugs ranges as high as 30 percent of the total rock mass with an average of 5 percent to 10 percent. Fractures connect some of the vuggy zones, the connections thereby increasing the permeability of the rock mass. Comprehensive subsurface explorations, careful inspection of all excavations, and monitoring of foundation grouting (Subsection 2.5.4) ensure that no cavities of detrimental size underlie the plant structures. Several sinkholes are known in Whiteford, Bedford, and Ida Townships of Monroe County (about 15 to 20 miles from the site), but none are reported or have been encountered in the site area (Reference 4). Nearly all occur in rocks of the Detroit River Group, which lie stratigraphically above the Bass Islands Group and are not present at the site.

A study of older published reports of drillers' logs and of four modern reports, including detailed study of well logs and cuttings conducted by Eschman, indicates that no salt deposits underlie the Fermi site (Reference l).

Figure 2.5-21 indicates the thickness of salt deposits in the Salina Group in southeastern Michigan. The contours shown represent points of equal thickness. The 0 isopach line or contour, therefore, represents the outer margin of the salt beds. The Fermi site is outside the salt area. The nearest occurrence of salt is shown to be about 10 to 15 miles north of the site.

There is no solution mining within 17 miles of the site and the local geology indicates that there is no likelihood of future solution-mining activity in the site area, because minable salt does not occur within 15 miles.

The closest reported salt-mining operation was in Wayne County about 17 miles north-northeast of the Fermi site (Reference 28). This is the same general area of current active mining operations that was studied in detail in the D&M report of the River Rouge Generating Plant site (Reference 29).

Accidental gas blowouts, associated with oil and gas exploration activity, have occurred to the north in the region (Reference 30). In blowouts, gas has been known to travel several miles along permeable horizons from the source well and cause damage in the outcrop area of the permeable stratum. However, there is no anticipated danger of gas blowouts at the site since the highest relatively permeable stratum in the area is the Salina E formation, which outcrops beyond the shoreline in Lake Erie.

The results of ground water chemical analyses show that ground water at the site contains concentrations of sulfates that are potentially deleterious to portland cement, concrete, or grout. The potential for sulfates affecting cement, concrete, or grout stems from their chemical composition.

When certain alumina-bearing compounds are present in the cement of a hardened concrete, its exposure to water containing sulfate ions results in the formation of ettringite, accompanied by a volumetric expansion within the fabric of the hardened paste, which can result in disruption of the gel structure. Hence, for concretes that will be exposed to sulfate containing soils or waters, low tricalcium aluminate ($3\ CaO \bullet A1_2O_3$) cements are often specified (Reference 31). For this reason, Type V, modified Type II, and Canadian Standards Association (CSA) A5-1971 cement was used for grouting and for all subsurface concrete construction that would come into contact with the ground water. Since there is no known tricalcium aluminate present within the Category I crushed-rock backfill and it is not bonded like a concrete or cement grout, there would be no similar deleterious effect upon the crushed-rock backfill. Consolidation characteristics are described in Subsection 2.5.4.

2.5.1.2.8. Test Borings

Geologic borings were drilled at the Fermi 2 site in 1968, 1969, and 1972 to determine the details of the lithology, structure, and physical properties of the subsurface strata. Borings were drilled in l970 to determine static and dynamic soil and rock properties. The borings range in depth from 12.1 to 324.7 ft below the ground surface and were drilled at the locations indicated in Figures 2.5-13 and 2.5-14.

Detailed descriptions of the soil and rock encountered in the borings are presented in Figures 2.5-24 to 2.5-56. The soils were classified. The Unified Soil Classification System is described in Figure 2.5-57.

Rock was cored utilizing NX and BX coring equipment and samples of the overburden soils were obtained. The field exploration program was conducted under the technical direction and supervision of D&M. Rock core from other borings drilled under the supervision of Soil and Foundations Associates was carefully examined by D&M.

Five of the borings were utilized for pressure tests to obtain water leakage data as an aid in establishing criteria for dewatering and foundation grouting. The results of pressure testing are shown to the right of boring logs 201, 203, 209, 210, and RHR-3 in Figures 2.5-33, 2.5-35, 2.5-42, 2.5-43, and 2.5-50.

2.5.1.2.9. Geophysical Explorations

Geophysical investigations performed at the site in 1968 consisted of a seismic refraction survey and a borehole geophysical survey. The velocity of compressional wave propagation and other dynamic properties of the natural subsurface materials were determined by these studies, and were used in evaluating the response of the materials to earthquake loading. The results of the field geophysical studies are presented in Figures 2.5-58 through 2.5-61. Micromotions were measured to indicate the pattern of vibration at the site based on ambient background vibration analyses. These measurements, given in Table 2.5-4, are of assistance in estimating any predominant natural period of vibration at the site.

Poisson's ratio and other dynamic moduli for the various materials (crushed-rock fill, glacial till, Bass Islands Group) in the stratigraphic section at the site were estimated based on computed and/or empirical data for similar materials. Shear wave velocities for the upper bedrock at the site were computed using the measured compressional wave velocities from the refraction survey and estimated Poisson's ratio. The computed shear wave velocities were then confirmed by the data developed in the borehole geophysical survey. In general, relatively good agreement was obtained from these two methods of evaluating shear wave velocity.

Compressional wave velocities for the deeper rock strata have been measured in the region. These data were used to compute shear wave velocities for the deeper rock strata, based on estimates of Poisson's ratio measured in similar materials.

Measured and computed geophysical data for the stratigraphic section at the site are presented in Figure 2.5-58.

2.5.1.2.9.1. Geophysical Borehole Logging

Borehole geophysical measurements were made in three deep borings by the Birdwell Division of Seismograph Service Corporation. Four types of logs were run, providing the following categories of reduced data:

a. Compressional wave velocity (in situ) (Figure 2.5-58) at each 1-ft interval

b. Shear wave velocity (in situ) (Figure 2.5-58) at each 1-ft interval. (In these three borings the shear velocity was not measured directly, but was calculated from an empirical relationship between compressional velocity and bulk density)

c. Poisson's ratio (Figure 2.5-58) computed from compressional wave velocity and shear wave velocity

d. Bulk density, derived from density log (Figure 2.5-58).

Representative logs are shown graphically in Figures 2.5-59 and 2.5-60.

2.5.1.2.9.2. Seismic Refraction Survey

Two seismic refraction surveys, shown in Figure 2.5-61, were conducted to evaluate the bedrock characteristics at the site during the 1968 Fermi 2 investigation. The seismic lines were located along the barrier beach at the east edge of the site, as shown in Figure 2.5-22. One line was 250 ft long and the other was 500 ft long with some overlap in coverage. The results of the seismic refraction surveys were used to obtain dynamic properties of the foundation materials. Permanent records of the compressional waves generated from this survey were obtained using an Electro- Technical Labs ER75012 Seismic Timer, a 12-trace refraction seismograph. Geophone spacing was 25 and 50 ft, respectively, for the two lines. The compressional velocities measured during these studies are presented in Figures 2.5-58 and 2.5-61. Access to additional geophysical refraction work in southeastern Michigan was provided by others. The compressional wave velocities measured in other regional surveys were slightly higher than the results obtained during this study. The other profiles were in slightly different material, higher in the geologic column.

During the refraction surveys, the vibration levels within the existing Fermi 1 plant, and wave data generated in the foundation materials by the explosive charges, were monitored by a blast monitoring program.

2.5.1.2.9.3. Ambient Vibration Measurements

Ambient vibration measurements were made at two locations during the 1968 Fermi 2 investigation using D&M Micromotion Equipment (Hosaka Recording System). This equipment, which measures ambient ground displacements, has a magnification of up to 150,000. The equipment is capable of recording ground displacements ranging in frequency from 1 cycle per second to 30 cycles per second. The ambient vibration records can be used to indicate predominant periods of ground motion at the site, under the test strain levels.

Ambient station measurement No. 1 was obtained on 2 ft of soil covering a rock outcrop in an old quarry located in the northwest portion of the site. The second measurement was on approximately 20 ft of soil overlying rock. At the first location, the intensity of ground motion was very low with only a slight suggestion of predominant periods, indicative of hard rock. At the second observation point, the intensity of ground motion was so low that it was obscured by machinery noise. The depth of bedrock at each location and the predominant ground periods observed are indicated in Table 2.5-4.

2.5.1.2.10. Laboratory Tests

During the 1968 investigations of Fermi 2, representative rock cores that were extracted from certain borings were subjected to a laboratory testing program to evaluate the physical properties of the rock encountered at the site (References 1 and 2). The depths of the rock cores that were tested and tabulated in Table 2.5-5 and in Appendix 2D represent depths from the original ground surface. In some cases the rock samples tested were from above the foundation level. Testing of rock samples from this zone was carried out in order to arrive at conservative foundation design parameters since the rock above foundation level is more weathered and less competent than the rock below. Laboratory tests included the following:

a. Density tests

b. Unconfined compression tests

c. Shockscope tests

d. Resonant column tests.

The density and unconfined compression tests were performed in accordance with ASTM standards. The shockscope and resonant column tests were performed according to generally accepted methods. There are no ASTM standards for these tests.

Chemical analyses of ground water samples were performed during the 1969 investigation.

Additional laboratory testing was performed in 1972 on soil samples and rock core obtained from borings at the Fermi 2 RHR complex (Reference 3).

2.5.1.2.10.1. Static Tests

Density Tests - Density tests were performed on representative rock cores that were selected from 1968 and 1969 borings made during the investigation of Fermi 2. The results of these tests are given in Table 2.5-5.

Unconfined Compression Tests - During the 1968 and 1969 Fermi 2 boring program, several representative unconfined compression tests were performed on selected rock samples to evaluate the strength and elasticity characteristics of the bedrock. The tests on the rock cores were performed by the Robert W. Hunt Company in accordance with ASTM standards. The results of the rock compression tests and associated density determinations are presented in Table 2.5-5.

Later, during the 1972 foundation investigation for the RHR complex, additional unconfined compression tests were performed by the Robert W. Hunt Company. The results of these tests are given in Table 2.5-6.

2.5.1.2.10.2. Dynamic Tests

Shockscope Tests - Several samples of the rock materials underlying the site were tested in the shockscope during the 1968 and 1969 studies. The shockscope is an instrument developed by D&M to measure the velocity of propagation of compressional waves in the material tested. The velocity of compressional wave propagation observed in the laboratory is used for correlation purposes with the field velocity measurements obtained in the geophysical refraction and borehole surveys.

In the shockscope test, samples are subjected to a physical shock under a range of confining pressures, and the time necessary for the shock wave to travel the length of the samples is measured using an oscilloscope. The velocity of compressional wave propagation is then computed. Since this velocity is proportional to the dynamic modulus of elasticity of the sample, the data also are used in evaluating dynamic elastic properties. The results of the tests are presented in Table 2.5-7.

Resonant Column Tests - Resonant column tests were performed on two representative samples of rock from the 1968 boring program to determine the shear modulus of rigidity of these materials. The samples are subjected to steady-state, sinusoidal, torsional forces applied to the top of the sample. The frequency of the force application is varied until the resonant frequency (the frequency associated with the maximum steady-state amplitude) is attained. The shear modulus is computed from the resonant frequency of the sample. The results of the resonant column tests are presented in Table 2.5-8.

2.5.1.2.11. Static and Dynamic Properties of Foundation Materials

Static and dynamic soil and rock properties of foundation materials for Fermi 2 were determined for the reactor/auxiliary building and adjacent turbine and office service buildings and are presented in Table 2.5-9 (Reference 32). The properties were modified for the Fermi 2 RHR complex in order to be representative of the local soil and rock conditions. The properties used for design criteria for the RHR complex are presented in Table 2.5-10 (Reference 3).

2.5.2. Vibratory Ground Motion

Basic Fermi 2 site vibratory ground-motion evaluations were conducted by D&M in 1968. A reaffirmation of the acceptability of this early work was provided by Weston Geophysical in 1982. The following paragraphs of this section present the data summarized from the original D&M investigation. However, any recent data of significance are identified and appropriately noted.

2.5.2.1. Geologic Conditions of the Site

A complete discussion of the regional stratigraphy, structure, and geologic history is found in Subsection 2.5.1. This site is located within the Central Stable Region of North America, an area in which the geologic structure is relatively simple. The region is characterized by a system of broad, circular to oblong sedimentary basins that include the Michigan, Appalachian, and Illinois Basins. Stable regions, including the Cincinnati Arch Complex (including the Findlay, Algonquin, and Kankakee Arches), separate the basins. Numerous secondary features are superimposed on these broad structures. The site lies along the southeast edge of the Michigan Basin and northwest of the axis of the Findlay Arch.

Precambrian crystalline basement rock lies about 3100 ft below the ground surface in the vicinity of the site. The crystalline basement complex is mantled by sedimentary rocks of Paleozoic age (Subsection 2.5.1.1.2.2). The bedrock surface at the site ranges in depth from approximately 15 to 30 ft below the existing ground surface. The overburden materials consist of sands, silts, and clays of Pleistocene age.

The uppermost bedrock unit at the site consists of the Bass Islands dolomite of Late Silurian age. Prior to glaciation, the Bass Islands Group was covered by deeply weathered and jointed rocks that experienced solution activity. Glacial advance and retreat scoured the younger rocks, and exposed the hard and relatively unweathered Bass Islands Group. The Bass Islands dolomite is on the order of 80 ft thick in the site area. The Salina Group underlies the Bass Islands and is about 525 ft thick near the site. This material consists of interbedded shales, limestones, and dolomites and is underlain by the Niagaran dolomite.

Faults have not been identified within the basement rocks or overlying sedimentary strata at the site. The closest fault, the Bowling Green Fault, is postulated approximately 35 miles southwest of the site. The vertical displacement of this fault is thought to be several hundred feet. Other known faults in the area are more distant from the site. Most faults in the region are believed to have been dormant since late Paleozoic time, at least 200 million years ago (Subsection 2.5.1). Folding is known throughout southeastern Michigan. The most prominent secondary feature is the Howell Anticline, located in the southeastern portion of the Michigan Basin. Since the area has undergone multiple Pleistocene glaciation, it may be inferred that this region has been subjected to repeated slight bending in the last few hundred thousand years (Subsection 2.5.1).

2.5.2.2. Underlying Tectonic Structures

A discussion of tectonic structures in the region surrounding the site is found in Subsection 2.5.1. The most significant structural features are listed below:

a. The Bowling Green Fault trends north-south in north-western Ohio. An inferred extension of this fault lies approximately 35 miles southwest of the site (Subsection 2.5.1.1.3.2)

b. The Howell Anticline, the most prominent fold in the region, approaches to within about 25 miles north of the site and extends approximately 80 miles to the northwest (Subsection 2.5.1.1.3.1)

c. The Chatham Sag is a broad, gentle, northwest-trending syncline that has been mapped as far south as the north shore of Lake Erie. The axis of the syncline lies about 50 miles northeast of the site. A system of faults, including the Electric Fault, is associated with this structure (Subsection 2.5.1.1.3.1)

d. The Keweenawan Fault System, which is characterized by vertical displacements from a few thousand feet to more than 9000 ft, lies northwest of the Michigan Basin approximately 430 miles northwest of the site. It has a northeast trend on the Keweenawan Peninsula in Lake Superior (Subsection 2.5.1.1.3.2)

e. The Rough Creek-Kentucky River fault complex in southern Illinois and central Kentucky approaches to within about 350 miles south of the site (Subsection 2.5.1.1.3.2).

2.5.2.3. Behavior During Prior Earthquakes

Although a few distant earthquakes have been felt at the site, detailed onsite studies suggest that their intensities have not been sufficient to affect local surface or subsurface materials. There is no physical evidence at the site to indicate that the area has experienced seismic activity at any time.

2.5.2.4. Engineering Properties of Materials Underlying the Site

The engineering properties of unconsolidated surficial deposits and bedrock are presented in Subsections 2.5.1 and 2.5.4. Seismic wave velocities are presented in Subsections 2.5.1.2.9, 2.5.1.2.9.2, and 2.5.4.2; density values are presented in Subsections 2.5.1.2.9.1, 2.5.1.2.10, and 2.5.4.2; water contents are indicated by wet and dry density values given in Subsection 2.5.1.2.10; rock quality designation is presented below and in Subsection 2.5.4.2; and strength characteristics are given in Subsections 2.5.1.2.9.1 and 2.5.4.2.

2.5.2.5. Earthquake History

2.5.2.5.1. 1968 Evaluation

The site is located in one of the most seismically stable regions in the United States. No earthquake epicenter has been located closer than about 25 miles and only seven earthquakes have been reported within 50 miles of the site since the beginning of the 19th century. None of these shocks were greater than Intensity V on the Modified Mercalli Scale.* Eleven earthquake epicenters of Intensity V to VIII have been reported within 50 to 100 miles of the site and another 24 of Intensity V to VII are located at distances between 100 and 200 miles. The closest Intensity VII shock was located at 90 miles and the closest Intensity VIII shock was located at 100 miles from the site.

A list of larger earthquakes located 200 or more miles from the site is presented in Table 2.5-12.

A list of earthquakes with epicenters located within a distance of about 200 miles from the site is presented in Table 2.5-13. This list presents all reported earthquakes within 50 miles of the site and significant shock (Intensity V and greater) within 200 miles of the site. The epicenters of these shocks are shown in Figure 2.5-62.

---

* All intensity values in this subsection refer to the Modified Mercalli Scale. The intensity scale, which is described in Table 2.5-11, is a means of indicating the relative size of an earthquake in terms of its perceptible effect.

Although at least six shocks have been felt at the site within the past two centuries, the maximum intensity at the site has not exceeded Intensity IV. None of the recorded earthquakes caused any damage at or near the site.

Since the beginning of the 19th century, twelve earthquakes of Intensity V or greater have been reported within 100 miles of the site, and only 37 earthquakes of Intensity V or greater have been reported within about 200 miles of the site. The 1776 and 1925 events have not been located precisely enough to plot on the figure. Few were of high enough intensity to cause structural damage to reasonably well-built structures. None of these shocks were greater than Intensity VIII and only six can be considered more than minor disturbances. These earthquakes occurred in 1875 (Intensity VII), 1930 (Intensity VI and VII), 1931 (Intensity VII), and two in 1937 (Intensity VII and VIII). The epicenter of the closest of these shocks was about 100 miles from the site. These six earthquakes, along with a number of smaller shocks, are concentrated in a 40-mile-long northeast-southwest-trending zone extending south of Lima, Ohio. This zone of earthquake activity is located near the juncture of the Findlay, Cincinnati, and Kankakee Arches.

The earthquakes closest to the site were four Intensity III and IV shocks near Toledo, Ohio (about 30 miles distance), an 1877 Intensity V shock west of Detroit, Michigan (about 30 miles from the site), and a 1961 Intensity V shock in northern Ohio (about 55 miles south of the site). The several Intensity III and IV shocks were reported in the Toledo newspapers. These shocks were not felt at the site. The 1961 earthquake occurred near the Bowling Green Fault and/or the confluence of the Bowling Green Fault with the axis of the Findlay Arch. The 1877 Detroit shock has not been related to any specific geologic structure. Although one or more of these small shocks may have been felt in the vicinity of the site, there were no reports of disturbance near the site, and no damaging effects were experienced. It is estimated that intensities at the site due to these shocks were on the order of III or less. The other five earthquakes within 50 miles of the site were Intensity V or smaller and probably were not felt at the site.

For purposes of this study, it is considered that the most significant earthquakes in the region were the 1937 Intensity VII to VIII earthquakes south of Lima, Ohio; the 1947 Intensity VI earthquake in south-central Michigan; the 1943 Intensity V earthquake in Lake Erie, about 100 miles east of the site; and the 1961 Intensity V earthquake in northern Ohio. This evaluation has been made considering such factors as epicentral intensity (with regard to both damage to structures and perceptible area), distance from the site, and geologic structure (with regard to the possible relationship of geologic structure near the earthquake epicenter to structure near the site). A discussion of each of these significant earthquakes follows.

The earthquake of March 8, 1937, was the single most significant shock recorded within 200 miles of the site during the period of record. The shock occurred in an area that has experienced the most concentrated earthquake activity within the region.

The area is located at the south end of the Findlay Arch near the confluence of the Cincinnati and Kankakee Arches. Residual stress fields from late Mississippian time may still be slightly active in this area and this locality is probably weaker than the surrounding region due to the confluence of structural features. Earthquakes in the region were generally located at the transition between major tectonic features, rather than within a structural block. The earthquake was felt in an area of about 150,000 square miles. The shock was reported in the

Detroit newspapers and was felt near the site with about Intensity IV. The effect in Michigan was not great and no damage resulted.

The earthquake of August 9, 1947, occurred at approximately 8:47 p.m. northeast of Kalamazoo, Michigan. The effects near the epicenter were minor, consisting primarily of damage to a few brick chimneys. There also were reports of loose plaster shaken from ceilings and loose bricks shaken from a few buildings. Based on the damage reports, the epicentral intensity of this earthquake was Intensity VI. The earthquake was felt within an area almost 200 miles in radius. The shock was felt in the vicinity of the site with Intensity III or less. This shock may be related to the Tekonsha oil field structure (see Subsection 2.5.1.1.3.2).

The earthquake of March 8, 1943, occurred at about 11:26 p.m. The maximum intensity of this shock was probably Intensity V and the duration of shaking was only several seconds. It was felt in a relatively large and irregular area extending from Toronto, Ontario, as far south as Zanesville, Ohio. The total perceptible area of this shock was on the order of 40,000 square miles. Its location in the middle of Lake Erie reduced the area likely to sustain damage. The damage from this earthquake was trivial, with the highest intensity (VI) reported in Cleveland, Ohio. In Detroit, houses shook and windows rattled, but there were no reports of damage or of tall-building disturbance which is usual for more distant larger shocks. The shock was felt in the vicinity of the site and was reported to be about Intensity III. This shock may be related to an extension of the Chatham Sag into the northern part of Lake Erie.

The Intensity V earthquake of February 22, 1961, was the largest and most recent shock within 55 miles of the site. The epicenter of this shock has been located near the southern end of the Bowling Green Fault. Since only one seismograph recorded this shock, its specific location is somewhat tenuous. The shock was felt only in the local area and no damage resulted. The shock was not felt in the vicinity of the site. The limited perceptibility of this recent earthquake, indicating a rather low energy release, minimizes its significance in this study.

2.5.2.5.2. 1986 Reaffirmation

Earthquake reassessment activities, in which new site-specific earthquakes were defined and which provided documentation of the satisfactory conclusions reached from evaluation of the preceding earthquake history, were completed in 1982.

Additional seismic activity has occurred since 1968 and is summarized through July of 1986 in the following paragraphs.

Six more earthquakes have occurred within 200 miles of the site. Two of these were minor disturbances located near Colechester, Ontario, with epicentral intensities of III and IV. One occurred in 1968 near Attica, Michigan, with an epicentral intensity of V. The three others were located in Ohio near Celina, Perry, and St. Mary's and had intensities of VI, VI, and V respectively.

Six other earthquakes can be added to the list of earthquakes located 200 or more miles from the site. A 1975 earthquake was located near Wellston, Ohio (Intensity V), about 215 miles from the site. A major earthquake shook Sharpsburg, Kentucky (Intensity VII) in July 1980, about 300 miles from the site. A 1984 earthquake was located near Sudbury, Ontario (Intensity V), about 350 miles from the site. Two other 1984 earthquakes of Intensity V were located about 285 miles from the site near Clay City, Indiana. Finally, one 1985 earthquake near Edgebrook, Illinois, which is located about 250 miles from the site also had an intensity of V.

Documentation for all these earthquakes has been provided in Tables 2.5-12 and 2.5-13 and their epicenters are shown in Figure 2.5-62.

The most significant earthquakes since 1968 are the 1977 Ohio earthquake, the 1980 Kentucky earthquake, and the 1986 Perry earthquake.

The June 1977 earthquake was located near Celina, Ohio, and had a Richter magnitude of 3.2. The earthquake was felt over about 550 sq km^2 of western Ohio from Celina, south to Chickasaw, west to Fort Recovery, and north to Rockford. Several instances of slight damage were reported in the area. The maximum intensity reported was a VI near Celina, Coldwater, Fort Recovery, and Rockford, Ohio.

Damage ranged from sidewalk cracks to plaster cracks and hairline cracks in exterior walls. The estimated intensity at the site is a II.

The shock of July 27, 1980, is the strongest earthquake to be centered in Kentucky and the strongest earthquake to be felt in this region since the southern Illinois earthquake of 1968. It was felt over an area of approximately 600,000 km^2 of the central United States and Canada. The epicenter was located near Sharpsburg, Kentucky, and the epicentral magnitude and intensity were 5.1 and VII respectively. The worst damage was at Maysville, Kentucky, approximately 50 km north of the epicenter, where 37 business structures and 269 residences suffered damage of some degree. Most of the significant damage to structures occurred in the older downtown section of the city. The damage was mostly to older brick structures probably built during the middle 1800s.

Ground cracks were reported to have occurred about 12 km from the epicenter at Owingsville and Little Rock, Kentucky. Reports of the duration of ground vibration were about 15 sec of strong motions and up to several minutes for sensible vibrations.

The intensity in Michigan varied from II to IV and was reported to be at II in Monroe, Michigan.

The earthquake of January 1986, was located about 11 miles south of the Perry Nuclear Power Plant site and had a Richter magnitude of 4.96.

The earthquake was rated as a Modified Mercalli Intensity of VI. Seventeen people were treated for minor injuries. Structural damage was confined to slightly damaged chimneys, cracks in concrete and under blockwalls, some cracked and fallen plaster, a few broken windows, and some well-water silting.

The January 31, 1986, Ohio earthquake was felt at the Fermi site as a Mercalli Intensity IV event. No unusual conditions were observed. The earthquake was not strong enough to be designated an event at Fermi. However, detailed earthquake instrumentation evaluations were completed and evaluation procedures and instrumentation interpretation techniques were verified.

2.5.2.6. Correlation of Epicenters With Geologic Structures

The majority of the significant earthquakes in the region can be associated with well-defined geologic structural zones (Figure 2.5-62). The major geologic structures are described in Subsection 2.5.1.1.3 and are shown in Figures 2.5-6 and 2.5-7. As indicated by Tables 2.5-1 and 2.5-2, the folding and faulting in the central stable region are principally Paleozoic. Recent investigations (References 33 and 34) have indicated that the present seismic activity is not related to surface faulting. Seismic activity occurs in regions bounded by structures of Paleozoic age. The random nature of epicentral locations is the result of stress release in randomly distributed Precambrian crustal blocks (Subsection 2.5.1.1.5.2 contains a more complete discussion). Any present seismic activity occurring near a fault or fold of Paleozoic age does not indicate that the structure is active.

To the north and west of the site, earthquakes are rare and appear to occur near anticlinal structures in northern Michigan. To the west of the site, earthquake activity has consisted of infrequent minor shocks that occur in the random epicentral region of southern Wisconsin and northern and central Illinois. To the south, at Anna, Ohio, recent investigations (Reference 35) conducted in the area indicate that earthquake activity is associated with complex Precambrian basement structures. Geologic conditions in this area are unique and the seismic events that occurred here cannot be considered random. However, as described in Subsection 2.5.2.9, in defining the maximum earthquake, an event similar to the Anna event was considered to be able to occur along the axis of the Findlay Arch at its closest approach to the site. These recent studies only indicate that the acceleration values used in design are more conservative than had previously been assumed.

The zone of major earthquake activity closest to the site is in the vicinity of New Madrid, Missouri, more than 500 miles to the southwest. Earthquakes near New Madrid in 1811 and 1812 are considered among the largest ever to have occurred in the United States. It is reported that these shocks (possible Intensity XI) were felt in an area of 2 million square miles and changed the surficial topography in an area of about 30,000 to 50,000 square miles. The structural damage resulting from these earthquakes was small due to the lack of construction and habitation in the region.

It is estimated that intensities felt in the vicinity of the Fermi site due to these shocks were probably on the order of III to IV. Their influence would be predominant only at low frequencies and is enveloped by existing design criteria. These earthquakes occurred within the extensively faulted New Madrid (Reel Foot) seismographic region (Reference 36). The geologic structure in southern Illinois and western Kentucky is not related to the geologic structure in the vicinity of the site. The Rough Creek fault complex crosses major regional structures and probably forms a boundary separating the stable continental interior to the north from the seismogenic upper Mississippi Embayment. There is no geologic evidence to relate this fault system with structure or faulting within the continental interior. Thus, the seismically active region at the boundary and to the south should be considered dissimilar and distinct from the seismically quiet region to the north.

Another area of concentrated earthquake activity is in the vicinity of Cleveland, Ohio. Since the turn of the century, five Intensity V shocks have been reported in this area. No shock larger than Intensity V has been reported and none of these earthquakes were large enough to have been felt in Michigan. These shocks have not been related to a known tectonic feature. Several small shocks in southern Michigan, northern Indiana, and in Lake Erie, similarly, cannot be positively related to known faults. The 1947 southern Michigan shock apparently is coincident with the alignment of the Tekonsha oil field and may be associated with oil field structures. Structure and faulting is inferred for the oil field. The validity of an Intensity VI shock in 1883 in southern Michigan has been questioned. Although the magnitude of this earthquake is dubious, its location may indicate a relation to oil field structures.

The 1947 Intensity VI south-central Michigan shock and the 1943 Intensity V Lake Erie shock are the largest earthquakes in the region that cannot be positively related to specific tectonic features. Since the geologic structures in the region are believed to have been dormant since Paleozoic time, earthquake activity in the area may represent final crustal readjustment to Pleistocene glacial advance and retreat. Glacial rebound in the site area is nonexistent as far as is known.

2.5.2.7. Identification of Capable Faults

No known capable faults occur within 200 miles of the site. Significant tectonic structures that occur within 200 miles of the site, however, are described in Subsection 2.5.2.2 and their locations are shown in Figure 2.5-7. A description of these structures is included in Subsection 2.5.1.1.3 and a summary of the major faults is given in Table 2.5-2. Information on the activity of the structures is included in Subsections 2.5.2.5 and 2.5.2.6.

2.5.2.8. Description of Capable Faults

No known capable faults occur within 200 miles of the site. For a description of regional faulting, see Subsection 2.5.3.

2.5.2.9. Maximum Earthquake

The effect at the site of a possible future earthquake similar to a large historical shock has been investigated. For this evaluation, the first shock considered was the March 8, 1937, Intensity VIII earthquake near Lima, Ohio. Should a shock similar to this earthquake occur in the vicinity of the confluence of the Findlay, Cincinnati, and Kankakee Arches, the attenuated ground acceleration at the site would be less than 5 percent of gravity.

A review of the regional seismic history indicates that the shocks occurring near Lima, Ohio, have been localized within a very small area. The epicentral areas generally trend north-south and are quite limited in extent. An additional shock (1961) was located near the confluence of the Bowling Green Fault and the axis of the Findlay Arch. Even if a shock as large as the 1937 Lima shock were to occur at this location, or at the closest approach of the Bowling Green Fault, or the axis of the Findlay Arch to the site, the maximum expected ground acceleration would be less than 10 percent of gravity.

The 1811-1812 Intensity XII New Madrid, Missouri, series of earthquakes was also studied. Should a shock as large occur as close to the site as the closest approach of the Rough Creek-Kentucky River fault complex (about 350 miles), the attenuated ground acceleration at the site would be less than 5 percent of gravity.

It is also concluded that either of these occurrences would result in ground motion at the site significantly less than that selected for the safe-shutdown earthquake (SSE).

Small earthquakes similar to the 1947 and 1943 shocks (Subsection 2.5.2.6) could occur in the vicinity of the site. On this basis, the effect of a shock similar to the 1947 south-central Michigan or the 1943 Lake Erie earthquake with an epicenter near the site has been considered. A conservative estimate of the maximum horizontal ground acceleration at the rock surface, due to such a shock, is less than 10 percent of gravity.

Confirmatory site-specific earthquake evaluations were completed in 1982 to reaffirm the acceptability of the established Fermi 2 facility seismic design bases. This site-specific evaluation was completed assuming a Richter magnitude 4.9 to 5.9 quake with an epicenter less than 25 km from the site. This assumption is consistent with a quake at the Fermi 2 site similar to that which occurred in Anna, Ohio, in March 1937, and which would also account for a quake at the site such as the July 27, 1980, Kentucky experience in the Central Stable Region as well as the recent January 31, 1986, Perry, Ohio, event.

Site-specific spectra were derived directly from representative real-time histories for the appropriate magnitude and distance, and foundation conditions similar to the Fermi site. The 84 percentile of such spectra represented the comparative evaluation level for which the facility seismic design capability was reaffirmed.

2.5.2.10. Safe-Shutdown Earthquake

Category I structures at the plant are founded on rock and are designed so that they can be safely shut down in the event ground accelerations at the site exceed those that are operationally tolerable. Consequently, an evaluation has been made of the degree of ground motion that is remotely possible, considering both seismic history and geologic structure. In developing the SSE evaluation, consideration was given to the fact that there is a history of minor to moderate earthquake activity in the region that cannot be related directly to known tectonic features. Category I structures, systems, and components are designed for a safe shutdown due to horizontal zero period ground accelerations at the rock surface at foundation level, of 15 percent of gravity (0.15g).

2.5.2.11. Site-Specific Earthquake

In response to a request from the Geosciences Branch, a site- specific earthquake ground response spectrum (essentially per Regulatory Guide 1.60 pegged at 0.15g horizontal) was developed, exhibiting a significantly higher ground response than the SSE ground response. Reevaluation of structures, systems, and components required for cold shutdown was presented to the NRC in the Supplementary Seismic Evaluation Report, Detroit Edison Report No. EF2-53332, Revision 1, dated July 15, 1981. Also see Subsection 3.7.1.2.1.

2.5.2.12. Operating-Basis Earthquake

On the basis of the seismic history of the area, it does not appear likely that the site will be subjected to significant earthquake ground motion during the life of the plant. However, Category I structures are conservatively designed to respond, within elastic limits, and with no loss of function, to a horizontal ground acceleration on the rock surface at foundation level of 8 percent of gravity (0.08g). Subsequent review by Weston Geophysical demonstrated that the operating-basis earthquake (OBE) peak horizontal ground acceleration of 0.08g has a return period, as a minimum, of the order of 100 to 300 years.

2.5.3. Surface Faulting

No faults are known within 25 miles of the site. Detailed information concerning faulting on a regional and site basis is included in Subsections 2.5.1.1.3 and 2.5.2.7.

2.5.3.1. Geologic Conditions of the Site

Details of the stratigraphy, structure, and geologic history of the site are found in Subsection 2.5.1.2.

2.5.3.2. Evidence of Fault Offset

No faults are known within 25 miles of the site (Subsection 2.5.1.1.3).

2.5.3.3. Identification of Capable Faults

No faults are known within 25 miles of the site (Subsection 2.5.1.1.3).

2.5.3.4. Earthquakes Associated With Capable Faults

No faults are known within 25 miles of the site, and no earthquakes have been reported closer than 25 miles from the site (Subsections 2.5.1.1.3 and 2.5.2.5).

2.5.3.5. Correlation of Epicenters With Capable Faults

No faults or earthquake epicenters have been reported within 25 miles of the site (Subsections 2.5.1.1.3 and 2.5.2.5).

2.5.3.6. Description of Capable Faults

No faults are known within 25 miles of the site (Subsection 2.5.1.1.3).

2.5.3.7. Zone Requiring Detailed Faulting Investigation

There is no known geologic basis for the possible existence of faulting in the site area. Therefore a detailed faulting investigation is not warranted.

2.5.3.8. Results of Faulting Investigation

A review of all available literature, conferences with geological organizations, and onsite investigations revealed that no surface or subsurface faults exist within 25 miles of the site (Subsection 2.5.1.1.3.2).

2.5.3.9. Design Basis for Surface Faulting

Surface faulting at the site is not considered for design.

2.5.4. Stability of Subsurface Materials

2.5.4.1. Geologic Features

Pertinent geologic features of the site are discussed in detail in Subsection 2.5.1.2. Competent bedrock strata underlie the site and there are no major solution cavities or zones of solution weathering in the site area. However, due to the presence of zones of extensively fractured or highly vugged rock, pressure grouting was used to provide assurance that zones of this type are not horizontally continuous across the site. The foundation rock will satisfactorily support all static and dynamic loads imposed by all Category I and other heavy settlement sensitive structures.

2.5.4.2. Properties of Underlying Materials

A description of the site geology is given in Subsection 2.5.1.2. Test boring data are presented in Subsection 2.5.1.2.8. Grain- size classification is presented in Subsection 2.5.1.2.8; consolidation characteristics are given in Subsection 2.5.4.5.2; water content is indicated by wet and dry densities given in Subsection 2.5.1.2.10; unit weight values are given in Subsection 2.5.1.2.9; shear moduli are presented below; damping is considered below; and Poisson's ratio values are given below and in Subsection 2.5.1.2.9. Seismic wave velocities are given below and in Subsection 2.5.1.2.8. Density values are given below. Rock quality designations are considered below and in Subsection 2.5.2.4. Strength characteristics are given below.

Based on an analysis of the results of laboratory testing together with a review of published data and a comparative evaluation of the soil and rock materials at the residual heat removal (RHR) complex (Reference 3) with those determined for the reactor site (Reference 2), design parameters were developed and are presented in Tables 2.5-9 and 2.5-10.

The parameters presented in Tables 2.5-9 and 2.5-10 are discussed below. A brief description of the method of determining the values is given, and the range of variation is discussed.

2.5.4.2.1. Density

The densities given for the rock fill material were determined from large-scale density tests performed in a compacted test fill (Reference 2). In determining the submerged density, the rock fill material was assumed to have a specific gravity equivalent to that of dolomite. The range of variation given is considered appropriate for a controlled compacted fill of 1.5 in. and smaller crusher-run rock. The densities for the in situ glacial till and their range of variation were assessed from the moisture- density tests performed on relatively undisturbed samples. An appropriate specific gravity was used in calculating the submerged density.

Bedrock density and its range of variation were determined from the results of measured densities of representative rock cores.

2.5.4.2.2. Wave Velocities

The compression and shear wave velocities presented in Table 2.5-9 for the crushed-rock fill, glacial till, and in situ rock are measured values (References 1, 2, and 3). The range of variation of wave velocities has been estimated with consideration for the inherent uncertainties in methods of measurement and variations in grain size, density, and strength of the various materials.

2.5.4.2.3. Poisson's Ratio

The tabulated values of Poisson's ratio for the compacted rock fill and glacial till were computed from the shear and compression wave velocities. Where possible, the load-settlement data from plate load tests were compared to provide a further check on the values computed from the wave velocities. Values for in situ rock were estimated from the seismic investigation (Reference 1).

The range of variation for Poisson's ratio was estimated with consideration for probable differences in wave velocities, grain size, density, and strength of the materials being considered.

2.5.4.2.4. Static Modulus of Elasticity

The tabulated static moduli of elasticity for the rock fill and glacial till were computed from the results of load-settlement behavior recorded during plate load testing and, for the glacial till, from unconfined compression tests performed on relatively undisturbed samples (References 1, 2, and 3).

Laboratory values for static modulus of elasticity were derived from unconfined compression tests. Based on certain empirical formulae (Reference 37) and literature research (References 38 and 39), combined with experience, knowledge, or rock characteristics such as Rock Quality Designation (RQD), vugs, discontinuities, and clay seams and tempered with conservatism, a factor of 0.25 was applied to the average laboratory values. This figure was then taken to be the in situ static modulus of elasticity. A range of ±50 percent was utilized in presenting this value to account for the expected variability of characteristics within the Bass Islands Group.

2.5.4.2.5. Dynamic Modulus of Elasticity

The dynamic moduli for the glacial till were determined from elastic analysis of the data provided by the Pulsating Load Triaxial Tests. The dynamic moduli of the compacted rock fill and the bedrock were determined by elastic analysis of the results of the field seismic studies (References 2 and 3).

The range of values presented reflects the accuracy of field measurement and analysis together with the anticipated variations in grain size, density, and/or strength of the various materials.

2.5.4.2.6. Shear Moduli

The shear moduli of the till maerials were computed from the results of Pulsating Load Triaxial Tests. For the compacted rock fill and the bedrock, the shear moduli were computed using the elastic relationship between the shear modulus, modulus of elasticity, and Poisson's ratio. The range of values reflects inherent uncertainties in methods of analysis and anticipated variations in grain size, density, and/or strength of the various materials.

2.5.4.2.7. Damping Values

The tabulated values of damping are based largely on a review of available published data. The values of damping presented for the glacial till were computed from the results of Pulsating Load Triaxial testing. The damping capacity of the bedrock was developed from various dynamic tests (Reference 1). All of the tabulated damping values are expressed as a percentage of critical damping.

2.5.4.2.8. Rock Quality

The quality of the rock as observed in recovered drill core was evaluated by measuring:

a. Rock quality designation

b. Fragmented zones

c. Fracture density.

The data are included on the core boring logs (Figures 2.5-33 through 2.5-55).

The average RQD in the upper 15 to 20 ft of bedrock in all borings at the RHR complex was 47 percent, or the "poor" quality classification. The average core recovery throughout this depth interval was 92.4 percent, sufficiently high to yield reliable RQD values.

Fragmented zones are present. They range in thickness from 6 in. to 3 ft and occur at different elevations in each boring. The lack of depth and thickness correlation between borings suggests that the fragmented zones are not continuous laterally across the site.

Fracture density ranged typically from very close (less than 2 in.) to close (2 to 6 in.) in the upper 15 to 20 ft of bedrock at both the RHR complex and the reactor site. The fracture density is directly influenced by the spacing of shale partings along with the core separates during drilling operations and subsequent handling.

2.5.4.2.9. Rock Strength

Corrected values for ultimate compressive strength and modulus of elasticity of bedrock, as determined by laboratory unconfined compression tests, are presented in Table 2.5-5. Elastic moduli values were computed from plots of unit axial stress versus unit axial strain derived from laboratory test results. Records of these laboratory test results are contained in Appendix 2D. Results of unconfined compression tests on rock from borings taken from the reactor site and from the RHR complex are presented in Tables 2.5-5 and 2.5-6.

2.5.4.3. Plot Plan

A topographic map of the site showing the location of Fermi 2 facilities is given in Figure 2.4-3. The plant facilities are shown in relation to bedrock topography in Figure 2.5-12. The boring plan in relation to plant facility locations is given in Figures 2.5-13 and 2.5-14. Subsurface sections in relation to plant facilities are presented in Figures 2.5-15 through 2.5-20.

Structural geology in relation to facility location is shown in Figures 2.5-22 and 2.5-23.

2.5.4.4. Soil and Rock Characteristics

A table and profiles of a compressional and shear wave velocity survey are presented in Subsection 2.5.1 and in Figures 2.5-58 through 2.5-61. Graphic core boring logs are presented in Subsection 2.5.1 and in Figures 2.5-24 through 2.5-56. Compressional and shear wave velocities are presented in Subsections 2.5.1.2.9, 2.5.1.2.10, and 2.5.4.2.

2.5.4.5. Excavations and Backfill

2.5.4.5.1. Rock Excavation

Early in the reactor building excavation, a test blasting program was conducted to control the excavation blasting at Fermi 2 relative to Fermi 1 (References 13, 40, 41, and 42). Ground motions were measured at varying distances from test blasts for a selected range of blast loads, and attenuation data were developed as shown in Figure 2.5-63. The blasting criteria for limiting onsite seismic disturbances were (a) particle velocity limited to 1 in./sec, and (b) particle acceleration limited to 5 percent of gravity. The blasting program was carefully supervised by qualified engineering personnel and was monitored with instruments.

Subsequent to blasting operations, the exposed foundation bedrock was sluiced with high-pressure water jets and carefully examined by a qualified geologist to ensure that no excessive natural fracturing or blasting back-break existed that might be unsuitable for foundation support. All heavily fractured rock, clay seams, weathered shale, and other unsuitable materials exposed at final foundation grade were removed.

Based on the limiting criteria, the production shot loads for the reactor/auxiliary building foundation excavation were as follows.

Pounds per Delay	Minimum Distance From Fermi 1 (ft)
25	400
40	500
50	600
65	700
80	800
100	900
150	1000
175	1100
200	1200

The charge limitation for the initial blasting to excavate for the RHR complex foundation was based on the distance to Fermi 2 facilities, as follows:

Pounds per Delay	Distance to the Nearest 144-in.-Diameter Circulating Water Pipe (ft)
0.30	60
0.60	75
1.40	100
3.50	150
6.25	200

On the basis of blast-induced ground or structure motions measured during initial blasts (Reference 43), the charge limitation was increased as follows:

Pounds per Delay	Distance to the Circulating Water Pipe (ft)
1.0	60
1.0	75
1.4	100
3.5	150
6.25	200

2.5.4.5.2. Earthwork

Fill materials required to raise the site to required final grade were obtained from an onsite rock quarry and supplemented by offsite quarry-supplied rock. Fill placed at the site and properly compacted was used for the support of minor structures. All Category I and other major structures are supported on competent bedrock; the walls were framed and placed on the structural base slab. Crushed rock was then compacted in layers between the walls and the blast-excavated rock face.

A test section of compacted stone fill material was constructed to permit onsite plate load testing and seismic studies of the fill material (Reference 3). Plate load tests were performed on both the compacted crushed-rock fill and the in situ glacial till. The locations of the plate load tests are indicated in Figure 2.5-14. The results of the plate load tests are given in Table 2.5-14. A seismic investigation of the compacted crushed- rock test area was also performed. The results of the compression wave velocity measurements are shown in Figure 2.5-64.

Information on compaction criteria, gradation criteria, methods of placing and compacting, and thickness of lifts of the crushed- rock structural backfill is found in Detroit Edison specification 3071-37, Fill Materials, Placement and Compaction (Appendix 2C), and in Building Work specification for RHR Complex 3071-142.

Because of the difficulty of preparing representative samples for laboratory testing, there were no laboratory static or dynamic tests performed on samples of the crushed-stone compacted fill material. Crushed-stone compacted fill material obtained a high degree of density when placed in accordance with specifications 3071-37 and 3071-142. This dense compacted-rock fill with its select gradation was further reinforced by the interlocking mechanism of the angular, well-graded particle sizes of the rock fragments and afforded resistance to penetration by conventional sampling methods. Field plate load and seismic tests were used as the basis for deriving the values presented in Table 2.5-9.

The replacement of the underground service water piping has been analyzed in accordance with the UFSAR to allow the use of controlled Low Strength Material (CLSM) and 21AA backfill material in the installation of the buried pipe. This results in partial CLSM and 21AA backfill material against the RHR complex walls.

Consolidation tests were done on relatively undisturbed samples of glacial till (Reference 3). The results of the tests are shown in Figure 2.5-65.

There are no Category I buildings placed directly on crushed-rock fill. Additional testing on the in-place structural backfill after its placement in accordance with the specification for such placement was not performed. The onsite quality control program required constant inspection to ensure that the work was being performed in accordance with the referenced specification. Since the test results taken from the large compacted test fill area formed the basis for developing the specification, assurance that specification objectives throughout the site were being met was obtained by using trained personnel in a continuously monitored quality control (QC) program.

Fill that did not meet the specification requirements was rejected. Construction supervision and constant QC inspection were utilized to ensure that all work was continuously performed in accordance with the specifications.

During the course of safety evaluation review, the NRC requested additional information regarding backfill (drawings) for structures and components. This information was provided to the NRC with Reference 32 in June 1981, wherein it was mentioned that the following representative drawings show the backfill at the site: 6C721-2106, 6C721-2324, 6M721-2680, and 6M721-4232.

2.5.4.6. Ground Water Conditions

A summary of ground water conditions appears in Subsection 2.4.13. The history of ground water conditions at the site is summarized below.

The natural surficial deposits at the site consist of low- permeability glacial till, lacustrine clay, and peat. The surficial deposits locally act as a confining layer above the Paleozoic bedrock aquifer, and a slight artesian pressure exists at the site.

Various parameters were investigated and their relationships to local ground water features have been noted.

Pressure tests were conducted in borings 201, 203, 209, and 210 in 1969 during the comprehensive foundation investigation for the reactor/auxiliary building. Test data are shown in Table 2.5-15. The results of these tests are presented to the right of the boring logs as shown on Figures 2.5-33, 2.5-35, 2.5-42, and 2.5-43. Pressure testing was accomplished by means of inflatable packers set in the area to be tested. Water under pressure was forced into this area and the rate of take of the water at various pressures was recorded in gallons per minute. From these data, permeability of the rock was calculated by use of the following formula:

$$K = C_p \frac{Q}{H} \qquad (2.5\text{-}1)$$

where

K = permeability in feet per year

Q = flow in gallons per minute

H = head of water in feet of water acting on the test section

C_p = a constant of 4900 for nx-sized hole and a 10-ft test section (Reference 44)

Ground water observations were made by observing the rate of artesian flow at varying depths. These observations were made by drilling to a certain depth and collecting water as it flowed from the top of the boring and timing the rate of filling of a container of known volume in gallons. It was then possible to determine rate of artesian flow in gallons per minute at various levels in the boring.

Further ground water observations were made after completion of the borings by inserting standpipes in the borings, allowing the water to rise to its static level, and measuring the elevation of the top of the water. Other observations were made at this time in regard to water quality. These observations ranged from simply noting the odor of H_2S gas (shown on the boring logs) to collecting ground water samples for chemical analyses of the ground water.

In 1972, foundation investigations for the RHR complex included the installation of six piezometers in borings RHR 1, 2, 5, 6, 7, and 8. The installation of these piezometers and data gathered from them refute the 1969 water-level data in that water levels are generally much lower and artesian flow is not noted. This is due exclusively to construction dewatering. The overall result has been to reverse the ground water gradient at the plant site from toward the lake to away from the lake.

During quarry operations between 1969 and 1972, a decline in ground water level occurred. Also, during this period a decline occurred because of a regional drought condition. After the spring of 1971, the quarry operation was restricted to the southern end. The northern part was diked and functioned as a ground water recharge pit, with the water level maintained full at about Elevation 570 ft. Quarry operations ceased on June 30, 1972. Water-level observations were made during and after the quarry operations in several observation wells, as shown in Figure 2.4-25. Water-level data are given in Table 2.4-7.

As mentioned above, dewatering was carried out specifically for rock excavation. Conventional dewatering by pumping from sumps was employed. A grout curtain was constructed around the reactor/auxiliary building rock excavation to decrease the extent of dewatering required and to minimize the extent of depression of the surrounding ground water level.

The curtain wall grout plan for the excavation of the Fermi 2 reactor/auxiliary building (References 45 and 46) delineated 96 grout holes spaced at 12-ft centers and located as shown in Figure 2.5-66. A grout curtain was not used for the RHR complex excavation.

Grouting of the rock mass under the plant facilities will force that moving ground water which would have flowed through the grouted rock to be diverted around it. This diversion will increase slightly the ground water flow rate in the rock immediately outside and below the grout curtain and might increase slightly the solutioning of the carbonate rocks in that zone. In view of the low flow rate of the ground water in the bedrock aquifer (see Subsection 2.4.13.2), the minor expected increase in flow rate through diversion of ground water around the grout curtain is not expected to significantly accelerate solutioning at the site.

Water samples for laboratory analyses were obtained from stratigraphic horizons within the site area during the 1969 boring program. The elevations at which water samples were obtained are noted in the boring logs. Some water samples were obtained from artesian flows at various depths during the borings, usually after the boring had flowed for several hours. After completion of the boring, the remaining samples were obtained from borings 210 and 209 at 10-ft intervals between double-inflatable packers from artesian flow through a 3/4-in. discharge pipe. At each sample interval, the water flowed a minimum of 20 minutes before a sample was taken.

Selected ground water samples were tested to determine pH, sulfate content, and chloride content. These tests were performed by Mr. Bernard Erlin, Materials and Concrete Consultant. The results of chemical analyses of ground water samples are shown in Table 2.5-16. All of the ground water tested had a relatively high sulfate content, in the range of 1168 to 1865 ppm. The depth at which ground water samples were obtained varied from the rock surface to more than 200 ft below the rock surface. No marked variation of sulfate content with depth was observed.

The chloride content of the ground water, as sampled, ranged from 21 to 1164 ppm. The random and occasional high chloride contents measured were affected by boring operations where salt was used as an additive to the boring fluid. Salt was used with the boring fluid in borings 209 and 210 and in zones of close fractures; this would have affected the chloride content of ground water sampled from adjacent borings. Based on the results of measured chloride content of samples that should not have been affected by salt in the boring fluid, the natural ground water at the site appears to have a chloride content of less than 100 ppm.

The hydrogen ion concentration (pH) of the ground water ranged from 7.3 to 8.1; thus, the ground water is not acidic.

Although the ground water was not tested for the presence of free carbon dioxide, it can reasonably be assumed that the water has been saturated with calcium carbonate by its passage through limestone and dolomitic bedrock.

2.5.4.7. Response of Soil and Rock To Dynamic Loading

Response spectra for the SSE and the OBE are presented in Figures 2.5-67 and 2.5-68 respectively.

The SSE (originally designated design-basis earthquake or DBE on the project) was anchored at the zero period acceleration level previously described and configured to match the shape of existing spectra for similar site conditions. At the time the facility design bases were established, spectra from El Centro 1940, Olympia 1949, El Centro 1934, Helena 1935, and Taft 1952 were used in developing envelope spectra for design bases purposes.

The OBE was similarly shaped but anchored at a zero period acceleration approximately half the SSE. In the decade since the Fermi design bases were established, more conservative assumptions have been made regarding the shape of facility site response spectra in intermediate frequency ranges. For this reason, the Fermi project developed a site-specific earthquake response spectrum, incorporating all potential conservatisms, and reevaluated those items in the facility necessary for shutdown with a loss of offsite power, to ensure the acceptability of the plant with respect to site-specific earthquake excitation. These activities reaffirmed the Fermi 2 seismic design adequacy.

Soil structure interaction phenomena were evaluated at the Fermi site, and found to be negligible. Category I structures at Fermi 2 are founded in bedrock. A study completed for the Fermi 2 structures founded on rock showed that it can be safely assumed in accordance with existing studies and the unique finite element analysis undertaken for Fermi, that the Fermi 2 foundation behaves as a rigid medium, and that soil structure interaction effects are negligible. Therefore, the site earthquake response spectra developed for the bedrock represent the base excitation to be experienced by facility Category I structures.

Category I buried piping and electrical ducting runs between Category I structures at the Fermi site. These buried pipes and ducts have been subjected to a rigorous dynamic analysis including the effects of interaction with the supporting foundation material. Flexibility has been provided at all building and manhole intersection points to minimize potential concrete strains. The design integrity of these buried components is proven by evaluation of anticipated earthquake wave propagation phenomena.

The response spectra indicate the estimated response of a structure subjected to earthquake ground motion. The spectra are presented over a range of frequencies corresponding to the natural frequencies of the various structural elements. The spectra represent the maximum amplitude of motion in the various elements of the structure for typical degrees of damping. Response spectra are also discussed in Section 3.7.

2.5.4.8. Liquefaction Potential

All Category I structures are supported within the Bass Islands dolomite, which is not susceptible to liquefaction.

2.5.4.9. Earthquake Design Basis

The earthquake design basis is presented in Subsection 2.5.2.

2.5.4.10. Static Analyses

The strength of the foundation rock was evaluated in the laboratory by means of unconfined compression tests (Subsection 2.5.1.2.10). Considering these values to be appropriate for rock with an RQD of 100, a reduction factor was selected based on an assessment of the measured RQD values, information on vug volume and size, fracture orientation and spacing, and presence of clay and shale seams (Subsection 2.5.1.2.2.2). On this basis, the ultimate bearing capacity of the rock mass in the plant and RHR complex is considered to be on the order of 300,000 lb/ft^2. Using a factor of safety of 12, the recommended design bearing capacity is 25,000 lb/ft^2. However, no credit was taken for a possible increase in the recommended bearing capacity by rock grouting.

Settlement was computed using the elastic moduli information with modifications based on experience, RQD, vugs, discontinuities, and clay seams to produce conservative deformation moduli appropriate for the in situ rock. The total settlement of the RHR complex is estimated to be on the order of 0.25 in. for an assumed applied pressure of 3000 lb/ft^2. The total settlement of the reactor /auxiliary building is conservatively estimated to be on the order of 0.3 to 0.5 in. for an assumed applied pressure of 25,000 lb/ft^2.

Computed lateral pressures are presented in Table 2.5-17. In computing lateral pressures appropriate for the compacted rock fill, it was necessary to estimate the probable angle of internal friction of this material. Based on observation of the material placed in the field and on research of available published data, the angle of internal friction was assumed to be 40°.

All static lateral pressure data presented in Table 2.5-17 are expressed as equivalent fluid pressures. For rigid walls, the tabulated values of lateral pressures are derived for the case of earth pressure "at rest." For cantilever walls, the tabulated values are derived for the case of "active" earth pressure.

Dynamic lateral pressure increments due to rock fill were determined using methods described in Reference 47. The dynamic increments of lateral pressure on the walls of the substructures due to ground water were obtained using Westergard's Theory (Reference 48), modified by Matuo and Ohara (Reference 49). These lateral pressure increments for the RHR complex and reactor/auxiliary building are provided in Figures 3.8-48 and 3.8-49, respectively.

Static pressures imposed by rock on rigid or cantilever walls above the ground water level will be negligible. The lateral pressure in rock cuts below the water table will be limited to hydrostatic water pressure.

2.5.4.11. Criteria and Design Methods

2.5.4.11.1. Foundations

The criteria for foundation support are based on the properties of the underlying materials (Subsection 2.5.4.2) and soil and rock characteristics (Subsection 2.5.4.4).

The ultimate bearing capacity of the rock mass in the plant area is estimated to be on the order of 300,000 lb/ft^2 (Subsection 2.5.4.10). Assuming a combined static and dynamic maximum loading as high as 25,000 lb/ft^2, the factor of safety against further foundation failure could exceed 12. Considering the rock to be strengthened by the grouting operations, the factor of safety is considerably in excess of 12. The average foundation load data for Category I and other structures are given in Table 2.5-18. The average foundation loads are considerably less than the assumed 25,000 lb/ft^2; therefore, the factor of safety will be larger than 12.

The criteria for seismic design are presented in Subsections 2.5.2.10 and 2.5.2.11. Seismic design methods are presented in Section 3.7.

2.5.4.11.2. Cement

In consideration of the high sulfate content of the natural ground water, sulfate-resistant cement was used for all cement grout and subsurface concrete that will be in contact with the ground water. Type V portland cement conforming to the requirements of ASTM Designation C150-68 was used. In concrete work above Elevation 573.0 ft, Type II portland cement conforming to the requirements of ASTM Designation C150-68 was used. As stated in Subsection 2.5.1.2.7, CSA A5-1971 cement was also used.

The use of calcium chloride or other chlorides as admixtures incorporated into concrete or grout mixtures was prohibited as such admixtures reduce the resistance of the concrete or grout to sulfate attack.

2.5.4.12. Techniques To Improve Subsurface Conditions

2.5.4.12.1. Grouting - Reactor/Auxiliary Building

Rock strata below the foundation levels of the Category I structures were pressure grouted. It ensured that no continuous open zones existed across the excavation in the bedrock. The complete grouting program for the reactor/auxiliary building was successfully carried out (References 50, 51, and 52).

The sequence of grouting operations for the reactor/auxiliary building consisted of drilling, washing, pressure testing, and grouting each grout hole. The elevations of the bases of grout holes were selected for the reactor/auxiliary building at elevations of 483 and 499 ft, respectively. These elevations were chosen on careful study of RQD, core recovery, and fracture data, modified after visual inspection of the rock core itself. Since the in situ rock was judged to be sufficiently sound to support the vertical loads and grouting was performed only to provide a more homogeneous rock mass beneath the structures, it was judged that grouting into the underlying Salina Group would have no effect on foundation stability. Grouting was performed in two stages, herein referred to as first and second zones, extending to depths of 6 and 50 ft below the rock surface, respectively. Initial or primary holes within each zone were spaced 30 ft on centers, and final closure was achieved by subsequently grouting all intermediate holes (secondary, tertiary, and quaternary holes). The locations of all holes are presented in Figures 2.5-69 and 2.5-70.

During grouting operations, two additional grout holes were drilled (Nos. 75A and 76A). Hole 75A was drilled to replace hole 75, which was abandoned when a drill bit was lodged in the hole. Hole 76A was drilled because of the low grout take (1.5 ft^3) in hole 77. The relatively low grout take in hole 76A indicated that intermediate holes were probably not necessary when low grout takes are recorded.

All grout holes were drilled with percussion drilling equipment, and any anomalies in the general rate of penetration of drilling were noted. On some holes, detailed logs of rate of penetration were recorded. These records assisted in delineating the extent of rock fracturing and thus assisted the planning of grout mixes. In general, the rate of penetration of rock varied between 20 and 50 sec/ft. Very few voids were encountered; the largest was a 20-in. void observed in hole 67. All grout holes penetrated to an elevation of 515 ft, with the exception of holes 51 and 27, which extended to 518 and 526 ft, respectively. These two holes were terminated short because of drilling difficulties.

Subsequent to drilling operations, holes were washed and pressure tested. On many holes, the drilling operations combined with a relatively large flow of ground water provided clean holes. Consequently, no additional washing was required. Each hole was pressure tested at a selected pressure and the steady water take was recorded. The results of pressure testing were used in determining the initial grout mixes for each particular hole.

Grout mixes injected into the grout holes all contained a 2:1 ratio of cement to flyash. The ratio of water to cement plus flyash varied from 3:1 to slightly less than 1:1. For holes with high grout takes, final grout mixes included sand, which was added to give a sand-to-cement ratio of 1:1 or 1.5:1. All holes were pressure grouted in one stage. The grouting of each hole was started with a water-to-cement plus flyash ratio of 3:1 or 2:1. If the pressure did not increase after approximately 10 ft^3 of grout had been pumped, then the mix was thickened initially by decreasing the water-to-cement ratio and then further, if necessary, by adding sand to the mix. All holes were grouted to refusal. Individual grout takes for various mixes are summarized in Table 2.5-19.

A total of 1644 ft^3 of pressure grout was injected into the grout holes. An additional 72.5 ft^3 of grout was used to backfill the upper portion of the holes above the packer. Table 2.5-20 summarizes the grout take for each zone. Detailed descriptions of the foundation rock encountered in five exploratory borings, drilled following completion of the grouting program, are presented in Figures 2.5-71 through 2.5-75. Grout encountered in rock cores is noted in the logs of borings. Only one void of 0.3 ft was encountered in the post-grout exploratory boring in boring 216. Since boring 216 was drilled within 5 ft of a secondary grout hole and the void contained no grout, it was not an interconnected void, but an isolated feature. Upon completion, all five of the exploratory borings were tremie grouted.

Subsequent to grouting operations, a complete rock subgrade inspection of the reactor/auxiliary building was carried out; the results of this inspection are summarized in Figure 2.5-76.

2.5.4.12.2. Grouting - Residual Heat Removal Complex

The sequence of grouting operations (References 53 and 54) for the RHR complex consisted of drilling, washing, and grouting each grout hole. The elevation of the bases of the holes was selected at 530 ft. Grouting was performed in two zones extending to depths of 6 and 20 ft below a concrete leveling mat placed over the original rock surface at Elevation 550 ft. Initial or primary holes within each zone were spaced 30 ft on centers and final closure was achieved by subsequently grouting all intermediate holes (secondary, tertiary, and a few quaternary holes). Figures 2.5-77 through 2.5-81 show locations of all holes, as well as amounts of grout taken.

Prior to drilling and grouting operations, eight exploratory holes were core drilled to depths of 20 ft, and then washed and pressure tested. The logs of these borings are shown in Figures 2.5-82 through 2.5-85. Each interval was tested at a selected pressure and the steady water take was recorded.

All grout holes were drilled with percussion drilling equipment and then washed prior to grouting. Grout mixes injected into the grout holes contained a 1:1 to 1.5:1 ratio of cement to flyash. The ratio of water to cement plus flyash varied from 3:1 to approximately 1:1. The grouting of each hole was generally started with a water-to-cement plus flyash ratio of 3:1 and if the pressure did not increase after approximately 10 minutes, the mix was thickened by decreasing the water-to-cement ratio. All holes were grouted to refusal.

Table B1, Appendix 2B, summarizes the grout take for each zone. Detailed descriptions of the foundation rock encountered in eight exploratory borings drilled following completion of the grouting program are presented in Figures 2.5-86 through 2.5-89, and water-pressure test results are shown in Table B2, Appendix 2B.

Subsequent to cleaning the exposed rock surface, and prior to placement of the concrete mat, a complete rock subgrade inspection was carried out. A map summarizing the results of this inspection is shown in Figure 2.5-90. In addition, photographs were taken completely covering the side walls of the excavation and are available for inspection.

A detailed report on the results of the foundation treatment is found in Appendix 2B.

2.5.4.12.3. Effectiveness of Grouting Program

The grouting program was intended to seal cracks in the foundation bedrock that may have been horizontally continuous. As part of the preliminary explorations and later the grouting program, observations were made during drilling with respect to water losses and dropping of drill rods. It was observed that water losses were generally not great and that there were no instances of drill rod drop. Based on these observations, no areas of major or continuous solution activity were detected. However, the core recovered did show vugs, indicating that minor solution activity was present. To ensure that no continuous horizontal zones could be present below Category I structures, pressure grouting was undertaken. The grouting program has the further benefit of enhancing the bearing capacity of the rock.

The grouting program consisted of drilling primary, secondary, and, where necessary, tertiary grout holes until the requirements for discontinuing grouting were achieved. Subsequent to grouting, a number of holes were drilled to ascertain the effectiveness of the grouting program. The borings drilled after grouting generally produced the same results as the exploratory holes prior to grouting. That is, the core recovery and RQD showed no appreciable difference. Furthermore, the postgrouting borings showed very little evidence of grout in the core or drill water.

The lack of grout in postgrouting borings is attributed to the nonexistence of open or continuous solutioning in the bedrock. The low grout takes during consolidation grouting and the lack of grout in postgrouting borings provide evidence of the noncontinuity of any open features. In addition, the lack of both drill rod drops and water losses in postgrouting borings further indicates that no open channels exist in the bedrock foundation.

2.5.4.12.4. Base Slab Construction

The reactor/auxiliary building base slab is a 4-ft-thick reinforced-concrete slab consisting of 4000 psi concrete at 28 days with ASTM A-615 grade 60 reinforcing steel. The slab is supported by a leveling slab also constructed of 4000 psi concrete that is in turn supported by pressure-grouted competent bedrock. Shortly after placement of the base slab, radial superficial cracks appeared. A report covering the investigation and treatment of these cracks is documented in Reference 55.

All possibilities that may have caused the cracking of the slab were considered. However, after a review of all of the postulated potential causes for the surface hairline cracks, and a detailed observation and mapping of the location, arrangement, depth, and thickness of the cracks themselves, it is concluded that the cracks were most probably caused by the restraint of the slab at its perimeter during temperature fluctuations and by shrinkage strains that developed during the curing of the thick and heavily reinforced concrete slab. The cracks were very thin, and most of them did not penetrate the full depth of the slab. The lack of differential vertical displacement on both sides of a crack indicated that vertical shear planes resulting from upheaval or settlement of the underlying concrete level slab or grouted bedrock had not occurred. The radial symmetry of the cracks further supported the belief that vertical displacement, local, random, or general in orientation, did not occur. As stated on page A7 of the D&M report "Results of Rock Foundation Treatment," dated January 12, 1975 (Reference 23), "No zones of excessive fracturing or highly vugged material exist in horizontal layers across the site; localized openings in the foundation rock have been adequately treated; and the near surface fractures have been filled." Part B of the same referenced report outlines the careful attention placed on preparing the rock surface to receive the 2- to 4-ft-thick level mat and then the 4-ft-thick structural slab that later developed thin radial superficial cracks.

After reviewing these data, reviewing the conclusions presented by consultants, and observing and investigating the extent and orientation of the cracking, it is concluded that the source of the cracking is not the solutioning or jointing in the bedrock. The placement of crushed-rock fill outside the subbasement walls and at an elevation higher than the slab was not related to the cracking. The schedule for fill placement was done one section at a time and generally followed the initial observation of radial cracking.

2.5.5. Slope Stability

During the excavation for the reactor/auxiliary building and RHR complex, which included blasting, there were no instances of instability of the excavation slopes and therefore no need for stabilization measures.

There are no excavation or natural slopes whose failure could adversely affect the safe operation of the plant. However, a shore barrier was erected at the east end of the plant bordering on Lake Erie. For a discussion of the shore barrier, see Subsections 2.4.5 and 3.4.4.5.

[a] BI = Bass Islands Group.
S = Salina Group.

TABLE 2.5-8 RESONANT COLUMN TEST RESULTS

Boring Number	Depth (ft)	Formation[a]	Rock Type	Shear Modulus (lb/ft^2)
32A	25	BI	Dolomite	150×10^6
25	96	S	Calcareous Shale	30×10^6

[a] BI = Bass Islands Group.
S = Salina Group.

TABLE 2.5-9 STATIC AND DYNAMIC SOIL AND ROCK PROPERTIES - REACTOR/AUXILIARY BUILDING

Property	Crushed-Rock Fill	In Situ Glacial Till	Bass Islands Bedrock
Density (lb/ft^3):			
Dry density	139 ± 4%	125 ± 4%	150 ± 10%
Wet density	144 ± 5%	140 ± 5%	--
Submerged density	90 ± 3%	80 ± 3%	110 ± 10%
Wave velocities (ft/sec):			
Compression wave	2,500 ± 15%	7,700 ± 7%	13,000 ± 10%
Shear wave	900 ± 25%	2,200 ± 15%	7,600 ± 15%
Poisson's Ratio:			
Static or dynamic	0.4 ± 10%	0.45 ± 10%	0.24 ± 10%
Modulus of elasticity (lb/ft^2):			
Static	$1.2 \times 10^6 \pm 25\%$	$0.5 \times 10^6 \pm 20\%$	$120 \times 10^6 \pm 50\%$
Dynamic	$4.0 \times 10^6 \pm 30\%$	$1.2 \times 10^6 \pm 30\%$	$180 \times 10^6 \pm 50\%$
Increase per foot of depth	$0.48 \times 10^6 \pm 25\%$	$0.48 \times 10^6 \pm 20\%$	0
Shear modulus (lb/ft^2):			
Dynamic	$1.4 \times 10^6 \pm 30\%$	$0.4 \times 10^6 \pm 30\%$	$72 \times 10^6 \pm 50\%$
Increase per foot of depth	$0.17 \times 10^6 \pm 25\%$	$0.17 \times 10^6 \pm 20\%$	0
Damping values (percent of critical):			
Within earthquake levels	7% to 10%	5% to 8%	1%

TABLE 2.5-10 STATIC AND DYNAMIC SOIL AND ROCK PROPERTIES - RHR COMPLEX

	Crushed-Rock Fill	Glacial Till[a]	Bass Islands Bedrock
Density (lb/ft^3)			
Dry density	139 ± 4%	124 ± 2%	150 ± 10%
Wet density	144 ± 5%	139 ± 2%	
Submerged density	90 ± 3%	77 ± 2%	110 ± 10%
Wave velocities (ft/sec)			
Compression wave	2500 ± 15%	7700 ± 7%	13000 ± 10%
Shear wave	900 ± 25%	2200 ± 15%	7600 ± 15%
Poisson's Ratio			
Static or dynamic	0.4 ± 10%	0.45 ± 10%	0.24 ± 10%
Static modulus of elasticity (lb/ft^2)	1.2×10^6 ± 25%	4.0×10^5 ± 30%	120×10^6 ± 50%
Dynamic modulus of elasticity (lb/ft^2)			
Single 1.0%		1.2×10^5 ± 50%	
Amplitude shear 0.1%	4.0×10^6 ± 30%	4×10^5 ± 50%	180×10^6 ± 50%
Strain 0.01%		13×10^5 ± 50%	
Static modulus of rigidity (lb/ft^2)	4.0×10^5 ± 30%	1.4×10^5 ± 30%	48×10^6 ± 50%
Dynamic modulus of rigidity (lb/ft^2)			
Single 1.0%		0.7×10^5 ± 50%	
Amplitude shear 0.1%	1.4×10^6 ± 30%	2.5×10^5 ± 50%	72×10^6 ± 50%
Strain 0.01%		7.5×10^5 ± 50%	
Damping values (percent of critical damping)			
Single 1.0%		19.0%	
Amplitude shear 0.1%	7% to 10%	17.0%	1%
Strain 0.01%		9.0%	
Modulus of subgrade reaction (lb/ft^3)	1.0×10^6 ± 25%		6.5×10^5 ± 50%

[a] Values reported were determined specifically for in situ conditions. However, the glacial till, compacted to at least 95 percent of maximum dry density, is expected to exhibit static and dynamic properties that fall within the ranges of variation reported in this table.

TABLE 2.5-11 MODIFIED MERCALLI INTENSITY (DAMAGE) SCALE OF 1931 (Abridged)

I. Not felt except by a very few under especially favorable circumstances (I, Rossi-Forel Scale)

II. Felt only by a few persons at rest, especially on upper floors of buildings. Delicately suspended objects may swing (I to II, Rossi-Forel Scale)

III. Felt quite noticeably indoors, especially on upper floors of buildings, but many people do not recognize it as an earthquake. Standing motorcars may rock slightly. Vibration like passing of truck. Duration estimated (III, Rossi-Forel Scale)

IV. During the day felt indoors by many, outdoors by few. At night some awakened. Dishes, windows, doors disturbed; walls make creaking sound. Sensation like heavy truck striking building. Standing motorcars rocked noticeably (IV to V, Rossi-Forel Scale)

V. Felt by nearly everyone, many awakened. Some dishes, windows, etc., broken; a few instances of cracked plaster; unstable objects overturned. Disturbances of trees, poles, and other tall objects sometimes noticed. Pendulum clocks may stop (V to VI, Rossi-Forel Scale)

VI. Felt by all, many frightened and run outdoors. Some heavy furniture moved; a few instances of fallen plaster or damaged chimneys. Damage slight (VI to VII, Rossi-Forel Scale)

VII. Everybody runs outdoors. Damage negligible in buildings of good design and construction; slight to moderate in well-built ordinary structures; considerable in poorly built or badly designed structures; some chimneys broken. Noticed by persons driving motorcars (VII, Rossi-Forel Scale)

VIII. Damage slight in specially designed structures; considerable in ordinary substantial buildings, with partial collapse; great in poorly built structures. Panel walls thrown out of frame structures. Fall of chimneys, factory stacks, columns, monuments, walls. Heavy furniture overturned. Sand and mud ejected in small amounts. Changes in well water. Persons driving motorcars disturbed (VII+ to IX-, Rossi-Forel Scale)

IX. Damage considerable in specially designed structures; well-designed frame structures thrown out of plumb; great in substantial buildings, with partial collapse. Buildings shifted off foundations. Ground cracked conspicuously. Underground pipes broken (IX+, Rossi-Forel Scale)

X. Some well-built wooden structures destroyed; most masonry and frame structures destroyed with foundations; ground badly cracked. Rails bent. Landslides considerable from river banks and steep slopes. Shifted sand and mud. Water splashed (slopped) over banks (X, Rossi-Forel Scale)

XI. Few, if any (masonry) structures remain standing. Bridges destroyed. Broad fissures in ground. Underground pipelines completely out of service. Earth slumps and land slips in soft ground. Rails bent greatly

XII. Damage total. Waves seen on ground surface. Lines of sight and level distorted. Objects thrown upward into the air

TABLE 2.5-12 DISTANT EARTHQUAKE EPICENTERS (200 OR MORE MILES FROM THE SITE) (1800-1986)

210	14 - 24	15	15	15.8	2220
	23 - 33	30	20	15.5	1090
	45 - 55	50	20	11.5	486
	54 - 64	50	20	16.5	697
	63 - 73	50	15	21.0	888
	72 - 82	50	20	21.0	888
	81 - 91	50	20	20.0	845
	90 - 100	50	20	15.0	634

Note: Permeabilities were calculated using the method outlined in Reference 4; i.e., using the formula K = Cp (Q/H)

where K = permeability in feet per year

Cp = a constant dependent on hole size

Q = flow in gallons per minute

H = applied pressure in feet of water units

TABLE 2.5-16 CHEMICAL ANALYSES OF GROUND WATER

[a] BI = Bass Islands Group.
S = Salina Group.

TABLE 2.5-17 LATERAL PRESSURE VALUES[a]

Lateral Pressure ($lb/ft^2/ft$)	Crushed-Rock Fill	Bass Islands Bedrock
Static-rigid wall above water	96[b,c]	0
Static-rigid wall submerged	122[b,c]	63
Static-cantilever wall above water	32[c]	0
Static-cantilever wall submerged	80[c]	63
Dynamic-rigid wall above water	[d]	-
Dynamic-rigid wall below water	[d]	-

[a] During the course of safety evaluation review, the NRC requested additional information regarding the technique for the dynamic lateral pressure computation. This information was provided to the NRC as Reference 32.

[b] Alternate values calculated per Reference 56 were used in the re-analysis of some subsurface exterior walls.

[c] A factor of safety of 1.5 is applied to these values when the foundation walls are required to perform safety-related functions.

[d] See Figures 3.8-48 and 3.8-49.

TABLE 2.5-18 FOUNDATION DATA

	Approximate Plan Dimensions (ft x ft)	Foundation Elevations[a] (ft)	Approximate Uniform Applied Foundation Load (lb/ft^2)
Category I			
Reactor building	120 x 155	536	7500
Auxiliary building	80 x 155	536	4000 to 5000
RHR Complex	120 x 310	547	4000 to 5000
Other structures			
Turbine house	210 x 375	558	5000
Radwaste building	100 x 190	552	2500

[a] USGS datum.

[a] All grout holes were brought to refusal with a grout pressure ranging from 8 psi to 20 psi with the exception of holes 2, 3, and 68 in which there was a heavy grout return through the surface of the rock which was highly fractured above packer.

[b] An additional 72-1/2 ft^3 of grout was used for filling inside the casing subsequent to pressure grouting.

[c] Mix A – Water:cement + flyash ratio of 2:1 or greater.

[d] Mix B - Water:cement + flyash ratio of 1.5:1 or less

[e] Mix C - Water:cement + flyash ratio of 1:1 or less plus a water:sand ratio of 1:1.

TABLE 2.5-20 SUMMARY OF GROUTING FIRST ZONE GROUTING

(holes drilled 10 ft into rock)

Holes Drilled	Holes With Take	Percent Holes With Take	Sacks Cement and Flyash	Unit Take (sacks per foot of hole)
Primary	75	87	1629.00	3.17
Secondary	65	75	1066.25	2.08
Tertiary	39	29	174.00	0.21
Quaternary	7	27	109.25	0.84
Total	186	--	2978.00	--
Average		52.75		1.58

SECOND ZONE GROUTING

(holes drilled approximately 50 ft into rock)

Holes Drilled	Holes With Take	Percent Holes With Take	Sacks Cement and Flyash	Unit Take (sacks per foot of hole)
Primary	91	99	1340.25	0.46
Secondary	89	100	652.50	0.31
Tertiary	47	98	357.75	0.18
Quaternary	9	100	106.50	0.27
Total	236	--	2457.00	--
Average		99.22		0.31

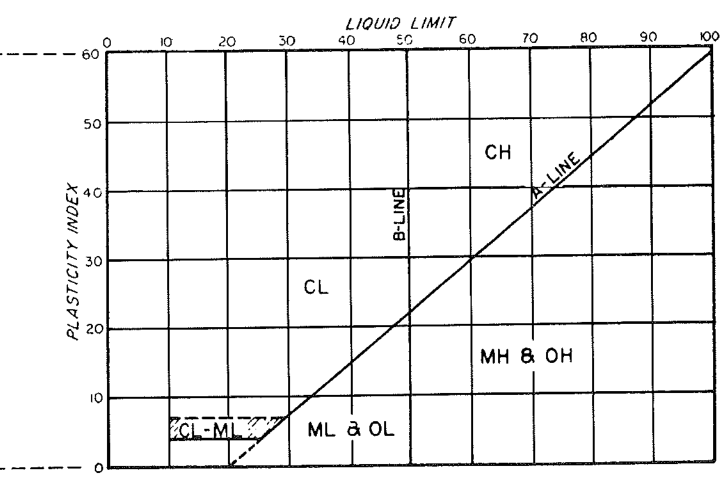
GRADATION CHART



PLASTICITY CHART

NOTES:
1. DUAL SYMBOLS ARE USED TO INDICATE BORDERLINE CLASSIFICATIONS.
2. WHEN SHOWN ON THE BORING LOGS, THE FOLLOWING TERMS ARE USED TO DESCRIBE THE CONSISTENCY OF COHESIVE SOILS AND THE RELATIVE COMPACTNESS OF COHESIONLESS SOILS.

COHESIVE SOILS

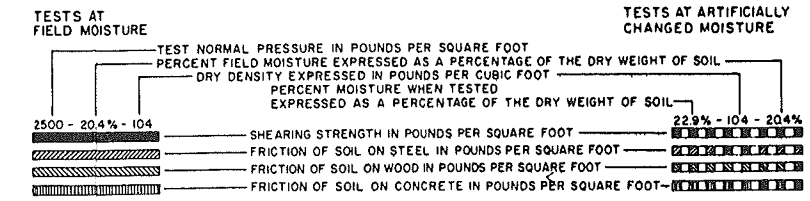
	(APPROXIMATE SHEARING STRENGTH IN KSF)
VERY SOFT	LESS THAN 25
SOFT	0.25 TO 0.5
MEDIUM STIFF	0.5 TO 1.0
STIFF	1.0 TO 2.0
VERY STIFF	2.0 TO 4.0
HARD	GREATER THAN 4.0

COHESIONLESS SOILS

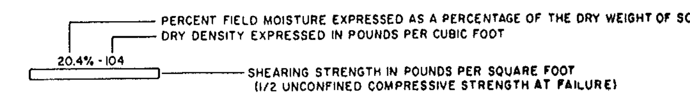
VERY LOOSE
LOOSE
MEDIUM DENSE
DENSE
VERY DENSE

THESE ARE USUALLY BASED ON AN EXAMINATION OF SOIL SAMPLES, PENETRATION RESISTANCE, AND SOIL DENSITY DATA.

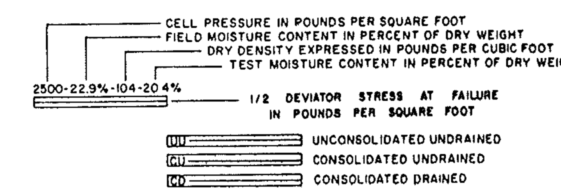
KEY TO TEST DATA



DIRECT SHEAR AND FRICTION TESTS



UNCONFINED COMPRESSION TESTS



TRIAXIAL COMPRESSION TESTS

YIELD, PEAK OR ULTIMATE STRENGTHS ARE IDENTIFIED ON SHEAR TEST DATA ON THE BORING LOGS AS FOLLOWS:

* YIELD STRENGTH
** PEAK STRENGTH
*** ULTIMATE STRENGTH

SHEAR TEST RESULTS

■ INDICATES UNDISTURBED SAMPLE
☒ INDICATES DISTURBED SAMPLE
□ INDICATES SAMPLING ATTEMPT WITH NO RECOVERY

I INDICATES LENGTH OF CORING RUN

NOTE:
DEFINITIONS OF ANY ADDITIONAL DATA REGARDING SAMPLES ARE ENTERED ON THE FIRST LOG ON WHICH THE DATA APPEAR.

ELEVATIONS REFER TO N.Y.M.T., 1935

RQD - ROCK QUALITY DESIGNATION
A MODIFIED CORE RECOVERY PERCENTAGE IN WHICH ALL THE PIECES OF SOUND CORE OVER 4 INCHES LONG ARE COUNTED AS RECOVERY. THE MODIFIED SUM OF CORE RECOVERED IS THEN EXPRESSED AS A PERCENTAGE OF THE TOTAL LENGTH OF THE CORE RUN.

% - VUGS INDICATES THE ESTIMATED RATIO OF VUGGED CORE SURFACE AREA TO TOTAL CORE SURFACE AREA. BOTH OPEN AND FILLED VUGS ARE INCLUDED IN THE VUGGED CATEGORY.

FRACTURE DENSITY TERMINOLOGY
VERY CLOSE-LESS THAN 2 INCHES APART
CLOSE-2 TO 6 INCHES
MODERATELY CLOSE-6 TO 12 INCHES
WIDE -GREATER THAN 12 INCHES

REPORT

ROCK FOUNDATION TREATMENT

RESIDUAL HEAT REMOVAL COMPLEX

FERMI II NUCLEAR POWER PLANT

FOR

THE DETROIT EDISON COMPANY

INTRODUCTION

This report describes the rock foundation treatment program for the Residual Heat Removal Complex at the Fermi II Nuclear Power Plant located near Monroe, Michigan. The primary purpose of the rock foundation treatment program was to explore for solution cavities or features and if found grout them in order to minimize the potential for ground motion amplification in the event of an earthquake.

The foundation treatment consisted of two separate operations: rock surface preparation and clean-up (Part A) and rock grouting (Part B). Detailed descriptions of both operations are presented herein.*

---

* Note: all references listed separately at end of report.

PART A

FOUNDATION ROCK SURFACE PREPARATION AND CLEAN-UP

Foundation Rock Surface Preparation and Clean-up

General

Upon the completion of the RHR complex excavation and prior to the placement of a concrete leveling mat for the grouting program, preparation and clean-up of the foundation rock surface was performed as recommended (Reference 1). All loose debris, loosely-chinked rock fragments, mud films and most clay was removed by high pressure jetting and by mechanical and hand equipment. The supervision and inspection of this program was carried out by Dames & Moore between February 19, 1974 and April 1, 1974.

Scope

The scope of our services during this phase of the foundation rock treatment was as follows:

1 - To supervise and inspect the clean-up of the foundation rock surface prior to placement of the concrete leveling mat;

2 - To prepare a geologic map of the rock surface features;

3 - To assist the AEC representative during his inspection of a cleaned portion of the foundation rock surface;

4 - To work closely on a daily basis with personnel of Ralph M. Parsons Company, the general contractor in order to coordinate the clean-up and leveling mat placement and to report progress to representatives of the Detroit Edison Company.

General Surface Geology

Lithology - The foundation rock surface consists of light brownish-gray, very fine-grained dolomite, a few areas of which are roughly textured and covered by black, paper-thin shale.

Much of the foundation rock surface is irregular, generally containing 2- to 4-foot diameter and 1/2- to 1- foot high mounds of medium to thin-bedded dolomite. These mounds or dome-like features are characterized by: (1) a wavy onionskin structure; (2) healed, massive brecciation due to primary sedimentary processes; and (3) vugs which vary from 1 inch to 1 foot in maximum dimension and contain celestite crystals. The northwest corner of the foundation is an exception to the general rock surface because there, the rock is evenly bedded and contains no mounds of brecciated dolomite.

The mounds are of sedimentary origin and were probably formed by the accumulation of layers of algae and lime mud in the original environment of deposition. In several places along the rock walls of the foundation, vertical zones of massive sedimentary breccia occur which are several feet wide and taper to a flattened top at bedding planes. These flattened tops are the result of truncation by primary erosional processes. One of these zones near column line intersection A8 is flanked and overlain by unbrecciated, layered, dolomite dipping downward from both sides. Below the brecciated zone the general dip of the strata appears to be uninterrupted, thus indicating a non-tectonic origin. The zone is well-cemented and exhibits no more fracturing than is evident throughout other parts of the excavation. Because of the similarity of the mounds observed both on the foundation floor and on the walls they are considered the same type of feature and sedimentary in origin.

Gray clay seams ranging from 1/8 inch to 2 inches in thickness fill some joints and some bedding plane fractures. This clay appears to be of the same physical character as that of the overlying glacial till. The fillings, therefore, are probably derived from the till. Areas of sedimentary breccia and clay fillings are shown on Plate A1, and detailed descriptions of the subsurface dolomite to a depth of 20 feet below the excavation surface are given on Plates B6 through B13.

Structure - Bedding plane attitudes vary from point to point in the foundation and in general seem to reflect the presence of the above mentioned breccia mounds. Despite local variations there is an apparent structural dip of a few degrees in a northerly direction. This compares favorably with the regional dip of a few degrees northwest towards the center of the Michigan Basin.

Fractures - The majority of the fractures in the foundation rock are tight, although some are filled with soft gray clay as described above. No displacements, tectonic breccias, or slickensided surfaces, other than slickensides associated with stylolites, were noted.

Most of the fractures are naturally occurring joints and can be grouped into three aprpproximately orthogonal sets. The dominant or major joint set trends from N21°-38°W and dips from

60°-80° to the southwest. Generally these joints vary in length from 5 to 30 feet but some are as much as 65 feet long. Spacing between joints is from 2 to 10 feet.

A bend of approximately 15° to the west of the major joint set occurs along a southwest-northeast zone from column line intersection A7 to the area of intersection E11. Since (1) many joints of the major set are continuous across this zone; and (2) no displacements or slickensides were noted along joints either parallel or transverse to the bend, therefore the bend only reflects a local variation in the orientation of the major joint set.

A minor set of joints trends from N54°-72°E and dips from 30°-60° to the northwest. Generally, these joints vary in length from 2 to 10 feet but some are as much as 30 feet long. Spacing between these joints is from 1 to 5 feet. In general, joints of the minor set are more irregular than those of the major set and certain ones terminate against major joints.

Bedding plane joints, which undulate but are essentially horizontal, are spaced from 6 inches to 2 feet apart. As seen in the rock walls of the sides of the foundation and in the sumps, these joints are generally tight but occassionally exhibit some minor openings which are often clay-filled as described above.

Also present are numerous relatively short, irregular fractures. Many of these, especially those radiating from the diamond-cored shot holes, can be attributed to the blasting program.

Procedures

A recommended procedure for rock surface preparation is described in Reference 1.

Following the initial program of blasting and mucking for the RHR Complex excavation, the rock surface was cleared of clay, rock fragments, and loosely-chinked rock by rubber-tired backhoes. At this point a veneer of gravel-to cobble-sized rock and clay remained. A high-pressure water hose, attached to a backhoe and moved laterally was then used for washing. This was subsequently followed by picks, shovels, brooms, hand-held water hoses and air-jet equipment for dental cleaning. Later, a three-man team working with a high-pressure water hose having a flattened nozzle was found to be very effective for the total removal of remaining surface debris. A ten-foot diameter area of thinly layered dolomite in the northwest section of the foundation was found to have open bedding plane fractures. A backhoe-mounted pneumatic hammer and picks were used to remove this section of rock which extended to a depth of 6 inches.

Following completion of the cleaning operation in a given area the rock surface was inspected and all features mapped. All open or closed fractures, joints, clay seams, and other structures or rock types were noted. These mapped features are shown on Plate A1, Foundation Rock Surface Features.

The foundation rock walls were inspected but not mapped. Photographs of the walls were taken instead by the Detroit Edison Company, and these are available for examination.

Conclusions

Based on our technical supervision and inspection of the rock surface preparation and clean-up, it is our opinion that the work has been carried out in accordance with project plans and specifications. During an AEC inspection of a cleaned portion of the excavation, it was determined that the clean-up had been done satisfactorily and that no detrimental structural features existed on the foundation surface. The surface was also free of any loose rock, mud films or clay which might prevent an effective bond with the concrete leveling mat, which was subsequently placed over the rock surface.

PART B

FOUNDATION ROCK GROUTING

Foundation Rock Grouting

General

Specifications and criteria for the foundation grouting program were prepared by Sargent & Lundy Engineers for the Residual Heat Removal Complex (Reference 3). Any modifications to the grouting procedure were effected by the Detroit Edison Company after consultation with representatives of Sargent and Lundy. Data on water pressure tests, drilling, grout takes, sand-cement-water ratios and grout pressures were recorded on a daily basis by the Lee Turzillo Contracting Company and regularly distributed to representatives of the Ralph M. Parson Company. The complete grouting program was observed by Dames & Moore between March 20, 1974, and May 1, 1974. Where pertinent, recommendations on the program were made by Dames & Moore to representatives of The Detroit Edison Company.

Purpose

The primary purpose of the rock foundation grouting program was to minimize the potential for ground motion amplification in the event of an earthquake through consolidation by grouting of any solution features in the foundation.

Scope

The scope of our services during this phase of the rock foundation treatment was as follows:

1 - To supervise the location and logging of eight exploratory test holes which were core drilled

prior to grouting operations;

2 - To observe the water pressure testing of the eight preliminary test holes;

3 - To observe grouting operations performed by the Lee Turzillo Contracting Company which included drilling, washing and grouting primary, secondary, tertiary and quaternary sets of holes;

4 - To supervise the location and logging of eight exploratory test holes which were core drilled following the grouting operations;

5 - To observe water pressure testing and grouting of the eight final test holes;

6 - To discuss on a daily basis progress of the foundation treatment program with representatives of the Ralph M. Parsons Company and The Detroit Edison Company.

Procedures

In order to evaluate conditions which might be encountered during the grouting operations, eight exploratory holes were core drilled, logged and water pressure tested prior to the commencement of grouting. The pressure testing was performed by setting an air inflatable packer 5 feet from the bottom of a hole, pressure testing that interval, and then moving the packer up the hole 5 feet at a time. The test intervals, therefore, ranged from 5 feet to 20 feet for the four tests in each exploratory hole. This method was the standard procedure used for all pressure testing in the exploratory holes although the original specifications called for the testing of discrete 5-foot intervals. When more than 80 percent of the grouting program had been completed, eight additional exploratory core holes were begun in order to compare final rock conditions with conditions before grouting. These final eight test holes were logged and pressure tested in the manner of the preliminary holes and the last of these holes were drilled following the end of the grouting operations. Flow rates from the water pressure tests performed on the 16 exploratory holes are presented in Table B2. The positions of all the exploratory holes are shown on Plates B1 through B5.

The sequence of grouting operations consisted of drilling, washing and grouting each grout hole. The elevation of the bases of the grout holes was selected (Reference 3) for the RHR Complex at 530 feet. A concrete leveling mat or slab at elevation 550 feet was placed over the excavated, cleaned rock surface. The leveling mat varied in thickness from approximately 6 inches to 2 feet due to the irregularity of the excavated rock surface. Grouting of primary and secondary holes was performed in two zones, hereafter referred to as first and second zones, extending to depths of 6 and 20 feet, respectively. Tertiary holes as well as the few quarternary holes were grouted in single stages to elevations 530 feet and 540 feet respectively. Primary holes were spaced 30 feet on centers and final closure was achieved by subsequently grouting necessary intermediate holes (secondary, tertiary, and some quarternary holes). The locations of all holes are presented in Plates B-1 through B-5, Foundation Treatment. The volume of grout injected into each hole during each sequence of grouting is shown on those plates. The grout takes shown on plates B-1 and B-2 would only be for primary holes, the grout takes shown on plates B-3 and B-4 would only show those for secondary holes and plate B-5 only shows grout takes corresponding to tertiary and quarternary holes. A detailed description of the grouting procedure is presented below.

Prior to grouting, 2 1/2 foot long, 4-inch diameter casings were drilled and cemented into the concrete leveling mat and rock to a depth of 2 feet leaving approximately 6 inches of stick-up. This step tended to reduce surface leakage around the pipes during subsequent grouting. Primary grout holes of the first zone were drilled on approximately 30-foot centers, 6 feet into concrete and rock, to elevation 544. Crawler mounted percussion drills were used to drill the 3-inch diameter grout holes. All holes were washed thoroughly with air and water prior to grouting. Grouting of each hole in the first zone (Plate B1) was done as a single stage with a 1.6:1 water/cement plus fly ash ratio under pressure from 5 to 12 psi. A few primary holes were grouted with a water/cement plus fly ash ratio of 1.2:1. In areas of high take, grout frequently flowed from the nearby holes, in which case the initial hole was temporarily sealed and the flowing holes injected to refusal.

Second zone grouting (Plate B2) was begun by extending the primary holes to a depth of 20 feet to elevation 530 feet. All holes were grouted to their full depth as a single stage with the mechanical packer set at the top of the hole and pressure held between 20 and 50 psi. A mix of 2:1 water/cement plus fly ash was generally used, although in the north and south sump areas the ratio was thickened to 1.2:1 or 1:1 water/cement plus fly ash.

Each secondary hole was located at the geometric center of four primary holes. Grouting of the secondary holes in the first zone (Plate B3) was done in the same manner as were the primary holes. Initially the mix was 3:1 water/cement plus fly ash, but when holes began taking grout the ratio was thickened to 1.8:1 and in a few cases to 1.2:1. Grouting of the second zone (Plate B4) was continued by extending the first zone secondary holes to a depth of 20 feet to elevation 530 feet. Grout mixes for the second zone, secondary holes were 1.2:1 water/cement plus fly ash, except in one case when a 1:1 ration was used.

Tertiary grout holes are at the center of the 15-foot square formed by two primary and two secondary holes. These holes were drilled 20 feet deep to an elevation of 530 feet and grouted as a single zone (Plate B5) rather than using the two-zone procedure as was done with the primary and secondary holes. The reason for this was the general very low take in grouting the second zone - secondary holes. A ratio of 1.2:1 water/cement plus fly ash was generally used. In the only area where grout takes were significant, five quarternary holes, each located in the center of the diamond formed by a primary, secondary, and two tertiary holes, were drilled and grouted to a depth of 10 feet. A 20-foot deep core hole completed this quarternary array and was grouted at the same time.

All grout holes were grouted to refusal. In holes in which grout interconnections occurred, packers were set and maintained until back pressure reduced to zero. Some grout leaks occurred in the north and south sumps, especially during the first zone primary grouting, and where significant these were dry packed by hand with cement. Subsequent first zone grouting indicated these areas were sealed.

As noted above in grouting the first and second zones, injection gage pressures ranged from 5 to 12 psi and from 20 to 50 psi, respectively. These pressures were changes made to the original specifications and were felt necessary by the contractor in order to properly move the grout and to counter any artesian pressures, which were indicated in some cases by slight water flows from a number of the open holes. The ground water surface in the general area of the plant is approximately 575 feet and is, therefore, 25 feet above the RHR foundation rock surface or 45 feet above the bases of the grout holes. Local artesian conditions may have existed despite the dewatering program. In a few instances pressure build-ups may have been indicated by water flows from previously grouted holes. These holes were each regrouted. To determine if heaving of the concrete leveling mat was occurring due to grout being forced between the concrete leveling mat and the rock, elevations on the concrete surface were checked by transit from time to time. No changes in elevations were observed. It was also noted in all eight final core-drilled exploratory holes that the concrete mat was tightly-bonded to the rock surface.

Table B1 summarizes the volume of grout injected into the foundation for the RHR Complex. There is a general decrease in unit take, both from first to second zone grouting and from primary to secondary to tertiary holes within these zones. The unit take of the secondary holes in the first zone is 94 percent of the take of the primary holes in that zone, and by comparison the secondary holes of the second zone showed a unit take which was 18 percent of that of the primary holes in that zone. The unit take and the tertiary holes is consistent with a decrease in grout take and seems to confirm the single zone grouting which was used at this point.

Visual inspection of the leveling mat following completion of the grouting program confirmed that virtually all water flow had been eliminated, including all artesian flow from each of three preliminary borings which predated the RHR excavation in the vicinity of holes S43, P6, and P48.

Conclusions

Exploration drilling both prior to and after grouting along with careful observation of the drilling of the grout holes and amount of grout take prove there are no continuous open solution features in the foundation of the RHR Complex.

APPENDIX 2C

THE DETROIT EDISON COMPANY
SPECIFICATION

FILL MATERIALS,PLACEMENT AND COMPACTION

Enrico Fermi Atomic Power Plant
6400 Dixie Highway
Stony Creek, Monroe County,
Michigan.

THE DETROIT EDISON COMPANY
SPECIFICATION

SPECIFICATION 3071-37
PREPARED BY
ENGINEERING DESIGN &
SERVICES DEPARTMENT

Issued: 11-27-70

FILL MATERIALS, PLACEMENT AND COMPACTION

Enrico Fermi Atomic Power Plant
6400 Dixie Highway
Stony Creek, Monroe County,
Michigan.

PART 1 : GENERAL

1-01 GENERAL CONDITIONS

a. All work under this contract shall be governed by "The General Conditions of the Contract", Edison Specification 3071, this specification and the applicable drawings and bills of material.

b. The Contractor, including his suppliers and sub-contractors, shall conform to Edison Specification 3071-8B, "Field Contractor Quality Assurance Requirements for Construction, Installation and Erection of Quality Levels 1 and 2 Structures and Equipment. Quality Levels 1 and 2 will apply to this work as defined on the drawings and bills of material.

c. The term, Engineer, used herein shall mean the Architectural-Civil Design Division of Edison's Engineering Design and Services Department or its authorized representative.

1-02 SCOPE

a. Furnish all labor, supervision, and equipment necessary to perform the filling, compaction, and grading as described herein and as shown on the drawings.

b. Fill materials shall be from sources designated and approved by the Engineer.

PART 2 : PRODUCT

2-01 GENERAL

a. All fill materials shall be maintained free of foreign matter such as vegetation, organic matter, rubbish, metal scrap, and ice.

2-02 QUARRY RUN ROCK FILL

a. Material shall be shattered rock obtained by blasting or ripping in rock cuts. Shattered rock shall be reasonably well graded with a maximum size not to exceed ½ cubic yard.

b. No specific moisture content at time of placing is required.

c. Shattered rock shall be deposited on the fill and pushed over the end of the fill by means of bulldozers or other equipment into approximately horizontal layers not exceeding 3 feet in thickness. The final surface of the Quarry Run Rock Fill shall be so choked with small rock fragments and fines that there will be no infiltration of any soil which may subsequently be placed on this surface. Where insufficient rock fines are available to properly choke the surface, sand or fine gravel and sand shall be used.

2-03 CRUSHER RUN ROCK FILL - 6 INCH AND UNDER

a. Material shall be that obtained by crushing Quarry Run Rock (see 2-02 a) and shall be graded as follows:

Sieve Size - U.S. Standard	Percent Passing.
6 inch	95
3 inch	30- 75

Loss by washing 0-10 percent.

2-03 <u>CRUSHER RUN ROCK FILL - 6 INCH AND UNDER</u> Cont'd

b. No specific moisture content at time of placing is required.

c. <u>TYPE A</u>: Material shall be spread in approximately horizontal layers not exceeding 15 inches in thickness and compacted by 2 passes of a vibratory type compactor.

<u>TYPE B</u>: Material shall be spread in approximately horizontal layers not exceeding 15 inches in thickness and compacted by one pass of the treads of a crawler type tractor weighing 40,000 pounds or more.

2-04 CRUSHER RUN ROCK FILL - 1½ INCH AND UNDER

a. Material shall be that obtained by crushing Quarry Run Rock (see 2-02 a) and shall be graded as follows:

Sieve Size - U.S. Standard	Percent Passing.
2 inch	100
1½ inch	95-100
½ inch	25-50
No. 10	6-18
No. 200	3-10

b. The moisture content at time of placing shall be not greater than 12 percent.

c. <u>TYPE A</u>: Material shall be spread in approximately horizontal layers not exceeding 12 inches in thickness and compacted by a minimum of six passes of a vibratory type compactor to not less than 95 percent of the maximum unit weight.

<u>TYPE B</u>: Material shall be spread in approximately horizontal layers not exceeding 12 inches in thickness and compacted by one pass of the treads of a crawler type tractor weighing 40,000 pounds or more.

2-05 SELECT GRANULAR FILL

a. Material shall be graded as follows:

Sieve Size - U.S. Standard.	Percent Passing.
2½ inch	100
1 inch	60-100
No. 100	0-30

Loss by washing 0-7 percent.

b. The moisture content at time of placing shall not vary more than ± 2% of optimum.

c. Material shall be spread in approximately horizontal layers not exceeding 15 inches in thickness and compacted to not less than 95 percent of the maximum unit weight.

2-06 MISCELLANEOUS GRANULAR FILL

a. Material shall be graded as follows:

Sieve Size - U.S. Standard	Percent Passing.
3 inch	100

Loss by washing 0-15 percent.

b. The moisture content at time of placing shall not vary more than ± 1% of optimum.

c. Material shall be spread in approximately horizontal layers not exceeding 15 inches in thickness and compacted to not less than 95 percent of the maximum unit weight.

2-07 QUARRY SCREENINGS FILL

a. Material shall be screenings obtained from the crusher operation at the France Stone Quarry, Monroe, Michigan and shall be graded as follows:

Sieve Size - U.S. Standard	Percent Passing.
No. 4.	90-100
No. 10.	50-65
No. 40.	25-40
No. 200	20 maximum.

2-07 QUARRY SCREENINGS FILL Cont'd

b. The moisture content at time of placing shall not vary more than ± 2% of optimum.

c. TYPE A: Material shall be spread in approximately horizontal layers not exceeding 9 inches in thickness and compacted to not less than 100 percent of the maximum unit weight.

TYPE B: Material shall be spread in approximately horizontal layers not exceeding 9 inches in thickness and compacted to not less than 95 percent of the maximum unit weight.

2-08 SELECT CLAY FILL

a. Material shall be the sandy silty clay (till) obtained from site excavation below approximate elevation 565.

b. The moisture content at time of placing shall be no greater than optimum nor less than 2% below optimum.

c. TYPE A: Material shall be spread in approximately horizontal layers not exceeding 9 inches in thickness and compacted to not less than 100 percent of the maximum unit weight.

TYPE B: Material shall be spread in approximately horizontal layers not exceeding 9 inches in thickness and compacted to not less than 95 percent of the maximum unit weight.

2-09 MISCELLANEOUS CLAY FILL

a. Material shall be clay from on or off-site sources not meeting Select Clay Fill description.

b. The moisture content at time of placing shall not vary more than ± 2% of optimum.

c. Material shall be spread in approximately horizontal layers not exceeding 9 inches in thickness and compacted to not less than 95 percent of the maximum unit weight.

PART 3 : EXECUTION

3-01 FOUNDATION REQUIREMENTS

a. The foundation material on which the fill is to be placed shall be as specified on the drawings and its suitability shall be approved by the Engineer prior to placing fill.

b. The surface of the sandy silty clay till (below approximate elevation 565 in the main building area) on which fill is to be placed shall be graded as required to provide for drainage and eliminate ponding.

3-02 LAYER THICKNESS

a. Thickness of layers in excess of that specified will be permitted only after satisfactory demonstration by the Contractor that the required density can be obtained. Whenever the required density is not obtained after such permission is granted, the thickness of the layers shall be reduced upon instructions of the Engineer.

b. The thickness of the first layer of materials other than clay to be constructed on poorly drained soil may be increased to a maximum of 24 inches upon approval by the Engineer.

3-03 COMPACTION

a. One pass of the treads of a crawler type tractor is defined as the required number of successive tractor trips which, by means of sufficient overlap, will insure complete coverage of an entire layer by the tractor treads.

b. One pass of a vibratory compactor is defined as the required number of successive tractor trips which, by means of sufficient overlap, will insure complete coverage of an entire layer by the compacting device.

c. A vibratory compactor is defined as one of the following:

Plate type vibratory compactor, tractor mounted, as manufactured by International Vibrator or Jackson Vibrators, Inc.

Drum type vibratory compactor, tractor drawn, such as Hyster C200B, Vibro-Plus CH33, or equal as approved by the Engineer.

3-03 COMPACTION Cont'd

d. In areas inaccessable to large equipment, obtain required compaction with mechanical vibrators for granular fill, and with mechanical rammers for cohesive fill.

3-04 COLD WEATHER RESTRICTIONS

a. Frozen material shall not be placed in the fill. All ice and snow shall be removed from the surface of the foundation material before fill is placed thereon. In addition where the fill is to support a structure, all ground containing frost within limits of 1 on 1 slopes spreading outward in all directions from the bottom of structure footings shall be removed. In other areas ground containing more than 4 inches of frost shall be removed. Ground containing less than 4 inches of frost and not used for fill which will support structure footings need not be removed.

b. The placing of materials described in sections 2-07, 2-08 and 2-09 shall be limited to the period between May 1 and November 1 unless otherwise approved by the Engineer.

3-05 DRAINAGE

a. The surface of the fill shall be maintained with sufficient slope to provide for runoff of surface water from every point.

b. The working surface of fill described in Sections 2-07, 2-08 and 2-09 shall regularly be sealed with a smooth-wheel static roller at the close of each working day and shall be sealed during the day when practicable prior to rainfall.

c. Filling shall be conducted so that no obstruction to drainage from other sections of the fill area is created at any time. Sumps, if any, will be continuously maintained in effective operating condition.

d. The Contractor shall protect compacted fill and foundation material in excavated areas from becoming rutted or distorted. All rutting or distortion caused by the Contractor's operation shall be corrected by the Contractor at his expense before any succeeding layers are placed.

3-06 FILL AGAINST STRUCTURES

a. Fill shall not be placed against any portion of a structure until the required surface finishing and waterproofing of such portions have been completed. Waterproofing materials shall be protected as required to prevent damage which might occur from fill operations.

b. Fill which will cause a horizontal loading on an unshored portion of a structure shall not be placed until the concrete has attained at least 70 percent of its design strength.

c. Fill around isolated structures such as piers shall be placed on opposite sides at the same time to equalize horizontal loadings.

3-07 MAXIMUM UNIT WEIGHT

a. Maximum unit weight when used as a measure of compaction or density of cohesive soils having a loss by washing greater than 10 percent, shall be understood to mean the maximum weight per cubic foot as determined using the One-Point T-99 Test or the AASHO T-99 Test as described in the MDSH Density Control Handbook, August,1969.

b. The One-Point Michigan Cone Test or the Michigan Cone Test as described in the MDSH Density Control Handbook, August, 1969, modified as follows, will be used for determining the maximum unit weight for granular materials having a loss by washing of 10 percent or less:

For granular soils having a unit weight of 120 pounds per cubic foot or less, the unit weight will be determined at any moisture content between 6 percent and a point short of saturation.

For granular soils having a unit weight over 120 pounds per cubic foot, the unit weight will be determined at the moisture content, between 6 percent and a point short of saturation, which will give the maximum weight.

c. In-place density of materials shall be obtained using a volumeter which measures the volume of a hole by means of a rubber balloon and water under air pressure.

PART 4 : SPECIFICATIONS AND STANDARDS

4-01 EDISON SPECIFICATIONS

a. 3071, The General Conditions of the Contract.

b. 3071-8B, Field Contractor Quality Assurance Requirements for Construction, Installation and Erection of Quality Levels 1 and 2 Structures and Equipment.

Tests On Stone Cores

Job: No. 7605-002-16

Dames and Moore
309 West Jackson Boulevard
Chicago, Illinois 60606

Attention: Mr. D. G. Staggs

Gentlemen:

We report test results on four (4) stone cores obtained by our representative at your office on December 17, 1968 marked as shown in the following tabulations:

The sample cores were prepared for test by us.

Test core size: Diameter 2.00 inches Length 4.00 inches

Sample Core Designation			Compressive Strength		Modulus of Elasticity	Weight
Boring Number	Depth Feet	Classification	Maximum Load Lbs.	Per Square Inch Lbs.	At 50% of Maximum Load, Lbs. Per Square Inch	Per Cubic Foot Lbs.
20	27	Dolomite	49,200	15,661	13,346,000	154.02
32A	52	Oolite	30,400	9,677	4,359,000	145.29
28	106	Argillaceous Dolomite	28,400	9,040	2,601,000	162.12
4	58	Dolomite	24,500	7,799	- - -	137.80

Specific Gravity:

	Sample Core Designation			
Boring No.	20	32A	28	4
Depth, Ft.	27	52	106	58
Classification	Dolomite	Oolite	Argillaceous Dolomite	Dolomite
Specific Gravity:-	2.47	2.33	2.60	2.21

CHAPTER 3: DESIGN OF STRUCTURES, COMPONENTS, EQUIPMENT, AND SYSTEMS

3.1 CONFORMANCE WITH GENERAL DESIGN CRITERIA

3.1.1 Summary Description

This section contains an evaluation of the design basis of Fermi 2 as measured against the General Design Criteria (GDC) for Nuclear Power Plants, Appendix A of 10 CFR 50, effective May 21, 1971, and subsequently amended July 7, 1971. The General Design Criteria, which are divided into six groups, are intended to establish minimum requirements for the design of nuclear power plants.

The GDC were not written specifically for the BWR; rather, they were intended as a guide to the design of all water-cooled nuclear power plants. As a result, the criteria are generic in nature and subject to a variety of interpretations. For this reason, there are some cases where conformance to a particular criterion is not directly assessable. In these cases, the conformance of plant design to the interpretation of the criterion is discussed. In the discussion of each criterion, the section of the UFSAR where more detailed information is presented to demonstrate compliance with or exception to the criterion is referenced.

Based on the content herein, Edison concludes that the design of Fermi 2 is in accordance with and satisfies the GDC.

3.1.2 Criterion Conformance

3.1.2.1 Group I, Overall Requirements (Criteria 1-5)

3.1.2.1.1 Criterion 1 - Quality Standards and Records

Structures, systems, and components important to safety shall be designed, fabricated, erected, and tested to quality standards commensurate with the importance of the safety functions to be performed. Where generally recognized codes and standards are used, they shall be identified and evaluated to determine their applicability, adequacy, and sufficiency and shall be supplemented or modified as necessary to assure a quality product in keeping with the required safety function. A Quality Assurance Program shall be established and implemented in order to provide adequate assurance that these structures, systems, and components will satisfactorily perform their safety functions. Appropriate records of the design, fabrication, erection, and testing of structures, systems, and components important to safety shall be maintained by or under the control of the nuclear power unit licensee throughout the life of the unit.

Criterion 1 Conformance - Structures, systems, and components important to safety are listed in Table 3.2-1. The total Quality Assurance Program is described in Chapter 17 and is applied to the items contained in Table 3.2-1. The Quality Assurance Program ensures sound engineering in all phases of design and construction through conformity to regulatory requirements and design bases described in the license application. In addition, the program ensures adherence to specified standards in fabrication and construction. It also includes the observance of proper preoperational and operational testing and maintenance procedures. Documentation of the foregoing is provided by keeping appropriate records. The total

Quality Assurance Program of Edison and its principal contractors is responsive to and satisfies the intent of the quality-related requirements of 10 CFR 50, including Appendix B.

Structures, systems, and components are first classified in Section 3.2 with respect to their location and service, and their relationship to the safety function to be performed. Recognized codes and standards are applied to the equipment in these classifications, as necessary, to ensure a quality product in keeping with the required safety function.

Documents are maintained that demonstrate that all the requirements of the Quality Assurance Program are being satisfied. This documentation shows that appropriate codes, standards, and regulatory requirements are observed, specified materials are used, correct procedures are used, qualified personnel are provided, and the finished parts and components meet the applicable specifications for safe and reliable operation. These records are available so that any desired item of information is retrievable for reference. These records will be maintained in accordance with the guidance of ANSI N45.2.9-1974, Requirements for Collection, Storage, and Maintenance of Quality Assurance Records for Nuclear Power Plants, and Regulatory Guide 1.88, Revision 2, as addressed in Appendix A.

The detailed Quality Assurance Program set forth in Chapter 17, and developed by Edison and its contractors, satisfies the requirements of Criterion 1.

For further discussion, see the following:

h. Section 7.2 - Reactor Protection System

i. Section 7.3 - Engineered Safety Feature Systems

j. Section 7.6 - Other Systems Required for Safety and Power Generation

k. Chapter 8 - Electrical Power Systems

l. Chapter 12 - Radiation Protection.

3.1.2.1.2 Criterion 2 - Design Bases for Protection Against Natural Phenomena

Structures, systems, and components important to safety shall be designed to withstand the effects of natural phenomena such as earthquakes, tornados, hurricanes, floods, tsunami, and seiches without loss of capability to perform their safety functions. The design bases for these structures, systems, and components shall reflect: (1) appropriate consideration of the most severe of the natural phenomena that have been historically reported for the site and surrounding area, with sufficient margin for the limited accuracy, quantity and period of time in which the historical data have been accumulated; (2) appropriate combinations of the effects of normal and accident conditions with the effects of the natural phenomena; and (3) the importance of the safety functions to be performed.

Criterion 2 Conformance - The design bases enumerated in this criterion are incorporated into the design of structures, systems, and components of Fermi 2. Among the natural phenomena considered are wind and tornado loadings, including static and dynamic water level loadings caused by floods, hurricanes, and other severe storms with wave runup effects; and seismic loadings. In each case the most severe of these phenomena is used as the design basis, together with appropriate combinations of normal and accident conditions. These design bases are developed from detailed analysis of the occurrence and history of these phenomena in the area surrounding the plant location. The method of incorporating these effects is discussed later in Chapter 3. The natural phenomena of the area are discussed in Chapter 2.

A detailed discussion can be found in the following:

a. Section 2.3 - Meteorology
b. Section 2.4 - Hydrological Engineering
c. Section 2.5 - Geology and Seismology
d. Section 3.2 - Classification of Structures, Components, and Systems
e. Section 3.3 - Wind and Tornado Loadings
f. Section 3.4 - Water Level (Flood) Design
g. Section 3.5 - Missile Protection
h. Section 3.7 - Seismic Design
i. Section 3.8 - Design of Category I Structures
j. Section 3.9 - Mechanical Systems and Components
k. Section 3.10 - Seismic Design of Category I Instrumentation and Electrical Equipment.

3.1.2.1.3 Criterion 3 - Fire Protection

Structures, systems, and components important to safety shall be designed and located to minimize, consistent with other safety requirements, the probability and effect of fires and explosions. Noncombustible and heat-resistant materials shall be used wherever practical throughout the unit, particularly in locations such as the containment and main control room. Fire detection and fighting systems of appropriate capacity and capability shall be provided and designed to minimize the adverse effects of fires on structures, systems, and components important to safety. Fire-fighting systems shall be designed to assure that their rupture or inadvertent operation does not significantly impair the safety capability of these structures, systems, and components.

Criterion 3 Conformance - The design of Fermi 2 is in full compliance with this criterion. The use of noncombustible and heat-resistant materials is maximized. Fire protection and detection measures of appropriate capacities are incorporated in the design, with particular emphasis given to areas containing safety systems, such as the Control Center, and components of engineered safety feature (ESF) systems. The fire protection system (FPS) does not, by rupture or inadvertent operation, prevent the safe shutdown of the plant. The FPS, described in Subsection 9.5.1, provides an adequate supply of water and/or chemicals to fire-fighting stations throughout the plant. The FPS meets the requirements of the applicable laws, codes, and requirements of the State of Michigan, and adheres to the NFPA standards and NEPIA recommendations (Subsection 9.5.1).

A diesel-driven fire pump and a motor-driven fire pump are each independently capable of satisfying plant fire-fighting water requirements. Standby carbon dioxide and Halon systems are provided for fire protection in the diesel generator area and electrical areas in the auxiliary building. The main and auxiliary transformers are protected with deluge fire-fighting equipment. In addition, portable fire extinguishers, hose reels, and hydrants are strategically located throughout the plant area.

Hydrogen, lubrication, and fuel-oil storage facilities are located, designed, and protected to minimize both the probability and effects of fire and explosion. The FPS is discussed in detail in Subsection 9.5.1.

Further discussion of fire protection can be found in the following:

a. Section 6.4 - Habitability Systems

b. Section 8.3 - Onsite Power Systems

c. Section 9.5 - Other Auxiliary Systems

d. Section 14.1 - Test Program.

3.1.2.1.4 Criterion 4 - Environmental and Missile Design Bases

Structures, systems, and components important to safety shall be designed to accommodate the effects of, and to be compatible with, the environmental conditions associated with normal operation, maintenance, testing and postulated accidents, including loss-of-coolant accidents. These structures, systems, and components shall be appropriately protected against dynamic effects, including the effects of missiles, pipe whipping, and discharging fluids, that may result from equipment failures and from events and conditions outside the nuclear power unit.

Criterion 4 Conformance - Safety-related systems, components, and structures have been designed to accommodate all normal or routine environmental conditions, and conditions associated with postulated accidents including a LOCA. Safety-related systems and components are designed to function properly in the most severe environmental conditions in which their functions are required.

Analyses are performed to determine the effects of missiles, pipe whip, and the jet force of fluid discharge, both inside and outside the primary containment. Where required, restraints, missile shields, additional separation, or additional structural strength are incorporated into the design to ensure proper functioning of safety-related plant features.

Further discussion of environmental and missile design bases can be found in Sections 3.3 through 3.12, and particularly in the following sections.

a. Section 3.5 - Missile Protection

b. Section 3.6 - Protection Against Dynamic Effects Associated with the Postulated Rupture of Piping

c. Section 3.11 - Environmental Design of Mechanical and Electrical Equipment

d. Section 10.2 - Turbine Generator.

3.1.2.1.5 Criterion 5 - Sharing of Structures, Systems, and Components

Structures, systems, and components important to safety shall not be shared between nuclear power units unless it is shown that their ability to perform their functions, including, in the event of an accident in one unit, an orderly shutdown and cooldown of the remaining units, is not significantly impaired by the sharing.

Criterion 5 Conformance - There are no safety-related systems or components that are shared with another unit.

3.1.2.2 Group II, Protection by Multiple Fission Product Barriers (Criteria 10-19)

3.1.2.2.1 Criterion 10 - Reactor Design

The reactor core and associated coolant, control, and protection systems shall be designed with appropriate margin to assure that specified acceptable fuel design limits are not exceeded during any condition of normal operation, including the effects of anticipated operational occurrences.

Criterion 10 Conformance - The reactor core components consist of fuel assemblies, control rods, in-core ion chambers, and related items. The mechanical design is based on conservative application of stress limits, operating experience, and experimental test results. The fuel is designed to provide high integrity over a complete range of power levels including transient conditions. The core is sized with sufficient heat-transfer area and coolant flow to ensure that there is no fuel damage under normal conditions or anticipated operational occurrences.

The reactor protection system (RPS) is designed to monitor certain reactor parameters, sense abnormalities, and scram the reactor, thereby preventing fuel damage when trip points are exceeded. Scram trip setpoints are selected on the basis of operating experience and safety design. There is no case in which the scram trip setpoints allow the core to exceed the thermal-hydraulic safety limits. Power for the RPS is supplied by an independent high-inertia ac motor-generator set. Alternative electrical power is available to the RPS buses.

An analysis and evaluation has been made of the effects on core fuel following adverse plant operating conditions. The results of abnormal operational transients are presented in Chapter 15.

The reactor core and associated coolant, control, and protection systems are designed to ensure that the specified fuel design limits are not exceeded during conditions of normal or abnormal operation. Therefore, they meet the requirements of Criterion 10.

For further discussion, see the following:

a. Section 4.2 - Fuel System Design

b. Section 4.3 - Nuclear Design

c. Section 4.4 - Thermal and Hydraulic Design

d. Section 5.5 - Component and Subsystem Design

e. Section 6.3 - Emergency Core Cooling System

f. Section 7.2 - Reactor Protection System

g. Chapter 15 - Accident Analyses.

3.1.2.2.2 Criterion 11 - Reactor Inherent Protection

The reactor core and associated plant systems shall be designed so that in the power operating range the net effect of the prompt inherent nuclear feedback characteristics tends to compensate for a rapid increase in reactivity.

Criterion 11 Conformance - The reactor core is designed to have a reactivity response that regulates or damps changes, both in power level and in spatial distributions of power production, to a level consistent with safe and efficient operation.

The inherent dynamic behavior of the core is characterized in terms of (a) fuel temperature or Doppler coefficient, (b) moderator void coefficient, and (c) moderator temperature coefficient. The combined effects of these coefficients in the power range are termed the power coefficient. Doppler reactivity feedback occurs simultaneously with a change in fuel temperature and opposes the power change that caused it. Moreover, it contributes to system stability. Because the Doppler reactivity opposes load changes, it is desirable to maintain a large ratio between moderator void coefficient and Doppler coefficient for optimum load-following capability. The BWR has an inherently large moderator-to-Doppler coefficients ratio, which permits use of coolant flow rate for load following.

In a BWR, the moderator void coefficient is of importance while the BWR is operating at power. Nuclear design requires the void coefficient inside the fuel channel to be negative. The negative void reactivity coefficients provide an inherent negative feedback during power transients.

The reactor is designed so that the moderator temperature coefficient is small and positive in the cold condition; however, the overall power reactivity coefficient is negative.

The reactor core and associated coolant system are designed so that in the power operating range, prompt inherent dynamic behavior tends to compensate for any rapid increase in reactivity in accordance with Criterion 11.

For further discussion, see the following:

a. Section 4.3 - Nuclear Design

b. Section 4.4 - Thermal and Hydraulic Design.

3.1.2.2.3 Criterion 12 - Suppression of Reactor Power Oscillations

The reactor core and associated coolant, control, and protection systems shall be designed to assure that power oscillations which can result in conditions exceeding specified acceptable fuel design limits are not possible or can be reliably and readily detected and suppressed.

Criterion l2 Conformance - The reactor core is designed to ensure that no power oscillation will cause the fuel design limits to be exceeded. The power reactivity coefficient is the composite simultaneous effect of the fuel temperature or Doppler coefficient, moderator void coefficient, and moderator temperature coefficient, on the change in power level. It is negative and well within the range required for adequate damping of power and spatial xenon disturbances. Operating experience has shown that large BWRs are inherently stable against xenon-induced power instability. The large negative operating coefficient provides

a. Good load following with well-damped behavior and little undershoot or overshoot in the heat-transfer response

b. Load following with recirculation flow control

c. Strong damping of spatial power disturbances.

The RPS design provides protection from excessive fuel cladding temperatures and protects the nuclear system process barrier from excessive pressures that threaten the integrity of the system. Local abnormalities are sensed, and, if protection system limits are reached, corrective action is initiated through an automatic scram. High integrity of the protection system is achieved through the combination of logic arrangement, trip channel redundancy, power supply redundancy, and physical separation.

The reactor core and associated coolant, control, and protection systems are designed to suppress any power oscillations that could result in exceeding fuel design limits. These systems ensure that Criterion 12 is met.

For further discussion see the following:

a. Section 4.2 - Fuel System Design

b. Section 4.3 - Nuclear Design

c. Section 4.4 - Thermal and Hydraulic Design

d. Section 5.2 - Integrity of Reactor Coolant Pressure Boundary

e. Section 7.2 - Reactor Protection System

f. Section 7.7 - Control Systems Not Required for Safety

g. Chapter 15 - Accident Analyses.

3.1.2.2.4 Criterion 13 - Instrumentation and Control

Instrumentation shall be provided to monitor variables and systems over their anticipated ranges for normal operation, for anticipated operational occurrences, and for accident conditions as appropriate to assure adequate safety, including those variables and systems that can affect the fission process, the integrity of the reactor core, the reactor coolant pressure boundary, and the containment and its associated systems. Appropriate controls shall be provided to maintain these variables and systems within prescribed operating ranges.

Criterion 13 Conformance - The fission process is monitored and controlled for all conditions from source range through power operating range. The neutron monitoring system (NMS) detects core conditions that threaten the overall integrity of the fuel barrier caused by excess power generation and provides a signal to the RPS. Fission counters, located in the core, are used for the source range through power operating range. The detectors are located to provide maximum sensitivity to control rod movement during startup, and to provide optimum monitoring in the intermediate and power ranges.

The source range monitor (SRM) subsystem provides neutron flux information during reactor startup and low-flux-level operations. Detectors are inserted into the core for a reactor startup and withdrawn after neutron flux is indicated on the intermediate range monitor (IRM) subsystem. The SRM can provide detection of less than a 20-sec period under the worst possible startup conditions, and is capable of generating a trip signal to block rod withdrawal.

The IRM monitors neutron flux from the upper portion of the SRM to the lower portion of the power range monitor (PRM) subsystems. The IRM is capable of either generating a trip signal to block rod withdrawal or scram the reactor.

The local power range monitor (LPRM) subsystem consists of fission chambers located throughout the core, signal conditioning equipment, and trip functions. The LPRM signals are also used in the average power range monitor (APRM) subsystem, rod block monitor (RBM) subsystem, and Integrated Plant Computer System (IPCS). The RBM is designed to prevent local fuel damage as a result of a single rod withdrawal error under a condition of allowed RBM bypass.

The traversing in-core probe (TIP) subsystem provides a signal proportional to the axial neutron flux distribution of the core. This system provides a means of accurately calibrating the LPRM signal by correlation with the TIP signal.

The reactor protection system (RPS) protects the fuel barriers and the nuclear process barrier by monitoring plant parameters and causing a reactor scram when predetermined setpoints are exceeded.

The reactor manual control system (RMCS) consists of the electrical circuitry, switches, indicators, and alarm devices required for the manipulation of the control rods and surveillance equipment. Separation between the scram function and the normal rod control functions prevents failures in the reactor manual control circuitry from affecting the scram circuitry.

Reactor pressure vessel (RPV) instrumentation monitors the RPV temperatures, water levels, water flow rate, internal pressure, and water leakage detection from the top head flange. This information is used to assess conditions existing inside the RPV and to assess the physical condition of the RPV. Reactor pressure vessel temperatures are recorded on a multipoint recorder in the control center. Controlled heating and cooling rates allow thermal stress to be appropriately limited. Reactor pressure and vessel water level are also indicated in the control center, in addition to recirculation loop flow, core flow, and the differential pressure between the RPV annulus outside of the core and the core inlet plenum.

To provide protection against the consequences of accidents involving the release of radioactive materials from the fuel and nuclear system process barrier, the containment and reactor vessel isolation control system initiates automatic isolation of appropriate pipelines whenever monitored variables exceed pre-selected operational limits.

Nuclear system leakage limits are established so that appropriate action can be taken to ensure the integrity of the nuclear system process barrier. Nuclear system leakage rates classified as identified leakage rates flow to the equipment drain, and those classified as unidentified leakage rates flow to the floor drain sumps. The permissible total leakage rate limit to these sumps is based on NRC requirements. Leakage detection is in accordance with Regulatory Guide 1.45, Reactor Coolant Pressure Boundary Leakage Detection Systems. Flow integrators and recorders are used to determine the leakage by monitoring flow pumped from the drain sumps. The unidentified leakage rate as discussed in Subsection 5.2.7.4 is limited to a value that is less than the value that has been conservatively calculated to be a minimum leakage from a crack large enough to propagate rapidly. The limited leakage volume still allows time for identification and corrective action before integrity of the process barrier is threatened.

The sequence-of-events recorders receive inputs from plant variables, including the primary variables of the RPS. The inputs are scanned and monitored for change of state. The IPCS provides a quick and accurate determination of the core thermal performance. Data reduction, accounting, and logging functions of the IPCS further supplement procedural requirements for control rod manipulation during reactor startup and shutdown.

As previously indicated, adequate instrumentation is provided to monitor system variables in the reactor core, reactor coolant pressure boundary (RCPB), and reactor containment. Appropriate controls are provided to maintain the variables within the operating range and to initiate the necessary corrective action in the event of abnormal operational occurrence or accident. This arrangement of instrumentation and controls meets the requirements of Criterion 13.

For further discussion, see the following:

a. Section 4.2 - Fuel System Design

b. Section 5.2 - Integrity of Reactor Coolant Pressure Boundary

c. Section 5.5 - Component and Subsystem Design

d. Section 6.2 - Containment Systems

e. Section 7.2 - Reactor Protection System

f. Section 7.3 - Engineered Safety Feature Systems

g. Section 7.6 - Other Systems Required for Safety and Power Generation

h. Section 7.7 - Control Systems Not Required for Safety.

3.1.2.2.5 Criterion 14 - Reactor Coolant Pressure Boundary

The reactor coolant pressure boundary shall be designed, fabricated, erected, and tested so as to have an extremely low probability of abnormal leakage, of rapidly propagating failure, and of gross rupture.

Criterion 14 Conformance - The piping and equipment pressure parts, which extend through the outer isolation valve(s) but which are within the RCPB, are designed, fabricated, erected, and tested to provide a high degree of integrity throughout the plant lifetime. Systems and components within the RCPB are classified in Section 3.2 as Code Group A. The design requirements, codes, and standards applied to this Code Group ensure a quality product in keeping with the safety functions to be performed.

To minimize the possibility of brittle fracture within the RCPB, the fracture or notch properties and the operating temperature of ferritic materials are controlled to ensure adequate toughness when the system is pressurized to more than 20 percent of the design pressure. Subsection 5.2.4 describes the methods used to control toughness properties. Materials are to be impact tested in accordance with ASME Boiler and Pressure Vessel (B&PV) Code Section III, 1971. The fracture toughness temperature requirements of the RCPB materials also apply for the RCPB piping which penetrates the containment, up to and including the outermost isolation valve.

Piping and equipment pressure parts of the RCPB are assembled and erected by welding unless applicable codes permit flanged or screwed joints. The welding procedures used are designed to produce welds of complete fusion and free of unacceptable defects. All welding procedures, welders, and welding machine operators are qualified in accordance with the requirements of Section IX of the ASME B&PV Code for the materials to be welded.

Qualification records, including the results of procedure and performance qualification tests and identification symbols assigned to each welder, are maintained.

Subsection 5.2.3 contains the detailed material and examination requirements for the piping and equipment of the RCPB prior to and after its assembly and erection. Leakage testing and surveillance are accomplished as described in the evaluation against Criterion 30.

The design, fabrication, erection, and testing of the RCPB ensures an extremely low probability of failure or abnormal leakage, thus satisfying the requirements of Criterion 14.

For further discussion, see the following:

a. Chapter 3 - Design of Structures, Components, and Systems
b. Section 5.4 - Reactor Pressure Vessel and Appurtenances
c. Section 5.5 - Component and Subsystem Design
d. Section 5.2 - Integrity of Reactor Coolant Pressure Boundary
e. Section 15.0 - General (Accident Analyses)
f. Chapter 17 - Quality Assurance.

3.1.2.2.6 Criterion 15 - Reactor Coolant System Design

The reactor coolant system and associated auxiliary, control, and protection systems shall be designed with sufficient margin to assure that the design conditions of the reactor coolant pressure boundary are not exceeded during any condition of normal operation, including anticipated operational occurrences.

Criterion 15 Conformance - The reactor coolant system consists of the RPV and appurtenances, the reactor circulation system, the nuclear system pressure relief system, the main steam lines, the reactor core isolation cooling (RCIC) system, and the residual heat removal (RHR) system. These systems are designed, fabricated, erected, and tested to meet stringent quality requirements and appropriate codes and standards that ensure high integrity of the RCPB throughout the plant lifetime. The reactor coolant system is designed and fabricated to meet the requirements of the ASME B&PV Code Section III, as required by 10 CFR 50.55a, including special waiver provisions.

The auxiliary, control, and protection systems associated with the reactor coolant system act to provide sufficient margin to ensure that the design conditions of the RCPB are not exceeded during any condition of normal operation, including anticipated operational occurrences. As described in the evaluation of Criterion 13, instrumentation is provided to monitor essential variables to ensure that they are within prescribed operating limits. If the monitored variables exceed their predetermined settings, the auxiliary control and protection systems automatically respond to maintain the variables and systems within allowable design limits.

An example of the integrated protective action scheme, which provides sufficient margin to ensure that the design conditions of the RCPB are not exceeded, is the automatic initiation of the nuclear system pressure relief system on receipt of an overpressure signal. To accomplish overpressure protection, a number of pressure-operated relief valves are provided that can discharge steam from the nuclear system to the suppression pool. The nuclear system pressure relief system also provides automatic depressurization of the nuclear system in the event of a LOCA in which the RPV is not depressurized by the accident. The depressurization of the nuclear system in this situation allows operation of the low-pressure emergency core cooling systems (ECCS) to supply enough cooling water to adequately cool the core. In a similar manner, other auxiliary, control, and protection systems provide assurance that the design conditions of the RCPB are not exceeded during any conditions of normal operation, including anticipated operational occurrences.

The application of appropriate codes, standards, and high quality requirements to the reactor coolant system and the design features of its associated auxiliary, control, and protection systems, ensures that the requirements of Criterion 15 are satisfied.

For further discussion, see the following:

a. Chapter 3 - Design of Structures, Components, Equipment, and Systems

b. Section 5.2 - Integrity of Reactor Coolant Pressure Boundary

c. Section 5.4 - Reactor Pressure Vessel and Appurtenances

d. Section 5.5 - Component and Subsystem Design

e. Section 6.3 - Emergency Core Cooling System

f. Section 7.6 - Other Systems Required for Safety and Power Generation

g. Section 15.0 - General (Accident Analyses).

3.1.2.2.7 Criterion 16 - Containment Design

Reactor containment and associated systems shall be provided to establish an essentially leaktight barrier against the uncontrolled release of radioactivity to the environment and to assure that the containment design conditions important to safety are not exceeded for as long as postulated accident conditions require.

Criterion 16 Conformance - The primary containment, which includes the drywell and suppression pool, has been designed, fabricated, and erected so as to accommodate, without failure, the pressures and temperatures resulting from the double-ended rupture (or equivalent failure) of any coolant pipe within the primary containment. The primary containment encloses the reactor coolant system and associated instrumentation and controls. During accident conditions, valves which isolate systems that penetrate the primary containment become part of the containment barrier.

The secondary containment, a building that contains the primary containment as well as portions of the reactor process systems and refueling facilities, is maintained at a negative pressure under accident conditions to ensure against leakage. The interior atmosphere is processed to control emissions to the environs so that offsite dose levels are maintained well below the requirements of 10 CFR 100 or 10 CFR 50.67.

Periodic testing and inspection verify the integrity of the reactor containment. Further information on the reactor containment and associated systems can be found in the following:

a. Section 3.8 - Design of Category I Structures

b. Section 6.2 - Containment Systems

c. Section 14.1 - Test Program.

3.1.2.2.8 Criterion 17 - Electric Power Systems

An onsite electric power system and an offsite electric power system shall be provided to permit functioning of structures, systems, and components important to safety. The safety function for each system (assuming the other system is not functioning) shall be to provide sufficient capacity and capability to assure that (1) specific acceptable fuel design limits and design conditions of the RCPB are not exceeded as a result of anticipated operational occurrences, and (2) the core is cooled, and containment integrity and other vital functions are maintained in the event of postulated accidents.

The onsite electric power supplies, including the batteries, and the onsite electric distribution system, shall have sufficient independence, redundancy, and testability to perform their safety functions assuming a single failure.

Electric power from the transmission network to the onsite electric distribution system shall be supplied by two physically independent circuits (not necessarily on separate rights of way) designed and located so as to minimize to the extent practical the likelihood of their simultaneous failure under operating and postulated accidents and environmental conditions. A switchyard common to both circuits is acceptable. Each of these circuits shall be designed to be available in sufficient time following a loss of all onsite alternating current power supplies and the other offsite electric power circuit, to assure that specified acceptable fuel design limits and design conditions of the reactor coolant pressure boundary are not exceeded. One of these circuits shall be designed to be available within a few seconds following a loss of coolant accident to assure that core cooling, containment integrity, and other vital safety functions are maintained. Provisions shall be included to minimize the probability of losing electric power from any of the remaining supplies as a result of, or coincident with, the loss of power generated by the nuclear power unit, the loss of power from the transmission network, or the loss of power from the onsite electrical power supplies.

Criterion 17 Conformance - The Fermi 2 onsite power system has four separate emergency diesel generators (EDGs), each of which supplies a separate bus. There are two independent and redundant divisions of ESF, each of which can be powered by a division pair of the

EDGs through their associated buses. The diesel generators are of sufficient capacity to provide minimum essential emergency loads, including a single failure, such as the loss of a diesel generator or essential bus. The diesel generators are located in a Category I structure with fire-barrier separation between diesel generators.

Also provided are separate battery power sources to supply power to the separate and redundant ESF dc loads and controls. The battery system consists of two redundant 260/130-V and 24/48-V supplies and chargers. The chargers can be supplied from offsite power or the EDGs, in emergency situations.

The offsite power sources consist of 120-kV and 345-kV independent systems with associated buses and transformers. These supply power to the 4160-V buses. The redundancy of buses within the plant and the division of critical loads between buses yield a system of high reliability and integrity.

The EDGs and batteries have been designed to allow periodic testing and inspection without interruption of normal plant operation. Fault detection and isolation provisions prevent the propagation of faults to alternative systems.

With the above electric system design, Criterion 17 is believed to be satisfied.

Further information on the electric power systems can be found in the following:

a. Section 3.10 - Seismic Design of Category I Instrumentation and Electrical Equipment

b. Chapter 8 - Electric Power.

3.1.2.2.9 Criterion 18 - Inspection and Testing of Electrical Power Systems

Electrical power systems important to safety shall be designed to permit appropriate periodic inspection and testing of important areas and features such as wiring, insulation, connections, and switchboards, to assess the continuity of the systems and the condition of their components. The system shall be designed with a capability to test periodically (1) the operability and functional performance of the components of the systems, such as onsite power sources, relays, switches, and buses, and (2) the operability of the systems as a whole, and, under conditions as close to design as practical, the full operation sequence that brings the systems into operation, including operation of applicable portions of the protection system, and the transfer of power among the nuclear power unit, the offsite power system, and the onsite power system.

Criterion 18 Conformance - Provisions are made in the design of the offsite and onsite power systems for the inspection and testing of appropriate areas of the system. The EDG system can be tested without interruption of normal operations. The battery system is also designed for periodic testing. The offsite power systems are normally operating; therefore, the status of both the offsite systems and the onsite systems is indicated in the main control room. All systems are designed for periodic inspection. Further information can be found in the following:

a. Chapter 8 - Electric Power

b. Section 14.1 - Test Program.

3.1.2.2.10 Criterion 19 - Main Control Room

A control room shall be provided from which actions can be taken to operate the nuclear power unit safely under normal conditions and to maintain it in a safe condition under accident conditions, including loss-of-coolant accidents. Adequate radiation protection shall be provided to permit access and occupancy of the control room under accident conditions without personnel receiving radiation exposures in excess of 5 rem whole body, or its equivalent to any part of the body, for the duration of the accident.

Equipment at appropriate locations outside the control room shall be provided (1) with a design capability for prompt hot shutdown of the reactor, including necessary instrumentation and controls to maintain the unit in a safe condition during hot shutdown, and (2) with a potential capability for subsequent cold shutdown of the reactor through the use of suitable procedures.

Holders of operating licenses using an alternative source term under § 50.67, shall meet the requirements of this criterion, except that with regard to control room access and occupancy, adequate radiation protection shall be provided to ensure that radiation exposures shall not exceed 0.05 Sv (5 rem) total effective dose equivalent (TEDE) as defined in § 50.2 for the duration of the accident.

Criterion 19 Conformance - The design of the main control room allows continuous occupancy by operating personnel under all operating and accident conditions, including LOCA. All control stations, switches, controllers, and indicators necessary to safely operate and shut down the plant are located in the control center.

Shielding is provided to limit the exposure of control center personnel to a level significantly less than the 5 rem whole-body limit. The control center air conditioning system (CCACS) provides air filtration, recirculation, temperature, and/or humidity control, and has sufficient redundancy to ensure the availability of the system. Recirculation of main control room air is initiated upon a high radiation alarm, with makeup outside air provided to pressurize the control room and selected from the intake with the lower radiation level. Air-operated isolation and recirculation valves can be manually operated. Entrance and exit from the plant (and main control room) in emergency situations are controlled to limit personnel dose to less than 5 rem for the duration of the accident.

Because of the shielding and ventilation systems provided, evacuation of the main control room is a highly improbable event. If, for some reason, evacuation is required, safe shutdown of the reactor can be accomplished from a remote shutdown station. There are sufficient controls and indications at this station to bring the reactor safely to a hot shutdown condition. There is also the capability to bring the reactor to a cold shutdown condition from outside the main control room.

For use of the alternative source term under 10 CFR 50.67, the exposure limit is 5 rem TEDE. Specific accidents that apply the alternative source term per 10 CFR 50.67, and thus utilize the 5 rem TEDE limit, are identified in Section 1.2.1.2.2.3.

Further discussions concerning this criterion are in the following:

a. Section 6.4 - Habitability Systems

b. Section 7.5 - Safety-Related and Power Generation Display Instrumentation

c. Section 9.4 - Air Conditioning, Heating, Cooling, and Ventilation Systems

d. Section 12.1 - Shielding

e. Chapter 15 - Accident Analyses.

3.1.2.3 Group III, Protection and Reactivity Control Systems (Criteria 20 - 29)

3.1.2.3.1 Criterion 20 - Protection System Functions

The protection system shall be designed (1) to initiate automatically the operation of appropriate systems including the reactivity control systems, to assure that specified acceptable fuel design limits are not exceeded as a result of anticipated operational occurrences and (2) to sense accident conditions and to initiate the operation of systems and components important to safety.

Criterion 20 Conformance - The RPS is designed to provide timely protection against the onset and consequences of conditions that threaten the integrity of the fuel barrier and the nuclear system process barrier. Fuel damage is prevented by initiation of an automatic reactor shutdown if monitored nuclear system variables exceed preestablished limits of anticipated operational occurrences. Scram trip settings are selected and verified to be far enough above or below operating levels so as to provide proper protection but not be subject to spurious scrams. The RPS includes the motor-generator power system, sensors, relays, bypass circuitry, and switches that signal the control rod system to scram. The scrams initiated by nuclear system variables, nuclear system high pressure, turbine stop valve closure, turbine control valve fast closure, and RPV low water level will prevent fuel damage following abnormal operational transients. Specifically, these process parameters initiate a scram in time to prevent the core from exceeding thermal-hydraulic safety limits during abnormal operational transients. Response by the RPS is prompt and the total scram time is short.

A fully withdrawn control rod (withdrawn to 144 in.) will traverse 90 percent of its full stroke in less than 3.5 sec, which is sufficient to ensure that acceptable fuel design limits are not exceeded.

In addition to the RPS, which provides automatic shutdown of the reactor to prevent fuel damage, protection systems are provided to sense accident conditions and initiate automatically the operation of other systems and components important to safety. Systems such as the ECCS are initiated automatically to limit the extent of fuel damage following a LOCA. Other systems automatically isolate the RPV or the containment to prevent the release of significant amounts of radioactive materials from the fuel and the nuclear system process barrier. The controls and instrumentation for the ECCS and the isolation systems are initiated automatically when monitored variables exceed preselected operational limits.

The design of the protection system satisfies the functional requirements as specified in Criterion 20.

For further discussion, see the following:

a. Section 4.2 - Fuel System Design

b. Section 5.2 - Integrity of Reactor Coolant Pressure Boundary

c. Section 5.5 - Component and Subsystem Design

d. Section 6.3 - Emergency Core Cooling System

e. Section 7.2 - Reactor Protection System

f. Section 7.3 - Engineered Safety Feature Systems

g. Section 7.6 - Other Systems Required for Safety and Power Generation

h. Chapter 15 - Accident Analyses.

3.1.2.3.2 Criterion 21 - Protection System Reliability and Testability

The protection system shall be designed for high functional reliability and inservice testability commensurate with the safety functions to be performed. Redundancy and independence designed into the protection system shall be sufficient to assure that (1) no single failure results in loss of the protection function and (2) removal from service of any component or channel does not result in loss of the required minimum redundancy unless the acceptable reliability of operation of the protection system can be otherwise demonstrated. The protection system shall be designed to permit periodic testing of its functioning when the reactor is in operation, including a capability to test channels independently to determine failures and losses of redundancy that may have occurred.

Criterion 21 Conformance - The RPS design provides assurance that, through redundancy, each channel has sufficient reliability to fulfill the single-failure criterion. No single component failure, intentional bypass, maintenance operation, calibration operation, or test to verify operational availability will impair the ability of the system to perform its intended safety function. Additionally, the system design ensures that when a scram trip point is exceeded there is a high scram probability. However, should a scram not occur, other monitored components will scram the reactor if their trip points are exceeded. There is sufficient electrical and physical separation between channels and between trip logics monitoring the same variable to prevent environmental factors, electrical transients, and physical events from impairing the ability of the system to respond correctly.

The RPS includes design features that permit inservice testing. This ensures the functional reliability of the system should the reactor variable exceed the corrective action setpoint.

The RPS initiates an automatic reactor shutdown if the monitored plant variables exceed preestablished limits. This system is arranged into two independently powered trip systems. Each trip system has three trip logics, two of which produce an automatic trip signal. The logic scheme is a one-out-of-two twice arrangement. The RPS can be tested during reactor operation. Manual scram testing is performed by operating one of the two manual scram controls. This tests one trip system. The total test verifies the ability to deenergize the scram pilot valve solenoids. Indicating lights verify that the actuator contacts have opened. This capability for a thorough testing program significantly increases reliability.

Control rod drive (CRD) operability can be tested during normal reactor operation. Drive position indicators and in-core neutron detectors are used to verify control rod movement. Each control rod can be withdrawn one notch and then reinserted to the original position without significantly perturbing the nuclear system. One control rod is tested at a time.

Control rod mechanism overdrive demonstrates rod-to-drive coupling integrity. Hydraulic supply subsystem pressures can be observed on control center instrumentation. Moreover, the hydraulic control unit scram accumulator and the scram discharge volume level are continuously monitored.

The main steam line isolation valves (MSIVs) may be tested during full reactor operation. They can be closed to 90 percent of full-open position without affecting reactor operation. If reactor power is reduced sufficiently, the isolation valves may be fully closed. Means are provided to evaluate valve stem leakage during reactor shutdown. During refueling operation, valve leakage rates can be determined.

Testing of the RHR system can be performed during normal operation. Main system pumps can be evaluated by taking suction from the suppression pool and discharging through test lines back to the suppression pool. System design and operating procedures also permit the testing of discharge valves into the reactor recirculation loops and into the containment spray headers. The low-pressure coolant injection (LPCI) mode can be tested after reactor shutdown. Each active component of the ECCS provided to operate in a design-basis accident (DBA) is designed to be operable for test purposes during normal operation of the nuclear system, except where such tests directly affect reactor operation.

The high functional reliability, redundancy, and inservice testability of the protection system satisfies the requirements specified in Criterion 21.

For further discussion, see the following:

a. Section 4.2 - Fuel System Design

b. Section 5.5 - Component and Subsystems Design

c. Section 6.2 - Containment Systems

d. Section 6.3 - Emergency Core Cooling System

e. Section 7.2 - Reactor Protection System

f. Section 7.3 - Engineered Safety Feature System

g. Section 14.1 - Test Program

h. Chapter 15 - Accident Analyses.

3.1.2.3.3 Criterion 22 - Protection System Independence

The protection system shall be designed to assure that the effects of natural phenomena, and of normal operating, maintenance, testing, and postulated accident conditions on redundant channels do not result in loss of the protection function, or shall be demonstrated to be acceptable on some other defined basis. Design techniques, such as functional diversity or diversity in component design and principles of operation, shall be used to the extent practical to prevent loss of the protection function.

Criterion 22 Conformance - The components of protection systems are designed so that the mechanical and thermal environment resulting from any emergency situation in which the components are required to function will not interfere with the operation of that function. Wiring for the RPS outside of the main control room enclosures is run in rigid metallic wireways. The RPS wireways in certain instances are shared by wiring from the corresponding containment and RPV isolation control system channel, but the wires from duplicate sensors on a common process tap are run in separate wireways. The system sensors are electrically and physically separated. Only one trip actuator logic circuit from each trip may be run in the same wireway.

The RPS is designed to permit maintenance and diagnostic work while the reactor is operating. This is accomplished without restricting the plant operation or hindering the output of these safety functions. The flexibility in design afforded the protection system allows operational system testing by the use of an independent trip channel for each trip logic input. When an essential monitored variable exceeds its scram trip point, it is sensed by at least two independent sensors in each trip system. An intentional bypass, maintenance operation, calibration operation, or test will result in a single channel trip. This leaves at least two trip channels per monitored variable capable of initiating a scram. Although each trip system contains two trip channels, only one channel in each trip system must trip to initiate a scram. Thus, the arrangement of two trip channels per trip system ensures that scram will occur as a monitored variable exceeds its scram setting.

The protection system meets the design requirements for functional and physical independence as specified in Criterion 22.

For further discussion, see the following:

a. Section 4.2 - Fuel System Design

b. Section 5.5 - Component and Subsystem Design

c. Section 7.2 - Reactor Protection System

d. Section 7.3 - Engineered Safety Feature Systems

e. Chapter 15 - Accident Analyses.

3.1.2.3.4 Criterion 23 - Protection System Failure Modes

The protection system shall be designed to fail into a safe state or into a state demonstrated to be acceptable on some other defined basis if conditions such as disconnection of the system, loss of energy (e.g., electric power, instrument air), or postulated adverse environments (e.g., extreme heat or cold, fire, pressure, steam, water, and radiation) are experienced.

Criterion 23 Conformance - The RPS is designed to fail into a safe state. Use of an independent trip channel for each trip logic allows the system to sustain any trip channel failure without preventing the other sensors monitoring the same variable from initiating a scram. A single sensor or trip channel failure will cause a channel trip. Only one trip channel in each trip system must be actuated to initiate a scram. Intentional bypass, maintenance operation, calibration operation, or test will result in a single channel trip. A failure of any one RPS input or subsystem component will produce a trip in one of two channels. This condition is insufficient to produce a reactor scram, but the system is ready to perform its protective function upon another trip.

The environmental conditions in which the instrumentation and equipment of the RPS must operate were considered in establishing the component specifications. Instrumentation specifications are based on the worst expected ambient conditions in which the instruments must operate.

The failure modes of the protection system are such that it will fail into a safe state as required by Criterion 23.

For further discussion, see the following:

a. Section 3.11 - Environmental Design of Mechanical and Electrical Equipment

b. Section 7.2 - Reactor Protection System

c. Section 7.3 - Engineered Safety Feature Systems

d. Chapter 8 - Electric Power.

3.1.2.3.5 Criterion 24 - Separation of Protection and Control Systems

The protection system shall be separated from control systems to the extent that failure of any single control system component or channel, or failure or removal from service of any single protection system component or channel which is common to the control and protection systems leaves intact a system satisfying all reliability, redundancy, and independence requirements of the protection system. Interconnection of the protection and control systems shall be limited so as to assure that safety is not significantly impaired.

Criterion 24 Conformance - There is separation between the RPS and the process control systems. Sensors, trip channels, and trip logics of the RPS are not used directly for automatic control of process systems. Therefore, failure in the controls and instrumentation of process systems cannot induce failure of any portion of the protection system. High scram reliability is designed into the RPS and hydraulic control unit for the CRD. The scram signal and the mode of operation overrides all other signals.

The containment and RPV isolation control systems are designed so that any one failure, maintenance operation, calibration operation, or test to verify operational availability will not impair the functional ability of the isolation control system to respond to essential variables. Corresponding isolation control system channels and RPS channels are not separated from each other, since common power supplies, relay cabinets, primary sensors, and wireways are used for both systems. However, because of the fail-safe design and the one-out-of-two taken twice logic, no single failure in either system can cause failure to scram or failure to isolate.

The protection system is separated from control systems as required in Criterion 24.

For further discussion, see the following:

a. Section 3.12 - Separation Criteria for Safety-Related Mechanical and Electrical Equipment

b. Section 4.2 - Fuel System Design

c. Section 7.2 - Reactor Protection System

d. Section 7.3 - Engineered Safety Feature Systems.

3.1.2.3.6 Criterion 25 - Protection System Requirements for Reactivity Control Malfunctions

The protection system shall be designed to assure that specified acceptable fuel design limits are not exceeded for any single malfunction of the reactivity control systems, such as accidental withdrawal (not ejection or dropout) of control rods.

Criterion 25 Conformance - The RPS provides protection against the onset and consequences of conditions that threaten the integrity of the fuel barrier and the nuclear system process barrier. Any monitored variable that exceeds the scram setpoint will initiate an automatic scram and not impair the remaining variables from being monitored. If one channel fails, the remaining portions of the RPS shall function.

The RMCS is designed so that no single failure can negate the effectiveness of a reactor scram. The circuitry for the RMCS is completely independent of the circuitry controlling the scram valves. This separation of the scram and normal rod control functions prevents failures in the reactor manual control circuitry from affecting the scram circuitry. Because each control rod is controlled as an individual unit, a failure that results in energizing any of the insert or withdrawal solenoid valves can affect only one control rod. The effectiveness of a reactor scram is not impaired by the malfunctioning of any one control rod.

The most serious rod withdrawal errors occur when the reactor is operating in the power region and the operator withdraws the maximum worth rod. Fuel damage in this event is prevented by the timely action of the rod block monitor, which acts to stop rod movement before safety limits are reached.

The design of the protection system ensures that specified acceptable fuel limits are not exceeded for any single malfunction of the reactivity control systems as specified in Criterion 25.

For further discussion, see the following:

a. Section 4.2 - Fuel System Design

b. Section 4.3 - Nuclear Design

c. Section 4.4 - Thermal and Hydraulic Design

d. Section 7.2 - Reactor Protection System

e. Section 7.6 - Other Systems Required for Safety and Power Generation

f. Section 7.7 - Control Systems Not Required for Safety

g. Chapter 15 - Accident Analyses.

3.1.2.3.7 Criterion 26 - Reactivity Control System Redundancy and Capability

Two independent reactivity control systems of different design principles shall be provided. One of the systems shall use control rods, preferably including a positive means for inserting the rods, and shall be capable of reliably controlling reactivity changes to assure that under conditions of normal operation, including anticipated operational occurrences, and with appropriate margin for malfunctions such as stuck rods, specified acceptable fuel design limits are not exceeded. The second reactivity control system shall be capable of reliably controlling the rate of reactivity changes resulting from planned, normal power changes (including xenon burnout) to assure acceptable fuel design limits are not exceeded. One of the systems shall be capable of holding the reactor core subcritical under all temperature conditions.

Criterion 26 Conformance - Two independent reactivity control systems using different design principles are provided. The normal method of reactivity control uses control rod assemblies that contain boron carbide (B_4C) powder in the Ultra-MD control rods, and a combination of B_4C and hafnium in the Duralife 140, Marathon C, and Ultra-HD control rods. Positive insertion of these control rods is provided by means of the control rod drive hydraulic system. The control rods are capable of reliably controlling reactivity changes during normal operation (e.g., power changes, power shaping, xenon burnout, normal startup, and shutdown) via operator-controlled insertions and withdrawals. The control rods are also capable of maintaining the core within acceptable fuel design limits during anticipated operational occurrences via the automatic scram function. The occurrence of a limited number of stuck rods during a scram will not adversely affect the capability to maintain the core within fuel design limits.

The circuitry for manual insertion or withdrawal of control rods is completely independent of the circuitry for reactor scram. This separation of the scram and normal rod control functions prevents failures in the reactor manual control circuitry from affecting the scram circuitry. Two sources of scram energy (accumulator pressure and reactor vessel pressure) provide needed scram performance over the entire range of reactor pressure (i.e., from operating conditions to cold shutdown). The design of the control rod system includes an appropriate margin for malfunctions such as stuck rods. Control rod withdrawal sequences and patterns are selected prior to operation to achieve optimum core performance and, simultaneously, low individual rod worths. Because of the carefully planned and regulated rod withdrawal sequence, prompt shutdown of the reactor can be achieved with the insertion of a small number of the many independent control rods. In the event that a reactor scram is necessary, the occurrence of a limited number of stuck rods will not hinder the capability of the control rod system to render the core subcritical.

The second independent reactivity control system is provided by the reactor coolant recirculation system. By varying reactor flow, it is possible to affect the type of reactivity changes necessary for planned, normal power changes (including xenon burnout). In the event that reactor flow is suddenly increased to its maximum value (pump runout), the core will not exceed fuel design limits because the power flow map defines the allowable initial operating states so that the pump runout will not violate these limits.

The control rod system is capable of holding the reactor core subcritical under all temperature conditions, even when the control rod of highest worth is assumed to be stuck in the fully withdrawn position. This shutdown capability of the control rod system is made possible by designing the fuel with burnable poison (Gd_2O_3) to control the high reactivity of fresh fuel. In addition, the standby liquid control system (SLCS) is available to add soluble boron to the core and render it subcritical.

The redundancy and capabilities of the reactivity control systems for Fermi 2 satisfy the requirements of Criterion 26.

For further discussion, see the following:

a. Section 4.2 - Fuel System Design

b. Section 7.4 - Systems Required for Safe Shutdown

c. Section 7.6 - Other Systems Required for Safety and Power Generation

d. Section 7.7 - Control Systems Not Required for Safety.

3.1.2.3.8 Criterion 27 - Combined Reactivity Control Systems Capability

The reactivity control system shall be designed to have a combined capability in conjunction with poison addition by the emergency core cooling system, of reliably controlling reactivity changes to assure that under postulated accident conditions and with appropriate margin for stuck rods the capability to cool the core is maintained.

Criterion 27 Conformance - There is no credible event applicable to the BWR which requires combined capability of the control rod system and poison additions by the emergency core cooling network. The primary reactivity control system for the BWR during postulated accident conditions is the control rod system. Abnormalities are sensed and, if protection system limits are reached, corrective action is initiated through an automatic scram. High integrity of the protection system is achieved through the combination of logic arrangement, trip channel redundancy, power supply redundancy, and physical separation. High reliability of reactor scram is further achieved by the separation of scram and manual control circuitry, individual control units for each control rod, and fail-safe design features built into the rod drive system. Response by the RPS is prompt, and the total scram time is short.

In reactor operation, there is a spectrum of possible control rod worths, depending on the reactor state and the control rod pattern chosen for operation. Control rod withdrawal sequences and patterns are selected to achieve optimum core performance and low individual rod worths. The RWM prevents rod withdrawal other than by the preselected rod withdrawal pattern. These functions assist the operator with an effective backup control rod monitoring routine that enforces adherence to established startup, shutdown, and low-power-level operations. As a result of this carefully planned procedure, prompt shutdown of the reactor can be achieved with scram insertion of less than half of the many independent control rods. If accident conditions require a reactor scram, this can be accomplished rapidly with appropriate margin for the unlikely occurrence of malfunctions such as stuck rods.

The reactor core design assists in maintaining the stability of the core under accident conditions as well as during power operation. Reactivity coefficients in the power range that contribute to system stability are (1) fuel temperature or Doppler coefficient, (2) moderator void coefficient, and (3) moderator temperature coefficient. The overall power reactivity coefficient is negative and provides a strong negative reactivity feedback under severe power transient conditions.

The design of the reactivity control systems ensures reliable control of reactivity under postulated accident conditions with appropriate margin for stuck rods. The capability of cooling the core is maintained under all postulated accident conditions. Thus, Criterion 27 is satisfied.

For further discussion, see the following:

a. Section 4.2 - Fuel System Design

b. Section 4.3 - Nuclear Design

c. Section 4.4 - Thermal and Hydraulic Design

d. Section 7.2 - Reactor Protection System

e. Section 7.6 - Other Systems Required for Safety and Power Generation

f. Section 7.7 - Control Systems Not Required for Safety

g. Chapter 15 - Accident Analyses.

3.1.2.3.9 Criterion 28 - Reactivity Limits

The reactivity control systems shall be designed with appropriate limits on the potential amount and rate of reactivity increase to assure that the effects of postulated reactivity accidents can neither (1) result in damage to the reactor coolant pressure boundary greater than limited local yielding nor (2) sufficiently disturb the core, its support structures or other reactor pressure vessel internals to impair significantly the capability to cool the core. These postulated reactivity accidents shall include consideration of rod ejection (unless prevented by positive means), rod dropout, steam line rupture changes in reactor coolant temperature and pressure, and cold water addition.

Criterion 28 Conformance - The control rod system design incorporates appropriate limits on the potential amount and rate of reactivity increase. Control rod withdrawal sequences and patterns are selected to achieve optimum core performance and low individual rod worths. The RWM prevents withdrawal other than by the preselected rod withdrawal pattern. These functions assist the operator with an effective backup control rod monitoring routine that enforces adherence to established startup, shutdown, and low-power-level operations control rod procedures.

The control rod mechanical design incorporates a hydraulic velocity limiter that prevents rapid rod ejection. This engineered safeguard protects against a high reactivity insertion rate by limiting the control rod velocity to less than 5 fps. Normal rod movement is limited to 6-in. increments, and the rod withdrawal rate is limited to 3 in./sec by the hydraulic valve.

The plant safety analysis (Chapter 15) provides detailed evaluations of the postulated reactivity accidents as well as abnormal operational transients. Analyses are included for rod dropout, steam line rupture, changes in reactor coolant temperature and pressure, and cold water addition. The initial conditions, assumptions, calculational models, sequences of events, and anticipated results of each postulated occurrence are covered. The results of these analyses indicate that none of the postulated reactivity transients or accidents result in damage to the RCPB. In addition, the integrity of the core, its support structures, or other RPV internals is maintained so that the capability of cooling the core is not impaired for any of the postulated reactivity accidents described in the plant safety analysis.

The design features of the reactivity control system, which limit the potential amount and rate of reactivity increase, ensure that Criterion 28 is satisfied for all postulated reactivity accidents.

For further discussion, see the following:

a. Chapter 3 - Design of Structures, Components, Equipment, and Systems

b. Section 4.2 - Fuel System Design

c. Section 4.3 - Nuclear Design

e. Section 5.2 - Integrity of Reactor Coolant Pressure Boundary

f. Section 5.4 - Reactor Pressure Vessel and Appurtenances

g. Section 5.5 - Component and Subsystem Design

h. Section 7.6 - Other Systems Required for Safety and Power Generation

i. Chapter 15 - Accident Analyses.

3.1.2.3.10 Criterion 29 - Protection Against Anticipated Operational Occurrences

The protection and reactivity control systems shall be designed to assure an extremely high probability of accomplishing their safety functions in the event of anticipated operational occurrences.

Criterion 29 Conformance - The high functional reliability of the protection and reactivity control systems is achieved through the combination of logic arrangement, redundancy, physical and electrical independence, functional separation, fail-safe design, and inservice testability. These design features are discussed in Criteria 21, 22, 23, 24, and 26.

An extremely high probability of correct protection and reactivity control systems response to anticipated operational occurrences is maintained by a thorough program of inservice testing and surveillance. Active components can be tested or removed from service for maintenance during reactor operation without compromising the protection or reactivity control functions even in the event of a subsequent single failure. Components important to safety such as the CRD, MSIVs, and RHR pumps are tested during normal reactor operation. Functional testing and calibration schedules are developed using experience. These schedules represent optimized protection and reactivity control system reliability by considering both the failure probabilities of individual components and the reliability effects during individual component testing on the portion of the system not under going testing. The capability for inservice testing ensures the high functional reliability of protection and reactivity control systems should a reactor variable exceed the corrective action setpoint.

The capabilities of the protection and reactivity control systems to perform their safety functions in the event of anticipated operational occurrences meet the requirements of Criterion 29.

For further discussion, see the following:

a. Section 4.2 - Fuel System Design

b. Section 5.5 - Component and Subsystem Design

c. Section 6.2 - Containment Systems

d. Section 6.3 - Emergency Core Cooling System

e. Section 7.2 - Reactor Protection System

f. Section 7.3 - Engineered Safety Feature Systems

g. Chapter 15 - Accident Analyses.

3.1.2.4 Group IV, Fluid Systems (Criteria 30-46)

3.1.2.4.1 Criterion 30 - Quality of Reactor Coolant Pressure Boundary

Components which are part of the reactor coolant pressure boundary shall be designed, fabricated, erected, and tested to the highest quality standards practical. Means shall be provided for detecting and, to the extent practical, identifying the location of the source of reactor coolant leakage.

Criterion 30 Conformance - By using conservative design practices and detailed quality control procedures, the pressure-retaining components of the RCPB are designed and fabricated to retain their integrity during normal and postulated accident conditions. Accordingly, components that comprise the RCPB are designed, fabricated, erected, and tested in accordance with the recognized industry codes and standards listed in Sections 5.2, 5.4, and 5.5. Further, product and process quality planning is provided as described in Chapter 17 to ensure conformance with the applicable codes and standards and to retain appropriate documented evidence verifying compliance. Because the subject matter of this criterion deals with aspects of the RCPB, further discussion on this subject is treated in the response to Criterion 14, Reactor Coolant Pressure Boundary.

Means are provided for detecting reactor coolant leakage. The leak detection system consists of sensors and instruments to detect, annunciate, and in some cases, isolate the RCPB from potentially hazardous leaks before predetermined limits are exceeded. Small leaks are detected by temperature and pressure changes, increased condensate flow from the primary containment cooling system, increased frequency of sump pump operation, and measurement of fission product concentration. In addition to these, large leaks are detected by changes in flow rates in process lines and reactor water level. The allowable leakage rates are based on the predicted and experimentally determined behavior of cracks in pipes, the ability to make up coolant system leakage, the normally expected background leakage due to equipment design, and the detection capability of the various sensors and instruments. The total leakage rate limit is established so that, in the absence of normal ac power associated with a loss of feedwater supply, makeup capabilities are provided by the RCIC system. While the leak detection system provides protection from small leaks, the ECCS network provides protection for the complete range of discharges from ruptured pipes. Thus, protection is provided for the full spectrum of possible discharges. The RCPB and the leak detection system are designed to meet the requirements of Criterion 30.

For further discussion, see the following:

a. Chapter 3 - Design of Structures, Components, Equipment and Systems

b. Section 5.2 - Integrity of Reactor Coolant Pressure Boundary

c. Section 5.4 - Reactor Pressure Vessel and Appurtenances

d. Section 5.5 - Component and Subsystem Design

e. Section 7.6 - Other Systems Required for Safety and Power Generation

f. Section 15.0 - Accident Analyses

g. Chapter 17 - Quality Assurance.

3.1.2.4.2 Criterion 31 - Fracture Prevention of Reactor Coolant Pressure Boundary

The reactor coolant pressure boundary shall be designed with sufficient margin to assure that when stressed under operating, maintenance, testing, and postulated accident conditions (1) the boundary behaves in a nonbrittle manner and (2) the probability of rapidly propagating fracture is minimized. The design shall reflect consideration of service temperatures and other conditions of the boundary material under operating, maintenance, testing, and postulated accident conditions and the uncertainties in determining (1) material properties, (2) the effects of irradiation on material properties, (3) residual, steady-state, and transient stresses, and (4) size of flaws.

Criterion 31 Conformance - Brittle fracture control of pressure-retaining ferritic materials is provided to ensure protection against nonductile fracture. To minimize the possibility of brittle fracture failure of the RPV, it is designed to meet the requirements of ASME B&PV Code Section III, 1968 Edition through Summer 1969 addenda, which considers material properties; steady-state and transient stresses; and the size of flaws, and conforms very closely with Appendix G, which was added in the Summer 1972 Addenda (see Section 5.2 for a discussion of the degree of conformance.)

The nil ductility transition (NDT) temperature is defined as the temperature below which ferritic steel fails in a brittle rather than ductile manner. The RT_{NDT} temperature increases as a function of neutron exposure at integrated neutron exposures greater than 1.0 x 10^{17} n/cm^2 with neutrons of energies in excess of 1 MeV. Since the material RT_{NDT} temperature dictates the minimum operating temperature at which the reactor vessel can be pressurized, it is desirable for the NDT temperature to be low.

The reactor assembly design provides an annular space from the outermost fuel assemblies to the inner surface of the RPV that serves to attenuate the fast neutron flux incident upon the reactor vessel wall. This annular volume contains the core shroud, jet pump assemblies, and reactor coolant. Assuming plant operation at rated power, and end-of-life (EOL) cumulative Effective Full Power Years (EFPY) of 52 EFPY, the maximum fast neutron fluence at the inner surface of the RPV is calculated to be 1.03 x 10^{18} n/cm^2 (fast neutron fluence consists of neutrons having energies greater than 1 MeV) as detailed in Table 4.3-2. EOL RT_{NDT} temperature as calculated from the EOL fluence and chemical composition indicates a substantial margin against the occurrence of brittle fracture. For hydrostatic test, the RPV will not be pressurized until the RPV temperature exceeds the RT_{NDT} by at least 60°F

The RCPB piping, pumps, and valves are designed, maintained, and tested such that adequate assurance is provided that the boundary will behave in a nonbrittle manner throughout the life of the plant.

For further discussion, see the following:

a. Chapter 3 - Design of Structures, Components, Equipment, and Systems

b. Section 5.2 - Integrity of Reactor Coolant Pressure Boundary

c. Section 5.4 - Reactor Pressure Vessel and Appurtenances.

3.1.2.4.3 Criterion 32 - Inspection of Reactor Coolant Pressure Boundary

Components which are part of the reactor coolant pressure boundary shall be designed to permit (1) periodic inspection and testing of important areas and features to assess their structural and leaktight integrity, and (2) an appropriate material surveillance program for the reactor pressure vessel.

Criterion 32 Conformance - The RPV design and engineering effort includes provisions for inservice inspection. Removable plugs in the sacrificial shield and/or removable panels in the insulation provide access for examination of the vessel and its appurtenances. In addition, all of the remaining portion of the RCPB is provided with removable insulation. Inspection of the RCPB is in accordance with the ASME B&PV Code Section XI. The Inservice Inspection Plan, access provisions, and areas of restricted access are defined in Section 5.2.

Reactor pressure vessel material surveillance samples are located within the RPV to enable periodic monitoring of material properties with exposure. The program includes specimens of the base metal, heat-affected zone metal, and weld material. The samples are placed near the core midplane to obtain maximum exposures. Tests include tensile and impact testing. The test program is in accordance with ASTM El85-73 and the appropriate requirements of 10 CFR 50, Appendixes G and H. Subsequent to developing this surveillance program, the BWRVIP developed an integrated surveillance program (ISP) which replaces the Fermi specific surveillance program. This program is described in section 5.2.4.4.3.

The plant testing and inspection programs ensure that the requirements of Criterion 32 will be met.

For further discussion, see the following:

a. Chapter 3 - Design of Structures, Components, Equipment, and Systems

b. Section 5.2 - Integrity of Reactor Coolant Pressure Boundary

c. Section 5.4 - Reactor Pressure Vessel and Appurtenances

d. Section 5.5 - Component and Subsystem Design

e. Section 14.1 - Test Program.

3.1.2.4.4 Criterion 33 - Reactor Coolant Makeup

A system to supply reactor coolant makeup for protection against small breaks in the reactor coolant pressure boundary shall be provided. The system safety function shall be to assure that specified acceptable fuel design limits are not exceeded as a result of reactor coolant loss due to leakage from the reactor coolant pressure boundary and rupture of small piping or other small components which are part of the boundary. The system shall be designed to assure that for onsite electric power system operation (assuming offsite power is not available) and for offsite electric power system operation (assuming onsite power is not available) the system safety function can be accomplished using the piping, pumps, and valves used to maintain coolant inventory during normal reactor operation.

Criterion 33 Conformance - Means provided for detecting reactor coolant leakage are discussed in the conformance to Criterion 30. As stated, the RCIC system provides makeup for small leaks, and the ECCS provides core cooling for the complete range of discharges from ruptured pipes. Protection is provided for the full spectrum of possible discharges to the extent that fuel clad temperature limits are not exceeded utilizing either onsite or offsite redundant power sources.

The plant is designed to provide ample reactor coolant makeup for protection against small leaks in the RCPB for anticipated operational occurrences and postulated accident conditions. The design of these systems meets the requirements of Criterion 33.

For further discussion, see the following:

a. Section 5.2 - Integrity of Reactor Coolant Pressure Boundary

b. Section 5.6 - Instrumentation Requirements

c. Section 6.3 - Emergency Core Cooling System

d. Section 7.6 - Other Systems Required for Safety and Power Generation.

3.1.2.4.5 Criterion 34 - Residual Heat Removal

A system to remove residual heat shall be provided. The system safety function shall be to transfer fission product decay heat and other residual heat from the reactor core at a rate such that specified acceptable fuel design limits and the design conditions of the reactor coolant pressure boundary are not exceeded.

Suitable redundancy in components and features, and suitable interconnections, leak detection, and isolation capabilities shall be provided to assure that for onsite electric power system operation (assuming offsite power is not available) and for offsite electric power system operation (assuming onsite power is not available) the system safety function can be accomplished, assuming a single failure.

Criterion 34 Conformance - The RHR system provides the means to

a. Remove decay heat and residual heat from the nuclear system so that refueling and nuclear system servicing can be performed

b. Supplement the fuel pool cooling and cleanup system capacity during shutdown to provide additional cooling capacity.

The RHR system is designed for three modes of operation:

a. Shutdown cooling

b. Containment cooling

c. LPCI.

The LPCI mode of operation, part of the ECCS, does not apply to Criterion 34 since its purpose is to reflood the core rather than remove decay heat.

The major equipment of the RHR system consists of two heat exchangers, four main system pumps, and four service water pumps. The equipment is connected by associated valves and piping, and the instrumentation and controls are provided for proper system operation. The main system pumps are sized on the basis of the flow required during the LPCI mode of operation, which is the mode requiring the maximum flow rate. The heat exchangers were sized on the basis of the required duty for the steam condensing function, which is the mode requiring the maximum heat exchanger capacity. However, Edison has decided to delete the steam condensing mode of the RHR system and has disconnected the equipment that would be necessary to use this mode of RHR.

One loop, consisting of a heat exchanger, two main system pumps in parallel, and associated piping, is located in one area of the reactor building. The other heat exchanger, pumps, and piping (forming a second loop) are located in another area of the reactor building to minimize the possibility of a single physical event causing the loss of the entire system. The two loops of the RHR system are cross connected by a single header, making it possible to supply either loop from the pumps in the other loop. Either of these redundant loops can fully meet the most limiting of the three modes of operation.

The division and redundancy in the RHR system apply to the electric power system also. As discussed in Section 8.3, the electric power system is divided into two separate, redundant divisions, each of which is independently capable of supplying power to one group of the redundant safety equipment and components required for safe shutdown at the plant. Each division is supplied by electrically and physically separate offsite power sources. Four 2850-kW standby diesel generators, two in each division, supply adequate power to their respective division in the event that offsite power is not available. The diesel generators, buses, and switchgear of Division I are electrically and physically separated such that no single failure could interrupt both divisions of electric power. Also, all of the above onsite emergency ac power equipment is housed in Category I structures that also provide protection against missiles and natural phenomena. The batteries, buses, and other equipment of the dc power systems are likewise divided into two redundant, separate, full-capacity divisions with the same equipment protection as provided for the ac power systems. Thus, the power from onsite and offsite power systems conforms to Criterion 34.

The RHR system is adequate to remove residual heat from the reactor core and ensure that fuel and RCPB design limits are not exceeded. Redundant offsite and onsite electric power systems are provided. The design of the RHR system, including its power supply, meets the requirements of Criterion 34.

For further discussion, see the following:

a. Section 5.5 - Component and Subsystem Design

b. Section 6.3 - Emergency Core Cooling Systems

c. Section 7.3 - Engineered Safety Feature Systems

d. Section 8.3 - Onsite Power Systems

e. Section 9.2 - Water Systems

f. Chapter 15 - Accident Analyses.

3.1.2.4.6 <u>Criterion 35 - Emergency Core Cooling</u>

A system to provide abundant emergency core cooling shall be provided. The system safety function shall be to transfer heat from the reactor core following any loss of reactor coolant at a rate such that (l) fuel and clad damage that could interfere with continued effective core cooling is prevented and (2) clad metal-water reaction is limited to negligible amounts.

Suitable redundancy in components and features, and suitable interconnections, leak detection, isolation, and containment capabilities shall be provided to assure that for onsite electric power system operation (assuming offsite power is not available) and for offsite electric power system operation (assuming onsite power is not available) the system safety function can be accomplished, assuming a single failure.

<u>Criterion 35 Conformance</u> - The ECCS consists of the following: (1) high pressure coolant injection system (HPCI), (2) automatic depressurization system (ADS), (3) core spray system, and (4) LPCI (an operating mode of the RHR system). The ECCS is designed to limit fuel cladding temperature over the complete spectrum of possible break sizes in the nuclear system process barrier, including a complete and sudden circumferential rupture of the largest pipe connected to the reactor vessel.

The HPCI system consists of a steam turbine, a constant-flow pump, system piping, valves, controls, and instrumentation. The HPCI system ensures that the reactor core is adequately cooled to prevent excessive fuel clad temperatures for breaks in the nuclear system that do not result in rapid depressurization of the RPV. The HPCI continues to operate until RPV pressure is below the pressure at which LPCI operation or core spray system operation maintains core cooling. Water to supply the HPCI and core spray systems is available from either the condensate storage tank or the suppression pool. The supply of water for LPCI operation is available from the suppression pool only.

In case the capability of the feedwater pumps, CRD pumps, RCIC, and HPCI is not sufficient to maintain the reactor water level, the ADS functions to reduce the reactor pressure so that flow from LPCI and the core spray system enters the RPV in time to cool the core and prevent excessive fuel clad temperature. The ADS uses five of the nuclear system pressure relief valves to relieve the high-pressure steam to the suppression pool.

Two independent loops are provided as a part of the core spray system. Each loop consists of a pair of centrifugal water pumps driven by electric motors, a spray sparger in the RPV above the core, piping and valves to convey water from the suppression pool to the sparger, and the associated instrumentation and controls instrumentation. In cases of low water level in the RPV or high pressure in the drywell, the core spray system automatically sprays water onto the top of the fuel assemblies in time, and at a sufficient flow rate, to cool the core and prevent excessive fuel temperature. The LPCI system starts from the same signals that initiate the core spray and operates independently to achieve the same objective by flooding the RPV.

In cases of low water level in the reactor or high pressure in the containment drywell, the LPCI mode of the RHR system pumps water into the RPV in time to flood the core and prevent excessive fuel temperature. Low-pressure coolant injection operation provides protection to the core in case of a large break in the nuclear system when the feedwater pumps and the HPCI system are unable to maintain RPV water level. Protection provided by LPCI also extends to a small break where the ADS has operated to lower the RPV pressure which would result in the LPCI and the core spray system starting to provide core cooling.

Results of the performance of the ECCS for the entire spectrum of liquid line breaks are discussed in Section 6.3.

3.1.2.4.7 Criterion 36 - Inspection of Emergency Core Cooling System

The emergency core cooling system shall be designed to permit appropriate periodic inspection of important components, such as spray rings in the reactor pressure vessel, water injection nozzles, and piping, to assure the integrity and capability of the system.

Criterion 36 Conformance - The ECCS is designed as discussed in Criterion 35. The engineering and design efforts for the ECCS include inservice inspection considerations. The spray rings within the vessel are accessible for inspection during each refueling outage. Removable plugs in the sacrificial shield and/or panels in the insulation provide access for examination of nozzles. Removable insulation is provided on the ECCS piping out to and including the first isolation valve outside containment. Inspection of the ECCS is in accordance with the intent of Section XI of the ASME Code. The Inservice Inspection Plan, access provisions, and areas of restricted access are defined in Section 5.2.

During plant operations, the pumps, valves, piping, instrumentation, wiring, and other components outside the primary containment can be visually inspected at any time. Components inside the primary containment can be inspected when the drywell is open for access. When the RPV is open, for refueling or other purposes, the spargers and other internals can be inspected. Portions of the ECCS that are part of the RCPB are designed to specifications for inservice inspection to detect defects. Particular attention is given to the reactor nozzles and the core spray and feedwater spargers. The design of the RPV and internals for inservice inspection and the plant testing and inspection program ensure that the requirements of Criterion 36 are met.

For further discussion, see the following:

a. Section 4.2 - Fuel System Design

b. Section 5.2 - Integrity of Reactor Coolant Pressure Boundary

c. Section 5.4 - Reactor Pressure Vessel and Appurtenances

d. Section 7.3 - Engineered Safety Feature Systems.

3.1.2.4.8 Criterion 37 - Testing of Emergency Core Cooling System

The emergency core cooling system shall be designed to permit appropriate periodic pressure and functional testing to assure (1) the structural and leaktight integrity of its components, (2) the operability and performance of the active components of the system, and (3) the operability of the system as a whole and, under conditions as close to design as practical, the performance of the full operational sequence that brings the system into operation, including operation of applicable portions of the protection system, the transfer between normal and emergency power sources, and the operation of the associated cooling water system.

Criterion 37 Conformance - The ECCS consists of the HPCI system, ADS, LPCI mode of the RHR system, and core spray system. Each of these systems is provided with sufficient test connections and isolation valves to permit appropriate periodic functional testing that ensures the structural and leaktight integrity of its components.

The HPCI, LPCI, and core spray systems are designed to permit periodic testing to ensure the operability and performance of the active components of each system.

The pumps and valves of these systems will be tested periodically to verify operability. Flow-rate tests will be conducted on the core spray, LPCI, and HPCI systems. The ADS logic will be tested on a routine basis. Operability of the safety/relief valves will be tested when they are removed on a periodic schedule for valve testing and overhaul.

The complete ECCS will be subjected to tests in order to verify the performance of the full operational (Section 14.1) sequence that brings each component system into operation. The operation of the associated cooling water systems is discussed in the evaluation of Criterion 46. It is concluded that the requirements of Criterion 37 are met.

For further discussion, see the following:

a. Section 5.2 - Integrity of Reactor Coolant Pressure Boundary

b. Section 6.3 - Emergency Core Cooling System

c. Section 7.3 - Engineered Safety Feature Systems

d. Chapter 8 - Electric Power

e. Section 14.1 - Test Program.

3.1.2.4.9 <u>Criterion 38 - Containment Heat Removal</u>

A system to remove heat from the reactor containment shall be provided. The system safety function shall be to reduce rapidly, consistent with the functioning of other associated systems, the containment pressure and temperature following any loss-of-coolant accident and maintain them at acceptably low levels.

Suitable redundancy in components and features, and suitable interconnections, leak detection, isolation, and containment capabilities shall be provided to assure that for onsite electrical power system operation (assuming offsite power is not available) and for offsite electrical power system operation (assuming onsite power is not available) the system safety function can be accomplished, assuming a single failure.

<u>Criterion 38 Conformance</u> - In the event of a LOCA within the reactor containment, the pressure suppression system will rapidly condense the steam to prevent containment overpressure. The containment feature of pressure suppression employs two separate compartmented sections of the primary containment: the drywell that houses the nuclear system and the suppression chamber containing a large volume of water. Any increase in pressure in the drywell from a leak in the nuclear system is relieved below the surface of the suppression chamber water pool by connecting vent lines, thereby condensing steam being released to the drywell. Any pressure buildup in the suppression chamber is equalized with the drywell by a vent line and vacuum breaker arrangement. Cooling systems remove heat from the reactor core, the drywell, and water in the suppression chamber during accident conditions. Thus, continuous cooling of the primary containment is provided.

The ECCS is actuated to provide core cooling in the event of a LOCA. Low water level in the RPV or high pressure in the drywell will initiate the ECCS to prevent excessive fuel temperature. Sufficient water is provided in the suppression pool to accommodate the initial energy that can transiently be released into the drywell from the postulated pipe failure.

The suppression chamber is sized to contain this water, in addition to the water displaced from the reactor primary system, together with the free air initially contained in the drywell.

Either or both RHR system loops, which include the heat exchangers, can be manually activated to remove energy from the containment in the containment cooling mode. The redundancy and capability of the offsite and onsite electric power systems to provide power for the RHR system are presented in the Criterion 34 Conformance Evaluation.

The pressure suppression system is capable of rapid containment pressure and temperature reduction following a LOCA so that design limits are not exceeded. Redundant offsite and onsite electric power systems provide assurances that system safety functions can be accomplished. The design of the containment heat removal system meets the requirements of Criterion 38.

For further discussion, see the following:

a. Section 5.5 - Component and Subsystem Design

b. Section 6.2 - Containment Systems

c. Section 6.3 - Emergency Core Cooling System

d. Section 7.3 - Engineered Safety Feature Systems

e. Chapter 8 - Electric Power

f. Chapter 9 - Auxiliary Systems

g. Chapter 15 - Accident Analyses.

3.1.2.4.10 Criterion 39 - Inspection of Containment Heat Removal System

The containment heat removal system shall be designed to permit appropriate periodic inspection of important components, such as the torus, sumps, spray nozzles, and piping to assure the integrity and capability of the system.

Criterion 39 Conformance - Provisions are made to facilitate periodic inspection of active components and other important equipment of the containment pressure-reducing systems. During plant operations, the pumps, valves, piping, instrumentation, wiring, and other components outside the primary containment can be visually inspected at any time, and will be inspected periodically. Components inside the primary containment can be inspected when the drywell is open for access. The testing frequencies of most components will be correlated with the component inspection.

The pressure suppression chamber is designed to permit appropriate periodic inspection. Space is provided outside the chamber for inspection and maintenance. There are two hatches that permit access to the suppression chamber for inspection.

The containment heat removal system is designed to permit periodic inspection of major components both outside and inside the primary containment as discussed in Section 14.1. This design meets the requirements of Criterion 39.

For further discussion, see the following:

a. Section 5.5 - Component and Subsystem Design
b. Section 6.2 - Containment Systems
c. Section 6.3 - Emergency Core Cooling System
d. Section 7.3 - Engineered Safety Feature Systems
e. Section 9.2 - Water Systems
f. Section 14.1 - Test Program.

3.1.2.4.11 Criterion 40 - Testing of Containment Heat Removal System

The containment heat removal system shall be designed to permit appropriate periodic pressure and functional testing to assure (1) the structural and leaktight integrity of its components, (2) the operability and performance of the active components of the systems, and (3) the operability of the system as a whole, and, under conditions as close to the design as practical, the performance of the full operational sequence that brings the system into operation, including operation of applicable portions of the protection system, the transfer between normal and emergency power sources, and the operation of the associated cooling water system.

Criterion 40 Conformance - The containment heat removal function is accomplished by the containment cooling mode of the RHR system. This mode consists of the suppression pool cooling subsystem and containment spray subsystem.

The RHR system is provided with sufficient test connections and isolation valves to permit periodic pressure testing. The containment spray mode is subjected to a periodic air test.

The pumps and valves of the RHR system will be operated periodically to verify operability. The containment spray mode is not fully testable, but the operation of the initiation signal and components can be verified. The suppression pool cooling mode is not automatically initiated, but operation of the components is periodically verified. The operation of associated cooling water systems is discussed in the response to Design Criterion 46. It is concluded that the requirements of Criterion 40 are met.

For further discussion, see the following:

a. Section 5.5 - Component and Subsystem Design
b. Section 7.3 - Engineered Safety Feature Systems
c. Chapter 8 - Electric Power
d. Section 14.1 - Test Program.

3.1.2.4.12 Criterion 41 - Containment Atmosphere Cleanup

Systems to control fission products, hydrogen, oxygen, and other substances which may be released into the reactor containment shall be provided as necessary to reduce, consistent with the functioning of other associated systems, the concentration and quantity of fission products released to the environment following postulated accidents, and to control the concentration of hydrogen or oxygen and other substances in the containment atmosphere following postulated accidents, to assure that containment integrity is maintained.

Each system shall have suitable redundancy in components and features, and suitable interconnections, leak detection, isolation, and containment capabilities to assure that for onsite electric power system operation (assuming offsite power is not available) and for offsite electric power system operation (assuming onsite power is not available) its safety function can be accomplished, assuming a single failure.

Criterion 41 Conformance - Fission products or other materials that leak into the drywell following postulated accidents are mostly contained in the drywell. Those that leak to the reactor building are processed by the standby gas treatment system (SGTS). The SGTS draws air from the reactor building and discharges it through a high-efficiency particulate air (HEPA) filter and deep-bed charcoal filters to reduce the levels of radiation before exhausting the air to the environment. The SGTS is designed to meet Category I requirements and can be powered from either the onsite or offsite power sources. An on-line continuous gas monitoring system allows operating personnel to evaluate the drywell atmospheric conditions, including hydrogen and oxygen concentration. To counteract the buildup of combustible gases to unacceptable limits, the drywell is rendered inert with nitrogen gas. For further details, see Sections 6.2 and 9.3.6.

3.1.2.4.13 Criterion 42 - Inspection of Containment Atmosphere Cleanup Systems

The containment atmosphere cleanup systems shall be designed to permit appropriate periodic inspection of important components such as filter frames, ducts, and piping to assure the integrity and capability of the systems.

Criterion 42 Conformance - All parts of the systems described for Criterion 41 can be inspected periodically (except small lengths of piping or ducting passing through concrete shielding) for visible indications of damage or potential failure. Access is provided to all active components for inspection and maintenance. Section 6.2, Containment Systems, includes a description of the preoperational and inservice performance inspection programs to ensure the integrity and capability of the containment atmosphere cleanup systems. For further details, see Section 6.2.

3.1.2.4.14 Criterion 43 - Testing of Containment Atmosphere Cleanup Systems

The containment atmosphere cleanup systems shall be designed to permit appropriate periodic pressure and functional testing to assure (1) the structural and leaktight integrity of its components, (2) the operability and performance of the active components of the systems such as fans, filters, dampers, pumps, and valves and (3) the operability of the systems as a whole and, under conditions as close to design as practical, the performance of the full operational sequence that brings the systems into operation, including operation of applicable portions of the protection system, the transfer between normal and emergency power sources, and the operation of associated systems.

Criterion 43 Conformance - The integrity of the containment atmosphere cleanup systems is verified by preoperational and inservice testing. Testing (including filter dioctyl phthalate penetration testing [DOP] and freon testing) for the SGTS is discussed in Section 6.2. Inspection and testing of the containment are also discussed in Sections 6.2 and 14.1.

Testability of the power sources is described in Chapter 8. For further discussion, see the following:

a. Section 6.2 - Containment Systems

b. Chapter 8 - Electric Power

c. Section 14.1 - Test Program.

3.1.2.4.15 Criterion 44 - Cooling Water

A system to transfer heat from structures, systems, and components important to safety to an ultimate heat sink shall be provided. The system safety function shall be to transfer the combined heat load of these structures, systems, and components under normal operating and accident conditions.

Suitable redundance in components and features, and suitable interconnection, leak detection, and isolation capabilities shall be provided to assure that for onsite electric power system operation (assuming offsite power is not available) and for offsite electric power system operation (assuming onsite power is not available) the system safety function can be accomplished assuming a single failure.

Criterion 44 Conformance - The RHR service water (RHRSW) system, the emergency equipment service water (EESW) system, and the EDG service water system are designed in accordance with Criterion 44 to transfer heat from structures, systems, and components important to safety, to the ultimate heat sink under normal operating and accident conditions. The systems have suitable redundancy to accommodate a single failure without hindering the safety function of the systems. Appropriate leak-detection capability is provided. The RHRSW system is provided to remove heat from the RHR system during plant shutdown and post-accident conditions. The EDG service water system removes heat rejected by the EDG when operating and the EESW provides cooling water for equipment required to operate during and following an accident, as needed.

Electric power for the operation of each system may be supplied from offsite or onsite power sources, with distribution arranged such that a single failure will not prevent the system from performing its safety function.

For discussion of the above systems, see the following:

a. Subsection 5.5.7 - Residual Heat Removal System

b. Chapter 8 - Electric Power

c. Section 9.2 - Water Systems.

3.1.2.4.16 Criterion 45 - Inspection of Cooling Water System

The cooling water system shall be designed to permit appropriate periodic inspection of important components, such as heat exchangers and piping, to assure the integrity and capability of the system.

Criterion 45 Conformance - The systems discussed under Criterion 44 Conformance are designed to permit periodic inspection and/or monitor system integrity. Where physical inspection is not possible (e.g., buried pipes) periodic integrity testing, such as hydrostatic testing, is performed. Periodic inspection requirements are also established. For further details, see Section 9.2, Water Systems.

3.1.2.4.17 Criterion 46 - Testing of Cooling Water System

The cooling water system shall be designed to permit appropriate periodic pressure and functional testing to assure, (1) the structural and leaktight integrity of its components, (2) the operability and the performance of the active components of the system, and (3) the operability of the system as a whole and, under conditions as close to design as practical, the performance of the full operational sequence that brings the system into operation for reactor shutdown and for loss of coolant accidents, including operation of applicable portions of the protection system and the transfer between normal and emergency power sources.

Criterion 46 Conformance - The service water systems discussed in the conformance to Criterion 44 are designed to conform to the requirements of Criterion 46. Provisions are made for testing the actuation of the systems from both normal and emergency power sources, and for monitoring the integrity of components. Initial and periodic testing of these systems is described in Section 14.1. For further details, see the following:

a. Section 9.2 - Water Systems

b. Section 14.1 - Test Program.

3.1.2.5 Group V, Reactor Containment (Criteria 50-57)

3.1.2.5.1 Criterion 50 - Containment Design Basis

The reactor containment structure, including access openings, penetrations, and the containment heat removal system shall be designed so that the containment structure and its internal compartments can accommodate, without exceeding the design leakage rate and, with sufficient margin, the calculated pressure and temperature conditions resulting from any loss-of-coolant accident. This margin shall reflect consideration of (1) the effects of potential energy sources which have not been included in the determination of the peak conditions, such as energy in steam generators and energy from metal-water and other chemical reactions that may result from degraded emergency core cooling functioning; (2) the limited experience and experimental data available for defining accident phenomena and containment responses, and (3) the conservatism of the calculational model and input parameters.

Criterion 50 Conformance - The reactor containment structures, including access openings, penetrations, and the containment heat removal system are designed with sufficient margin to meet the intent of Criterion 50. The design includes consideration of metal/water reactions and other chemical reactions subsequent to the postulated LOCA. The primary reactor containment consists of the drywell, pressure suppression chamber, and interconnecting vent pipes and vent header.

The containment was initially designed for 56 psig at 281°F. Subsequently, the containment has been analyzed for the envelope of conditions representing the spectrum of LOCAs by Chicago Bridge and Iron Company (CBI), the design fabricator, and is considered adequate without exception. Metal temperatures are not expected to reach the maximum temperature of 340°F, except for localized impingement areas. Continued integrity of the primary containment is ensured by initial and periodic testing and inspection.

Further discussion of containment design may be found in the following:

a. Section 3.8 - Design of Category I Structures

b. Section 6.2 - Containment Systems

c. Section 14.1 - Test Program.

3.1.2.5.2 Criterion 51 - Fracture Prevention of Containment Pressure Boundary

The reactor containment boundary shall be designed with sufficient margin to assure that under operating, maintenance, testing, and postulated accident conditions (1) ferritic materials behave in a non-brittle manner and (2) the probability of rapidly propagating fracture is minimized. The design shall reflect consideration of service temperatures and other conditions of the containment boundary material during operation, maintenance, testing, and postulated accident conditions and the uncertainties in determining (1) material properties (2) residual, steady-state, and transient stresses, and (3) size of flaws.

Criterion 51 Conformance - Operational, test, and postulated accident temperatures are combined with appropriate pressures and other loads in the load-combination equations of Section 3.8. The resulting loads are used in determining the required material properties and construction methods according to the ASME B&PV Code, and AISC requirements, as well as specific material requirements imposed by other codes, standards, and special considerations. All of these codes, standards, special requirements, and analytical techniques used in determining the adequacy of containment material fracture toughness, are given in Section 3.8. Methods of ensuring compliance with these codes are covered by the Quality Assurance Program discussed in Chapter 17.

For further discussion of containment design, refer to the following:

a. Section 3.8 - Design of Category I Structures

b. Section 6.2 - Containment Systems.

3.1.2.5.3 Criterion 52 - Capability for Containment Leakage Rate Testing

The reactor containment and other equipment which may be subjected to containment test conditions shall be designed so that periodic integrated leakage rate testing can be conducted at containment design pressure.

Criterion 52 Conformance - Provisions for containment leakage rate testing conform to Criterion 52. Section 6.2 discusses the provisions for containment leakage rate testing which conform to this criterion as well as to 10 CFR 50, Appendix J, Option B. Containment leak rate testing is discussed in the following:

a. Section 3.8 - Design of Category I Structures

b. Section 6.2 - Containment Systems.

3.1.2.5.4 Criterion 53 - Provisions for Containment Testing and Inspection

The reactor containment shall be designed to permit (1) appropriate periodic inspection of all important areas, such as penetrations, (2) an appropriate surveillance program and (3) periodic testing at containment design pressure of the leak-tightness of penetrations which have resilient seals and expansion bellows.

Criterion 53 Conformance - The reactor containment design permits access to penetrations and other important areas for implementation of the surveillance program described in the Technical Specifications. Penetrations and resilient seals and bellows are inspected visually, and leaktightness is verified by periodic containment pressure tests. The frequency of inspection will be consistent with the leakage rate for the individual units. Initial leak rate tests of the containment vessel and necessary action were performed to ensure that the actual leak rate was below the design values. Provisions in containment design for the performance of the tests are described in Section 6.2, Containment Systems.

3.1.2.5.5 Criterion 54 - Piping Systems Penetrating Containment

Piping systems penetrating primary reactor containment shall be provided with leak detection, isolation, and containment capabilities having redundancy, reliability, and performance capabilities which reflect the importance to safety of isolating these piping systems. Such piping systems shall be designed with a capability to test periodically the operability of the isolation valves and associated apparatus and to determine if valve leakage is within acceptable limits.

Criterion 54 Conformance - Piping systems penetrating the containment are designed to withstand a pressure at least equal to the containment maximum internal pressure. All piping systems penetrating the containment are provided with isolation valves.

Proper valve closing time is achieved by appropriate selection of valve, operating type, and operator size. Isolation valve closing time was verified during the functional performance tests prior to reactor startup. The design of piping systems penetrating reactor containment includes provisions for appropriate testing of isolation valves and valve leakage.

Major leaks in the pipe are located by increased temperature, radiation, and/or drain sump flow. Provisions are made to permit leakage testing of the isolation valves. For further discussion, see Section 6.2, Containment Systems.

3.1.2.5.6 Criterion 55 - Reactor Coolant Pressure Boundary Penetrating Containment

Each line that is part of the reactor coolant pressure boundary and that penetrates primary reactor containment shall be provided with containment isolation valves as follows, unless it can be demonstrated that the containment isolation provisions for a specific class of lines, such as instrument lines, are acceptable on some other defined basis:

a. one locked closed isolation valve inside and one locked closed isolation valve outside containment, or

b. one automatic isolation valve inside and one locked closed isolation valve outside containment, or

c. one locked closed isolation valve inside and one automatic isolation valve outside containment. A simple check valve may not be used as the automatic isolation valve outside containment, or

d. one automatic isolation valve inside and one automatic isolation valve outside containment. A simple check valve may not be used as the automatic isolation valve outside containment.

Isolation valves outside containment shall be located as close to containment as practical and upon loss of actuating power, automatic isolation valves shall be designed to take the position that provides greater safety.

Other appropriate requirements to minimize the probability or consequences of an accidental rupture of these lines or of lines connected to them shall be provided as necessary to assure adequate safety. Determination of the appropriateness of these requirements, such as higher quality in design, fabrication, and testing, additional provisions for inservice inspection, protection against more severe natural phenomena, and additional isolation valves and containment shall include consideration of the population density, use characteristics, and physical characteristics of the site environs.

Criterion 55 Conformance - Conformance to this criterion is discussed on a line-by-line basis in Subsection 6.2.4.2.2.2. It is shown that Fermi 2 conforms to this criterion to the extent that it is consistent with the safety requirements of the various systems. Several lines required to be open for injecting liquids following accidents use testable check valves for isolation (feedwater, SLCS, and ECCS discharge lines).

3.1.2.5.7 Criterion 56 - Primary Containment Isolation

Each line that connects directly to the containment atmosphere and penetrates primary reactor containment shall be provided with containment isolation valves as follows, unless it can be demonstrated that the containment isolation provisions for a specific class of lines, such as instrument lines, are acceptable on some other defined basis:

a. one locked closed isolation valve inside and one locked closed isolation valve outside containment, or

b. one automatic isolation valve inside and one locked closed isolation valve outside containment, or

c. one locked closed isolation valve inside and one automatic isolation valve outside containment. A simple check valve may not be used as the automatic isolation valve outside containment, or

d. one automatic isolation valve inside and one automatic isolation valve outside containment. A simple check valve may not be used as the automatic isolation valve outside containment.

Isolation valves outside containment shall be located as close to the containment as practical and upon loss of actuating power, automatic isolation valves shall be designed to take the position that provides greater safety.

Criterion 56 Conformance - Conformance to this criterion is discussed in Subsection 6.2.4.2.2.3. This criterion requires one isolation valve inside the containment and one outside. Fermi 2 is based on the design basis that placing isolation valves inside the suppression chamber would reduce the reliability of the connecting systems. Justification for this configuration is included in Subsection 6.2.4.2.2.3.1.

3.1.2.5.8 Criterion 57 - Closed System Isolation Valves

Each line that penetrates primary reactor containment and is neither part of the reactor coolant pressure boundary nor connected directly to the containment atmosphere shall have at least one containment isolation valve which shall be either automatic, or locked closed, or capable of remote manual operation. This valve shall be outside the containment and located as close to the containment as practical. A simple check valve may not be used as the automatic isolation valve.

Criterion 57 Conformance - Piping forming a closed loop within the containment is provided with isolation valves in accordance with Criterion 57. Each line that penetrates the primary reactor containment and is neither part of the RCPB nor connected directly to the containment atmosphere has at least one containment isolation valve that is either automatic or locked closed, or capable of remote manual operation. This valve is located outside the containment but as close to the containment as practicable.

Containment isolation valves and the associated tables and figures are discussed in Section 6.2, Containment Systems.

3.1.2.6 Group VI, Fuel and Radioactivity Control (Criteria 60-64)

3.1.2.6.1 Criterion 60 - Control of Releases of Radioactive Materials to the Environment

The nuclear power unit design shall include means to control suitably the release of radioactive materials in gaseous and liquid effluents and to handle radioactive solid wastes produced during normal reactor operation, including anticipated operational occurrences. Sufficient holdup capacity shall be provided for retention of gaseous and liquid effluents containing radioactive materials, particularly where unfavorable site environmental conditions can be expected to impose unusual operational limitations upon the release of such effluents to the environment.

Criterion 60 Conformance - An extensive system, including filtration, evaporation, and demineralization, has been designed for liquid waste treatment. Offgas from the steam-jet air ejector is processed by appropriate holdup in charcoal delay beds. Liquid wastes are normally processed (dewatered, solidified, etc.) and packaged in suitable containers for eventual disposition in licensed burial grounds. Should any condition exist that could prevent safe release of liquid waste, the liquid radwaste system has ample tankage to permit deferring the release. This system is designed to be able to receive anticipated surges in liquid waste volumes. The offgas system is capable of safely processing, for release, considerably more radioactive gas than would be expected during normal plant conditions and anticipated operational occurrences. For additional information, refer to Chapter 11.

Fermi 2 potable water was originally supplied from the onsite Fermi 1 water treatment plant and pumped through the Fermi 2 distribution system. Under this condition, the system was not subject to the requirements of Design Criterion 60. In 1995, the Fermi 2 water supply was connected to the Frenchtown Township Water Treatment Plant (FTWTP) system, and the Fermi 1 plant was abandoned.

The Fermi 2 potable water supplies the makeup demineralizer system and the sanitary, drinking, kitchen, and safety shower systems. The makeup demineralizer system is the only interconnection between the potable water and systems having the potential for containing radioactive material. At this interconnection, the potable water system is protected by an air gap, an NRC accepted design provision to prevent the inadvertent contamination of the FTWTP system with radioactive material.

3.1.2.6.2 Criterion 61 - Fuel Storage and Handling and Radioactivity Control

The fuel storage and handling, radioactive waste, and other systems which may contain radioactivity shall be designed to assure adequate safety under normal and postulated accident conditions. These systems shall be designed (1) with a capability to permit appropriate periodic inspection and testing of components important to safety, (2) with suitable shielding for radiation protection, (3) with appropriate containment, confinement, and filtering systems, (4) with a residual heat removal capability having reliability and testability that reflect the importance to safety of decay heat and other residual heat removal, and (5) to prevent significant reduction in fuel storage coolant inventory under accident conditions.

Criterion 61 Conformance

New-Fuel Storage - New fuel may be placed in the fuel storage pool or placed in dry storage in the new-fuel storage vault located inside the secondary containment (reactor building). The geometric design of the storage racks precludes accidental criticality (see Criterion 62 Conformance Evaluation). Use of the new fuel storage vault is subject to the restrictions discussed in Section 9.1.1.2.1.

Spent-Fuel Handling and Storage - The handling of new- and spent-fuel assemblies for reactor refueling is within the reactor building. Fuel storage pool water is allowed to flood the reactor well to provide shielding above the reactor and spent fuel. Fuel pool water is circulated through the fuel pool cooling and cleanup (FPCC) system to maintain fuel pool temperature, purity, clarity, and level. Storage racks preclude accidental criticality (see Criterion 62 Conformance Evaluation).

Reliable decay heat removal is provided by the closed-loop FPCC system. It consists of two circulating pumps, two heat exchangers, two filter-demineralizers, two skimmer surge tanks, and the required piping, valves, and instrumentation. The pool water is circulated through the system; suction is taken from surge tanks, flow passes through the heat exchanger and filters, and is discharged through diffusers at the bottom of the fuel pool and reactor well. Pool water temperature is maintained below 125°F when removing the maximum normal heat load from the pool with the reactor building closed cooling water temperature at its maximum. If it appears that the pool temperature will exceed 150°F, the FPCC system can be connected to the RHR system.

This increases the cooling capacity of the FPCC system and ensures that the temperature will not exceed 150°F.

There are no connections to the fuel storage pool that could allow the fuel pool to be drained below the pool gate between the reactor well and fuel pool. The high and low level switches indicate pool-water-level changes in the main control room and pump room. Pool-water-level indication is painted on the pool walls. Fission product concentration in the pool water is minimized by use of the filter-demineralizer. This minimizes the release of fission products from the pool to the reactor building environment.

No testing is planned because at least one pump, heat exchanger, and filter-demineralizer are continuously in operation while fuel is stored in the pool. Duplicate units are operated periodically to handle abnormal heat loads or to replace a unit for servicing. Routine visual inspection of the system components, instrumentation, and trouble alarms are adequate to verify system operability.

Dry Spent Fuel Storage - Storage of spent fuel at the Fermi Independent Spent Fuel Storage Installation (ISFSI) is governed by the regulations in 10 CFR 72 that are applicable to Part 72 general licensees, and the Certificate of Compliance (CoC) for the spent fuel storage cask. Furthermore, in accordance with the provisions of 10 CFR 50.68(c), while a spent fuel transportation package approved under 10 CFR 71 or a spent fuel storage cask approved under 10 CFR 72 is in the spent fuel pool:

1. The requirements of 10 CFR 50.68(b) do not apply to the fuel located within that package or cask, and
2. The requirements of 10 CFR 71 or 10 CFR 72, as applicable, and the requirements of the package or cask CoC apply to the fuel within that package or cask.

Radioactive Waste System - The radioactive waste systems provide all equipment or connections for portable systems necessary to collect, process, and prepare for disposal all radioactive liquid, gaseous, and solid waste produced as a result of reactor operation. Liquid radwastes are classified, contained, and treated as high or low conductivity, chemical, sludges, or concentrated wastes. Processing includes filtration, ion exchange, analysis, and dilution. Liquid wastes are also decanted, and sludge is accumulated for disposal as solid radwaste. Wet solid wastes are packaged in approved disposal containers. Dry solid radwastes are packaged in strong, tight containers. Gaseous radwastes are monitored, processed, recorded, and controlled so that radiation doses to persons outside the controlled area are below those allowed by applicable regulations.

Accessible portions of the reactor and radwaste buildings have sufficient shielding to maintain dose rates within the limits set forth in 10 CFR 20. The radwaste building is designed to preclude accidental release of radioactive materials to the environs.

The radwaste systems are used on a routine basis and do not require specific testing to ensure operability. Performance is observed by radiation monitors during operation.

The fuel storage and handling, and radioactive waste systems are designed to ensure adequate safety under normal and postulated accident conditions. The design of these systems meets the requirements of Criterion 61.

For further discussion, see the following:

a. Section 5.5 - Component and Subsystem Design

b. Section 6.2 - Containment Systems

c. Section 9.1 - Fuel Storage and Handling

d. Section 9.3 - Process Auxiliaries

e. Chapter 11 - Radioactive Waste Management

f. Chapter 12 - Radiation Protection

g. Section 14.1 - Test Program.

3.1.2.6.3 Criterion 62 - Prevention of Criticality in Fuel Storage and Handling

Criticality in the fuel storage and handling system shall be prevented by physical systems or processes, preferably by use of geometrically safe configurations.

Criterion 62 Conformance - Appropriate plant fuel handling and storage facilities are provided to preclude accidental criticality for new and spent fuel. Criticality in fuel storage is prevented by the geometrically safe configuration of the storage rack. There is sufficient spacing between the assemblies to ensure that the array, when fully loaded, is substantially subcritical. Fuel elements are limited by rack design to only toploading and fuel assembly positions. The fuel racks are Category I structures.

New fuel may be stored underwater in the spent fuel pool or placed in dry storage in the top-loaded new-fuel storage vault subject to the restrictions discussed in Section 9.1.1.2.1. This vault contains a drain to prevent the accumulation of water. The new-fuel storage vault racks (located inside the secondary containment) are designed to prevent an accidental critical array, even in the event that the vault becomes flooded or subjected to seismic loadings. The 6.625 in. by 11.5 in. center-to-center new-fuel assembly spacing limits the effective multiplication factor of the array to not more than 0.90 for new dry fuel. The effective neutron multiplication factor of the reactor (k_{eff}) will not exceed 0.95 if the new fuel is flooded.

Spent fuel is stored under water in the spent fuel pool. The high-density spent-fuel racks are constructed of stainless steel and include sheets of Boraflex or Boral, which are neutron attenuators. Sheets of Boraflex are used in all walls of the racks that contain Boraflex. For the racks that contain Boral, Boral panels are not needed on the exterior walls of modules facing non-fuel regions. In addition, Boral panels are used on only one exterior surface of the modules that face each other across the small water gap between the modules. The remaining conventional (low-density) spent-fuel racks are constructed of aluminum.

The spent-fuel storage racks are Category I structures designed to ensure that a k_{eff} not greater than 0.95 is maintained when the racks are fully loaded with fuel of the highest anticipated reactivity and flooded with unborated water at room temperature (68°F). The calculated k_{eff} includes a margin for uncertainty in k_{eff} calculations and in mechanical tolerances, statistically combined, so that the true k_{eff} will be less than 0.95 with a 95 percent probability at a 95 percent confidence level.

Refueling interlocks include circuitry that senses conditions of the refueling equipment and the control rods. These interlocks reinforce operational procedures that prohibit making the reactor critical. The fuel handling system is designed to provide a safe, effective means of transporting and handling fuel and is designed to minimize the possibility of mishandling or improper operation.

The use of conventional and of geometrically safe configurations for new-fuel storage and conventional and high-density storage racks for spent-fuel storage and the design of fuel handling systems preclude accidental criticality in accordance with Criterion 62.

For further discussion, see the following:

a. Section 7.6 - All Other Systems Required for Safety and Power Generation

b. Section 9.1 - Fuel Storage and Handling.

Dry Spent Fuel Storage - Storage of spent fuel at the Fermi Independent Spent Fuel Storage Installation (ISFSI) is governed by the regulations in 10 CFR 72 that are applicable to Part 72 general licensees, and the Certificate of Compliance (CoC) for the spent fuel storage cask. Furthermore, in accordance with the provisions of 10 CFR 50.68(c), while a spent fuel transportation package approved under 10 CFR 71 or a spent fuel storage cask approved under 10 CFR 72 is in the spent fuel pool:

1. The requirements of 10 CFR 50.68(b) do not apply to the fuel located within that package or cask, and

2. The requirements of 10 CFR 71 or 10 CFR 72, as applicable, and the requirements of the package or cask CoC apply to the fuel within that package or cask.

3.1.2.6.4 Criterion 63 - Monitoring Fuel and Waste Storage

Appropriate systems shall be provided in fuel storage and radioactive waste systems and associated handling areas, (1) to detect conditions that may result in loss of residual heat removal capability and excessive radiation levels, and (2) to initiate appropriate safety actions.

Criterion 63 Conformance - Appropriate systems have been provided to meet the requirements of this criterion. A malfunction of the FPCC system, which could result in loss of RHR capability and excessive radiation levels, is alarmed in the main control room. Alarmed conditions include low fuel pool cooling water pump discharge pressure, high/low level in the fuel storage pool and skimmer surge tanks, and flow in the drain lines between fuel pool gates between fuel pool and reactor well. System temperature is also continuously monitored and alarmed in the main control room. The reactor building ventilation radiation monitoring system detects abnormal amounts of radioactivity and initiates appropriate action to control the release of radioactive material to the environs.

Area radiation and tank and sump levels are monitored and alarmed to give indication of conditions that may result in excessive radiation levels in radioactive waste system areas. These systems satisfy the requirements of Criterion 63.

For further discussion, see the following:

a. Section 7.6 - Other Systems Required for Safety and Power Generation

b. Section 9.1 - Fuel Storage and Handling

c. Section 11.2 - Liquid Radwaste System

d. Section 11.3 - Gaseous Radwaste System

e. Section 11.5 - Solid Radwaste System

f. Section 11.7 - Onsite Storage Facility.

3.1.2.6.5 Criterion 64 - Radioactivity-Release Monitoring

Means shall be provided for monitoring the reactor containment atmosphere, spaces containing components for recirculation of loss of coolant accident fluids, effluent discharge paths, and the plant environs for radioactivity that may be released from normal operations, including anticipated operational occurrences, and from postulated accidents.

Criterion 64 Conformance - Means have been provided for monitoring radioactivity releases resulting from normal and anticipated operational occurrences.

The following station releases are monitored:

a. Gaseous releases from the offgas system and the gland seal exhaust delay pipe

b. Liquid discharge to the circulating water pond decant line

c. Reactor building ventilation

d. Radwaste building ventilation

e. Turbine building ventilation

f. Deleted

g. Onsite storage building ventilation.

In addition, the drywell containment atmosphere is monitored by onsite monitors.

For further discussion of the means and equipment used for monitoring radioactivity releases, see the following:

a. Section 5.2 - Integrity of Reactor Coolant Pressure Boundary

b. Section 7.6 - Other Systems Required for Safety and Power Generation

c. Section 11.4 - Process and Effluent Radiation Monitor Systems.

3.2 CLASSIFICATION OF STRUCTURES, COMPONENTS, AND SYSTEMS

Certain structures, components, and systems of the nuclear plant are considered important to safety because they perform safety actions required to avoid or mitigate the consequences of abnormal operational transients or accidents. The purpose of this section is to classify structures, components, and systems according to the importance of the safety functions they perform. In addition, design requirements are placed on such equipment to ensure the proper performance of safety actions, when required.

3.2.1 Seismic Classification

Plant structures, systems, and components important to safety are designed to withstand the effects of a safe-shutdown earthquake (SSE) and remain functional if they are necessary to ensure

a. Integrity of the reactor coolant pressure boundary (RCPB)

b. Capability to shut down the reactor and maintain it in a safe condition

c. Capability to prevent or mitigate the consequences of accidents that could result in potential offsite exposures comparable to the guideline exposures set forth in 10 CFR 50.67 or 10 CFR 100.

Plant structures, systems, and components, including their foundations and supports, designed to remain functional in the event of an SSE and an operating-basis earthquake (OBE), are designated as Category I, as generically indicated in Table 3.2-1. A detailed tabulation of all Fermi 2 facility Category I equipment items is provided in the Central Component System (CECO). In this tabulation, each equipment item is described, facility installation locations are noted, the aseismic qualification basis is summarized, and the representative qualification documentation is identified. The CECO list is updated to reflect the facility item's aseismic status on a continual basis. The method of seismic qualification of some items is indicated in Table 3.2-2.

The Fermi 2 design fully conforms to the requirements of Regulatory Guide 1.29, Revision 3, Seismic Design Classification.

The radwaste system for the Fermi 2 plant is excluded from Category I criteria since the conservatively calculated offsite whole-body dose from radwaste system failure does not exceed 0.5 rem as specified in Regulatory Guide 1.29. The dose-rate considerations and analyses are discussed in Chapter 11, particularly in Subsections 11.2.3 and 11.3.3.

The recirculation pumps of a BWR plant are not considered essential for safe plant shutdown under either normal or abnormal conditions, even though Paragraph (h) of the Regulatory Position of this guide implies that reactor coolant pumps are required for safety. Thus, the pump seal purge system is not designed to meet Category I requirements with the exception of the components required for containment isolation. However, the pump seal and motor cooling water system are Category I, consistent with the structural design of the pumps and the recirculation system.

All Category I structures, systems, and components have been analyzed under the loading conditions of the SSE and OBE. Since the two earthquakes vary in intensity, the design of

Category I structures, components, and systems to resist each earthquake and other loads is based on levels of material stress or load factors, whichever is applicable, and yield margins of safety appropriate for each earthquake. The margin of safety provided for Category I structures, components, and systems for the SSE is sufficiently large to ensure that their safety functions are not jeopardized. For further details of specific seismic design criteria, refer to

a. Sections 3.7 and 3.9 for mechanical design criteria

b. Sections 3.7 and 3.8 for structural design criteria

c. Sections 3.7 and 3.10 for electrical design criteria

d. Sections 3.7 and 3.10 for instrumentation and control design criteria.

3.2.2 System Quality Group Classification

System Quality Group classifications as defined in Regulatory Guide 1.26 have been determined for each water-, steam-, or radioactive waste-containing component of those applicable fluid systems relied upon to

a. Prevent or mitigate the consequences of accidents and malfunctions originating within the RCPB

b. Permit shutdown of the reactor and maintain it in the safe-shutdown condition

c. Contain radioactive material.

A tabulation of Quality Group classification for each component so defined is shown in Table 3.2-1. Figures 3.2-1 and 3.2-2 depict the relative locations of these components along with their Quality Group classification.

Regulatory Guide 1.26 was still under development at the completion of the AEC staff review of the Fermi 2 construction permit application. Thus, the minimum code requirements for each Quality Group classification were those proposed by Edison and accepted by the AEC staff as evidenced in Subsection 3.3.3 and Table 3.3-3 of the AEC Safety Evaluation Report (Reference 1) resulting from their review. The substance of the table is shown in Table 3.2-3. Subsequent to issuance of the construction permit, Edison requested waiver from the requirements of 10 CFR 50.55a, which became effective July 12, 1971. The differences between the code requirements of Section 50.55a and those actually used, which were those required at the time of procurement of the component, are shown in Table 3.2-4. These differences were the subject of a waiver requested by Edison and approved by the AEC (Reference 2) except for Valve B31-F023. Reference 2 listed the purchase order date as October 1970 and code applied as NPVC, 70, for Valve B31-F023 in error. The correct data are November 1969 and NPVC, 68, as listed in Table 3.2-4.

XLIV. Locally mounted instrumentation with safety function (not rack or panel mounted)	GE, E	R,A,H	I	N/A	S,B	IEEE	
XLV. Fire detection, suppression, and extinguishing systems, emergency lighting, and breathing apparatus	E	All	N/A	N/A	N/A	N/A	s

Note a

Safety-related instrumentation and control systems and components are identified in Chapter 7 and will be subject to the operational QA Program requirements.

Note aa

The reactor refueling bellows was designed, fabricated, and installed as ASME Class 2 but was not N-stamped.

Note b

A module is an assembly of interconnected components that constitutes an identifiable device or piece of equipment. For example, electrical modules include sensors, power supplies, and signal processors; mechanical modules include turbines, strainers, and orifices.

Note c

GE = Supplied by General Electric

E = Supplied by the Detroit Edison Company.

Note d

Location abbreviations are:

A = Auxiliary building

C = Part of, or within, primary containment

H = RHR complex

I = Independent Spent Fuel Storage Installation (ISFSI) Equipment Storage Building

J = Independent Spent Fuel Storage Installation (ISFSI) Storage Pad

K = ISFSI Fabrication Pad

L = ISFSI Transfer Pad

M = Any other location

N = ISFSI Cask Transfer Facility

O = Outdoors onsite

P = Circulating water pump house

R = Reactor building

T = Turbine building

W = Radwaste building

Note e

I = The equipment is constructed in accordance with the seismic requirements for the SSE and OBE as described in Section 3.7.

K = The equipment is constructed in accordance with the seismic requirements as described in Section 3.10.

NA = The seismic requirements for the SSE are not applicable to the equipment.

II/I = The equipment is constructed in accordance with the seismic requirements of Category II/I described in Section 3.7.

Note f

The structure, system, or component is constructed in accordance with the codes listed in Table 3.2-3.

Note g

B = The structure, system, or component meets the QA requirements of 10 CFR 50, Appendix B, in accordance with the QA Program described in Chapter 17.

S = Items ordered with specific QA requirements identified in the purchase documents. This includes items purchased prior to the issuance of 10 CFR 50, Appendix B (35 FR 10499, June 27, 1970). For example, this would include items purchased under the contract with General Electric (the NSSS supplier), which was effective August 15, 1968.

BM = The system or component will be maintained according to the requirements of 10 CFR 50, Appendix B, but was not originally procured according to Appendix B.

App 17.2A = ISFSI Storage Pad and ISFSI Cask Transfer Facility are ITS-C; See UFSAR Appendix 17.2A

Note h

Notation for principal construction codes is:

III-A,B,C,1,2,3 - ASME Boiler and Pressure Vessel Code Section III, Class A,B,C,1,2, or 3 or Subsection NE, Class NE. (Pre-1971 versions of the code used the Class A,B,C, designation while 1971 and later versions used the Class 1,2,3 designation. Equipment was ordered throughout a period requiring use of both designations)

VIII - ASME Boiler and Pressure Vessel Code Section VIII, Pressure Vessels, Division I

B31.7-1,2,3 - ANSI Nuclear Power Piping Code Class 1, II, III

B31.1.0 - ANSI B31.1.0 Standard Code for Pressure Piping, Power Piping

NPVC - 1,2,3 Draft ASME Code for Pumps and Valves for Nuclear Power, Class I,II,III

IEEE 308-1971 - IEEE Criteria for Class 1E Electric System, for Nuclear Power Generating Station

IEEE 317-1971 - IEEE Standard for Electric Penetration Assemblies in Containment Structures for Nuclear Power Generating Stations

IEEE 344-1971 - Guide for Seismic Qualification of Class I Electrical Equipment for Nuclear Power Generating Stations.

IEEE/ICC/WG-12-32 - Proposed Guide for Type Tests of Class I Cables and Connections Installed Inside the Containment of Nuclear Generating Stations

TEMA-C,R - Tubular Exchanger Manufacturer Association, Class C,R

ACI 318 - Building Code Requirements for Reinforced Concrete 1963 and 1971. Note: Code Year 2005 used for ISFSI structures and the second set of Category I 4160-V underground ducts, manholes and cable vault structures only.

ACI 349-01 – Code Requirements for Nuclear Safety-Related Concrete Structures and Commentary

AEG-VIII - Manufactured in West Germany in accordance with ASME Boiler and Pressure Vessel Code Section VIII, Division I, but not code stamped. Code compliance certified by third-party inspectors

AISC - Specification for the Design Fabrication and Erection of Structural Steel for Buildings

API 650 - Welded steel tanks for oil storage

API 620 - Specifications for Welded Steel Storage Tanks

B96.1 - USAS B96.1 - Welded aluminum alloy field-erected storage tanks

B16.5 - ANSI B16.5 - Steel pipe flanges and flanged fittings

EOCI - Electric Overhead Crane Institute.

(Other Civil and Structural Codes are given in Section 3.8.)

Note i

Maintenance on all components within the reactor internal structures will be performed in accordance with 10 CFR 50, Appendix B.

Note j

1. All instrument lines that are connected to the RCPB and are not utilized to actuate safety systems are Quality Group D from the outer isolation valve or the process shutoff valve (root valve) to the sensing instrumentation

2. All other instrument lines:

    - Through the root valve; shall be of the same classification as the system to which they are attached

    - Beyond the root valve, if used to actuate a safety system; shall be of the same classification as the system to which they are attached

    - Beyond the root valve; if not used to actuate a safety system, are Quality Group D.

3. All sample lines from the outer isolation valve or the process root valve through the remainder of the sampling system are Quality Group D

4. Portions of instrument lines (regardless of the originating quality group) passing through primary containment are part of a penetration assembly that is part of containment. As such, these lines are Quality Group B, consistent with the Containment Quality Group. This is in accordance with Regulatory Guide 1.11 and Note 2(a) referenced from 10 CFR 50.55a(d)(2).

Note k

The recirculation pumps of a BWR plant are not considered essential for safe plant shutdown under either normal or abnormal conditions, even though Paragraph (h) of the Regulatory Position of Regulatory Guide 1.29 implies that reactor coolant pumps are required for safety. Thus, the pump seal purge system is not designed to meet Category I requirements with the exception of the components required for containment isolation. However, the pump seal and motor cooling water system are Category I, consistent with the structural design of the pumps and the recirculation system.

Note l

The hydraulic control unit (HCU) is a GE factory-assembled engineered module of valves, tubing, piping, and stored water which controls a single control rod drive (CRD) by the application of precisely timed sequences of pressures and flows. Control is accomplished by slow insertion or withdrawal of the control rods for power control, and rapid insertion for reactor scram

Although the HCU, as a unit, is field installed and connected by process piping, many of its internal parts differ markedly from process piping components because of the more complex functions they must provide. Thus, although the codes and standards invoked by the Group A, B, C, D pressure integrity quality levels clearly apply at all levels to the interfaces between the HCU and the connecting conventional piping components (e.g., pipe nipples, fittings, simple hand valves, etc.), it is considered that they do not apply to the specialty parts (e.g., solenoid valves, pneumatic components, and instruments)

The design and construction specification for the HCU invoke such codes and standards as can be reasonably applied to individual parts in developing required quality levels, but these codes and standards are supplemented with additional requirements for these parts and for the remaining parts and details. For example: (1) all welds are LP inspected, (2) all socket welds are inspected for gap between pipe and socket bottom, (3) all welding is performed by qualified welders, and (4) all work is done per written procedures

Quality Group D is generally applicable because the codes and standards invoked by that group contain clauses that permit the use of manufacturer's standards and proven design techniques which are not explicitly defined within the codes of Quality Groups A, B, or C. This is supplemented by the QC techniques described above.

Note m

The standby liquid control system storage tank is Group D plus the following additional QC:

a. Spot radiographic inspection was performed on all vertical and horizontal shell butt welds and on all bottom butt welds. Methods, techniques, and acceptance standards were in accordance with the requirements of API 650

b. Liquid-penetrant inspection was performed on all tank nozzle welds below and including the overflow nozzle both internal and external to the tank. All fillet and socket welds received a random liquid penetrant examination. Methods, technique, and acceptance standards were in accordance with the ASME B&PV Code Section VIII, Division I.

Note n

The RCIC and HPCI turbines do not fall within the applicable design codes. To ensure that the turbine is fabricated to the standards commensurate with their safety and performance requirements, GE has established specific design requirements for this component. These requirements are given in the appropriate GE internal documents.

Note o

The radwaste system for Fermi 2 is excluded from Category I criteria because the conservatively calculated offsite whole-body dose from radwaste system failure does not exceed 0.5 rem as specified in Regulatory Guide 1.29. The dose-rate considerations and analyses are discussed in Chapter 11, particularly Subsections 11.2.3 and 11.3.3.

Note p

Section VIII of ASME B&PV Code and ANSI B31.1.0 apply downstream of the outermost isolation valves.

Note q

Three valves, one inside and two outside the containment, are placed in the RWCU influent line. The RWCU effluent line has two valves, one inside and one outside containment. The RWCU system beyond the third isolation valve G3352F119 on the influent line up to the outside containment isolation valve G3352F220 on the effluent line is constructed in accordance with the applicable codes of Code Group D.

Note r

The first valve capable of timely actuation in branch lines connected to the main steam lines between the outermost containment isolation valve and the third isolation valve, meets all of the pressure integrity requirements of Group D plus the following additional requirements:

1. Pressure-retaining components of all cast parts of valves are subject to volumetric examination or surface examination methods. Ultrasonic examination to equivalent standards is used as an alternate to radiographic methods. If size or configuration does not permit effective volumetric examination, magnetic-particle or liquid-penetrant methods are substituted

2. All inspection records are retained for the life of the plant. These records include data pertaining to the qualification of inspection personnel, examination procedures, and examination results. A certification has been obtained from the vendors of the turbine stop valves and turbine bypass valves stating that all cast pressure-retaining parts of a size and configuration for which volumetric examination methods are effective have been examined by radiographic methods by qualified personnel. Ultrasonic examination to equivalent standards may be used as an alternative to radiographic methods.

Note s

The spring-loaded piston operator of the valve is held open by air pressure during normal operation. Fail-open solenoid valves are used to release air pressure and to permit the check valve piston operators to close. The valves are remote manually operated from the main control room using signals that indicate loss of feedwater flow.

The classification of the feedwater line from the reactor pressure vessel through the third isolation valve is Quality Group A. The remainder of these systems is Quality Code Group D.

Note t

The specific IEEE construction codes used for a particular component may be found in the purchase document referenced in the Master Instrument List.

Note u

The outermost valve of the three isolation valves in the feedwater lines is similar to a boiler feed pump check valve.

Note v

The condensate storage tank is designed, fabricated, and tested to meet the intent of API 650. In addition, the specifications for the tank require that

1. All shell joints are full penetration and fusion welds
2. All shell joints are radiographed 100 percent
3. Shell to bottom joint is 100 percent liquid penetrant examined.

Note w

Fire detection, suppression, and extinguishing systems, emergency lighting, and breathing apparatus impacting safety-related areas of the plant are periodically inspected, maintained, and tested for proper operation per the Operational QA Program Requirements.

Note x

Residual heat removal (RHR) head spray line between reactor pressure vessel and bulkhead penetration is removed. Therefore, head spray portion of RHR shutdown cooling is no longer part of the reactor coolant pressure boundary. Also, an in-line blank orifice plate isolates the head spray piping from the RHR System. The head spray piping and its associated components have been downgraded to Quality Group B (piping and components between and including isolation valves E1150F022 and E1150F023) or Quality Group D (all other head spray piping and components that are not part of the RHR System pressure boundary).

Note y

The fuel preparation machines are used for removing and replacing channels on fuel assemblies and fuel bundle inspection. They are not required to prevent or mitigate the consequences of postulated accidents. Therefore, they are classified QA level non-Q and seismic category II/I. They were originally supplied by GE as passive, safety-related components, seismically qualified to the Fermi 2 design basis OBE and SSE seismic events.

Note z

The reactor recirculation pumps are upgraded to the 4th generation design. The modified RCPB components were designed and manufactured to ASME III, Class 1, 1989, No addenda.

---

These code requirements were established and agreed to by the AEC during the Construction Permit Review (AEC Staff Safety Evaluation Report, Table 3.3.3) and do not, in all cases, conform to the codes indicated in Regulatory Guide 1.26. However, as noted under Principal Construction Code, Table 3.2-1, many of the construction codes actually used exceed the above and meet the Regulatory Guide 1.26 requirements. For example, the primary electrical penetrations conform to ASME B&PV Code Section III, Subsection NE, Class NE.

These requirements were supplemented and modified as shown in Table 3.2-4 and explained in Subsection 3.2.2.

For code definitions, see Note h of Table 3.2-1.

3.3 WIND AND TORNADO LOADINGS

3.3.1 Wind Loadings

3.3.1.1 Design Wind Velocity

For service load conditions, the Category I structures of Fermi 2 are designed to withstand a 90 mph fastest-mile sustained wind velocity, 30 ft above ground level. This wind velocity has a l00-year recurrence interval.

3.3.1.2 Basis for Wind Velocity Selection

The wind velocity and recurrence interval is based on ASCE Paper No. 6038 by H. C. S. Thom (Reference 1). The 90-mph velocity for the Fermi site was read from Figure 5 of this paper. Figure 3.3-1 is a reproduction of Figure 5 of ASCE Paper No. 6038. This paper is referenced in the ANSI A58.1-1972 Code (Reference 2) for selecting basic wind speeds for locations in the United States.

The design of 90 mph is conservative for the Fermi 2 site when compared to measured values recorded at Detroit City Airport and Toledo, Ohio. As discussed in Subsection 2.3.1, the fastest-mile wind recorded was 77 mph at Detroit City Airport.

3.3.1.3 Vertical Velocity Distribution and Gust Factor

The relationships to determine the vertical velocity distribution of the wind are obtained from page 1139 of ASCE Paper No. 3269 (Reference 3) for coastal areas and are as follows:

for $V_{30} \leq 60$ mph

$$V_z = V_{30}\left(\frac{z}{30}\right)^{0.3} \qquad (3.3\text{-}1)$$

for $V_{30} > 60$ mph

$$V_z = V_{30}\left(\frac{z}{30}\right)^{x} \qquad (3.3\text{-}2)$$

where

V_{30} = basic wind velocity (mph) at height 30 ft above ground level (grade)

x = factor which varies from 0.3 when V_{30} = 60 mph to 0.143 when V_{30} = 130 mph (Reference 3)

V_z = wind velocity (mph) at height (z) above grade

z = distance above grade in feet

Thus, at heights between 100 and 150 ft above grade, the height of the upper portion of the reactor building, the wind velocity is calculated to be 123.5 mph. Gust factors have also been determined by the methods given on pages 1124 through 1198 in ASCE Paper No. 3269 (Reference 3). For all Category I structures, the gust factor varies linearly from 1.1 at grade level to 1.0 at 400 ft. However, a gust factor of 1.1 was used for the full height of both the reactor/auxiliary building and the residual heat removal (RHR) complex except for the blow-away siding design during the design tornado, where a factor of 1.0 was used.

3.3.1.4 Determination of Applied Forces

The design wind velocity specified in Subsection 3.3.1.1 is translated into an equivalent static pressure according to the provisions outlined on pages 1150-1151 in ASCE Paper No. 3269 (Reference 3). The dynamic pressure is the product of one-half the air density and the square of the resultant design velocity, and represents the kinetic energy per unit volume of moving air. For standard air and velocity, V_z, in mph, pressure in pounds per square foot is given by

$$q = 0.002558\ V_z^2 \qquad (3.3\text{-}3)$$

The equivalent static pressure to be applied to the structure is given by

$$p = q \times C_D \qquad (3.3\text{-}4)$$

where

p = average pressure, pounds per square foot

C_D = average pressure coefficient

q = dynamic pressure, pounds per square foot

Positive and negative average pressure coefficients of 0.9 and 0.5, respectively, which include the appropriate shape and drag coefficients, are applied to the walls of rectangular flat-topped structures. An average pressure coefficient of 0.8 is used for roof suction. Table 3.3-1 lists the equivalent static pressure as a function of height above grade for rectangular flat-topped Category I structures.

3.3.2 Tornado Loadings

If tornadic winds traverse the site, the reactor is capable of being shut down and secured in a safe-shutdown mode. Some minor superstructure damage could be incurred by the reactor/auxiliary building. Damage could occur to other nonseismic structures suchas the turbine building, condensate storage tanks, and incoming power lines, without affecting the ability to shut down the reactor and maintain integrity of containment and essential heat removal systems during and following a tornado that might traverse the site. Simultaneous damage to all of these items is not expected. However, as a design objective, the reactor is capable of being safely shut down and maintained in a safe-shutdown condition with the loss of all such nonseismic structures. Components that directly affect the ultimate safe shutdown of the plant are located either under the protection of reinforced concrete or underground.

Where structural failure could affect the operation and functions of the primary containment and reactor primary system, and for structures affecting equipment necessary for safe shutdown of the reactor, tornado effects are considered in the design of these structures.

3.3.2.1 Applicable Design Parameters

For extreme environmental load conditions, the Category I structures housing the systems required for a safe shutdown of the plant in the event of a tornado are designed to withstand the effects of a tornado by providing either sufficiently strong structures or appropriate venting. With the exception of the 4160-V RHR cable vaults, manholes, and ductbanks, the design parameters of the Fermi 2 design-basis tornado are

a. A rotational wind velocity of 300 mph
b. A translational wind velocity of 60 mph
c. An external pressure drop of 3 psi at the rate of 1 psi/sec.

Although the Fermi 2 design was established before the issuance of Regulatory Guide 1.76, Design Basis Tornado for Nuclear Power Plants (April 1974), the above parameters compare well with this guide. The rotational and translational wind velocities given in the guide are slightly different (290 mph and 70 mph, respectively). However, the total maximum velocity is the same. Likewise, although the rate of pressure drop given in the guide is faster (2 psi/sec), the magnitude of the pressure drop is the same.

The tornado missile design of the 4160-V RHR cable vaults and the manholes and ductbanks between these cable vaults and the Reactor/Auxiliary building cable vaults is based on criteria established in Regulatory Guide 1.76, Revision 1 (March 2007) and tornado missile analysis methods specified in NUREG-0800, Standard Review Plan 3.5.3 Revision 3, dated March 2007.

The Design Basis Tornado wind characteristics in accordance with Regulatory Guide 1.76 Revision 1 (March 2007) are as follows:

a. A maximum wind velocity of 230 mph
b. A maximum rotational wind velocity of 184 mph
c. A translational wind velocity of 46 mph
d. An external pressure drop of 1.2 psi at the rate of 0.5 psi/sec

Tornado wind velocity and pressure drop corresponding to the tornado generated missiles is used to evaluate the adequacy of the 4160-V RHR cable vaults and the manholes and ductbanks between these cable vaults and the Reactor/Auxiliary building cable vaults.

3.3.2.2 Determination of Forces on Structures

All tornado wind pressure and differential pressure effects are considered static in application since the natural period of the building structures and their exposed elements are short compared with the rise in time of the applied design pressures.

The tornado wind rotational velocity varies linearly with radius (r) from zero at the center to a maximum at a distance R_c from the center and inversely with r as r increases beyond R_c. That is

$$v = \frac{c}{r} \text{ for } r > R_c \text{ (Reference 4)} \qquad (3.3\text{-}5)$$

where

V = velocity, fps

r = radial distance from center of tornado, ft

c = a constant for tornadoes empirically established at 10^5 ft^2/sec (Reference 4)

At the design rotation velocity of 300 mph (440 fps), r = R_c and is 227 ft, as determined from the above equation. The resulting rotational velocity is shown in Figure 3.3-2. The total velocity profile is obtained by algebraically adding 60 mph translational velocity to the rotational velocity profile. This is also shown in Figure 3.3-2. This results in a maximum velocity of 360 mph on the strong side of the tornado and a maximum velocity of 240 mph on the weak side. The rotational velocity distribution also varies according to the elevation above ground level reaching a maximum 300 mph at a point approximately 225 ft above ground (Reference 5), which is approximately 75 ft above the top of the reactor building. However, no reduction in rotational wind velocities is used, and therefore the analysis is conservative.

The maximum differential pressure of 3 psi occurs as a result of vortex action at the center of the tornado. Differential pressure as a function of cyclonic radius for the model (Reference 4) is given by the expressions:

$$p(r) = \rho V_c^2 \left[1.0 - 0.5\left({}^{r}/_{R_c}\right)^2\right] \text{ for } r < R_c \qquad (3.3\text{-}6)$$

$$p(r) = 0.5\,\rho V_c^2 \left({}^{R_c}/_{r}\right)^2 \text{ for } r \geq R_c \qquad (3.3\text{-}7)$$

where

p(r) = pressure drop, lb/ft^2

ρ = mass density of air = 0.002376 $lb\text{-}sec^2/ft^4$

V_c = maximum rotational velocity = 440 fps

The standard value of air density is assumed because, although the air density is expected to be reduced, its effect may be offset by the presence of dust. The pressure diagram resulting from the evaluation of the above equations is presented in Figure 3.3-3.

The tornado velocity is converted to an equivalent static pressure according to the procedures given in ASCE Paper No. 3269 (Reference 3), conservatively considering no variation with height and a gust factor of 1.0. This pressure is then combined with the barometric pressure.

When a flat object is placed in a tornado wind, the load on it is equal to the sum of the windward pressure and leeward pressure as the barometric pressure drop on both faces cancels out. However, when an unvented, enclosed object is placed in a tornado wind, the total windward pressure equals the leeward velocity pressure plus the barometric pressure drop. The total pressure diagrams for the vented and unvented cases are shown in Figure 3.3-4.

Most structures are unvented. However, the reactor/auxiliary building above the fifth floor is designed to vent as discussed in Subsection 3.3.2.3.2.

Category I structures have been designed to withstand the effects due to simultaneous action of tornado wind velocity pressures, atmospheric pressure drop, and a single tornado-generated missile.

The 4160-V RHR cable vaults, manholes, and ductbanks have been designed to simultaneous action of tornado wind velocity pressure, pressure drop, and a single tornado-generated missile in accordance with Regulatory Guide 1.76 Revision 1 (March 2007) and NUREG-0800, Standard Review Plan 3.5.3 Revision 3, dated March 2007.

Design tornado loads were found by making use of the following expression:

$$W_T = (p + C_p q)A + M_T \qquad (3.3\text{-}8)$$

where

W_T = design tornado load

p = atmospheric pressure drop

q = wind velocity pressure

C_p = pressure coefficient described in Subsection 3.3.1.4

A = exposed area under consideration

M_T = effects of single tornado-generated missile

Both overall (overturning, sliding) and local effects of tornado-generated loads W_T have been investigated. Structure under consideration was placed at various locations in the tornado wind field, and the governing combination of p and q was selected for each particular effect.

The effects of tornado missiles are local in nature. Accordingly, they have been taken into account in the design of structural elements and disregarded in case of overturning and sliding.

3.3.2.3 Ability of Category I Structures To Perform Despite Failure of Structures Not Designed for Tornado Loads

3.3.2.3.1 General

Superficial structural damage can be tolerated by the reactor/ auxiliary building and the RHR complex. Nonseismic structures such as the turbine building, condensate storage tanks, and incoming power distribution system can withstand some structural damage without affecting the safe-shutdown capabilities of Category I structures and equipment. As indicated in Table 3.3-2, systems required for a safe shutdown of the reactor are housed in well-protected structures.

3.3.2.3.2 Reactor/Auxiliary Building Above the Fifth Floor (Blow-Away Siding)

The panels and roof above the refueling floor are designed to release (blow away) during the design-basis tornado, as described in Section 3.8, while the remainder of the exposed frame is designed for the full tornado load. The design and analyses of these panels under tornado loadings have been presented to and accepted by the AEC by Reference 6. Further design requirements imposed on this portion of the reactor building are as follows:

a. For the design-basis tornado, and assuming that panels equivalent to 10 percent of the surface area of the panels are caught and do not release, the stress levels of the structural steel frame of this portion of the reactor building must not exceed 95 percent of the yield stress

b. With all siding in place, the reactor building will be capable of withstanding a 200-mph tornado wind at stress levels limited to 95 percent of the yield strength of the steel.

This additional load limitation provides a range of pressure within which the siding is designed to blow off.

For the reactor building above the refueling floor, the maximum load on the projected area of the exposed steel supporting frame with 10 percent of the siding is 464 lb/ft^2 during the design- basis tornado, while the maximum load on the structure for the 200-mph tornado with the siding all intact is -98 lb/ft^2 (suction) on the leeward side and 46 lb/ft^2 on the windward side. Surface pressure for the remainder of the reactor and auxiliary buildings and the RHR complex is included in the loading combinations considered in Section 3.8.

A postulated explosion of the 20,000-gallon liquid hydrogen tank at the HWC gas facility may also cause some damage to the roof and siding of the reactor building above the refueling floor. The hydrogen tank has been located sufficiently far from the reactor building to assure that blast forces from an explosion would be less than the pressure forces from a design basis tornado. Therefore, the tornado analysis bounds the effects of a hydrogen-tank explosion at the roof and siding above the refueling floor.

3.3.2.3.3 Fuel Pool Exposure

In the unlikely event of a tornado of sufficient severity to cause the panels above the refueling floor to release, the spent-fuel pool would be exposed. This concern was identified by the AEC as Post Construction Permit Open Item No. 9. The AEC had requested additional spent-fuel protection, but agreed later that no additional protection was required (Reference 7).

With the siding blown off during the design-basis tornado, the refueling floor would be exposed. However, based on the GE publication, "Tornado Protection for the Spent Fuel Storage Pool," APED-5696, Class-I (November 1968), there is no credible mechanism by which a significant amount of water could be sucked from the fuel pool by a tornado. The fuel stored in the spent-fuel storage pool would be protected by approximately 22 ft. 6 in. of water covering the tops of the fuel storage racks and by the racks themselves.

3.3.2.3.4 Crane and Crane Support Structures

The reactor building superstructure steel frame and anchor bolts are designed for the design-basis tornado described in Subsection 3.3.2.2 at a stress level of 95 percent of yield. Therefore, there would be no danger of failure of the columns supporting the crane bridge and trolley. Moreover, the crane and trolley are restrained from motion in the horizontal direction when not in use by "dead-man" safety pins.

The crane is provided with electrically operated locking bars effectively connecting the unloaded crane to the runway when not in use and capable of withstanding a design-basis tornado wind force of 410 lb/ft^2 due to a 360-mph resultant wind velocity. Restraints are provided on the crane bridge and trolley to prevent either from leaving their respective rails due to horizontal and vertical displacement in the event of a design-basis earthquake. For further details, see Subsection 3.7.3.18. Vent holes are provided in girders and other enclosed structures such as trolley frame, trucks, and electrical cabinets of such size to withstand an atmospheric pressure reduction of 1.0 psi/sec, maximum reduction of 3 psi, due to the design-basis pressure transient.

3.3.2.3.5 Other Venting

Because of the depressurization that can occur when the very low- pressure area within the funnel of a tornado engulfs a structure, structures housing equipment necessary for safe shutdown must either be designed for the depressurization, or be vented. In the Fermi 2 design, all such structures, with the exception of the steam tunnel, are designed for the depressurization. Venting of the steam tunnel is accomplished by blowout panels that are designed to release in the event of external depressurization.

3.3.2.3.6 Residual Heat Removal Complex

The RHR complex cooling towers are exposed to the flight of potential missiles. However, as discussed in Section 3.5, the probability of damage is negligible.

All systems contained in the RHR complex are divided into two separate and redundant groups, Division I and Division II, with a thick wall between the two divisions that serves as a missile barrier. This further reduces the probability of safety-related systems not being able to perform their functions. The RHR complex is described in Section 9.2.

3.3.2.3.7 Tornado Failure of Nonseismic Structures

Protection against the possibility of failure of Category I structures due to the tornado-induced failure of nonseismic structures is provided by the inherent structural integrity of the Category I structures to mitigate other postulated, equally severe events. Further, the site building arrangement (see Figure 1.2-5), as well as the history and probability of tornadoes likely to occur at the site, minimizes the probability of a tornado engulfing a nonseismic structure.

3.3.2.3.7.1 Probability of Occurrence

The probability of a design-basis tornado occurring at the 1000-acre Fermi site is 4.075×10^{-5}, or a recurrence interval of 24,500 years (Subsection 2.3.1.3.2). This probability is significantly further diminished by factoring in the horizontal surface area occupied by the Fermi 2 Category I structures - approximately 1 acre.

3.3.2.3.7.2 Category I - Nonseismic Structure Arrangement

Category I structures are located with respect to nonseismic structures in a manner that minimizes, if not eliminates, the probability of failure of a Category I structure due to the tornado-induced failure of the nonseismic structure. The impingement of a nonseismic structure upon a Category I structure, or the generation of missiles from a nonseismic structure, are the only unlikely events that could be postulated to occur.

Some temporary trailers and miscellaneous construction material may be stored near Category I structures to support plant outages.

There is a refuel outage building adjacent to the south wall of the reactor building and a small prefabricated metal building housing nitrogen inerting equipment immediately west of the reactor building. In addition, approximately 30 ft west of the RHR complex, there is a 345-kV switchyard. To the north is a reinforced-concrete cooling tower.

To the east is the turbine house-radwaste building, which consists of a reinforced-concrete structure and steel superstructure. The failure of other nonseismic structures further eastward of the turbine house-radwaste building would not affect the Category I structures, as missiles or impingement caused by their failure would affect only the reinforced-concrete turbine house. The turbine house can absorb energy resulting from either another nonseismic structure failure, or its own partial failure.

3.3.2.3.7.3 Turbine Building

The improbable direct strike of a tornado on the turbine building could result in a worst-case event where portions of the metal siding and support columns and girders deform and impinge against the thick, heavily reinforced concrete wall of the adjacent reactor/auxiliary building (see Figure 1.2-20). This impingement could result in superficial structural damage, but would not prevent the reactor from being brought into a safe-shutdown mode.

The collapse of the turbine building roof would not affect the operation of any safety-related equipment. There is no safety- related equipment in the turbine building that would be required to operate if the roof were to collapse.

A postulated explosion of the 20,000-gallon liquid hydrogen tank at the HWC gas facility may also cause some damage to the roof and siding of the turbine building above the operating floor. The hydrogen tank has been located sufficiently far from the turbine building to assure that blast forces from an explosion would be minimized, and that stop and control valve closure inputs to the reactor protection system would remain functional. However, even if trip function (direct scram) is postulated to fail, other diverse signals, such as reactor pressure and high neutron flux, will scram the reactor. Therefore the consequences of a turbine trip with a postulated failure of direct scram are bounded by the design basis earthquake event.

3.3.2.3.7.4 Category I Buildings

The Fermi 2 Category I buildings are designed for the postulated severe loading conditions in appropriate loading combinations (Section 3.8). Their construction generally consists of thick, heavily reinforced concrete walls. A spectrum of missiles was selected, approved by the NRC, and used as a design basis for these buildings. As discussed in 3.3.2.3.7.2, the arrangement of nonseismic structures with respect to Category I buildings minimizes the effect of a nonseismic structure failure on Category I buildings.

TORNADO WIND PRESSURE – VENTED AND UNVENTED

3.4 WATER LEVEL (FLOOD) DESIGN

3.4.1 Flood Elevations

From consideration of several types of hypothetical flooding, it was found that the maximum stillwater elevation that could occur at the site is 586.9 ft (New York Mean Tide, 1935), and results from the probable maximum meteorological event (PMME), with a storm path along the axis of Lake Erie (N 67.5° E). Flood design is discussed in Subsection 2.4.2 and the maximum elevation determination in Subsection 2.4.5.

All Category I components are protected from the adverse effects of the maximum flood elevation by their location within reinforced-concrete Category I structures, as described in this section and in Chapter 2.

As stated in Subsection 2.4.2, Fermi 2 Category I structures and components are designed against flooding up to a minimum elevation of 588 ft, or 1.1 ft above the maximum stillwater elevation.

3.4.2 Phenomena Considered in Design Load Calculations

Category I structures and components are designed for the static and hydrodynamic forces associated with wind-generated waves as specified in Subsection 2.4.5. The effects of a tsunami are not considered because the site is located in an area designated as having potentially minor seismic activity. Any seismic disturbance would be local and would result in only minor excitations in Lake Erie. Tsunami considerations are discussed in Subsection 2.4.6.

3.4.3 Flood Force Application

The pressure induced by the maximum stillwater elevation is considered to be hydrostatic. A lateral pressure distribution below the flood line on the walls of the Category I structures is determined. From this, the uplift pressure on the Category I structure basement slabs and flotation potential is then calculated. This pressure is included in the load combinations considered in the design of the slabs. Pressures induced by wave action are discussed in Subsection 2.4.5.

3.4.4 Flood Protection

Flood protection for Fermi 2 Category I structures and components includes waterproofing the structure, designing the structure to withstand the hydrostatic and hydrodynamic forces associated with flooding, maximum usage of watertight seals and penetrations below the maximum flood elevation, and locating the Category I components within the reinforced-concrete Category I structures.

3.4.4.1 Reactor Building Structure

The Category I reactor/auxiliary building, which houses safety-related systems and components, is designed against flooding to Elevation 588.0 ft, or 1.1 ft above the PMME stillwater flood elevation of 586.9 ft. All doors and penetrations through the outside walls below the design flood elevation are of watertight design.

As stated in Subsection 2.4.2.2.2, there are only a few essential penetrations in the exterior walls of the reactor/auxiliary building. All of these penetrations below Elevation 588.0 ft are watertight.

The presence of the turbine building prevents waves and wave runup above the sill elevations on the east wall of the reactor/ auxiliary building, thereby preventing flooding of the building. The south wall of the reactor/auxiliary building has two large openings and several waterproofed pipe-sleeved openings. The large openings are an air-locked rail car door and an air-locked personnel door. Both of these air-locked doors are completely waterproofed to preclude wave runup flooding.

In addition, all watertight doors have signs on both sides stating that the door is to be secured closed except for immediate use.

The several watertight sleeve openings, the walls of the building, and the watertight doors are designed to withstand the hydrostatic head of the maximum flood level. Maximum wave effects and forces are discussed in Subsection 2.4.5.4.

Leakage is not expected through the several watertight access openings and the waterproofed sleeved openings in the reactor/ auxiliary building.

The walls of the reactor/auxiliary building are waterproofed below the finished grade elevation of 583.0 ft.

Waterstops on all construction joints and water seal rings on all penetrations are provided on all openings below the maximum flood level. The waterstops are joined to form a continuous watertight seal. Joint preparation and joint sealants are in conformance with the recommendations and the guidelines of American Concrete Institute (ACI) standards. All work is inspected by qualified personnel to ensure that leakage is kept to a minimum.

All interior floor drain systems inside the reactor/auxiliary building are independent of the yard storm drainage system, and therefore no potential water backflow into the structure is anticipated during the design flood condition. Shore protection is not required to preclude flooding of this structure.

3.4.4.2 Residual Heat Removal Complex Structure

The residual heat removal (RHR) complex is watertight to Elevation 590.0 ft. There are no openings on the north, south, and west walls. All pipe and electrical penetrations on the east wall below Elevation 590.0 ft are waterproofed. However, if any amount of leakage should occur, it would go directly into an RHR Complex compartment. Then, it is pumped to the Circulating Water Reservoir.

The remaining openings to be considered would be the access doors on the east wall. These doors are normally closed and locked, and have their thresholds at Elevation 590.0 ft. They are of steel construction and are shielded behind reinforced-concrete missile walls. The insignificant amount of runup above the flooded elevation of 586.9 ft may find its way through the door threshold and door jambs, at Elevation 590.0 ft, and be diverted into the floor drain system in the building. The leakage through the gaps of the doors could never exceed the drain capacity of the Elevation 590.0-ft floor drain system. The structure is also designed to withstand the wave action associated with this flooding. (Refer to Subsection 2.4.2.2.3, Residual Heat Removal Complex Flood Criteria.)

The RHR complex is described in Subsection 9.2.5.

The RHR complex reservoir is floodproof. The reservoir overflow is a nonsiphon floodproof post. All active equipment that could be damaged by water (pump motors, switchgear, diesel generators) is located above the maximum water flood level.

Moreover, all interior floor drains are independent of the yard storm drain system. Thus, there is no potential for backflow flooding. Walls of the RHR complex below grade level are watertight.

3.4.4.3 Category I Yard Structures

The Category I piping and electrical ducts between the RHR complex and the reactor building are below the site flood elevation of 586.9 ft during the PMME. The RHR supply, RHR return, and emergency equipment service water pipelines to both divisions will continue to function during the flood.

There are two sets of Category I ductbanks between the RHR complex and the Reactor/Auxiliary building, with a Division I and Division II ductbank in each set. In each case, the buried cable ducts between the RHR complex and the Reactor/Auxiliary building provide adequate cable separation to maintain independence of redundant circuits.

The first set of ductbanks was installed during plant construction. The physical separation of the two redundant, below-grade circuits is 30 ft at the point the cable ducts leave the southeast corner of the reactor building. The ducts make a sweeping bend, with a minimum separation of 20 ft between them. After the bend, the ducts parallel the reactor building in a westerly direction, with 24 ft of separation. This separation is constant until the ducts pass under the rail car air lock, where the separation widens until the ducts enter (still below grade) the RHR complex.

Each circuit is separately housed in a cast-in-place, rectangular reinforced-concrete duct. The duct is covered by successive layers of compacted-rock fill placed up to the finished site nominal grade of 583 ft. The duct runs vary in elevation from 573 ft minimum to 580 ft maximum. Since the maximum ground-water elevation is 576 ft, the cables are not specifically designed for continuous underwater service. For low voltage power, control and instrumentation cables, there is no long term mechanism for water related insulation degradation due to lack of voltage stressor or a credible common mode failure mechanism. Therefore, low voltage cables perform their design functions while their external surface remains continuously wetted due to surrounding water. 4160-V essential power circuits are not routed within these ductbanks.

The second set of 4160-V RHR cable vaults, ductbanks and associated manholes is installed above the maximum ground water elevation of 576.0 ft with ducts sloped to the manholes, such that circuits contained are not subject to continuous wetting. These are also cast-in-place, rectangular reinforced concrete ductbanks, but are located with the ductbank top approximately six inches below the surface and manhole covers at grade level. 4160-V essential power circuits are routed within these ductbanks. Although the manholes and cable vaults may be subject to flooding during the duration of the PMME, the 4160-V essential bus tie cables are qualified for wet conditions in excess of six months, which is greater than this duration.

The minimum elevation for cable termination in either the RHR complex or the reactor building is 588.7 ft, which is above the site probable stillwater elevation of 586.9 ft.

3.4.4.4 Internal Flood Protection

3.4.4.4.1 General

Category I and nonseismic structures are provided with equipment and floor drainage systems designed to collect and remove all waste liquids from their points of origin to a suitable disposal area in a controlled and safe manner. All collected liquid waste is routed to sumps in each of the respective buildings, where it is allowed to accumulate for periodic discharge to the radwaste building for treatment. Abnormal sump water levels (high-high or low-low) are annunciated in the control room. The locations of the sumps and sump pumps, the capacity of each sump and sump pump, and the design bases for equipment and floor drainage systems of each building are described in Subsection 9.3.3.

To prevent backflow flooding through the equipment and floor drainage systems, the following considerations were included in the system design:

a. Independence of building systems to negate the possibility of abnormal occurrences in one building from affecting normal operation in other buildings

b. Check valves and manual isolation valves in each sump pump discharge line to prevent backflow to the sump.

c. Redundant check valves and a manual isolation valve located in both the equipment drain and floor drain 6-inch transfer lines near the secondary containment boundary to prevent backflow into secondary containment.

3.4.4.4.2 Design Analyses

The potential for backflow flooding through the equipment and floor drainage systems due to the PMME flood is evaluated as follows:

a. The PMME is postulated to have occurred and the associated flooding in the turbine building will be consistent with the site water-level accumulation during the incident

b. Flood water would enter the equipment or floor drainage piping system through the collector tanks and their overflow lines in the radwaste building. These overflow lines are provided for routing the collection tank overflow to the radwaste building sumps. The collection tanks are in the basement (approximate Elevation 557 ft) of the radwaste building. As the floodwaters rise, the collection tanks would be filled through the overflow line and the system piping would be backfilled to the check valves in the 6-inch transfer lines.

c. Redundant check valves and a manual isolation valve in both the floor and equipment drain transfer lines are located near the secondary containment boundary just before the pipe exits into the turbine building. The design configuration allows for periodic leak testing of the check valves and this combined with redundancy of the check valves, and the presence of a manual isolation valve ensures that no single active failure will result in backflow flooding into the reactor building such that the safe shutdown capability of the reactor through the emergency core cooling system (ECCS) would be affected.

3.4.4.5 Shore Barrier

Neither the reactor/auxiliary building nor the RHR complex depends on a shore barrier to preclude flooding of the structures.

Although the Category I structures do not require protection against flooding from wave runup, a shore barrier is included in the Fermi 2 plant design to protect other portions of the plant from wave effects. The design of the shore barrier was approved by the AEC by Reference 1. The shore barrier was designed by Dames & Moore, specialists in applied earth sciences.

The shore barrier is a rubble mound revetment with a cover of armor stone, which fronts the Fermi 2 unit as shown in Figure 2.4-22. It has a toe elevation of 572 ft, a crest elevation of 583 ft, and a lakeward-side slope of 2:1 (horizontal to vertical). The design allows for the possibility of a 6 percent to 8 percent displacement of stone during the PMME. The design of the barrier is further discussed in Subsection 2.4.5 and shown in cross section in Figure 2.4-22. The barrier preserves the integrity of the plant site fill placed to Elevation 583 ft as well as protecting the main plant portion of the site against wave forces. The purpose and design of the barrier are also discussed in Subsection 2.4.5.7.

The surveillance requirements and limiting conditions for operation of the shore barrier are contained in the Technical Requirements Manual.

3.4.4.6 Condensate Storage Tanks

The condensate storage tanks are not seismic structures. However, a seismic analysis was performed for the condensate storage tanks using the Fermi 2 design-basis earthquake with the tank in the fully loaded condition. The maximum shell stresses were found to be well within the allowable limits. Tank rupture is not anticipated. For added conservatism, a containing barrier has been built around the tanks, and modifications to the site grade have been made in the immediate vicinity of the tanks. This will prevent any of the condensate liquid from reaching the distant yard drainage system should leakage occur. The Category I structures are located approximately 600 ft west of the condensate storage tanks.

3.4 WATER LEVEL (FLOOD) DESIGN

3.5 MISSILE PROTECTION

Protection against the hypothetical effects of missiles is provided in accordance with the following damage limit criteria:

a. The integrity of the containment system is maintained

b. The capability for shutdown of the reactor and maintenance of core cooling capability is maintained

c. A missile accident that is not a LOCA does not initiate a LOCA.

Where possible, missile protection is achieved through basic plant component arrangement such that, if a missile-generating failure should occur, the direction of the flight of the missile would be away from Category I structures or other critical system components. Examples of such arrangements are shown in Figure 3.5-1, Sheets 1 through 6, which show the general arrangement of piping, pumps, motor, valves, and other equipment in the drywell indicating component missile protection by separation. Where it is impossible to provide protection through selective plant layout and where the structures available do not provide sufficient missile protection, barriers are provided to prevent potential missiles from damaging critical systems and structures.

An analysis of potential missiles and the missile protection provided follows. Although it is not given in the order specified in Regulatory Guide 1.70, the information requested in the guide is presented. The reason for the change in order is to present a more comprehensive discussion of the missile protection included in the Fermi 2 design.

3.5.1 Missile Selection (Sources)

3.5.1.1 Missiles From Pressurized Equipment

3.5.1.1.1 Missiles Considered

Potential missiles from pressurized equipment that were investigated include the following:

a. Valve bonnets (large and small)

b. Valve stems

c. Thermowells

d. Vessel head bolts

e. Pieces of pipe

f. High-pressure gas cylinders.

3.5.1.1.2 Design Evaluation

Using conservative assumptions, it has been determined that the potential missiles from items a. through e. above, originating from fluid lines, cannot achieve sufficient energy to penetrate the drywell, critical system components, or missile shields to the extent that safe reactor shutdown would be impaired. An added conservatism exists because of the separation criteria and barriers described in Subsections 3.5.3 and 3.5.4. The probability of incapacitating more than one of the redundant reactor protection system (RPS) safe-shutdown and engineered safety feature (ESF) system components by a single missile is negligible. The driving force for these potential missiles is assumed to come from the kinetic energy of the water or steam.

In the event of a break in a fluid-carrying component, the velocity of the exiting fluid is determined. The drag force of the fluid that propels a missile is proportional to the product of the fluid mass density and velocity squared. By applying this drag force to each potential missile, the missile attaining the most kinetic energy is determined. Damage resulting from impact of this missile is then analyzed. Small missiles are assumed to achieve maximum fluid velocity instantly, which is conservative because a missile requires a finite time to accelerate to this velocity after being dislodged. In addition, missiles in a horizontal trajectory tend to fall out of the fluid jet. Therefore, the driving force acts for a shorter time and the missile probably achieves a velocity lower than its maximum.

High-pressure gas cylinders on the Fermi 2 site that are capable of generating potentially high-energy missiles are as follows:

a. Hydrogen gas storage cylinders

b. Service gas storage cylinders (welding gases, nitrogen, and spare breathing air)

c. Emergency breathing air cylinders

d. Oxygen and hydrogen reagent cylinders

e. Hydrogen and oxygen storage vessels at the HWC Gas Supply Facility

The hydrogen and service gas storage cylinders are located more than 300 ft from the reactor building. Any potential missiles must first pass through the first floor of the turbine building and through several concrete walls (with a combined thickness of more than 5 ft) before reaching the reactor building wall. There is insufficient energy stored in these cylinders for any potential missile to penetrate these walls.

Emergency breathing air cylinders are stored in seismically qualified storage racks located along the north wall of the reactor building ventilation room. The concrete walls of this room are sufficient to prevent any potential missiles from reaching critical locations outside of this room. Equipment inside this room can be damaged by potential missiles, but this will not prevent a safe reactor shutdown. A design-basis earthquake (DBE) will not initiate emergency breathing air cylinder damage because the cylinders are secured in seismically qualified storage racks.

The primary containment hydrogen monitors require supplies of hydrogen and oxygen to act as reagent gases. These cylinders are located adjacent to each monitor, thereby minimizing the tubing run to each instrument. The cylinders, regulators, piping, and racks are seismically designed and installed. The racks are also designed to restrain the cylinders to prevent them from becoming missiles if punctured.

Using the barrier and procedures of Subsections 3.5.3 and 3.5.4, respectively, results of the investigation showed that additional missile barriers for potential missiles from pressurized equipment are not required. With the assumption of maximum missile velocity and minimum missile energy required for perforation, the results are conservative.

The HWC gas supply facility is located approximately 1100 feet northwest of the nearest safety-related structure (the RHR Complex). The hydrogen and oxygen storage tanks and the gaseous hydrogen tube bank are designed to remain in position during the design basis earthquake. Since the site for the HWC Gas Storage Facility was chosen to provide the required separation from safety-related structures, a release from this location would not affect plant safety. Potential blast effects from tank ruptures are enveloped by the existing analyses of the design basis tornado and design basis earthquake.

3.5.1.2 Missiles From Rotating Equipment

3.5.1.2.1 Missiles Considered

Potential missiles from rotating equipment, which could require a missile barrier, include

a. High-pressure turbine rotor segment

b. Low-pressure turbine rotor segment

c. Recirculation pump or motor segment

d. Emergency diesel generator (EDG) segment.

All probable paths of flight of these potential missiles have been investigated.

3.5.1.2.2 Design Evaluation

As stated in Subsection 10.2.3, after the low pressure (LP) turbine rotor replacement during RF05, there is no design basis turbine missile at Fermi 2. The HP turbine rotor was replaced in RF07. The new HP turbine rotor, which was reviewed for overspeed capability, was found to be higher in overspeed than the maximum theoretical overspeed of the unit (LP rotors and generator). Moreover, the seventh stage blades of the HP turbine rotor are smaller in length and lighter in weight that the eighth stage blades of the LP turbine rotors. Based on this, it is concluded that the HP turbine rotor missile analysis is bounded by the LP turbine missile analysis. The HP turbine rotor and generator rotor missiles cannot completely breach their respective outer casings. The new HP and LP turbine rotors are of monoblock construction. The monoblock rotors have higher speed capability than the maximum attainable speed of the turbine generator units. Per General Electric, the supplier of the new rotors, the probability of missiles being generated is well below 10 to the -8 power.

The most substantial piece of nuclear steam supply system (NSSS) rotating equipment is the reactor recirculation system (RRS) pump and motor. This potential missile source is addressed in detail in References 3 and 4.

It is concluded in Reference 3 that destructive pump overspeed can result in certain types of missiles. A careful examination of shaft and coupling failures shows that the fragments will not result in damage to the containment or to vital equipment.

a. Low-Energy Missiles (Kinetic Energy Less Than 1000 ft-lb)

Low-energy-level missiles may be created at motor speeds of 300 percent of rated as a result of failure of the end structure of the rotor. The structure consists of the retaining ring, the end ring, and the fans. Missiles potentially generated in this manner will strike the overhanging ends of the stator coils, the stator coil bracing, support structures, and two walls of 1/2-in.-thick steel plate. Because of the ability of these structures to absorb energy, it is concluded that missiles would not escape this structure. It is at this point that frictional forces would tend to bring the overspeed sequence to a stop

b. Medium-Energy Missiles (Kinetic Energy Less Than 20,000 ft-lb)

   In the postulated event that the body of the rotor were to burst, medium-energy missiles could be created. The likelihood that these missiles would escape the motor is considered less than the likelihood of escape for the low-energy missiles described above, because of the additional amount of material constraining missile escape, such as the stator coil, field coils, and stator frame directly adjacent to the rotor

c. The Motor As a Potential Missile

   Since bolting is capable of carrying greater torque loads than the pump shaft, pump bolt failure is precluded. Since pump shaft failure decouples the rotor from the overspeed driving blowdown force, only those cases with peak torques less than those required for pump shaft failure (five times rated) will have the capability of driving the motor to overspeed. When missile-generation probabilities are considered along with a discussion of the actual load-bearing capabilities of the system, it is evident that these considerations support the conclusion that it is unrealistic that the motor would become a missile.

It is concluded in Reference 4 that destructive overspeed of the pump and motor could occur as a result of a full double-ended pipe break LOCA in the recirculation pump suction line. In the event of motor failure, the motor stator and frame structure would prevent the release of any missiles as indicated above. In the event of pump destructive overspeed, impeller missiles could be produced. However, they will not penetrate the pump case. They could be ejected from the open end of the broken pipe. However, pipe restraints have been installed to prevent potential missile points in the pipe from developing. (See Subsection 5.5.1.4.)

Potential missiles from an EDG would be small auxiliary items knocked loose from the engine exterior by blows from within. Analysis has shown that the maximum velocity of these missiles would be 40 fps, with a maximum mass of 5 lb each. These missiles are of lower energy than potential tornado-generated missiles. As the external walls of the EDG rooms are constructed to withstand the tornado-generated missiles, missiles ejected from an EDG will be contained within that EDG room and therefore cannot incapacitate another EDG in the other division.

3.5.1.3 Tornado-Generated Missiles

3.5.1.3.1 General

Tornado forces and the design-basis tornado are discussed in Section 3.3. Objects lying in the path of tornadoes may be picked up by the tornado due to aerodynamic lift force or due to the rapid pressure reduction that may have injected the object into the tornado wind field. The objects that are potential missiles vary in size, shape, and number. The design-basis missiles selected for consideration in the Fermi 2 design are a 4-in. x 12-in. x 12-ft plank with a density of 40 lb/ft^3, and a 4000-lb passenger car traveling at 50 mph at a maximum of 25 ft above grade elevation. The design-basis missiles are given in Subsection 12.2.1.7.1 of the PSAR.

For the Category I 4160-V electrical ductbanks between the RHR cable vaults and the Reactor/Auxiliary building cable vaults, the top of the ductbanks is located approximately six inches below grade, the top of the manholes is located at grade level, and RHR cable vaults are located above grade. The design for this ductbank system is based on Regulatory Guide 1.76 Revision 1 (March 2007) (Reference 17) and, as such, the design is evaluated for the design-basis tornado missiles described in Regulatory Guide 1.76 Revision 1.

3.5.1.3.2 Additional Analyses

The missile barriers listed in Subsection 3.5.3 provide protection against tornado generated missiles; however, three areas received additional analysis to ensure resistance to tornado generated missiles. They are the spent fuel pool, the fan blades of the cooling towers in the Residual Heat Removal (RHR) complex, and the miscellaneous penetrations and openings in the exterior walls of the Reactor/Auxiliary Building and RHR Complex.

3.5.1.3.2.1 Spent Fuel Pool - Reactor Building

As the siding above the refueling floor is designed to release in the event of a design-basis tornado, potential damage to fuel in the spent fuel pool from tornado-generated missiles is of concern. The AEC noted this concern in its Safety Evaluation Report on the Construction Permit (Reference 2). The concern was identified as Post Construction Permit Open Item No. 9. This concern has also been the subject of analyses submitted to the AEC by GE (Reference 5). The Edison position on this open item was submitted to the AEC in August 1973 (Reference 6). The Edison position was based on the GE report (Reference 5) and a study of the probability of a tornado striking the site and showed that the probability of damage to fuel in the spent fuel pool by a tornado-borne missile is extremely small (7×10^{-10} per year) and that no additional protection is required. The AEC waived the requirement to provide tornado protection of the spent fuel pool in June 1974 (Reference 7) based on its own independent assessment. The AEC cited the low probability of a tornado, the lower likelihood that objects could be lifted to the elevation of the fuel pool and become missiles, and the expectation that where spent fuel damage were to occur, the associated offsite exposure radiological consequences would likely be within 10CFR100 limits.

3.5.1.3.2.2 Residual Heat Removal Complex Mechanical Draft Cooling Towers

A study was performed to determine the probability that both cooling tower divisions can be rendered out-of-service by tornado- generated missiles entering the fan discharge stack (Reference 8). The result of this study, as determined below, is that this probability is very small and is conservatively estimated between 10^{-9} and 10^{-10} per year. The RHR cooling towers and their missile protection features are described in Subsection 9.2.5.

In the cooling tower study, several potential design-basis tornado missiles are considered. These represent the complete range of all possible missiles that may be potential threats to the safety of the cooling towers:

a. A 4-in. x 1-ft x 12-ft wood plank

b. A 13.5-in.-diameter x 35-ft-long utility pole

c. A 1-in.-diameter x 3-ft-long steel rod

d. A 6-in.-diameter x 15-ft-long schedule 40 steel pipe

e. A 12-in.-diameter x 15-ft-long schedule 40 steel pipe.

Other missiles cited in the literature, such as a 2-in. x 4-in. x 1-ft wood piece, a 9-in. brick, a 6-in. x 12-in. x 2-in.-thick concrete slab, a 1-ft block concrete, and a "standard" automobile are not able to reach the level of the cooling towers if they are injected at ground level or at elevations of 200 ft or less (Reference 9).

Each design-basis missile was then analyzed for its ability to impact the cooling tower fan blades.

Using the three-dimensional wind flow field proposed by Bates and Swanson (Reference 10), the vertical impact velocities of the design-basis missiles at different roof elevations have been calculated assuming the objects are injected into the tornado wind field at different elevations. The results are shown in Table 3.5-1.

None of the missiles except the wood plank picked up at ground level or injected at 50-ft or 100-ft elevations, is able to reach the level of the cooling tower. The steel rod injected at 50 ft and other objects injected into the tornado wind field at higher elevations (250 ft) may be hurled into the cooling towers, but only a few missiles could be of this type.

Even if a missile lands in the cooling tower, it will not damage the cooling tower fan blades. The Marley Company, the manufacturer of the Fermi 2 RHR complex mechanical draft cooling towers, has calculated that the fan blades would safely withstand the impact from an object weighing 17 lb falling freely from an elevation of 250 ft. This is equivalent to a kinetic energy of about 8.5×10^4 ft-lb. Therefore, the fan blades are able to withstand the impact from smaller missiles; e.g., design-basis missile c. listed above (1-in.-diameter x 3-ft-long steel rod).

The number of missiles assumed to impact a cooling tower is then determined. The number of missiles that are injected into the tornado field depends on factors such as the number of "loose" objects lying in an area of a 3000-ft radius circle around the RHR complex, which contains the cooling towers. Therefore, the number of missiles injected into the tornado funnel cannot be decided with any degree of certainty. It is assumed that of all the potentially damaging objects available, two of them will be picked up by the design-basis tornado at just the right time and location to become a missile.

The cooling tower system is designed such that it can function even if one tower division is damaged and rendered out of operation. Therefore, for the cooling tower system to be out of service, both tower divisions must be damaged simultaneously by tornado missiles. For this to happen, the following sequence of events must occur:

a. A tornado strikes a point in the plant site. Based on the meteorological data and on Thom's model, the probability of this event is calculated as 7×10^{-4} per year

b. An object which is accelerated horizontally does not bounce and is ejected into the tornado at a 45° angle. This probability is conservatively estimated at 10^{-1}

c. The object maintains the orientation inside the tornado and exposes its maximum cross-sectional area to the full wind force. Since objects will tend to tumble, the probability of this event is conservatively estimated at 10^{-1}

d. The object is thrown into a cooling tower division. Objects of the type being considered here could land anywhere within 100 ft of the tornado funnel. This is a circular area of 500 ft diameter. The area of the cooling tower fan discharges in the RHR complex is about 850 ft^2. Therefore, the probability of a missile landing in a cooling tower division is approximately 4.3×10^{-3}. This is multiplied by two because it was assumed earlier that the two objects would be injected into the tornado wind field

e. The missiles land simultaneously in both tower divisions. The probability of this joint occurrence is calculated as the product of the probability of one missile landing in one tower division and the probability of the second missile landing in the other tower division simultaneously. Using the concept of statistical independence of these events, the probability of the joint event is conservatively estimated to be between 10^{-9} and 10^{-10} per year.

The draft ANSI standard on Plant Design Against Missiles (Reference 11) recommends that no protective measures be required if the combined probability of missile ejection and subsequent unacceptable damage is less than 10^{-7} per year. As the probability of tornado damage to the cooling tower unit calculated above is considerably lower than the acceptable limit, and because certain components and portions of the tower structure are hardened against tornado missiles and the fan blades can be replaced after a tornado (as described in subsection 9.2.5.2.2), it is concluded that no missile protective covers are required for the cooling towers. It may be noted that the probability evaluated herein is very conservative because most tornadoes have velocities lower than 300 mph. Some missiles, even though hurled into the towers, may lose part of their kinetic energy if they strike the walls. Such missiles are not effective in damaging the fan blades.

The 8-lb steel-rod missile could damage the fan blades if the velocity were high enough (i.e., slightly higher than listed in Table 3.5-1). The latest probability study on damage to the towers indicated a probability of 5×10^{-18} per year for all four cooling tower fans to be damaged by 20 steel-rod (rebar) missiles.

3.5.1.3.2.3 Exterior Walls/Roofs - Reactor/Auxiliary Building/RHR Complex

The exterior walls/roofs of the Reactor, Auxiliary, and Residual Heat Removal Complex buildings have been designed to resist the impact of tornado-generated missiles such that the safety related systems and components required for safe shutdown as identified in Tables 3.3-2 and 3.5-2 are generally protected. A limited number of these Seismic Category I systems and components located outside of (or otherwise not protected by these) Seismic Category I structures are evaluated based on a probabilistic missile damage analysis (Reference 19). The specific targets for which no tornado missile protection was required based on the risk analysis are listed in Table 3.5-3. The specific acceptance criterion for tornado damage for the unprotected systems and components required for safe-shutdown following a tornado event is that the cumulative sum of the mean damage probabilities for these systems and components be less than 10^{-6} per year as established in References 27 and 28. The aggregate mean damage probability corresponding to the scope of equipment identified in Table 3.5-3 is less than 10^{-6} per yr, which satisfies the regulatory acceptance criterion.

The manner in which these targets were identified and selected for evaluation is described under the "Scope" section below. The use of TORMIS as an appropriate tool for evaluating tornado missile risk was generically accepted by the NRC in Reference 23 subject to site-specific approval of the first application. The "Analysis" section below describes the manner and degree to which the Fermi 2 analysis meets the constraints of the original NRC SER (Reference 23) or was otherwise found to be acceptable in the site-specific SER approving its use (Reference 25).

3.5.1.3.2.3.1 Scope

The exterior walls/roofs of the Reactor, Auxiliary, and Residual Heat Removal Complex buildings have been designed to resist the impact of tornado-generated missiles such that the safety related systems and components required for safe shutdown identified in Tables 3.3-2 and 3.5-2 are generally protected. A limited number of these Seismic Category I systems and components located outside of (or otherwise not protected by these) Seismic Category I structures are evaluated as not requiring unique tornado missile protection by burial or barriers on the basis of a probabilistic missile damage analysis.

Table 3.5-3 identifies the specific features evaluated in the probabilistic tornado missile analysis. The specific targets included in this table represent wall penetrations and doors in the exterior surfaces of these structures. Generally, specific safety-related targets are not associated with any particular penetration; hence, the tornado missile hazard associated with these penetrations and openings is limited to and characterized by the probability of missile penetration of the target itself. However, specific safety-related targets can be associated with missiles penetrating the reactor building railroad air lock doors, the first floor auxiliary building south wall entrance, and the EDG removable wall panels.

Unprotected safety-related equipment not identified in UFSAR Table 3.3-2 as being required for safe reactor shutdown following a tornado was not included as targets. Examples include Control Room Emergency Filtration system south emergency makeup intake, the south portion of the Auxiliary Building rooftop and the Standby Gas Treatment equipment located on the refuel floor. In addition, the RHR Mechanical Draft Cooling Towers which are specifically licensed for post-tornado repair and restoration (See UFSAR Section 3.5.1.3.2.2) and the Spent Fuel Pool which was evaluated on the basis of an alternative risk analysis (See Section 3.5.1.3.2.1) were both excluded from the scope of analysis.

Other features that were excluded for this risk analysis are the buried underground cable vaults between the RHR complex and the auxiliary building, the EDG fuel oil tank vents and the EDG exhaust stacks, which are located on the roof of the RHR complex. Both of these rooftop features are provided with tornado missile shield protection specifically designed to prevent vertically travelling missiles from entering the RHR complex and damaging the EDG fuel oil tanks and diesel engines.

3.5.1.3.2.3.2 Analysis

The mean cumulative damage probability for the targets identified in Table 3.5-3 was evaluated using TORMIS, a Monte Carlo based program for simulating tornados that was developed from the NRC approved EPRI version of this program (References 20, 21, 22). Major inputs to the analysis include:

a. the regional probabilities of the occurrence of tornados
b. the location and size of eligible targets
c. location and number of potential missile sources

Given these inputs, TORMIS computes the hit and damage probabilities associated with each target. These probabilities are post-processed to generate the aggregate risk associated with all targets. The term “target damage” is used in a general sense to mean any damage (or “loss of function”) criteria caused by a tornado missile hitting the target. Target damage is not necessarily the same as target hit, but hit can equal damage for fragile equipment. The “damage” probabilities included in this analysis consisted of using the built-in TORMIS penetration, spall, and perforation equations for selected steel and concrete targets. In addition, the missile size, impact orientation, and velocity vector orientation were used to compute the probabilities of missiles entering “pipe-penetration” type openings. The TORMIS feature for overall structural response damage modeling capability was not used for this analysis.

In Reference 23, the NRC approved use of the (EPRI) TORMIS methodology subject to the following constraints:

1. Data on tornado characteristics should be employed for both broad regions and small areas around the site. The most conservative values should be used in the risk analysis or justification provided for those values selected.
2. The EPRI study proposes a modified tornado classification, Modified F (F')-scale for which the velocity ranges are lower by as much as 25% than the velocity ranges originally proposed in the Fujita (F)-scale. Insufficient documentation was provided in the studies in support of the reduced F'-scale. The F-scale tornado classification should therefore be used in order to obtain conservative results.
3. Reductions in tornado wind speed near the ground due to surface friction effects are not sufficiently documented in the EPRI study. Such reductions were not consistently accounted for when estimating tornado wind speeds at 33 feet above grade on the basis of observed damage at lower elevations. Therefore, users should calculate the effect of assuming velocity profiles with ratios Vo (speed at ground level) ÷ V33 (speed at 33 feet elevation) higher than that in the EPRI study. Discussion of sensitivity of the results to changes in the modeling of the tornado wind speed profile near the ground should be provided.
4. The assumptions concerning the locations and numbers of potential missiles presented at a specific site are not well established in the EPRI studies. However, The EPRI methodology allows site specific information on tornado missile availability to be incorporated in the risk calculation. Therefore, users should provide sufficient

information to justify the assumed missile density based on site specific missile sources and dominant tornado paths of travel.

5. Once the EPRI methodology has been chosen, justification should be provided for any deviations from the calculation approach.

Also, as generically approved in Reference 23 (and clarified through Reference 26), the TORMIS methodology is not approved for proposing:

a. elimination of existing tornado barriers

b. technical specification (TS) changes, or

c. plant modifications

The description of the Fermi 2 site-specific TORMIS analysis was reviewed against the criteria established in References 23 and 26 and was approved in Reference 25 based on the following characteristics:

1. Definition of the Fermi 2 TORMIS Tornado Sub-Region

A site-specific analysis was performed to generate a tornado hazard curve data set for the TORMIS analysis. The tornado data retained in the National Climatic Data Center Storm Events Data Base (NCDC, 2006) files for the years 1950-2005 were used to analyze both broad and small regions around Fermi 2 in order to identify a suitable representative sub-region for the site. Tornado occurrences were mapped for the large region, a 15º longitude x 15º latitude area centered on the Fermi 2 site, and statistical tests were performed using 1º x 1º and 3º x 3º blocks to identify a suitably homogeneous sub-region. The historical records of tornado occurrences within the sub-region tornado were used to establish the tornado occurrence rate, (Enhanced-Fujita) EF-scale intensities, path length, width, and direction variables to be specified as input for use in the TORMIS analysis.

The statistical analysis of the sub-region data established a mean occurrence rate of 3.1E-4 per year over the 56-year period. In accordance with the TORMIS methodology, backwards averaging was used to estimate a detrended occurrence rate to correct for changes in the annual reporting trends. The adjusted mean occurrence rate was determined to be 4.002E-4/year based on the 30-year backwards average.

2. Tornado Windspeed Intensity

The analysis utilizes the original Enhanced Fujita (EF) scale windspeeds as per Reference 24. Though the 1983 NRC SER called for the use of the F-scale of tornado intensity for assigning tornado windspeeds to each intensity category (F1-F5), the EF-scale was subsequently adopted in the positions of NRC Reg. Guide 1.76 Revision 1 that are based on Reference 24.

3. Characterization of Tornado Windspeed as a Function of Height Above Ground Elevation

The Fermi 2 TORMIS simulations were performed with the TORMIS rotational velocity Profile 3, which has increased near ground windspeeds over Profile 5; the profile used in the 1981 EPRI TORMIS reports. Hence, the Fermi 2 runs were made with higher near ground windspeeds than in the EPRI study. A sensitivity study was conducted by running the original EPRI profiles and comparing the results. The most conservative profile with highest near ground windspeeds was conservatively used.

4. Missile Characterization and Site-Structure Models

Walkdowns of the Fermi 2 site were performed to characterize the missile sources and plant configuration. This information was developed into the plant modeling inputs for the TORMIS analysis that describe the facility by specifying the geometry, location, and material properties of the structures/components and the location of potential missile sources. Missile sources (buildings, houses, storage areas, vehicles, etc.) were catalogued and modeled to a distance of approximately 2,500 feet. This is done by specifying missile origin zones around the facility and a statistical description of missile types, based on the facility survey. The site surveys were conducted just prior to refueling outages to maximize the estimated population of available missiles and missiles sources. The Fermi 2 site missiles include the 20 standard TORMIS missiles in Reference 21, including structural sections, pipes, wood members, other construction materials, and an automobile category. In addition to the 20 standard TORMIS missile types, three Fermi 2 specific missiles were created for the analysis, one to represent scaffold clamps of which there were a large number present during the site walkdown, one to represent the sections of metal siding that enclose the upper portions of the Reactor and Turbine Buildings, and the third to represent the large number of concrete block also identified during the site walkdowns. The TORMIS analysis used over 200,000 missiles in the simulations of EF5 tornadoes striking Fermi 2.

5. Deviations from the Original EPRI Methodology

The Fermi 2 analysis is performed using an update of TORMIS developed from the original EPRI NP-2005 source code. With some exceptions, this version of TORMIS implements the original NRC SER approved methodology. Revisions of the original NRC-approved version of the code generally implement changes necessary to enable continued use of the program on modern computing platforms and to enable analysis of larger problems. Specifically, the original main frame based random number generator has been replaced with a new machine independent algorithm and the code was re-dimensioned to allow larger numbers of missiles and surfaces.

The updated TORMIS program implements an algorithm for evaluating the risk of damage to piping penetrations credited in the Fermi 2 analysis that was not present in the original NRC approved methodology. The method consists of identifying the minimum required missile size, angle of orientation and angle of incidence at impact necessary for a missile to be capable of passing through a pipe penetration target. Missiles that are too large, not oriented correctly, or that impinge obliquely on a target are screened out based on these criteria. This method eliminates from the calculated cumulative risk those impacts which would not realistically have resulted in missile penetration of a pipe penetration target.

3.5.1.3.3 Conclusion

As a result of these studies, the tornado-generated missiles to be considered in barrier design are the wood plank and the automobile, previously described.

3.5.1.4 Site-Related Missiles

3.5.1.4.1 Airplanes

Airports in the vicinity of the Fermi 2 site are listed in Table 2.2-2 and shown in Figure 2.2-1. Table 2.2-2 also lists the proximity to the site, number of and type of aircraft, and other physical and operations data. As discussed in Section 2.2, the nearest airport (2 miles away) cannot accommodate aircraft large enough to be a hazard to Fermi 2 and the nearest major airport is too far away (19 miles north-northwest of the site) to be considered a potential hazard with regard to large-aircraft takeoff and landing. In addition, there are no nearby military airports that could be expected to accommodate aircraft with bomb or explosive loads.

3.5.1.4.2 Military Activities

There are no military facilities within 10 miles of the plant. There are two restricted areas in Lake Erie, 20 and 27 miles from the plant, which are used as impact areas for small arms, ground artillery, and anti-aircraft artillery from Camp Perry and from the test-firing range at Erie Industrial Park. However, restriction to weapon horizontal-firing range and direction, as well as the nature of the projectiles, preclude a threat to the plant.

3.5.1.5 Primary Containment Internal Missiles

The potential for missiles inside the containment due to gravitational effects from unrestrained equipment is possible only during maintenance situations. All equipment and components located inside the containment and associated with reactor operation and safety are restrained. Equipment moved into the containment for maintenance operations (including hoists) is controlled by administrative procedures and is removed when personnel leave the maintenance site or prior to returning to reactor operation. Where possible and practical, maintenance equipment used inside the containment is temporarily restrained. In view of the above, any missiles due to gravitational effects are expected to be relatively small and any resulting damage is anticipated to be minor.

3.5.2 Selected Missiles

As a result of the investigations described in Subsection 3.5.l, the missiles to be considered in barrier design are the tornado generated missiles. These missiles are those considered as a design basis in the PSAR and approved by the AEC as documented in the AEC Safety Evaluation Report (Reference 2). For the Category I 4160-V electrical ductbanks between the RHR cable vaults at the RHR complex and the Reactor/Auxiliary building, the tornado missiles identified in Regulatory Guide 1.76 Revision 1 (Reference 17) are considered.

3.5.2.1 Tornado-Generated Missiles

The tornado-generated missiles are a 4-in. x 12-in. x 12-ft wood plank with a density of 40 lb/ft^3, traveling end-on at a velocity of 255 mph with a contact area of 48 in.^{2}; and a 4000 lb passenger car traveling through the air at 50 mph at a maximum 25 ft above grade elevation. The car has a contact area of 20 ft^2. In the case of tornado-generated missiles, it is assumed that only walls and other vertical exposed surfaces are subject to impacts. Roof structures would be subject only to free-falling ballistic-type projectiles (e.g., wood or stone debris) without high tornadic wind force components. If penetration of the roof structures should occur, such penetration would not constitute a hazard, since the projectile would have very low energy, and the concrete floors and walls protect safety-related equipment for safe shutdown.

The following Design Basis Tornado missiles from Table 2 of Regulatory Guide 1.76 Revision 1 (March 2007) (Reference 17) are considered for the Category I 4160-V RHR cable vaults and the manholes and ductbanks between these cable vaults and the Reactor/Auxiliary building cable vaults:

a. 6.625” diameter x 15 ft long Schedule 40 steel pipe weighing 287 lbs and traveling horizontally at 135 fps

b. 4,000 lb, 16.4 ft x 6.6 ft x 4.3 passenger car traveling horizontally through the air at 135 fps at a maximum height of 30 ft above ground

c. 1” diameter solid steel sphere, weighing 0.147 lb and traveling horizontally at 26 fps

Vertical missiles are all missiles listed above with a vertical velocity equal to 67% of their horizontal speed.

In addition, the following missiles addressed in the Safety Evaluation Report are also evaluated for penetration resistance and regeneration of secondary missiles:

a. 1” diameter x 3 ft long steel rod weighing 8 lbs, traveling horizontally at 250 fps

b. 13.5” diameter x 35 ft long utility pole weighing 1490 lbs, traveling at 247 fps

Vertical missiles are all missiles listed above with a vertical velocity equal to 67% of their horizontal speed.

3.5.3 Missile Barriers and Loadings

Structures, shields, and barriers designed to withstand missile effects are given in Table 3.5-2 according to the equipment protected. In addition to these barriers, the steel plate primary containment vessel is completely enclosed in and surrounded by a reinforced-concrete structure as described in Subsection 3.8.4. This concrete structure, in addition to serving as a radiation shield for personnel in the reactor building, provides a major structural barrier for the protection of the containment and reactor system against missiles that may be generated external to the primary containment.

The suppression chamber has no source of internal or external missile generation. The vent pipes connecting the suppression chamber to the drywell are protected by jet deflectors. The vent discharge headers and piping are designed to withstand the jet reaction force caused by flow discharge into the suppression pool. The control rod drive (CRD) mechanisms are located in a concrete vault below the reactor pressure vessel.

3.5.4 Barrier Design Procedures

3.5.4.1 Overall Structural Response

To determine the capability of the missile barriers provided, the impact and penetration of potential missiles must be determined. Since the missile mass is small compared with the mass of any Category I structure, the only meaningful overall structural response is that of the structural element impacted by the missile. The overall response of the structural element is investigated by designing the element for the forces transmitted to it by the missile.

3.5.4.2 Edge Impact

For edge impact, punching shear stress was checked after obtaining the maximum force impacted to the element by the missile. The punching shear stress is given by the following expressions:

$$Qs = \frac{mV_o}{t_d s} \quad \text{(for rigid missles)} \qquad (3.5\text{-}2)$$

$$Qs = \frac{F_1}{s} \quad \text{(for nonrigid missles)} \qquad (3.5\text{-}3)$$

where

F_1 = maximum contact force = $1.14WV_o$

and

t_d = impact time = $\frac{2D}{V_o}$

D' = penetration depth calculated by modified Petry Formula (Subsection 3.5.4.7)

V_o = initial velocity of missile

m = mass of missile

s = perimeter of area enclosed by a border extending one-half of the panel thickness beyond contact area

W = weight of missile

3.5.4.3 Central Impact

For central impact in the case of rigid missiles, the maximum force impacted to a structural element is calculated by the following expression:

$$F = \frac{mV_o2}{2D'} \qquad (3.5\text{-}4)$$

and

$$t_d = \text{duration of force} = \frac{2D'}{V_o} \qquad (3.5\text{-}5)$$

After the force F and its duration t_d are obtained, the element is designed for this dynamic load. For central impact in the case of nonrigid missiles, the panel is modeled as a single degree of freedom system with equivalent mass and equivalent stiffness. The equation of motion for impact is solved to get maximum deflection of the element. This deflection is compared with allowable (or ductility ratio) to arrive at a satisfactory design.

3.5.4.4 Impact Analytical Procedures

The impact of the missile is considered plastic because of the local unrecoverable deformations of either the missile or the target or of both. The velocity of the missile and the target (concrete panel) after the impact, V_a, is determined from the consideration of conservation of linear momentum and is expressed by the following equation:

$$M_m V_i = M_m V_a + M_e V_a \qquad (3.5\text{-}6)$$

where

M_m = mass of missile

V_i = velocity of impact

M_e = effective mass of target

For the Category I 4160-V RHR cable vaults and the manholes and ductbanks between these cable vaults and the Reactor/Auxiliary building cable vaults, overall structural response is based on the dynamic response of the structures and impulse-load time history. A simplified method based on idealization of the structure to an equivalent single-degree-of freedom system is utilized.

The procedure used in determining impactive force and time duration of the impact follows the guidance in Reference 16.

The impactive force and time duration of a hard missile, such as the 6" diameter schedule 40 steel pipe, is determined by the expression shown in Section 3.5.4.3. The impactive force and time duration for soft missiles, such as the automobile and wood plank, is determined by the Riera formula, as outlined in Reference 16.

3.5.4.5 Punching Shear Analytical Procedure

Reinforced-concrete panels are checked for the punching shear failure and the flexural yielding failures. The effective mass, M_e, of the panel for the case of punching shear failure is obtained as follows:

$$M_e = (A + d)(B + d)dw \qquad (3.5\text{-}7)$$

where

A, B = dimensions of missile

d = thickness of panel

w = density of target material

3.5.4.6 Flexural Failure Analytical Procedure

The effective mass for the case of flexural failure of a panel is defined as that mass which must be concentrated at the point of impact on an equivalent weightless slab so that it will have the same kinetic energy as the actual slab when the point of impact is subjected to unit velocity.

For a flexural failure, the energy transferred to the slab is compared with its energy capacity at an appropriate ductility ratio. For a punching shear failure, the shear capacity at the critical section is compared with the shear force transferred to the slab.

3.5.4.7 Depth of Penetration Analytical Procedure

The depth of penetration into concrete walls is calculated using the Modified Petry Formula (Reference 12). The concrete barrier thickness was selected to prevent secondary missiles formed by scabbing from damaging both divisions of protected systems safe shutdown equipment.

Concrete wall/slab thickness provided for the Category I 4160-V RHR cable vaults, manholes, manhole covers, and ductbanks between these cable vaults and the Reactor/Auxiliary building cable vaults are more than the minimum acceptable barrier thickness required as shown in Table 1 of NUREG-0800, Standard Review Plan 3.5.3 Revision 3, dated March 2007 (Reference 18).

Modified Petry Formula (Reference 12) is used to determine the concrete protective cover thickness to prevent penetration and regeneration of secondary missiles for the two additional tornado missiles identified in the Safety Evaluation Report.

The method of calculation used to determine the energy required to penetrate a steel plate is based on extensive tests conducted by the Stanford Research Institute (Reference 13). During these tests, rod-shaped missiles were impacted against square steel plates having clamped edges. The results of the tests are described by the following expression for minimum energy per unit diameter of missile required for perforation of a steel plate:

$$\frac{E}{D} = U\left(0.344T^2 + \frac{W}{W_s}0.032T\right) \qquad (3.5\text{-}8)$$

where

E = critical energy required for penetration, ft-lb

D = diameter of missile, in.

U = ultimate tensile strength of steel plate, lb/in.^{2}

T = plate thickness, in.

W = length of side of square window in the target frame between the rigid supports, in.

W_s = test constant = 4 in.

No composite section (concrete with steel plate backing or the like) has been used for missile-resistant structural elements.

The impact of a turbine-generator missile on the reactor building or auxiliary building is discussed and references are cited in Subsection l0.2.3. The impact of a turbine missile on the RHR complex has also been evaluated.

3.5.5 Missile Barrier Features

The missile barriers listed in Table 3.5-2 provide adequate protection against potential tornado-generated missiles. In addition, it has been shown that the probability of missile damage to either fuel in the spent-fuel pool or the RHR cooling tower fans, both of which could be exposed to such damage, is extremely small. Together with the redundancy and separation provided, the missile protection provided for Fermi 2 is adequate.

The general arrangement of piping and equipment in the drywell showing the separation of redundant systems is given in Figure 3.5-1, Sheets 1 through 6.

For assumed failures of the high pressure coolant injection (HPCI) system, the automatic depressurization system (ADS) functions to reduce the reactor pressure to a value low enough to allow the low pressure coolant injection (LPCI) and core spray systems to pump water to the reactor pressure vessel (RPV) in time to cool the core consistent with the design basis. (See Subsection 6.3.2.2.2.) The ADS uses five of the 15 safety/relief valves (SRVs) of the nuclear boiler pressure-relief system to achieve the automatic blowdown to the suppression pool. Protection from simultaneous damage to the HPCI steam line inside the containment and to the SRVs designated for ADS function due to pipe whip or fragments of pipes is provided by physical separation. The HPCI steam source is provided from main steam line A, while only the SRVs on main steam lines C and D are considered available for performance of the ADS function.

3.6 PROTECTION AGAINST DYNAMIC EFFECTS ASSOCIATED WITH THE POSTULATED RUPTURE OF PIPING

Fermi 2 is designed with appropriate protection against the consequences of a LOCA. Specifically included are an emergency core cooling system (ECCS) to protect the core from the thermal-hydraulic consequences of a LOCA; a containment system to protect the public from the radiological consequences of a LOCA; and a system of restraints, equipment, piping arrangements with physical separation of redundant components, and protective shields to limit damage escalation from the dynamic effects (i.e., blowdown jet forces and pipe whip) associated with a LOCA.

The design provisions and corresponding criteria for the emergency core cooling and containment systems are covered in Chapter 6. Subsection 3.6.1 describes the measures that have been used to ensure that the containment vessel and all essential equipment within the containment, including components of the reactor coolant pressure boundary (RCPB), engineered safety feature (ESF) systems, and equipment supports, are adequately protected against the postulated LOCA dynamic effects.

The measures taken for protection against dynamic effects associated with the postulated rupture of high- and moderate-energy fluid piping outside the containment are described in Subsection 3.6.2.

Detailed analytical methods and computer codes are discussed in Subsection 3.6.3.

3.6.1 Protection Against Dynamic Effects Associated With the Postulated Rupture of Piping Inside the Containment

3.6.1.1 Systems in Which Design-Basis Pipe Breaks Occur

3.6.1.1.1 Break Location Criteria

All piping that is part of the RCPB and that is subject to reactor pressure continuously during normal plant operation, is considered as a potential initiator of a pipe break, and is analyzed for its dynamic effects damage potential. Piping that is never or only infrequently (i.e., during test operations) subject to reactor pressure is not considered as an initiator of a pipe break. Initial pipe-break events are not assumed to occur in pump and valve bodies because of their greater wall thickness and their location in the low-stress portions of the piping systems.

3.6.1.1.2 Longitudinal and Circumferential Breaks

The following types of breaks were postulated in the RCPB piping systems: (1) circumferential breaks were postulated in piping having a nominal diameter greater than 1 in. and (2) longitudinal breaks were postulated in piping having a nominal diameter greater than 4 in.

Except where limited by structural design features, a circumferential break results in pipe severance with full separation. The break was assumed perpendicular to the longitudinal axis of the pipe at the break location. The fluid discharge coefficient at the break was determined from analytical or experimental work.

A longitudinal break results in an axial split without severance. For design purposes, the longitudinal break was assumed to be rectangular in shape, with an area equal to the largest piping cross-sectional flow area at the point of break.

3.6.1.1.3 Major Piping Systems Considered for Dynamic Effects of Postulated Pipe Breaks

The major piping systems inside the containment considered for protection against dynamic effects of the postulated ruptures of piping are the piping associated with the following systems:

a. Main steam system-inside and outside the containment

b. Recirculation system

c. Feedwater system

d. High-pressure coolant injection (HPCI) system

e. Reactor core isolation cooling (RCIC) system

f. Core spray (CS) systems

g. Residual heat removal (RHR) supply and return lines.

These and other minor non-safety class system (see Subsection 3.6.1.1.4) pipe-break analyses have been submitted to the AEC in References 1 through 11.

References 1 through 11 describe the Fermi 2 conservative design against the dynamic effects of postulated pipe ruptures inside the containment and they show that the requirements of 10 CFR 50, Appendix A, and 10 CFR 100, as well as the intent of Regulatory Guide 1.46, are in fact met. Supplemental analyses have also been completed to establish as-built compliance with these criteria.

In addition, a detailed analysis of a postulated line break in the region of a reactor vessel nozzle safe-end and its effects on the sacrificial shield wall was performed in response to ACRS concerns and was submitted to the AEC (References 12 and 13).

There are no ASME Boiler and Pressure Vessel (B&PV) Code Section III, Class 2 and 3, high-energy piping systems located inside the primary containment.

3.6.1.1.4 Consideration of Other Systems (Non-Safety Class Systems)

Certain "other" systems (see Section 3.2) and components are not required for the safe shutdown of the reactor nor are they required for the limitation of the offsite release in the event of a LOCA. However, while none of this equipment is needed during or following a LOCA, some dynamic effects must be considered where a non-safety class system or component failure could initiate or escalate a LOCA in one of the following systems or components:

a. Reactor water cleanup (RWCU) system

b. RPV vent line

c. Main steam drains

d. Standby liquid control system.

3.6.1.2 Design-Basis Pipe-Break Criteria

The following definitions are used for piping run terminology.

Main Run - Piping interconnecting terminal ends. All branch lines from the main run are considered branch runs, with the exception of the following:

a. Free-ended branch lines throughout which there is no significant restraint to thermal expansion are considered part of the main run

b. All ASME B&PV Code Section III, Class 1, branch lines that are included with the main run piping in the code stress analysis computer mathematical model are considered part of the main run.

Piping Run - A main or branch run.

Terminal End - Piping originating at the structure or components (such as vessel and equipment nozzles and structural piping anchors) that acts as a rigid constraint to the thermal expansion. Typically, the anchors assumed for the piping code stress analysis are considered terminal ends. In-line fittings, such as valves, not assumed to be anchored in the piping code stress analysis, are not terminal ends. The branch connection to the main run is one of the terminal ends of a branch run, except where the branch run was classified as part of a main run as defined above.

Break Location in ASME B&PV Section III, Class 1 Piping Runs

Postulated pipe-break locations are selected in accordance with the intent of Regulatory Guide 1.46; NRC Branch Technical Position (BTP) APCSB 3.1, Appendix B; and as expanded in NRC BTP MEB 3-1. For ASME Section III, Class 1 piping systems, the postulated break locations are as follows:

a. The terminal ends of the pressurized portions of the run

b. At intermediate locations between the terminal ends where the maximum stress range between any two load sets (including zero load set), according to Subarticle NB- 3600 of ASME Section III for upset plant conditions and an independent operating-basis earthquake (OBE) event transient, exceeds the following:

1. If the stress range calculated using Equation 10 of the Code exceeds 2.4 S_m but is not greater than 3 S_m, no breaks will be postulated unless the cumulative usage factor exceeds 0.1

2. If the stress ranges, as calculated by Equation 12 or 13 of the Code, exceed 2.4 S_m, or if the cumulative usage factor exceeds 0.1 when Equation 10 exceeds 3 S_m.

c. Arbitrary intermediate pipe breaks no longer need to be postulated, per Generic Letter 87-11

3.6.1.2.1 Core Cooling Requirements

The designed emergency core cooling system (ECCS) capability can be maintained provided that dynamic-effect consequences do not exceed the following break area, break combination, and maintenance of minimum core cooling requirements.

3.6.1.2.1.1 Maximum Allowable Break Areas

The maximum allowable break areas are as follows:

a. For breaks involving recirculation piping, the total effective area of all broken pipes, including the effective area of the recirculation line break, shall not exceed the total effective area of the design-basis double-ended recirculation line break (see Subsection 6.2.1.3). By limiting the total area of all broken pipes involving recirculation loops to an area less than or equal to that of the design-basis accident (DBA) (circumferential break of recirculation loop), no accident could be more severe than the DBA

b. For breaks not involving recirculation piping, the effects are much less severe than recirculation line breaks. Hence, the total break area can be allowed to be larger than the recirculation breaks. Therefore, the total break area shall not exceed the sum of one feedwater header pipe area, one steam line (upstream of flow limiter) pipe area, and one core spray pipe area.

3.6.1.2.1.2 Break Combinations

In addition to the pipe-break-area restrictions, breaks involving one recirculation loop shall not result in loss of function or damage to the other recirculation loop or loss of coolant from the other loop in excess of that which would result from a break of the attached cleanup connection on the suction side of the loop.

3.6.1.2.1.3 Required Cooling Systems

To ensure compliance with Appendix A of 10 CFR 50, General Design Criteria for Nuclear Power Plants, the following cooling system requirements, including all required support systems, must be met after an additional single active safety system failure:

a. For breaks not involving recirculation piping, at least two low-pressure coolant injection (LPCI) pumps or one core spray system shall be available for core cooling

b. For breaks involving recirculation piping, at least one core spray line and two LPCI pumps or two core spray lines shall be available for core cooling

c. For a steam line break with a total effective break area of less than 0.4 ft^2, either the HPCI or automatic depressurization system (ADS) shall be available for reactor depressurization. At least (n-l) ADS valves must be available (n = total number of ADS valves)

d. For liquid breaks such as cleanup suction or combination of liquid and steam breaks whose total break area is less than 1.0 ft^2 and in which the ADS system is required for depressurization, at least (n-l) ADS valves must be available

e. For breaks smaller than the equivalent flow area of one open ADS valve, at least (n-l) ADS valves must be available. However, the required number of ADS valves will be one less for each additional steam break area equivalent to the area of one open ADS valve.

3.6.1.2.2 Containment System Integrity

The following shall be considered in addressing the LOCA dynamic effects with respect to containment system integrity:

a. Leaktightness of the primary containment fission product barrier shall be ensured throughout any LOCA, unless analyses show that offsite dose consequences are within 10 CFR 50.67 guidelines or 10 CFR 100 guidelines

b. For lines that penetrate the drywell and are normally closed during operation, the inboard isolation valve shall be as close as practical to the reactor pressure vessel. This arrangement reduces the length of pipe subject to a pipe break

c. For lines that penetrate the primary containment and are open during normal operation, the outboard isolation valve shall be as close as practical to the primary containment.

3.6.1.2.3 Control Rod Insertion Capability

To maintain the ability to insert the control rods in the event of a pipe break, the control rod drive (CRD) withdrawal lines shall be protected from the dynamic effects so that no more than one in any nine-rod array is allowed to be completely crimped (totally blocked). Complete severance of withdrawal lines will not affect the rod-insert function. Protection for the CRD insertion lines is not required since a reactor pressure of 600 psig or higher can adequately insert the control rods.

3.6.1.3 Design Loading Combinations

Design criteria, design stress limits, and various loading combinations for safety class system components and equipment, including the RCPB system components, are described in detail in Subsection 3.9.2. Design criteria, design stress limits, and loading combinations for various types of pipe-whip restraints and support systems for Fermi 2 are described in Subsection 3.6.1.5 (see also References 1 through 11).

A description of analytical methods and computer codes used is given in Subsections 3.6.1.4 and 3.6.1.7, respectively.

3.6.1.4 Dynamic Analyses

3.6.1.4.1 Analytical Methods

3.6.1.4.1.1 General Description of Analytical Methods

The prediction of time-dependent and steady-thrust reaction loads caused by blowdown of subcooled, saturated, and two-phase fluid from a ruptured pipe is used in design and evaluation of dynamic effects of pipe breaks. Unsteady loads result from depressurization wave propagation that causes the various sections of pipe to be loaded with time-dependent forces. Steady blowdown thrust loads are all equivalent to a corresponding thrust applied normal to the plane of the break and opposite to fluid blowdown velocity. These loads can be computed for each section of the piping system, and corresponding external restraints can be provided if it is necessary to limit the movement of the piping system. A detailed description of the analytical assumptions and methods used to compute these blowdown loads is given in Section A of Reference 1 and in References 2 and 5.

A schematic diagram representing modeling of physical systems in pipe-whip analysis is given in Figure 3.6-1.

3.6.1.4.1.2 Blowdown Types and Associated Thrust Loads

The blowdown types and associated thrust loads considered in the analyses are summarized in this subsection.

The two components of the thrust reaction load considered are

a. Blowdown thrust - This thrust is caused by fluid acceleration from the break and static pressure in the break itself

b. Wave thrust - This thrust is caused by momentum transfer associated with decompression and compression waves (sonic waves) propagating in the various pipe sections. It is assumed that simple pipe bends and turns (without flow-area change) do not attenuate the traveling pressure waves or cause reflections.

Only the wave thrust produces reaction loads on bound pipe segments, whereas blowdown thrust applies only to the broken pipe segment. In the initial phase of a blowdown caused by a pipe rupture, both the wave and blowdown thrusts are present and they are additive. However, when the steady blowdown phase is reached, the wave thrust becomes zero and all bound pipe segment reaction loads disappear.

In designing protective devices to minimize the effects of pipe rupture, the jet impingement loads on surrounding mechanical system components, equipment, and structures were also considered to ensure that the effects of pipe rupture would not propagate to other vital plant systems.

3.6.1.4.1.3 Circumferential Breaks and Associated Thrust Loads

When analyzing a case where a single straight segment of broken pipe is attached to a pressure vessel, the magnitudes of both blowdown and wave thrust loads are computed. Depending on the state of the fluid in the piping system, nonflashing liquid or vapor phase, the resulting thrust loads will be different, as shown in Figures 3.6-2 and 3.6-3, respectively.

However, bends, friction, and flashing of near-saturated water all affect the blowdown characteristics. Therefore, for actual analyses, these factors were taken into account and the resulting time-dependent thrust force diagrams are modified as shown in Figure 3.6-4 for steam lines. Figure 3.6-4 shows a typical timethrust diagram for a line containing steam. After the initial wave thrust has died down, the blowdown thrust approaches the steady-state value.

a. Friction effects - Thrust reaction forces are attenuated by pipe friction that exerts its most direct effect on the blowdown rate. Figure 3.6-5 shows the steady-state thrust as a function of the friction coefficient (K = FL/D) for steam and saturated water. Reference 2, Section II-F, summarizes the methods used for including friction effects

b. Flashing effects - The effects of phase change are much less important for vapor flows than for low-quality saturated liquid/vapor mixtures. Therefore, methods for predicting time-dependent and steady blowdown properties of vapors are relatively straightforward. However, methods for predicting time-dependent blowdown of saturated mixtures must provide somewhat higher than expected loads for design purposes. Refer to Reference 14, Paragraph 4.2, for analytical development

c. Traveling speed of wave thrust - Flow disturbances propagate at sonic speed relative to the fluid. The sonic speed is important in predicting time-dependent flow properties before steady blowdown rates are reached. For development of sonic velocities used in the Fermi 2 design, refer to Reference 1 and Reference 2, Section II-C.

3.6.1.4.1.4 Longitudinal Breaks and Associated Thrust Loads

In the case of a longitudinal break of a pipe, the blowdown flow will come from both the upstream and the downstream directions except for lines with a dead end. For longitudinal breaks in dead-end lines, the analysis is similar to the analysis of circumferential breaks. If the longitudinal break area is sufficiently small, flow rate will be limited by the break itself; however, if the break is large, flow rate will be limited by the sum of upstream and downstream pipe areas or any applicable restriction area. The geometric character of a longitudinal pipe fracture is still relatively uncertain. Therefore, it is reasonable to consider an ideal, short nozzle-type break rather than a sharp-edged orifice-type break that would reduce the computed reaction thrust. A longitudinal break is shown in Figure 3.6-6. Figures 3.6-7 and 3.6-8 show thrusts for longitudinal breaks. In Fermi 2 piping system analyses, it is postulated that a longitudinal break area is equal to the pipe flow cross-sectional area. Refer to Reference 1, Section I of Reference 2, and Reference 14 for details on the analysis of thrust loads for longitudinal breaks.

3.6.1.4.1.5 Jet Impingement Loads

Jet impingement loads result from blowdown flow that forms a jet of fluid and imparts impact forces to pipes or other mechanical and structural target objects in its path. Analysis for components subject to jet impingement loads is described in Section D of Reference 1.

3.6.1.4.2 Modeling of Physical Systems

3.6.1.4.2.1 Circumferential Break Model

The circumferential break pipe/restraint system is modeled in the analyses such that the pipe immediately upstream of the elbow is loaded as a beam whose point of fixity is usually taken at a fitting or at the nonpiping component element such as a pump, vessel, or containment penetration. The weights of these pipes are small compared to the blowdown thrust loads; therefore, gravitational forces are neglected in the model. However, the mass of all piping, fittings, valves, or any other concentrated weight is considered in the dynamic analysis to account for the inertial effects of these masses. A schematic diagram of pipe/restraint is shown in Figure 3.6-9 for the circumferential break case.

The weight of the beam section, L, shown in Figure 3.6-9 is treated as a distributed mass. If a concentrated weight exists in the beam between the restraint and the break, it is treated in the model as an additional point mass transferred to the beam end at the break location line of action. The restraint closest to the broken end is assumed to carry the total dynamic load. No credit is taken for additional restraints, if any, along the pipe that would reduce the loading on the primary restraint.

3.6.1.4.2.2 Longitudinal Break Model

Figure 3.6-l0 shows a model in which a longitudinal break occurs along the bend of an elbow. The model elements are generally similar to those of the circumferential break. However, an additional element, the equivalent beam restraint, L_3, is present as shown in the figure. This element shares the applied load with the beam element from the instant the break occurs. The applied load in the longitudinal break case has two components. The first component, F_{BA}, acts parallel to the axis of the equivalent beam restraint as a compression force if the equivalent beam restraint ends in a true point of fixity; that is, a vessel, containment penetration, etc. If the equivalent beam restraint does not end at a point of fixity, the force F_{BA} will load some other combination of beams and equivalent beam restraint. The second component, F_{BB}, acts perpendicular to the equivalent beam restraint, L_3, and the beam, L. The equivalent beam restraint is treated in the model as a beam spring whose force is directly opposite to the thrust load. The mass, however, is treated as an additional equivalent point mass along with any other concentrated loads it may contain, applied to the end of the beam section.

3.6.1.4.2.3 Pipe Response Modes of the Model

The five pipe response modes of the model are as follows:

a. First response mode - The first mode of response is the free movement of the piping system before it contacts the restraint. In this mode, the energy that is not dissipated as deformation energy of the beam in the circumferential break and of the beam and equivalent beam restraint in the longitudinal break, becomes kinetic energy of the beam system

b. Second response mode - This response mode is initiated the instant the pipe hits the restraint. Analysis of this response mode requires a complex mathematical model because of the multilink response of the system involved. In this mode the thrust force, restraint force, and pipe-bending resistance moments all have to be considered to compute the accelerations, velocities, and displacements at the broken end of the pipe

c. Third response mode - In this mode the restraint and the bound end of the pipe have ceased to move, but the free end of the pipe is still in motion. During this period, the forces and moments of the various load elements, the energy balance, and the kinetic energy are computed as a function of the displacement. If the kinetic energy is computed to be zero or negative, the free end of the pipe is assumed to be stationary

d. Fourth response mode - In this mode the movement at the free end of the beam relative to the bound end is zero, and the computation process continues as in the third mode

e. Fifth response mode - In this mode the steady-state response of the piping system is computed. The computed steady-state load is compared to the maximum allowable restraint load.

The five modes of response listed above describe the computational process used in the dynamic analysis of pipe rupture thrusts and corresponding effects on the pipe-whip restraints. Details of the computer code used in this analysis are given in Reference 5. The results of the analyses are reported in Reference 1.

3.6.1.5 Protective Measures

Protection against the dynamic effects of a pipe rupture is provided in the form of pipe-whip restraints, equipment shields, and physical separation of piping, equipment, and instrumentation.

Detailed analyses of pipe restraints and restraint support systems, and test results of the pipe restraints installed in Fermi 2 are described in References 1 and 9, respectively, which were submitted to the AEC as topical reports. Supplemental analyses were also performed for the as-built configuration.

3.6.1.5.1 Pipe Restraint Design

3.6.1.5.1.1 Design Criteria

Pipe restraints, as differentiated from piping supports, are designed to function and carry loads for an extremely low probability of gross failures in the RCPB and other vital safety system piping. The RCPB piping integrity does not depend on the piping restraints during normal, upset, emergency, or faulted conditions as defined in paragraph NB-3113, Section III, of the ASME B&PV Code, but relies on piping supports to maintain the piping design stress values and/or piping integrity.

The pipe restraints (that is, those devices that serve only to control the movement of a ruptured pipe following gross failure) are subjected to once-in-a-lifetime loading. Local pipe and restraint deformations that occur upon impact do not further affect the integrity of the RCPB. For the purpose of design, the pipe-break event is considered to be a faulted condition and the pipe, its restraints, and structure to which the restraint is attached, are analyzed accordingly.

Piping within the broken loop shall no longer be considered part of the RCPB. Plastic deformation in the pipe is considered as a potential energy absorber. Limits of strain can be imposed that are similar to strain levels allowed in restraint plastic members. Piping systems are designed so that plastic instability does not occur in the pipe at the design dynamic and static loads.

Therefore, the design objectives governing the extent of permissible damage resulting from postulated dynamic effects of pipe whip are as follows:

a. The integrity of the primary containment system must be maintained

b. Safe shutdown and maintenance of core cooling integrity must be ensured.

To ensure the previous general design criteria of pipe restraints, the following specific design requirements must be met.

a. The restraints shall in no way increase the RCPB stresses by their presence during any mode of reactor operation or condition

b. The restraint system shall function to stop the movement of a pipe failure (gross loss of piping integrity) without allowing damage to critical components or missile generation.

3.6.1.5.1.2 Types of Pipe Restraint Components

To establish a design basis relating to material selection, fabrication, inspection, installation, quality assurance, and applicable design limits, three types of restraint hardware are defined. In addition, the structural and civil components are considered as a separate type.

a. Type I - Restraint energy absorption members - Those members that, under the influence of impacting pipes (pipe whip), will absorb energy by significant plastic deformation (e.g., U-bolts, rods, cables)

b. Type II - Restraint connecting members - Those components that form a direct link between the restraint plastic members and the structure (e.g., clevises, brackets, pins)

c. Type III - Restraint connecting member structural attachments - Those fasteners that provide the method of securing the restraint connecting members to the structure (e.g., weld attachments, bolts)

d. Type IV - Structural and civil components - Those steel and concrete structures that ultimately must carry the restraint load (e.g., sacrificial shield, trusses).

3.6.1.5.1.3 Loading Basis for Pipe Restraints

For the purpose of designing the pipe restraints as defined in Subsection 3.6.1.5.1.2, the following faulted loading combinations are used:

a. Dynamic Loading

1. Blowdown thrust of the pipe section that impacts the restraint

2. Dynamic inertia loads of the moving pipe section that is accelerated by the blowdown thrust and impacts the restraint.

b. Static Loading

1. Maximum steady-state blowdown thrust following initial dynamic loading when pipe movement ceases

2. Effective piping weight on the restraint, if significant.

3.6.1.5.1.4 Design Basis for Pipe Restraints

The four types of pipe restraints are

Type I

a. Materials - All materials that are used to absorb energy through significant plastic deformation shall conform to

1. ASME B&PV Code Section III, Subsection NB, Class 1 Components, or

2. ASTM specifications with consideration for brittle fracture control.

b. Inspection - Inspection and identification of material shall conform to

1. ASME B&PV Code Section III, Subsection NB, Class 1 Components (Section V, Non-Destructive Examination Methods), or

2. ASTM specification procedures, including volumetric and surface inspection.

c. Design limits

1. Design local strain - The permanent deformation in metallic ductile materials shall be limited to 50 percent of the minimum actual uniform elongation based on restraint material tests for stainless steel restraint bars

2. Design steady-state load - The maximum restraining load will be limited to:

(a) 80 percent of the minimum calculated static ultimate restraint strength at the drywell design temperature for bar-type restraints

(b) 75 percent of certified minimum breaking strength for cables determined on the basis of tests (Reference 14).

3. Dynamic material mechanical properties - The material selected must exhibit tensile impact properties that are not less than

(a) 70 percent of the static percent elongation

(b) 80 percent of the statistically determined minimum total energy absorption.

Type II

a. Materials - Material selection shall conform to ASTM Specifications, including considerations for brittle fracture control

b. Inspection - Inspection shall conform to ASME/ASTM requirements or process qualification and finished parts surface inspection per ASTM methods

c. Design limits - Design limits shall be based on the following stress limits:

1. Primary stresses shall be limited to the higher of

(a) 70 percent of S_u , where S_u = minimum ultimate strength by tests or ASTM Specification

(b) $S_y + 1/3 (S_u - S_y)$, where S_y = minimum yield strength by tests or ASTM Specification.

Type III

a. Fasteners

1. Materials - Fastener materials shall conform to ASTM and ASME requirements

2. Inspection - All fasteners shall be inspected or certified per applicable ASTM and ASME specifications

3. Design limits - Same as Type II.

b. Welds

1. Materials - Weld material for attachment to carbon steel structures shall conform to AWS/ASME specification per:

(a) AWS A5.1, A5.5, or A5.17, low hydrogen electrode for metal arc welding, or

(b) AWS A5.18 or A5.20 filler metal for MIG or TIG welding.

2. Procedures - Procedures and welders shall be qualified per AWS Code D1.0 - latest edition for welding in building structures

3. Design limits - Design limits shall be based on the following stress limits:

The maximum primary weld stress intensity (two times maximum shear stress) will be limited to three times AWS or AISC allowable weld shear stress.

Type IV

Design requirements for structural equipment are not codified to the same extent as for the mechanical and electrical equipment. The industry recognizes this inadequacy and is actively working in this area. For example, standards for concrete containment are being developed by both the ASME and the American Concrete Institute (ACI). It is also impractical to "qualify" a structure as is done for electrical or instrument components. It is therefore current practice within the industry for structural requirements to be developed and specified by a qualified structural engineer, and for those requirements and methods of implementing the design to be reviewed by the NRC. Structures are designed to respond to conditions associated with the specific structure including operational and accident loadings, seismic loadings, wind loadings, and tornado loadings.

The design-basis approach of categorizing components is consistent in allowing less stringent inspection requirements for those components subject to lower stresses. Considerable strength margins exist in Types II through IV even to the limit of load capacity (fracture) of a Category I component. It is recognized that impact properties in all components must be considered since brittle-type failures could reduce the restraint system effectiveness. For details of load combinations, design limits, stress criteria, and materials specifications, see Section 3.8.

3.6.1.5.1.5 Design Basis for Seismic Guide

The normal function of a seismic guide is to support a piping system and limit deflection under seismic loading. Because of the limited space in the area of the inboard main steam isolation valve (MSIV), it was necessary in this particular case to combine the function of a seismic guide with the function of a pipe-whip restraint. Details are described in Reference 1.

The seismic guide is designed with a low clearance to maintain small deflections during seismic events, so that the containment penetration and the inboard MSIV will not be subjected to high stresses. To limit the pipe motion within the confines of available space in the event of a pipe rupture, the existing seismic guide was redesigned to include the function of a low-clearance pipe-whip restraint.

The seismic guide contains 40 crushable energy-absorbing stainless steel tubes with a 1-in. outside diameter, a 0.156-in.-thick wall, and a 10-in. length. These tubes will not be in contact with the pipes under normal and/or seismic events. However, in the event of a pipe rupture requiring the pipe-whip restraint to function, the pipe is free to work on the crushable tubes, thus dissipating its kinetic energy to the tubes.

3.6.1.5.1.6 Verification Tests for Pipe-Whip Restraints

The dynamic test program conducted by Edison with the assistance of GE verifies the adequacy of the Fermi 2 pipe-whip restraint designs. The concept of large-clearance design with plastic deformation of restraint material to absorb the kinetic energy of a whipping pipe has been proven in these tests, which are described in Reference 9.

The overall conclusion can be drawn from the results of the actual tests that sufficient conservatism exists in the analysis methods used to initially predict the effectiveness of the design concept in restraining vital piping without hindering their normal expansion and contraction in the course of plant operation. Therefore, it is concluded that the pipe-whip restraint designs are effective, with sufficient margins to meet all of the safety design requirements.

3.6.1.5.1.7 Design Basis for Recirculation System Restraints

Restraints for the recirculation system piping are the GE cable-type restraints. These restraints are discussed in Reference 14.

3.6.1.5.2 Separation and Protective Provisions for Safety- Related Systems and Equipment

3.6.1.5.2.1 Separation Criteria

Separation of safety-related mechanical and electrical systems and equipment is provided such that the General Design Criteria of 10 CFR 50 are fulfilled by providing the protection against the single-failure criterion. That is, all safety-related systems and equipment are arranged such that a single failure of any active component in a redundant system does not result in a loss of capability of the system to perform its safety function (see Section 3.12).

3.6.1.5.2.2 System Separation

The mechanical and electrical systems and equipment separation are as follows:

a. Mechanical systems and equipment - Piping for a redundant safety system is run independent of its counterpart. Supports, restraints, and mechanical components of redundant piping of the same system are not shared in common, unless it can be shown that such sharing does not significantly impair their ability to perform their safety functions.

   The systems and equipment that meet the separation criteria are as follows:

   1. LPCI
   2. CS
   3. HPCI
   4. ADS
   5. RCIC.

b. Electrical systems and equipment - The electrical portions of the following systems are affected by the separation criteria:

   1. Reactor protection
   2. HPCI
   3. CS
   4. RHR
   5. Emergency closed cooling water (ECCW)

6. RCIC.

The corresponding electrical equipment includes

1. Instrument channels
2. Trip systems
3. Trip actuators
4. Standby power sources
5. Average power range monitor
6. Intermediate range monitor.

These systems and equipment have also been designed and fabricated in accordance with the intent of IEEE Standard 279-1971 and IEEE Standard 308-1971, as applicable.

3.6.1.5.2.3 Physical Separation

The physical separation for mechanical and electrical systems and equipment is as follows:

a. Mechanical systems and equipment

   1. Mechanical equipment and piping, including control safety conduit and tubing and containment penetrations for safety-related systems, are physically separated to meet the single-failure criterion

   2. The ADS is physically separated from the HPCI system such that no portion of the HPCI influent line or HPCI steam supply line is located within the jet impingement damage distance or pipe-whip damage distance of any component considered essential to the ADS operation

   3. Provisions are made to ensure that no single failure could incapacitate both the HPCI and RCIC systems.

b. Electrical systems and equipment

   Electrical equipment and wiring for the reactor protection system (RPS) and the ECCS subsystems are physically separated under separate divisions, designated as Divisions I and II, to conform to the requirements of the single-failure criterion by arrangement and/or protective barriers.

3.6.1.5.3 Protective Shields and Jet Deflectors

Jet deflectors are provided in the drywell at the inlet of each vent pipe to prevent possible damage from jet forces, which might accompany a pipe break in the drywell. In addition, piping and electrical penetrations in the primary containment are either designed to withstand or are shielded from the jet impingement forces arising from the rupture of the largest local pipe or connection. Details of the piping penetration jet deflectors are discussed in Subsection 3.8.2.1.3.1. The sacrificial shield and the containment floor also act as shields for the pipe-whip and jet impingement forces arising from a break in the unrestrained portions of the pipe inside the drywell.

3.6.1.6 Pipe-Whip Restraint Support System

Pipe-whip restraints are provided at required locations along the length of pipes under pressure to withstand forces arising from whipping of the pipes in the event of a postulated pipe rupture. These restraints are designed so that the energy dissipated during whipping of the pipe after rupture is absorbed by plastic yielding of the restraints; this provision of absorption of energy by plastic yielding results in further reduction of the reactive force due to whipping. Depending upon the location of the restraints and configuration of the piping network, the restraints are attached directly to the sacrificial shield, through trusses to the sacrificial shield, directly to the reactor pressure vessel (RPV) pedestal, or through trusses to the RPV pedestal and drywell floor. The design of the pipe-whip restraint support system (PWRSS) is described in Reference 1.

3.6.1.6.1 Design Criteria

3.6.1.6.1.1 Design Basis

The structural analysis of the components of the PWRSS is performed using linear elastic methods. The stresses resulting from such an analysis for the load combinations involving pipe rupture forces are limited to Φfy, where f_y is the maximum stress resulting in first yielding of the structure as specified in AISC and ACI specifications, and Φ is the reserve strength factor, which depends on the type of structure and ranges in value from 0.85 to 0.95. The reserve strength factors are used to ascertain that the structure does not reach first yield under the specified load combinations. This factor also includes the effect of strength variation in materials and workmanship.

An underlying assumption in the design of the PWRSS is that only one pipe-rupture event can take place in any given instant.

The design forces for the PWRSS are derived from the results of the dynamic pipe-whip analyses, described in the preceding subsections, and expressed as equivalent static loads. In deriving these equivalent static loads, consideration is given to the following parameters:

a. Time dependence of pipe-rupture loads

b. Flexibility and damping of the components of the PWRSS

c. Second-order effects in the restraints, such as strain hardening and variation of material properties with rate of strain.

3.6.1.6.1.2 Load Combinations and Allowable Stresses

The load combinations described here involve only the loads due to pipe-whip forces and corresponding allowable stresses. The values of allowable stresses are the maximum possible values. The actual limiting values for design are dependent on the type, function, and method of construction of the particular structure; and hence, if necessary, the values of allowable stresses are suitably reduced. The load combinations and allowable stresses given are applicable to all components of the PWRSS.

a. Load Combinations for Design of PWRSS Components

Load Combination category	D	L	T_a	P_a	R	E	E'	M
Abnormal/severe environment	1.0	1.0	1.0	1.0	1.0	1.0		
Abnormal/extreme environmental	1.0	1.0	1.0	1.0	1.0		1.0	1.0

NOTES:

1. Loads not applicable to a particular structure under consideration may be deleted.

2. If for any load combination the effect of any load other than D reduces the total load, it shall be deleted from the combination.

NOTATION

D = Dead load of structure plus any other permanent loads

L = Conventional floor live loads and movable equipment loads

T_a = Thermal effects that may occur during an accident

P_a = Pressure loads that may occur during an accident

R = Statically equivalent forces arising out of effects that include jet impingement, dynamic rupture load associated with whipping pipe, and accidental thermal pipe reaction

E = Operating-basis earthquake (OBE) effects

E' = Safe-shutdown (formerly design-basis) earthquake (SSE) effects

M = Effects of missile impact

b. Allowable Stresses

1. Concrete

(a) Compression

Membrane	$0.60f_c'$
Membrane plus flexural	$0.75\ f_c'$
Local compression	$0.90\ f_c'$

(b) Shear

Permissible nominal shear stress and design of necessary shear reinforcement are as per the provisions in Chapter 11 of ACI 318-71, Building Code Requirements for Reinforced Concrete

(c) Membrane Shear

The principal stresses resulting from membrane shear and normal stresses are computed for all combinations. If the principal tension is greater than $3\sqrt{f'_c}$ in localized areas, then reinforcing steel is provided to carry the total tensile force

In addition to the specific requirements stated above, all the other provisions of ACI 318-71 apply.

2. Reinforcing Steel

   Tension $0.9\ f_y$

   Compression (load carrying) $0.9\ f_y$

3. Structural Steel

   The allowable stresses are 1.6 times those given in AISC specifications. The following requirements are also satisfied:

   (a) Allowable shear stress = $\frac{0.95\ F_y}{\sqrt{3}}$

   (b) Allowable shear stress in fillet welds = 1.6 times those given in AISC specifications.

   (c) Allowable tensile stress in a plane perpendicular to the plate thickness = $\frac{2}{3} F_y$

NOTATION

f'_c = Specified compressive strength of concrete, psi

f_y = Specified yield strength of reinforcement

F_y = Specified yield strength of structural steel

3.6.1.6.1.3 Components of Pipe-Whip Restraint Support System

The primary components in the PWRSS are

a. Pipe-whip restraints

b. Sacrificial shield

c. Trusses

d. Reactor support pedestal

e. Drywell floor.

A schematic representation of interactions among various components of the PWRSS is given in Figure 3.6-11; the relative locations of the components are shown in Figure 3.6-12.

Some descriptions of structures, analytical methods, loads, and stresses for the design of PWRSS are given in Reference 15.

3.6.1.7 Computer Programs Used in Analysis and Design of Pipe- Whip Restraints and Restraint Support Systems

The computer programs used in the analysis and design of pipe-whip restraints and restraint support systems are:

a. PDA - PDA (Pipe Dynamic Analysis Program for Pipe Rupture Movement) was developed by GE to solve nonlinear, two-dimensional dynamic equations of pipe-whip and the restraining device motions. This program is used to generate the time-dependent forcing functions for the design of pipe-whip restraint devices. For a detailed program description refer to Reference 5

b. INDIA - INDIA (Interaction Diagram for Reinforced Concrete Members) was developed and is maintained by Sargent & Lundy (S&L). It has been designed to plot the bending moment-axial load interaction diagram for reinforced-concrete members

   Interaction diagrams can be obtained for any of the criteria of design, ultimate strength, yield strength, or working stress. Both compression and tension axial loads are considered, as well as positive and negative moments

   The program output includes a listing of the results for the specified design criterion. The interaction diagram is plotted, if so desired

c. KALSHEL - KALSHEL (Kalnins' Shell of Revolution) was developed by A. Kalnins of Lehigh University and is maintained by S&L. The program analyzes thin axisymmetric shells of revolution for arbitrary load conditions. It is based on a computation scheme set forth in the publication by A. Kalnins, "Analysis of Shells of Revolution Subjected to Symmetrical and Nonsymmetrical Loads," Journal of Applied Mechanics, ASME, Vol. 31, September, 1969, pp. 467-476. For the solution, the general boundary value problem of a rotationally symmetric shell is transformed into a new system of first-order ordinary differential equations. An Adams method of numerical integration is used as a basis for the solution of transformed equations

   The shell wall may vary in thickness along the meridian and may consist of up to four layers of different isotropic or orthotropic materials. Branch shells may be connected to the main shell. Surface loads and live loads in the radial, tangential, and/or meridional directions and meridional moments may be considered in the analysis. Temperature distributions that may be considered to vary linearly across the thickness may also be considered. All loads may be asymmetric

   The program output includes the shell displacements in the radial, tangential, and meridional directions, meridional rotations, meridional moment, hoop moment, meridional force, hoop force, transverse shear force, and twist shear force. Outer fiber stresses calculated from the stress resultants may also be obtained. Sargent & Lundy has modified the program to sum the displacement and stress resultants of the individual Fourier harmonics along meridians at specified angles

d. <u>SLSAP</u> - SLSAP (Sargent & Lundy Structural Analysis Program) was developed by E. L. Wilson of the University of California, Berkeley, and is maintained by S&L. The program uses the stiffness matrix method to analyze two-and three-dimensional frames, trusses, and grids, three-dimensional elastic axially symmetrical solids, plates, and shells for arbitrary static loads. Dynamic analyses for frequencies and mode shapes, spectral analysis, and numerical integration analyses are also possible

   The program allows materials with arbitrary elastic constants, combined loading, rigid members, elastic supports, and a combination of different element types

   The program output includes displacement and rotations of all joints or nodes, forces or stresses in members or elements, frequencies and mode shapes, and dynamic response in terms of displacements and forces

e. <u>SOR-III</u> - SOR-III (Shell of Revolution) was developed by Knolls Atomic Power Laboratory for the AEC. It is maintained by S&L. The program analyzes thin shells of revolution subjected to axisymmetric loading by numerically integrating the governing differential equations using a generalized Adams-Moulton method

   Arbitrary distribution of normal, tangential, and moment surface loadings, as well as edge forces and deflections, may be considered in the axisymmetric loadings. Input of boundary conditions allows for the consideration of elastic support conditions. The effect of temperature variations along the meridian or across the thickness is also considered

   The program output includes shell displacements, outer fiber stresses and strains, and stress resultants

f. <u>STRESS-II</u> - STRESS-II (Structural Engineering Systems Solver) was developed by Massachusetts Institute of Technology and is maintained by University Computing Company. It uses the stiffness matrix method to analyze plane and space trusses and frames and plane grids

   The structure can be analyzed for arbitrary joint loads, member loads, temperature changes, and joint displacements. A plotting feature is available with the program

   The output includes joint displacements, equilibrium check, and reactions and member forces

g. <u>TEMCO-III</u> - TEMCO-III (Reinforced Concrete Sections Under Eccentric Loads and Thermal Gradients) was developed and is maintained by S&L. It analyzes reinforced-concrete sections subjected to combined external loads and thermal gradients. The analysis may be done assuming either a cracked or an uncracked section. Temperature effects are induced in the section by reactions created by translational or rotational restraints

   The analysis may be done for separate or combined action of tensile or compressive axial force, shear force, bending moment, and thermal gradients

The program output includes the location of the neutral axis, stresses in the steel and concrete, and an equilibrium check

h. Additional computer program descriptions are given in Section 3.13.

3.6.2 Protection Against Dynamic Effects Associated With the Postulated Rupture of Piping Outside Containment

The evaluation of pipe breaks of high-energy systems outside the containment includes the main steam and feedwater lines, the HPCI system, the RCIC system, the RWCU system, reactor building heating steam lines, and the CRD system.

Evaluation of the effects of through-wall leakage cracks in moderate-energy piping systems is also reported in this section. The evaluation takes into account the potential damaging effects of either water flooding or spraying from the pipe crack, and considers the overall capability of achieving reactor shutdown and maintaining a cold-shutdown condition.

The plot plan with the relative sizes of major structures is shown in Figure 1.2-5. The reactor portion of the reactor/ auxiliary building, including the primary containment, contains most of the Level I systems and components. Areas within the auxiliary portion of the reactor/auxiliary building that contain Level I systems and components are

a. Main control room and associated heating, ventilating and air conditioning (HVAC) room

b. Switchgear room

c. DC power supply rooms

d. Relay rooms

e. Cable spreading rooms

f. Standby gas treatment compartments

g. HVAC rooms.

The standby ac power system, residual heat removal service water (RHRSW) pumps and emergency equipment service water (EESW) pumps are housed in the RHR complex, a physically separate structure.

The reactor/auxiliary building is mounted on a common foundation in which the reactor portion is separated from the auxiliary portion by a sealed wall. The sealed wall between the reactor building and auxiliary building is for secondary containment purposes. Piping systems whose operating pressure and temperature conditions are consistent with a high-energy classification, as defined in Subsection 3.6.2.1.2.1, are listed in Subsection 3.6.2.1.3.

In all cases investigated, conservatism was exercised in determining the consequences resulting from the postulated pipe break. These results were in turn used to develop design provisions that would provide the necessary protection to mitigate any adverse effects on the ability to achieve a safe reactor shutdown. These design provisions are detailed in the sections describing the adverse conditions they were intended to mitigate, and are summarized in Section 3.6.2.4. The modifications to plant design called out herein provide assurance against unacceptable consequences of the postulated pipe breaks.

The reactor/auxiliary building floor plans are shown in Figures 3.6-13 through 3.6-19. The floor plans include a room, area, and compartment number system that is referred to throughout this section, particularly in the discussion on the environmental effects of high-energy pipe breaks and the moderate-energy pipe breaks. By cross reference, an easy method is provided for following the discussion.

3.6.2.1 Design-Basis Pipe Break Evaluation

The design-basis pipe break was postulated to occur in all high-energy piping systems defined in Subsection 3.6.2.1.2.1. Throughwall leakage cracks were postulated to occur in all moderate-energy piping systems defined in Subsection 3.6.2.1.2.l.

3.6.2.1.1 Approach To Evaluation

The approach to the evaluation of postulated breaks in high-energy fluid systems and through-wall leakage cracks in moderate energy fluid systems is described in this section. The approach takes into consideration the rules and guidance provided in the following:

a. AEC letter dated December 15, 1972, and the errata sheet dated January 12, 1973 (Reference 16)

b. AEC letter dated July 12, 1973 (Reference 17)

c. Branch Technical Position ASB 3-1 (formerly BTP APCSB 3-1), "Protection Against Postulated Piping Failures in Fluid Systems Outside Containment," July 1981 (Reference 18)

d. Branch Technical Position MEB 3-1, "Postulated Rupture Locations in Fluid System Piping Inside and Outside Containment," July 1981 (Reference 19)

In instances where the provisions of the above documents differ, to the extent practical based on the stage of design and construction of the plant, the evaluation methods are based on the guidance provided in the Items c. and d. Branch Technical Positions.

3.6.2.1.1.1 High-Energy Fluid Systems

A summary of the basic approach used in the evaluation of the consequences of high-energy pipe breaks is as follows:

a. Pipe-break locations are as given in Subsection 3.6.2.1.2.2

b. Evaluation of the direct consequences of the break on systems and components required for a safe cold shutdown, taking into consideration the effects of pipe whip, jet impingement, flooding, and environmental conditions (temperature, pressure, and humidity)

c. Evaluation of the ability of Category I structures to withstand the effects of the pipe break, taking into consideration the effects of pipe whip, jet impingement, flooding, pressure, and temperature in combination with the specified seismic event loads and normal plant loads

d. A determination of the remaining systems and components available to ensure and maintain a safe cold shutdown. This determination is made in accordance with Subsection 3.6.2.1.4 and Table 3.6-1. In making this determination, the following assumptions were made with regard to the operability of these systems and components:

1. If the pipe break directly results in a turbine-generator trip or an RPS trip (scram), offsite power is assumed to be unavailable.
2. A single component failure is assumed to occur in addition to the postulated pipe break and any other system or component failures resulting as a direct consequence of this pipe break.
3. Operator action is assumed l0 minutes after pipe break.

e. Assurance that the escape of steam, water, and heat from structures enclosing the ruptured pipe does not prevent occupation of the main control room, nor does it impair the ability of instrumentation, electric power supplies, components, and controls to initiate, actuate, and complete a safety action. In this regard, a loss of redundancy, but not the loss of a function, is permissible.

3.6.2.1.1.2 Moderate-Energy Fluid Systems

A summary of the basic approach used in the evaluation of the consequences of moderate-energy through-wall leakage cracks is given below.

a. For piping systems located in areas containing systems and components important to safety, through-wall leakage cracks were postulated at the most adverse locations to determine the effects from both water spray and flooding. In areas where safety systems and components are not located, the effects of flooding in other areas were considered

b. Evaluation of direct consequences of leakage cracks on systems and components, taking into account the effects of resulting water spray and flooding

c. A determination was made of systems and components available to ensure and maintain a safe cold shutdown

   This determination was made in accordance with Subsection 3.6.2.1.4 and Table 3.6-1. In making this determination, the following assumptions were made with regard to the operability of these systems and components:

   1. If water spray or flooding from the pipe crack directly results in a turbine-generator trip or an RPS trip (scram), offsite power was assumed to be unavailable
   2. A single component failure was assumed to occur in addition to the system or component failures resulting from water spray or flooding. In the event the pipe crack is assumed to occur in one of two or more redundant trains of a dual-purpose essential system, failure of components in the other train or trains of that system was not assumed

3. Operator action was assumed l0 minutes after the pipe crack.

d. It is established that water spray or flooding does not prevent occupation of the main control room, nor does it impair the ability of instrumentation, electric power supplies, components, and controls to initiate, actuate, and complete a safety action

e. In the event a safe shutdown cannot be ensured considering those systems failed or assumed to have failed as a consequence of the leakage cracks, plant modifications were instituted or protection was provided to those systems or components.

3.6.2.1.2 Design-Basis Pipe Break Criteria

3.6.2.1.2.1 Definition of High-Energy Fluid Systems

High-energy fluid systems include those systems that under normal or upset plant conditions are pressurized during operation and one of the following conditions exists:

a. The maximum operating temperature exceeds 200°F

b. The maximum operating pressure exceeds 275 psig.

A fluid system meeting the above definition less than 2 percent of the time is not considered a high-energy fluid system.

Moderate-energy fluid systems include those that during normal plant conditions are either in operation or maintained pressurized under conditions where both of the following conditions exist:

a. The maximum operating temperature is 200°F or less

b. The maximum operating pressure is 275 psig or less.

3.6.2.1.2.2 Design-Basis High-Energy Break/Crack Locations

Break locations are postulated outside the containment in accordance with the following criteria:

a. ASME B&PV Code Section III, Class 1, pipe breaks are postulated to occur at the following locations in each piping run or branch run:

1. The terminal ends

2. Any intermediate locations between terminal ends, where the maximum stress range as calculated by Equation 10, and either Equation 12 or 13, of NB-3653, derived on an elastically calculated basis under the loadings associated with normal and upset plant conditions, exceeds 2.4 S_m

3. Any intermediate location between terminal ends where the cumulative usage factor derived from the pipe fatigue analysis and based on all normal, upset, and testing plant conditions exceeds 0.1

4. Arbitrary intermediate pipe breaks no longer need to be postulated, per Generic Letter 87-11

b. ASME B&PV Code Section III, Class 2 and 3, pipe breaks are postulated to occur at the following locations in each piping run or branch run:

1. The terminal ends

2. Any intermediate location between terminal ends, where the stresses as calculated by Equations 9 and 10 of NC/ND-3652, derived on an elastically calculated basis under the loadings associated with normal and upset plant conditions, exceed 0.8 (1.2 S_h + S_a)

3. Arbitrary intermediate pipe breaks no loner need to be postulated, per Generic Letter 87-11

c. In situations where detailed stress analyses of ASME B&PV Code Section III, Class 2 and 3, piping systems are not used to select postulated break locations, and, in the case of those high-energy systems outside the containment that are not analyzed to ASME III Code requirements, break locations are conservatively assumed to occur at all fitting welds where a break has the potential of causing unacceptable damage to systems and/or components necessary to effect and/or maintain a safe shutdown.

d. The break analysis of seismically analyzed non-ASME class piping is postulated according to the requirements for ASME Class 2 and 3 piping.

For those portions of the piping passing through the primary containment penetrations and extending to the first outboard isolation valve, pipe breaks were not postulated since the piping was conservatively designed and restrained beyond the valve such that, in the event of a postulated pipe break outside the containment, the transmitted pipe loads will neither impair the operability of the valve nor affect the integrity of the piping of the containment penetration.

Design criteria for piping between the primary containment and outboard isolation valves provide for maximum stresses considering all normal and upset conditions as calculated by the equations in Paragraph NB-3653 of ASME B&PV Code Section III, which may not exceed the following limits:

a. If Equation 10 results in $S < 2.4\ S_m$, no other requirement need be met

b. If Equation 10 results in $S > 2.4\ S_m$, then Equations 12 and 13 must result in $S < 2.4\ S_m$ and Equation 14 must yield a value of $U < 0.1$.

3.6.2.1.2.3 Design-Basis Break Types and Orientation

The following high-energy breaks are postulated at the locations described in Subsection 3.6.2.1.2.2:

a. Circumferential breaks in piping runs and branch runs exceeding 1 in. nominal pipe size

b. Longitudinal breaks in piping runs and branch runs 4 in. nominal pipe size and larger

c. Longitudinal breaks are not postulated at terminal ends.

Longitudinal breaks are considered parallel to the axis of the pipe and oriented at any point around the pipe circumference.

Circumferential breaks are considered to be perpendicular to the axis of the pipe.

The break area is equal to the internal cross-sectional area of the ruptured pipe in the case of circumferential breaks and longitudinal breaks. Longitudinal breaks extend a distance of one diameter on each side of the break location.

3.6.2.1.2.4 Design-Basis Through-Wall Leakage Cracks

Through-wall leakage cracks in piping exceeding 1 in. nominal pipe size were generally postulated at the most adverse locations in moderate-energy piping systems located in areas that contain systems and components important to safety, but in which no high-energy systems are present. However, through-wall leakage cracks need not be postulated in portions of piping where the calculated stresses satisfy BTP MEB 3-1 (reference 19) exclusion criteria. These through-wall leakage cracks were assumed to be half the pipe diameter in length and half the pipe wall thickness in width.

3.6.2.1.3 Identification of Energy Systems

The high- and moderate-energy systems included in this evaluation are identified below.

3.6.2.1.3.1 High-Energy Piping Systems

The piping systems located inside the reactor/auxiliary building but outside the primary containment and meeting the definition of high-energy systems, defined in Subsection 3.6.2.1.2.1, are

a. Main steam

b. Feedwater

c. High-pressure coolant injection system steam supply

d. Reactor core isolation cooling system steam supply

e. Reactor water cleanup

f. Control rod drive insert and withdrawal lines and charging line

g. Reactor building heating steam lines.

The piping systems listed below have normal/upset pressure and/or temperature conditions that fall into the high energy category; however, since these systems are operated less than 2 percent of the time, they are not considered high-energy systems. This is consistent with the definitions presented in Subsection (3.6.2.1.2.1).

These systems are

a. Residual heat removal system

b. Core spray system

c. Reactor core isolation cooling system discharge

d. High pressure coolant injection system discharge.

3.6.2.1.3.2 Moderate-Energy Systems

Appropriate portions of the following piping systems meeting the definition of moderate-energy systems as defined in Subsection (3.6.2.1.2.1) were evaluated:

a. Residual heat removal system

b. Core spray system

c. High-pressure coolant injection system

d. Fire protection system

e. Reactor core isolation cooling system

f. Fuel pool cleanup system

g. Reactor building closed cooling water system

h. Service water

i. Emergency equipment cooling water

j. Reactor water cleanup system

k. Control rod drive system

l. Torus water management system

m. Chilled water system

n. Reactor building heating steam system

o. Supplemental cooling chilled water system.

3.6.2.1.4 Identification of Systems and Components Required for Safe Shutdown

The systems and components that contribute to attaining and maintaining a safe shutdown are listed in Table 3.6-1. The listing is broken down into two categories. The first, General Requirements, indicates those systems or components that are required regardless of the piping break being evaluated. The second, Specific Requirements, indicates the additional systems and components required for specified pipe breaks (i.e., main steam line, feedwater line, etc.).

These systems and components were evaluated with respect to the effects of a postulated break of a high- or moderate-energy fluid system.

3.6.2.1.5 Assessment of Acceptability

3.6.2.1.5.1 Components and Equipment

From the approach to evaluation defined in Subsection 3.6.2.1.1, the component and/or equipment was evaluated and an assessment made of its acceptability to the hypothetical accident by the following:

a. The loss of function of a component is acceptable if an analysis can show that a redundant component or backup system is available to perform the component's safety function and to ensure safe reactor shutdown

b. An evaluation of a component's capability to perform is based on its ability to function in the environmental conditions of flooding present after the postulated pipe break

c. An evaluation of a component's capability to perform is based on its ability to withstand the impact forces of an impacting pipe. Throughout the evaluation, the impacted component is conservatively assumed incapable of performing its function. An exception to this assumption is the case where one pipe impacts another pipe of equal or greater size and equal or greater wall thickness

d. An evaluation of a component's capability to perform is based on its ability to withstand the environmental conditions of pressure, temperature, and humidity during blowdown compared to the allowable pressure, temperature and humidity conditions of the equipment design specifications and/or test qualifications

e. An evaluation of a component's capability to perform is based on its ability to function in the conditions of high-energy jet impingement.

3.6.2.1.5.2 Structures

In accordance with the approach to evaluation (Subsection (3.6.2.1.1), plant structures and structural components have been analyzed to demonstrate ability to withstand the pipe whip impact, jet impingement, temperature, pressurization, and flooding hydrostatic loads resulting from postulated ruptures. Plant structures include those located within the reactor/auxiliary building. The overall criteria governing acceptability of structural loads resulting from postulated ruptures are as follows.

a. Damage to any structure caused by consequences of a postulated rupture, either directly or indirectly through failure of an adjacent structure, may not impair the function of any systems or equipment required to place and maintain the reactor in a cold-shutdown condition

b. The design leaktightness of the primary containment shall be preserved in the event of a postulated rupture

c. The structural integrity of the main control room to achieve a safe cold shutdown shall be preserved in the event of a postulated rupture.

The criteria for acceptability of loads on structural components resulting from postulated ruptures are given in Subsection (3.8.4.5.1).

A dynamic response amplification factor of 2.0 was used to account for the dynamic effects of impact loading when used in conjunction with a static evaluation. In those cases where a dynamic evaluation was performed, the amplification factor was explicitly determined through the dynamic analysis techniques.

In the analysis of structural components such as single beams or slabs whose failure would not jeopardize the overall structural integrity, the effects of direct stress, flexure, shear, buckling, and of the reversal of normal design loads due to pipe rupture were considered. These analyses were generally performed using limit analysis techniques, such as collapse load analysis for beams and frames and yield line theory for concrete slabs, which account for resistance of structural elements into their plastic range. The allowable loads were determined on the basis of the maximum ductility factors in Table 3.6-2, derived from Reference 20. The maximum deflections under the applied loads did not exceed the applicable ductility factor times the deflection at first yield in the structure.

Maximum section strength of concrete structures was computed using the ultimate strength design method. Maximum section strength of steel members was based on the assumption of elastic-perfectly-plastic material properties and the plastic design criteria in References 21 and 22. Material yield strength was multiplied by the dynamic increase factors specified in Table 3.6-3, derived from Reference 23 for analyses under rapidly applied pipe rupture loads. Statistical variation in material properties and elevated temperature effects was accounted for in a conservative manner.

The methods used in the structural analyses are presented in Subsection 3.6.3.

3.6.2.1.6 Identification of Analysis Requirements

Not all postulated pipe-break locations in the main steam or feedwater lines were subjected to a dynamic pipe whip analysis since, under certain conditions, the loss of a component is acceptable (Subsection 3.6.2.1.5.1).

The pipe ruptures are assumed at locations where the consequence of the pipe whip, either due to the longitudinal or the circumferential pipe ruptures, has the worst potential effect with respect to a particular system or component required for safe shutdown (Table 3.6-1). All areas of postulated pipe break were conservatively examined. For areas where the damage levels were acceptable, a further evaluation was not required. For areas where a damage potential existed and this damage would preclude the safe shutdown of the reactor, these areas were so listed and further evaluated.

One or more of the exclusion criteria defined in Table 3.6-4 and listed below were used to locate areas where no damage potential exists from pipe whip or jet impingement, or where damage would not preclude the safe reactor shutdown or maintenance of primary containment:

a. Separation

b. Distance

c. Redundancy

d. Backup

e. Self-elimination

f. Size

g. Low pressure

h. Barrier

i. Testing condition

j. Scarcity of usage

k. Safe area

l. Minimum size

3.6.2.2 High-Energy Pipe Break Analyses

The high-energy pipe-break analyses for those systems identified in Subsection 3.6.2.1.3.1 are reported in this section.

3.6.2.2.1 Main Steam Line Break in Steam Tunnel

The evaluation of the consequences of a break in the main steam line was carried out as described below.

Breaks of main steam lines in the turbine building were not subject to detailed evaluation because the equipment located in the Turbine Building steam tunnel is either not required for safe shutdown or has been analyzed and found to be able to perform its shutdown function in the conditions present after a break. The only consequences of such a break would be the backflow of steam into the auxiliary building comparable to that resulting from a break in the steam tunnel.

3.6.2.2.1.1 Review of Potential Damage

A review of the potential damage resulting from the break of a main steam line was carried out in accordance with Subsection 3.6.2.1.6 to identify the need for a dynamic pipe whip or jet impingement analysis. The review took into consideration the equipment required to ensure a safe shutdown as discussed in Subsection 3.4 and summarized in Table 3.6-1. The results of this review are documented in Reference 24.

3.6.2.2.1.2 Pipe Break Analysis

The main steam lines outside the containment are routed in an enclosed concrete tunnel through the auxiliary building and into the turbine building, as shown in Figure 3.6-20. The steam tunnel, which serves to isolate the main steam lines from most of the plant safety-related equipment, is provided with relief doors to alleviate pressures that would result in the event of a pipe rupture. In accordance with the criteria given in Subsection 3.6.2.1.2.2, longitudinal and circumferential design-basis ruptures were postulated at each end of each elbow in the main steam lines between the outboard isolation valves and the steam tunnel exit to the turbine building. Critical crack breaks were also postulated at all adverse locations in this piping. As an alternative to postulating ruptures between the containment and outboard isolation valves, the piping was designed to meet the normal operating stress criteria presented in Subsection 3.6.2.1.2.2, and was provided with rigid restraints to limit transmission of bending and torsional loads through the valves in the event of a downstream rupture. The postulated rupture locations are shown in Figure 3.6-20.

Analyses were performed to assess quantitatively the pipe whip, jet impingement, compartment pressure and steam environment effects of these postulated ruptures. Since the routing of all four main steam lines in the tunnel is nearly identical, in most cases the analyses were performed for only one line and the results extrapolated to the other three. The predicted rupture effects were evaluated to identify cases in which unacceptable damage to structures, systems or components required for shutdown could result. Finally, designs were developed for modifications required to prevent the occurrence of any unacceptable damage.

A description of the rupture effects analyses, the damage evaluations, and the required modifications for the main steam lines in the steam tunnel is given in the following sections.

3.6.2.2.1.2.1 Short-Term Blowdown Analysis

Blowdown analyses were performed for postulated main steam line breaks using the methods presented in Reference 25. The resulting thrust time-histories were then used as input for subsequent pipe whip and jet impingement analyses, using the methods outlined in Subsection 3.6.3.

To determine conservatively the thrusts resulting from the postulated ruptures, the following assumptions were made:

a. The reservoir pressures in the main steam system were assumed to be 1060 psia

b. On the reactor side of the breaks, the flow limiters were assumed to be the only resistance to flow

c. On the turbine side of the breaks, the lines between the break and the header were considered the only resistance to flow.

For the analyses, the RPV and the main steam header were assumed to be reservoirs. Since the routing of the four main steam lines in the area of interest is essentially the same, only one line was analyzed. The analyses were carried out for a time sufficient to allow for the use time of all restraint reactions. Typical thrust time histories resulting from the analyses are shown in Figure 3.6-21.

3.6.2.2.1.2.2 Pressurization and Environmental Analyses

These analyses were performed to predict maximum compartment pressures and steam environment conditions resulting from postulated design-basis ruptures in the steam tunnel. The tunnel is provided with two sets of pressure relief doors for venting. The upper set of pressure relief doors opens into the turbine building; the lower set opens into the first floor of the auxiliary building.

The environmental analyses were evaluated for uprated power conditions. Changes in the governing parameters were used to scale the affected environmental conditions. This resulted in a small increase in peak temperatures and pressure.

Immediately after a postulated main steam line break in the steam tunnel, saturated steam will flow from the break. However, due to the rise in reactor water level during blowdown, a flashing two-phase mixture of steam and water will soon begin to flow out of the break. The mass flow rate of the two-phase mixture is considerably higher than that of the saturated steam and continues until terminated by the closure of the MSIV.

The steam exiting from the break will pressurize the tunnel, and the pressure relief doors will be forced open by the pressure differential between the tunnel and the adjacent compartments. Within a few milliseconds, a mixture of steam and air will be flowing through the upper and lower sets of pressure relief doors into the turbine building and the first floor auxiliary building.

The operating condition analyzed is based on MSIV closure time of 10.5 sec. The break mass used in the calculation is shown in Figure 3.6-22 (Reference 26). Flow from the upstream side of the break was calculated assuming critical flow at the flow limiter of the broken line. Flow from the downstream side of the break is supplied by the 52 in. manifold which is in turn supplied by the three unbroken steam lines. Flow through the downstream side of the break is limited by critical flow at the end of the broken pipe.

A break in one of the main steam lines in the steam tunnel would affect only the steam tunnel, first floor Auxiliary Building, and the Turbine Building (Figure 3.6-23). Break mass and energy would be vented directly to the first floor Auxiliary Building through the lower steam tunnel pressure relief doors and then to the Turbine Building through large openings in the east wall of the first floor Auxiliary Building. Mass and energy would also be released directly from the steam tunnel to the Turbine Building second floor through the upper pressure relief doors.

Isolation of the main steam line break would be initiated almost immediately as the pressure drop across the flow restrictor for the broken line exceeds the setpoint of redundant pressure differential trip units, which send a signal to the nuclear steam supply systems (NSSS). The NSSS deenergize the main steam isolation valve solenoids for the broken and unbroken lines initiating valve closure. In addition, redundant steam tunnel high temperature leak detection trip units would also initiate MSIV closure.

The environmental responses for the steam tunnel and first floor Auxiliary Building due to a main steam line break are discussed in this section. The Turbine Building second floor confined area is included in the main steam line break model. However, the environmental response of this area is not discussed since failure of the safety related instrumentation and third MSIVs located in the Turbine Building will not prevent safe shutdown of the plant.

The plot of break flow versus time used in the computer model is shown in Figure 3.6-22. The "steps" in this plot correspond to the times at which a two-phase mixture reaches the upstream and downstream ends of the break. As can be seen in the plot, closure of the isolation valve does not begin to affect the break flow until approximately 8.6 seconds. The MSIV is closed at 10.5 seconds. However, the break flow is continuous to 13.0 seconds due to expansion of the inventory of steam and water in the piping downstream of the MSIV.

Pressure response versus time plots are shown in Figures 3.6-24 and 3.6-27 for the steam tunnel and Auxiliary Building first floor. The peak pressure value of 5.1 psig occurs in the steam tunnel at 8.6 seconds after the break. The time corresponds to the end of the highest plateau of the break flow curve. The pressure profile decreases from this peak to a negative pressure at 13.0 seconds due to condensation of the steam on cooler wall and floor surfaces.

The peak first floor Auxiliary Building pressure of 0.9 psig occurs at approximately 0.8 second after the break.

The plots of temperature versus time for the steam tunnel and first floor Auxiliary Building are shown in Figures 3.6-25 and 3.6-28, respectively. The temperatures in both rooms climb to the saturation temperature for the given room pressure as the air is exhausted through the vent openings. The peak temperatures are 228°F and 215°F for the steam tunnel and first floor Auxiliary Building, respectively. The relative humidity in both rooms reaches 100 percent within 0.5 second and remains at this level for the duration of the evaluation. Plots of humidity versus time are shown in Figures 3.6-26 and 3.6-29. The effect of the resultant temperature and humidity on safe shutdown equipment has been evaluated.

3.6.2.2.1.2.3 Pipe Whip Evaluation

Analyses were performed to assess pipe whip consequences on safety-related structures, systems, and components in the steam tunnel. Since most considerations and potential problems in this area are common to the main steam and feedwater lines, these systems will be discussed together in this section.

The calculated blowdown thrust forces for main steam and feedwater ruptures are given earlier in this subsection. The methods used in the pipe whip analyses are given in Subsection 3.6.3. Details of the structural evaluation for pipe whip impact are also given in Subsection 3.6.3; a brief summary of results of this evaluation follows:

a. Loads from pipe whip impact from main steam and feedwater line breaks could cause failure of the lower tunnel floor at elevation 583 ft 6 in.

b. Loads from pipe whip impact from a main steam line break could cause failure of the 4-ft 4-in. west wall between the steam tunnel and reactor building.

c. Pipe whip from a break of either line could induce unacceptable stresses in the isolation valves on the pipe between the valves and the primary containment

d. The remaining steam tunnel walls, the upper tunnel floor at elevation 626 ft 6 in., and the tunnel ceiling are all adequately designed to withstand pipe whip impact.

Designs were developed for main steam and feedwater line pipe whip restraints as described later in this subsection. The restraints are intended to prevent occurrence of the unacceptable consequences identified in Items a and b above. In addition, the combined action of the pipe whip restraints and the anchor framework just outside of main steam and feedwater flued heads (anchor framework is designed for pipe-break loads) prevents damage to the isolation valves, to the containment penetrations, and to the containment shell, caused by the transmission of bending and torsional loads through the piping in the event of a postulated rupture.

3.6.2.2.1.2.4 Jet Impingement Evaluation

Jet impingement effects were postulated for the main steam and feedwater line breaks in the vicinity of the isolation valves. The dynamic force on each valve was calculated in accordance with the methods presented in Subsection 3.6.3 and a stress evaluation of each valve and its interconnected piping was undertaken. It was determined that, although the MSIVs and feedwater check valves could safely withstand the dynamic impingement force, the HPCI, steam drain, and RCIC isolation valves' motor operator linkage and structure would be subjected to stress levels above the allowable value of 2 S_m (42,000 psia). In addition, the tunnel floor at elevation 583 ft 6 in. would fail as a result of jet impingement. A direct jet impingement would cause failure of the lower pressure relief doors; however, the jet would not cause failure to the 4-ft 4-in. shield wall outside the doors in the auxiliary building. The pressure relief doors are not required for safe shutdown.

To protect against the loss of function of the HPCI, RCIC, and steam drain isolation valves as a result of the postulated pipe break, jet impingement barriers were incorporated as a part of the pipe restraint system as shown in Figure 3.6-30, Sheets 1 through 3. A jet impingement barrier is also provided to protect the tunnel floor.

3.6.2.2.1.2.5 Structural Evaluation

Steam Tunnel Description

The lower portion of the steam tunnel (Figures 3.6-31 and 3.6-32) is 32 ft 9 in. long by 30 ft 0 in. wide with a 2-ft-thick slab floor at elevation 583 feet 6 in. All floor and wall slabs are doubly reinforced. The lower floor slab contains No. 7 steel reinforcing bars at 12 in. and is supported on 27WF160 and 27WF145 I-beams spaced 7°30' running in a radial pattern from the containment center. The north and south walls are reinforced concrete 4 ft 8 in. thick containing No. 9 steel reinforcing bars at 12 in. The west wall (next to the containment) is 4 ft 4 in. thick with No. 7 steel reinforcing bars at 12 in. The east wall contains 20 pressure relief panels 3 ft 6 in. by 5 ft 6 in. Directly outside the pressure relief panels, in the auxiliary building, is a 4-ft 4-in.-thick reinforced-concrete wall containing No. 8 steel reinforcing bars at 12 in. Joining this wall are 3-ft-thick side walls containing No. 7 steel reinforcing bars at 12 in. This outside structure provides radiation shielding.

Entrance to the lower portion of the steam tunnel may be made through a personnel door or through an equipment passage. The 3 x 7 ft personnel door is accessible to the outside through a side alcove. It is a seal-tight steel door, designed to withstand a 2.5 psig inward pressure and an outward pressure greater than 7 psi. The 6 x 8 ft equipment passage may be opened from the inside only by removing solid concrete shield blocks, unbolting a 3/8-in. steel plate, and then removing concrete shielding plank from the side of the aisle. This closure was designed for a 2.5 psi inward pressure and outward pressure greater than 7 psi (Reference 26).

Effects of Pipe Whip and Jet Impingement

The evaluation of tunnel structural elements for pipe whip impact and jet impingement loads was based on the criteria given in Subsection 3.6.2.1.5.2 and the methods given in Subsection 3.6.3.

The calculated blowdown thrust forces for main steam and feedwater ruptures, the methods for determination of jet impingement loads from these thrust forces, and the methods used in the pipe whip analyses are also given in Subsection 3.6.3. Yield line theory was used for analysis of concrete slabs (References 28 through 31).

Pipe Whip Restraints and Jet Impingement Shields

The main steam, feedwater, and HPCI steam piping in the steam tunnel are equipped with two restraint assemblies. These assemblies, acting in conjunction with the anchor framework just outside the main steam, feedwater, and HPCI steam flued heads, prevent the occurrence of the unacceptable consequences identified earlier in this section. Final designs are shown in Figure 3.6-30, Sheets 1 through 3, and are discussed below.

The restraint assemblies each consist of an assembly of six elastically designed plane frames situated around the main steam, feedwater, and HPCI steam piping immediately adjacent to the drywell penetrations, and an assembly of six energy-absorbing U-bolt devices situated on the main steam and feedwater lines directly above and east of the lower frames. The lower framework assembly is equipped with jet impingement shielding. Functions of these assemblies are listed below.

a. The lower assembly frames act as normal operating pipe supports and as pipe whip restraints. Lateral and vertical pipe motion is prevented; axial motion is permitted. The assembly frames are shimmed to fit around the pipes, allowing for out-of-roundness and diametric expansion

b. The lower assembly frames and shields prevent the following:

    1. Pipe whip onto, and subsequent failure of, the steam tunnel floor at elevation 583 ft 6 in.

    2. Jet impingement onto, and subsequent failure of, the steam tunnel floor at elevation 583 ft 6 in., and the HPCI, RCIC, and steam drain isolation valves

    3. Overloading of the isolation valves, piping between the isolation valves and the drywell penetrations, the drywell penetrations, and the containment shell, caused by transmission of pipe-rupture loads by the main steam, feedwater, and HPCI steam piping, acting individually or with the upper assembly.

c. The upper assembly restraints clear the pipes during all normal operating conditions, and act only in the event of a rupture. They prevent the following:

    1. Pipe whip onto, and subsequent failure of, the north, south, and west walls of the steam tunnel, adjacent to their locations

    2. Overloading of the isolation valves, piping between the isolation valves and drywell penetrations, the drywell penetrations, and the containment shell as described in Item b above. These restraints act with the lower assembly.

Final design of the lower and upper assemblies was based on the criteria given in Subsection 3.6.2.1.5.2, and the methods given in Subsection 3.6.3. The material used for the lower assembly members and the U-bolt attachment structures in the upper assembly is ASTM A 588 steel. The energy-absorbing U bolts used in the upper assembly are made of A479, type 304, stainless steel. Blowdown thrusts used for the design are shown in Figures 3.6-33 and 3.6-34. A value of 1.26 PA (where P is the operating pressure of the line and A is the flow area of the pipe) was used for the design blowdown thrust for all HPCI steam piping restraints. The thrusts were assumed to act instantaneously and to remain constant for the duration of the blowdown event.

Effect of Tunnel Pressurization on Steam Tunnel Structures

As indicated in Subsection 3.6.2.2.1.2.2, the calculated pressure resulting from a main steam line break in the steam tunnel was 5.1 psig for an MSIV closure time of 10.5 sec. The pressure resulting from the conservative 10.5 sec closure time of the MSIVs does not have an adverse effect on the structures.

The lower floor at elevation 583 ft 6 in. is the critical structure in the tunnel. It was designed for the load combinations and acceptance criteria shown in Table 3.6-5. The floor slab has been evaluated for a maximum pressure of 5.1 psig and found to be adequate.

All other structural elements of the steam tunnel will withstand higher pressures.

3.6.2.2.2 Feedwater Line Breaks in Steam Tunnel

The evaluation of the consequence of a break in the feedwater lines was carried out as described below.

3.6.2.2.2.1 Review of Potential Damage

As in the case of the main steam line break, a review of the potential damage caused by a feedwater line break was made to identify the need for a dynamic pipe whip or jet impingement analysis. The results of this review are documented in Reference 24.

In view of these results, a dynamic pipe whip and jet impingement analysis was carried out.

3.6.2.2.2.2 Feedwater Break Analysis

The feedwater lines outside the containment are routed in the same concrete tunnel through the Auxiliary Building and into the Turbine Building. In accordance with the criteria given in Subsection 3.6.2.1.2.2, longitudinal and circumferential design-basis ruptures were postulated at each end of each elbow in the feedwater lines between the outboard isolation check valves and the steam tunnel exit to the turbine building. Critical crack breaks were postulated at all adverse locations in this piping. As an alternative to postulating ruptures between the containment and outboard isolation check valves, the piping was designed to meet the normal operating stress criteria presented in Subsection 3.6.2.1.2.2, and was provided with restraints to limit transmission of bending and torsional loads through the valves in the event of an upstream rupture. The postulated rupture locations are shown in Figure 3.6-35.

Analyses were performed to assess quantitatively the pipe whip, jet impingement, and flooding effects of these postulated ruptures. Since the routing of the two feedwater lines in the tunnel is nearly identical, in most cases the analyses were performed for only one line and results extrapolated to the other line. The predicted rupture effects were evaluated to identify cases in which unacceptable damage to structures, systems, or components required for shutdown could result. Finally, designs were developed for modifications required to prevent occurrence of unacceptable damage.

A description of the rupture effects analyses, the damage evaluations, and the required modifications for the feedwater lines in the steam tunnel is given in the following sections.

3.6.2.2.2.2.1 Short-Term Blowdown Analysis

Blowdown analyses were performed for the postulated feedwater line breaks using the methods presented in Reference 25. The resulting thrust time-histories were then used as input for subsequent pipe whip and jet impingement analyses using the methods outlined in Subsection 3.6.3.

To determine conservatively the thrusts resulting from the postulated ruptures, the following assumptions were made:

a. The reservoir pressures for the feedwater line were assumed to be 1135 psia

b. Only the so-called "slower wave" (Reference 25) was considered in evaluating "wave force" (Reference 25) components on the open segments of piping.

As the routing of the two feedwater lines in the area of interest is essentially the same, only one line was analyzed.

As a result of check-valve closure, the thrust time-histories have the following characteristics.

a. Reactor side circumferential break thrusts do not reach a steady value that is larger than the initial value because the check valves between the breaks and the RPV close during the blowdown event

b. Longitudinal break thrusts have the same steady-state values as pump side circumferential break thrusts at the same location because check-valve closure prevents feeding of the break from the reactor side.

The analyses were carried out for a period of time sufficient to allow for the rise time of all restraint reactions. Typical thrust time-histories resulting from the analyses are shown in Figures 3.6-33 and 3.6-34.

3.6.2.2.2.2.2 Flooding Analysis

This subsection presents the analysis of flooding effects due to a postulated feedwater pipe rupture outside containment. The various locations that could be flooded are discussed as well as the assumptions and flow events following postulated pipe breaks. The results of the analysis are presented last.

Figure 3.6-36 shows the bottom floor of the steam tunnel and the first floor of the Auxiliary Building. The lower west portion of the steam tunnel is shown in Figure 3.6-35. The tunnel is provided with a lower pressure relief door composed of steel panels that individually swing up on hinges. Along the east wall of the Auxiliary Building first floor are large openings to the Turbine Building. The bottoms of these openings are located 6 ft above the floor.

Figure 3.6-37 shows a block diagram of the main features of the feedwater system. During normal plant operation, the condensate is pumped from the hotwell through various subsystems such as polishing demineralizers and the feedwater heaters to the reactor.

The entire feedwater system is classified as high energy. The two feedwater lines are routed from the reactor feed pumps on the first floor of the Turbine Building up to the No. 6 feedwater heaters located on the Turbine Building third floor. The feedwater lines are headered together downstream of the No. 6 heaters and then branch again into two parallel lines to drop down through the third floor slab into the second floor where they enter the steam tunnel.

The lines penetrate the steam tunnel upper pressure relief doors and continue parallel to the main steam lines until they enter primary containment.

As with the main steam lines, only that portion of the feedwater lines on the reactor side of the upper pressure relief doors is considered for pipe break. Feedwater breaks upstream of the doors are not evaluated since no safety-related equipment is located in the Turbine Building except for the third set of MSIVs which are not required for mitigation of break effects. Adequate seals exist to prevent Turbine Building breaks from affecting the Reactor and Auxiliary Buildings.

The analysis of the feedwater line break scenario assumes failure of the feedwater startup control valve in the open position. This single failure was selected to maximize flooding in affected areas of the plant. The feedwater line break would not be isolated until the condensate and heater feed pumps trip on low hotwell level. Operator action was not considered for the 8-1/2 minutes during which water flows through the postulated pipe break.

The basic flood model for the feedwater line break in the steam tunnel is shown in Figure 3.6-38. The fluid released from the feedwater break would be dispersed over the steam tunnel floor. A portion of the break fluid would flash to steam and pressurize the steam tunnel for a short period following the break.

The water dispersed over the steam tunnel floor would begin to drain to the northeast corner room sump. However, the break flow will greatly exceed the capacity of the floor drains and the steam tunnel flood depth would continue to increase. At a flood elevation of 584 ft 9 in. water would begin to flow through the equipment drain in the steam tunnel to the southeast corner room sump. As the steam tunnel flood depth continues to rise, the head of water would open the pressure relief doors allowing break fluid to enter first floor Auxiliary Building.

The first floor Auxiliary Building floor drains have been capped. Therefore, flow through the drain lines in this room does not occur.

As the first floor Auxiliary Building flood depth continues to increase, flow through numerous equipment drains whose funnels are at various elevations would occur. The equipment drains from first floor Auxiliary Building header join those from the steam tunnel, which lead to the southeast corner room.

The steam tunnel and first floor Auxiliary Building are watertight to flood depths of 10 and 4 feet, respectively. Therefore, these are the only rooms directly affected by flooding. Flooding in other rooms results only from floor and equipment drain flow. Floor and equipment drains flow to the northeast and southeast corner rooms, respectively, will exceed the capacity of the sumps. Therefore, the flood depth in these rooms will continue to increase. If the flood depths increase to a certain level, flooding of the torus and HPCI rooms will occur.

Table 3.6-6 indicates break flow rate and the sequence of events following a feedwater line break in the steam tunnel. The table is based on the assumption that the feedwater startup control valve failed in the open position. The sequence of events after the break is discussed below.

Immediately following the break, feedwater flow increases to 43,000 gpm, tripping the reactor feed pumps on low suction pressure (300 psig). Tripping the reactor feed pumps does not decrease the break flow because the heater feed, heater drain, and condensate pumps are capable of maintaining this flow rate. This flow rate remains constant until 57 seconds after the break when the fast closure reactor feedwater pump discharge valves are closed. Flow is then diverted through the startup level control valve and the break flow is reduced to 21,800 gpm. At 64.0 seconds, the heater number 5 level control valves are fully closed and heater drain pump flow is isolated from the break. As a result, the break flow decreased to 20,000 gpm and remains at this level until 447 seconds, at which time the condensate and heater feed pumps trip on low hotwell level totally isolating the break. The inventory of water in the piping downstream of the reactor feed pumps is then assumed to be discharged from the break over a one-minute period. The steam tunnel drains to the southeast corner room through equipment drains and the northeast corner room through floor drains.

The steam tunnel and Auxiliary Building first floor, where the Reactor Building closed cooling water (RBCCW) heat exchanger room is located, reach peak flood depths of 4 ft 6 in. and 3 ft 10 in., respectively. The steam tunnel and RBCCW heat exchanger room flood elevations then begin to decrease due to flow through the steam tunnel floor and equipment drains (DRN). The RBCCW heat exchanger room drains to the southeast corner room of the Auxiliary Building.

The northeast corner room peak flood depth of 7 ft is reached due to floor drain flow into the sump. Equipment drain flow causes flooding in the southeast corner room to a depth of 14 ft approximately 10 hours after the line break, at which point water would begin to spill into the torus and HPCI rooms. The torus room flood depth reached 14.8 in. and the HPCI room would reach a peak flood depth of 78.8 in. based on worst case door failure combinations for the given room.

The safe shutdown path considers systems necessary to scram the reactor, depressurize the reactor, and to establish and maintain core cooling utilizing the residual heat removal (RHR) system. For feedwater line breaks, the availability of offsite power maximizes the consequential effects of flooding. Therefore, offsite power was assumed to be available. If offsite power is not available, the condensate and heater feed pumps will trip, thus ending the break scenario sooner. No water will be lost from the reactor, whether offsite power is available or not, since the feedwater check valves are designed to close immediately. HPCI will restore water level to compensate for the loss of feedwater flow. The vessel can be manually depressurized by using the main steam safety relief valves. After pressure reduction, the operator places the RHR system (Division 1 or Division 2) in the low pressure coolant injection mode. The residual heat removal service water (RHRSW) system is used as the heat sink in the RHR cooling mode.

The evaluation shows the first floor Auxiliary Building (RBCCW heat exchanger room), the northeast corner room (Division 1 core spray and reactor core isolation cooling (RCIC)), the southeast corner room (Division 2 core spray), high pressure coolant injection (HPCI) and the torus room flooded. Under these conditions the plant can achieve safe shutdown by using the main steam safety relief valves and both divisions of RHR.

3.6.2.2.2.2.3 Effects of Feedwater Jet Impingement and Pipe Whip

The analyses of the effects of pipe whip and jet impingement for feedwater line rupture in the steam tunnel have been discussed previously, in conjunction with the analyses for main steam line ruptures in the steam tunnel, in Subsections 3.6.2.2.1.2.3 and 3.6.2.2.1.2.4.

3.6.2.2.2.2.4 Structural Evaluation

The evaluation of structural components for ability to withstand loads resulting from postulated feedwater line ruptures in the steam tunnel closely parallels that previously described in Subsection 3.6.2.2.1.2.5 for postulated main steam line ruptures, and details will not be repeated here.

The pipe whip impact and jet impingement loads resulting from a postulated feedwater line rupture could cause failure of the lower tunnel floor at elevation 583 ft 6 in.; however, the restraints described in Subsection 3.6.2.2.1.2.5 are intended to prevent this failure. The tunnel walls, upper floor at elevation 626 ft 8 in., and ceiling are adequately designed to withstand the pipe whip impact and jet impingement loads that would result from the postulated feedwater line ruptures.

The 1.9 psig maximum lower tunnel floor hydrostatic pressure that could result from flooding after a postulated feedwater line break is less than the 5.1 psig steam pressure that would follow a postulated steam line break with a 10.5 sec MSIV closure. It has been previously determined that the lower tunnel floor is adequately designed to withstand this pressure. Pressurization effects from flashing feedwater are also bounded by the main steam line break.

The structural evaluation also indicated that the auxiliary building is adequately designed to withstand the 1.7 psig hydrostatic pressure resulting from maximum possible flooding on the first floor.

3.6.2.2.3 High Pressure Coolant Injection System

The evaluation of the consequences of a pipe break in the HPCI system was carried out as described below and in references 24, 33 and 64.

The only portion of the HPCI system piping that is classified as high energy is the HPCI turbine steam supply line. This line exits from the primary containment into the steam tunnel near the main steam and feedwater lines. The line then drops through the steam tunnel floor to the torus area, where it is routed adjacent to the torus before entering the HPCI pump room (room SB7), where the line connects to the HPCI turbine.

Figure 3.6-39 shows the HPCI turbine steam supply line and its relation to building structures and components.

3.6.2.2.3.1 Review of Potential Damage

As in the case of the main steam and feedwater line breaks, a review of the potential damage resulting from a break in the HPCI steam line was carried out in accordance with Subsection 3.6.2.1.6 to identify the need for a dynamic pipe whip or jet impingement analysis. The review took into consideration the equipment required to ensure a safe shutdown, as discussed in Subsection 3.6.2.1.4 and listed in Table 3.6-1.

This review, combined with other considerations such as existing pipe restraints, established the following areas of concern with respect to pipe whip and/or jet impingement:

a. Effect on the HPCI isolation valve and containment penetration

b. Effect on the torus in the vicinity of the HPCI line in the torus room.

In addition, the environmental effects investigation was limited to a break in the HPCI room.

3.6.2.2.3.2 Pipe-Break Analysis

The criteria given in Subsection 3.6.2.1.2.2 have been applied in determining the locations of the postulated pipe breaks. The terminal end break locations are defined at the connection to the outboard containment isolation valve and the connection to the HPCI turbine stop valve. The Class 1 piping between the containment and the outboard isolation valve is designed to meet the normal operating stress criteria presented in Subsection 3.6.2.1.2.2. The detailed stress analysis of the piping determined that the predicted stresses at all locations between the terminal ends are substantially less than the stress limits established in Subsection 3.6.2.1.2.2. Therefore, no arbitrary intermediate pipe breaks were postulated per Generic Letter 87-11.

The postulated break locations in the HPCI steam supply line are included in Figure 3.6-39. With the criteria of Subsection 3.6.2.1.2.3.c, only circumferential-type breaks are postulated at each break. As required, analyses were performed to assess quantitatively the pipe whip, jet impingement, and environmental effects of these postulated ruptures.

3.6.2.2.3.2.1 Blowdown Analyses

Blowdown analyses were performed for postulated HPCI turbine steam supply line breaks using the PRTHRUST program as discussed in Subsection 3.6.3. To conservatively maximize blowdown thrust forces for input to the pipe whip and jet impingement calculations, the full-size 10-in. line was assumed to be initially at rated reactor pressure conditions (1060 psia saturated steam, zero flow). The primary containment isolation valves were assumed to be in their normal operating position, and the HPCI turbine stop valve was assumed to be closed.

The analyses were carried out for a period of approximately 0.5 sec, a time sufficient to develop maximum pipe whip and jet impingement response. It should be noted that this length of time is insufficient to allow activation of operable components, and the balance of plant systems (other than the broken system) continue to operate in the normal way.

The blowdown thrust was calculated as a function of time for circumferential breaks at each of the locations indicated in Figure 3.6-39. These results were then used in jet impingement and pipe whip analyses according to the methods described in Subsection 3.6.3 and discussed below.

Characteristically, the thrust is equal to line pressure times area at the instant of rupture, and increases thereafter as fluid is accelerated from the break. Within a short time, however, choking takes place at the break, and thrust drops sharply as the line pressure decays. The HPCI turbine side-break forces decay to zero as the steam in the line is depleted. Reactor side-break forces decay to a quasi-steady-state thrust, controlled by choking in the shutoff valve in the 1-in. bypass line around the outboard isolation valve.

A "longer-term" blowdown analysis was conducted as the initiating calculation of the environmental conditions resulting from a postulated break in a high energy piping system as described in Subsection 3.6.3.

A preliminary hand calculation showed that a full blowdown of the 10-in. steam line, under the assumption of loss of offsite power and failure of the dc isolation valve, together with a startup time of 10 sec for the diesel generator to initiate closure of the ac isolation valve, would result in unacceptably high pressures and temperatures in the reactor building. To avoid this situation, a 1-in. bypass line and shutoff valve around the outboard isolation valve were incorporated into the system with the normal mode of the outboard isolation valve in the closed position, as shown in Figure 3.6-39. The analysis incorporated the 1-in. bypass line.

The following assumptions were made for the "longer-term" blowdown analysis:

a. The line is initially at rated reactor pressure conditions of 1060 psia and saturated steam

b. The inboard steam line isolation valve and bypass line isolation valve are in their normally open positions

c. The outboard isolation valve is in its normally closed position

d. The HPCI turbine stop valve is closed

e. The dc valve in the 1-in. bypass line fails to close

f. Choke flow through the bypass line takes place until the inboard isolation valve is closed by operator action or high area temperature.

Immediately after the postulated break, steam from the downstream side of the outboard isolation valve is rapidly released from the break, and choke flow through the 1-in. bypass line continues to release steam until the inboard isolation valve is closed.

3.6.2.2.3.2.2 Environmental Analysis

Environmental analyses were performed using the "CVPT-REPORT" and “KITTY6” programs (described in Subsection 3.6.3) to predict the maximum compartment pressures, temperatures, and humidities resulting from postulated design-basis ruptures of the HPCI steam supply line. The steam line traverses three compartments: the steam tunnel, the torus room, and the HPCI pump room. The environmental analyses were evaluated for uprated power conditions.

The Steam Tunnel (Room 109)

No specific analysis was performed for HPCI steam line breaks in the steam tunnel, as the resulting conditions are bounded by the main steam line breaks discussed in Subsection 3.6.2.2.1 on the basis of mass flow and steam conditions.

Torus Room (Room SB2)

There are no postulated HPCI steam line breaks in the torus area.

HPCI Pump Room (Room SB7)

An environmental analysis was performed for a postulated break in the HPCI pump room, and the environmental response of affected compartments was determined. The analytical model showing the control volumes and the flow paths is provided in References 33 and 64.

Results of Analysis for HPCI Line Break in HPCI Room

After the postulated break, the HPCI pump room (SB7) would rapidly fill with steam and vent to room B7 and southeast corner room (SB6 and B6). Room B6 is connected via a stairwell to the first floor which, in turn, is connected to the second, third, and fourth floors via staircases and the equipment hatchway.

The compartmental (control volume) pressure and humidity responses are provided in Reference 33, and the temperature responses are provided in Reference 64. An evaluation has been performed to include the effect of power uprate. Maximum calculated pressure and temperature are 1.23 psig and 183°F in the HPCI pump room.

3.6.2.2.3.2.3 Pipe Whip Evaluation

Consideration was given to the effects of HPCI steam line pipe whip on safety-related structures, systems, and components in the steam tunnel, torus area, and the HPCI room. Where required, analyses were performed to assess pipe whip consequences. See Reference 24.

Effects in Steam Tunnel (Room l09)

Without a pipe whip restraint, the HPCI line pipe whip in the steam tunnel could potentially damage the outboard isolation valve and the primary containment penetration. However, this was anticipated in consideration of the restraints for the steam and feedwater lines in the tunnel, and restraints were provided for the HPCI line as well. The restraint design is discussed in Subsection 3.6.2.2.1.2.5.

Effects in Torus Room (Room SB2)

There are no postulated HPCI steam line breaks in the torus area.

Effects in HPCI Room (Room SB7)

The shutdown capability for the HPCI steam line break in the HPCI pump room is demonstrated in Reference 24.

The concrete structural components within the room were found to be adequately designed to withstand pipe whip impact loads.

Damage Evaluation

Damage evaluation and modifications instituted as a result of the pipe whip evaluation are discussed in Subsection 3.6.2.2.3.2.5.

3.6.2.2.3.2.4 Jet Impingement Evaluation

As in the case of pipe whip, the evaluation was carried out for each area through which the HPCI steam line passes. The evaluation and results are described in Reference 24.

Effects in Steam Tunnel (Room 109)

Jet impingement could adversely affect the HPCI outboard isolation valve. However, the jet impingement shields provided for protection against main steam line breaks would also protect against the HPCI line breaks.

With the inclusion of the 1.75-in. jet deflector plate provided for the main steam line break, jet impingement would not adversely affect any of the concrete structures.

Effects in Torus Room (Room SB2)

There are no postulated HPCI steam line breaks in the torus area.

Effects in HPCI Pump Room (Room SB7)

The shutdown capability for the HPCI steam line break in the HPCI pump room is demonstrated in Reference 24.

The concrete structural components were found to be adequately designed to withstand jet impingement loads.

Damage Evaluation

Damage evaluation and modifications instituted as a result of the jet impingement evaluation are discussed in Subsection (3.6.2.2.3.2.5).

3.6.2.2.3.2.5 System, Component, and Structural Damage Evaluation

An evaluation (Reference 24) was made of the direct damage resulting from HPCI steam line pipe whip or jet impingement. The evaluation included effects on various systems, components, and structures, as well as impact on the ability to achieve a safe shutdown. Plant features that mitigate the consequences of HPCI steam line breaks are described below.

Steam Tunnel (Room 109)

As indicated in Subsection 3.6.2.2.3.2.3, provision of HPCI steam line pipe restraints was incorporated into the steam line/ feedwater line restraint system. The restraints, together with the piping sleeve provided where the steam line passes through the steam tunnel floor, preclude unacceptable damage to the HPCI isolation valve or the primary containment penetration. Incorporated with the restraints is a shield to protect the isolation valve from jet impingement.

Torus Room (Room SB2)

There are no postulated HPCI steam line breaks in the torus area.

Evaluation of Environmental Effects on Systems, Components, and Structures

The equipment, including active and passive components, listed in Table 3.6-1 as required for attaining and maintaining a safe-shutdown condition after a postulated break in the HPCI steam line, was evaluated for its functional capability under the pressure, temperature, and humidity conditions resulting from the pipe break. It was determined that the environmental conditions would not adversely affect the operation of the required systems.

HPCI steam line breaks in the steam tunnel or HPCI pump room would not result in a reactor protection system (RPS) trip because the bypass line around the outboard isolation valves would severely minimize the RPV inventory loss. Normal shutdown procedures would be used in the case of HPCI steam line breaks.

It is concluded, therefore, that with the bypass line around the outboard isolation valve (Subsection 3.6.2.2.3.2.1) and the pipe whip restraints (Subsection 3.6.2.2.3.2.5) incorporated into the design, a break in the HPCI steam supply line will not jeopardize the ability to attain and maintain a safe shutdown.

3.6.2.2.4 Reactor Core Isolation Cooling System

The evaluation of the consequences of a break in the RCIC system was carried out as described below and in References 24, 33 and 64.

The only portion of the RCIC piping system that is classified as high energy is the RCIC steam supply line. This line exits from the primary containment into the steam tunnel near the main steam and feedwater lines. The line then drops through the steam tunnel floor to the torus area, where it is routed adjacent to the torus before entering the north core spray and RCIC pump room. Figure 3.6-41 shows the RCIC steam supply line configuration and its relation to building structures and components.

3.6.2.2.4.1 Review of Potential Damage

A review of the potential damage resulting from a break in the RCIC steam supply line was carried out in accordance with Subsection 3.6.2.1.6 to identify the need for a dynamic pipe whip or jet impingement analysis. The review took into consideration the equipment required to ensure a safe shutdown as discussed in Section 3.6.2.1.4 and Table 3.6-1.

In addition, the environmental effects investigation was conducted for a break in the northeast corner room, as discussed in Subsection 3.6.2.2.4.2.

3.6.2.2.4.2 Pipe-Break Analysis

The criteria given in Subsection 3.6.2.1.2.2 have been applied in determining the locations of the postulated pipe breaks. The terminal end break locations are defined at the connection to the outboard containment isolation valve and the connection to the RCIC turbine stop valve. The Class 1 piping between the containment and the outboard isolation valve is designed to meet the normal operating stress criteria presented in Subsection 3.6.2.1.2.2. The detailed stress analysis of the piping determined that the predicted stresses at all locations between the terminal ends are less than the stress limits established in Subsection 3.6.2.1.2.2. Therefore, no intermediate break locations have been postulated between the terminal ends.

The postulated break locations in the RCIC steam supply line are included in Figures 3.6-41 and 3.6-42. With the criteria of Subsection 3.6.2.1.2.3, Item c., only circumferential-type breaks are postulated at each break location. As required, analyses were performed to assess quantitatively the pipe whip, jet impingement, and environmental effects of these postulated ruptures.

3.6.2.2.4.2.1 Blowdown Analysis

For the pipe whip analysis, blowdown thrust loads at all critical break locations, as identified above, were calculated using an ideal gas model to determine the forcing functions. For jet impingement analyses, the exit plane thrust was calculated as 1.26 PA, where P is the fluid saturation pressure and A is the pipe flow area.

A "longer-term" blowdown analysis was conducted to determine the environmental conditions resulting from a postulated break in a high-energy piping system, as described in references 33, 64, and 65.

The following assumptions were made for the "longer-term" blowdown analysis:

a. The line is initially at rated reactor pressure conditions of 1060 psia and saturated steam

b. The line isolation valves are in their normally open position

c. The RCIC turbine stop valve and the motor-operated bypass valve are closed

d. The dc-powered isolation valve fails to close

e. The ac-powered isolation valve closes 29 sec after the line break. Closure time includes diesel generator startup and valve closure time, Reference 65.

f. Choked flow occurs at the most limiting restriction.

Immediately after the postulated break, the flow from the upstream side of the break increases rapidly to the critical flow for the break, and decreases with closing of the isolation valve. Steam flow rate as a function of time after the postulated break is provided in References 33 and 65.

3.6.2.2.4.2.2 Environmental Analysis

Environmental analyses were performed using the "CVPT-REPORT" and “KITTY6” programs (described in Subsection 3.6.3) to predict maximum compartment pressures, temperatures, and humidities resulting from postulated design-basis ruptures of the RCIC steam supply line. The steam line traverses three compartments: the steam tunnel, the torus room, and the RCIC pump room. The environmental analyses were evaluated for uprated power conditions.

The Steam Tunnel (Room 109)

No specific analysis was performed for RCIC steam line breaks in the steam tunnel, as the resulting conditions are bounded by those produced by the main steam line breaks discussed in Subsection 3.6.2.2.1.2.2 on the basis of mass flow and steam conditions.

Torus Room (Room SB2)

There are no postulated RCIC steam line breaks in the torus room.

RCIC Pump Room (Room SB5)

An environmental analysis was performed for postulated RCIC line breaks in the northeast corner room, and the environmental response of affected compartments was determined. The environmental analysis model showing the control volumes and the flow paths are provided in References 33 and 64.

Results of Environmental Analysis

For RCIC Steam Line Break in Torus Room

There are no postulated RCIC steam line breaks in the torus area.

For RCIC Steam Line Break in the RCIC Pump Room

After the postulated break, the RCIC pump room SB5 would rapidly fill with steam and, via a stairwell, vent to the basement of the reactor building, which in turn is connected to the first, second, third, and fourth floors via staircases and the equipment hatchway. Steam is also vented from the first floor to remaining corner rooms (B1/SB1, B3/SB3, B6/SB6) via staircases and equipment hatches. Each corner room vents to the torus room through pressure relief seals that open at 0.1 psid. Steam is also vented from the torus room to the pipe tunnel through open penetrations and from the RCIC pump room via pressure relief seals which open at 0.1 psid. A vent opening between the pipe tunnel and the first floor auxiliary building is provided and is designed to open at 0.33 psid to vent steam to the auxiliary building and subsequently to the turbine building.

The compartmental (control volume) pressure and humidity responses are provided in Reference 33, and the temperature responses are provided in Reference 64. Calculated pressure and temperature are 0.48 psig and <237°F in the RCIC pump room.

3.6.2.2.4.2.3 Pipe Whip Evaluation

Analyses were performed (Reference 24) to assess pipe whip consequences on safety-related structures, systems, and components in the main steam tunnel, in the event of a postulated design basis break of the RCIC steam line.

Blowdown thrust loads were calculated using the methods discussed in Subsection 3.6.2.2.4.2.1. The methods used in conducting the pipe whip analysis, and the details of the structural evaluation for pipe whip impact, are given in Subsection 3.6.3.

A summary of the results of the pipe whip evaluation for each room traversed by the RCIC steam line is presented below.

Effects in Steam Tunnel (Room 109)

Loads due to pipe whip could damage the outboard RCIC steam isolation valve. The containment penetration assembly would not be damaged, due to the existence of a separate containment penetration flued head support structure.

Effects in Torus Room (Rooms SB2 and B2)

There are no postulated RCIC steam line breaks in the torus area.

Effects in RCIC Pump Room

An evaluation of the effects of pipe whip is described in Reference 24.

Effects on Structural Components

The reinforced-concrete structures were found to be adequately designed to withstand pipe whip impact loads when analyzed in accordance with Subsection 3.6.3.

3.6.2.2.4.2.4 Jet Impingement Evaluation

As in the case of pipe whip, an evaluation (Reference 24) was carried out for each room traversed by the RCIC steam line. The jet impingement loads from the calculated thrust forces were determined by the methods described in Subsection 3.6.3.

Effects in Steam Tunnel

Jet impingement loadings due to a break in the RCIC steam line in the steam tunnel could damage the top works of the RCIC outboard isolation valve and render it inoperative.

Effects on Structural Components

The reinforced-concrete structures were found to be adequately designed to withstand jet impingement loads when analyzed by the methods described in Subsection 3.6.3.

3.6.2.2.4.2.5 System, Component, and Structural Damage Evaluation

An evaluation (Reference 24) was made of the direct damage resulting from the RCIC steam line break on various systems, components, and structures as well as its impact on the ability to attain a safe shutdown. The plant features that mitigate the consequences of RCIC steam line breaks are described below.

Steam Tunnel

The RCIC outboard isolation valve could be damaged by either pipe whip or jet impingement. Referring to Table 3.6-1, it is seen that a general requirement for a safe shutdown is to maintain the integrity of the primary containment. If the inboard isolation valve is assumed to fail in accordance with assumption d.2. of Subsection 3.6.2.1.1.1 and the outboard valve is damaged, the primary containment would be lost, representing an unacceptable condition.

To mitigate this condition, the RCIC steam line in the steam tunnel is equipped with a steel-plate pipe restraint that will prevent pipe whip from imposing unacceptably high loadings on the outboard isolation valve. The restraint design concurrently provides protection against jet impingement on the isolation valve top works, thereby ensuring its operability.

Torus Room

There are no postulated RCIC steam line breaks in the torus area.

Pipe Whip Restraints and Jet Impingement Shields

Designs for pipe whip restraints and jet impingement shields to protect from unacceptable damage resulting from RCIC steam line breaks in the steam tunnel are described below.

Steam Tunnel

The design for the pipe whip restraint and the jet impingement shield is as follows. The restraint is of the close-clearance plate type and, together with the piping sleeve previously provided where the pipe passes through the steam tunnel floor, serves to prevent the line from deflecting excessively in either the torsional or bending modes and hence prevents the development of excessive stresses in the outboard RCIC steam line isolation valve or in the piping between the isolation valve and the primary containment penetration flued head. Due to its configuration, this restraint also serves to protect the RCIC outer isolation valve from jet impingement.

Torus Room

There are no postulated RCIC steam line breaks in the torus area.

3.6.2.2.4.3 Evaluation of Ability To Attain and Maintain a Safe Shutdown

A break in the RCIC steam supply line in the steam tunnel may result in activation of the high-temperature signal in the steam tunnel, with concurrent closure of the MSIVs and subsequent RPS trip (scram). Therefore, this evaluation assumes loss of offsite power, as indicated in Subsection 3.6.2.1.1.1.

All of the systems and components listed in Table 3.6-1 as required for a safe shutdown will be operable. All required redundant components will be available, with the exception of Division I core spray, which is assumed to have failed, together with the RCIC system for the pipe break in the RCIC pump room.

As a result of reactor scram and primary containment isolation, reactor shutdown cannot be attained by normal shutdown procedures for a break in the steam tunnel, although they could and probably would be used for the break in the RCIC pump room.

The RCIC system will be automatically isolated by activation of one of the three signals listed in Table 3.6-1. Reactor depressurization can be achieved through use of the HPCI system to maintain water level and remotely operated relief valves to depressurize the RPV.

On depressurization, Division II core spray and LPCI would be available to maintain water level. Suppression pool cooling and maintaining a long-term safe shutdown can be accomplished by operation of the RHR system.

Applying the single failure criterion, operable redundant or backup systems are available to ensure that each required function is carried out. If HPCI is unavailable, depressurization can be accomplished by the ADS alone, while coolant water inventory is maintained at an acceptable level. Division II core spray or LPCI independently can maintain acceptable water levels after depressurization, and redundancy in RHR will ensure suppression pool cooling and the ability to maintain a long-term safe shutdown.

It is concluded, therefore, that a break in the RCIC steam supply line will not jeopardize the ability to attain and maintain a safe shutdown.

3.6.2.2.5 Reactor Water Cleanup System (RWCU)

The reactor water cleanup (RWCU) system removes water from the reactor recirculation system for decontamination by a demineralizer system and then returns the water to the reactor through the feedwater system. The RWCU line leaves the containment, entering the second floor of the reactor building, as shown in Figure 3.6-43. From this area, the line divides into two smaller lines that feed the RWCU recirculation pumps. The water is pumped through heat exchangers to a demineralizer system. The cleaned-up water is reheated by the heat exchangers and enters the feedwater system in the steam tunnel after being routed through a pipe chase to the torus area.

3.6.2.2.5.1 Review of Potential Damage

As in the preceding evaluations, a review of the potential damage resulting from a break in the RWCU piping system was carried out in accordance with Subsection 3.6.2.1.6 to identify the need for a dynamic pipe whip or jet impingement analysis.

Based on this review, the following concerns were identified regarding pipe whip and jet impingement:

a. Effect on outboard isolation valves and the primary containment penetration in room 224

b. Effects on the RWCU line isolation valves that connect to the feedwater line in the steam tunnel

c. Effects on the torus and other Category I systems and components in the torus room.

In addition, the environmental conditions and effects resulting from an RWCU line break required evaluation.

3.6.2.2.5.2 Pipe-Break Analysis

The criteria given in Subsection 3.6.2.1.2.2 have been applied in determining the locations of the postulated pipe breaks. The Class 1 piping between the containment and the outboard isolation valve is designed to meet the normal operating stress criteria presented in Subsection 3.6.2.1.2.2.

The postulated break locations in the seismically analyzed portion of the RWCU water line are included in Figure 3.6-44. With the criteria of Subsection 3.6.2.1.2.3, Item c., only circumferential-type breaks are postulated at each break. As required, analyses were performed to assess quantitatively the pipe whip, jet impingement, and environmental effects of these postulated ruptures.

3.6.2.2.5.2.1 Blowdown Analysis

A short-term blowdown analysis was performed for a rupture of an RWCU line downstream of the outboard isolation valve in room 224 and in room 219, using hand calculation methods to determine thrust loads for use in evaluating the potential damage due to pipe whip and jet impingement. Although pipe breaks are no longer postulated in room 224, this break analysis bounds other postulated breaks in room 219. To conservatively maximize blowdown thrust, the lines were assumed to be at the reactor recirculation line normal operating conditions.

Initially, the thrust would be equal to the line pressure at the time of the break times the break area. The thrust would then rapidly rise to a steady-state force of 1.26PA, where P is the fluid saturation pressure (910 psia) and A is the break area. The steady-state force would equal 27,300 lb and was taken as a constant value in the subsequent damage evaluation.

Similar evaluations were conducted for the postulated break in the torus room. Blowdown force for a postulated rupture of the RWCU line at anchor G33-3245-G34 was performed using Fauske's two-phase flow model (Reference 35). To conservatively maximize the blowdown forces, the line was assumed to be at maximum operating temperature and pressure (532°F and 1244 psia).

A "longer-term" blowdown analysis was conducted to determine the environmental conditions resulting from a postulated break in the RWCU system. Although a pipe break immediately downstream of the RWCU suction line outboard isolation valve is no longer postulated, this break analysis was used as a bounding case for other postulated breaks.

The following assumptions were made for the "longer-term" blowdown analysis:

a. The line is initially at 1060 psia and 534°F.

b. Deleted

c. The ac-powered isolation valve closes 23 sec after detection of the line break. This time includes instrument and loop response time and valve closure time. References 64 and 65.

Immediately after the postulated break, the flow rate from the upstream side of the break will consist of an initially high flow rate during the inventory blowdown followed by a smaller rate during steady-state blowdown. This flow rate is provided in References 33 and 65.

3.6.2.2.5.2.2 Environmental Analysis

Environmental analyses were performed using the "CVPT-REPORT" or “KITTY6” programs (described in Subsection 3.6.3) to predict the maximum compartment pressures, temperatures, and humidities resulting from postulated design-basis ruptures of the RWCU high-energy line. The environmental analyses were evaluated for uprated power conditions.

RWCU Pump Rooms (Rooms 217 and 218)

An environmental analysis was performed for an RWCU line break in pump room B, and the environmental response of affected compartments was determined. The environmental response for a break in pump room A would be similar. The environmental analysis model showing the control volumes and flow paths is provided in Reference 33.

RWCU Holdup and Heat Exchanger Rooms (Rooms 224 and 219)

An environmental analysis was performed for an RWCU line break in the hold-up pipe room 224. Although pipe breaks in room 224 are no longer postulated, this break analysis bounds all other postulated breaks in room 219; therefore, was maintained as a bounding analysis. No analysis was performed for the heat exchanger room 219. The environmental analysis models showing the control volumes and flow paths are provided in References 33 and 64.

Torus Room (SB2)

An environmental analysis was performed for an RWCU line break in the torus room. RWCU system isolation is automatically initiated following the break. The redundant

RWCU system flow comparator instrumentation is assumed to fail. However, the torus room RWCU leak detection thermocouple setpoints are reached.

Steam Tunnel (Room 109)

No pipe breaks are postulated for the RWCU line in the steam tunnel. Conditions in the steam tunnel are bounded by the main steam line breaks discussed in subsection 3.6.2.2.1.

Results of Analysis for RWCU Break in Room 218

Both pump rooms feature a stacked brick wall on the east side for shielding purposes only. On collapse of the stacked brick wall, break mass and energy is vented to the second floor, which is connected via staircases and the equipment hatchway to the first, third, and fourth floors of the reactor building. No essential equipment is located in the missile path of the collapsing wall. The maximum calculated temperature in pump room B was 214°F at a pressure of 0.97 psig. All other areas are bounded by the RWCU break in room 224.

Results of Analysis for RWCU Break in Room 224

Although pipe breaks in room 224 are no longer postulated, this break analysis bounds breaks in room 219. The heat exchanger (219) and holdup (224) rooms feature a common stacked brick wall on the west side, 24 in. thick, for shielding purposes only. Break mass and energy is vented to the reactor building on collapse of the stacked brick wall in the same manner as room 218. The maximum temperatures and pressures calculated for the hold-up pipe room and heat exchanger room were <216°F and 9.7 psig and <215°F and 1.18 psig. The reactor building second floor temperature and pressure calculated were 156°F and 1.14 psig. All other areas showed equal or lower temperatures and pressures.

The maximum pressure of 9.7 psig predicted for room 224 exceeded the capacity of the wall between the hold-up room and the heat exchanger room. The short term environmental analysis was updated to bound the actual RWCU breaks in the RWCU heat exchanger room (instead of a bounding break of the largest pipe in the worst location) and to recompute the differential pressure across the wall between the hold-up room and the heat exchanger room. The computer code COMPARE was utilized in the analysis. The revised analysis calculated a maximum differential pressure of 1.5 psid across the wall which is acceptable.

Results of Analysis for RWCU Break in Torus Room

A steady-state temperature of 191°F with 100 percent humidity would result in the torus room. The pressures in the reactor building are bounded by the RCIC steam line break environmental conditions, as discussed in Subsection 3.6.2.2.4.

3.6.2.2.5.2.3 Pipe Whip Evaluation

Consideration was given to the effects of RWCU-water-line pipe whip on safety-related structures, systems, and components in the rooms where the high-energy portion of the water lines coexists with such structures and equipment. The results of these evaluations are reported in Reference 24.

3.6.2.2.5.2.4 Jet Impingement Evaluation

As in the case of pipe whip, an evaluation was carried out to assess how jet impingement resulting from a break in the RWCU high-energy water line would affect safety-related structures, systems, and components. The results of these evaluations are reported in Reference 24.

3.6.2.2.5.2.5 Evaluation of System, Component, and Structural Damage

An evaluation was made of the damage resulting directly from the RWCU water line break. The evaluation included effects on various systems, components, and structures as well as impact on the ability to achieve a safe shutdown. The RWCU line in the torus room was provided with pipe whip restraints to protect the torus from the effects of design-basis breaks. A review of the consequences of pipe whip and jet impingement loadings resulting from a postulated break in the RWCU piping determined that no important structural element would be damaged by pipe whip or jet impingement.

Pipe Whip Restraints and Jet Impingement Shields

Design of restraints was based on the criteria given in Subsection 3.6.2.3.2 and the methods given in Subsection 3.6.2.1.5. The restraints provided for the RWCU pump discharge line in the torus room direct the thrust loads resulting from postulated breaks into the reactor building walls and prevent the broken line from impacting the torus. An analysis to determine member sizes was made assuming a conservative steady-state thrust loading, applied instantaneously and assumed to be constant for the entire blowdown event. A dynamic impact factor of 2 was assumed to account for the sudden nature of the loading.

Evaluation of Environmental Effects on Systems, Components, and Structures

Equipment, including active and passive components, listed in Table 3.6-1 as required for attaining and maintaining a safe-shutdown condition after a postulated break in the RWCU system was evaluated with respect to its functional capability under the pressure, temperature, and humidity conditions resulting from the pipe break. It was determined that the environmental conditions would not adversely affect the operation of the required systems.

The structural framing of the reactor/auxiliary building was analyzed in accordance with the methods described in Subsection 3.6.3 for the effects of RWCU water line breaks. The interior walls and slabs of the compartment were analyzed for the effects of pressurization in accordance with the methods described in Subsection 3.6.3, and were found to be acceptable. The maximum differential pressure between the external walls and atmospheric pressure is well within the 3-psig tornado design pressure differential.

In view of the above, no adverse consequences due to environmental effects of the RWCU line break have been identified.

3.6.2.2.5.3 Evaluation of Ability To Attain and Maintain a Safe Shutdown

A break in the RWCU water line would not result in a turbine generator trip or an RPS trip. Therefore, this evaluation assumes that offsite power is available.

Referring to Table 3.6-1, all systems and components listed as required for a safe shutdown will be operable, as will all redundant components. No single component failure can be assigned that would preclude attaining and maintaining a safe shutdown.

It is concluded, therefore, that a break in the RWCU water line will not jeopardize the ability to attain and maintain a safe shutdown.

3.6.2.2.6 Control Rod Drive System

An evaluation of the consequences of a pipe break in the control rod drive (CRD) system was carried out as described below.

Those portions of the CRD system piping outside the containment that are classified as high energy are the 1-in. insert and 3/4-in. withdraw lines running from the hydraulic control units to the drives, and the 2-in. water charging line.

The piping from the hydraulic control units to the scram discharge system is pressurized to high-energy conditions less than 0.1 percent of the system operating time. The balance of the time this portion of piping is vented to the atmosphere. Accordingly, in conformance to NRC guidance, it is permissible to treat this portion of the piping as moderate-energy piping. The consequences of a break in moderate-energy lines are addressed in Subsection 3.6.2.3. In response to additional NRC comments on a break in this portion of piping, GE published two generic evaluations (References 36 and 37), and the BWR Owners Group submitted a report on scram discharge pipe integrity (Reference 38). The applicability of these evaluations to Fermi 2 was addressed in Reference 39, along with additional plant-unique information as needed to address the NRC comments. The conclusion of the studies indicates that the mechanical quality, maintenance procedures, operator actions, and existing system performance are sufficient to satisfactorily guarantee scram discharge piping system integrity. In addition, even if a break were to occur, it was shown that the break would contribute negligibly to the risk of core uncovering.

3.6.2.2.6.1 Review of Potential Damage

As in the case of the previously discussed systems, a review of the potential damage resulting from a break in any of the CRD piping was conducted in accordance with the methods described in Subsection 3.6.2.1.6. The review took into account the equipment required for a safe shutdown, as discussed in Subsection 3.6.2.1.4 and Table 3.6-1.

This review (Reference 24) established that there would be no adverse consequences resulting from any break of the CRD piping.

Environmental effects were not analyzed for a break in the CRD line because of the highly subcooled nature of the water. There would be no flashing of the liquid that escapes the postulated break and consequently no adverse environmental response.

3.6.2.2.6.2 Pipe-Break Analyses

3.6.2.2.6.2.1 Blowdown Analyses

Blowdown thrust loads used to assess the effects of pipe whips were generated by conservative hand calculational methods, as described in Subsection 3.6.3.

3.6.2.2.6.2.2 Environmental Analyses

Effects related to the spraying or flooding of components in the area of a CRD line break have been considered and are included in the analysis of moderate-energy systems provided in Subsection 3.6.2.3.

3.6.2.2.6.2.3 Pipe Whip Evaluation

Analyses were performed to assess the pipe whip consequences on the safety-related structures, systems, and equipment that might be damaged as a result of a design-basis break in the CRD piping.

Blowdown thrust loads were hand-calculated, as discussed in Subsection 3.6.2.2.6.2.1. The methods used in the structural evaluation for pipe whip impact are discussed in Subsection 3.6.3.

As a result of the review of the consequences of pipe whip caused from breaks in the CRD system piping, it was determined that no safety-related structural elements would be damaged by a whipping pipe.

3.6.2.2.6.2.4 Jet Impingement Evaluation

Because of the highly subcooled condition of the water in the CRD piping outside the primary containment, the line would depressurize almost instantaneously after a design-basis break. The flow rate out of the break would be limited by the capacity of the CRD pumps (260 gpm at 0-ft head), and flow velocity from the break will not exceed 11 fps. As a result, no unacceptable consequences due to jet impingement loadings could be identified for a design-basis break in the CRD system outside the primary containment.

The effects of crack breaks in this piping are the effects expected from breaks in moderate-energy systems, that is, spraying and flooding.

3.6.2.2.6.2.5 Evaluation of System, Component, and Structural Damage

An evaluation was made of the direct damage resulting from a break in the CRD piping system on various systems, components, and structures, and its impact on the ability to achieve a safe shutdown. This evaluation was made by reference to Subsections 3.6.2.1.4 and 3.6.2.1.5, and Table 3.6-1. No adverse consequences were identified.

3.6.2.2.6.3 Evaluation of Ability To Attain and Maintain a Safe Shutdown

There would be no adverse consequences resulting from a break in the CRD piping that could preclude attaining and maintaining a safe shutdown.

3.6.2.2.7 Reactor Building Heating System

An evaluation of the consequences of a pipe break in the reactor building heating system was carried out as described below. The piping of this system is routed through most of the floors and rooms in the reactor and auxiliary buildings. Only the steam lines of the building heating system are classified as high energy.

3.6.2.2.7.1 Review of Potential Damage

As in the case of the previously discussed systems, a review (Reference 24) of the potential damage resulting from a break in any of the building heating steam lines was conducted in accordance with the methods described in Subsection 3.6.1. The review took into account the equipment required for a safe shutdown, as discussed in Subsection 3.6.2.1.4 and Table 3.6-1.

The pressure in the reactor building heating steam lines (15 psig) is less than that which can cause a pipe to whip from postulated breaks. Subsequently, blowdown analyses, pipe whip evaluations and jet impingement evaluations were not performed. The effects of cracks in this piping are the same as those expected from breaks in moderate-energy systems; that is, spraying. An evaluation of the spraying effects on various systems, components, and structures did not identify any adverse consequences. The environmental effects of temperature and humidity were also analyzed for a break in the building heating steam lines. Secondary containment isolation valves are provided in the steam supply lines to isolate the steam source on indication of a break.

3.6.2.2.7.2 Evaluation of Ability To Attain and Maintain a Safe Shutdown

The loss of the building heating system does not affect the safe shutdown capability of the reactor.

3.6.2.2.8 Non-Safety-Grade Systems

A review of plant safety with regard to high-energy pipe breaks was performed using the format established by the BWR Owners Group in response to H. R. Denton's letter, Potential Unreviewed Safety Question on Interaction Between Non-Safety-Grade Systems and Safety-Grade Systems.

From this review, Edison has concluded that no identified safety action would be negated by the failure of non-safety equipment resulting from the environmental effects of a high-energy pipe break. The only minor area of concern is the temperature effects of the pipe break on the level instrumentation sensing lines, and this has been addressed and resolved in the generic BWR report, NEDO-24708.

This review indicates that no previously established safety limits would be violated by the environmental effects.

It is desirable that operator action be taken to quickly mitigate the effects of the failures in most cases.

The specific systems and areas considered are included in Table 3.6-8.

3.6.2.3 Moderate-Energy Pipe-Break Evaluation

Moderate-energy piping systems, as defined in Subsection 3.6.2.1.2.1 and listed in Subsection 3.6.2.1.3.2 have been evaluated (Reference 24) for postulated through-wall leakage cracks (refer to Subsection 3.6.2.1.1.2 for the method and Subsection 3.6.2.1.2.4 for the design bases for the crack size and location). The components and/or equipment required for the safe shutdown of the reactor were evaluated and, if necessary, provided with measures to protect and ensure their operability. The evaluation for the moderate-energy piping systems encompasses an analysis of both flooding and spraying effects.

The consequences of flooding would depend on the crack size, crack flow rate, drainage rate of the compartment, and the location within the compartment of the components required for safe shutdown. An accumulation rate (defined as the crack flow rate minus the drainage rate) was determined for each compartment, and the potential for water accumulation in each compartment was examined. If accumulation posed a flooding threat to components or equipment, an examination was undertaken to determine the possibility of damaging each component within that compartment and the acceptability of such damage. Where drain paths exist such that water accumulation may occur in adjacent compartments, an evaluation of the components and equipment damage in those compartments was carried out.

The consequences of spraying would depend on the spray distance and the spray angle. The spraying distance was determined for the highest-pressure line within each compartment in which components and/or equipment are located.

In many cases, numerous break locations were selected within each compartment so as to maximize the effect on any one component and/or equipment within that compartment. An examination of each component and/or equipment required for safe reactor shutdown was completed to determine the acceptability of damage. In either analysis, whether for the case of flooding or for the case of spraying, the basic problem was to establish whether the effect of a postulated leakage crack has the potential of preventing the safe shutdown of the reactor when combined with a random failure of a single component.

3.6.2.3.1 Analytical Procedure

A step-by-step procedure was used to determine which of the components within the reactor/auxiliary building and the residual heat removal (RHR) complex could have the potential of being damaged by either flooding or spraying. The steps include listing components and/or equipment required for safe shutdown, located in areas affected by spray or flooding. On the basis of the crack flow rates (Subsection 3.6.2.3.3.) and spray distances (Subsection 3.6.2.3.3.) for each postulated crack, a determination was made as to which of these components could fail as a result of spray or submergence. Finally, the ability to achieve safe shutdown was evaluated, assuming a single active failure in addition to the failures caused by spray and flooding (Subsection 3.6.2.1.1.2).

3.6.2.3.2 Evaluation Guidelines

The basic guidelines used in evaluating the effects of flooding or spraying were as follows:

a. All water pipes were assumed to have the required pressure to produce a spray that would reach the most distant walls in direct line of the spray; if unacceptable damage would result, this assumption was reviewed and validated

b. All valve operator motors have NEMA 4 enclosures and were not assumed to fail from water spray

c. All motors other than valve operators were evaluated on an individual basis. If they were in open drip-proof enclosures, they were assumed to fail when exposed to a spray

d. All motors were assumed to fail if submersed due to flooding, except the subbasement floor drain sump motors

e. Cables are waterproof and would be unaffected by flooding or water spray

f. Motor control centers and switchgear were assumed to fail if sprayed or if submersed due to flooding

g. Essential instruments that are NEMA 4 rated were not assumed to fail from water spray

h. All instruments were assumed to fail if submersed due to flooding

i. Essential local terminal boxes that are NEMA 4 rated were not assumed to fail from spraying effects

j. All terminal boxes were assumed to fail if submersed due to flooding.

3.6.2.3.3 Analytical Methods

As indicated in the analytical procedures (Subsection 3.6.2.3.1) for flooding and spraying, calculations must be performed to find the crack flow rate and the spraying distance for postulated through-wall leakage cracks. The methods used to determine these parameters are described in Reference 24.

3.6.2.3.4 Results of Evaluation

From the evaluations of flooding and spraying effects, it was possible to identify certain components and/or equipment that required protective measures to prevent their loss of function as a result of the pipe crack.

3.6.2.3.4.1 Protective Measures To Mitigate Flooding Effects

3.6.2.3.4.1.1 Residual Heat Removal Complex

The QA Level I components located in the RHR complex are

a. Standby diesel generators (four)

b. RHR service water pumps (four)

c. Emergency equipment service water system (EESWS) pumps (two)

d. Diesel generator service water (DGSW) pumps (four)

e. RHR cooling towers (four)

f. 4160-V switchgear, 480-V switchgear, and motor control centers

g. Standby diesel generator heating, ventilation and air conditioning (HVAC) systems.

Because of the structural arrangement and openings for drainage, a moderate-energy pipe rupture in those areas cannot cause a flooding problem.

3.6.2.3.4.1.2 Reactor/Auxiliary Building

Subbasement Flooding

The floor drains, open stairwells, and other openings (equipment hatches, pipe chases, and various penetrations) provide ample access to the subbasement for any water that would leak from a postulated pipe crack occurring on any floor of the reactor/ auxiliary building. Therefore, the analysis of damage from flooding in the subbasement covers floods that would result from pipe breaks on other floors as well as from breaks in the subbasement.

Flooding in the subbasement can occur in the torus room (room SB2), any of the corner rooms (rooms SB1, SB3, SB5, or SB6) or the HPCI room (room SB7). The maximum flooding rate in the torus room would result from an RHR pump discharge line. Other moderate-energy lines in the torus room would have a lower leakage rate, and thus an evaluation of the RHR leak represents the envelope for leaks from other systems. Secondary containment isolation valves are provided in the torus water management system (TWMS) return line to the torus to isolate the condensate systems on indication of leakage (see Figure 9.2-13).

The maximum flooding rate in a corner room would result from an RHR return line. Other moderate-energy lines in the corner rooms would have a lower leakage rate. Flooding in a corner room due to leakage from an operating system in that room would be self-contained and self-limiting since it would stop when the pump stops due to submergence of the pump motors. For the case of a leak in one RHR division corner room while the other division is in operation, the presence of a leak would be readily identified by the sump level indication and the system would be turned off.

Leaks of a magnitude great enough to cause flooding would be detected by water line pressure and flow instrumentation, leak-detection instrumentation, or the activation of the sump pumps and sump overflow alarms.

Shutdown Capability Evaluation

Indications that there is water leakage into the subbasement in excess of specified limits call for an immediate controlled shutdown. Since there would be no turbine generator or RPS trip resulting from a moderate-energy pipe break, offsite power would be available and shutdown would be carried out by normal shutdown procedures.

In cases of moderate-energy piping leakage, operator action would be required to identify the leaking system and the location of the leak. Instrumentation of various types is available to allow the operator to identify the leaking system. In most cases, location of the leak would require a search of the areas traversed by the identified leaking system. Some of the safety-related equipment in the subbasement prone to damage by flooding is the equipment in the specific corner rooms indicated in Figure 3.6-13 and the various pump suction valves in the torus room. If a leak in an RHR pump discharge line resulted in flooding in the torus room and the flooding proceeded at the fastest rate, more than 2 hr would be required to flood the motor operators of the RHR suction valves; thus the operator would have adequate time to locate and terminate the leak without damage to any safety-related system or component.

In applying the single-component failure criterion, the only system required for normal shutdown that could be made inoperable is the RHR system. Should a leak develop in one division of the RHR, and the single-failure criterion were applied to the RHR divisional cross-tie valve, both divisions of the RHR would be disabled since continued operation of the nonleaking division would force water out of the leaking division and there would be no method of determining the leaking division. In this event, the primary system would be held at low-pressure hot standby until the malfunctioning valve were repaired and closed so that the leaking division could be identified. Once this were accomplished, the system could be taken down to a cold shutdown using the redundant RHR division, where the single-failure criterion is not applied in accordance with Subsection 3.6.2.1.1.2.

Loss of equipment in any single corner room together with an assumed single failure would not preclude attaining and maintaining a safe shutdown.

Basement

The basement consists of the four corner rooms enclosing various instrument racks. The flow rate from pipe cracks in any room in the basement would be relatively small; in all cases the water would drain to the subbasement rooms, and the evaluation for the subbasement flooding applies.

First Floor

Water accumulation could occur in a few areas on this floor; however, no safe-shutdown equipment is located in these areas. In other areas, sufficient floor drains and/or other openings (doors and stairwells) are provided to limit the accumulation to a few inches in depth. The water that leaked on this floor would eventually flow down to the subbasement, and the evaluation for the subbasement flooding applies.

Where RBCCW supplemental cooling supply and return piping to the Division I EECW loop passes along the floor between the control rod drive hydraulic control units, the HCUs have been evaluated for the impact of spray and jet impingement and found not to be impacted as a result of postulated cracks in this piping.

Second Floor

In general, the water that leaked on this floor from a postulated pipe crack in moderate-energy piping would drain to the subbasement area through the floor openings and/or stairwells, where its effect would be smaller than that of the postulated pipe crack in the subbasement.

Moderate-energy lines located in room 209 have the potential of damaging nearby electrical equipment as a result of postulated pipe cracks. These lines were shrouded to preclude this possibility.

Third Floor

The third floor contains the control room complex (room 308), motor control center (room 320), RPS motor-generator sets (rooms 32l and 322), switchgear (room 323), and batteries (rooms 325 and 326). The doors from room 3l8 provide access to the control room complex and to the switchgear room through the motor control center room. These rooms contain equipment that is sensitive to moisture and is required for the safe reactor shutdown.

Room 320 contains emergency equipment cooling water (EECW) supply and return lines that are routed near the motor control center cabinets, divisional cable trays, and fire protection system elements. The lines are shrouded to prevent these items from being sprayed and to prevent any significant water accumulation in room 320 in the event of a leakage crack in the lines. Room 318 contains no safety-related equipment. Water from a crack in either the EECW lines or fire protection header located in this room would spread directly to the turbine building. No significant accumulation of water in room 318 will be experienced. The closure strips that have been installed at the bottom of doors leading from room 318 into room 308 or room 320 will prevent water from spreading into the control room. In addition, small leakage allowed through the door in room 320 will not affect the equipment.

Fourth Floor

The secondary containment ventilation room (room 416) contains four pipes of about equal potential for causing flood damage. Two pathways are available for the spread of water; the open stairway (room 319) leading down to room 318, and the equipment hatch located over room 320. Water retained on the floor of room 416 will spread over the large floor area. No significant accumulation will be experienced.

Water descending the stairway will spread over the floor surface of room 318 into the turbine building. No significant accumulation will be experienced.

Water could leak into room 320 via the small holes in the equipment hatch. The water would spread over the room 320 floor surface and into adjacent rooms (rooms 321, 322, 323, 325, and 326). These rooms contain safety-related equipment that could be affected by water spray or accumulation. Therefore, a perimeter curb has been installed around the hatch. Also, a plastic cover has been installed over the hatch. The fire-protection line that is routed over the hatch area has also been shrouded. These measures will prevent water from leaking into room 320.

Fifth Floor

There is little effect on reactor safe shutdown from a postulated pipe crack in a moderate-energy piping system on this floor. Sufficient floor drains and openings to floors below (staircases and equipment hatches) have been provided to prevent flooding from postulated leaks. The water from this floor going to floors below has less effect than that of a postulated pipe crack on those floors. However, the following are some of the rooms that have been modified to mitigate the effect of a postulated pipe crack on this floor.

A maximum flow rate of 78 gpm from a postulated pipe crack of a moderate-energy reactor building closed cooling water (RBCCW) line is postulated in room 509. A floor drain is provided to prevent any water accumulation; however, there are duct penetrations leading to the control room below. To mitigate any possibility of water flowing through these penetrations, each penetration was sealed after its installation. A pipe crack can also lead to water flow down the stairwell leading to room 3l9 and thus to room 318.

3.6.2.3.4.2 Protective Measures To Mitigate Spraying Effects

3.6.2.3.4.2.1 Residual Heat Removal Complex

The safety-related components and equipment located in the RHR complex were discussed in Subsection 3.6.2.3.4.1.1. Water spray can adversely affect some safety-related equipment. Because of the separation arrangement, however, this damage would be limited to one division in any one system. Since the single-failure criterion is not applied to a redundant train of a dual-purpose system damaged by a pipe crack, the ability to achieve and maintain a safe shutdown is not jeopardized.

3.6.2.3.4.2.2 Reactor/Auxiliary Building

Following the procedure presented in Subsection 3.6.2.3.1, components and equipment required to ensure a safe shutdown and having the potential of being damaged as a result of a water spray from a moderate-energy pipe crack were identified. See Subsection 3.6.2.3.4.1.2.

3.6.2.4 Conclusions

3.6.2.4.1 High-Energy Piping Systems

Following the criteria described in Subsection 3.6.2.1, the main steam, feedwater, HPCI steam, RCIC steam, RWCU, building heating steam line, and CRD systems were evaluated for the effects of pipe rupture outside primary containment. This evaluation, described in Subsection 3.6.2.2, encompassed the effects of pipe whip, jet impingement, flooding, and environmental effects. The conclusions that were reached are described below.

3.6.2.4.1.1 Pipe Whip Effects

The effects of the unrestrained motion of segments of the afore-mentioned piping systems, due to thrust loads developed at postulated piping breaks, have been investigated. Pipe restraint designs have been installed that will mitigate the adverse effects of the pipe whip.

3.6.2.4.1.2 Jet Impingement Effects

The effects of jet impingement from the postulated piping breaks have been investigated. To mitigate the consequences of jet impingement, several postulated break locations are equipped with jet impingement shields to protect the affected systems, structures, and equipment.

3.6.2.4.1.3 Environmental and Flooding Effects

The environmental effects, including flooding and the effluent of a steam/air mixture, of postulated high-energy piping breaks have been investigated. It has been concluded that the components and equipment required for effecting and maintaining a safe shutdown are protected and the main control room will remain habitable.

3.6.2.4.1.4 Pressurization Effects

The pressurization effects of a postulated high-energy line break on the main steam tunnel, reactor/auxiliary building structures, and certain components and equipment have been investigated. The components and equipment required to effect and maintain a safe shutdown are protected and the main control room will remain habitable.

3.6.2.4.2 Moderate-Energy Piping Systems

Following the criteria described in Subsection 3.6.2.1, moderate-energy piping systems were evaluated for the effects of throughwall leakage cracks. This evaluation, described in Subsection 3.6.2.3, encompassed the effects of flooding and spraying. The conclusions reached are described below.

In the event of substantial flooding in the torus room, resulting primarily from an RHR pump discharge line leak, but including other lines as well, operator action is required to terminate the leakage. Maintenance work would be required to achieve and maintain a cold shutdown if the single-component failure criterion were applied to the cross-tie valve between the two RHR divisions.

Flooding into the third floor control room or switchgear room containing equipment required for a safe shutdown has been evaluated. Provisions were made to ensure that such flooding cannot occur either directly from other areas of the third floor or by leakage through penetrations from above. In addition, moderate-energy lines presently located in the third floor switchgear room are shrouded to preclude the possibility of spraying and flooding.

3.6.3 Analysis Methods and Procedures

The methods and procedures used for the evaluation of pipe breaks of high-energy systems outside containment are presented in Subsections 3.6.3.1 through 3.6.3.4.

3.6.3.1 Blowdown and Environmental Effects Analyses

An analysis was performed to predict system blowdown response for each of the postulated high-energy line ruptures. The blowdown information is used to determine pipe whip forces and jet impingement characteristics, and may also be used as input in a number of other thermal-hydraulic analyses, depending on the requirements and problems anticipated for a particular break. In cases where structural damage could result from overpressure caused by rupture, the blowdown flow results are input in a compartment pressurization analysis. In situations where building temperature and humidity in the postbreak environment could damage required electrical, instrumentation, or control equipment, the blowdown flow results are input in a building environment analysis. Postulated ruptures resulting in release of significant amounts of subcooled water were evaluated for effects of flooding in the building housing the broken lines.

The criteria and methods to be used for the thermal-hydraulic analyses are described below.

3.6.3.1.1 Blowdown Analysis

The blowdown analyses may be characterized as either short term or long term in nature, depending on the purpose for which the results are used. Thrust data required for pipe whip analysis can be obtained in short-term analyses (about 500 msec real time) since maximum piping response is reached within this time. Mass and energy flow data required for compartment pressurization, environmental, and flooding analyses must be based on longer term blowdown information since the severity of these effects may increase with continuing flow from the break.

Typically, the duration of short-term analyses is insufficient to allow activation of operable components (other than check valves), and the balance of plant systems (other than the inoperable system) continue to operate in the normal way. For the long-term analyses, consideration must be given to action of operable components, interaction of other systems with the broken system, and the effects of shutdown of the reactor.

The following general criteria govern the blowdown analysis:

a. Analyses shall consider flow from both sides of the break

b. Discharge coefficients shall equal 1.0 for all breaks

c. Credit shall be taken for flow limiters, line restrictions, and pipe friction as applicable

d. Breaks shall be assumed to occur instantaneously

e. The initial conditions for a break shall be the worst-case operational condition.

3.6.3.1.2 PRTHRUST Program

The blowdown analyses were performed using the computer program PRTHRUST (Reference 40). The PRTHRUST program is a modification of RELAP3 (Reference 41), the AEC's presently accepted LOCA analysis code (Reference 42) for the specific requirements of pipe rupture analysis. In PRTHRUST, the fluid system is mathematically modeled as an assemblage of control volumes interconnected by flow paths. Characteristics of control volume include the state of the contained fluid and possible energy addition. Control volumes are used to model such components as pressure vessels, steam generators, heat exchangers, and the piping volumes. Flow paths are used to interconnect control volumes and may include operable valves, check valves, fills, and pumps. The program allows actuation of operable devices, such as valves, to be triggered at a specific time or based on a physical signal such as pressure or flow at a point in the system. The variation in pump performance under transient conditions is considered. A core model is available for cases in which transient reactor performance effects blowdown.

Initial values for the problem are taken as steady-state operating conditions for the system. The transient is initiated by instantaneously opening a leak in the system. The solution proceeds by step-by-step integrations of the governing fluid equations with time. The requirement for conservation of mass and energy in a volume is satisfied at each time step. State properties in the volumes are calculated using thermodynamic state equations and the ASME steam tables (Reference 43) for subcooled, saturated or superheated fluids. The flow rate for flow paths between volumes is calculated using both the one-dimensional momentum equation and Moody's two-phase choked flow model (Reference 44). The lesser of the two flows is assumed to govern.

The PRTHRUST program output includes time-history values of mass flow, pressure, temperature, enthalpy, and other thermodynamic quantities at specified points in the system and at the break. This information is suitable for input in subsequent jet impingement, compartment pressurization, environmental, and flooding analyses as required.

The program also calculates break thrust as a function of time. This calculation is facilitated by placement of control volume(s) in the model between the break and the piping elbow(s) nearest the break, and is carried out using the following equation.

$$T = T_{pt} + T_{mt} + T_a = (P_t - P_e)A + \frac{\rho A V^2}{g} + \frac{\Delta(MV)}{\Delta t g} \qquad (3.6\text{-}5)$$

where

T	=	total thrust at break
T_{pt}	=	pressure thrust
T_{mt}	=	momentum thrust
T_a	=	thrust due to fluid acceleration
P_t	=	throat pressure at break
P_e	=	ambient pressure
A	=	break area
ρ	=	density
V	=	velocity
g	=	Newton's constant
M	=	mass
t	=	time

Throat pressure is given by the Moody correlation (Reference 44) for choked flow, and is taken as equal to ambient pressure for nonchoked flow. The momentum change term is equal to zero for steady flow.

3.6.3.1.3 Building Pressurization and Environmental Analyses

In cases where compartment pressure or steam environment resulting from a postulated rupture could result in damage to structures, systems, or equipment required for safe shutdown, an analysis was performed to assess the magnitude of these effects. Only the worstcase break in each compartment was analyzed.

The mass and energy input from the break was determined by a long-term blowdown analysis, assuming the most adverse reactor operating conditions. The analyses of longterm compartment pressures and environment are generally performed using the CONTEMPT-LT or KITTY6 computer program. Where expedient, however, conservative hand calculated mass and energy balance is used. The failure point of all components (doors, vents, walls, etc.) that may alter fluid flow paths are determined and the effects of such failures considered in the analyses. The initial positions of all doors or other movable vents are assumed to be in the most adverse normal condition. A discharge coefficient of 0.6 is conservatively assumed for all vent areas unless another value can be justified analytically.

3.6.3.1.4 CONTEMPT-LT Computer Program

The CONTEMPT-LT computer program (Reference 45) predicts the time-history of pressure, temperature, and humidity response in a group of interconnected compartments, resulting from a high energy pipe break in one compartment. Input break characteristics are the mass and energy flows computed in the blowdown analyses. In the program, compartments are represented by control volumes, and are interconnected by flow paths representing the venting areas. Venting to the outside may also be considered. Vents may be opened at a specified pressure to represent active components or failure of components such as doors.

Each control volume is separated into variable liquid and vapor regions. While each region is assumed to be uniform temperature, the liquid and vapor temperature may be different. Mass and energy transfer between the two regions is permitted, based on condensation and/or evaporation correlations, as applicable. The program solution is by step-by-step integration of the mass conservation and energy equations with time.

The program also includes the capability to perform one-dimensional heat conduction calculations. This capability can be used to account for the heat sinking effect of various building components by specifying appropriate initial and boundary conditions. The effect of building venting and leakage can be accounted for through use of available correlations for flow through small and large openings.

The CONTEMPT-LT output includes values of building pressure, temperature, and relative humidity in each compartment as a function of time.

3.6.3.1.5 Flooding Analyses

The analyses for flooding effects were carried out using hand calculational methods. Input was taken from mass and energy flow results of blowdown analyses for pressurized water lines. Consideration was also given to flooding caused by steam condensation as determined in the building environment analyses described in the preceding section. The flooding analysis for a particular compartment was performed only for the worst-case break for that compartment, although possible secondary effects, such as rupture of a second line by a whipping pipe, were considered.

The most adverse system operating conditions were assumed at the time of the break. In determining the mass of water released, failure of the active component leading to the maximum release was assumed.

The flooding analysis method was based on determination of compartment free volumes as functions of elevation, along with available drainage capability and flow-path characteristics between connecting compartments.

Using this information along with calculated water flow rates, the maximum water level and rate of water-level rise was determined for each compartment.

3.6.3.1.6 CVPT-REPORT Computer Program

The CVPT-REPORT computer program is used for the determination of compartment pressure and environmental response due to a postulated instantaneous pipe rupture in a high-energy piping system.

CVPT-REPORT is a design and analysis tool that can treat one compartment or 16 interconnected compartments of a completely arbitrary arrangement. Interconnecting paths modeled as orifices or pipe sections are accepted by the program. The break flow rate from the postulated break is determined by the program throughout the incident by considering input conditions of reactor vessel steady-state fluid conditions, pipe losses to the break point, flow restrictions, and isolation valve actuation cycles, including closing times and flow choking.

The CVPT-REPORT program uses a step-by-step integration method of the mass conservation and energy equations with time to obtain the environmental response of each compartment during the incident. State properties in the compartments are calculated using thermodynamic uniform-flow, uniform-state equations and the ASME steam tables for wet, saturated, or superheated steam. The flow rate for flow paths between compartments is calculated using the Darcy formula for compressible flow through orifices or a formula for compressible isothermal flow in pipelines. For postulated breaks where the process fluid is saturated or superheated steam, the mass flow rate out of the break is calculated by using a formula for the choked flow of a compressible gas through an isentropic nozzle. For cases where the process fluid is saturated liquid, the mass flow rate out of the break is determined by using the Darcy formula for the discharge of fluid through valves. The heat-transfer effect to the compartment walls is considered through incorporation of the Uchida heat transfer coefficients for a range of air-to-steam ratios (Reference 46).

The CVPT-REPORT program output includes time-history response of mass flow rate, and the pressure, temperature, and humidity of each compartment. This information is suitable for input into any subsequent long-term analysis or structural and component damage analysis.

3.6.3.1.7 KITTY6 Computer Program

The KITTY6 computer program is used to determine transient temperature and pressure responses in various areas of the reactor building for the HELB and LOCA accident cases. This problem is a transient heat transfer problem which depends upon the initial conditions, the boundary conditions and the characteristics of the system. The problem is solved numerically using the computer program KITTY6.

KITTY6 calculates node properties and path heat flow and mass flow rates for transients in user specified solid and/or fluid channel configurations. Paths between nodes may be used to model conductive, convective and radiative heat transfer and mass and enthalpy transport. In the compressible fluid system (CFS) of the model, elevation effects may be accounted for, compressible fluid flow paths may be represented as either of inertial or non-inertial (pseudo-steady) types, and limitation of flow path rates to the choking flows may be elected. Water and as many as five noncondensible gas species may be treated in the CFS. Provided the configuration specification, material properties, boundary conditions, internal heat generation rates, selected fluid flow rates and required printout times, KITTY6 computes and prints the node properties (temperature, pressure, density, composition and mass flow rates), and path mass and energy flow rates at user specified time intervals.

KITTY6 was utilized to re-evaluate environmental conditions resulting from HPCI, RCIC and RWCU breaks as referenced in the previous sections. The original short-term analyses for these breaks were not impacted by the revised environmental analyses.

3.6.3.2 Jet Impingement Analysis

This section defines analytical methods used for performing the jet impingement evaluation. The effects of jet impingement were considered for all longitudinal design-basis, longitudinal crack, and circumferential crack breaks. The jet impingement effects resulting from fluid discharge from both ends of the severed pipe were considered for all circumferential design-basis breaks, unless it could be shown that the two ends are sufficiently restrained to prevent offset after rupture. The sweep of the jet was considered for all design-basis breaks subject to pipe whip.

The break opening configuration for postulated design-basis breaks is defined in Subsection 3.6.1.1.2. The fluid jet is assumed to fan out to form a circular or prismatic cone issuing from the break opening. Jet impingement pressure on a target struck by the jet is calculated by determining total thrust at the break, and assuming this total integrated thrust remains constant at any plane of interest in the cone.

The axis of the jet is parallel to the pipe axis for design-basis circumferential breaks and perpendicular to the pipe axis for all other break types. The characteristics of the jet shapes for the various postulated break types are shown in Figure 3.6-45.

3.6.3.2.1 Total Thrust Load

The calculation of thrust on the pipe after rupture was described in the blowdown analysis. Using the principle of conservation of momentum, the steady-state jet thrust can be equated to the thrust on the pipe. This conclusion has been confirmed by Moody (Reference 47).

The total jet thrust for breaks can be equated to the maximum in the quasi-steady-state region of the thrust time curve. The rise time for the jet thrust can be taken as the time to reach this quasi-steady-state peak. The initial peak in the thrust-time curve, which is caused by acceleration of fluid from the pipe, does not influence the jet impingement load on a target. A graph showing determination of total thrust from the PRTHRUST results is shown in Figure 3.6-46.

3.6.3.2.2 Coning Angle

The fluid jets from steam or flashing water breaks were assumed to fan out with a constant half angle of l2.5°. The experimental basis for this assumption is found in Reference 48, which includes photographs of jets of both steam (about l00 psia saturated) and water (at 2250 psia and 550°F). For subcooled, nonflashing breaks, a jet divergence angle of l0° was assumed.

3.6.3.2.3 Jet Temperature

The jet temperature will vary with distance from the jet source. However, jet temperature will not exceed the stagnation temperature based upon an isenthalpic expansion of jet fluid. The jet temperature limits are

For steam line breaks:

$$T_j = 330°F \tag{3.6-6}$$

For liquid line breaks:

$$T_j = 240°F \text{ maximum} \tag{3.6-7}$$

$$= \text{Fluid temperature if less than } 240°F \tag{3.6-8}$$

where

T_j = jet stagnation temperature (°F)

3.6.3.2.4 Target Loading

The normal load applied to a target by the jet issuing from a postulated break may be expressed as

$$F = T\frac{A_i}{A_j} S_F D_{LF} \tag{3.6-9}$$

where

T = total thrust of jet (lb_f)

A_i = cross-sectional area of jet intercepted by target structure

A_j = total cross-sectional area of jet at target structure

S_F = shape factor

D_{LF} = dynamic load factor

The total thrust T has been defined previously in the blowdown analysis. The ratio A_i/A_j represents the proportion of the total mass flow interrupted by the target structure. The dynamic load factor D_{LF} accounts for the rapid application of the load. A dynamic load factor of two should be used in the absence of an analysis justifying a lower value.

The shape factor S_F depends on the projected section and orientation of the target struck by the jet and is a measure of the target's potential for changing the momentum of the jet.

Typical shape factors for perpendicular impingement at turbulent flow conditions are

a. 0.5 to 0.6 for piping spans up to ten diameters

b. 0.4 for spherical shapes

c. 0.2 for ellipsoidal shapes (stream lined)

d. 1.25 for flat plates.

The force determined using the above formula and factors represents the integral of a uniform pressure applied normally to the target impinged upon by the jet.

3.6.3.3 Pipe Whip Analysis

A pipe whip analysis was carried out for each of the design-basis ruptures postulated in high-energy lines identified as requiring this type of analysis. This analysis serves initially to identify situations in which whipping pipes could cause unacceptable damage to systems, equipment, or structures, and later to develop locations and design loads for restraints required to prevent unacceptable pipe whips. The steps in the pipe whip analysis are as follows:

a. An analysis is performed to predict piping response to the rupture thrust load. This analysis determines whether maximum moments and torque in the piping exceed values necessary to cause plastic hinging and whether a sufficient number of plastic hinges form to effect a plastic failure mechanism or pipe whip

b. If pipe whip takes place, the trajectory of the whipping pipe is traced to identify impact on systems, equipment, or structures. Mechanical, HVAC, electrical, instrumentation, and control components are considered to fail upon impact by whipping pipes, unless stress analyses justify otherwise. Structural components are evaluated to determine whether pipe whip impact causes failure in accordance with the methods described in this section and in Subsection 3.6.3.4

c. Locations selected for pipe restraints prevent the occurrence of unacceptable pipe whips. Sizing analyses were performed to determine stiffness and strength characteristics of these restraints.

d. Finally, a dynamic response analysis of the complete piping system and identified restraints was performed. This analysis verified the fact that unacceptable pipe whips do not occur in the restrained system, and provided maximum reaction loads for use in final design of the restraints.

The criteria for the pipe whip evaluation, and the analytical formulation of the analyses described above, is given in the following sections.

3.6.3.3.1 Criteria for Analysis

The following general criteria were applied in the pipe whip evaluation:

a. The dynamic nature of the piping thrust load shall be considered. In the absence of analytical justification to the contrary, a dynamic load factor of 2.0 shall be used

b. Nonlinear (elastic-plastic strain hardening) pipe and restraint material properties shall be considered. Pipe whip shall be considered to take place on attainment of a hinge mechanism in which maximum fiber strain reached 50 percent of that strain corresponding to maximum stress in a one-dimensional tensile test

c. Pipe whip was considered to result in unrestrained motion of the pipe along a path governed by the hinge mechanism and the direction of the vector thrust of the break force. A maximum of 180° rotation was assumed to take place about any hinge

d. The effect of rapid strain rate on material properties was considered. In the absence of justification to the contrary, a l0 percent increase in yield and ultimate stress under dynamic load was assumed

e. Variations between lower- and upper-bound material properties were considered in the most conservative fashion. For example, use of lower-bound properties provided a conservative prediction of pipe whip, while use of upper-bound properties was conservative for determination of maximum restraint loads. In the absence of data justifying the contrary, lower bounds were taken as minimum guaranteed properties, with a 40-percent statistical increase for upper-bound properties

f. Where possible, required pipe whip protection was provided by designing normal operating pipe restraints to withstand pipe rupture loads. Pipe whip restraints required at locations where resultant piping thermal stress would preclude use of rigid supports were designed with an initial clearance sufficient to allow. free thermal expansion of the pipe. The clearance restraints used a deformable energy-absorbing component retained by a support substructure. Energy-absorbing components were designed to withstand pipe impact without exceeding 50 percent of ultimate capacity. Rigid supports and support substructures were designed in accordance with the criteria given in Subsection 3.6.2.1.5.

3.6.3.3.2 <u>Preliminary Pipe Whip Evaluation</u>

The methods in this section were used to determine whether pipe whip takes place for a given postulated rupture, and to determine the kinetic energy of whipping pipes on impact with a target.

A pipe whip occurs when a hinge mechanism forms in the system that has a structural resistance less than the applied thrust force. The mechanisms consist of straight runs of pipe connected by fittings (elbows, etc.) that yield under a combination of internal moment and torsion. The condition for formation of a plastic hinge at a given location in a piping system is

$$\left(\frac{iM^2}{M_{ult}} + \frac{T}{T_{ult}}\right) \; 2 \geq 1 \qquad (3.6\text{-}10)$$

where

M = applied moment

= $\sqrt{M_l^2 + M_2^2}$

M_1, M_2 = moment components in plane perpendicular to pipe centerline

M_{ult} = ultimate moment

i = stress intensification factors for elbows, tees, etc.

T = applied torque

T_{ult} = ultimate torque

The ultimate moment and torque are limited by the allowable 50 percent uniform ultimate strain. Expressions for these quantities, based on assumed elastic-linear strain-hardening material properties, are given by the following:

$$M_{ult} = \sigma_y Z_p + (\sigma_{ult} - \sigma_y) Z_e \qquad (3.6\text{-}11)$$

$$T_{ult} = t_y z_{tp} + (t_{ult} - t_y) Z_{te} \qquad (3.6\text{-}12)$$

where

σ_{ult} = tensile stress corresponding to 50 percent of strain at maximum tensile stress

σ_y = tensile yield stress

Z_p = plastic bending section modulus

= $(4/3)(r_o^3 - r_i^3)$

Z_e = elastic bending section modulus

= $\frac{\pi(r_o^4 - r_i^4)}{4r_o}$

t_y = shear yield stress

= $\sigma_y/2$ (maximum shear theory)

t_{ult} = ultimate shear stress

= $\sigma_{ult}/2$

Z_{te} = elastic torsion section modulus

= $\frac{\pi(r_o^4 - r_i^4)}{2r_o}$

Z_{tp} = plastic torsion section modulus

= $\frac{2\pi}{3}(r_o^3 - r_i^3)$

r_o = pipe outside radius

r_i = pipe inside radius

Formation of a sufficient number of hinges produces a mechanism that moves under the action of the blowdown force and is resisted by the constant limit load and inertia of the mechanism. The resulting motion may be determined using simple kinematic formulas.

As an example, the motion resulting from a postulated longitudinal break at joint B is to be determined for the piping system shown in Figure 3.6-47.

The structural resistance (R_e) can be determined by subjecting the mechanism to a virtual displacement (w). Equating the work done by the limit load to the strain energy dissipated in the yield hinges (all hinges assumed to have the same plastic moment) results in

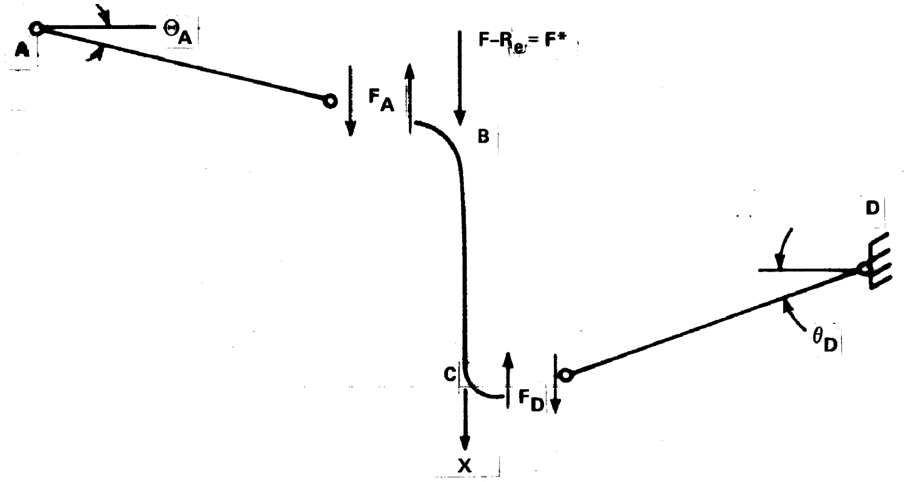
$$R_e(w) = 2M_p\theta_A + 2M_p\theta_D \qquad (3.6\text{-}13)$$

Substituting $\theta_A = {}^{w}/_{L_A}$, $\theta_D = {}^{w}/_{L_C}$, and eliminating w yields

$$R_e = 2M_p\left(\frac{1}{L_A} + \frac{1}{L_C}\right) \qquad (3.6\text{-}14)$$

If the blowdown force exceeds R_e, the system is unstable and pipe whip takes place. Section A-B will rotate clockwise about point A, and Section C-D will rotate counterclockwise about point D; in other words, the trajectory is determined assuming the runs are inextensional.

Impact velocity is determined by writing the dynamic equilibrium equations for the hinge mechanism subject to the action of the net force (blowdown force less structural resistance).



For Section A-B

$$F_AL_A = I_{AB}\ddot{\theta}_A \qquad (3.6\text{-}15)$$

For Section B-C

$$F - R_e - F_A - F_D = M_{BC}\ddot{X} \qquad (3.6\text{-}16)$$

For Section C-D

$$F_DL_C = I_{CD}\ddot{\theta}_D \qquad (3.6\text{-}17)$$

where

I = rotational mass moment of inertia of pipe about one end

$= \frac{ML^2}{3}$

M = mass of pipe

L = length of pipe

Substituting the expression for mass moment of inertia and $\theta = \chi L$, and combining the three equations, results in

$$F^* = F - R_e = \left[\frac{M_{AB}}{3} + M_{BC} + \frac{M_{CD}}{3}\right]\ddot{\chi} = M^*\ddot{\chi} \quad (3.6\text{-}18)$$

where

F^* = apparent force

M^* = apparent mass of mechanism

Having the force F^* and the apparent mass M^*, the velocity and kinetic energy at any displacement d is given by

$$V_d = \sqrt{2\frac{F^*}{M^*}d} \quad (3.6\text{-}19)$$

and the kinetic energy is given by

$$(KE)_d = \frac{M^*V_d^2}{2} = F^*d \quad (3.6\text{-}20)$$

= Work done during displacement

The formulation described above can be altered very simply to evaluate the case of a circumferential (guillotine) break at point C. In this case, the limit load for Section C-D is given by

$$R_e = \frac{M_p}{L_{CD}} \quad (3.6\text{-}21)$$

where

F^* = $F - R_e$ as before

M^* = $\frac{1}{3}M_{CD}$

and the equations for velocity and kinetic energy at any displacement can be applied as before.

The formulation above can thus be used to evaluate whether pipe whip takes place, the trajectory of the whip if formed, and the kinetic energy of the whipping pipe on impact with a target.

3.6.3.3.3 Preliminary Design of Pipe Whip Restraints

The preliminary design of pipe whip restraints designed to maintain contact with the pipe during all operating conditions were carried out using the SAP IV computer program (Reference 49). The preliminary design of pipe whip restraints designed with an initial clearance between pipe and restraints were carried out using the RAP computer program (Reference 50). The descriptions of these programs and methods for their use are given below.

3.6.3.3.4 RAP Computer Program

The RAP program performs a time-step integration solution of the dynamic equilibrium equation for a mass (the pipe) subjected to a force-time-history (the blowdown force) impacting a bilinear strain-hardening viscous-damped spring (the restraint). The pipe mass assumed in RAP is the apparent mass of the whip mechanism as described in the preceding section. The solution makes use of kinematic relationships among accelerations, velocities, and displacements at the beginning and end of each time step to reduce the second-order differential equation of motion to a form that may be solved algebraically over the time increment (References 50 and 51).

The incremental equilibrium equation for the system shown in Figure 3.6-48 is the following:

$$M\Delta\ddot{X} + C\Delta\dot{X} + K\Delta X = \Delta F \qquad (3.6\text{-}22)$$

where

M = effective mass of pipe

C = viscous damping coefficient

K = restraint stiffness

F = applied blowdown force

X = displacement

Δ = an increment of succeeding quantity

· = superscript indicating derivative w.r.t. time

In addition, if the acceleration of the mass is assumed to change linearly over a time step, the following relationships can be written:

$$\Delta\ddot{X}_{N+1} = \frac{6}{DT^2}\Delta X_{N+1} - \frac{6}{DT}\dot{X}_N - 3\ddot{X}_N \qquad (3.6\text{-}23)$$

$$\Delta\dot{X}_{N+1} = \frac{3}{DT}\Delta X_{N+1} - 3\dot{X}_N - \frac{DT}{2}\ddot{X}_N \qquad (3.6\text{-}24)$$

where the subscript "N" represents a quantity taken at the "Nth" time step and DT is the length of the time step. If Equations 3.6-23 and 3.6-24 are substituted into Equation 3.3-22, the result is

$$\left\{\frac{6M}{DT^2} + \frac{3C}{DT} + K\right\}\Delta X_{N+1} = \Delta F + \left\{\frac{6M}{DT} + 3C\right\}\dot{X}_N + \left\{3M + \frac{DT(C)}{2}\right\}\ddot{X}_N \qquad (3.6\text{-}25)$$

which can be solved for ΔX_{N+l}, since $\dot{X}_N$ and $\ddot{X}_N$ are known initial conditions at the beginning of the time step. Having ΔX_{N+l}, Equations 3.6-23 and 3.6-24 can be used to determine the change in acceleration and velocity during the time increment. At each step during the incremental process, the status of the restraint is checked to determine whether it is detached, elastically loading, plastically loading, or elastically unloading, and appropriate changes are made to the initial gap, yield deflection, and restraint stiffness.

3.6.3.3.5 SAP IV Computer Program

SAP IV (Reference 49) is a finite element computer program for linear elastic analysis of arbitrary three dimensional structures. The program includes a variety of beam, plate, shell, and solid elements. The program can consider applied static loads, thermal expansion, seismic response spectra, and time-history dynamic loads. The program numerical techniques and core storage allocation methods have been designed to permit analysis of largescale problems at reasonable cost, although smaller problems can be solved with no loss in efficiency.

3.6.3.3.6 Final Analysis of Piping System and Restraints

The final system analysis was performed to verify that the restraints selected fulfill their intended function in preventing unacceptable pipe whips, and to provide final design loads on the restraints. The final system analysis was carried out using the PIPERUP computer program (Reference 52).

The PIPERUP computer program performs nonlinear dynamic analysis of piping systems subjected to rupture thrust forces. PIPERUP can be used both to predict formation of pipe whips and to determine loads on piping anchors and pipe whip restraints. The program is based on the finite element method of analysis, with the piping represented as an assemblage of straight and curved beam elements, and the restraints as axial and rotational springs. The solution is a time-step integration of the system equations of motion.

Piping element stiffness is arranged to permit representation of elastic and linear strain-hardening material properties. Each element is initially represented as a combination of these sub-elements, whose sum stiffness equals the elastic stiffness of the pipe. If at a given time-step the element internal forces are detected to exceed the yield capacity of the pipe, one of the subelements is hinged, such that the stiffness of the remaining two subelements corresponds to the strain-hardening modulus of the material. The analysis is then continued; if the internal forces are later detected to exceed the ultimate capacity of the pipe, the second subelement is hinged, leaving a single subelement with a very small stiffness. Prediction of the yield and ultimate hinge transitions is based on a formulation derived in accordance with the von Mises theory, which considers biaxial bending and torsional stresses. In the event that unloading occurs from the plastic region, such unloading is along the elastic line (isotropic strain-hardening model). Prediction of a plastic collapse mechanism, or pipe whip, is based on detection of excessive deflections.

The modeling of restraints in the analysis can include initial gaps, and elastic and linear strain-hardening stiffnesses. The effects of impact on restraint loading are accounted for automatically in the solution technique.

Program output includes time-history values of deformation, internal loads, material strains, restraint reactions, and identification of pipe whip mechanisms.

3.6.3.4 Structural Analysis

Structural analyses were performed to assess the ability of essential plant structures and structural components to withstand loads resulting from postulated ruptures. These analyses included

a. Analysis of structural components and structures for pipe whip impacts and jet impingements

b. Analysis of structural components for compartment pressure, temperature, and hydrostatic flooding loads

c. Analysis of piping anchor structures for pipe-break loads

d. Analysis of structures and structural support systems for pipe whip restraint and jet impingement barrier reaction loads.

The criteria governing acceptability of postulated rupture loads on essential structures and structural components have been given in Subsection 3.6.2.1.5. As indicated in that section, the structural analyses are generally performed using limit analysis techniques, such as collapse load analysis for beams and frames and yield line theory for concrete slabs, which account for resistance of structural elements into their plastic range. The description of these techniques follows.

3.6.3.4.1 Characteristics of Pipe Rupture Loads

The structural loads resulting from pipe rupture can, in general, be categorized as either impulsive or impactive in nature. The time variation of impactive dynamic loads is dependent on the initial kinetic energy of the impacting body, and on the stiffness and inertial resistance of the impacting body and the structure to which the loads are applied. The time variation of impulsive dynamic loads is determined independently by factors other than structural mass or stiffness. The jet impingement, compartment pressure, and pipe restraint reaction loads resulting from pipe rupture are impulsive, while loads applied by whipping pipes are impactive. In situations where the applied force-time function is known, structural response can be computed accurately using time-history analysis techniques. This is, in fact, the case for all impulsive loads, and for certain impactive load cases. It is also possible to obtain simplified conservative solutions for many cases of practical interest. The analysis for impactive loads can be made using energy and momentum balance methods. The solution for impulsive loads can also be obtained using energy methods, or by equivalent static analysis using dynamic load factors.

3.6.3.4.2 Energy Balance Methods

Solution for structural response by energy methods is predicated on the equality:

Work Done on System = Energy Absorbed by System

The energy is absorbed as strain energy by the structure, and is equal to the area under the resistance-displacement curve (Figure 3.6-49) for the structure under load, or

$$E_S = \int_0^{X_m} R(X)dx \qquad (3.6\text{-}26)$$

where

E_s = strain energy absorbed

$R(X)$ = resistance-displacement function at point of loading

dx = deflection

X_m = maximum deflection under load

If the assumption of elastic-perfectly plastic-material properties are made, the energy absorbed is given by (see Figure 3.6-49)

$$E_s = R_e \left(X_m - \frac{1}{2} X_e \right)$$

where

R_e = resistance at yield

X_e = deflection at yield

For an elastic-plastic structure subject to initial loads, the energy absorbed is given by (see Figure 3.6-49)

$$E_s = [R_e - R_o] \left[x_m - \frac{x_e + x_o}{2} \right] \qquad (3.6\text{-}27)$$

where

R_o = equivalent resistance required for initial loads

x_o = displacement associated with R_o

3.6.3.4.3 Evaluation of Resistance-Displacement Functions

The evaluation of structure-resistance-displacement functions can be carried out using standard limit analyses techniques for most cases of practical interest. Acceptable methods for determination of resistance-displacement functions are demonstrated in two commonly encountered examples, as follows:

a. Point load on fixed-fixed beam - The resistance load at full yield for a fixed-fixed beam loaded at the center (Figure 3.6-50) can be determined using the principle of virtual work (References 53 and 54).

$$R_e = \frac{8M_P}{L} \qquad (3.6\text{-}28)$$

where

M_P = maximum section strength

L = length of beam

The deflection at yield X_e is given by

$$X_e = \frac{R_e L^3}{192EI} \qquad (3.6\text{-}29)$$

where

E = Young's modulus

I = section moment of inertia

For a steel beam, M_p is given by (see Reference 22)

$$M_p = F_y z \tag{3.6-30}$$

where

F_y = yield stress

z = plastic section modulus

For a concrete beam, M_p is given by (see Reference 55)

$$M_p = 0.9\left[(A_S - A'_s)F_y\left(d - a/2\right) + A'_s F_y (d - d')\right] \tag{3.6-31}$$

where

A_s = tensile steel reinforcing area

A'_s = compressive steel reinforcing area

F_y = steel yield stress (may be increased by dynamic increase factors)

$d - d'$ = distance between tensile and compressive reinforcing

$a = \frac{(p-p')F_y d}{0.85 f'_c}$

The above formula is predicated on the assumption that the beam is under-reinforced, or

$$(p - p') \leq 0.75 p_b \tag{3.6-32}$$

where

p = ratio of tensile steel

p' = ratio of compressive steel

p_b = balanced steel ratio

Computation of deflection for a concrete beam shall be based on the average moment of inertia for the cracked and uncracked sections, which may be approximated by (Reference 31)

$$I_a = \frac{bd^3}{2}(5.5p + 0.083) \tag{3.6-33}$$

where

b = width of beam

d = effective depth

All information necessary to quantify resistance- displacement curves for the fixed-fixed beam shown in Figure 3.6-50 is now present. Although the resistance of the beam in this example was governed by bending capability of the section, it should be noted that bending/shear interaction may substantially influence resistance of other systems, particularly where loads are applied near supports. Methods that may be used for other beam configurations and for frames are described in References 22, 53, and 54.

b. Point load on concrete slab - The resistance- displacement functions for concrete slabs may be found using yield line theory. As an example, typical yield line patterns for rectangular slabs under point loads are shown in Figure 3.6-51 (Reference 55). The yield load for a complete circular fan-type failure in an isotropically reinforced rectangular slab with equal tensile and compressive reinforcing steel is given by Reference 56.

$$R_e = 4\pi M_p \quad (3.6\text{-}34)$$

and the deflection at yield is given by

$$X_e = \frac{\alpha R_e a^2}{EI_a}(1 - \gamma^2) \quad (3.6\text{-}35)$$

The term α is dependent on the slab length-to-width ratio and may be obtained from Reference 57. Concrete slabs should also be checked for punching shear failure (see Reference 56) particularly where loads are applied close to edge supports.

3.6.3.4.4 Time-History Analysis Methods

The preceding section has described simplified analysis methods in which the energy absorption capability of the affected structure or structural component is compared to the initial kinetic energy of an impacting body or to the work done by an impulsive force. Application of the simplified methods generally requires use of conservative assumptions concerning the nature of the motive force and the strength of the structure. If necessary, the degree of conservatism can be reduced by use of a more accurate time-history analysis solution. Available time-history solutions range from simple single degree of freedom (first mode) approximations to highly detailed elasto-plastic finite element models. Nearly all time-history methods compute response to a specified force-time function, although a few solutions are available for specified initial structural velocities. Determination of forcing functions for impulsive loads is discussed in Subsection 3.6.3.4.7 and for impactive loads in Subsection 3.6.3.4.8.

3.6.3.4.5 Single Degree of Freedom Solutions

Methods are presented in Reference 31 for time-history analysis of single degree of freedom systems. Figures 2.7 through 2.9 of Reference 31 may be used to determine peak response to applied rectangular pulse, triangular pulse and ramp forcing functions for elastic systems. Where Figures 2.7 through 2.9 of Reference 31 are used to compute peak response, such response remained within elastic limits for the materials. Figures 2.23 through 2.26 of Reference 31 may be used to determine peak response to applied rectangular pulse, triangular pulse, and ramp forcing functions for elasto-plastic systems. Where Figures 2.23 through 2.26 of Reference 31 are used to compute peak response, the assumed resistance-displacement function was computed in accordance with methods described for the evaluation of resistance-displacement functions. It should be noted that the validity of the one degree of freedom response curves in Reference 31 is predicated on the assumption that dominant response occurs in the structure fundamental mode. The validity of this assumption was verified by application of the curves using the second structure mode. If peak response in the second mode exceeds 10 percent of that in the fundamental mode, a more detailed representation of the structure was used, as described below.

3.6.3.4.6 Numerical Methods of Structural Analysis

For structural problems in which the assumptions required to perform simplified analysis are excessively inaccurate or conservative, more general techniques are available in the form of automated discretization techniques. The two most common discretization techniques are finite element, wherein the structural continuum is modeled as an assemblage of discrete regions, and finite difference wherein the differential equations governing structural behavior are satisfied at discrete points. In either case, the result of the discretization process is a system of equations, generally of a size well beyond the scope of hand computations.

SAP (Structural Analysis Program) (Reference 49), a finite element computer program, was used to perform linear elastic dynamic analysis of complex structures and structural components.

3.6.3.4.7 Analysis for Impulsive Loads

As indicated previously, the analysis for impulsive loads can be carried out using energy balance techniques. As an example, the work done by an instantaneously applied constant magnitude impulsive force F in displacing a structure from rest to a maximum displacement X_m can be equated to the energy absorbed by the structure.

$$FX_m = R_e\left(\frac{X_e}{2} + (X_m - X_e)\right) \qquad (3.6\text{-}36)$$

The structure does not fail if the maximum displacement X_m is less than the ultimate displacement, or

$$X_m \leq \mu X_e \qquad (3.6\text{-}37)$$

By substituting and rearranging the two equations, we obtain the minimum required structural resistance as

$$R_e \geq \frac{F\mu}{\mu - {}^{1}/_{2}} \qquad (3.6\text{-}38)$$

where

R_e = resistance at yield

F = applied force

μ = allowable ductility ratio

It should be noted that this solution is always conservative in that it neglects both decrease in response due to finite rise time of the impulsive force, and the strain-hardening resistance of the structure. A more definitive solution may be obtained using the time-history analysis methods. Since the rise time of most impulsive loads (jet impingement and compartment pressure) resulting from pipe rupture substantially exceeds the fundamental period of the target structures, a one degree of freedom analysis is normally sufficient. Where time-history methods are used to compute response to impulsive loads, acceptability of maximum response will be governed by the ductility ratios.

3.6.3.4.8 Analysis for Impactive Loads

Overall structural response to impactive loads, such as whipping pipes, is dependent on the initial kinetic energy of the impacting body and the inertial (mass) and stiffness characteristics of the impacting body and target structure. It is appropriate to categorize impact problems in terms of the relative "hardness" (stiffness and inertial resistance) of the impacting body and target structure. Where the target structure is harder than the impacting body, the loading applied to the structure will be determined by the collapse of the impacting body. Where the impacting body is harder than the target structure, the loading on the target structure will be determined by the course of embedment of the body into the structure. Both of these cases approach what is termed plastic impact in mechanics. However, if the hardness of the impacting body and target structure is nearly equal, an elastic impact occurs. The solution for pipe impact problems may be obtained by energy/momentum balance methods, by time-history analysis methods, or by a combination of these two methods.

3.6.3.4.8.1 Analysis Using Energy and Momentum Balance

The analysis using energy and momentum balance is based on equating energy imparted to the target structure after impact to the maximum resultant strain energy. Using conservation of momentum to determine target velocity after impact we obtain

$$V_t = \frac{V_s m(1+e)}{M+m} \qquad (3.6\text{-}39)$$

where

V_t = target velocity after impact

m = effective mass of striking body (pipe)

M = effective mass of target structure

e = coefficient of restitution

V_s = velocity of striking body

Knowing target velocity after impact, the kinetic energy of the target after impact E_t is given by

$$E_t = \frac{MV_t^2}{2} \qquad (3.6\text{-}40)$$

Solution for maximum response is then found by equating the initial kinetic energy plus the work done by external forces to the strain energy at maximum displacement. For an elastic-perfectly-plastic system subject to impact, and an instantaneously applied constant magnitude force F, this equation is

$$\frac{MV_t^2}{2} + FX_m = R_e\left(\frac{X_e}{2} + (X_m - X_e)\right) \qquad (3.6\text{-}41)$$

The structure does not fail if the maximum deflection X_m obtained from the equation above is less than the ultimate deflection, or

$$X_m \leq \mu X_e \quad (3.6\text{-}42)$$

Alternatively, the structure survives if energy absorption required is less than the structure's energy absorption capability, that is,

$$\frac{MV_t^2}{2} + F\mu X_e \leq \left(R_e X_e \left(\mu - \frac{1}{2}\right)\right) \quad (3.6\text{-}43)$$

The acceptability of pipe whip impact can be conservatively evaluated for all cases based on the above equations and the following conservative assumptions:

a. Impact is elastic (e = 1)

b. The effective mass of the whipping pipe equals one-third of the mass between adjacent hinge(s) making up the pipe whip mechanism (Reference 59) for sections of pipe impacting side-on, and full mass for sections of pipe impacting end-on

c. The velocity of the pipe at impact is taken either from the piping dynamic analysis or determined using kinematic relationships

d. The effective mass of the target corresponds to that of a circular plug through the target thickness with diameter equal to pipe diameter plus target thickness (Reference 60). If the target is a beam, plug width may not exceed beam width

e. The resistance-displacement function for the target structure is computed using the energy balance methods

f. Acceptability of impact is governed by the allowable ductility factor in Table 3.6-2.

The simplified method is conservative both in assuming elastic impact (ignoring energy absorbed in local plastic deformation of the pipe and target structure on impact), and in assuming a lower limit target effective mass. A more definitive analysis is obtained by using more complex time-history analysis methods, as described in the following section.

3.6.3.4.8.2 Combined Time-History and Energy Balance Methods

In these methods, a time-history forcing function characterizing impact is established based on local deformation of the impacting body or target structure during impact. By taking into account local deformation during impact, the conservatism noted in the preceding section in assuming fully elastic impact is removed. By applying the computed forcing function in a structure dynamic response analysis, a realistic value of structure effective mass can be determined, based on the failure mechanism determined for the structure.

The case of a "hard" body impacting a relatively "soft" structure has been treated in Reference 61. This case would correspond, for example, to a heavy-walled pipe striking a thin shell.

The case of a relatively "soft" body striking a "hard" structure would correspond to a whipping pipe striking a massive concrete structure. The formulation for this analysis was derived from methods presented for evaluation of response to aircraft impact in Reference 62 and 63, and is presented below.

The force applied during impact includes a component due to blowdown thrust and an impulse component. The blowdown thrust component is simply that calculated in the thermal-hydraulic analysis previously described. The impulse component is that portion of the wall reaction that removes the kinetic energy from the pipe. It can be calculated by considering the change in momentum as the pipe crushes from length L + ΔX to length L, as shown in Figure 3.6-52.

Impulse = Change in momentum

$$F\Delta t = M_p(V - \Delta V) - \left(M_p V + \mu_S \Delta X V\right) \tag{3.6-44}$$

$$F\Delta t = -M_p \Delta V - \mu_S \Delta X V \tag{3.6-45}$$

$$F = -M_p \frac{\Delta V}{\Delta t} - \mu_S \frac{\Delta X}{\Delta t} V \tag{3.6-46}$$

$$F = -M_p a - \mu_S V^2 \tag{3.6-47}$$

Taking a force balance on the uncrushed portion of pipe

$$M_p a = K_p = \text{Crushing strength of pipe} \tag{3.6-48}$$

Then the force on the wall, F_W is

$$F_W = -F = K_p + \mu_S V^2 \tag{3.6-49}$$

where

F = $F(t)$ = impulse reaction applied to structure after impact

K_P = $K_P(x)$ = crushing strength of pipe

μ_S = $\mu_S(x)$ = mass of pipe stopped per unit of deflection

X = $X(t)$ = total distance crushed

t = time

V = velocity of uncrushed portion of pipe

M_P = mass of uncrushed portion of pipe

a = acceleration of uncrushed portion of pipe

This equation can be conservatively evaluated to find the impact force time-history based on the following assumptions:

a. The impulse reaction is applied to a target structure area with a maximum dimension not exceeding pipe diameter

b. Pipe crushing strength is based on local collapse of the pipe walls up to the point where the pipe is fully "flattened." Pipe crushing strength after "flattening" is limited to the lesser of piping or target ultimate compressive stress

c. The mass of pipe stopped can be calculated using geometric considerations up to the point where the pipe is fully "flattened." The mass of the pipe stopped after "flattening" is equal to one-third of the mass between adjacent plastic hinges for sections of pipe impacting side-on and full mass for sections of pipe impacting end-on

d. The impulse force drops to zero when the integral impulse force by time applied is equal to the initial momentum of the impacting pipe.

A typical force-time history after impact, generated in the above fashion, is shown in Figure 3.6-53. The force is equal to the blowdown force at first contact between the pipe and structure, and begins to increase thereafter as the pipe crushes. Once the pipe is fully crushed, the force rises to the limit of pipe or wall compressive strength. Once the pipe momentum is exhausted, the force drops again to the level of the blowdown thrust.

The force-time history thus determined is then applied in a time-history response analysis previously described. The time-history analysis is carried out up to formation of a plastic collapse mechanism in the target structure (up to limit load). Acceptability of the target structure response is determined using an energy balance as follows.

Work done on structure + kinetic energy of structure

= Maximum strain energy of structure

$$\int_{X_e}^{X_m} F dz + {}^1\!/_2\, MV^2 = R_e(X_m - X_e) \qquad (3.6\text{-}50)$$

where

F = applied force (see Figure 3.6-53)

Z = deflection

X_e = deflection at onset of collapse (from time-history analysis)

X_m = maximum deflection

M = effective mass of target structure (see Table 5-l from Reference 59, and Table 3.6-8)

V = velocity of target structure at onset of collapse (from time-history analysis)

R_e = limit resistance of structure

As long as F falls below R_e, the pipe kinetic energy will be reduced during impact with the structure by conversion to strain energy. Acceptability is again governed by

$$X_m \leq \mu X_e \qquad (3.6\text{-}51)$$

where μ is taken from Table 3.6-2.

TABLE 3.6-1 SYSTEMS AND COMPONENTS REQUIRED FOR SAFE SHUTDOWN

Component or System

General Requirements

- Primary containment
- Pressure relief device
  - Safety/relief valves
  - Pressure suppression pool (passive)
- Main control room complex and control room air conditioning including intake radiation monitoring equipment
- Electrical power
  - Offsite power
  - Standby ac power
  - Emergency dc power
- Scram protection (reactor protection system)
- Control rod drive system (portion required for scam)
  - a. Turbine control valve fast signal, or
  - b. Reactor low water level signal, etc.[a]
- Core cooling
- Incident detection circuitry (start ECCS)
- RHR torus cooling mode (one loop)
- RHR service water to available RHR heat exchanger
- Core water to:
  - Diesel generator jacket cooling
  - RBCCW or EECW available to RHR pump motors
  - RBCCW or EECW available to RHR room coolers
- Instrumentation
  - Reactor water level indication
  - Temperature indication
- Control air system (noninterruptible portion – 1 division)

TABLE 3.6-1 SYSTEMS AND COMPONENTS REQUIRED FOR SAFE SHUTDOWN

Specific Requirements

For Main Steam Line Break

Flow restrictors (passive)

Isolation system control; incident detection circuitry

a. High temperature in main steam line tunnel
b. High steam line flow, or
c. Reactor low water level

Main steam line isolation valves

Feedwater check valves

Core cooling

a. HPCI
b. RHR plus remote-operated SRVs

Equipment cooling water (RBCCW or EECW) to room coolers

For Feedwater Line Break

Feedwater check valves

Isolation system control: incident detection circuitry

a. High temperature in main steam line tunnel, or
b. Reactor low water level

Main steam line isolation valves

Core cooling

a. HPCI
b. RHR

Equipment cooling water (RBCCW or EECW) to RHR room coolers

For High Pressure Coolant Injection System (HPCI) Steam Line Break

Isolation system control; incident detection circuitry

a. High temperature in HPCI steam line chase, or
b. High HPCI steam line flow, or
c. HPCI turbine steam line low pressure

HPCI isolation valves

Core cooling

a. RHR plus remote-operated SRVs

TABLE 3.6-1 SYSTEMS AND COMPONENTS REQUIRED FOR SAFE SHUTDOWN

RBCCW or EECW to room coolers

For Reactor Core Isolation Cooling System (RCIC)

Steam Line Break

Isolation systems control; incident detection circuitry

a. High temperature in RCIC steam line chase, or

b. High RCIC steam line flow, or

c. RCIC turbine steam line low pressure

RCIC isolation valves

Core cooling

a. HPCI plus remote-operated relief valves

b. RHR

RBCCW or EECW to HPCI room coolers

For Reactor Water Cleanup System (RWCU) Line Break

Isolation system control; incident detection circuitry

a. Flow imbalance, or

b. Low reactor water level, or

c. High temperature in RWCU pipe chase

RWCU isolation valves

Core cooling

a. HPCI and remote-operated relief valves, or

b. RHR plus remote-operated relief valves

RBCCW or EECW to HPCI room cooler

RBCCW or EECW to RCIC room cooler

---

[a] RPS trip signals resulting from loss of coolant:

1. Reactor vessel low water level
2. Main steam isolation valve closure
3. Primary containment (drywell) high pressure.

TABLE 3.6-2 MAXIMUM DUCTILITY FACTORS

1. Tension reinforced concrete beams and slabs (flexure controls design)
   $\mu = \frac{0.05}{p}$; $\mu \leq 12.5$

2. Doubly reinforced concrete beams and slabs (flexure controls design)
   $\mu = \frac{0.05}{p-p'}$; $\mu \leq 15.0$

3. Concrete beams and slabs in region requiring shear reinforcement
   a. Shear carried by concrete and stirrups — $\mu = 1.3$
   b. Shear carried completely by stirrups — $\mu = 3.0$

4. Concrete columns — $\mu = 1.3$

5. Structural steel tension members — $\mu = 0.5 \frac{\varepsilon_u}{\varepsilon_y}$

6. Structural steel flexural members
   a. Open sections (I, WF, T, etc.) — $\mu \leq 12.5$
   b. Closed sections (pipe, box, etc.) — $\mu \leq 25.0$
   c. Members where shear governs design — $\mu \leq 6.0$

7. Structural steel columns
   $\mu \leq 1.0$ for $\ell/r < 30$
   $\mu \leq 3.0$ for $30 \leq \ell/r \leq 60$
   $\mu \leq 6.0$ for $\ell/r > 60$

Notes

A_s = Area of tension reinforcement
A'_s = Area of compressive reinforcement
b = Width of section
d = Depth of section to reinforcement
p = Percentage tensile reinforcement
p' = Percentage compression reinforcement
$\mathcal{E}u$ = Uniform ultimate strain of material
$\mathcal{E}y$ = Strain at yield of material
ℓ = Effective length of column
r = Radius of gyration
(See AISC-69 Specifications)

TABLE 3.6-3 DYNAMIC INCREASE FACTORS (DIF)

I.	Reinforced or Prestressed Concrete	DIF
	Concrete	
	Compression	1.25
	Diagonal tension and direct shear (punch out)	1.0
	Bond	1.0
	Reinforcing Steel	
	Tension	1.2
	Compression	1.2
	Diagonal tension and direct shear (stirrups)	1.0
II.	Structural Steel	
	Flexure and tension	1.2
	Compression	1.2
	Shear	1.0

TABLE 3.6-4 REASONS FOR EXCLUSIONS

Index No.	Reasons	Explanation
(R1)	Separation	System in separate compartment.
(R2)	Distance	System separated by distance but in the same compartment.
(R3)	Redundancy	System function can be performed by two or more identical units.
(R4)	Back-up	System function can be replaced by the function of a different system.
(R5)	Self-eliminating	Pipe rupture caused damage only to the system itself.
(R6)	Size criteria	Pipe of an equal or larger diameter and equal or heavier wall thickness than the broken pipe is considered not damaged.
(R7)	Low pressure	Pressure inside the pipe is too low to cause a pipe whip.
(R8)	Barrier	System protected by barrier.
(R9)	Testing condition	Pipe line used only at testing condition or emergency condition, etc.
(R10)	Scarcity of usage	Duration of operation of the pipe is less than 2 percent of the duration of reactor operation.
(R11)	Safe area	Pipe routing in area where no system related with safe shutdown is located.
(R12)	Minimum size	Pipe smaller than 4 in. is not required for the analysis of longitudinal pipe break or pipe equal to or less than 1 in. is not required for the analysis of circumferential break.

[a] Index number used for permanent identification of components excluded from further consideration.

TABLE 3.6-5 LOADING COMBINATIONS FOR ELASTIC DESIGN OF STEEL STRUCTURES AND ULTIMATE STRENGTH OF CONCRETE STRUCTURES (STEAM TUNNEL)[a]

Load Combination Number	Overall Loading Equation[b]
	Elastic Design of Steel Structures
1	$1.5\ S = D + L + T_a + R_a + P_a$
2	$1.5\ S = D + L + T_a + R_a + P_a + 1.0\ (Y_j + Y_r + Y_m) + Feqo$
3	$1.5\ S = D + L + T_a + R_a + P_a + 1.0\ (Y_j + Y_r + Y_m) + Feqs$
	Ultimate Strength of Concrete Structures
1	$U_1 = D + L + T_a + R_a + 1.0\ P_a$
2	$U_1 = D + L + T_a + R_a + 1.0\ P_a + 1.0\ (Y_r + Y_j + Y_m) + 1.0\ Feqo$
3	$U_1 = D + L + T_a + R_a + 1.0\ P_a + 1.0\ (Y_r + Y_j + Y_m) + 1.0\ Feqs$

Symbols

D	Dead load of the structure, including any permanent equipment loads
Feqo	Loads generated by operating-basis earthquake
Feqs	Loads generated by the safe-shutdown earthquake
L	Live loads
P_a	Compartmental pressure due to pipe break
R_a	Pipe reaction under thermal conditions due to pipe rupture and including pipe reactions during normal operating conditions
T_a	Thermal loads due to pipe rupture and including thermal loads during normal operating conditions
Y_j	Jet impingement due to pipe rupture
Y_m	Missile effects due to pipe rupture
Y_r	High-energy pipe break reactions
S	Section strength based on elastic design methods and the allowable stresses as described in the AISC
U_1	Section strength based on ultimate strength design methods as described in ACI 318-63

[a] Loads not applicable to a particular system under consideration may be deleted.

[b] Effects for time-dependent loads will be superimposed accordingly.

TABLE 3.6-6 FLOW AND EVENTS POSTULATED FOR FEEDWATER BREAK

Approximate Time (sec)	Flow Rate (gpm)	Event
0		Break
0+	43,000	o Feedwater flow jumps to 43,000 GPM o RFP tripped on low suction pressure
7	43,000	o Reactor water level (L3) trip initiates a SCRAM trip o SCRAM trip initiates closure of feedwater pump discharge valves o Post SCRAM feedwater control automatically put into service
14	43,000	Steam tunnel leak detection system temperature exceeded.
22	43,000	After an 8.0 second instrument channel response time MSIV closure is initiated.
26	43,000	Vessel water level (L2) trip initates HPCI and RCIC operation. RCIC is not taken credit for in the scenario, since it is not environmentally qualified and because the NE corner room is affected by flooding.
32	43,000	After a 10 second MSIV closure time, the MSIVs are fully closed.
56	43,000	After the HPCI initiation signal, HPCI reaches rated flow within 30 to 60 sec. Fifty-six sec corresponds to the assumption of a 30 sec response time.
57	21,800	After an 8-second delay (in addition to the 30-second post scram delay) and a 12-second closure time, fast closure valves V12-2531 and V12-2532 are closed and all flow is forced through the start up level control valve.
64	20,000	The number 5 feedwater heater level control valves are closed and flow through the heater drain pumps is isolated from the break.
117	20,000	The RFP slow closure discharge valves are fully closed (V12-2503, V12-2504). This has no effect on the break flow but is noted to provide assurance that failure of the fast closure valves would not be as severe as failure of the start up control valve. Closure of these valves requires 80 seconds plus a 30 second delay.

TABLE 3.6-6 FLOW AND EVENTS POSTULATED FOR FEEDWATER BREAK

Approximate Time (sec)	Flow Rate (gpm)	Event
279	20,000	Reactor water level is restored by HPCI, which would close the startup control valve had it not been assumed to fail. Two hundred seventy-nine sec corresponds to the assumption of a 30 sec response HPCI time. This time may be up to 30 sec longer, assuming a 60 sec HPCI response time.
447	20,000	Condensate and heater feed pumps trip on low hotwell level and pumped flow is assumed to decrease to zero.
		The water inventory (13725 gal.) downstream of the RFPs is assumed to be discharged from the break over 1 minute period by gravity flow.
507	0	The water inventory in the piping is totally discharged.
	185,734 gallons	

TABLE 3.6-7 FEEDWATER LINE BREAK IN STEAM TUNNEL MAXIMUM FLOOD HEIGHT

Affected Area	Flood Elevation, ft	Flood Depth, in.
Steam Tunnel	587.98	53.7
RBCCW Room	587.31	45.8
NE Corner Room	546.74	80.9
SE Corner Room	554.08	169.0
Torus Room	541.23	14.8
HPCI Room	546.57	78.8

Note: This table lists maximum flood heights for each area, maximum heights do not occur simultaneously for all rooms.

3.7 SEISMIC DESIGN

For purposes of seismic design, structures, systems, and components are categorized as follows:

Category I: Safety-Related Structures, Systems, and Components

Plant structures, systems, and components, including their foundations and supports, that are required to be designed to remain functional in the event of a safe-shutdown earthquake (SSE) as described in Regulatory Guide 1.29, are designated Category I. A detailed discussion on the design Category I structures and components is provided in the following sections.

Category II/I: Non-Safety-Related Items in a Safety-Related Envelope

Non-safety-related components--control, electrical, mechanical, or structural--in a safety-related envelope are designated Category II/I. The continued functioning of these items is not required, but their failure could reduce the functioning of plant Category I items. Hangers and supports for Category II/I components carrying safety-related items are Category I.

Category II/I items are designed to maintain their structural and mounting integrity. For normal (operating) loads, the maximum stresses in components are required to remain within code-specified allowable limits. Components may be stressed beyond the yield limit stress during SSE loading. A reasonable limit, depending on material capability, is placed on the allowable ductility ratio. Test and/or analysis may be performed to establish Category II/I component ductility levels to be satisfactory under postulated loads.

Nonseismic: Non-Safety-Related Structures and Associated Non-Safety-Related Components

Structures and components designated as Nonseismic are designed by the appropriate state-of-the-art methods.

3.7.1 Seismic Input

3.7.1.1 Design Response Spectra

The design-basis earthquake (DBE) as referred to in the Preliminary Safety Analysis Report (PSAR) and other documents is referred to herein as the SSE.

The results of the seismological studies performed by Dames & Moore (D&M) for Fermi 2 are summarized below.

Confirmatory site-specific earthquake evaluations were recently completed by Weston Geophysical to reaffirm the acceptability of the established Fermi 2 facility aseismic design bases.

Site-specific spectra were developed from real time-history data representing quakes with a magnitude never to be exceeded at the site and subsurface conditions similar to those at the site.

The site is located in one of the seismically stable regions in the United States. As shown by Figure 3.7-1, no earthquake epicenter has been located closer than about 15 miles and only nine earthquakes have been reported within 50 miles of the site since the beginning of the 19th century. None of these shocks were greater than Intensity V on the Modified Mercalli Scale (Table 3.7-1). Twelve earthquake epicenters of Intensity V or greater have been reported within 50 to 100 miles of the site and another 27 of Intensity V or greater were located at distances between 100 and 200 miles. These more distant shocks ranged up to Intensity VIII.

The closest reported earthquake of Intensity V or greater was in the 1877 shock west of Detroit, Michigan. This earthquake caused no damage near its epicenter and was not felt in the vicinity of the site. The remaining eight earthquakes, within 50 miles of the site, were of Intensity IV or smaller and none were larger than Intensity III at the site. The largest regional shocks occurred in 1937 near Lima, Ohio, in 1977 near Celina, Ohio, in 1980 near Sharpsburg, Kentucky, and in 1986 near Perry, Ohio. Although these shocks may have had epicentral intensities as great as VIII, none were greater than Intensity IV shocks at the site. The effect of these shocks in Michigan was not great and no damage resulted.

Although several shocks have been felt at the site within about the past two centuries, the maximum intensity at the site has not exceeded IV. None of the recorded earthquakes caused any damage at or near the site (Subsection 2.5.2).

With few exceptions, the significant earthquakes reported in the region can be associated with well-defined geologic structural zones (Subsection 2.5.2). To the north and east of the site, earthquakes are scarce and appear to be related to anticlinal structure in northern Michigan. To the west of the site, earthquake activity has consisted of infrequent minor shocks that can be related to faulting in southern Wisconsin and northern and central Illinois. To the south, earthquakes are believed to be related to the confluence of the Findlay, Cincinnati, and Kankakee Arches. There are no known faults within 25 miles of the site.

The site response spectra for the operating-basis earthquake (OBE) and the SSE, for the horizontal direction, are shown in Figures 3.7-2 and 3.7-3. Vertical ground motion for the SSE and OBE are taken as 2/3 (0.667) of the maximum horizontal ground acceleration. The maximum ground acceleration for horizontal motion for the SSE is 0.15g and for the OBE is 0.08g. These earthquakes for the stable Fermi site are very conservative and were selected jointly between Edison and the AEC staff and have received their acceptance (see Safety Evaluation by DRL, May 17, 1971). Earthquake history and other pertinent information on site geology and seismology are included in Section 2.5.

3.7.1.2 Design Response Spectra Derivation

3.7.1.2.1 General

The shapes of the OBE and SSE spectra essentially conform to the 1940 El Centro, California spectra with minor embellishments to accommodate the 1949 Olympia, Washington, and the 1935 Helena, Montana, experiences. The spectra are anchored at horizontal zero period accelerations of .08 and .15g respectively with corresponding vertical accelerations of .05 and .10g.

Internal equipment response spectra were derived based on detailed time-history analysis of the buildings subjected to numerous time-history base excitations. Time histories were employed in addition to those used to describe the shape of the basic ground spectra to ensure a broadband frequency content for equipment aseismic qualification purposes. In this regard, scaled earthquake records were used for generating the internal equipment response spectra. These internal building location spectra are arrived at by averaging the results obtained from four scaled earthquake records. The four earthquakes and their horizontal time-history records are the following:

a. N-S - El Centro, Calif., May 18, 1940

b. N-S - El Centro, Calif., December 30, 1934

c. S-80-W - Olympia, Wash., April 13, 1949

d. N-21-E - Taft, Calif., July 21, 1952.

Ground response spectra for a system with 2 percent of critical damping have been generated for each of the previous earthquake records.

In the generation of the ground spectra for each record, 60 periods from 0.1 sec to 1.0 sec were considered.

To determine what time duration of each record is required to ensure that maximum responses on the floor slab were obtained, response spectra were generated for each record using different time lengths of the records, all starting from zero time. The durations of the record required to give maximum responses in the period range of interest have been determined to be as follows:

a. 1940 El Centro - 7 sec

b. 1934 El Centro - 13 sec

c. 1949 Olympia - 20 sec

d. 1952 Taft - 10 sec.

Each earthquake record was scaled so that the area under the acceleration response spectra, obtained from the record duration previously indicated, between the periods 0.1 sec and 1.0 sec, equaled the area under the recommended OBE spectra between the corresponding periods for a 2 percent-damped system. The ground accelerations obtained by the previous scaling procedure, used to simulate the horizontal OBE, are as follows:

a. 1940 El Centro - 0.053g

b. 1934 El Centro - 0.078g

c. 1949 Olympia - 0.077g

d. 1952 Taft - 0.062g.

Response spectra from the earthquake records scaled to simulate the horizontal OBE were plotted over the recommended OBE spectra and are presented in Figures 3.7-4 through 3.7-7. The maximum ground accelerations for SSE were obtained by multiplying the previous values by two. The resulting ground response spectra for OBE and SSE are shown in Figures 3.7-2 and 3.7-3, respectively. The vertical components of the four previously described earthquakes were used to generate vertical spectra. Again the duration of each record required to give maximum responses in the period range of interest was determined. The durations of each record used in generating response spectra are as follows:

a. 1940 El Centro - 10.0 sec

b. 1934 El Centro - 10.8 sec

c. 1949 Olympia - 12.5 sec

d. 1952 Taft - 12.5 sec.

To determine the scaled vertical ground acceleration, a_{VS}, the following relationship has been used:

$$a_{VS} = a_{HS} * \frac{a_V * A_V}{a_H * A_H} \quad (3.7\text{-}1)$$

where

a_{HS} = scaled horizontal ground acceleration

a_V = actual vertical ground acceleration

a_H = actual horizontal ground acceleration

A_V = actual area of vertical ground response spectrum (0.lg maximum, acceleration)

A_H = actual area of horizontal ground response spectrum (0.1g maximum, acceleration)

Maximum vertical ground accelerations used to generate vertical internal building spectra for OBE are as follows:

a. 1940 El Centro - 0.0204g

b. 1934 El Centro - 0.0240g

c. 1949 Olympia - 0.0256g

d. 1952 Taft - 0.0395g.

Maximum vertical ground accelerations for SSE were obtained by multiplying the previous values by a factor of two. The OBE vertical spectra are shown in Figure 3.7-8. The SSE vertical spectra are shown in Figure 3.7-9.

3.7.1.2.2 Supplementary Seismic Evaluation

In response to requests for information from the NRC Geosciences Branch, a site-specific ground response spectrum was developed, exhibiting a significantly higher ground response than the SSE ground response. Structures, systems, and components required for cold shutdown have been reevaluated for this higher site-specific earthquake, and the plant's capability to safely shut down has been confirmed. A detailed description of the evaluation program, analytical results, and conclusions can be found in the Supplementary Seismic Evaluation Report, Detroit Edison Report No. EF2-53,332 (Reference 1). Additional information on certain details of the analysis (provided in response to NRC questions) and the results of additional analyses performed subsequent to the Reference 1 report are listed in Reference 2.

Site-specific ground motion spectra were developed from real time-history data as previously described. Category I structures were then proven to adequately resist this excitation by means of a response spectrum evaluation equivalent in technique to that initially used for facility design purposes.

Internal equipment spectra were, however, generated from a synthesized ground motion time history, rather than the averaged real time histories used for original internal spectral generation purposes.

These supplementary evaluations reaffirmed the original facility aseismic design basis acceptability.

3.7.1.2.3 Response Spectra and Seismic Analysis Methods Used for Piping Snubber Reduction

OBE and SSE seismic loads for drywell piping snubber reduction purposes were analyzed using the following method:

> ASME Code Case N-411-1 damping values were applied with the uniform support motion response spectra analysis method in accordance with Regulatory Guide 1.84, Revision 27. Closely spaced modes were combined in accordance with Regulatory Guide 1.92.

This method included high-frequency modes per NUREG-1061, Volume 4, recommendations. The total combined response of high-frequency modes is combined by the Square Root of the Sum of the Squares (SRSS) method with the total combined response from lower-frequency modes to determine the overall structural peak response. When Code Case N-411-1 was used for earthquake loads, it was not mixed with Regulatory Guide 1.61 damping criteria for the same load case. Seismic inertia and anchor movement loads were combined by the SRSS method.

New building response spectra using Regulatory Guide 1.60 ground motion input were developed using the containment model used for the Cycle 3 fuel load. Direct generation of response spectra and Code Case N-397 spectra broadening techniques were not used in developing the new response spectra. The horizontal OBE spectra was anchored at 0.08g and the SSE spectra was anchored at 0.15g. Response spectra peaks were broadened by +15 percent.

These methods and spectra were applied in the seismic analysis of selected drywell piping systems in order to reduce the number of snubber supports.

3.7.1.3 Critical Damping Values

The damping values (expressed as a percentage of critical damping) of common structures and equipment in the Fermi 2 plant are listed in Table 3.7-2. The damping values used for the Fermi 2 project are in some cases higher than those specified in Regulatory Guide 1.61. These higher values were taken from Reference 3, prior to the issuance of Regulatory Guide 1.61. The damping values for HVAC systems, as delineated in Reference 19, were used for the CCHVAC System and SGTS duct and duct support revalidation effort. The specified systems and subsystems which were not listed were classified within one of the items in the table. Other damping values have been used when justified by specific data such as data obtained by testing.

3.7.1.4 Bases for Site-Dependent Analysis

No site-dependent analysis was necessary for Fermi 2 since the Fermi site is founded on bedrock (Subsection 3.7.1.6).

3.7.1.5 Soil-Supported Category I Structures

As described in Section 2.5 and Subsection 3.7.1.6, all Category I structures are supported directly on bedrock.

3.7.1.6 Soil-Structure Interaction

Structures Founded on Rock

Category I structures at Fermi 2 are founded on bedrock. A study was completed for Fermi 2 structures founded on rock (Reference 4) in which it was shown that for the Fermi site, soil-structure interaction was insignificant. The findings of this study are in agreement with the conclusions drawn by other researchers who report that soil-structure interaction is significant only when the shear wave velocity of the soil is less than 1000 fps (References 5 and 6). Since the shear wave velocity of the rock at the Fermi site is 7600 fps, it can be safely assumed, in accordance with the literature (References 5 and 6) and finite element analysis undertaken (Reference 4), that the Fermi 2 medium behaves as a rigid foundation. Therefore, the spectra developed for the bedrock represent the response to the base excitation.

3.7.2 Seismic System Analysis

3.7.2.1 Seismic Analysis Methods

3.7.2.1.1 General Description

The calculation of the dynamic response of a nuclear power plant complex subjected to an earthquake loading can generally be divided into two broad areas of analysis. The first is the analysis of major buildings and structures which house and/or support Category I systems and components. The second is the analysis of Category I systems and components. This subsection deals with the first area of analysis: seismic system analysis.

The necessity for division into two categories is that it is not practical to accomplish the analysis of major structures, systems, and components contained therein in a single dynamic analysis. The analysis is completed in steps. Major seismic systems, such as Category I structures, are modeled and analyzed. The motion of major structures, obtained from their analysis, is then used as the forcing function in the dynamic analysis of smaller Category I systems and components.

The classification of major buildings and structures, and Category I systems and components, is complicated by the fact that all systems and components that possess sufficient mass and stiffness to influence the dynamic behavior of major buildings and structures must be incorporated in the analysis of the major buildings and structures.

Seismic systems are defined as those systems in contact with the ground and thus are excited directly by the site response spectra, or the equivalent time-history motion. For each seismic system, there is a corresponding dynamic model. Seismic systems are discussed in this subsection and they include the reactor/ auxiliary building, residual heat removal (RHR) complex, buried piping, and buried electrical ducts. Subsystems are those in contact with or coupled to the seismic system and thus are excited by the response spectra derived from the system analysis. Subsystem analysis is discussed in Subsection 3.7.3, where the specific analyses for piping, reactor pressure vessel (RPV) and its internals, components, cable tray supports, cranes, racks, ventilation ducts, and tanks are contained in Subsections 3.7.3.6, 3.7.3.15, 3.7.3.16, 3.7.3.17, and 3.7.3.19.

The following criteria are used for system and subsystem decoupling.

a. If the mass of a component or equipment is less than 1 percent of the mass of its supporting structure, the component or equipment is treated as a subsystem and its mass may not be included in the system model

b. If the mass of a component or equipment is between 1 and 10 percent of the mass of its supporting structure, an approximate model of the component or equipment is included in the system model. Later, detailed subsystem analyses are made for this component or equipment

c. If the mass of a component or equipment is more than 10 percent of the mass of its supporting structures, a detailed model of the component or equipment is included in the system model.

3.7.2.1.2 Analysis of Building Structure Systems

To determine the exact dynamic forces acting on a structure, the accelerations (and, therefore, the displacements) of every mass particle must be evaluated. As any real structure's mass is distributed over the spatial extent of the structure, an infinite number of coordinates is required to describe the motion of every mass particle when the structure is subjected to a dynamic load. Calculation of time-dependent displacements at every point in a complex structure is impossible, but the analysis can be simplified by the judicious selection of a limited number of displacement components or coordinates. In dynamic structural analysis, two different assumptions are used to specify the deflected shape of a structure. These are referred to as the lumped-mass approach and the distributed-coordinate approach. The lumped-mass approach is the most convenient and versatile method to use in analyzing complex structural configurations found in a nuclear power plant. This approach was used in the seismic analysis of the Fermi 2 plant structures.

In the lumped-mass idealization, it is assumed that the entire mass of the structure is concentrated at a number of discrete points. A six-degree-of-freedom lumped mass would be general, in the sense that the discrete mass would possess all possible degrees of freedom. But in many structures, certain degrees of freedom may be neglected because the mass-stiffness configuration of the structure is such that these neglected degrees of freedom would not give rise to significant inertia forces if they were considered.

Recognition of the degrees of freedom in a structure that do not contribute to its dynamic response simplifies the modeling of the degrees of freedom that do contribute to the dynamic response of the structure. A series of computer programs, developed and validated for the analysis of nuclear power plant structures, are used to analyze Category I building structures. The criteria used in developing these programs are (1) consideration of the degrees of freedom encountered in the dynamic analysis of a nuclear power plant; (2) ease of inputting mass-stiffness properties from the structural drawings; and (3) ease of using output in structural design. The three programs used in the dynamic analysis of major structures are

a. Dynamic Seismic Analysis of Shear Structures (DSASS)

b. Matrix Analysis of Seismic Stress (MASS-IV)

c. Dynamic Analysis of Structures (DYNAS).

Each of these programs was used in the analysis of a specific type of structure. The program DYNAS can be used for the analysis of any type of structure, system, or equipment. All three programs use the modal method of analysis of a lumped-mass model, but the stiffness properties that interconnect the masses are read in the programs differently, because each program considers different degrees of freedom of the masses. The forcing function can either be acceleration spectra or a time-dependent base acceleration record. The descriptions of these programs are presented in Section 3.13.

The seismic motion of all Category I structures has been determined by applying the earthquake ground motions to appropriate dynamic models. In general, interaction between Category I and nonseismic structures has been eliminated by providing separate foundations for the structures. Also, rattlespace between abutting buildings has been provided so that seismic motion between buildings will be unimpeded.

Throughout the analysis of building structures, the coordinate directions are defined as the x, y, and z axes. The x and y axes denote the two principal horizontal directions and the z axis denotes the vertical direction.

3.7.2.1.2.1 <u>Criteria Used in Modeling Techniques</u>

<u>Horizontal Analysis</u>

The site response spectra presented in Figures 3.7-2 and 3.7-3 have been interpreted as one horizontal component of the OBE and the SSE, respectively.

These spectra are based on the free field vibratory accelerations, before plant structures are in place, at the elevation of the foundation of the structure being analyzed.

Action of the two horizontal components of the ground motion has been considered by analyzing the dynamic models for excitations parallel to the principal horizontal axes of the model. The model used is a discrete-lumped-mass, dynamic model having coupled modes; that is, a static force in one principal direction results in modal displacements in the other principal direction. For models in which the displacements of the two horizontal principal directions were statically coupled, analysis for excitations parallel to a model's two horizontal principal axes, has been accomplished by

a. The response spectra method of analysis (used for the design of structures modeled in system analyses), which involves

1. Analyzing the model for x-excitation

2. Analyzing the model for y-excitation

3. Combining the results of Steps 1 and 2 by the following equation:

$$\sigma_d = \sqrt{\sigma_{cx}^2 + \sigma_{cy}^2} \qquad \text{square root of the sum of squares} \qquad (3.7\text{-}2)$$

where

σ_d = design seismic stress

σ_{cx} = stress component from x-direction seismic excitation

σ_{cy} = stress component from y-direction seismic excitation

b. The time-history method of analysis is used to generate response spectra for subsystem analyses by

1. Analyzing the model for x-excitation

2. Computing the average of the four x-excitations

3. Analyzing the model for y-excitation

4. Computing the average of the four y-excitation

5. Plotting the maximum of the average x-spectra and average y-spectra.

Site-specific internal building spectra were developed using a single synthesized time history for analysis. In this work, the spectra were thus generated directly and no averaging was necessary.

The horizontal dynamic analysis was performed using a shear structure system, a frame structure system, and a combined shear-frame structure system. A description of these analysis systems are as follows:

a. Shear structure system - The plant building structures are complex systems, asymmetric in plan, with heavy concrete slabs at the various floor elevations. These slabs are interconnected with numerous concrete shear walls and/or heavy cross-braced steel members. The overall height dimensions are smaller than the plan dimensions. This low height-to-plan ratio indicates that under lateral loads the predominant deformations of the long shear walls are shear deformations. Consequently, the relative rotations of the slabs about horizontal axes do not cause significant deformations; but, due to asymmetrical mass-stiffness distribution, rotation of the slabs about a vertical axis does occur when this type of structure is subjected to lateral loads. Since the predominant deformation of this type of structure under horizontal seismic loading is a horizontal shear deformation of the walls, it has been referred to as a shear structure system

Figure 3.7-10 shows a simplified shear structure system and the x-y-z axis system where the z-axis is vertical and the x- and y-axes are parallel to the principal axes of the structures. The significant deformations of the structure under horizontal seismic excitation are described with three coordinates, X, Y, and θ_z. These three degrees of freedom describe the motion of the concrete slab. Neglect of the θ_x, θ_y, and Z degrees of freedom implies that the slab mass moves in a horizontal plane

In describing the shear structure system model, the words "model slab" are substituted for the words "lumped-mass," because the mass of the actual structure was simulated in the model with virtually infinite rigid slabs located at the elevations of the major floor slabs and roof of the structure

The mass of the walls between two floors was lumped to the floors that they connect. The mass of equipment supported on slabs in the actual structure is included in the calculated mass of the virtually infinite rigid slabs. The actual slabs are considered to be infinitely rigid in their own planes. The rigid body motions of the model slabs consist of three degrees of freedom: horizontal translation in two perpendicular directions and rotation about a vertical axis. The model slabs are interconnected by weightless elastic springs that possess stiffness in the x- or y-direction and simulate the shear walls and vertical bracing in the structure. These springs are distributed horizontally on the model slabs so that the torsional stiffness interconnecting two slabs is approximated

Since the ends of the springs are considered to be horizontally distributed on the spatial extent of the model slabs, the model slabs are not point masses. Rather, they may be thought of as rigid bodies with horizontal dimensions only, because the mass of the actual structure has been considered to be lumped in the planes of the model slabs. This is the advantage of the slabspring model over the lumped-mass frame model

Three coordinates are required to describe the motion of each model slab. Therefore, three mass parameters are determined for each model slab. These mass parameters for the ith slab of the model are

1. M_{xi}, associated with x-translation
2. M_{yi}, associated with y-translation
3. $I_{\theta i}$, associated with the rotation about a vertical axis.

The mass parameters associated with x-translation and y-translation are the same and are equal to the mass of the slab. The mass polar moment of inertia, θ_z, is about a vertical axis through the centroid of the slab

To evaluate the stiffness of the structural components that interconnect slabs, the following assumptions are made.

1. All floor and roof slabs are considered rigid in their own planes; no point can displace another point relative to it on the same slab

2. Walls interconnecting slabs offer resistance only to relative displacement of slabs parallel to their line of action

3. The stiffness of small reinforced-concrete columns or walls and steel framing other than the braced bents is neglected, because their stiffness is small compared to the stiffness of shear walls.

When resisting lateral loads applied parallel to the long dimension, most walls act as short, deep beams; therefore, the contribution of shear to the deflection is considered in calculating the stiffness of a wall

The stiffness of steel framing which acts as springs was evaluated with conventional elastic frame or truss analysis computer programs such as EASE (Section 3.13)

Dynamic analysis of the shear structure systems was accomplished with the computer program DSASS. The input to DSASS is compiled by using the code, Spring Slab Analysis (SSANA). The centroid, total weight, and the weight moment of inertia about the vertical centroidal axis of the slabs; the spring constants; and the location of springs with respect to the slab centroid were calculated by SSANA. The description and analytical details of programs SSANA and DSASS are in Section 3.13.

b. <u>Frame structure system</u> - In the shear structure system, the motion of the structure's mass is restricted to a horizontal plane. For many structural systems under dynamic loading, motions are not restricted to a horizontal plane, and all six possible degrees of freedom of the discrete masses are required to describe the dynamic behavior of the structure. Dynamic analysis of this type of structure was accomplished by the program MASS-IV. This is a general frame program that can be used to analyze a plane frame, truss, grid, space truss, and space frame

c. <u>Combined shear-frame structure system</u> - The shear-type structures with three degrees of freedom for each slab mass and the frame-type structures with six degrees of freedom for each mass could both be present in a building system. The analysis of a coupled shear-frame structure was performed by DYNAS, which combines the features of DSASS and MASS-IV. Rigid or flexible frame members are used to connect the joints of the frame members to the slab centroids where interconnections exist.

<u>Vertical Analysis</u>

The dynamic behavior of a building in the vertical direction is a function of the wall axial stiffness, the floor system flexural stiffness, and the mass distribution. An examination of the vertical mass distribution of a building structure shows that there are mass concentrations at the floor elevations. A plane-frame model was developed to simulate the behavior of the building in the vertical direction.

Figure 3.7-11 shows an example of a plane frame, typical of that used to simulate a building's dynamic response in the vertical direction. The horizontal members in the model simulate the flexural stiffness of the floor systems. The lumped masses shown on the schematic simulate the mass of the building structure and the mass of equipment supported by the structure. Although only two wall systems are shown in Figure 3.7-11, any number of wall systems can be incorporated in an analysis. The number of wall systems depends upon the layout of the structure to be analyzed. The mass distribution in the model consisting of the actual structure's mass concentrated at floor slab elevation is distributed between the walls and the horizontal members. This mass distribution is used because part of the actual structure's mass moves with the walls, whereas part of the mass motion is amplified because of slab flexibility. The flexural stiffness of the horizontal members is adjusted to represent the stiffness of the actual floor systems. Since a floor system consists of slabs of various thicknesses, beams, and openings, and since it is supported by interior and exterior walls, many periods of vibration occur in the floor system at a single elevation when a building structure is subjected to vertical seismic loading. Therefore, the periods of vibration of a floor system cannot be simulated by a single horizontal member in a frame model. For this reason, a multimember-mass system has been used to simulate a complex floor system (see upper level on Figure 3.7-11). Each member-mass system is adjusted to have frequency characteristics matching one of the calculated frequencies of the actual slab system. The analysis of the vertical model is performed by the MASS-IV program.

Response spectra are generated at each mass of the system used to represent a slab. These spectra are plotted on a single plot and enveloped with a smooth curve. The floor slabs were designed by using seismic coefficients obtained from the rigid end (frequency response greater than 33 Hz) of the resulting spectra. Vertical seismic stresses in the building walls were obtained from the vertical members of the vertical models. Equipment supported on a slab was designed using the resulting spectra as the vertical seismic load. Equipment located near walls was designed using response spectra generated on masses located on the vertical members.

3.7.2.1.2.2 Description of Mathematical Models

Horizontal Seismic Analysis

The massive stiff floor slab-shear wall configurations of the reactor/auxiliary building (Figures 3.7-12 through 3.7-14) and the RHR complex are modeled as a slab-spring system. The slabs, treated as infinitely rigid in their own planes, are interconnected by weightless linear elastic springs used to simulate the stiffness of shear walls within the structural system, as described in Subsection 3.7.2.1.2.1.

Rotations about the horizontal axes could be significant in the reactor containment portion of the reactor/auxiliary building. Since these degrees of freedom, θ_x and θ_y, cannot be modeled with the slab model, a conventional three-dimensional frame analytical model is used to model the containment shield, the containment vessel, the RPV and internals, the reactor support pedestal, and the biological shield. The lumped masses in this portion of the model are allowed X, Y, θ_x, θ_y, and θ_z degrees of freedom, and are interconnected with frame members. The slab model and the frame model are connected by axial springs at various elevations to represent the behavior of the actual structure more accurately. The configuration of this model is shown in Figure 3.7-15 except for the model of the RPV and its internals, which is shown in Figure 3.7-16. The RPV is supported by the reactor pedestal at Mass 29 and laterally supported at Masses 26 and 32 by the refueling bellows and stabilizer, respectively. The seismic methods and analysis procedures for the RPV and its internals are described in Subsection 3.7.3.15.

The reactor building crane bridge and associated steel structures (between the fifth floor and the roof) have been simulated in the horizontal dynamic model as shown in Figure 3.7-17. The model is based on the assumption that the crane would be parked at the end bay during a seismic event. The vertical lines represent steel columns connected by rigid members at the bottom and top ends to the mass centroids of Slabs 5 and 6, respectively. (NOTE: Subsequent to the original analysis, an analysis (Reference 22) was performed which qualifies the crane girder steel superstructure interior support columns for the crane deadload plus rated load combined with either wind or seismic loads. The additional analysis assumes that the overhead crane is located anywhere along the crane's travel path to maximize the member stresses.)

The mass parameters of the reactor/auxiliary building slabs in the dynamic model are presented in Tables 3.7-3 and 3.7-4. These mass properties are calculated by considering the mass of the actual structure concentrated at the slab elevations, and distributed laterally on virtual infinitely rigid slabs in accordance with the lateral mass distribution in the structure. Therefore, each model slab represents the concrete of, and equipment on, actual slabs and the tributary mass of equipment structure between slabs. Both the translational and rotational inertia of the actual structure are taken into consideration.

The lumped masses in the frame part of the reactor/auxiliary building model are calculated from the physical properties of the containment and reactor support system, and are also presented in Table 3.7-4. However, the properties of the masses for the RPV are not included in this table.

The stiffness elements that interconnect the lumped masses of the dynamic models are shown schematically in Figure 3.7-15 for the reactor/auxiliary building and Figure 3.7-18 for the RHR complex. The solid vertical lines interconnecting slabs represent groups of linear elastic springs that simulate the stiffness of the walls in the structural complex. The walls in the building complex that are considered to act as springs are shown in Figures 3.7-19 through 3.7-24 for the reactor/auxiliary building, and Figures 3.7-25 through 3.7-27 for the RHR complex with walls parallel to the X-axis treated as X-springs and walls parallel to the Y-axis treated as Y-springs.

Each wall or group of walls considered to act as a spring in this analysis is assigned a six-digit identification number which is shown on the figures. For any identification number that does not have six digits, leading zeros are implied. The digits of the identification number convey the following information:

a. <u>First two digits</u> - slab number that the lower end of the spring is connected to

b. <u>Second two digits</u> - slab number that the upper end of the spring is connected to

c. <u>Third two digits</u> - ith spring with its lower end connected to the slab given by the lst two digits (if the 3rd two digits form an even number, the wall is a Y-spring and if these two digits form an odd number, the wall is an X-spring).

Frame members in the reactor containment portion of the model are represented on Figure 3.7-15 with dashed lines. The properties of these members are calculated from the physical properties of the primary containment, the reactor support pedestal, and the biological shield. Table 3.7-5 presents the properties and the topography of the frame members of the reactor/auxiliary building model, except for the members of the RPV part of the frame model. To eliminate assigning artificial horizontal distances between the centroids of masses in the containment and pedestal-shield cantilevers, the stiffness of the connections represented by horizontal dotted lines in Figure 3.7-15 is given in Table 3.7-6 as stiffness coefficients.

To evaluate the stiffness of the structural components that interconnect the masses of the shear models shown in Figures 3.7-15 and 3.7-18, the following assumptions have been made:

a. All points on the same slab translate in the horizontal plane passing through the mass-center of the slab and the slab rotates only about the vertical axis

b. The walls offer resistance to relative displacements between slabs only in their longitudinal direction.

When resisting lateral loads applied parallel to the long dimension, most walls act as short, deep beams; therefore, the contributions of both flexure and shear to the deflection must be considered in calculating the stiffness of a wall. The stiffness of an individual wall was calculated by the following formula:

$$K = \frac{1}{\Delta} \tag{3.7-3}$$

$$\Delta = \frac{1.2h}{GA} + \frac{h^3}{12EI} \tag{3.7-4}$$

where

h	=	height of wall
I	=	moment of inertia of wall for bending about centroidal axis perpendicular to length of wall
A	=	cross-sectional area of wall
E	=	elastic modulus of concrete
G	=	shear modulus of concrete
K	=	stiffness
Δ	=	deflection of wall due to a unit force

Vertical Seismic Analyses

No attempt was made to set up a three-dimensional model on account of the excessive number of degrees of freedom. The vertical dynamic model of the building was developed on the basis that the amplification in the vertical direction is a function of the axial stiffness of the walls and bending stiffness of the beam-slab system.

The vertical stiffness is due mainly to two structural systems in each model. They are

a. Reactor/auxiliary building model

   1. The reactor containment shield (right side of Figure 3.7-28)

   2. Reactor/auxiliary building walls (left side of Figure 3.7-28).

b. RHR complex model

1. The cooling tower walls (right side of Figure 3.7-29)
2. The RHR building wall (left side of Figure 3.7-29).

The two wall systems are connected by the reactor building floor slab at all the floor elevations for the reactor building model and at Elevation 617 ft for the RHR complex model. The auxiliary building floor slab is represented by a single-degree-of-freedom system connected to the joints of the reactor/auxiliary building wall system at each elevation.

In the dynamic model formulated for these analyses, the masses can displace, relative to one another, with one degree of freedom in the vertical direction. The mass parameters are calculated in the following manner:

a. The masses are concentrated at joints (as shown in Figures 3.7-28 and 3.7-29) and interconnected by weightless linear springs that simulate the stiffness of the slabs or walls
b. In general, the wall masses are lumped equally to the nearest joints
c. For the slabs, it has been assumed that one-third of the total slab mass is effective; the remaining mass of the slab was lumped with the wall mass at that elevation
d. The mass of the reactor containment shield includes only the mass of concrete and contributory slab mass.

The determination of the spring stiffness and the modification of the original model, to simulate higher mode contribution of slabs, is described as follows:

a. <u>Wall springs</u> - For the wall system, the effective area is the sum of the areas of all the individual walls at a particular level. The walls that are connected monolithically with the top and bottom slab only, provide vertical stiffness. For the reactor containment shield, the effective area is that of a circular ring. In cases where the radius changes between two mass points, the average area is used
b. <u>Slab springs</u>
   1. <u>Slab natural frequency</u> - The stiffness of a member representing a slab in the vertical model simulates the lowest natural frequency of the slab. As a grid model is analyzed to determine the lowest natural frequency of a typical slab, the frequencies of other floors are determined based on the grid analysis and standard formulae
   2. <u>Modification of the model</u> - To determine the response spectrum of the slab at a particular level, the model is modified at that level to include the multi-degree behavior of the slab system. The stiffness and mass properties of slabs at other levels are not changed and correspond to the lowest fundamental frequency of the slab at that level. The modified vertical model for determining slab response spectrum at Elevation 684 ft 6 in. of the reactor /auxiliary building is shown in Figure 3.7-30. The slab system at this level consists of six masses and the springs on each side are connected to the same wall joint. The total effective slab mass is

divided by the number of masses and is assigned to each individual mass. In this case, Mass l simulates the stiffness of the lowest natural frequency of the slab as calculated before, and the rest of the masses were assigned frequencies higher than the calculated natural frequency at regular intervals. The highest frequency assigned, 30 Hz (Reference 25), has negligible amplification. Similarly, the stiffness parameters of the auxiliary building slab system are determined. The model for Elevation 6l3 ft 6 in. of the reactor/ auxiliary building is shown in Figure 3.7-31. The model for the RHR complex is shown in Figure 3.7-29.

3.7.2.1.2.3 Analysis of Mathematical Models for Structures

To determine the free vibrational characteristics of the dynamic models, the model equation for a multi-degree lumped-mass system may be written as

$$[\mathrm{M}]\{\ddot{\mathrm{x}}\} + [\mathrm{K}]\{\mathrm{x}\} = 0 \qquad (3.7\text{-}5)$$

where

[M]	=	mass matrix
[K]	=	stiffness matrix
$\{x\}$, $\{\ddot{x}\}$	=	displacement, acceleration vectors

where the mode shapes and frequencies are solved in accordance with

$$[\mathrm{K} - \omega_n^2 \mathrm{M}]\{\phi_n\} = 0 \qquad (3.7\text{-}6)$$

This set of equations has as eigenvalues the squares of the circular natural frequencies, ω_n. Associated with each frequency is a mode shape ϕ_n which may be arranged as one of the columns of the matrix $[\phi]$.

The modal participation factors are given by

$$[\Gamma]\ \mathrm{n_i} = \frac{[\phi]^{\mathrm{T}}[\mathrm{M}]\ [\mathrm{D}]_{\mathrm{i}}}{[\phi]^{\mathrm{T}}\ [\mathrm{M}]\ [\phi]} \qquad (3.7\text{-}7)$$

where

$[\Gamma]n_i$	=	participation factor
$[\phi]^T$	=	transpose of mode shape vector for nth mode
$[D]_i$	=	earthquake direction vector referring to direction i

The response of the system in one mode, A_i, is given by

$$A_{\mathrm{i}} = \begin{Bmatrix} \mathrm{a_i^1} \\ \mathrm{a_i^2} \\ \vdots \\ \mathrm{a_i^n} \end{Bmatrix} = \mathrm{T_i}\ \{\phi_{\mathrm{i}}\}\mathrm{R_i} \qquad (3.7\text{-}8)$$

where

$\{\phi_i\}$ = one column of the matrix $[\phi]_n$ corresponding to the mode

T_i = corresponding element in column matrix of $[T_i]$

R_i = response of a single-degree-of-freedom system of period T_i and damping ratio B_i from specified ground response spectrum for the site

At any mass coordinate in the system, the total response, $\frac{k}{a}$, is given by

$$\frac{k}{a} = \sqrt{\sum_{i=1}^{n}\left(a_i^k\right)^2} \qquad (3.7\text{-}9)$$

where

a_i^k = response at coordinate k in ith mode

n = number of modes

Floor slab-shear wall type structures are modeled as a slab spring system in which the mass of the structure is lumped at floor slab elevations. The weight of each shear wall is lumped equally between the floor slab above and the floor slab below. The containment vessel, the concrete shield wall, the sacrificial shield, and the reactor support pedestal were modeled with a sufficient number of lumped masses so that all the modes up to 33 Hz can be extracted. The number of lumped masses for these elements was at least three more than the number of modes below 33 Hz as determined from closed form solutions.

Dynamic analysis has been carried out to include all the significant response modes.

The applicable stress/deformation criteria are described in Subsection 3.8.4.

3.7.2.1.2.4 Basis for Computing Combined Responses

In the original design performed in 1971, horizontal and vertical seismic effects were not combined in the structural design. In subsequent analyses, the effects of two statistically independent time histories were added algebraically and then combined with the vertical component effect by the SRSS rules.

3.7.2.1.3 Buried Electrical Ducts

3.7.2.1.3.1 General

There are two sets of Category I ductbanks between the RHR complex and the Reactor/Auxiliary building, with a Division I and Division II ductbank in each set. The first set of ductbanks was installed during plant construction. The analysis of these Category I buried electrical ducts is described in the following paragraphs.

The forces in the duct due to wave propagation in soil and rock are determined (Reference 7). The duct design is required to take into account the relative seismic displacements at its anchor points with the building, in addition to the strains induced due to wave propagation in the surrounding soil. The anchorage of the duct with the building and manhole is designed to be flexible such that 1 in. maximum displacement in any direction is allowed for analytical purposes. Thus, if the relative displacement of the buildings and duct at the anchorage is less than the maximum allowable displacement of 1 in., the flexural strains are only due to wave propagation.

The analytical procedure used to evaluate the seismic influence on buried electrical ducts considers the soil condition at the plant site. The method of analysis follows the method of Reference 8.

The second set of Category I 4160-V electrical ductbanks run between the RHR cable vaults and the Reactor/Auxiliary building cable vaults. These ductbanks (including the cable vaults and manholes) are designed as Seismic Category I components. The buried portion of the ductbank is designed for seismic response effects utilizing the approach identified in ASCE 4-98, as endorsed by NUREG-0800 Standard Review Plan, section 3.7.3 Revision 3 (March 2007). This approach is an extension of the Fermi 2 methodology used for the first set of Category I ductbanks. This extended methodology provides an accurate analytical means for the prediction of the seismic responses of buried structural components, specifically at bends and other geometric discontinuities, precluding the need for physical measures (such as loosely compacted sand) at these discontinuities. The ductbanks connecting to rigid structural components, such as the manholes and the transition vaults at the RHR and Auxiliary buildings, are provided with one inch physical gaps, similar to that for the first set of Category I ductbanks, to preclude locked in stresses due to potential differential displacements during and after postulated seismic events.

3.7.2.1.3.2 Analysis

The design of the ducts ascertains that the stresses caused by the strains do not exceed the acceptable safe limits in the event of an SSE.

The maximum axial strain in the straight portion of a duct has an upper bound equal to the maximum strain in the surrounding soil in the direction of the duct. If the wave length is much larger than the straight portion of the duct, the maximum strain in the duct is assumed to be uniform along the duct run. However, in cases where the duct is very long, the duct displaces relative to the surrounding soil because of strain incompatibility between the soil and the duct. The relative displacement between the soil and the end of the duct is determined by deducting frictional restraint to the movement of the duct from the upper-bound soil displacement in the direction of the duct.

The effect of axial displacement of a straight portion of duct relative to the soil, at bends and at juncture points, is evaluated by the "beam on elastic foundation" concept. To obtain forces in the bend, each bend is subjected to the relative displacement as obtained previously. A fill of well-graded, loosely compacted sand is provided on either side of the bend to avoid concentration of forces around the bend due to stiff subgrade, and to distribute the subgrade stresses uniformly.

The design of the new Category I 4160-V electrical ductbanks that run between the RHR cable vaults and the Reactor/Auxiliary building cable vaults uses a more conservative approach at bends and elbows. In the analysis, the elbow is treated as an inflexible structure, whereas longitudinal and traverse legs are treated as flexible structures, as outlined in the ASCE Report “Seismic Response of Buried Pipes and Structural Components” (1983) (Referenced in NUREG-0800, Standard Review Plan 3.5.3). Therefore, loosely compacted sand fill is not required on either side of the ductbanks bends.

The concrete structures of the new Category I 4160-V electrical ductbanks were analyzed using the guidance in accordance with ACI 349-01 “Code Requirements for Nuclear Safety

Related Concrete Structures" and Regulatory Guide 1.142 "Safety-Related Concrete Structures for Nuclear Power Plants (Other Than Reactor Vessels and Containments)".

For both the new and existing ductbanks, effects of flexural strains were evaluated at points of maximum possible curvature between the duct attachment points. As commonly observed, the strains associated with such effects were found to be negligibly small from the practical design standpoint.

The corresponding effects of flexural strains were similarly evaluated by means of calculation from the maximum possible curvature between the duct attachment points. As commonly observed, the strains associated with such effects were found to be negligibly small from the practical design standpoint.

3.7.2.1.4 Seismic Design of Category I Buried Piping

The seismic analysis of buried piping located between the RHR complex and the reactor/auxiliary building is performed in exactly the same way as the seismic analysis of buried electrical ducts described in Subsection 3.7.2.1.3. The stresses/strains do not exceed the acceptable safe limits in the event of an SSE.

During the course of safety evaluation review, at the request of the NRC, additional information on this was submitted. Included was Reference 9, which discussed lateral pressure and the analysis of buried piping, and which forwarded a February 3, 1970, D&M report, Reference 10. Also included were References 11 and 12, which added to the information provided by References 9 and 10.

The Category I structures and buried pipes and conduits have been structurally reassessed for the effect of the SSE.

In reference to LOCA stresses, the pertinent information on original load combinations and respective stress components, including those resulting from a LOCA, have been presented in Chapter 4 and in appendixes of the reassessment report.

The three components of the earthquake have been considered in the reassessment report. Two horizontal components have been considered to be acting simultaneously, and the vertical component has been added as an absolute sum or square root of the sum of the squares as appropriate.

A damping value of 7 percent has been used in accordance with Regulatory Guide 1.61, since the Category I structures are of reinforced-concrete construction, and the structural elements are highly stressed for the site-specific earthquake loading.

3.7.2.2 Natural Frequencies and Response Loads

The analysis of the models developed in Subsection 3.7.2.1 yields the natural frequencies, mode shapes, and modal responses of the overall system. These results are presented for both the horizontal and vertical analysis.

3.7.2.2.1 Reactor/Auxiliary Building

3.7.2.2.1.1 Horizontal Analysis

a. Frequencies and mode shapes - The periods, mode shapes, and dynamic response of the lumped-mass system are computed with the use of DYNAS. Table 3.7-7 presents the summary of the first 20 modal periods, the modal participation factors for X-direction base excitation, and the modal participation factors for Y-direction base excitation

b. Response spectrum - The program DYNAS was used to perform the time-history analysis of the dynamic model, damped with 2 percent and 5 percent of critical damping for the OBE and SSE, respectively, and to generate response spectra at selected mass centroids for E-W and N-S base excitations. Newmark's β-method of numerical integration for a linear system with time-dependent input base motion, combined with modal superposition, was used to obtain the motions of the lumped masses. The time-histories of the mass motions were not printed out of computer storage because of the large quantity of data, but rather response spectra generating subroutine used the stored slab motions to generate response spectra for specified masses

   Separate spectra curves are not plotted for the N-S excitation and the E-W excitation; rather, at each spectra period for a given spectra damping, the average response from the four N-S excitations from Subsection 3.7.1, and the average response from the four E-W excitations from Section 3.7.1 were calculated, and the maximum of the averages was plotted. The plotted spectra curves, with their valleys and peaks, were smoothed by enveloping the peaks with the envelope at a peak extending ten percent, on the period scale, to either side of the peak. The resulting smooth curves are presented in Figures 3.7-32 through 3.7-55 for OBE and Figure 3.7-56 through 3.7-79 for SSE

c. Displacement response - Table 3.7-8 summarizes the probable displacements obtained from this analysis.

3.7.2.2.1.2 Vertical Analysis

a. Frequencies and mode shapes - The vertical model shown in Figures 3.7-28, 3.7-30, and 3.7-31 has been analyzed by the MASS-IV program. Table 3.7-9 lists the periods and participation factors for 24 modes for the model shown in Figure 3.7-30. The variation of main structural period in models shown in Figures 3.7-28, 3.7-30, and 3.7-31 is negligible

   The vertical analysis was used to generate response spectra for the design of Category I equipment located at different floor levels. The forces in the structure are also determined by the response spectra method.

   The slabs and shear walls of the reactor building and the reactor containment are designed to withstand these forces due to vertical excitation

b. Response spectrum - A computer program, MASS-IV, was used to analyze the vertical models and generate vertical response spectra.

Response spectra were generated at two elevations (Elevation 613 ft 6 in. and 684 ft 6 in.) at the reactor containment shield, reactor/auxiliary building wall, reactor building slab, and auxiliary building slab for OBE (2 percent structural damping) and SSE (5 percent structural damping). The spectra at other elevations were not generated, but were classified in one of the two levels. At each period considered in the spectra generation process, the average response from the four earthquakes was calculated. These averages were plotted. The rough curves were smoothed by enveloping the peaks and extending 20 percent to either side of a peak. The vertical response spectra are presented in Figures 3.7-80 through 3.7-88 for OBE and in Figures 3.7-89 through 3.7-97 for SSE.

3.7.2.2.2 Residual Heat Removal Complex

3.7.2.2.2.1 Horizontal Analysis

a. Frequencies and mode shapes - The periods and mode shapes and dynamic responses of the lumped-mass system are computed by the use of DYNAS. A summary of the model periods and modal participation factors for the x and y excitations is presented in Reference 13

b. Response spectrum - The program DYNAS was used to perform the time-history analysis of the dynamic model, damped with 2 percent of critical damping, and generate response spectra at selected mass centroids for E-W and N-S base excitations. Newmark's β-method of numerical integration for a linear system with time-dependent input base motion, combined with modal superposition, was used to obtain the motions of the lumped masses. The time-histories of the mass motions were not printed out of computer storage because of the large quantity of data, but rather response spectra generating subroutine used the stored slab motions to generate response spectra for specified masses

   Separate spectra curves were plotted for the N-S excitation and the E-W excitation; at each spectra period for a given spectra damping, the average response from the four N-S excitations and the average response from the four E-W excitations were calculated

   The plotted spectra curves, with their valleys and peaks, were smoothed by enveloping the peaks with the envelope at a peak extending 10 percent, on the period scale, to either side of the peak's period

   The representative resulting smooth curves are presented in Figures 3.7-98 through 3.7-101 for OBE and in Figures 3.7-102 through 3.7-105 for SSE.

3.7.2.2.2.2 Vertical Analysis

a. Frequencies and mode shape - The periods, mode shapes, and dynamic response of the lumped-mass system are computed by the use of MASS-IV. A summary of the modal periods and modal participation factors for the x and y excitations is presented in Reference 13

b. Response spectrum - MASS-IV was used to analyze the vertical models and to generate vertical response

Response spectra were generated at two elevations (Elevation 590 ft, 0 in. and Elevation 617 ft, 0 in.) at the building walls and the building slabs for OBE (2 percent structural damping) and SSE (5 percent structural damping)

At each period considered in the spectra generation process, the average response from the four earthquakes was calculated. These averages were plotted. The rough curves were smoothed by enveloping the peaks with a smooth curve, which, as the period scale, extends 20 percent to either side of a peak. The representative vertical response spectra are presented in Figures 3.7-106 through 3.7-110 for OBE and in Figures 3.7-111 through 3.7-115 for SSE.

3.7.2.3 Procedures Used To Lump Masses

For dynamic analysis, Category I equipment was represented by lumped-mass systems that consist of discrete masses connected by weightless springs. The criteria used to lump masses were

a. Because the number of modes of a dynamic system is controlled by the number of masses used, the number of masses was chosen so that all significant modes are included

b. Mass was lumped at any point where a significant concentrated weight is located. Examples are the motor in the analysis of pump motor stand, and the propeller in the analysis of pump shaft

c. If the equipment has a free end overhang span whose flexibility is significant compared to the center span, a mass was lumped at the overhang span

d. When a mass was lumped between two supports, it was located at a point where the maximum displacement was expected to occur. This tends to conservatively lower the natural frequencies of the equipment. Similarly, in the case of live loads (mobile) and a variable support stiffness, the location of the load and the magnitude of support stiffness were chosen so as to yield the lowest frequency content for the system. This is to ensure conservative dynamic loads since equipment frequencies are such that the floor spectra peak is in the lower frequency range.

Slab masses were lumped in accordance with the procedures described in Subsection 3.7.2.1.2.1.

3.7.2.4 Rocking and Translational Response Summary

The site response spectra developed for Fermi 2 are the bedrock spectra. Since the Fermi 2 Category I structures are founded directly on bedrock, the rocking and translational effect due to soil structure interaction is not applicable to this location. See Subsection 3.7.1.6 for a description of the studies that document that the Fermi 2 site behaves as a rigid foundation.

3.7.2.5 Method Used To Couple Soil With Seismic System Structures

Fermi 2 Category I structures are all founded on bedrock and do not require an evaluation of soil structure interaction (Subsection 3.7.1.6).

3.7.2.6 Development of Floor Response Spectra

3.7.2.6.1 Introduction

If a structure is subjected to an earthquake, the base of a subsystem (or equipment) mounted on a floor slab or wall experiences the motion of the slab or wall. This motion may be significantly different from the input motion at the base of the structure. Therefore, the response spectra used in the analysis of the structure are not directly applicable to the analysis of subsystems mounted in the structure unless the subsystem element is modeled in the dynamic model of the structure. Also, unless the subsystem element is a rigid mass, rigidly connected to the slab or wall, the motion of the subsystem is different from the motion of the slab or wall, because the subsystem element is a flexible elastic system that responds dynamically to the motion of the slab. For these reasons, the motion experienced by a subsystem is the structure's base excitation modified as a function of the structure's characteristics, the subsystem's characteristics, and the mode of attachment to the structure.

To establish explicit slab or wall motions, applicable to development of subsystem design criteria, time-history forcing functions were used to excite the building models used in the system analysis. Resulting time-history slab or wall motions were used to generate response spectra for the analysis of subsystems supported in the building.

3.7.2.6.2 Horizontal Response Spectra

The seismic models used to generate the response spectra at various building elevations are described in Subsection 3.7.2.1.2. The base input forcing functions are described in Subsection 3.7.1.2 and shown in Figure 3.7-2 for OBE, and 3.7-3 for SSE. Site-specific analyses were completed using statistically independent synthesized time histories in orthogonal directions. The response spectrum evaluations for the reactor/auxiliary building and the RHR complex are described in Sutbsection 3.7.2.2.2. Representative reactor/auxiliary building horizontal response spectra for selected building elevations are shown in Figures 3.7-32 through 3.7-55 for OBE and Figures 3.7-56 through 3.7-79 for SSE. Representative RHR complex response spectra are shown in Figures 3.7-98 through 3.7-101, and 3.7-102 through 3.7-105 for OBE and SSE, respectively. The spectra ensemble defining the facility aseismic design bases is described in Subsection 3.7.2.2.1.1.

3.7.2.6.3 Vertical Response Spectra

The scaled time-history forcing functions for the vertical direction (Subsection 3.7.1.2) were used to perform time-history analyses of the vertical seismic models described in Subsection 3.7.2.l.2.2. A single synthesized time history was used for the site-specific evaluation.

The procedure for determining subsystem response spectra in the vertical direction is the same as for the horizontal direction, as described in Subsections 3.7.2.2.1.2 and 3.7.2.2.2.2.

In this case, response spectra were generated for uncoupled time-history motion in the vertical or z direction.

The resulting reactor/auxiliary building vertical response spectra for selected building elevations are shown in Figures 3.7-80 through 3.7-88 for OBE and in Figures 3.7-89 through 3.7-97 for SSE. The RHR complex response spectra are shown in Figures 3.7-106 through 3.7-110 and 3.7-111 through 3.7-115 for OBE and SSE, respectively.

3.7.2.7 Differential Seismic Movement of Interconnected Components

The effects of differential movements of interconnected components due to seismic disturbance were considered in the seismic analysis of the piping systems and components where they contribute significantly to the overall response (Subsection 3.7.3.6).

All means and mechanisms of interconnection are designed to limit the applicable stress and deformation to within the ASME Section III Code Allowable Limits.

3.7.2.8 Effects of Variations on Floor Response Spectra

The increase in peak width, to account for variations in structural properties and damping, is described in Subsection 3.7.2.2. Variations in material properties are described in Subsections 3.7.2.15.2 and 3.7.2.15.3.

3.7.2.9 Use of Constant Load Factors

Vertical seismic system multi-mass dynamic models were used to obtain vertical response loads for the seismic design of Category I structures, systems, and components (Subsection 3.7.2.1). A constant load factor was used only when it was established that the structure, system, and/or component under consideration was rigid.

3.7.2.10 Method Used To Account for Torsional Effects

Category I structures may have natural torsional modes of vibration due to eccentricities between the centers of rigidity and centers of mass of the structural elements. As described in Subsection 3.7.2.1.2.2, the torsional response was accounted for by interconnecting the slab with weightless resisting elements, parallel to the x and y axes, distributed on the slabs as the shear walls are distributed in the structure.

3.7.2.11 Comparison of Responses

The forces obtained from the response spectrum method of analysis were used in the design of structural components of the building. The floor response spectra were generated by time-history analyses (Figures 3.7-32 through 3.7-115). Comparisons of accelerations were made at various elevations in the building to ensure that the floor response spectrum was obtained from a seismic load equivalent to or greater than the seismic load specified by the site response spectra.

3.7.2.12 Methods for Seismic Analysis of Earth Structures

The design of Fermi 2 does not include Category I earth structures except the shore barrier which was designed to meet Category I requirements. The shore barrier was analyzed using the computer code ICES-SLOPE. Details on slope stability analysis of the shore barrier were provided to the NRC staff during their safety evaluation review (see Subsection 3.4.4.5 and References 14 through 17).

3.7.2.13 Methods To Determine Category I Structures/Overturning Moments

The overturning moments induced by seismic excitation were computed by applying the inertia forces determined in Subsection 3.7.2.1, with vertical inertia forces taken upward, reducing the structure's effective weight. The inertia force on each mass was determined by computing the square-root-of-sum-of-squares of the modal acceleration contributions for that mass. Tensile base reactions were not allowed.

3.7.2.14 Analysis Procedure for Damping

Structural damping is energy loss due to internal friction within the structural material and at connections. The damping force is a function of the intensity of motion and the stress levels induced in the system. Damping is also highly dependent on the makeup of the structural system and the energy absorption mechanisms within the system. Considerable energy is also absorbed at cracked surfaces when the elements on each side of the crack can move relative to one another. In the linear dynamic analysis, the procedure used to account properly for the previous damping in different elements of a coupled system model was as follows:

a. The structural damping of the various elements of the model was first specified. These values are referred to as the damping ratios (Bi) of the various components making up the complete systems

b. A modal analysis of the linear system model was performed. This results in a modal column matrix (ψ) normalized such that $\psi T\ M\psi = I$; where M is the mass matrix, I is the identity matrix, and ψT is the transpose of ψ

c. Using the kinetic energy of the individual components as a weighting function, the following equation was used to obtain a suitable damping ratio (Bi) for the ith mode.

$$B_i = \psi^T \left[B_j\right] M\psi \qquad (3.7\text{-}10)$$

The diagonal terms of this matrix product are the modal damping ratios (B_i) of the coupled system. The damping ratios (B_j) of the individual substructures making up the complete system under investigation were used as input to [B_j] in order to calculate B_i.

3.7.2.15 Miscellaneous Considerations

3.7.2.15.1 Parametric Study

To evaluate the effects of the variation in mass-stiffness parameters on the seismic response of the building systems analyzed, several cases were studied by varying the original stiffness properties, or original mass properties, or both.

3.7.2.15.2 Structural Material Parameter

The modulus of elasticity, e_c, for concrete is taken as

$$e_c = (W^{1.5})33\sqrt{f_c'} \qquad (3.7\text{-}11)$$

where

W = density of concrete, lb/ft^3

f_c' = specified compressive strength of concrete, $lb/in.^2$

The modulus of elasticity of nonprestressed steel reinforcement and steel structures is taken as $29 \times 10^6\ lb/in^2$.

3.7.2.15.3 Interconnecting Category I and Other Structures

No Category I and nonseismic structures are integrally connected. The nonseismic structure is provided with sufficient seismic rattlespace or a flexible boundary layer to ensure that there is no effect on the adjacent Category I structure.

3.7.3 Seismic Subsystem Analysis

3.7.3.1 Determination of Number of Earthquake Cycles

Seismic loading cycles were considered for those Category I systems requiring fatigue analysis by applicable codes. The number of seismic cycles at maximum load per seismic event used on the various Category I systems and components varies from 5 to 250 cycles, depending on the component's natural frequency. In addition, the magnitude of the cyclic load varies with each component. The stated number of loading cycles was determined by actually performing a time-history analysis of reactor systems subjected to the full durations of the El Centro, Taft, and Olympia earthquakes. The number of cycles selected was always conservative with respect to the usage factor; an example of these cycles is presented as follows.

a. For components - ASME Section III NB-3650 requires that a number of earthquake cycles used in the analysis of ASME III Code components be specified as part of the design mechanical loads. The following criteria were used for all equipment within the jurisdiction of this code:

   1. A total of two OBEs and one SSE was assumed during the lifetime of the plant

   2. For conservative component design, structures were assumed to cycle (full sign reversal) 20 times per earthquake

3. Systems and components classified as relatively rigid with respect to local structural response will "ride" with the structure and are thus assigned 20 stress cycles per earthquake

4. If the system and/or component is relatively flexible (fundamental frequency equal to or less than 50 percent of structural fundamental frequency), a 20-cycle criterion governs.

b. For piping systems - The dynamic analysis using the floor response spectra as input motion performs an actual cycle count of the first mode vibration. The duration of the earthquake is taken as 10 sec and the result is adjusted to consider reduced stress range cycles. The number of effective cycles determined varies around 200. For valves and many other mechanical items, a conservative number of 250 is used.

For the GE-supplied equipment, the reactor/auxiliary building dynamic model was excited by the same time-histories as previously specified. The modal response was truncated such that the response of three different frequency bandwidths could be studied: 0-10 Hz, 10-20 Hz, and 20-50 Hz. This was done to give a good approximation to the cyclic behavior expected from structures with different frequency content. Using the results from the three earthquakes and averaging the results from several different points on the dynamic model, the cyclic behavior was formed (Table 3.7-10).

Independent of earthquake or component frequency, 99.5 percent of the stress reversals occur below 75 percent of the maximum stress level, and 95 percent of the reversals lie below 50 percent of the maximum stress level. This relationship is shown in Figure 3.7-116.

In summary, the cyclic behavior number of fatigue cycles of a component during an earthquake was found in the following manner:

a. The fundamental frequency and peak seismic loads were found by a standard seismic analysis

b. The number of cycles which the component experiences were found from Table 3.7-10 according to the frequency range within which the fundamental frequency lies

c. For fatigue evaluation, 1/2 percent (0.005) of these cycles are conservatively assumed to be at the peak load, and 4.5 percent (0.045) at three-quarter peak. The remainder of the cycles will have negligible contribution to fatigue usage, as their resultant stresses are well below the fatigue limits set forth in the ASME B&PV Code Section III.

The SSE has the highest level of response. However, the encounter probability of the SSE is so small that it was not necessary to postulate the possibility of more than one SSE during the life of a plant. Fatigue evaluation due to the SSE was not necessary since it is an emergency condition and thus not required by ASME B&PV Code Section III.

The OBE is an upset condition and therefore, must be included in fatigue evaluations according to ASME B&PV Code Section III. Investigation of seismic histories in the PSARs of many plants show that during a 40-year life it is probable that five earthquakes with intensities one-tenth of their individual prescribed SSE intensity, and one earthquake approximately 20 percent of their individual prescribed SSE intensity, will occur. Therefore, the probability of even an OBE is extremely low. To cover the combined effects of these earthquakes and the cumulative effects of even lesser earthquakes, one OBE intensity earthquake was postulated for fatigue evaluation. Table 3.7-11 shows the calculated number of fatigue cycles and the number of fatigue cycles used in design.

3.7.3.2 Basis for Selection of Forcing Frequencies

Amplified response spectra (floor) developed for horizontal (two directions) and vertical direction earthquakes was the basic source of seismic design accelerations. As noted in Subsections 3.7.1.2 and 3.7.3.6, seismic accelerations are selected from the amplified response spectra based on natural frequency calculations for the component or system. All frequencies in the range of 0.25 to 33 Hz were considered in the analysis and testing of structures, systems, and components.

3.7.3.3 Root-Mean-Square Basis

The term "root-mean-square basis" is not to be used in the procedure for combining modal responses. The SRSS is used to describe the method of combining modal responses when used herein and is described as follows:

$$R = \sqrt{\sum_{i=1}^{n}(R_i)^2} \qquad (3.7\text{-}12)$$

where

R = combined response

R_i = response in the ith mode

n = number of modes considered in the analysis

3.7.3.4 Procedure for Combining Modal Responses

When a response spectrum method of analysis is used to analyze a system or subsystem, the maximum response (displacements, accelerations, shears, and moments) in each mode is calculated independently of time; whereas, actual modal responses are nearly independent functions of time, and maximum responses in different modes do not necessarily occur simultaneously. The maximum possible response is given by the sum of the maximum modal responses without regard to sign. It has been shown that the probable maximum response is equal to the square root of the sum of the squares of the modal maxima. This square-root criterion is used in combining the modal responses in the response-spectrum method of analysis, except in combining closely spaced in-phase modes of vibration.

These closely spaced coupled modes of vibration are detected by computing the model's modal responses and then using both the square-root criterion and the absolute-sum criterion in combining modes. In many locations in a complex model, both criteria give nearly equal results, indicating that a single mode is contributing to the response. If the two criteria give results that differ by a large amount, then more than one mode is contributing to the response. The modes that contribute are examined; if they are closely spaced coupled modes, they are combined using the absolute-sum criterion and are treated as a single mode when combined with the rest of the modes using the square-root criterion.

When the time-history method of seismic analysis is used, the physical displacements, accelerations, shears, and moments due to each mode are added algebraically at each instant of time. Hence, no criterion concerning the method of combining loads from the individual modes needs to be set.

3.7.3.5 Significant Dynamic Response Modes

All significant modes were included in modal dynamic analysis. Generally, the number of significant modes varied between 10 and 30 modes.

A static analysis was used in seismic design if the component, structure, or equipment was essentially rigid or could be properly represented by a single-degree-of-freedom system. If it was rigid, the static load was based on the zero-period acceleration.

If it could be properly represented by a single-degree-of-freedom system, the static load was based on the acceleration corresponding to the natural period of the system. Using the peak of the floor spectrum curve was a conservative approach.

When a static analysis based on the peak floor spectrum curve was used in the seismic design of a component, structure, or piece of equipment that could not be represented by a single-degree-of-freedom system, an amplification factor was used to bound anticipated multi-mode phenomena, or it was ensured that the fundamental natural period of the system was far enough from the period corresponding to the peak value. Therefore, the participation of the expected following modes would not cause the resultant acceleration to exceed the peak value used in the static analysis.

3.7.3.6 Design Criteria and Analytical Procedures for Piping

3.7.3.6.1 Introduction

All Category I piping was seismically analyzed by either a simplified analysis or a multi-degree dynamic analysis, depending on its quality group and nominal size, as shown in Table 3.7-12. The loading combinations correspond to various stress criteria; this is also shown in Table 3.7-12.

3.7.3.6.2 Design Spectra and Anchor Movement

Two orthogonal horizontal earthquake motions and one vertical earthquake motion were considered. The two horizontal earthquake spectra were distinctly applied in north-south and east-west directions along with a vertical response spectra. These spatial results were combined for each point in the piping model by the method of the SRSS.

Modal responses in seismic response analysis were combined using the methods described in NRC Regulatory Guide 1.92, Revision 1. All modes with frequencies of 33 Hz or less were considered.

In cases where more than one response spectrum was applied to a subsystem (i.e., if the system is supported from locations in the structure having different response spectra), an envelope of all applicable response spectra was applied to the subsystem. When GE piping systems are anchored and supported at points with different excitations, the multiple response spectra method was used.

Secondary stresses of piping systems due to seismic anchor movements were computed by using the maximum relative displacements in two horizontal and vertical directions as the boundary conditions at support (anchor) points. The computed secondary stresses were added absolutely to other stresses in accordance with the procedures specified in ANSI B-31.7, Nuclear Piping and ASME B&PV Code Section III-1971.

For the GE-supplied piping, the maximum value of the modal displacement was used in the static calculation of the stresses due to relative displacements in the response-spectrum method. Therefore, the mathematical model of the equipment was subjected to a maximum displacement at its supporting points obtained from the modal displacements. This procedure was repeated for the significant modes of the structure (modes contributing most to the total displacement response at the supporting point). The total stresses due to relative displacement were obtained by combining the modal results using the SRSS method. Since the maximum displacement for different modes does not occur at the same time, the SRSS method is a realistic and practical method.

3.7.3.6.3 Simplified Analysis

When simplified seismic analysis was used for piping, the system is restrained such that the combined seismic stress of the system (SRSS of all three excitations) is less than 7000 psi for the OBE. The methods used and their limitations are presented in Subsection 3.9.2.7. For equipment and piping supplied or analyzed by GE, a simplified dynamic analysis was not used.

3.7.3.6.4 Dynamic Analysis

The general procedure for the modal analysis response-spectrum method for piping systems is described in Subsection 3.7.3.16. Each pipeline is idealized as a mathematical model consisting of lumped masses connected by elastic members. Appendages having significant dynamic effects on the piping system, such as motors attached to motor-operated valves, are included in the model. Using the elastic properties of the pipe, the stiffness matrix for the piping system is determined. The flexibility matrix of each beam element includes axial, bending, shear, and torsional flexibilities. The size of the stiffness matrix for each piping structural element is 12 by 12, since six forces and moments and six deflections and rotations are considered by the piping flexibility program in each of the two nodes of an element.

The unrestrained general stiffness matrix [K] of a dynamic structural model is condensed to a square reduced-stiffness matrix [k]. The purpose of this procedure is to exclude rigid constraints and to condense rotational stiffness coordinates into dependent coordinates of the translational displacement stiffness matrix.

After development of stiffness and mass matrices, natural frequencies and their associated modal shapes are determined by solution of the following equation:

$$\{[\mathrm{k}] - \omega_i^2 \, [\mathrm{m}]\} \, [\mathrm{Q_i}] = 0 \qquad (3.7\text{-}13)$$

where

$[k]$ = square reduced-stiffness matrix

$[\omega_i]$ = natural frequencies of system (i = 1,2,...n)

$[m]$ = mass matrix

$[Q_i]$ = mode shape vector associated with ith mode

The ω values and $[Q_i]$ matrix for each of the n modes are computed (i = 1, 2,...n, where n equals degrees of freedom of the piping system dynamic structural model). For the acceleration response spectrum method of analysis, the maximum displacements in global coordinates are shown as:

$$\{y_{max_n}\} = [Q]\,\{q_{max}\} \qquad (3.7\text{-}14)$$

where

$[Q]$ = square matrix containing eigenvectors for each mode

$\{qmax\}$ = $[\omega_n^2]^{-1}\,[S_a]\,[M_n]^{-1}\,[Q]^T\,[m]D$

$[M_n]$ = generalized mass = $[Q]^T[m][Q]$

$\{D\}$ = direction vector

$[S_a]$ = matrix of special acceleration values

The maximum displacement equation can be rewritten as:

$$\{y_{max}\} = [Q][\omega_n^2]^{-1}[S_a]\{\Gamma\}_n \qquad (3.7\text{-}15)$$

where

$\{\Gamma\}_n$ = participation factor of system

$\{\Gamma\}_n$ = $[M_n]^{-1}[Q]^T[m]\{D\}$

Inertia forces for each mass point are then calculated from

$$\{F_{max}\}_n = [m]_n[Q][\omega_n^2]_d\{q_{max}\}_n \qquad (3.7\text{-}16)$$

(nxn)(nxd)(dxd) (dx1)

where

d = number of modes considered

The computation of internal moments at each mass node represents maximum seismic inertial responses due to excitations of vertical amplified response spectrum and horizontal amplified response spectrum applicable to the piping system. The stresses due to the inertia forces were determined using the SRSS of the horizontal responses and the vertical response.

The relative displacement between anchors was determined from the dynamic analysis of the structures. The results of the relative anchor point displacements were used for a static analysis to determine the additional stresses due to relative anchor point displacements as described in Subsection 3.7.3.6.2.

All of the calculations outlined in this subsection, except for those of the GE scope of supply, were performed by using the computer program AutoPIPE, PIPSYS, or NUPIPE, for the analysis of a three-dimensional piping system (Section 3.13).

3.7.3.6.5 Allowable Stress

Allowable stresses in the piping caused by an earthquake are in accordance with the ASME Code Section III. Internal moments and forces, computed in Subsection 3.7.3.6.4 as the seismic responses of the piping system, were then combined with deadweight, pressure, thermal, and other mechanical loads to complete the stress analysis of all Category I and some nonseismic piping.

For ASME Code Class 1 piping larger than 1-in. nominal pipe size, stress intensities and cumulative usage factors of the piping system were computed based on formulations specified in ASME Code Section III-1971, NB-3653. For ASME Code Class 1 piping, 1-in. nominal pipe size and smaller, the stress intensities were computed based on formulations specified in the ASME Code Section III-1971, NC-3650.

General seismic design and analysis criteria for ASME Code Classes 1, 2, and 3 are defined in Table 3.7-13. For additional information, see Section 3.9.

Allowable stresses in the earthquake restraint components such as shock suppressors are in accordance with stress limits established by American Institute of Steel Construction (AISC)-1969 for original plant design, subsequent design codes are as described in subsection 3.9.2.2.5.2.

3.7.3.7 Basis for Computing Combined Responses

The two horizontal components and one vertical component of ground motion are accounted for in the following manner:

a. Components - The procedure described in Subsection 3.7.3.16 for Category I component analysis in combining the dynamic responses from horizontal and vertical amplified response loading was based on

   1. Static analysis - The sum of the horizontal plus the vertical responses

   2. Dynamic analysis - The SRSS of the two horizontal modal responses and vertical modal responses.

b. Piping systems - The procedure described in Subsection 3.7.3.6 for Category I piping analysis in combining the dynamic responses from horizontal and vertical amplified response loading was based on the SRSS of the two horizontal spatial responses and the vertical spatial response.

Alternatively, for subsystems or components under the GE scope of supply, the two horizontal components and one vertical component of ground motion can be accounted for in the following manner: Two sets of seismic results are obtained.

First, the maximum value of the horizontal component of the earthquake is assumed to act in one horizontal direction simultaneous with the vertical component, and the loads are computed for this combination. Next, the maximum value of the horizontal component of the earthquake is assumed to act perpendicular to the direction previously assumed and simultaneous with the vertical component, and loads are computed for this combination. The larger of these two loads at each point in the system is used for design.

This method of analysis is based on the fact that the seismologist specified the maximum resultant value of the horizontal component of the earthquake when specifying the horizontal component of the SSE. Using this method, it is conservatively assumed that the horizontal and vertical components of the earthquake response occur simultaneously.

3.7.3.8 Amplified Seismic Responses

Constant load factors were not used for vertical floor response in the seismic design of Category I components. As described in Subsection 3.7.1.2, amplified response spectra (floor) were developed for horizontal (two directions) and vertical seismic excitation. Components and systems were designed for the combination of operating loads acting simultaneously with horizontal and vertical seismic loads based on these response spectra. As noted in Subsection 3.7.2.1, three directions of earthquake motion were considered.

In the simplified dynamic analysis described in Subsection 3.7.3.9 for Category I piping, constant load factors based on applicable amplified response spectra were used as the vertical and horizontal amplified floor response loading.

3.7.3.9 Use of Simplified Dynamic Analysis

Simplified dynamic analysis methods for piping are discussed in Subsection 3.9.2.7.

3.7.3.10 Modal Period Variation

The modal period variation was considered in the derivation of floor response spectra curves by widening the peaks of those curves (Subsection 3.7.2.6).

3.7.3.11 Torsional Effects of Eccentric Masses

If the torsional effect of the valve operator was likely to have a significant effect on the results of an analysis, the operator's mass and moment arm were included in the mathematical model. However, if the pipe stress due to the torsional effect was expected to be less than 500 lb/in^2, the offset moment due to the operator was neglected.

3.7.3.12 Piping Outside Containment Structure

Category I piping located outside the containment, but not buried, was analyzed so that allowable piping and structural stresses were not exceeded due to differential movement at support points, at containment penetrations, and at entry points into other structures, as specified in Subsection 3.7.3.6.

3.7.3.13 Interaction of Other Piping With Category I Piping

For systems that are partially Category I, the seismically qualified portion of the system extends to the first seismic constraint (anchor) beyond the isolation valves that separate the safety-related from the nonseismic portions of the system. The isolation valve(s) that defines the operational boundary location between seismic and nonseismic portions of the system is identified on the respective piping and instrumentation diagram(s). The specific constraint beyond the isolation valve that is included in the seismic analysis of the piping system would be identified on the "dash-2 version" of the system-piping isometric drawing(s). These isometric drawings are commonly referred to as the system hanger drawings. The hanger drawings and required seismic analyses are retained as permanent plant records.

3.7.3.14 Field Location of Supports and Restraints

The field location of seismic supports and restraints for piping and piping systems was so selected as to keep the seismic stresses and deflections below the allowable limits. The following procedure was used to ensure that the seismic constraints were actually applied consistent with the assumptions used in the seismic analysis of the piping:

a. The seismic analyst recommended approximate locations for seismic restraints

b. The piping designer and/or the field engineer found an exact location for each restraint (including the methods of attachment) and notified the seismic analyst of these locations by generating as-built field sketches

c. The final seismic analysis was performed using the agreed-upon locations to arrive at piping loads

d. The piping stress analysis was performed to ensure that applicable code limits are not exceeded.

The field location of seismic supports and restraints for GE Category I piping and piping system components was selected to satisfy the following two conditions:

a. The location selected must furnish the required response to control stresses and deflections to allowable limits

b. Adequate building strength for attachment of components must be available.

The final location of seismic supports and restraints for Category I piping, piping system components, and equipment, including the placement of snubbers, was checked against the drawings and instructions issued by the engineer. An additional examination of these supports and restraining devices by an engineer competent in the design of Category I systems and components was made to ensure that the location and characteristics of these supports and restraining devices were consistent with the dynamic and static analyses of the systems.

3.7.3.15 Seismic Analysis for the Reactor Pressure Vessel, Fuel Elements, Control Rod Assemblies, and Control Rod Drives

The seismic loads on the RPV and internals were based on a dynamic analysis of the reactor/auxiliary building, with the appropriate forcing function supplied at ground level. The seismic model of the RPV and internals is given in Figure 3.7-16.

This mathematical model consists of lumped masses connected by elastic (linear) members. Using the elastic properties of the structural components, the stiffness properties of the model were determined. This included the effects of both bending and shear. To facilitate hydrodynamic mass calculations, several mass points (fuel, shroud, vessel) were selected at the same elevation. The various lengths of control rod drive (CRD) housings were grouped into the two representative lengths shown. These lengths represent the longest and shortest housings in order to adequately represent the full range of frequency response of the housings.

The high fundamental natural frequencies of the CRD housings result in very small seismic loads. Furthermore, the small frequency differences between the housings due to the various lengths result in negligible differences in dynamic response. Hence, the modeling of intermediate length members becomes unnecessary. Not included in the mathematical model are light components such as jet pumps, in-core guide tubes and housings, sparger, and their supply headers. This reduces the complexity of the dynamic model.

The presence of fluid and other structural components (e.g., fuel within the RPV) introduces a dynamic coupling effect. Dynamic effects of water enclosed by the RPV were accounted for by introduction of a hydrodynamic mass matrix. This matrix served to link the equations of motion acceleration terms of points at the same elevation in concentric cylinders with a fluid entrapped in the annulus. The seismic model of the RPV and internals had two horizontal coordinates for each mass point considered in the analysis. The remaining translational coordinate (vertical) was excluded because the vertical frequencies of RPV and internals were well above the significant horizontal frequencies. Furthermore, all support structures, buildings, and containment walls have a common centerline, making the coupling effects negligible.

The vertical seismic loads acting on the structures within the RPV are based on a separate vertical dynamic analysis.

The multi-node mathematical model used represents the RPV, RPV internals, pedestal, and the shield wall by lumped masses and a set of springs idealizing both the inertial and stiffness properties of the system. Between mass points, the structural properties are reduced to uniform beam segments of crosssectional area, effective shear area, and moment of inertia. The two rotational coordinates about each node point were excluded because of the momentary contribution of rotary inertia from surrounding nodes. Since all deflections were assumed to be within the elastic range, the rigidity of some components was accounted for by equivalent linear springs.

The shroud support plate was loaded in its own plane during a seismic event, and hence was extremely stiff. Therefore, it was modeled as a rigid link in the translational direction. The shroud support gussets and the local flexibilities of the vessel and shroud contribute to the rotational flexibilities, and were thus modeled as an equivalent torsional spring. The foundation mat was considered to be fixed. The effect of the water inside the RPV was included in the vertical model by adding concentrated mass to the node points in the mathematical model.

The seismic analysis was performed by a modal super-position time-history analysis. Design calculations were made using one of the following: peak loads or accelerations from the response time histories; amplified response spectra appropriately broadened; or peak displacements created by each natural mode of the structure. Table 3.7-14 lists several of the seismic loads on the RPV and RPV internals.

3.7.3.16 Seismic Analysis of Components

3.7.3.16.1 General

All Category I equipment has been documented for seismic adequacy. Depending on equipment location, the basic source of seismic design data is either the ground response spectrum or the amplified response spectrum, derived through a dynamic analysis of the relevant structure.

The uncertainties in the calculated values of fundamental structural frequencies due to reasonable variations in the structural properties are taken into account in the use of amplified response spectra. The peak resonant period value(s) in the amplified response spectra was developed as described in Subsection 3.7.2.6.

Three principal methods of documenting adequacy for Category I components are

a. Analysis

b. Analysis and testing

c. Testing.

Static Analysis

Static analysis was used for equipment that could be characterized as a relatively simple structure. This type of analysis involves the multiplication of the equipment or component weight times the applicable acceleration value (direction-dependent loading) to produce forces that have been applied at the center of gravity in the horizontal and vertical directions. A stress analysis of equipment components, such as feet, hold-down bolts, and other structural members, has been performed to determine their adequacy.

In the specification of equipment for static analysis, two or more sets of acceleration data were provided, the choice of which set to use being dependent on the equipment's fundamental natural frequency. The relevant response curves were reviewed to determine a "cutoff frequency" which bounds the rigid range from the resonance range of the response curves. Components having fundamental natural frequencies above the cutoff frequency were analyzed to rigid range response accelerations.

For components having a fundamental natural frequency below the cutoff frequency, analysis was based on response accelerations that were not less than those indicated by the amplified response curves over the full frequency range of the component. If the fundamental mode of the component fell within any of the resonant response peaks, and if the component cannot be characterized as a single degree-of-freedom system, the resonant peak response acceleration was used.

Each of the three defined directions of earthquake input (two horizontal and one vertical taken orthogonally) was evaluated separately. The calculated results of the analyses were superimposed on an SRSS of the maximum horizontal with the vertical basis. The particular response values to be combined are optional (i.e., acceleration, force, stress) but must remain consistent throughout.

Dynamic Analysis

A detailed dynamic analysis was performed when component complexity or dynamic interaction precluded static analysis, or when static analysis had been too conservative.

To fully describe the behavior of a component subjected to dynamic loads, infinite numbers of coordinates are required. Since calculation at every point of a complex model is impractical, the analysis is simplified by a selection of a limited number of mass points. The lumped-mass approach is used in the dynamic analysis. In the lumped-mass idealizations, the main structure is divided into substructures, and the masses of these substructures are concentrated at a number of discrete points. The nature of these substructures and the stiffness properties of the corresponding modeling elements determine the minimum spacing of the mass points and the degrees of freedom to associate with each point. In accordance with the minimum spacing requirements, the analyst could then choose, for the model, particular mass points reflecting predominant masses of the components that give significant contribution to the total response.

In cases for which some dynamic degrees of freedom do not contribute to the total response, static or kinematic condensation was used in the analysis.

The normal mode approach was used for dynamic seismic analysis of components. Natural frequencies, eigenvectors, participation factors, and modal member-end forces and moments of the undamped structure were calculated. The system of equations that describe the free vibrations of an n-degree-of-freedom undamped structure is:

$$[\mathrm{M}]\left\{\ddot{\mathrm{X}}\right\}+[\mathrm{K}]\{\mathrm{X}\}=0 \tag{3.7-17}$$

where

$[\mathrm{M}]$	=	mass matrix
$[\mathrm{K}]$	=	stiffness matrix
$\{\mathrm{X}\},\left\{\ddot{\mathrm{X}}\right\}$	=	displacement, acceleration vectors

The mode shapes and frequencies were solved in accordance with:

$$[\mathrm{K}-\omega_{\mathrm{n}}^{2}\mathrm{M}]\{\phi\}_{\mathrm{n}}=0 \tag{3.7-18}$$

where

ω_{n}^{2}	=	frequency of nth mode
$\{\phi\}_{\mathrm{n}}$	=	mode shape vector for nth mode

Eigenvector-eigenvalue extraction routines, such as Householder-QR, Jacobi reduction, and inverse iteration, are used, depending upon the total number of dynamic degrees of freedom and the number of modes desired.

For each mode, the participation factor for the specific direction "i" is defined by:

$$\Gamma_{\mathrm{n_i}}=\frac{[\phi]^{\mathrm{T}}[\mathrm{M}][\mathrm{D}]_{\mathrm{i}}}{[\phi]^{\mathrm{T}}[\mathrm{M}][\phi]} \tag{3.7-19}$$

where

$\Gamma_{\mathrm{n_i}}$	=	participation factor shape vector for nth mode in ith direction
$[\phi]^{\mathrm{T}}$	=	transpose of mode
$[\mathrm{D}]_{\mathrm{i}}$	=	earthquake direction i

The modal member-end forces and moments were determined by:

$$[F_m]_n = [K_m]\,[\phi]_n \tag{3.7-20}$$

where

K_m = member stiffness matrix

For each modal frequency, the corresponding response acceleration was determined for a given level of equipment damping from the applicable response curve. Modes within the broadened response peak were assigned the peak resonant response value.

The maximum response for each mode was found by computing

$$\begin{aligned}
[\ddot{X}] &= \Gamma_{n_i} R_{n_i} [\phi]_n \\
[\dot{X}] &= \frac{1}{\omega_n}[\ddot{X}]_n \\
[X] &= \frac{1}{\omega_{n^2}}[\ddot{X}]_n \\
[F]_n &= \frac{\Gamma_n R_{n_i}}{\omega_n^2}[F_m]_n
\end{aligned} \tag{3.7-21}$$

where

$[\ddot{X}]_n$ = modal acceleration for nth mode

$[\dot{X}]_n$ = modal velocity for nth mode

$[X]_n$ = modal displacement for nth mode

$[F]_n$ = moment vectors for nth mode

R_{n_i} = spectral acceleration for nth mode in ith direction

The basis for combination of modal responses is described in Subsection 3.7.3.4.

Each of the three defined directions of earthquake input (two horizontal and one vertical taken orthogonally) were evaluated separately. The calculated results of the maximum horizontal and vertical directions were combined on an SRSS basis. The particular response values to be combined are optional (i.e., acceleration, force, stress) but must remain consistent throughout.

Testing

For tested equipment that has an operability function, the Fermi 2 requirements supplement other applicable industry standards (such as IEEE-344-1971, Section 3.10) or provide guidance for testing where no such codes are available. Equipment packages or components were shown to be adequate either by being tested individually, as part of a simulated structural section, or as part of an assembled module or unit. In any case, the minimum acceptance criteria were

a. No loss of function, or ability to function, during and/or after the proposed test, as required

b. No structural/electrical failure (i.e., connections and anchorages) that would compromise component integrity

c. No adverse or maloperation during and after the proposed test that could result in an improper safety action.

Equipment vendors and suppliers were required to formulate programs for qualifying the equipment in accordance with the conditions specified in the earthquake design requirements.

Sinusoidal, sine beat, and random input tests were accepted as methods of seismic qualification based on the particular component location, structure, and floor response characteristics. Structures, particularly at lower elevations, exhibit a broad frequency range response similar to the ground motion during an earthquake. This broad range frequency motion is filtered at higher structural elevations, and response becomes more sinusoidal in nature. Knowledge of the floor response characteristics of the structure generally dictates the requirements for testing. Periodic testing is applicable where periodic floor motion is indicated and, conversely, random input testing is most applicable for broad frequency range input to components. Periodic testing can be used to develop multiple peak floor responses, as well as single peak, providing sufficiently high force is used.

Conservative periodic (sine wave) inputs to the tested component have been specified regardless of floor input characteristics since the test requires a sine sweep throughout the full frequency range at "zero period" response levels associated with relevant floor and building locations, as well as the generally required resonance dwells at discovered equipment resonance requencies. Other less conservative but generally acceptable testing techniques (periodic) have been reviewed to ensure conservatism of test results.

Either single or multiaxis test results are considered acceptable. While multiaxis tests, with some definition of "most conservative phasing" are ideal, the availability of testing machines and techniques capable of attaining this ideal is severely limited.

General testing guidance criteria specified for components include the following:

a. Sinusoidal testing

   1. A frequency scan (2 octaves per minute maximum) at a constant acceleration level is performed for as much of the range between 1 and 35 Hz as practicable or justified. The objective of this test is to determine the natural frequencies and amplification factors of the tested equipment and its critical components or appurtenances and to ensure general seismic adequacy over the full frequency range of interest. The acceleration inputs used are the maximum rigid range accelerations indicated by the relevant response spectrum curves

   2. A dwell test of the equipment at its fundamental natural frequency is included at the acceleration values specified previously in Item 1. Additionally, other frequencies are selected if amplification factors of 2.0 or more are indicated. A minimum 15-sec duration is considered acceptable for each dwell.

b. Sine beat testing

A sine beat test is performed in conjunction with a sine scan and is an alternative to the dwell portion of the program outlined previously in Item 2. The sine beat test is performed at natural frequencies and bands of large amplification identified during the sine scan. The duration and peak amplitude of the beat for each particular test frequency are chosen to most nearly produce a magnitude of equipment response equivalent to that produced by the particular floor response spectrum at justifiable damping levels

Current practice indicates that a minimum of 10 cycles per beat should be used unless it can be shown that a lower number of cycles is sufficient to duplicate or exceed the response spectra for the equipment at the appropriate location. Five sine beats with a time delay between beats are commonly used

c. Random motion testing

Random excitation may be used for components. The excitation is controlled to provide a test response spectrum that is required to envelope the required response spectrum

Additionally, as stated in Subsection 3.10.1.1, components purchased after the issuance of IEEE-344-1975 are specified to be qualified to the requirements of that standard.

3.7.3.16.2 Category I Equipment

In the analysis of the building systems, the Category I equipment was lumped with the building floor on which the equipment is supported. The equipment was analyzed as a secondary system, and the model simulating the equipment was excited by the floor response spectra obtained from the time-history analysis of the building. However, the equipment model was included in the building model if the mass of the equipment was large enough to cause significant change in the building response.

Equipment was idealized as a mathematical model consisting of lumped masses connected by elastic members or springs. Results for some selected large generic nuclear steam supply system (NSSS) Category I equipment are given in Table 3.7-15. Seismic loadings due to two orthogonal horizontal directions and the vertical direction were combined as detailed in Subsection 3.7.3.7.

When the equipment was supported at more than two points located at different elevations in the building, the response spectrum at the elevation near the center of gravity of the equipment was chosen as the design spectrum for the GE equipment. An envelope of each applicable spectrum was developed for the equipment.

The relative displacement between supports was determined from the dynamic analysis of the structure. The relative support point displacements were used for a static analysis to determine the additional stresses due to support displacements. Further details are given in Subsection 3.7.3.6.2.

The seismic design criteria for Category I equipment and components are described in Section 3.9.

3.7.3.17 Cable Tray Support Systems

3.7.3.17.1 Introduction

A cable tray and its attachment to a building comprise a structural system used to support electrical cables in a power plant. This subsection describes some of the aspects that are considered in designing cable tray supports to meet seismic criteria. A cable tray system's response characteristics, its modal periods of vibration, its relation to the seismic load, and its floor response spectra determine how the system is analyzed to ensure that it meets the seismic criteria.

3.7.3.17.2 Analysis and Design

The cable trays and cable tray support system were evaluated to withstand forces caused due to dead load, live load, and seismic conditions.

The following combinations of dead load, live load, and earthquake were investigated and checked to determine the most severe condition:

a. Dead load of various components with allowable stresses according to AISC specifications. The dead load on cable trays consists of cables, trays, and attachments. In the case of hangers, it includes the dead weight of hangers also. The original cable tray design loading was 40lb/ft^2 generally, except in the relay room area, where it was 50 lb/ft^2. An on-going program was later established to monitor the actual weight of cables in the trays and to account for fire wrap, conduit and air drop loads. Cable tray design load is adjusted to reflect these actual loads. See Subsection 8.3.1.4.3 for additional information

b. Dead load plus a concentrated live load of 200 lb at the mid-span was specified for all trays with the exception of those in the drywell. For drywell trays, a dead load plus a concentrated live load of 250 lb was specified

c. Dead load plus earthquake.

The cable trays and the support system were modeled as a multidegree-of-freedom system with the mass of the cables plus tray lumped at the levels at which they are supported.

For vertical excitation, the fundamental period of vibration was computed by using a simplified model of a continuous beam with hinged ends. This approximation was found to be consistent with the numerous models studied for this purpose.

The response spectrum obtained from the analysis of the building was used in determining the response of the cable tray support.

The horizontal and vertical seismic excitations were assumed to be acting simultaneously along the principal axis on the cable tray system. The seismic response was computed by taking the SRSS of the individual responses.

It was observed that contribution due to nonfundamental modes was negligible, and hence the effect of closely spaced modes was negligible also.

The design was based on the 1968 edition of the "Specifications for the Design of Cold-Formed Steel Structural Members."

In the design specification for cable trays, deadweight loading did not include the weight of fire wrapping material or any other attachments, such as the top hat cover, which were subsequently added. Accordingly, hanger modifications were made where necessary, and the structural adequacy of the cable trays was verified.

3.7.3.18 Safeguard Against Derailing the Reactor/Auxiliary Building Crane

The crane is safeguarded against derailing in the three principal directions of seismic movement.

The crane was subjected to a detailed analysis (results reported in Reference 18). Seismic responses of the crane to an SSE based on the crane's fundamental frequency in the vertical and two horizontal directions (perpendicular and parallel to girder) in the loaded and unloaded conditions were determined on the basis of the reactor building seismic response spectra. Vertical accelerations did not exceed 0.431g and horizontal accelerations did not exceed 0.65g for the loaded and unloaded crane in all positions. Thus, no uplift is encountered.

In the horizontal direction parallel to the runway, the crane is regarded as a suspended mass in space. Maximum seismic acceleration is limited by the friction forces of the crane's wheels. In the parked position, the crane is locked to the runway by means of electrically operated locking bars on both sides of the crane. These bars are designed to secure the crane in a stationary position in the event of a tornado strike or horizontal seismic forces (Figure 3.8-32).

In the horizontal direction perpendicular to the runway, the crane bridge wheels have sufficient play on their axles to accommodate thermal movement and seismic deflection of the crane supporting structure. In the event that seismic deflections exceed axle play, the insides of the girders are provided with seismic end stops impacting on the runway structure.

The trolley is equipped with seismic end stops to prevent excessive movement perpendicular to its runway. The trolley is not restrained of movement parallel to its runway. The movement is expected to be minimal as only wheel friction forces are transmitted and also due to the stabilizing effect of the cable and hook assembly, which acts as a pendulum.

3.7.3.19 Other Subsystems

This subsection refers to the structural subsystems such as cranes, racks, ventilation ducts, and tanks. If the subsystem is idealized as a single-degree-of-freedom system, the forces in each direction are determined by applying, through the center of gravity, a static force equal to the weight of the subsystem multiplied by a frequency-dependent multiplier obtained from the floor response spectrum curve. In all other cases, the subsystem is modeled as a multidegree system with an adequate number of lumped masses that predict the true dynamic response of the subsystem. For tanks, the dynamic effect of fluid oscillations is considered in both the horizontal and vertical directions.

The Control Center (CC) HVAC System and Standby Gas Treatment System (SGTS) duct and duct supports were revalidated to demonstrate their structural adequacy under the combined effects of dead load, internal duct pressure (normal operating and maximum credible), and three-directional seismic (OBE and SSE) loads in accordance with the requirements and acceptance criteria contained in Reference 20.

The horizontal and vertical seismic excitations used for the revalidation of the CCHVAC and SGTS duct and duct supports were based on Figures 3.7-36 through 3.7-41, 3.7-83, 3.7-85, 3.7-86 and 3.7-87 for OBE, and on Figures 3.7-60 through 3.7-65, 3.7-92, 3.7-94, 3.7-95 and 3.7-96 for SSE. For revalidation of the duct systems under OBE effects, damping values of 4% and 2% were used for rectangular and round duct, respectively. For SSE effects, damping values of 7% and 4% were used for rectangular and round duct respectively.

Structural acceptance criteria for CCHVAC and SGTS duct and duct supports were based on the minimum published yield and ultimate strengths of the duct and duct support materials. Straight duct segment maximum stresses were limited to 0.9 Fy of the duct material for SSE effects (0.6 Fy for OBE effects) in accordance with ANSI/ASME-N509-1980 (Reference 21). Duct support allowable member stresses were governed by Table 3.8-19 for structural steel. Duct support anchorages (base plates and anchors) were also evaluated for adequacy. References 22 and 23 were used for the expansion anchor acceptance criteria. To conform to these acceptance criteria, duct system structural modifications were made where necessary, and the structural adequacy of the systems was verified.

3.7.4 Seismic Instrumentation Program

3.7.4.1 Comparison With Regulatory Guide 1.12

A seismic instrumentation program has been implemented to monitor and record the input motion and behavior of Fermi 2 in the event of an earthquake. The instrumentation program described below meets the intent of Regulatory Guide 1.12, Revision 1. (See Subsection A.1.12 for regulatory guide compliance statement.)

The seismic event recording system conceived and designed for Fermi 2 was documented in January 1972, prior to the issuance of Regulatory Guide 1.12. The project reviewed the Fermi 2 earthquake recording system for compliance with the requirements of Regulatory Guide 1.12, Revision 1, and concluded that the intent of Regulatory Guide 1.12 was satisfied. The seismic monitoring system is classified as Seismic Category II/I; however, it is designed, tested, mounted and maintained in a manner that gives a high degree of confidence that it will function during and after a seismic event of the Fermi 2 SSE. Seismic Category II/I is consistent with Regulatory Guide 1.29.

3.7.4.2 Location and Description of Instrumentation

Strong motion triaxial accelerographs are installed in two different reactor/auxiliary building locations. One of the accelerographs measures the response of the free field at the building foundation. The other device establishes the anticipated excitation to the reactor building containment structure and major internal equipment.

Strong motion triaxial response spectrum recorders are additionally installed at six seismically interesting plant locations. Three of these passive devices are contained in the reactor/auxiliary building, one at the free field/foundation location, adjacent to the active accelerograph, one in the relay room on the second floor, and one at the top of the reactor/

auxiliary building on the fifth floor. The other three response spectra recording devices are installed in the RHR complex. One of the devices is installed to measure the excitation to the diesel generators and the RHR pumps, a second device is installed to measure the excitation to the items at higher RHR complex elevations, and the third device is installed at a location in the RHR complex to measure the excitation experienced at the mechanical draft cooling towers.

3.7.4.2.1 Active Sensors

Active earthquake-recording instrumentation has been provided to measure and record the basic ground motion time-history acceleration, as well as the seismic excitation of the reactor/auxiliary building complex foundation and the primary containment structural elements including major internal equipment items. The complete system consists of an active seismic recording system and an active seismic playback system. The active seismic recording system consists of two triaxial accelerometers and a digital recorder. Both triaxial accelerometers are installed with the same geometrical orientation. The active seismic playback system consists of a computer and printer.

A seismic trigger activates the seismic recording system and indicates to control room personnel that a seismic event has occurred. The trigger is initiated from the High Pressure Coolant Injection (HPCI) room accelerometer, where free field and building foundation excitations are established. The seismic trigger senses any acceleration above a preset limit, 0.01g, and activates the recording system.

3.7.4.2.1.1 Active Instrumentation Locations

Triaxial accelerographs responding to acceleration excitation in three mutually perpendicular axes have been installed at two locations, as shown in Figure 3.7-117. The recording axes directions coincide with each other. A vertical axis is used, as well as two horizontal axes corresponding to the mutually orthogonal primary directions of the reactor/auxiliary building structure. The specific instrument locations are identified as follows:

a. Reactor/auxiliary building subbasement in the HPCI room (Figure 3.7-117, Location 1). This record is used for direct comparison with the ground motion and reactor building earthquake design excitation. This single triaxial earthquake accelerogram is used to establish not only the ground motion, but also the building foundation excitation, since it has been established that soil-structure interaction effects are negligible at Fermi 2

b. At the bottom of the RPV pedestal, adjacent to the floor at the base of the drywell (Figure 3.7-117, Location 2). This record is used to establish the primary containment element excitation, anticipated RPV motions, and the environment for major containment structure equipment items.

3.7.4.2.1.2 Active Instrumentation Specifications

Over the frequency range of interest (0.1 to 40 cps), the output of the seismic transducer is a voltage proportional to acceleration. This voltage is filtered and conditioned such that the overall sensitivity of the channel is approximately 2.5 V/g.

The seismic trigger is activated at the .01g level. This trigger not only initiates recording by the accelerometers, but also activates an operator indication and on-line monitor of the free field, subbasement time-history excitation. All data is stored in a unique file in memory, which is subsequently analyzed and available for evaluation.

3.7.4.2.2 Passive Sensors

Passive earthquake recording instrumentation has been provided throughout the complex to measure various ground motion and in-structure response spectra. These directly measured triaxial spectra may be used for comparison with basic facility design spectra without the need for intermediate data reduction. The passive instrumentation serves as a backup for the active sensors, and provides basic definitions of reactor/auxiliary building and RHR complex input motion and response phenomena. In addition, this instrumentation provides a direct definition of internal equipment environments in the Category I structures, as well as basic information defining the Category I structure and internal equipment response.

The complete system comprises 18 response-spectrum recorders (six triaxial spectrum recorders) that are identical in configuration and orientation and differ only in their installation location.

3.7.4.2.2.1 Passive Instrumentation Locations

Triaxial response spectrum recorders, which respond to accelerations in three mutually perpendicular axes, have been installed at six locations, as illustrated in Figures 3.7-117 and 3.7-119. These devices have been installed so that the directions of the recording axes coincide. One recording axis is vertical, and two are horizontal, corresponding to the mutually orthogonal directions of both the reactor/auxiliary building and RHR complex. The specific passive instrumentation locations are described as follows:

a. At the reactor/auxiliary building subbasement adjacent to the active accelerograph in the HPCI room (Figure 3.7-117, Location 1). Spectra generated at this location will be used to evaluate the recorded seismic spectra relative to the corresponding facility operating bases response spectra. These data will assist in the determination of the need to shut down the facility after an earthquake and will also be used for possible subsequent comparison with ground motion spectra generated from the active accelerometer records

b. At the reactor/auxiliary building second floor relay room (Figure 3.7-117, Location 4). These spectra will define the in-structure equipment environment at an intermediate height for investigation of critical Category I equipment

c. At the reactor/auxiliary building fifth floor (Figure 3.7-117, Location 5). This device will define the in-structure equipment environment spectra at an upper level for investigation of Category I elements at this structural elevation

d. At a critical location in the RHR complex (Figure 3.7-119, Location 6). This instrument will define the environment for investigation of the structural and equipment response for this Category I structure at the emergency diesel generator and RHR system pump location

e. At a critical location in the RHR complex (Figure 3.7-119, Location 7). This instrument will define the environment for the investigation of the structural and equipment response of this Category I structure at an elevated equipment location

f. At a third critical location in the RHR complex (Figure 3.7-119, Location 8). This instrument will define the environment for the investigation of the structural and equipment response of this Category I structure at an upper elevation corresponding to the sensitive region for mechanical draft cooling tower equipment apparatus.

3.7.4.2.2.2 Passive Instrumentation Specifications

There are 12 sensing elements included in each single response spectrum recorder. These elements provide a resolution of 1 percent of full scale at damping between 1 and 3 percent of critical, and are accurate in a temperature range of -50°C to +85°C. A tabular summary of representative reed frequencies and nominal full-scale acceleration limits follows:

Reed Number	Nominal Frequency (cps)	Nominal Full Scale Acceleration Limit (g)
1	2.0	±1.6
2	2.5	±2.5
3	3.2	±4
4	4.0	±6
5	5.0	±10
6	6.4	±16
7	8.0	±24
8	10.1	±34
9	12.7	±42
10	16.0	±64
11	20.2	±81
12	25.4	±90

3.7.4.3 Operator Seismic Event Notification and Recording System

The active seismic recording system is equipped with an earthquake event indicator which has been placed in the facility control room (Figure 3.7-117, Location 3). This event indicator notifies the control room operator that an excitation has occurred at the facility foundation level in excess of the 0.01g trigger setpoint.

Concurrent with this operator notification, the seismic trigger automatically activates the recording system and on-line monitor in the facility relay room (Figure 3.7-117, Location 4).

An earthquake is considered to have occurred if the trigger mechanism and companion event indicator are actuated. Post-earthquake data evaluation and reduction activities ensue in accordance with established project procedures.

The minimum system recording time is limited only by memory and will provide a minimum of 25 minutes of continuous recording. The lengths of pre-event and post-event memory are user selectable and recorded for ease of analysis. Continuous system actuation capability is ensured by an internal battery, which remains “trickle” charged from an ac power line. Minimum system accuracy is ± 8%.

The seismic recording system has playback capability enabling the facility operators to immediately obtain the representative acceleration time-history.

3.7.4.4 Post-Earthquake Evaluation Activities

An earthquake is considered to have occurred if the trigger mechanism is activated (.01g or larger) with attendant control room indication. Essential post-earthquake evaluation activities are summarized by the flow chart included in Figure 3.7-120.

In accordance with the requirements of Appendix A to 10 CFR 100, if the earthquake excitation exceeds that described by the facility OBE spectra, the reactor must be shut down to cease operation in as timely a manner as possible. The sequence of events by which this shutdown decision is made is described in Subsection 3.7.4.4.1. Subsequent earthquake data reduction and analysis activities are described in Subsections 3.7.4.4.2 and 3.7.4.4.3.

3.7.4.4.1 Immediate Operational Decision

Immediately upon signal indication of earthquake occurrences, the control room operator verifies that there are no abnormal changes in critical plant parameters as indicated by operational instrumentation. If any malfunctions are indicated by the instruments, shutdown is initiated as dictated by the severity of the malfunction.

In the absence of instrumentation-indicated malfunctions, plant personnel go to the relay room to examine the active earthquake system records, and to the HPCI subbasement location to extract the ground motion spectra from the passive measurement device.

In examining the active information, the earthquake ground motion response time-history from the subbasement location which is played on-line may immediately be evaluated as to whether or not the observed peak acceleration exceeds the OBE (.08g horizontal, .05g vertical). If the observed peak acceleration is greater than the OBE value, controlled shutdown activities are initiated.

Three directional response spectra are extracted from the passive earthquake recording device in the HPCI room subbasement location by recording the observed acceleration record associated with each of the tuned reeds at their various response frequencies. The spectra obtained from the passive recording device are compared with the facility OBE spectra, and if the response observed at any measured frequency exceeds that corresponding OBE level, facility shutdown is initiated. If not, the remaining passive data are extracted from all the passive instrumentation, the passive gages are reset, and the facility continues to operate with no further earthquake data investigation required.

If it is determined during the data operational evaluation process that the facility is to be shut down, data reduction and analysis activities ensue as described in the following subsections.

3.7.4.4.2 Earthquake Data Reduction

If the active or passive earthquake recording instrumentation indicates that the OBE design level was exceeded, data-reduction activities commence. In this regard, concurrent passive and active data reduction is accompanied by physical facility structural and component inspection.

All active data are reduced by generation of detailed acceleration time-histories from each active instrument. These time-histories are subsequently used to generate response spectra for all active instrument locations.

Passive spectral instrumentation exists at six varied facility locations. The 18 resulting passive measured response spectra are plotted after extraction of the necessary raw information from the recording devices.

Detailed inspection activities are documented for all Category I items, and any malfunctions or permanent distortions in the apparatus are recorded.

A document is prepared summarizing and presenting the reduced data for further evaluation purposes. Detailed earthquake data analysis activities are described in the following subsection.

3.7.4.4.3 Earthquake Data Analysis

Data reduction activities result in assembly of facility response spectra for representative locations and elevations at the Fermi 2 site in the Category I structures. These spectra are compared with the established facility SSE spectra for initial evaluation purposes. If the recorded event spectra do not exceed the facility established SSE spectra, no further investigation is necessary, and facility operations may resume. Certain essential structures and components were reassessed to a site-specific earthquake spectrum (larger than the SSE spectrum). Such items can be screened out of the investigation in a similar manner.

If there are spectra that exceed the SSE facility spectra at some facility locations, all Category I items in this proximity are noted and specifically evaluated with respect to the observed excitations. For each of these items identified, actual fragility level capability will be documented and compared with the excitation environment recorded. Items assessed to be satisfactory in this evaluation may be considered acceptable for continuing plant use.

If an item fragility level is equal to or less than the earthquake event excitation level recorded, a detailed dynamic analysis and/or system test combined with comprehensive item inspection will be required to establish whether or not the particular item is satisfactory for continuing facility service. If in this investigation it is established that tolerable permanent deformation or damage was sustained, the item will be considered satisfactory for continuing use. If not, the item shall be fully refurbished or a new item must be procured and installed for continuing plant operation.

3.7.5 Seismic Design Control

3.7.5.1 Introduction

Category I systems and components are designed to perform their intended function during and after the specified earthquakes. Category I items, at various locations in the reactor/auxiliary building and the RHR complex, are capable of withstanding the seismic excitation specified in the specifications (Subsection 3.7.5.2). Rational analyses or test results as described in this specification validating the seismic performance of all Category I items were submitted to Edison. Furthermore, independent documented reviews are performed to validate the adequacy of the seismic designs performed and to ensure the compatibility of such designs. The seismic design control procedure is outlined in Table 3.7-16.

All Category I structures, systems, and components were reviewed on an item-by-item basis. Nonseismic structures, systems, and components were examined to ensure that they do not adversely interact with close-proximity Category I items. General Electric-supplied items are subjected to a rigorous independent design review. The independent reviewer assists in an audit of GE seismic design documentation only, since independent design review is performed by GE.

Items that have significant mass and size relative to the building in which they are located were analyzed coupled to the structure itself to appropriately consider interaction effects. The RPV, primary containment, and crane are so considered in Subsection 3.7.2.1.2.2.

Items that are small enough relative to the building in which they are located so as not to influence the dynamic response of the building itself are considered uncoupled from the building. These items are validated to be capable of withstanding the earthquake excitation defined by the response of the building at the location where they are attached.

3.7.5.2 Seismic Performance Specification

To ensure that the various Fermi 2 vendors provide seismically adequate systems and components, a seismic performance specification was prepared.

It was specified in the seismic performance portion of the component specification that items mounted directly to a building are validated as capable of withstanding the excitation from the building at the location where they are attached. Design requirements are delineated in the specification. There are also other components that are attached to systems attached to the building rather than to the building itself. These components cannot be validated to the building excitation since it is necessary to consider the influence of the response of the system to which the component is attached.

In many cases, the component was procured as a part of the total system. A total system validation was required in this situation and the component validation was undertaken to the levels indicated as appropriate from the system analysis.

When a rigid component must be procured apart from the system to which it belongs, it is validated by the vendor to the mounting amplified acceleration or to the maximum acceleration on the response spectrum applicable for the parent system. This is conservative since essentially the assumption is made that the system is in resonance with the building. Nonrigid components are examined by the seismic design reviewer on an item-by-item basis.

A procurement specification is prepared for each item required for Fermi 2. Seismic provisions are accounted for by reference to the seismic performance portion of the specification. Generally, the location of the item being purchased is delineated so that the appropriate validation spectra are selected from the performance specification, unless plant-wide use qualification is required.

In addition, the potential vendors are informed that they must submit a description of their proposed validation with their basic bid package. A vendor is not selected until his seismic design approach is reviewed and found acceptable.

The seismic environment for items mounted directly to the structures is defined as a function of the item location in terms of vertical and horizontal response spectra. The vertical and horizontal excitations are assumed to act simultaneously. Figures 3.7-32 through 3.7-115 define the response spectra for both the reactor/auxiliary building and the RHR complex. Enveloping spectra have also been generated for plant-wide use qualification.

The seismic environment for rigid components not mounted directly to the structure, but rather mounted to a system that is connected to the structure, are validated to the peak acceleration indicated on the appropriate response spectrum. If the component is considered part of the system connected to the floor, then it is validated to the system acceleration obtained directly.

3.7.5.3 Seismic Acceptance Criteria

3.7.5.3.1 Validation Procedures

The seismic capability of vendor-supplied items is validated by either a rational dynamic response analysis or a suitable dynamic system test, or some combination of both as hereinafter specified.

3.7.5.3.2 Dynamic Response Analysis

The rational dynamic response analysis conforms to standard techniques of engineering mechanics. Stress and deformation of all elements of the vendor-supplied items are examined in accordance with the design criteria as shown in Sections 3.8 and 3.9. The vendor seismic dynamic response analysis is submitted to Edison for approval before acceptance of the items. The analysis submitted to Edison includes the following:

a. Description of the mathematical model used in the analysis

b. Description of the determination of properties such as the model mass distribution, damping, and stiffness characteristics

c. Development of the dynamic response analysis equations of motion

d. Discussion of experimental investigation supporting the given model and equations of motion

e. Description of the way the seismic input is applied in the analysis

f. Description of the solution techniques for the equations of motion

g. Evaluation of the seismic capability of the equipment including calculations of stress and deformation levels.

3.7.5.3.3 Dynamic System Test

Where dynamic system tests are made to verify the acceptability of the vendor-supplied items in accordance with the design criteria as shown in Sections 3.8 and 3.9, the tests impose upon the equipment a dynamic test environment equal to or greater than that specified in the earthquake criteria at all frequencies. Acceptable test environments are achieved by use of a controlled shaker table or a shock machine. Other test techniques are acceptable if the input is suitably defined. Before the testing is undertaken, a test procedure document is submitted to Edison for approval. This document contains a complete description of the testing to be done including descriptions of the following:

a. Method of measurement of the test environment including descriptions of active and passive instrumentation and techniques used in generating response spectra

b. Method of measurement of the response of the equipment including descriptions of active and passive instrumentation and operational testing

c. Method of deciding the adequacy of the equipment.

After the dynamic system tests are performed and before the acceptance of the equipment, a report summarizing the results of the testing is submitted to Edison for approval. The report includes pertinent test data as well as an analysis of the test data.

3.7.5.4 Independent Review

An independent review of the seismic design approach proposed by the various vendors is performed. In review of a proposed analytical validation, the approach is accepted or modifications are recommended. It is possible that for some items no analytical validation could be acceptable. In this case, it is recommended that the vendor be required to provide a test validation.

During the independent review of a proposed test validation, the approach is accepted or modifications are recommended.

The vendor then updates and modifies his seismic design package until it is accepted without any recommended modifications. The complete results of the seismic analysis either by testing or by calculations are documented in a clear and concise format and submitted.

The documentation submitted generally includes the following:

a. The abstract describes the purpose of the test or calculations and gives a brief description of the problem

b. The conclusions summarize the results obtained from the test or calculations. A concise statement is made regarding the conclusion reached, which is related to the purpose of the test or calculations

c. Both data and assumptions are listed. In the case of testing, the documentation includes the type of test machine used, the loads considered, and the efforts made to idealize the actual case in preparing the test. In the case of calculations, the documentation includes the loads considered, the weights used, the damping values chosen, and the assumptions used to convert the design criteria to actual loads, stresses, or displacements

d. A description of the test or the method of analysis is included. In the case of testing, the type of test, the input motion, and the generated response spectrum from this motion are presented. In the case of calculations, the analytical method, all analytical equations and their derivation from basic principles, any assumptions made to idealize boundary to initial conditions, the limitations of the applicability of the analysis (if any), and documentation to establish the validity of any computer program used are stated

e. The documentation outlines the results of the test or analytical calculations. In the case of testing, the measurements obtained, their interpretations, and numerical or graphical form of the test results are shown. In the case of calculations, design calculations as well as figures and sketches for the mathematical model showing loads, resultant forces, and displacements (if possible) are presented

f. Design drawings of the component and its support, including all necessary dimensions, are provided.

3.7.6 Testing of General Electric-Supplied Equipment

For GE-supplied essential mechanical equipment, two types of tests were used in the dynamic testing of equipment: free vibration and forced vibration tests. Dynamic analysis was also used for qualification of components. A description of the qualification methods is given below.

3.7.6.1 Free Vibration Test

This test was performed on equipment whose response is dominated by the fundamental mode. The critical damping ratio and fundamental frequency were determined from this test and were used to verify or supplement calculated values used in dynamic analysis of this equipment. This test was not used alone to demonstrate dynamic capability.

In this test an initial displacement or initial velocity was imparted to the equipment. The initial displacement was introduced by forcibly displacing the equipment and then suddenly releasing the force. The initial velocity was obtained by applying an impulse. Accelerometers or strain gages were mounted on the equipment. After first ensuring that the equipment was vibrating in its primary mode, the critical damping ratio was calculated from the logarithmic decrement.

3.7.6.2 Forced Vibration Test

The equipment was mounted on a shake table or driven by an eccentric shaker. The critical damping ratios, resonant frequencies, and the equipment's functional capability were determined.

The critical damping ratio of the equipment was determined by applying a sinusoidal acceleration and measuring the forced response curve (amplitude versus forcing frequency). The critical damping ratio was then calculated by using the half-power method, fitting a theoretical forced response curve through the data points, or direct reading of the resonant amplification. The vibratory motion used was such that the vibratory loads equaled or exceeded seismic loads represented by the applicable floor spectra. When testing was the only method used to demonstrate functional capability of equipment, the mounting conditions were simulated and the equipment was operating during and after the tests.

When the seismic testing is supplemented by analysis, the seismic stresses are added to those from normal and accident conditions in the appropriate loading combinations in order to ensure that the equipment will perform its required safety functions. Each type of equipment is examined individually to provide this assurance.

As an example of the approach required for extremely complicated geometrical configurations, the tests performed on the HPCI turbine are summarized below.

The major structures of the HPCI and reactor core isolation cooling (RCIC) turbines were qualified by dynamic analysis. The turbine-control-unit components were qualified by dynamic testing on a shake table with electrical and hydraulic systems functional. The actual mounting brackets were simulated in the test mounting. Vibration in all three perpendicular axes (two horizontal and one vertical) was accomplished by orienting the equipment in three directions on a horizontal shake table. A resonant search was made from 1 to 200 Hz, and the components with substantial resonances below 33 Hz were modified before the functional qualification test was performed. These modifications were applied to the standard design. This equipment was then tested with a sinusoidal input of 1.6g and then 3.0g for at least 30 sec at each of the arbitrary frequencies of 10, 15, and 23 Hz in each of the three perpendicular directions, with all systems operational. Since there were no functional failures, the equipment was deemed qualified for up to 3.0g horizontal or vertical maximum floor acceleration for all frequencies 33 Hz and below.

When required, all tests conducted will use methods and procedures comparable to those in the foregoing example. Furthermore, the amplitudes supplied at the support brackets will be equal to or greater than the levels predicted by system dynamic analysis.

TABLE 3.7-1 MODIFIED MERCALLI INTENSITY (DAMAGE) SCALE OF 1931 (Abridged)

I. Not felt except by a very few under especially favorable circumstances (I Rossi-Forel Scale).

II. Felt only by a few persons at rest, especially on upper floors of buildings. Delicately suspended objects may swing (I to II Rossi-Forel Scale).

III. Felt quite noticeably indoors, especially on upper floors of buildings, but many people do not recognize it as an earthquake. Standing motorcars may rock slightly. Vibration like passing of truck. Duration estimated (III Rossi-Forel Scale).

IV. During the day felt indoors by many, outdoors by few. At night some awakened. Dishes, windows, doors disturbed; walls make creaking sound. Sensation like heavy truck striking building. Standing motorcars rocked noticeably (IV to V Rossi-Forel Scale).

V. Felt by nearly everyone, many awakened. Some dishes, windows, etc., broken: a few instances of cracked plaster; unstable objects overturned. Disturbance of trees, poles, and other tall objects sometimes noticed. Pendulum clocks may stop (V to VI Rossi-Forel Scale).

VI. Felt by all, many frightened and run outdoors. Some heavy furniture moved; a few instances of fallen plaster or damaged chimneys. Damage slight (VI to VII Rossi-Forel Scale).

VII. Everybody runs outdoors. Damage negligible in buildings of good design and construction; slight to moderate in well-built ordinary structures; considerable in poorly built or badly designed structures; some chimneys broken. Noticed by persons driving motorcars (VIII Rossi-Forel Scale).

VIII. Damage slight in specially designed structures; considerable in ordinary substantial buildings with partial collapse; great in poorly built structures. Panel walls thrown out of frame structures. Fall of chimneys, factory stacks, columns, monuments, walls. Heavy furniture overturned. Sand and mud ejected in small amounts. Changes in well-water. Persons driving motorcars disturbed (VIII + to IX Rossi-Forel Scale).

IX. Damage considerable in specially designed structures; well-designed frame structures thrown out of plumb; great in substantial buildings, with partial collapse. Buildings shifted off foundations. Ground cracked conspicuously. Underground pipes broken (IX+ Rossi-Forel Scale).

X. Some well-built wooden structures destroyed; most masonry and frame structures destroyed with foundations; ground badly cracked. Rails bent. Landslides considerable from riverbanks and steep slopes. Shifted sand and mud. Water splashed (slopped) over banks (X Rossi-Forel Scale).

XI. Few, if any (masonry) structures remain standing. Bridges destroyed. Broad fissures in ground. Underground pipelines completely out of service. Earth slumps and land slips in soft ground. Rails bent greatly.

XII. Damage total. Waves seen on ground surfaces. Lines of sight and level distorted. Objects thrown upward into the air.

TABLE 3.7-2 DAMPING VALUES

Item	Percent of Critical: Operating-Basis Earthquake	Percent of Critical: Safe-Shutdown Earthquake
General		
Equipment and large-diameter piping	0.5	1.0
Small-diameter piping	0.5	1.0
Welded and H.S. bolted steel framed structures	2.0	5.0
Bolted and riveted steel framed structures	5.0	10.0
Welded structural Assemblies (equipment and supports)	2.0	4.0
Reinforced-concrete structures	2.0	5.0
Specific		
Reactor pressure vessel	2.0	2.0
CRD housing	3.5	3.5
Fuel	7.0	7.0
Drywell-building (coupled)	2.0	5.0
CCHVAC and SGTS Rectangular Ducts and Duct Supports	4.0	7.0
CCHVAC and SGTS Round Ducts and Duct Supports	2.0	4.0

TABLE 3.7-10 NUMBER OF DYNAMIC RESPONSE CYCLES EXPECTED DURING A SEISMIC EVENT

Frequency band (Hz)	0 to 10	10 to 20	20 to 50
Number of seismic cycles	168	359	643

TABLE 3.7-11 FATIGUE EVALUATION DUE TO SEISMIC LOAD

Component	Calculated No. of Cycles at Peak Stress	Design No. of OBE Cycles at Peak Stress
1. Reactor pressure vessel		
Vessel	< 3	10
Shroud support	< 3	10
Skirt	< 3	10
2. Category I piping		
Recirculation lines	< 3	60
Steam lines	< 3	60

TABLE 3.7-12 PIPING SYSTEM SEISMIC CRITERIA FOR PIPING LOCATED INSIDE BUILDING STRUCTURES

Group Classification	Type of Earthquake	Type of Seismic Analysis	Combined Stress Calculations	Stress Criteria
A (Size 1-1/4 in. NPS and larger)	OBE[a]	Dynamic response spectra	ASME Section III NB-3650	Normal and upset condition
	SSE[b]	Dynamic response spectra	ASME Section III NB-3650	Emergency and faulted condition
A (Size 1 in. NPS and smaller)	OBE	Response spectra	ASME Section III NC-3650	Normal and upset condition
	SSE	Response spectra	ASME Section III NC-3650	Emergency and faulted condition
B and C (Size 4 in. NPS and smaller)	OBE	Simplified dynamic analysis or dynamic response spectra	ASME B&PV Code - 1971 Section III, Sub-section NC-3650	Upset condition
	SSE	Simplified dynamic analysis or dynamic spectra response	ASME B&PV Code - 1971 Section III, Sub-section NC-3650	Emergency or faulted condition
D+	Unclassified but seismic Group B and C seismic criteria are used.			
D	None	None	ANSI-B-31.1.0	
B and C (Size 5 in. NPS and larger)	OBE	Dynamic Response Spectra	ASME B&PV Code - 1971 Section III, Sub-section NC-3650	Upset Condition
	SSE	Dynamic Response Spectra	ASME B&PV Code - 1971 Section III, Sub-section NC-3650	Emergency or faulted condition

[a] OBE = operating-basis earthquake.

[b] SSE = safe-shutdown earthquake.

TABLE 3.7-13 SEISMIC DESIGN LIMITS FOR CATEGORY I EQUIPMENT

Type of Earthquake	ASME Code Equipment	Loading Combination[a]	ASME Code Operating Category and Design Limits	Deflection Criteria[b]	Seismic Test Criteria[c]
OBE	Active	0.5 SSEL + OCL	Upset	For active equipment	For active equipment
OBE	Passive	0.5 SSEL + OCL	Upset	For passive equipment	For passive equipment
SSE	Active	SSEL + OCL + DSL	Upset or Emergency or Faulted	For active equipment	For active equipment
SSE	Passive	SSEL + OCL + DSL	Emergency or Faulted	For passive equipment	For passive equipment

[a] OCL stands for operating conditions loads, the loads acting on the equipment in each condition to which the equipment is subjected in accordance with "Normal Conditions" as defined by the ASME B&PV Code Section III, 1971.

SSEL stands for safe-shutdown earthquake loads, the seismic loads to which the equipment is subjected during the SSE.

DSL stands for other dynamic loads, such as relief valve blowdown loads. Earthquake loads are combined with otl dynamic loads as described in section 3.9.1.6.3.

[b] Deflection Criteria for Active Equipment: The deflection of any point on the equipment due to all applicable loads shall not impair the function of the equipment or any other Category I active equipment.

Deflection Criteria for Passive Equipment: The deflection of any point on the equipment due to all applicable loads shall not impair the function of any Category I active equipment.

[c] Test Criteria for Active Equipment: The equipment shall perform its intended function during and after the seismic test. Monitoring devices shall be installed during the test to verify that the equipment satisfies the above criteria. In cases where this is not possible, the equipment shall be tested for operation after the seismic test, and realistic engineering evidences which show that the equipment will function during the seismic test shall be presented.

Test Criteria for Passive Equipment: The equipment shall be inspected and checked after the seismic test to ensure that the pressure boundary integrity has been maintained.

TABLE 3.7-14 COMPARISON OF THE DESIGN AND COMPUTED HORIZONTAL SEISMIC LOADS OF REACTOR PRESSURE VESSEL AND INTERNALS

(Some Representative Values)

Location	Seismic Loads X-Excitation	Seismic Loads Y-Excitation	Allowable Loads
Top guide shear	74	116	687
Core plate shear	66	113	687
Stabilizer force (Total)	205	186	2,400
Max. fuel moment: Total	2,410	6,040	32,200
Per bundle	3.15	7.91	
Max. shroud moment	179,000	120,000	207,000
Max. shroud shear	732	537	1,184
Max. vessel skirt moment	101,000	106,000	1,152,000
Vessel skirt shear	286	280	2,600

Units: Moment - in-kip; Force - kip; Shear - kip

COMPARISON OF THE MAXIMUM SSE LOAD ON REACTOR VESSEL AND INTERNALS DUE TO VERTICAL EARTHQUAKE

Component	Seismic Load (kips)	Allowable Load (kips)
Shroud Support-Axial	183	>183[a]
Vessel Skirt-Axial	594	>594[a]

[a] That is, calculated loads result in stresses that are lower than allowable stress.

TABLE 3.7-15 COMPARISON OF CALCULATED SEISMIC LOADS TO DESIGN SEISMIC LOADS OF CATEGORY I EQUIPMENT, SSE CONDITION

(Some Generic NSSS Large Category I Items)

		Calculated Results		
	Equipment	Natural Frequency (Hz)	Seismic Loads	Design Seismic Load
1.	HPCI pump and turbine	>33	0.43g	1.5g
2.	RCIC pump and turbine	>33	0.43g	1.5g
3.	SLC tank	>33	0.8g	1.5g
4.	Spent-fuel racks	≈ 9[a]	0.46g	1.5g
5.				
6.	New-fuel racks	18.75[a]	0.22g	1.5g
7.	Refueling platform[b]	1.3	20,600 psi	36,000 psi
8.	Control room panels	Seismic adequacy determined by test		
9.	Fuel prep machine	>.79	0.1g	1.5g
			Fermi 2 only	
10.	RHR heat exchanger	>15	0.6g	1.5g
11.	Hydraulic control unit	>10.4	0.6g	4.9g

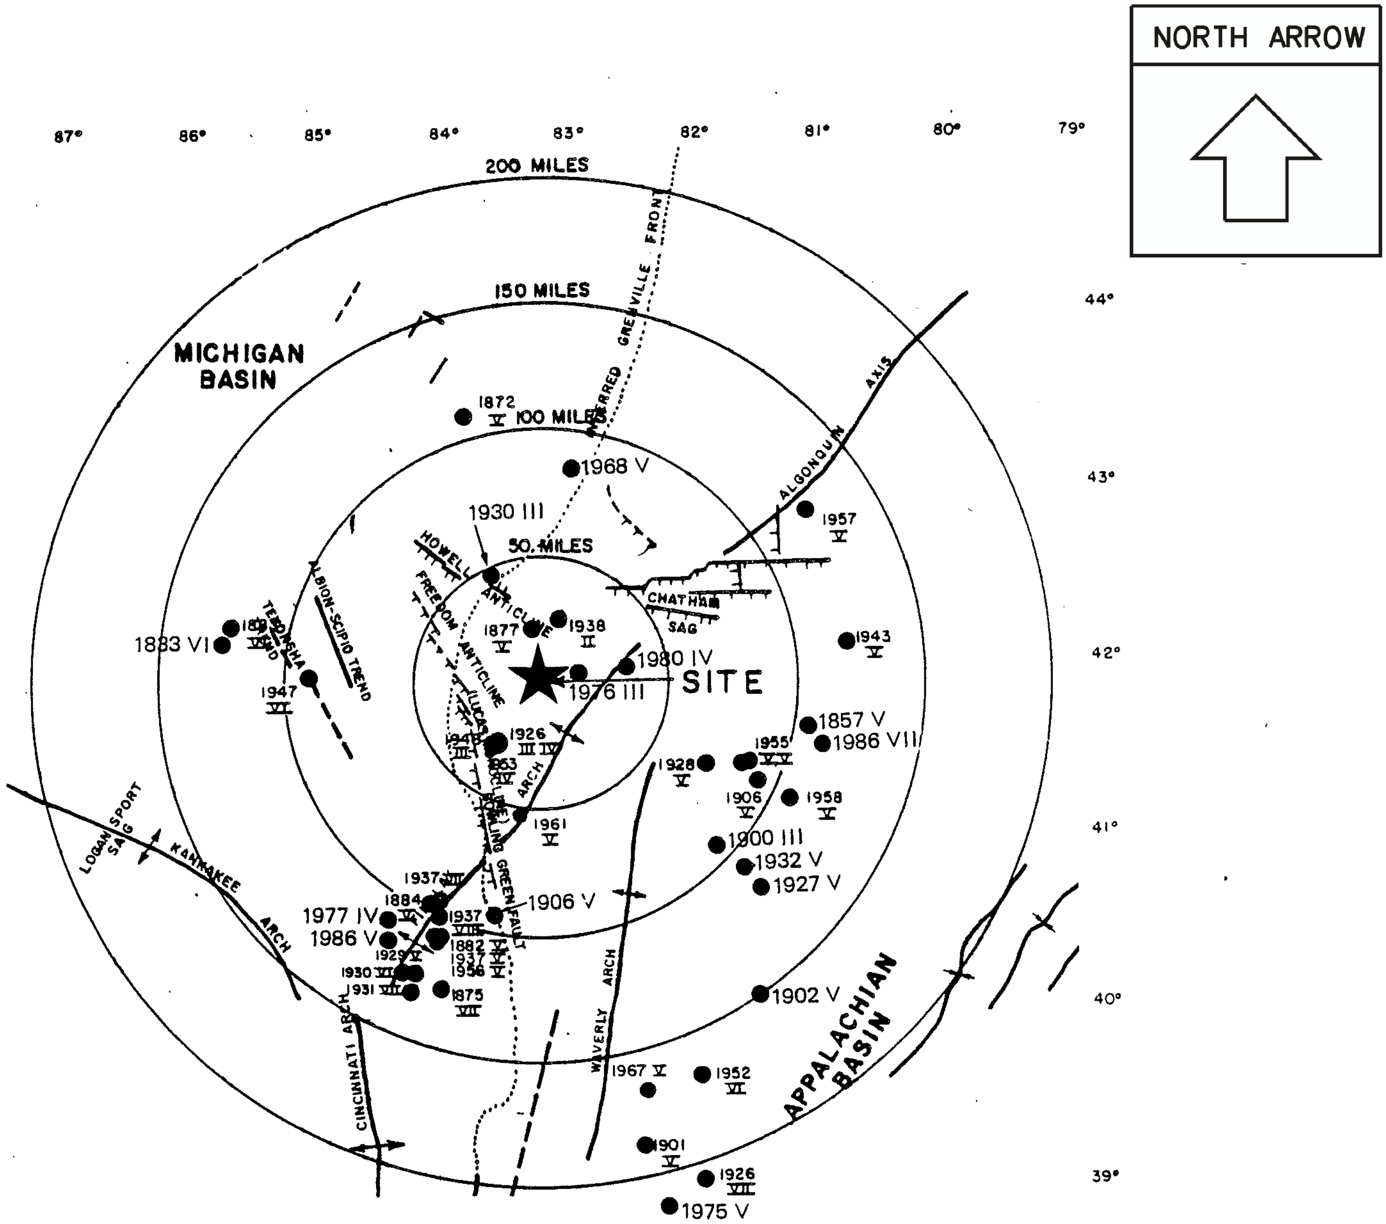
[a] Two percent Damping Calculated Lowest Natural Frequency.

[b] The refueling platform has been reclassified as Seismic Category II/I.

TABLE 3.7-16 SEISMIC DESIGN CONTROL ACTION ITEMS

(General Block Diagram)

Item	Responsibility	Description of Action			
1	Edison engineer (EE)	Prepare specification of vendor equipment			
2	EE	Transmit specification to the independent reviewer (IR) for aseismic performance review			
3	Independent reviewer (IR)	Review aseismic performance specification			
4	EE	Submit equipment specification to vendor (including the IR's review comments)			
5	Vendor	Select method of validation			
		Analytical		Testing	
		(or combination of both)			
6	Vendor	Perform analysis		Develop test procedures	
7	EE	Transmit report to the IR		Transmit test procedures to IR	
8	IR	Review report		Review test procedures	
9	EE			Action on test procedures:	
				Approved	Disapproved
				OK for testing	Modify and resubmit
10	Vendor			Perform test and submit report to Edison	
11	EE			Submit vendor test report to IR	
12	IR			Review report	
13	IR	Transmit documented review of report to Edison			
14	EE	Action on Analysis Report:		Action on Test Report:	
		Approved	Disapproved	Approved	Disapproved
15	Vendor		Revise analysis and resubmit		Perform revised test and resubmit
16	EE	File approved vendor validation package and IR report			
17	Vendor	File Edison's aseismic design approval			



NOTE: ALL REPORTED EARTHQUAKES WITHIN 50 MILES OF THE SITE ARE SHOWN. ONLY EARTHQUAKES OF INTENSITY V AND GREATER ARE SHOWN WITHIN 50 TO 200 MILES OF THE SITE.

3.8 DESIGN OF CATEGORY I STRUCTURES

3.8.1 Concrete Containment

Fermi 2 uses a steel primary containment. Subsection 3.8.2 and Reference 1 discuss the steel containment, and Subsection 3.8.4.1.1 discusses the concrete reactor building surrounding the primary steel containment and used as a secondary containment. Information about the foundation supporting these structures can be found in Subsection 3.8.5.

3.8.2 Steel Containment System (ASME Class B Components)

3.8.2.1 Description of the Containment

3.8.2.1.1 Introduction

The primary containment (known as the Mark I containment) is a leaktight steel-plate containment vessel consisting of a light- bulb-shaped drywell and a torus-shaped suppression chamber. The primary containment was designed, erected, and pressure-tested by the Chicago Bridge & Iron Company.

The basic objective of the primary containment system is to provide the capability, in the event of the postulated design- basis accident (DBA), that is, LOCA, to limit the release of fission products to the plant site environs so that offsite doses do not exceed the values specified in 10 CFR 50.67 or 10 CFR 100. The reactor building, in conjunction with the steel containment, is designed as a secondary containment. A standby gas treatment system (SGTS) is installed to exhaust (automatically or manually) the reactor building atmosphere by way of its filter system to a vent on the auxiliary building roof, thereby causing the reactor building internal pressure to be lower than the external pressure, so that leakage is into the reactor building.

To meet the basic safety objective, the following subsidiary objectives are achieved by the system or one or more of its components:

a. The primary containment system is capable of withstanding the conditions that could result from any of the postulated accidents for which the primary containment system is assumed to be functional, including the largest amount of energy release and mass flow associated with the DBA. The criteria set forth in the NRC's Safety Evaluation Report on the Mark I containment program, NUREG-0661 (Reference 2), have been applied as the basis for acceptance of the analysis methods and the primary containment system design

b. The primary containment system has a design margin for metal/water reactions and other chemical reactions subsequent to any postulated DBA for which the primary containment system is assumed to be functional, consistent with the performance objectives of the nuclear safety systems and engineered safety feature (ESF) systems

c. The primary containment system has the capability to maintain its functional integrity during any postulated design event, including protection against missiles from internal or external sources, excessive motion of pipes, and jet forces associated with the flow from the postulated rupture of any pipe within the containment

d. The primary containment system is capable of being filled with water as an accident recovery method for any postulated DBA in which a breach of the nuclear system primary barrier cannot be sealed

e. The primary containment system, in conjunction with other nuclear safety systems and ESF systems, is capable of limiting leakage during any of the postulated DBAs for which it is assumed to be functional such that offsite doses do not exceed guideline values

f. The primary containment system has the means of rapidly condensing the steam portion of the flow from the postulated design-basis rupture of a recirculation line

g. The primary containment system has the means to

    1. Conduct the flow from postulated pipe ruptures to the suppression chamber

    2. Distribute such flow uniformly throughout the pool

    3. Limit pressure differentials between the drywell and the suppression chamber during the various postaccident cooling modes

    4. Effectively quench the steam flow from safety/relief valve (SRV) discharges.

h. The primary containment system has the capability to rapidly close or isolate all pipes or ducts that penetrate the primary containment, thereby maintaining leakage within permissible limits

i. The primary containment system is capable of being periodically leak tested to confirm the integrity of the containment at pressure

j. The primary containment system is capable of storing sufficient water to supply the emergency core cooling system (ECCS) requirements.

3.8.2.1.2 General Description

The steel primary containment consists of a drywell, vent pipes, and suppression chamber, and houses the reactor pressure vessel (RPV), recirculation system, and other primary components.

The primary containment is a steel structure composed of a series of vertical cylinders and truncated cones which form a drywell. This drywell is attached to a suppression chamber through a series of vents. The suppression chamber is a steel pressure vessel in the shape of a torus. The drywell total free air volume and torus minimum air and water volumes are referenced in Table 6.2-1.

In the event of a process system piping failure within the drywell, reactor water and steam are released into the drywell air space. The resulting increased drywell pressure then forces a mixture of air, steam, and water through the vents into a pool of water stored in the suppression chamber. The steam condenses rapidly and completely in the suppression chamber, resulting in a rapid pressure reduction in the drywell. Air that is transferred to the suppression chamber pressurizes the chamber and subsequently is vented to the drywell to equalize the pressure between the two vessels. The specific suppression chamber hydrodynamic events that result from a process system piping failure are detailed in Reference 1. A containment cooling spray system is provided to remove heat from the drywell and suppression chamber. Appropriate isolation valves are actuated during this period to ensure containment of radioactive materials that might otherwise be released from the primary containment during the course of an accident.

The primary containment system free volume is capable of being inerted with a nitrogen atmosphere during normal operation. The containment atmosphere control system is capable of reducing and maintaining the oxygen content of the atmosphere below 3.9 percent during normal operation to eliminate the possibility of a hydrogen/oxygen reaction.

3.8.2.1.2.1 Description of the Drywell

The drywell is a steel pressure vessel with a spherical lower portion 68 ft in diameter and a cylindrical upper portion 38 ft 10 in. in diameter. The overall height is approximately 114 ft 8 in. The design, fabrication, inspection, and testing of the drywell comply with the requirements of Section III, Sub-section B, of the ASME Boiler and Pressure Vessel (B&PV) Code, 1968 edition. The thickness of the cylindrical portion of the drywell and the lower spherical portion has been determined by the rules defined in Section UG-27 of ASME Section VIII. The drywell is enclosed in a reinforced-concrete biological shield (Subsection 3.8.4) and is supported by the drywell pedestal, as shown in Figure 3.8-1. The biological shield provides resistance to deformation and buckling in areas where it backs up the steel shell. Below the transition zone located at elevation 659.5 ft (New York Mean Tide, 1935), the drywell is separated from the shield by a gap of approximately 2 in.; this gap is filled with a compressible polyurethane material to allow for movement between the drywell and concrete. The polyurethane sheets are coated on both sides with an epoxy resin binder to prevent water leakage into the foam. The bottom portion of the shell (below elevation 572 ft 6 in.) is totally embedded in concrete and therefore is not subject to significant thermal stresses. The lower portion of the transition zone is backed by compacted sand to aid in condensation drainage. There are four 1-1/2-in. drain lines that can be used to remove moisture from the sand cushion in case of leakage into the gap between the drywell and shield. Shielding over the top of the drywell is provided by a removable, segmented, reinforced-concrete shield plug. See Figure 3.8-2 for a developed view of the drywell and the drywell penetration schedule.

In addition to the drywell head, one double-door air lock and two bolted equipment hatches are provided for access to the drywell (Subsection 3.8.2.1.3.4 and Figures 3.8-3 and 3.8-4). The locking mechanism on each air-lock door is designed to maintain a tight seal when the doors are subject to either external or internal pressure. The doors are mechanically interlocked so that neither door can be operated unless the other door is closed and locked. The drywell head and hatch cover are bolted in place and sealed with gaskets. Provisions have been made to permit leakage testing of the door and hatch cover seals.

The drywell will be entered during low power operation; however, access is nonroutine, infrequent, and rigidly controlled.

The exposed interior surfaces of the drywell pressure boundary are coated as described in Subsection 6.2.1.6 to protect steel surfaces from galvanic corrosion and to facilitate decontamination.

Drywell and equipment sumps are provided at the bottom of the drywell to collect and drain waste liquids. All waste liquids are then routed from the drywell sumps to the radwaste building with the aid of sump pumps.

The supporting structure for the drywell and biological shield is described in Subsection 3.8.5.

3.8.2.1.2.2 Description of the Suppression Chamber and Vent System

The suppression vent system, which connects the drywell and the suppression chamber, conducts flow from the drywell to the suppression chamber without excessive resistance and distributes this flow effectively and uniformly in the pool following a postulated DBA, intermediate-break accident (IBA), or small-break accident (SBA) in the drywell. The suppression chamber receives this flow, the steam portion is condensed, and the noncondensible gases are released to the suppression chamber air space. The suppression chamber and vent system response due to a postulated design-basis pipe rupture or main steam relief valve operation is further discussed in Reference 1. The suppression-chamber-to- drywell vacuum breakers limit the pressure differential between the drywell and the suppression chamber during postaccident primary containment system cooling.

A total of eight circular vent pipes, 6 ft in diameter, form the connection between the drywell and the suppression chamber. Jet deflectors (Figure 3.8-5) are provided in the drywell at the inlet end of each vent pipe to prevent possible damage to the vent pipes from jet forces accompanying a pipe break in the drywell. The pipes are enclosed in sleeves and provided with expansion joints to accommodate differential motion between the drywell and the suppression chamber.

The suppression chamber is a torus-shaped, continuous, leaktight steel pressure vessel with a major diameter of 112 ft 6 in. situated below and encircling the drywell. The inside diameter of the mitered cylinders that make up the suppression chamber is 30 ft 6 in. The suppression chamber shell thickness is typically 0.587 in. above the horizontal centerline and 0.658 in. below the horizontal centerline, except at penetration locations where it is locally thicker.

The suppression chamber shell is reinforced at each mitered joint location by a T-shaped ring beam. The ring beam is braced laterally with stiffeners connecting the ring beam web to the suppression chamber shell.

The suppression chamber is supported vertically at each mitered joint location by inside and outside columns and by a saddle support that spans the inside and outside columns (Figure 3.8-6). The columns, associated column connection plates, and saddle support are located parallel to the mitered joint in the plane of the ring beam web. Space has been provided outside the chamber for inspection and maintenance.

The anchorage of the suppression chamber to the basemat is achieved by a system of base plates, stiffeners, and anchor bolts located at each column and at two locations on each saddle support.

The design, fabrication, inspection, and testing of the suppression chamber comply with the requirements of ASME B&PV Code Section III, Class B. The thickness of the torus-shaped pressure vessel has been determined by means of the rules defined in Sections UG-27 and UG-28 of ASME Section VIII.

The suppression chamber shell, supports, internals, and attachments have also been reevaluated (References 1, 3, and 4) to include the hydrodynamic loading events and analysis methods defined by Topical Report NEDO-21888, Mark I Containment Program Load Definition Report (Reference 5), and NUREG-0661 (Reference 2). The appropriate service limits and edition of Section III of the ASME Code, specified in NUREG-0661, have been applied to the reevaluation.

The chamber has a total volume of approximately 251,980 ft^3. The center of the torus lies slightly below the bottom of the drywell (see Figure 3.8-7 for a plan view of the suppression chamber).

The drywell vents are connected to a torus-shaped ring header, 4 ft 3 in. in diameter, placed within the air space of the suppression chamber. Eighty 24-in.-diameter downcomer pipes project from the ring header and terminate below the water surface in the chamber pool. The pool water level is maintained to ensure a 3.00- to 3.33-ft submergence of the downcomer pipes.

A vent from the primary containment system is provided and is normally closed, but permits the vent discharge to be routed to the plant SGTS to control the release of gases from the primary containment.

The physical parameters of the primary containment are summarized in Table 3.8-1.

The total water and steam volume of the reactor vessel and recirculation system are referenced in Table 3.8-1.

3.8.2.1.3 Primary Containment Penetrations

Penetrations carry piping, mechanical systems, and electrical wiring through the biological shield and primary containment vessel. These penetrations can be classified as follows:

a. Piping penetrations (sleeved and unsleeved)

b. Electrical service penetrations

c. Mechanical system penetrations (traversing in-core probe penetrations)

d. Access openings.

To maintain design containment integrity, containment penetrations have the following design characteristics:

a. Capability to withstand peak transient pressures

b. Capability to withstand without failure the forces caused by impingement of the fluid from the rupture of the largest local pipe or connection

c. Capability to accommodate without failure the thermal and mechanical stresses that may be encountered during all modes of operation.

The number and sizes of the drywell penetrations are shown in Table 3.8-2. The corresponding details of these penetrations are shown in Figure 3.8-8. Penetrations for the suppression chamber are listed in Table 3.8-3.

3.8.2.1.3.1 Pipe Penetrations

The two general types of pipe penetrations provided are (1) those that must accommodate thermal movement (sleeved), shown in Figure 3.8-9, and (2) those that experience relatively little thermal stress (unsleeved), as shown in Figures 3.8-10 and 3.8-11.

Sleeved Penetrations

Relative or thermal movement is accommodated wherever required by using bellows-type expansion joints. For this type of joint, the penetration sleeve passes through concrete and is welded to the primary containment vessel reinforcement plate. The process line that passes through the penetration is free to move axially, and a bellows expansion joint accommodates the movement. A guard pipe surrounds the process line and is designed to protect the bellows and maintain the penetration. Insulation and air gaps reduce thermal stresses and limit the radial heat flow resulting from convection and radiation from the pipe penetration, and keep the temperature of the concrete adjacent to the sleeve below 150°F. Also, penetrations accommodating hot pipes feature cooling coils on the guard pipe.

Where necessary, the penetration lines are anchored outside the containment to limit the movement of the lines relative to the containment. The bellows accommodates the relative movement between the pipe and the containment shell. This design ensures the integrity of the flexing penetration during plant operation. The configuration of the sleeved penetrations is shown in Figure 3.8-9.

Figure 3.8-12 shows a main steam line penetration assembly, its associated inboard and outboard isolation valves, the penetration flued head anchor structure, outboard pipe whip restraint structure, and the inboard pipe whip restraint/seismic guide. The configuration is typical of those cases where high-energy line penetrations are required to resist pipe whip or jet impingement loads due to postulated pipe breaks. Design details and criteria of the various components that make up the containment penetration system shown in Figure 3.8-12 are discussed below.

Penetration Assembly

The penetration assembly consists of the process pipe, guard pipe, penetration sleeve bellows, and flued head. The process pipe is mounted concentrically within the penetration. It is connected at the outboard side to the penetration flued head, and is considered part of the piping inside containment. The process pipe is constructed of ASME Type SA-l06, Grade B, or SA-333, Grade 6 material, and is designed in accordance with ASME III, Class 1 requirements.

For all normal and upset conditions specified, design criteria limits are provided in Subsection 3.6.2.1.2.2. It should be noted that for Fermi 2 the upset condition includes the operating-basis earthquake (OBE).

The guard pipe is designed to protect the containment penetration sleeve and the containment sleeve bellows from damage due to pressurization or jet impingement loads in the event of a break in the process pipe within the penetration assembly. A jet deflector ring mounted on the inboard end of the guard pipe protects the containment sleeve from damage due to jet impingements emanating from other sources inside the containment. The guard pipe connection is hinged to the flued head to prevent excessive bending loads from being transferred from the guard pipe to the flued head, in the event of a break in the process pipe. The hinged connection is provided with a bellows to ensure the pressure integrity of the guard pipe. The guard pipe is constructed from American Society for Testing and Materials (ASTM) A-106 Grade B, or A-155 Grade KCF 70 material. Design criteria limit the stress in the guard pipe and hinge bellows to 0.90 of the yield strength, when the guard pipe is subjected to the design pressure and temperature of the process pipe.

The flued head serves as an extension of the process pipe and the process pipe anchorage point, and as a part of the primary containment pressure boundary. The flued head is constructed from a one-piece forging of ASTM A-l05 Grade II, or ASTM A-182 type-304 or 316 material, as required for compatibility with the process piping. Design of the flued head is in accordance with ASME III Class 1 requirements. The flued head forging is ultrasonically examined and radiographed in accordance with ASME III requirements. Attachment of the flued head to the anchor structure is by mechanical means; there is no welding involved.

The containment sleeve bellows allows relative movement between the containment sleeve attached to the primary containment shell and the flued head anchored to the biological shield wall. The bellows is constructed of ASTM A-240 material. Design calculations are made per Expansion Joint Manufacturers Association (EJMA) standards. Design pressure and temperature for the bellows under the various operating modes (normal, upset, emergency, and faulted) are identical with those of the primary containment.

<u>Flued Head Anchor Structure</u>

The flued-head anchor structure is provided as a structural support between the primary containment penetration flued head and the biological shield wall. The structure is designed to accept normal and upset condition loads as well as piping system reactions as a result of emergency (safe-shutdown earthquake [SSE]) and faulted condition loads (pipe whip and/or jet thrust). The structure is fabricated from a series of built-up structural tubes made from ASTM A-588 material. Design criteria under the various loading conditions limit allowable stresses to the following:

a. Normal and upset (OBE) conditions - American Institute of Steel Construction (AISC) allowable stresses

b. Emergency conditions - 0.9 x yield strength

c. Faulted conditions - 0.9 x ultimate strength.

For anchor structures that support more than one flued head, only one pipe line is assumed to be in the faulted condition at a given time.

<u>Piping Between the Containment Penetration and the Outboard Isolation Valve</u>

Piping between the primary containment flued head and the outboard isolation valve is designed to ASME III Class 1 requirements. Maximum stresses, considering all normal and upset conditions, may not exceed the limits provided in Subsection 3.6.2.1.2.2.

Outboard Pipe Whip Restraint Structure

A pipe whip restraint structure is provided at the outboard side of the outboard isolation valve. The structure is designed to limit the bending and downward thrust loads associated with pipe whips resulting from postulated breaks downstream of the isolation valve. Torsional loads on the valve are controlled by a U-bolt-type restraint system on the riser at the top of the main steam tunnel. A complete description of the outboard restraint structures, including the relevant design criteria, is given in Subsection 3.6.2.2.1.2.

Inboard Pipe Whip Restraint and Seismic Guide

The inboard pipe whip restraint and seismic guide is a dual purpose structure. During seismic events, the guide serves to support the piping system and limit its deflections to acceptable limits. During pipe-break events, a series of crushable stainless-steel tubes in the annular space between the pipe and guide intercept the pipe and absorb its kinetic energy. A more complete description of the inboard pipe-whip restraint/seismic guide is given in Subsection 3.6.1.5.1.5 and in Reference 1 to Section 3.6.

Unsleeved Penetrations

Low-temperature pipelines that contain fluids whose temperature is 150°F or less, and that do not require anchorage to the biological shield, are routed through unsleeved penetration assemblies of the type shown in Figure 3.8-11. Design criteria and analyses for those unsleeved penetrations serving ASME III Class 1 piping systems are the same as those previously described for the sleeved penetrations.

Piping penetrations serving ASME III Class 2 and 3 piping systems are classified ASME III Class 2.

The primary containment piping penetration arrangement for Class 2 systems is typically made up of three major components. They are the piping from the inboard isolation valve to the flued head, the flued head proper, and the piping from the flued head to the outboard isolation valve.

The inboard and outboard process piping between the isolation valves is designed to meet the criteria defined in Subsection 3.6.2.1.2.2.

The fabrication and materials used for the construction of the unsleeved flued heads are similar to those described previously for the sleeved flued heads. Analyses are performed in accordance with the requirements of ASME III, Subsection NC-3000.

Penetration LOCA Thermal Overpressure

NRC Generic Letter 96-06, “Assurance of Equipment Operability and Containment Integrity During Design Basis Accident Conditions”, raises the concern that during a postulated LOCA, piping inside containment will be heated beyond its normal operating temperature. The temperature increase would cause water trapped in piping (isolated by closed valves) to expand and the resulting pressurization could challenge piping integrity. Nonessential penetrations with piping susceptible to LOCA thermal overpressure have been evaluated in accordance with the criteria of the ASME Boiler and Pressure Vessel Code, Section III, Appendix F. Alternatively, some susceptible penetrations will relieve the overpressure condition before the limits of Appendix F are exceeded.

3.8.2.1.3.2 Electrical Penetrations

Figure 3.8-13 shows an electrical penetration and associated radiation shields of the general type that is used for power, control, and instrumentation circuits. Electrical conductors penetrating the biological shield and primary containment pass through the penetrations that are mounted in steel pipe sleeves. The sleeves are welded to the primary containment vessel.

Electrical termination cabinets are mounted on each end of the penetration canisters, which are attached by bolted flange connections and with O-ring seals. Each primary containment electrical penetration has provisions for continual testing for leaktightness with a pressure gage.

3.8.2.1.3.3 Traversing In-Core Probe Penetration

A total of seven traversing in-core probe (TIP) penetrations (five for guide tubes, and two spares) pass from the reactor building through the primary containment. (See Figure 3.8-14.) Penetrations of the insertion guide tubes through the primary containment are sealed by brazing and meet the requirements of ASME Section VIII. These seals also meet the intent of ASME Section III, even though the ASME Code has no provisions for qualifying the procedures or performance.

3.8.2.1.3.4 Personnel and Equipment Access Lock

One personnel access lock is provided for access to the drywell (see Figure 3.8-4). The lock has two gasketed doors in series and is designed to withstand the drywell design pressure. The doors are mechanically interlocked to ensure that at least one door is locked at all times. The locking mechanisms are designed so that a tight seal is maintained when the doors are subjected to either internal or external pressure. The seals on this access opening are capable of being tested for leakage. Both doors are furnished with a pressure-equalizing connection.

Two equipment access hatches and a control rod drive (CRD) removal hatch are provided and welded in the spherical portion, thus permitting extensive maintenance of the drive mechanism. These hatches have double testable seals and are bolted in place. (Figures 3.8-3 and 3.8-4 show hatch details.) The double seals are provided with a leakage test tap with which the space enclosed between the seals is pressurized to containment design pressure to test for leakage through the seal when the cover or door is locked in place.

3.8.2.1.3.5 Access To the Suppression Chamber

Access from the reactor building to the suppression chamber is provided at two locations. Each is a 4-ft-diameter manhole entrance with a double-gasketed bolted cover connected to the chamber by a 4-ft-diameter steel pipe. These access ports are bolted closed when the primary containment is required, and are opened only when the primary system temperature falls below 212°F and the pressure suppression system is not required to be operational.

The double seals are provided with a leakage test tap by which the enclosed space between the seals is pressurized to containment design pressure to test for leakage through the seal when the cover is bolted in place.

Externally, access to the suppression chamber is provided by maintenance platforms and walkways.

3.8.2.1.3.6 Access for Refueling Operations

The drywell head is removed during refueling operations. This head is held in place by bolts and is sealed with a double seal. It is bolted closed when the primary containment is required and is opened only when the primary coolant temperature falls below 212°F and the pressure suppression system is not required to be operational.

The double seals are provided with a leakage test tap by which the enclosed space between the seals is pressurized to containment design pressure to test for leakage through the seal when the cover is bolted in place.

3.8.2.2 Applicable Codes, Standards, and Specifications

Table 3.8-4 contains a comprehensive listing of all applicable codes, standards, and specifications for Fermi 2.

3.8.2.2.1 Primary Containment Vessel and Suppression Chamber

a. ASME Codes - The ASME B&PV Code, 1968 edition up to and including summer l969 Addenda, including the following sections:

    1. Section II, "Material Specifications," Part A, "Ferrous" - All steel material used in the primary containment and the suppression chamber conforms to the requirements of this section

    2. Section III, Class B, including Code Cases 1330-2, 1177-6, 1431, and 1443 - This section is used for the design, fabrication, examination, testing, inspection, and material specification for the primary containment vessel (Subsection 3.8.2.1.2.1) and the suppression chamber and vent system (Subsection 3.8.2.1.2.2)

    3. Section VIII.

b. AISC Steel Construction Manual - The "Specification for the Design, Fabrication, and Erection of Structural Steel for Buildings," Sixth Edition, 1963, of the AISC is used in the design of non-pressure-retaining components

c. Code of Federal Regulations - The primary containment system leakage rate test is performed in accordance with the requirements of Appendix J, 10 CFR 50, "Reactor Containment Leakage Testing for Water-Cooled Power Reactors." The details of the type of testing performed are addressed in Subsection 6.2.4

d. ACI Specification ACI 318-63 - This American Concrete Institute (ACI) specification, titled "Building Code Requirements for Reinforced Concrete" and dated June 1963, is used in the design of the primary containment system

e. Steiger Occupation Safety and Health Act of l970

f. NUREG-0661 - "Safety Evaluation Report, Mark I Containment Long-Term Program," July 1980 (Reference 2), which establishes requirements affecting the design and operation of the primary containment system.

3.8.2.2.2 Penetrations

a. ASME Codes - The ASME B&PV Code, 1971 edition, including the following sections:

   1. Section II, "Material Specifications," Part A, "Ferrous" - All steel material used in the penetration conforms to the requirements of this section

   2. Section III, Class 1 and 2

   3. Section XI, for inservice inspection and baseline data accumulation, is used for examination and inspection

   4. The bellows used for the piping penetrations are designed in accordance with ASME Code Case 1177-6 (Subsection 3.8.2.3.2.2)

   5. Section VIII

   6. Section III, Subsection NE, is used for the design, fabrication, and testing of primary electrical penetrations (penetrations are class MC)

   7. Section IX is used for welding.

b. EJMA Specification - The design of all expansion joints conforms to the specifications of the EJMA

c. AISC Steel Construction Manual - The "Specification for the Design, Fabrication, and Erection of Structural Steel for Buildings," Sixth Edition, 1963, of the AISC is used in the design of non-pressure-retaining components

d. Code of Federal Regulations - The penetration leak- detection and leakage rate test is performed in accordance with the requirements of Appendix J, 10 CFR 50, "Reactor Containment Leakage Testing for Water-Cooled Power Reactors." The details of the type of testing performed are addressed in Subsection 6.2.4

e. IEEE Standard 317-1972 - This standard of the Institute of Electrical and Electronics Engineers (IEEE), titled "IEEE Standard for Electric Penetration Assemblies in Containment Structures for Nuclear Power Generating Stations," is used as a guide for the design, construction, testing, and installation of electrical penetrations

f. Steiger Occupation Safety and Health Act of 1970

g. NUREG-0661 - "Safety Evaluation Report, Mark I Containment Long-Term Program," July 1980, (Reference 2) which establishes requirements affecting the design and operation of the attachments to the suppression chamber.

3.8.2.2.3 Access Opening

a. ASME Codes - The ASME B&PV Code, l968 edition up to and including summer l969 addenda, including the following sections:

   1. Section II, "Material Specifications," Part A, "Ferrous" - All steel material used in the access opening conforms to the requirements of this section

   2. Section III, Class B, including Code Cases 1330-2, 1177-6, 1431, and 1443 - This section is used for the design, fabrication, examination, testing, inspection, and material specification for all access openings described in Subsections 3.8.2.1.3.4 through 3.8.2.1.3.6

   3. Section VIII.

b. AISC Steel Construction Manual - The "Specification for the Design, Fabrication, and Erection of Structural Steel for Buildings," Sixth Edition, 1963, of the AISC is used in the design of non-pressure-retaining components

c. Code of Federal Regulations - The access openings leak detection and leakage rate test is performed in accordance with the requirements of Appendix J, 10 CFR 50, "Reactor Containment Leakage Testing for Water-Cooled Power Reactors." The details of the type of testing performed are addressed in Subsection 6.2.4

d. Steiger Occupation Safety and Health Act of 1970.

3.8.2.2.4 Special Precautions

Special precautions in addition to those required by codes are taken in the fabrication of the drywell shell. The steel plate is preheated to a minimum temperature of 200°F before welding whenever seam thickness exceeds 1 in., regardless of the surrounding air temperature. Furthermore, the plate is preheated to a minimum temperature of l00°F before the welding of all seams 1 in. or less in thickness if the ambient temperature falls below 40°F.

3.8.2.3 Loads and Loading Combinations

3.8.2.3.1 General Description

The loads and loading combinations given in Tables 3.8-5 through 3.8-17 were applied in the design of the primary containment.

The suppression chamber, vent system, and piping penetrations have also been analyzed for load combinations, including seismic and hydrodynamic loads resulting from LOCA-related and safety/relief valve discharge events. These loads and load combinations are described in Fermi 2 Mark I containment long-term program plant unique analysis reports (References 1 and 3).

Following is a general description of the loads that are normally associated with containment vessel design:

a. Seismic load - Horizontal and vertical accelerations for both the OBE and the SSE are considered. The following maximum accelerations are used to determine the seismic loads on the structure

1. OBE

Horizontal	0.08g
Vertical	0.053g

2. SSE

Horizontal	0.15g
Vertical	0.10g

b. Pipe break loads

c. Bellows loads

d. Gallery floor loads

e. Hydrostatic load - The containment may be flooded to the operating floor level during fuel-retrieving operations after an accident

f. Construction loads

g. Jet impingement loads

h. Dead load

i. Selected design temperatures and pressures

1. Suppression chamber

Internal design pressure	56 psig
External design pressure minus internal pressure	2 psid
Maximum external pressure	2 psig
Internal design temperature	281°F

2. Drywell

Internal design pressure	56 psig
External design pressure minus internal pressure	2 psid
Maximum external pressure	2 psig

	Internal design temperature	340°F
3.	Vent pipes and vent header	
	Internal design pressure	56 psig
	External design pressure minus internal pressure	2 psid
	Internal design temperature	281°F

3.8.2.3.2 Loading Combinations

3.8.2.3.2.1 Drywell

a. Cylindrical and spherical portion (general shell loads) -These parts of the drywell are designed for the loads and loading combinations described in Table 3.8-5. Their design is in accordance with ASME Section III for Class B Vessels and the AISC Specification for non-pressure-retaining parts. The drywell is protected from pipe rupture jet and reaction forces as described in Subsection 3.6.1. The drywell is also protected from concentrated missile loads as described in Section 3.5. Flooding of the drywell to an elevation of 684 ft 6 in. may be necessary for postaccident recovery and is considered in Table 3.8-5. The allowable stress consideration for these loading combinations is presented in Figure 3.8-15

b. Drywell vent penetrations (accident loads) - The pressure-retaining parts of the drywell vent penetrations are designed for the loads and loading combinations described in Table 3.8-7. These parts are designed in accordance with ASME Section III for Class B Vessels

c. Spherical embedment (accident loads) - The spherical embedment section of the drywell is designed for the loads and loading combinations described in Table 3.8-8. It is designed in accordance with ASME Section III for Class B Vessels

d. Drywell knuckle region (accident loads) - The knuckle region of the drywell is designed for the loads and loading combinations described in Table 3.8-9. These parts are designed in accordance with ASME Section III for Class B Vessels

e. Drywell cone and top head (accident loads) - The cone and top head region of the drywell is designed for the loads and loading combinations described in Table 3.8-10. These parts are designed in accordance with ASME Section III for Class B Vessels

f. Drywell top flange - The drywell top flange is designed for the loads and loading combinations described in Table 3.8-11. Since the flanges are attached to, and are considered part of, the pressure boundary, their design is in accordance with ASME Section III for Class B Vessels. The water seal is designed in accordance with the AISC Specification

g. Equipment hatches - The equipment hatch doors and other pressure-retaining parts are designed for the loads and loading combinations listed in Table 3.8-12. The design of these parts is in accordance with ASME Section III for Class B Vessels

   Those parts that do not form part of the pressure boundary (i.e., support bracket, pin, etc.) are designed for the loads and loading combinations listed in Table 3.8-12. The design of these parts is in accordance with the AISC Specification

h. Personnel lock - The loads and loading combinations for the personnel locks are the same as those given for the equipment hatch in Table 3.8-12

   In addition, the personnel lock attachment to the drywell shell is designed for the seismic loading condition of the SSE applied at the lock center of gravity. The design of the attachment to the drywell is in accordance with ASME Section III for Class B Vessels, as shown in Table 3.8-12

i. Beam seats - These parts of the drywell are designed for the loads and loading combinations described in Table 3.8-13

   Since they are not pressure-retaining parts, their design is in accordance with the AISC Specification. The part of the drywell to which the supports are attached is a pressure-retaining part and is designed for the loads and loading combinations listed in Table 3.8-13, in accordance with ASME Section III for Class B Vessels

j. Spray header - These parts of the drywell are designed for the loads and loading combinations described in Table 3.8-14

   Since they are not pressure-retaining parts, their design is in accordance with the AISC Specification. The part of the drywell to which the supports are attached is a pressure-retaining part and is designed for the loads and loading combinations listed in Table 3.8-14, in accordance with ASME Section III for Class B Vessels

k. Vent jet deflectors - These parts of the drywell are designed for the loads and loading combinations described in Table 3.8-14

   Since they are not pressure-retaining parts, their design is in accordance with the AISC Specification. The part of the drywell to which the supports are attached is a pressure-retaining part and is designed for the loads and loading combinations listed in Table 3.8-14, in accordance with ASME Section III for Class B Vessels

l. Stabilizer connection - The stabilizer connection is designed for the loads and loading combinations described in Table 3.8-15

   Since these parts are not pressure-retaining parts, their design is in accordance with the AISC Specification. The part of the drywell to which the stabilizer plates are attached is a pressure-retaining part and is designed using the allowable limit specified in ASME Section III for Class B Vessels

m. Skirt - The skirt is designed for the loads and loading combinations described in Table 3.8-16

Since these parts are not pressure-retaining parts, their design is in accordance with the AISC Specification. The part of the drywell to which the skirt is attached is a pressure-retaining part and is designed using the allowable limit specified in ASME Section III for Class B vessels

n. Penetrations - All penetrations are designed in accordance with ASME Section III for Class B Vessels. Pressure area replacement has been completed on each penetration in addition to the design for piping loads completed on those having significant loading. The loads and loading combinations for those penetrations having significant piping reactions are described in Table 3.8-17.

3.8.2.3.2.2 Suppression Chamber

a. Cylindrical torus - These parts of the suppression chamber are designed for the loads and loading combinations described in Table 3.8-6 and Reference 1. Their design is in accordance with ASME Section III for Class B vessels and the AISC Specification for non-pressure- retaining parts. Flooding of the suppression chamber during accident recovery is considered in Table 3.8-6. The allowable stress considerations for the loading conditions applied in the original design are presented in Figure 3.8-15. The allowable stresses for the load and load combinations resulting from the subsequently identified LOCA-related and safety/relief valve discharge events are addressed in References 1 and 3.

b. Torus support system - These parts of the suppression chamber are designed for the loads and loading combinations described in Table 3.8-6 (conditions 5 through l0) and Reference 1. The allowable stress limitations are presented in Reference 1

c. Penetrations

1. Bellows/vent - The vent penetrations in the suppression chamber have been provided with a bellows expansion joint to limit stresses in the suppression chamber below those allowed by ASME Section III for Class B Vessels. The design of the bellows is in accordance with Code Case 1177-6 for the design movement specified below:

Axial (compression)	0.875 in.
Axial (tension)	0.375 in.
Lateral (positive or negative)	0.625 in.

2. General - All penetrations are designed in accordance with ASME Section III for Class B Vessels. Pressure area replacement has been completed on each penetration. The loads and loading combinations for the penetrations are presented in Reference 3.

3.8.2.4 Design and Analysis Procedures

The primary containment vessel was designed and has been analyzed in accordance with the ASME B&PV Code, 1968 edition including the summer 1969 addenda, Section III for Class B Vessels. The suppression chamber shell, supports, internals, and attachments have also been reevaluated (References 1 and 3) to include the hydrodynamic loading events and analysis methods defined by Topical Report NEDO-21888, "Mark I Containment Program Load Definition Report" (Reference 5), and NUREG-0661 (Reference 2). The appropriate service limits and editions of Section III of the ASME Code, specified in NUREG-0661, have been applied in the reevaluation. The NRC reviewed the Fermi 2 Plant Unique Analysis Report (PUAR) for the Mark I containment long-term program and concluded that the PUAR analysis verified that the completed containment modifications had restored the original design safety margin to the Fermi 2 Mark I containment (Reference 6).

3.8.2.4.1 Drywell

In general, the drywell has been analyzed and designed as an axisymmetrically loaded thin shell of revolution. The drywell has complete freedom of movement, except at its base, where it is rigidly attached to the drywell pedestal, and at its top, where it is restrained tangentially by the earthquake-stabilizer truss system (see Subsection 3.8.3 for a description of the earthquake-stabilizer truss system).

The primary shell membrane stresses have been computed for each of the load combinations specified in Subsection 3.8.2.3.2 by using the general equations for an axisymmetrically loaded shell of revolution. The derivation of these equations can be found in Chapter 14 of Reference 7. A CBI computer program, No. 7-78 (Section 3.13), which uses these equations to solve for the membrane forces, deflections, stresses, and strains, was used. The membrane stresses obtained from this analysis have been compared with the ASME allowables, and the compressive membrane stresses have been compared with the critical buckling stresses.

Shear and moment diagrams for both OBE and SSE accelerations have been calculated as outlined in Section 3.7 and are shown in Figures 3.8-16 through 3.8-21. These shears and moments are applied as static loads to determine the stresses in the drywell shell.

Included in the analysis of the drywell are the effects of dead and live loads, internal and external pressures, temperatures, earthquake loads, and the hydrostatic load of water in the drywell during an accident or refueling. The effects from penetrations, access openings, and beam seats are local in nature and are not considered to affect the overall analysis. These localized effects are analyzed individually as described in the following paragraphs. The drywell is reinforced around penetrations and access openings to minimize the effects from localized loads. The effects of significant nonaxisymmetric and transient loads are considered in all analyses.

During pressurization of the drywell, the vent pipes exert radial and vertical thrusts on the drywell shell. Because the vent pipes are equally spaced around the drywell circumference, the radial thrusts cancel each other. The upward lift of the vent pipes is conservatively neglected in the drywell analysis, because it opposes the shell weight. However, local membrane and secondary bending stresses are found at the local shell region of the vent penetration for the various vent thrusts specified in Subsection 3.8.2.3.2. This local shell analysis was completed by the method outlined in Welding Research Council Bulletin No. l07 (Reference 8), with the resulting stresses being compared with those allowed in ASME Section III for Class B Vessels. These penetrations have also been evaluated for the stress conditions resulting from the LOCA-related and safety/relief valve discharge events defined in NUREG-0661. The analytical-model and stress results are presented in Reference 1.

During erection and pressure testing, the drywell was supported by a temporary construction skirt anchored to the drywell pedestal. Openings in the skirt permit proper placing of concrete fill between the structural concrete pedestal and the drywell bottom.

The skirt is designed to provide for forces due to vent pipe thrust during the pressure test, wind load, and the dead load of the drywell vessel. On completion of the pressure tests, the skirt was embedded into the concrete slab. The local discontinuity region of the spherical shell to concrete embedment was analyzed by using the KALSHEL computer code developed by A. Kalnins of Yale University (see Section 3.13). This program performs the analysis of shells of revolution that are subject to symmetrical and nonsymmetrical loadings.

Included in the model loading are the restraining effects of the concrete surrounding the steel plates that make up the concrete transition section, as well as the effects of dead and live loads, internal and external pressures, temperatures, earthquake loads, and the hydrostatic load of water in the suppression pool (see Subsection 3.8.2.3.2). The boundary conditions for the transition section were taken as being fixed at the concrete junction. The stresses in those parts of the skirt that are not pressure-retaining were analyzed considering acting forces and moments, and were compared with the allowable limit of the AISC Specification. Refer to Subsection 3.8.3 for a discussion of the anchorage for the drywell floor to the drywell support pedestal.

The drywell shell was analyzed in the region of the knuckle for the accident condition to determine its discontinuity stresses. The knuckle was subjected to pressure loads acting normal to the shell, and to vertical loads resulting from dead, live, and seismic loads applied by the cylindrical shell to the knuckle.

The analysis was performed using the KALSHEL program. The boundary conditions were taken from the general shell analysis performed by CBI Program 7-78. Maximum primary stresses were calculated and compared with those allowed in ASME Section III for Class B Vessels.

The drywell shell was analyzed in the regions of the cone section and top head for the accident condition to determine the discontinuity stresses. The shell was subjected to an internal pressure of 56 psig. The boundary conditions were taken from general equilibrium equations.

The drywell head region is separated from the rest of the drywell by the bulkhead plate (Subsection 5.4.6.3.6.). During normal operation, atmospheres in the two regions communicate via eight 12-in. holes in the bulkhead plate. A study has been made on the head region pressure transient caused by the rupture in the head spray line.

The calculation was in two parts:

a. Mass flow out of the break

b. Pressure differential across the bulkhead plate for that mass flow rate.

Equations and physical parameters were obtained from standard engineering references and handbooks. Mass flow out of the break is based on choke flow in the 3-in. inside diameter pipe in the nozzle. Empirical equations for mass flow rate of steam under choke-flow conditions give a mass flow of 10^5 lb/sec.

Given this mass flow, the pressure drop across the bulkhead plate was calculated. The equation used was for flow rate through an orifice for cases other than choke flow. The equation includes the parameters of gas constant, R, ratio of specific heats, k, and discharge factor for the orifice, c. The values used for the parameters were selected to be representative of saturated steam, i.e., 65 lbf ft/lbm °R, 1.3 and 0.6 respectively.

The study showed the pressure in the head region would be 2 lb/in^2 greater than the drywell when all eight holes are open, and 8 lb/in^2 if half of the holes are blocked. These pressure differentials are far below design criteria on the drywell head and the bulkhead plate.

The design is in accordance with the allowable stress limits of ASME Section III for pressure-retaining parts and the AISC Specification for non-pressure-retaining elements. The loadings specified in Subsection 3.8.2.3.2 were used in the design calculations.

The drywell equipment hatches were analyzed using standard hand formulas taken from References 9, 10, and 11.

Their design is in accordance with the allowable stress limits of ASME Section III for pressure-retaining parts and the AISC Specification for non-pressure-retaining elements. The loadings specified in Subsection 3.8.2.3.2 were used in the design calculations and consist of jet forces, bolt loads, pressure (plus or minus), and earthquake forces. The local area between the equipment hatch and the drywell shell is designed to meet the area reinforcement requirement shown in Paragraph N-454 of ASME Section III.

The design evaluation of the personnel lock was completed by the same methods and loading conditions as those described for the equipment hatch, with the following exceptions:

a. A finite element study has been completed for the effect of jet forces on the rectangular door

b. Additional calculations were made for the overhang of the personnel lock with relation to local drywell shell stresses. Local stresses in the drywell were calculated by the methods outlined in Reference 8 for the loading conditions of dead weight and earthquake forces.

The beam seats, spray header, and jet deflectors were analyzed using standard hand formulas taken from References 7, 9, 10, 12, 13, and 14.

Their design is in accordance with the allowable stress limits of ASME Section III for pressure-retaining parts and the AISC Specification for non-pressure-retaining elements. The loadings specified in Subsection 3.8.2.3.2 were used in the design calculations and consist of dead and live loads, pressure, and jet forces. In addition, maximum compressive stresses were evaluated to the allowable limits specified in the buckling formulas prescribed in Welding Research Council (WRC) Standard 69.

The stabilizer mechanism is designed to transfer into the building the reaction due to seismic loads or seismic plus jet loads acting on the drywell, reactor, and shield. The stabilizer mechanism is composed of four components: (1) the connection between the reactor stabilizer and the drywell shell, (2) the male lug, (3) the female lug, and (4) the concrete shear connectors. The geometry of the stabilizer mechanism allows for radial and vertical movements due to pressure and temperature. Computed stresses in the stabilizer mechanism were found by standard elastic hand formulas taken from References 9 and 10.

The design of the stabilizer mechanism is in accordance with the allowable stress limits of ASME Section III for pressure- retaining parts and the AISC Specification for non-pressure-retaining elements. Anchorage to concrete structure was checked for allowable bearing and shear stresses in accordance with ACI 318-63. The loads and loading combinations are specified in Subsection 3.8.2.3.2.

All penetrations are designed for area replacement using the reinforcing requirements of ASME Section III. In addition, penetrations with significant nozzle loadings have been evaluated for those loadings by the methods presented in Reference 8. These loads and loading combinations are described in Subsection 3.8.2.3.2.

There are no pipe restraints attached to the drywell. However, in the event of a LOCA, pipes that penetrate the drywell may impart in-plane membrane forces to the shell.

In the areas where the drywell shell is not backed up by concrete (e.g., at the drywell head), primary stresses from all loads, including LOCA jet and piping reaction forces, are held within 0.90 times the yield strength of the material at the indicated temperature, as specified in Table N-424 of ASME Section III. The combined primary and secondary stresses are limited, in accordance with Paragraph N-414.4 of ASME Section III, to three times the allowable stress intensity values given in Table N-421 of ASME Section III.

In the areas where the drywell shell is backed by concrete, LOCA jet loadings and piping reaction forces were evaluated by conducting physical load-deflection tests. These tests were completed by CBI using a spherical shell segment of the same geometric configuration as that of the drywell sphere. Three tests were performed and consist of

a. The evaluation of the spherical shell deflection under the loading of a representative LOCA jet

b. The evaluation of the spherical shell deflection at an integrally reinforced penetration under the loading of a representative LOCA piping reaction

c. The evaluation of the spherical shell deflection at a pad reinforced penetration under the loading of a representative LOCA piping reaction.

In each test above, it has been shown that the steel shell can deflect up to 3 in. locally without failure. Considering the 2-in. gap between the drywell shell and the shielding concrete, this 3-in. deformation criterion ensures a conservative design. Permanent deformations are acceptable, providing that failure does not occur, as indicated by the above tests. The cylindrical drywell area was justified by a comparison of its rigidity to the sphere rigidity.

3.8.2.4.2 Suppression Chamber

The torus-shaped suppression chamber is designed as an axisymmetric shell of revolution. Analysis techniques similar to those used for the drywell were applied in the original design of the suppression chamber. The suppression chamber design has subsequently been reevaluated and modified for the effects of the LOCA-related loads and SRV discharge-related loads defined by NUREG-0661 (Reference 2) and the GE Report NEDO-21888, "Mark I Containment Program Load Definition Report" (Reference 5). The loads, load application methods, and structural analysis techniques applied in the suppression chamber reevaluation are described in References 1 and 3. The criteria set forth in NUREG-0661 and the original containment design specifications have been applied as a basis for acceptance of the analysis methods and the suppression chamber design.

3.8.2.5 Structural Acceptance Criteria

The structural acceptance criteria for stress and strain are specified in the codes. The following is a general listing of these criteria that for the suppression chamber have been supplemented or modified by the criteria set forth in NUREG-0661 (Reference 2):

a. The design of the primary containment is such that the stress intensities do not exceed the limits prescribed in Subarticle N-1320 of ASME Section III for Class B Vessels

b. The primary containment design details conform to the rules specified in Subarticle N-414 of ASME Section III

c. For configurations where compressive stresses occur, the critical buckling stresses were calculated, and the ratio of compressive stress to critical buckling stress was ascertained to be less than 1.0

d. Pneumatic testing is used for all pressure tests of the primary containment and is conducted in accordance with the requirements of Subarticle N-713 of ASME Section III

e. The ASME B&PV Code does not specifically address itself to deformation limits. However, the deformations have been limited by keeping the stresses within the elastic range of allowable stress requirements of ASME Section III. For local conditions, the biological shield, which is spaced 2 in. away from the primary containment, provides an ultimate limit for all local deformations

f. All non-pressure-retaining parts are designed such that no stresses exceed the limitation of the AISC Specification, Sixth Edition, 1963

g. All concrete bearing stresses are limited to the allowable stresses stated in ACI 318-63.

3.8.2.6 Design Loading Combination Stress Limits

The design loading combinations are categorized in Subsection 3.8.2.3.2. The design stress limits for these combinations are given in Subsection 3.8.2.5.

3.8.3 Concrete and Structural Steel Internal Structures of the Steel Containment

3.8.3.1 Description of the Internal Structures

The containment internal structures are Category I structures. They are mostly heavily reinforced-concrete walls and slabs, with the exception of structural steel flooring or truss systems. They are designed to support the principal nuclear steam supply equipment and the several floor levels within the containment. They are also designed for DBA condition and radiation shielding. The radiation will not adversely affect these structures. The containment internal structures include the following major components:

a. Sacrificial shield
b. Reactor pedestal
c. Drywell floor
d. Gallery floor levels
e. Earthquake-stabilizer truss system
f. Pipe-break-support truss system.

3.8.3.1.1 Sacrificial Shield

The sacrificial shield (Figure 3.8-22) is a composite structural steel and plain concrete open-ended cylindrical shell placed concentric to the reactor pressure vessel (RPV) vertical centerline (see Reference 15). It functions as a radiation and heat barrier between the RPV and the primary steel containment wall. Because of its proximity to the piping, it provides support for pipe whip restraints either directly or indirectly through a pipe-break- support truss system. The geometry of the shield is as follows.

a. Outside diameter: 29 ft 1 in.
b. Height: 48 ft 11-3/4 in.
c. Wall thickness: 1 ft 9-1/4 in.

The shield has 3/8-in.-minimum-thick steel plates on its exterior and interior surfaces and is stiffened meridionally by vertical steel columns. The steel plates are welded to the flanges of the columns, and the annular space between the plates is filled with grout.

Openings are provided in the shield for the passage of lines from the RPV to the drywell. Those openings which lie within an area 9 ft above and 16 ft below the centerline of the core are required to be shielded and are equipped with shielding doors. These doors are locked and will not open during a pipe break within the annulus. The openings above and below this band have no shielding requirements; they are covered with a light-weight rupture diaphragm designed to help relieve the annulus pressure should a break occur.

The exterior surfaces of the shield are sandblasted and coated as described in Subsection 6.2.1.6.

The shield is rigidly attached at the bottom to the reactor support pedestal; the top is free to displace in all directions, except tangential, which is restrained by an earthquake- stabilizer truss system.

3.8.3.1.2 Reactor Pedestal

The reactor pedestal concentric to the RPV vertical centerline (Figure 3.8-23) supports the RPV, sacrificial shield, and pipe whip restraints, which are attached to the pedestal, either directly or indirectly through a pipe-break-support truss system. The pedestal is a reinforced-concrete cylindrical shell with an outer radius of 14 ft 6-1/2 in. and a height of approximately 26 ft. The thickness of the shell varies from 4 ft at its base to 5 ft 6-1/2 in. at its top. The shell is reinforced on both faces by hoop and meridional steel and is integral with the drywell floor.

The RPV ring girder is bolted to a ring plate and then anchored to the top of the reactor pedestal with anchor bolts (Figure 3.8-24). Shear bars welded to the ring plate and embedded in the pedestal transfer tangential shear loads from the RPV to the pedestal; the anchor bolts resist vertical reactions and radial shear.

The inside and outside surfaces of the RPV support pedestal are coated with Nu-klad surfacer 110AA and one finish coat of Ameron polyamide epoxy No. 66.

This coating system protects the pedestal surfaces against attack by either demineralized (aggressive) water or radiation contamination and facilitates washdown.

3.8.3.1.3 Drywell Floor

The drywell floor is a reinforced-concrete pad poured on the bottom of the containment. It is connected to the basemat by special shear keys that transfer lateral forces to the mat (Figure 3.8-1). The shear lugs have anchors attached to them to transfer the uplift forces to the basemat. The main function of the drywell floor is to act as a foundation for the reactor support pedestal within the containment as well as to support the drywell vessel itself.

3.8.3.1.4 Gallery Floor Levels

There are two gallery floor levels within the containment; these serve as a means of access to the internals of the primary steel containment. The gallery levels consist of radial steel beams; the lower gallery is supported by the reactor pedestal, and the upper by the sacrificial shield.

3.8.3.1.5 Earthquake-Stabilizer Truss System

The earthquake-stabilizer truss system (Figure 3.8-25) is a structural steel truss constructed at the top elevation of the sacrificial shield. This system stabilizes the RPV and sacrificial shield under earthquake excitation by transferring the earthquake-induced forces to the concrete biological shield. The RPV is connected to the sacrificial shield, and the sacrificial shield, in turn, is connected to the primary steel containment by a steel truss arrangement. A special "shear lug" connection attaches the truss gusset plates to the containment wall. Similarly, a shear lug connection attaches the primary containment wall to the biological shield. Briefly, the shear lug connection permits radial movement and restrains tangential movement; this type of connection allows the primary steel containment to expand and contract freely under all service conditions.

3.8.3.1.6 Pipe-Break-Support Truss System

The primary steel containment is not designed to withstand loads imposed by pipe break restraints. Therefore, a structural steel pipe-break-support truss system is designed to carry those pipe restraints that cannot be carried by the steel containment (Reference 16 and

Section 3.6). The truss system is supported by the sacrificial shield, reactor pedestal, drywell floor, or any combination thereof (Figure 3.8-26).

3.8.3.2 Applicable Codes, Standards, and Specifications

This subsection lists the codes, specifications, standards of practice, regulatory guides, and other accepted industry guidelines that have been adopted to the extent applicable in the design and construction of the structures internal to the containment. To eliminate repetitious listing for each structure, the codes, standards, and specifications are listed and discussed in Table 3.8-4 and are given a specification reference number.

For each structure internal to the containment, the applicable specification reference numbers are as follows:

Structure	Specification Reference Numbers
Sacrificial shield	2 through 5, 8 through 11, 13 through 17, 20, 21, 23, 28, 34, 39, and 41
Reactor pedestal	1 through 9, 11, 13 through 17, 19, 20, 28, 34, 35, 38, 39, and 41
Drywell floor	Same as for the reactor pedestal
Gallery floor levels	20, 21, 23, 34, 39, and 41
Earthquake-stabilizer truss system	Same as for the gallery floor levels
Pipe-break-support truss system	Same as for the gallery floor levels

3.8.3.3 Loads and Loading Combinations

3.8.3.3.1 Sacrificial Shield

The sacrificial shield is designed for the following loads, in addition to its own dead and live loads (Reference 15):

a. Accident pressures caused by postulated pipe breaks at the nozzles of pipe lines, such as at the recirculation line

b. Thermal and pressure loads under normal operating and accident conditions

c. Pipe rupture loads transmitted by pipe whip restraints connected directly or indirectly through the pipe- break-support trusses to the sacrificial shield

d. Forces induced in either OBE or SSE.

The effects of shrinkage are minimized by designing the grout mix for minimal shrinkage (Subsection 3.8.4.6) and by prescribing construction techniques to minimize differential shrinkage. Where areas of critical shrinkage were defined in the design phase, appropriate shrinkage strains were input as loads in the analysis procedure.

The loading combinations and load factors shown in Tables 3.8-18 and 3.8-19 were applied in the design of the sacrificial shield. A project specification specifies the load combinations for which the sacrificial shield doors were designed.

3.8.3.3.2 Reactor Support Pedestal

The reactor support pedestal is designed to resist the following loads, in addition to its own dead load and live loads:

a. Dead and live loads from the RPV, sacrificial shield, gallery floor levels, and pipe-break-support trusses

b. Thermal and pressure loads under normal operating and accident conditions.

c. Pipe rupture loads transmitted by pipe whip restraints connected directly or indirectly through the pipe- break-support trusses to the reactor support pedestal

d. Forces induced in either OBE or SSE

e. Thermal, pressure, earthquake, and pipe rupture loads that act on the RPV and sacrificial shield and are transmitted to the reactor support pedestal via the support reactions.

The effects of shrinkage are minimized by designing the concrete mix for minimal shrinkage (Subsection 3.8.4.6) and by prescribing construction techniques to minimize differential shrinkage. Where areas of critical shrinkage were defined in the design phase, appropriate shrinkage strains were input as loads in the analysis procedure.

The loading combinations and load factors shown in Tables 3.8-19 and 3.8-20 were applied in the design of the reactor support pedestal.

3.8.3.3.3 Drywell Floor

The drywell floor is designed for the following loads in addition to its own dead and live loads:

a. The reactor pedestal support reactions (vertical, base shear, and overturning moment)

b. The reactions imposed by the pipe-break-support truss system

c. Thermal and pressure loads imposed during normal operating and accident conditions

d. Forces induced during an OBE or SSE.

The loading combinations and load factors shown in Tables 3.8-19 and 3.8-20 were applied in the design of the drywell floor.

3.8.3.3.4 Gallery Floor Levels

The gallery floor levels are designed for the following loads in addition to their own dead load:

a. A uniform platform load of 100 lb/ft^2

b. Miscellaneous loads from pipe hangers, ventilation ducts, and electrical cable trays

c. Forces induced during an OBE or SSE.

The loading combinations and load factors shown in Tables 3.8-l8 and 3.8-19 were applied in the design of the gallery floor levels.

3.8.3.3.5 Earthquake-Stabilizer Truss System

The earthquake-stabilizer truss system is designed for the following loads in addition to its own dead load (Reference 16):

a. Reactions imposed by the RPV overturning moment

b. Thermal and pressure loads imposed during normal operating and accident conditions

c. Forces induced during an OBE or SSE.

The loading combinations and load factors shown in Tables 3.8-18 and 3.8-19 were applied in the design of the earthquake- stabilizer truss system.

3.8.3.3.6 Pipe-Break-Support Truss System

The pipe-break-support truss system is designed for the following loads in addition to its own dead load:

a. Pipe whip restraint forces due to a rupture of the supported pipes (see Reference 16)

b. Miscellaneous loads from pipe hangers, ventilation ducts, and electrical cable trays as applicable

c. Temperature and pressure effects during normal operating and accident conditions.

The loading combinations and load factors shown in Tables 3.8-18 and 3.8-19 were applied in the design of the pipe-break-support truss system.

3.8.3.4 Design and Analysis Procedures

3.8.3.4.1 Sacrificial Shield

The sacrificial shield resists loads in the same manner as a meridionally stiffened cylindrical shell (Reference 15). The pipe whip restraints (Reference 16) are attached directly or through secondary members to column flanges, enabling the pipe whip forces to be rapidly distributed due to shell action. Buckling of the plates is prevented by welding studs to the plates and embedding the studs in the grout. The grout acts mainly as a radiation shield and is not reinforced to carry any direct or flexural stresses. However, because it is in an enclosed space, the grout has been designed to transfer shear forces between the exterior and interior plates.

The sacrificial shield is designed as an anisotropic, asymmetric, cylindrical shell. Asymmetry is due to the presence of openings in the shell. A Sargent & Lundy (S&L) three-dimensional finite element program, SLSAP, has been used to analyze the shield (Section 3.13).

The sacrificial shield columns have been modeled as beam elements; the plates and grout in between have been modeled as plane stress elements. The base of the shield was considered fixed in all directions against rotation and translation. The top of the shield was considered free to rotate and translate in all directions, except the tangential, which is fixed against translation by the earthquake-stabilizer truss system.

For both normal operating and accident conditions, the temperature gradients across the shield and their corresponding axial temperatures caused by radiation-generated heat were calculated by applying the principles of heat transfer. The temperature gradients and axial temperatures were input to the SLSAP model loading conditions (Subsection 3.8.3.3.1).

Loads were combined as appropriate, taking account of the postulated failure locations and types. It was concluded, because of the dynamic characteristics of the sacrificial shield, that peak restraint impact loads are local impulsive loads on the shield wall (Reference 15). These loads occur in the first milliseconds after rupture and are not combined with other loads. The shield wall is allowed to yield locally at regions of impact loads, provided

a. The overall capacity of the shield wall to resist elastically to the other forces listed is not affected

b. The local yielding does not produce effects that jeopardize the safety of other components.

The shield wall design is presently based on the maximum steady-state jet thrust of 1.25 p x A (where p is the pressure and A is the pipe area) at each postulated restraint location. This is conservative, since jet thrust loads decay, depending on break location proximity to feeding volumes.

For each loading condition, all the individual element stresses were output by SLSAP. A maximum stress envelope was then obtained for all the various load combinations specified in Subsection 3.8.3.3.1.

3.8.3.4.2 Reactor Support Pedestal

The reactor support pedestal is designed as a variable-thickness, axisymmetric cylindrical shell fixed at its base and free at its top. Two S&L shell structural analysis programs, SOR-III and KALSHEL (Section 3.13), were used to analyze the support. Geometry, thickness, boundary conditions, elastic properties, and loads are the inputs to both programs; stresses and force resultants at specified cross sections are the outputs. Thermal gradients and their corresponding axial temperatures caused by radiation-generated heat were calculated by applying the principles of heat transfer. The temperature gradients and axial temperatures were input as loads to SOR-III and KALSHEL.

The use of two independent analytical techniques, SOR-III and KALSHEL, provides a means of checking the analysis. Using the force-resultant outputs from SOR-III and KALSHEL, critical cross sections were chosen for detailed analysis by TEMCO-III (Section 3.13). The geometry of the concrete section and the force resultants acting on that section were inputs to TEMCO-III, and the reinforcing steel and concrete stresses are outputs. For sections that are critical in terms of allowable stresses, the capacity of a section under combined loads was verified by plotting an interaction diagram with the aid of the computer program INDIA (Section 3.13).

The top portion of the reactor support pedestal is designed to resist all seismic and pipe rupture forces transmitted through the RPV skirt and also the base of the shield wall. Pipe rupture forces and discontinuity forces at the base of the shield wall, resulting from pressurization of the annulus between the RPV and primary shield wall during a recirculation line break, were used to analyze and design the pedestal in combination with the seismic forces determined from the dynamic analysis of the reactor building.

In addition, the overturning moment and shear associated with a main steam line rupture in combination with seismic overturning moments and shears from the RPV and shield wall were used for the analysis and design of the pedestal.

The seismic and pipe rupture forces on the pedestal, discussed above, were used in combination with other loads as outlined in Subsection 3.8.3.3.2.

3.8.3.4.3 Drywell Floor

The drywell floor was analyzed using conventional elastic methods and designed in accordance with ACI 318-63 and/or ACI 318-71.

3.8.3.4.4 Gallery Floor Levels

The gallery floor levels were analyzed using conventional elastic methods and designed in accordance with the AISC Specification, 1969 Edition.

3.8.3.4.5 Earthquake-Stabilizer Truss System

The earthquake-stabilizer truss system was analyzed as a statically indeterminate truss by conventional elastic methods and designed in accordance with the AISC Specification, 1969 Edition. Applicable computer programs listed in Section 3.13 were used in part or totally for the structural analysis.

3.8.3.4.6 Pipe-Break-Support Truss System

The pipe-break-support truss system was analyzed by conventional elastic methods, as stated in the AISC Specification, 1969 Edition. Applicable computer programs listed in Section 3.13 were used in part or totally for the structural analysis.

3.8.3.5 Structural Acceptance Criteria

3.8.3.5.1 Sacrificial Shield

The stresses in the sacrificial shield steel plates are limited to those specified in the AISC Specification, 1969 Edition, Part I, when the steel plates were being designed for the loading combinations listed in Tables 3.8-18 and 3.8-19 (see Reference 15).

The appropriate factors of safety against yield used are those discussed in the Commentary to the 1969 AISC Specifications. The allowable steel stresses were increased to 1.6 times those specified above, subject to an upper limit of 0.95 f_y (yield stress), when designing for loading conditions 5, 10, and 11 in Table 3.8-18 and corresponding stresses in Table 3.8-19. In this situation a minimum design factor of safety of 1.0/0.95 = 1.05 against yield is ensured. In both cases, deformation of the steel plates is limited because the steel stresses are kept within the elastic range.

The stresses and strains in the plain concrete between the steel plates are limited to those specified by the Strength Design Method of ACI 318-71. The factors of safety against material strength are contained in the load factors listed in Tables 3.8-19 and 3.8-20, and the undercapacity factors (ϕ) are specified by ACI 318-71.

Earthquake-induced stresses and strains are limited to the aforementioned allowables; no increases are permitted.

3.8.3.5.2 Reactor Support Pedestal

The strain in the reinforcing steel and concrete is determined in accordance with ACI 318-63 and/or ACI 318-71.

The load combinations given in Tables 3.8-19 and 3.8-20 are designed for using the yield limit criteria. The yield limit strength of the structure was defined for this design as the upper limit of elastic behavior of the effective load-carrying material. The allowable stresses for this limit are in accordance with ACI 318, with the following limitations and clarifications:

a. Concrete

1. Compression

(a) Membrane stress = $0.6\ f_c'$

(b) Membrane plus flexural stress = $0.75\ f_c'$

(c) Local compression = $0.9\ f_c'$

2. Tangential shear

The principal stresses resulting from the tangential shear stresses and membrane stresses were computed for all load combinations. If principal tension greater than $3\sqrt{f_c'}$ developed in localized areas, the reinforcing steel was designed to carry the total tensile force.

b. Reinforcing Steel

1. Maximum tensile stress = $0.9\ f_y$

2. Maximum compressive stress = $0.9\ f_y$ (load carrying).

Deformations of the reactor support pedestal are limited by specifying a maximum allowable concrete strain of 0.002 in. per in. and by keeping the stresses in the reinforcing steel below yield. Redistribution of loads caused by plastic deformations is not permitted. The factors of safety against material strength are contained in the load factors listed in Table 3.8-20 and the under capacity factors (ϕ) specified in ACI 318. Serviceability checks in accordance with ACI 318 were made to ensure adequate crack control and to limit deformations.

As in the sacrificial shield, no increases in the allowable stresses or strains specified above were permitted when designing for earthquake-induced forces.

3.8.3.5.3 Drywell Floor

The stresses and strains in the reinforced-concrete floor are limited to those specified in ACI 318-63 and/or ACI 318-71. The factors of safety against material strength are contained in the load factors listed in Table 3.8-20 and in the under capacity factors (ϕ) of ACI 318. Serviceability checks are made in accordance with ACI 318 to limit cracking of the floor.

3.8.3.5.4 Gallery Floor Levels

The allowable steel stresses and strains for the gallery floor levels are as specified in Subsection 3.8.3.5.1. Steel member deflections were calculated and kept below the allowable AISC limits or below manufacturers' recommendations for equipment supported by the steel.

3.8.3.5.5 Earthquake-Stabilizer Truss System

The allowable steel stresses and strains in the earthquake-stabilizer truss system are specified in Subsection 3.8.3.5.1. No increases in the allowable stresses and strains were permitted when designing for the earthquake-induced forces.

3.8.3.5.6 Pipe-Break-Support Truss System

The allowable steel stresses and strains for the pipe-break-support truss system are specified in Subsection 3.8.3.5.l. Steel deflections were calculated and kept below allowable AISC limits or below manufacturers' recommendations for equipment supported by steel. For a discussion of the design criteria for the pipe break restraints, see Section 3.6.

3.8.3.6 Materials, Quality Control, and Special Construction Techniques

3.8.3.6.1 Sacrificial Shield

The construction materials and quality control (QC) procedures for the sacrificial shield conform to the standards set forth in Subsection 3.8.4.6.

Radiation damage to steel is caused by a neutron flux with neutrons of energy greater than l MeV. It has been ascertained that a neutron flux incident on the inside face of the sacrificial shield steel plate is 1.6 x 10^7 neutrons per square centimeter per second. This will result in a neutron fluence of 2.0 x 10^{16} n/cm^2 in the 40-year operating life of the plant.

The first indication of neutron damage to steel is a decrease in the brittle fracture transition temperature. This occurs at a fluence of about 10^{19} n/cm^{2,} which is three orders of magnitude greater than the inside steel plates of the sacrificial shield will experience. Therefore, there is no danger of radiation damage to the sacrificial shield plates.

3.8.3.6.2 Reactor Support Pedestal, Drywell Floor, Gallery Floor Levels, Earthquake-Stabilizer Truss System, and Pipe- Break-Support Truss System

The construction materials and QC procedures for these structures conform to the standards set forth in Subsection 3.8.4.6. These structures are not located in a region of high-energy neutron flux; thus, radiation damage to these structures is not expected.

3.8.3.7 Testing and Surveillance Requirements

3.8.3.7.1 Testing and Surveillance Requirements During Plant Construction Phase

The structures specified in Subsection 3.8.3.1 are visually inspected as part of the Quality Control program. Structural steel members are examined for corrosion, excessive deformation, and warpage; their bolted or welded connections are examined for tightness and soundness. The structural integrity of reinforced concrete members is evaluated by mapping cracks in critical areas identifiable by design and by checking for spalling and excessive deformations. Anchor bolts are inspected for tightness.

Rigorous inspection is carried out during construction and in conjunction with the quality control (QC) assurance procedures for structural materials outlined in Subsection 3.8.4.6.

3.8.3.7.2 Testing and Inservice Surveillance Requirements

No inservice structural integrity and/or performance tests are conducted for containment internal structures.

3.8.4 Other Category I Structures

3.8.4.1 Description of the Structures

All structures that contain or support safety-related systems and/or equipment are designed to withstand both seismic and tornado loads, including tornado-generated missiles. Seismic loads are not considered to act simultaneously with tornado loads. Subsection 3.3.2 identifies the Category I equipment and structures that are protected against tornadoes.

No unique materials or new features are used in the design or construction of the structures described in this section.

No concrete block masonry walls have been used as load-bearing walls in Category I structures. Piping or equipment is not supported on masonry walls. The walls are basically non-load- bearing partitions. However, minor attachments of weight totaling less than about 2 percent of the weight of the wall, e.g., junction boxes or key card readers, are permitted. In cases where the weight of items attached to the wall is significant compared to the weight of the wall, the actual weight of the attachment is considered in the design.

Masonry walls, with exception of seismic Category 1 control center pressure boundary walls, are classified as seismic Category II/I structures, and are, therefore, required to maintain structural integrity during a safe shutdown earthquake (SSE). Control center boundary walls are classified as seismic Category I, since they are required to maintain pressure boundary integrity.

The walls are analyzed for dead load plus SSE Load. External supporting steel is installed, where required, to limit tension stresses in the mortar joints to allowable levels.

The block walls are modeled as plate elements with boundary conditions reflecting actual field installations. The provisions of IEEE Standard 344-1975 are used in the seismic analysis of the walls, i.e., a multi-frequency excitation and multi-mode response factor of 1.5, or any other justified factor, is used as a multiplier to the corresponding spectral acceleration. For those walls proved to be rigid by dynamic analysis, with no resonances in the response spectrum amplification range, a zero period acceleration (ZPA) is used in the seismic analysis.

Following are the remaining Category I structures not discussed above or in Subsections 3.8.1, 3.8.2, 3.8.3, or 3.8.5:

a. Reactor/auxiliary building

b. Residual heat removal (RHR) complex

c. Category I Ductbanks.

3.8.4.1.1 Reactor/Auxiliary Building

The reactor/auxiliary building is a single structure that houses both the reactor and auxiliary portions of the building. In the following subsections, the reactor portion of the reactor/ auxiliary building will be referred to as the reactor building, and the auxiliary portion will be referred to as the auxiliary building.

3.8.4.1.1.1 Reactor Building

The reactor building, in conjunction with the reactor building heating and ventilating system and the SGTS, constitutes the secondary containment. The primary purposes of the secondary containment are

a. To minimize ground-level release of airborne radioactive materials

b. To provide means for a controlled release of the building atmosphere.

See Section 1.2 for general arrangement drawings of the reactor building.

The reactor building completely encloses the drywell and the suppression chamber and is supported on the reactor building foundation mat. The structure provides secondary containment when the primary containment is closed and in service, and it provides primary containment during reactor refueling and maintenance operations when the primary containment is open. The reactor building houses the refueling and reactor servicing equipment, biological shield, new- and spent-fuel storage facilities, and other reactor auxiliary or service equipment, including the reactor core cooling (RCIC) system, reactor water cleanup isolation system (RWCUS), standby liquid control system (SLCS), equipment for the CRD system, the reactor core and containment cooling system, and components of the electrical equipment.

The approximate overall dimensions of the reactor building are 116 ft by 162 ft in plan and 200 ft in height measured from the subbasement floor to the top of the parapet. The substructures and exterior walls of the building up to the refueling floor consist of poured-in-place reinforced concrete. Above the level of the refueling floor, the building structure is steel-framed with insulated metal siding with sealed joints. The reactor building has a built-up roof over insulated metal deck. The reactor building has access openings from the auxiliary building and the outside for personnel and equipment. The access openings from the outside are provided with interlocked doors that have weather-strip-type seals. Interconnecting services between the reactor building (Category I) and other nonseismic structures have the flexibility to allow for all relative movement between the structures.

The reactor building has two ventilation exhaust systems. During normal power operation, shutdown, or refueling, the normal ventilation system provides outside filtered air to all levels and equipment rooms within the building. Air is exhausted through a vent extending above the reactor building roof level. During emergencies, the normal ventilation system shuts down, and the reactor building is ventilated through the SGTS. This system causes the building internal pressure to be lower than the external pressure to ensure inleakage rather than outleakage. For a complete discussion of the heating, ventilating, and air conditioning (HVAC) system, see Section 9.4.

The biological shield is a major structure enclosed by the reactor building. This shield is a reinforced-concrete structure with a thickness of 4 to 7 ft; it extends from the bottom of the drywell to the top of the refueling floor, completely encasing the drywell structure (Figure 3.8-27). The top of the shield consists of a removable, segmented reinforced-concrete plug.

The main function of the biological shield is to serve as a radiation shield around the drywell; however, it also functions as a major mechanical barrier for the protection of the containment and reactor system against missiles that may be generated external to the primary containment. The shield resists deformation and buckling of the drywell walls over areas where the shield is in contact with the drywell. Above the transition zone, the drywell is separated from the reinforced concrete by a gap of approximately 2 in.; this gap is filled with a compressible material.

In addition to the above functions, the biological shield supports the various reactor building floor elevations that frame into it, and it resists the earthquake-induced forces that act on the RPV and sacrificial shield transferred to it through the earthquake-stabilizer truss system.

The spent-fuel storage pool, dryer-separator pool, and reactor refueling pool are reinforced-concrete structures completely lined with seam-welded stainless steel plate. The stainless steel liners prevent leakage. There are no connections that would allow the fuel storage pool to be drained below the pool grade between the reactor well and the fuel storage pool. Channels are located in the concrete directly behind the welded seams of the pool liners, and these are monitored to detect leakage from the pools. (Figures 3.8-28 through 3.8-31.)

The reactor building crane runway and supporting structure are designed as an integral part of the building superstructure to withstand earthquake accelerations at the level of the crane runway. See Figure 3.8-32 and Subsection 9.1.4.2 for details of the crane seismic safety features.

3.8.4.1.1.2 Auxiliary Building

The auxiliary building is a reinforced-concrete structure supported on a reinforced-concrete mat foundation. The exterior walls provide tornado missile protection. The main steam tunnel passes through this building. Other piping and electrical cables pass through this building in separate tunnels and connect with adjacent buildings. The reinforced-concrete steam tunnel walls, floor, and roof protect the equipment outside the tunnel from the effects of a postulated steam line break within the tunnel.

The approximate dimensions of the auxiliary building are 88 ft by 160 ft in plan and 161 ft in height, measured from the subbasement floor to the top of the parapet. See Section 1.2 for general arrangement drawings of the auxiliary building.

The auxiliary building walls, floors, and roof are constructed mainly of cast-in-place reinforced concrete. A seismic category II/I steel frame penthouse, approximately 51 ft by 20 ft in plan and 48 ft in height, with steel siding walls, is constructed on the auxiliary building roof to house the exhaust stack for the ventilation equipment located in the auxiliary building. For a complete description of the HVAC equipment in the auxiliary building, refer to Section 9.4. The auxiliary building is integrally connected to the reactor building by the common east wall of the reactor building, but separated from the turbine building by a 4-in. seismic rattle space. Services interconnecting the auxiliary and turbine buildings have the flexibility to allow for all relative movement between the two structures.

The auxiliary building houses the following major plant and safety-related systems and components:

a. Main control room

b. High-pressure coolant injection (HPCI) pumps and turbines

c. CRD pumps

d. Emergency equipment cooling water (EECW) heat exchanger and pumps

e. Main battery room

f. SGTS rooms

g. Main ventilation room

h. Main power distribution center for the reactor building

i. Switchgear rooms

j. Relay room.

3.8.4.1.2 Residual Heat Removal Complex

The RHR complex is a reinforced-concrete structure designed to serve as the ultimate heat sink for the reactor during normal shutdowns and postulated accident conditions. The structure is approximately 280 by 127 ft in plan and is located west of the reactor/auxiliary building. The complex consists of two divisions: Division I and Division II. Each division is comprised of a water reservoir, a pump house, a two-cell mechanical draft cooling tower, and two emergency diesel generators. Division I is in the south side, and Division II is in the north side of the complex. With the two reservoirs cross-connected to permit access to the entire ultimate heat sink inventory, each division has the capacity to safely and orderly shut down the reactor during normal and/or accident conditions completely independent of the other. See Section 1.2 for general arrangement drawings of the RHR complex.

The RHR complex houses the RHR service water (RHRSW), emergency equipment service water (EESW), and the diesel generator service water (DGSW) systems. During normal and/or accident shutdown conditions, the function of the RHRSW and EESW systems is to remove decay heat from the RHR heat exchangers and the EECW heat exchangers, respectively. The function of the DGSW system is to remove the heat from the emergency diesel generator heat exchangers during operation of the generators.

Adequate protection from potential postulated missiles has been provided, as described in Section 3.5.

Penetrations are provided for the RHRSW and EESW systems. All penetrations below Elevation 590.0 ft are watertight, as described in Subsection 2.4.2.

3.8.4.1.3 Category I Electrical Ductbank Concrete Structures

There are two sets of Category I concrete ductbanks and manholes located between the RHR complex and the Reactor/Auxiliary Building, with a Division I and Division II ductbank in each set. The first set was designed and installed during plant construction. The essential I&C and Control cables will remain in these ductbanks and the 4160-V essential power circuits are abandoned and new cables routed in the second set.

The second set of Category I ductbanks and associated, manholes and above ground cable vaults were installed to house the 4160-V essential power cables that replaced the abandoned cables in the original ductbanks due to water intrusion issues. These ductbanks also have spare conduits should the need arise to replace other essential cables in the original ductbanks.

Both set of ductbanks are cast-in-place rectangular shaped reinforced concrete ducts with each 4160-V circuit separately house in its own conduit.

3.8.4.2 Applicable Codes, Standards, and Specifications

This section lists the codes, specifications, standards of practice, regulatory guides, and other industry-accepted guidelines that have been adopted to the extent applicable in the design and construction of all Category I structures. To eliminate repetitious listing for each structure, the codes, standards, and specifications are described and discussed in Table 3.8-4 and given a specification reference number. For each Category I structure, the applicable specification reference numbers are as follows:

Reactor/auxiliary building	1 through 9, 11 through 17, 19, 20, 21, 23, 25, 26, 28, 30, and 32 through 42
RHR Complex	1A, 2B through 9, 11 through 17, 19, 20, 21, 23, 29 through 36, and 38 through 42
Category I Ductbanks	
First Set	1A, 2B through 9, 11 through 17, 19, 20, 38, 39, 41
Second Set	43 through 46

During the construction period many of the industry codes, specifications, and standards have been revised. Project specifications have been revised to incorporate later editions, as considered appropriate, than those listed in Table 3.8-4.

3.8.4.3 Loads and Loading Combinations

3.8.4.3.1 Reactor/Auxiliary Building

The load factors and loading combinations given in Tables 3.8-l8 and 3.8-20 for structural steel members and for reinforced-concrete members, respectively, and the corresponding allowable stress values given in Tables 3.8-19 and 3.8-20 have been applied in the design of the reactor/auxiliary building floor slabs, walls, roof, reactor building crane, equipment foundations, biological shield, spent-fuel pool and dryer-separator storage pool, and all other structures integral with the reactor/ auxiliary building, as outlined in Subsection 3.8.4.1.1. Following is a general discussion of the loads for which the aforementioned structures are designed.

3.8.4.3.1.1 Reactor Building Crane

The reactor building crane rails and columns are designed to carry loads transmitted from the crane for the loading combinations listed in Tables 3.8-18 and 3.8-19. The lateral force on the crane runway is 20 percent of the sum of the weights for the lift load and of the crane trolley applied at the top of each rail, one-half on each side of the runway, acting in either direction normal to the runway. The longitudinal force is 10 percent of the maximum wheel loads of the crane. An induced impact of 25 percent of the wheel load was included in the design of the support structure.

3.8.4.3.1.2 Reactor/Auxiliary Building Roof

In addition to its dead load, the reactor/auxiliary building roof is designed for a normal live load of 30 lb/ft^2. The roof purlins and decking are designed to withstand a suction pressure of 33 lb/ft^2 induced by a 90-mph wind (Subsection 3.3.1) and to blow off before a suction pressure of 72 lb/ft^2 induced by a 200-mph wind is reached. The roof decking is assumed to blow away when the wind velocity exceeds 200 mph. The structural steel frames are designed to withstand the effects of the tornado specified in Subsection 3.3.2.

3.8.4.3.1.3 Reactor/Auxiliary Building Walls

The reactor/auxiliary building walls, in addition to their own dead load, are designed for external and internal missiles and transient thermal gradients caused by the temperature differential between the exterior and interior environs (see Table 3.8-21 for the specified temperature ranges). The walls are designed to carry all members, equipment, and floor elevations framing into them.

The concrete walls up to the refueling floor elevation are designed to withstand the effects of the tornado (Subsection 3.3.2 and Reference 17). However, the metal siding walls above that elevation are designed to withstand a 90-mph wind, but are designed to blow away before a wind velocity of 200 mph is reached. Where blowout panels are not provided in walls that form totally enclosed compartments, the walls are designed for a tornado-induced internal pressure of 3 psi, as specified in Section 3.3.

Walls below grade are designed for lateral soil pressure, hydrostatic pressure from ground water level at elevation 576 ft and a surcharge of 500 lb/ft^2 under normal condition. In addition, these walls are designed for lateral soil pressure and maximum flood level specified in Section 3.4 under extreme environmental condition (similar to tornado case).

The reactor/auxiliary building walls, interacting with the reactor/auxiliary building floor slabs, are designed to resist the reactor/auxiliary building seismically induced base shears.

3.8.4.3.1.4 Reactor/Auxiliary Building Equipment Supports

To account for the effects of impact, machinery support reactions have been increased by the following percentages:

a. For elevator supports - 100 percent

b. For supports of light machinery (shaft or motor driven) -20 percent

c. For supports of reciprocating machinery or power-driven units - 50 percent

3.8.4.3.1.5 Reactor/Auxiliary Building Floor Slabs

In addition to the slab and equipment dead loads, conservative live loads have been selected for each slab. Pattern live loads have been applied to determine the maximum shears and moments in the slab. In addition to floor live and dead loads, slabs are designed for internal missiles, temperature gradients, and pressure differentials caused by operating or accident conditions as applicable.

Additionally, the reactor building slabs are loaded during ISFSI campaigns to transfer nuclear fuel from the spent fuel pool to the outdoor long-term Independent Spent Fuel Storage Installation (ISFSI) location. A HI-TRAC transfer cask with a loaded multi-purpose canister (MPC) is moved from the spent fuel pool to the Dryer-Separator Storage Pool for processing prior to movement to a low profile transport on the first floor to be moved outside the Reactor Building. Horizontal seismic loads on the HI-TRAC are reduced by an engineered Teflon friction reducing pad that is placed between the HI-TRAC and the floor of the Dryer Separator Pool and low profile transport. Horizontal seismic loads were reduced, thus reducing moments that tend to overturn the HI-TRAC such that it will not tip and induce additional vertical loads on RB slabs.

3.8.4.3.1.6 Biological Shield

In addition to its own dead load, the biological shield is designed for the temperature gradients T_a and T_o (Table 3.8-21) between the containment and exterior face of the shield, seismic loads, pipe break loads, missile loads (Section 3.5), and the dead and live load reactions of the floor elevations that frame into it.

3.8.4.3.1.7 Spent-Fuel Pool and Dryer-Separator Storage Pool

The spent-fuel pool and dryer-separator storage pool are designed for the following loads:

a. Dead load

b. Water load (including the hydrodynamic forces associated with the water set in motion by seismic accelerations)

c. Mechanical equipment loads

d. Temperature gradient caused by a maximum water temperature of 150°F

e. Accident and operating temperature differential between the containment and exterior walls for both summer and winter extremes (Table 3.8-21).

f. ISFSI HI-TRAC with a fuel-loaded multi-purpose canister (MPC).

All of the reactor/auxiliary building Category I structures and structural components are designed for the vertical and horizontal accelerations of both OBE and SSE.

3.8.4.3.2 Residual Heat Removal Complex

The load factors and loading combinations given in Table 3.8-20 for reinforced-concrete members and in Table 3.8-18 for structural steel members and the corresponding allowable stress values given in Table 3.8-19 have been applied in the design of the floor slabs, walls, equipment foundations, roof, and other structures integral with the RHR complex, as outlined in Subsection 3.8.4.3.

The discussion on the design loads for the roof, floor slabs, walls, and equipment supports found in Subsection 3.8.4.3.1 applies to the RHR complex (Reference 18). The roof of the RHR complex is designed for a total live load of 70 lb/ft^2. In addition, the RHR complex reservoir walls are designed for the hydrodynamic forces of the water in the reservoir set in motion by seismic accelerations.

3.8.4.4 Design and Analysis Procedures

3.8.4.4.1 Reactor/Auxiliary Building

The reactor/auxiliary building floor slabs, roof, walls, and miscellaneous structures integral with the reactor/auxiliary building have been analyzed and designed using conventional elastic techniques. All significant openings and discontinuities in structural members were included in the structural model. The boundary conditions selected for all structural models were determined by evaluating the stiffness (flexural, torsional, and axial) of all the members connected at a boundary point, and those conditions represent, to the extent practicable, the actual restraint conditions.

The reactor/auxiliary building walls, interacting with the floor slabs, are proportioned to resist the combination of seismically induced overturning moments, vertical loads, and shears in accordance with the applicable provisions of ACI 318. Adequate provisions are made to transfer wall moments, vertical loads, and shears to the mat foundation.

The computer programs used in the analysis of walls, floor slabs, beams, roof, reactor building crane, and all other structures are listed in Section 3.13.

3.8.4.4.1.1 Biological Shield

The biological shield was originally analyzed by two methods. The first analysis was based on elastic shell theory using the KALSHEL computer program. The second analysis was based on finite element theory using the computer program DYNAX (Section 3.13). The biological shield was considered to be fixed at its base and restrained by the fuel pools at its top. The results of the two independent analyses were compared, and the more conservative of the two was used for design. To determine the local effects at larger penetrations, the areas around those penetrations were modeled by finite element programs such as PLFEM-II or SLSAP (Section 3.13). The element nodes lie along the centerline of the shield, thus modeling the curvature of the wall. The size of the model was chosen such that the boundary conditions are compatible with those obtained from KALSHEL. The final load verification calculation of the Biological Shield Wall addressing additional loads was performed using ANSYS.

3.8.4.4.1.2 Spent-Fuel Pool and Dryer-Separator Storage Pool

The pools were originally analyzed as a beam simply supported at both ends by the reactor building exterior walls and rigidly supported at the middle by the biological shield. Two independent structural models were used in the analysis. First, the structure was modeled as beam elements using the appropriate stiffness and the STRESS program (Section 3.13). The STRESS output consists of the moments and shears in the pool walls for all loading conditions. Second, a finite element model was made using the PLFEM-II program. PLFEM-II output gives localized moments in the pool walls caused by hydrostatic and temperature loads. The design of the pool walls is in accordance with ACI 318 and is based mainly on the PLFEM-II output with reference being made to STRESS. The temperature gradient loads were analyzed by hand to verify the results from PLFEM-II.

In the case of the Spent Fuel Pool the analysis has been updated to incorporate final loads. The new analysis uses ANSYS to analyze the design of the Spent Fuel Pool.

During an Independent Spent Fuel Storage Installation (ISFSI) campaign or storage cask unloading, a HI-TRAC with multi-purpose canister (MPC) containing spent fuel is temporarily placed in the Dryer-Separator Storage Pool for processing. The Dryer-Separator Storage Pool structures were analyzed using the STAAD.Pro program by an equivalent frame method similar to that of the original calculation. The potential tipping and sliding motion of the cask in the Dryer Separator Storage Pool has been analyzed for OBE and SSE vertical and horizontal accelerations.

3.8.4.4.2 Residual Heat Removal Complex

The RHR complex structure was designed and analyzed using conventional elastic techniques as described for the reactor building. The computer programs used in the design and analysis process for the RHR complex are listed in Section 3.13.

3.8.4.4.3 Second Set of Category I Ductbanks and Associated Manholes and Cable Vaults

The Category I underground ductbanks, manholes and above ground cable vaults at the RHR complex have been constructed and analyzed to meet all the requirements of Category I structures as provided in ACI 349-01 and RG 1.142 & RG 1.76.

The load factors and loading combinations given in Table 3.8-20 for reinforced concrete structures have been applied in the design of these Category I structures.

3.8.4.5 Structural Acceptance Criteria

3.8.4.5.1 Reactor/Auxiliary Building

The stresses and strains in the reinforced-concrete walls, floor slabs, beams, and equipment supports in the reactor/auxiliary building are limited to those specified in ACI 318-63 and/or ACI 318-71. Serviceability checks are made in accordance with ACI 318-63 and/or ACI 318-71 to ensure crack control and to keep deflections below the limits prescribed by the manufacturers' recommendations for equipment supported by reinforced concrete.

The basic criterion for strength design is expressed as required strength versus calculated strength.

All members and all sections of members are proportioned to meet this criterion. The required strength is expressed in terms of design loads or their related internal moments and forces. Design loads are defined as loads that are multiplied by their appropriate load factor (safety factors), as given in Tables 3.8-19 and 3.8-20.

Calculated strength is that computed by the provisions of ACI 318-63 and/or ACI 318-71.

Stresses and strains in the structural steel used for the reactor/auxiliary building are limited to those specified in the 1969 AISC Specifications, Part I, when the loading combinations listed in Tables 3.8-18 and 3.8-19 were being designed for. The appropriate factors of safety against yield are those discussed in the Commentary to the 1969 AISC Specifications. The allowable steel stresses have been increased to 1.6 times those specified above, subject to an upper limit of 0.95 f_y (yield stress), when loading combinations 10 and 11 of Table 3.8-18 were being designed for. In this situation, a minimum factor of safety of 1.05 against yield has been ensured. In either case, deformations of structural steel members are limited because the stresses are kept within the elastic range, and redistribution of loads due to plastic deformations is not permitted. In addition, the deflections of all critical steel members were calculated and kept below the limits prescribed by the 1969 AISC Specifications or manufacturers' recommendations for equipment supported by steel.

The biological shield was designed using the yield limit criteria defined for the reactor support pedestal in Subsection 3.8.3.5.2.

3.8.4.5.2 Residual Heat Removal Complex

The structural acceptance criteria for the RHR complex are in accordance with the 1969 AISC Specification and ACI 318-71 and are similar in method to those described in Subsection 3.8.4.5.1.

3.8.4.5.3 Category I Ductbanks

There are two sets of Category I concrete ductbanks and manholes between the RHR complex and the Reactor/Auxiliary building, with a Division I and Division II ductbank in each set. The structural acceptance criteria for the first set of concrete ductbanks and associated manholes are in accordance with the Specifications and ACI 318-71 and are consistent with criteria described in Subsection 3.8.4.5.1 for concrete structures.

The design and construction acceptance criteria for the second set of Category I 4160-V ductbanks and associated, manholes and cable vaults is in accordance with ACI 349-01 Code, Reg. Guide 1.142 and RG 1.76.

3.8.4.6 Materials, Quality Control, and Special Construction Techniques

Noncombustible and fire-resistant materials are used wherever necessary throughout the facilities, particularly in areas containing critical portions, such as the containment, main control room, and components of ESF systems.

The construction materials for the reactor/auxiliary building and RHR complex structure conform to the standards set forth in the following discussion.

3.8.4.6.1 Concrete

"Specifications for Structural Concrete for Buildings," ACI 301, together with ACI 347, "Recommended Practice for Concrete Formwork," and ACI 318, "Building Code Requirements for Reinforced Concrete," form the general basis for the concrete specifications.

The requirements of ACI 301 have been supplemented as necessary with mandatory requirements relating to types and strengths of concrete, proportioning of ingredients, reinforcing steel, joint treatments, and testing.

Admixtures, types of cement, bonding of joints, embedded items, concrete curing, additional test specimens, additional testing services, cement and reinforcing-steel mill test report requirements, and additional concrete test requirements are specified in detail.

Specifications ACI 349-01 “Code Requirements for Nuclear Safety Related Concrete Structures” and Regulatory Guide 1.142 “Safety-Related Concrete Structures for Nuclear Power Plants (Other Than Reactor Vessels and Containments)” provide the general basis for the design and construction of the second set of Category I 4160-V ductbanks, manholes and cable vaults.

3.8.4.6.1.1 Materials

All cement conforms to either ASTM C150, "Specification for Portland Cement Types I, II, and V," or Canadian Standards Association (CSA) Standard A5, "Portland Cements." The cement meets the requirements of the edition of the standard or specification that was current at the time the cement was manufactured.

Certified copies of mill tests, showing that the cement met or exceeded the ASTM requirements for portland cement, are furnished by the manufacturer.

Aggregates conform to the Michigan Department of State Highways Standard Specifications for Road and Bridge Construction, Article 8.02. Fine aggregates are of the natural sand designation 2NS. Coarse aggregates are of the designation 6AA; these requirements equal or exceed those of ASTM Specification C33. Where a larger size aggregate is specified for use in mass concrete portions of the work, it conforms in all respects, except size, to designation 6AA. Aggregates are free from any materials that would be deleteriously reactive in any amount sufficient to cause excessive expansion of mortar or concrete.

Mixing water is clean and free from injurious amounts of oils, acids, alkalies, salts, organic materials, or other substances deleterious to concrete or steel. Water used, as required, for concrete produced at the onsite batch plant is supplied from the Frenchtown Township Water Treatment Plant. This water is tested as processed and meets the Michigan Department of Public Health Drinking Water Standards.

An air-entraining agent is used in concrete subject to weathering. This agent conforms to the requirements of the Standard Specification for Air-Entraining Admixtures for Concrete, ASTM C260. The solution is batched by means of a mechanical dispenser capable of accurate measurement and in such a manner as to ensure uniform distribution of the agent throughout the batch during the specified mixing period. Air-entrained cement is not used.

Fly ash is obtained from the Trenton Channel Power Plant, which is also owned by the applicant, The Detroit Edison Company; it conforms to ASTM Specification C6l8. The quantity of fly ash used is determined by making laboratory tests on trial batches containing various amounts of fly ash. The mix selected is that with the maximum fly-ash-to-cement ratio that consistently yielded the specified concrete strength and provided workability.

Other admixtures to control the rate of set, reduce the water content, or improve the workability and cohesiveness of concrete are used in specific instances and conform to ASTM C494. Such admixtures are used only after tests have been made in combination with the cement and aggregates being used and specifically approved. Calcium chloride is not used under any circumstances.

3.8.4.6.1.2 Mixing

The concrete used is normal-weight concrete, with an average density of 145 lb/ft^3. Concrete or grout used for neutron shielding contains boron frits.

The proportioning of structural concrete conforms to ACI 301. In general, concrete mixes have a 28-day specified strength of 4000 psi.

Proportions of ingredients are determined and tests are conducted in accordance with the methods of ACI 301 for combinations of materials to be established by trial mixes.

Batching and mixing conform to ACI 301 and ASTM C94. Concrete ingredients are batched in an onsite central batch plant and transported to the point of placement in truck mixers, operating at agitating speed. In the event of a malfunction of the onsite plant, concrete may be batched at an offsite backup plant and truck mixed.

Concrete protection for reinforcement, preparation and cleaning of construction joints, concrete mixing, delivering, placing, and curing, with the following exceptions, is equal to or exceeds the requirements of ACI 301. The slump is varied as part of the mix design within a range of a maximum of 5 in. and a minimum of 1 in. to suit the portion of the work being placed. The minimum slump is waived on concrete used in ramps or other sloping construction. The samples for the slump tests are taken at the end of the last conveyor, chute, or pipeline before the concrete is placed in the forms.

3.8.4.6.1.3 Placement

Placing of concrete is by bottom dump buckets, chuting, concrete pump, or conveyor belt. The rate of placing concrete is controlled so that concrete is effectively placed and compacted by vibrating, with particular attention given around embedded items and near the forms.

Vertical drops greater than 6 ft are not permitted for any concrete, except where suitable equipment is provided to prevent segregation.

Cold and hot weather placing temperatures are as follows:

a. Cold weather - The ingredients are heated whenever necessary to produce concrete having a temperature of not less than 45°F. When the concrete ingredients are heated, the maximum temperature of the concrete is 80°F. Heated concrete is obtained by heating the water or aggregates, or both

b. Hot weather - Concrete deposited in hot weather has a placing temperature that does not cause difficulty from loss of slump, flash set, or cold joints. In addition, the following maximum temperatures are adhered to unless noted otherwise on the drawings:

   1. 75°F - Sections 6 ft or less but greater than 2 ft 6 in. in least dimension
   2. 65°F - Sections greater than 6 ft in least dimension.
   3. 85°F - Sections 2 ft 6 in. or less in least dimension and all electrical duct or pipe encasements.

3.8.4.6.1.4 Curing

Curing and protection of freshly deposited concrete conform to ACI 301, with the following supplementary provisions:

a. Concrete cured with water is kept wet by covering with an approved water-saturated material, by a system of perforated pipes or mechanical sprinklers, and by other approved methods that keep surfaces continuously wet. Water used for curing is clean and free from any elements that might cause objectionable effects. Curing compounds are also used

b. When curing compounds are used on surfaces on which additional concrete is to be bonded, the curing compound manufacturer provides documentary evidence that the curing compound will not prevent bond. In the event the manufacturer is unable to prove that the curing compound does not prevent bond, the curing compound is completely removed from the joint surface prior to bonding the next layer of concrete.

3.8.4.6.2 Concrete Testing

The concrete mix is designed in accordance with ACI 301-72, using method 1. Revisions of approved mix designs will be in accordance with method 2. The trial mixes are tested in accordance with the ASTM standards listed below:

Test	ASTM Designation
Making and curing of the test specimen	C192
Air content	C231
Slump	C143
Compressive	C39

Compressive strength tests are made at 7 and 28 days. A minimum of two cylinders are used for each test.

Concrete strength tests are evaluated in accordance with ACI 301 and ACI 214.

Strength of concrete is considered satisfactory if the averages of all sets of strength test results of the laboratory cured specimens at 28 days' age are equal to or greater than the specified compressive strength (f_c') of the concrete.

The Edison computer code Concrete Quality Assurance is used to evaluate the concrete compression strength tests. This program uses as input the 7- and/or 28-day test results, from individual or multiple concrete mixes, and plots the average strength as well as the moving averages to provide a means of forecasting the longterm trend of compression testing. Statistical means are used to find the concrete quality assurance variables, test averages, cumulated averages, moving averages, as the required average strength (RAS). The RAS value is calculated using the following formula:

$$\text{RAS} = \frac{\text{design strength}}{1-\text{(ACI constant) (coefficient of variation)}}$$

where the ACI constant depends on the allowable number of tests with results falling below the design strength specified in ACI 2l4.

The field tests for slump of portland cement concrete are in accordance with ASTM C43. Any batch not meeting specified requirements is rejected. Slump tests are made frequently during concrete placement and each time concrete test specimens are made.

If cylinders should fail to meet the concrete strength requirements at 28 days, strength development and design strength requirements are reviewed. Where necessary, nondestructive tests and core tests are conducted in accordance with ASTM C42, "Method of Obtaining and Testing Drilled Cores and Sawed Beams of Concrete."

3.8.4.6.3 Reinforcing Steel

All reinforcing conforms to Grade 60 of the Standard Specification for Deformed Billet-Steel Bars for Concrete Reinforcement, ASTM A6l5.

Mill test reports showing actual chemical and physical properties, including bend tests, are furnished for each heat of steel used in making all reinforcing steel furnished.

Placing of reinforcing steel conforms to the requirements of Chapter 5 of ACI 30l, "Structural Concrete for Buildings," and Chapter 7 of ACI 3l8, "Building Code Requirements for Reinforced Concrete."

Typical reinforcing steel details are shown in Figures 3.8-33 through 3.8-38.

In addition to ASTM A615, Grade 60, reinforcing steel for the second set of Category I 4160-V ductbanks, manholes and cable vaults conforms to the requirements of ACI 301, “Structural Concrete for Buildings”, ACI 349-01, “Code Requirements for Nuclear Safety Related Concrete Structures” and RG 1.142, “Safety-Related Concrete Structures for Nuclear Power Plants (Other Than Reactor Vessels and Containments)”.

3.8.4.6.4 Reinforcing-Steel Inspection and Testing

The testing of reinforcing bars was generally in accordance with Regulatory Guide 1.15, Testing of Reinforcing Bars for Concrete Structures, as modified below. (Regulatory Guide 1.15 was withdrawn by the NRC in July 1981.)

At least one full-diameter specimen of each bar size from every heat is control tested in accordance with ASTM A615.

Tests are performed in the field test laboratory under the jurisdiction of Edison under the direct supervision of qualified personnel.

Three test samples of each bar size and heat are obtained from the fabricator upon his receipt of an acceptable shipment from the mill. Tensile and bend tests are performed, and, if acceptable, the fabricator is authorized to proceed with fabrication.

Reinforcing concrete steel is fabricated from certified material that has been accepted by Edison. Bending conforms to ACI 318 or ACI 349-01.

3.8.4.6.5 Reinforcing-Steel Splices

Where required by space limitations or by design requirements, splices in reinforcing bars are made by cadwelding. Cadwelding is done according to written field procedures that conform to the intent of Regulatory Guide 1.10 (withdrawn in July 1981).

In order to qualify operators for making cadweld process joints, each operator is required to prepare two qualification splices for each of the splice positions to be used. The joints are tensile tested, simulating field conditions and using the same materials as those to be used in the structure.

The ends of the reinforcing-steel bars to be joined by the Cadweld process are saw cut or flame cut. The ends of the bars are thoroughly cleaned of all rust, scale, grease, oil, water, or other foreign matter before the joints are made.

3.8.4.6.6 Cadweld Testing and Inspection

Cadweld process splices are visually inspected in accordance with Regulatory Guide 1.10 (withdrawn in July 1981). Visual inspection includes random inspection of the ends of the bars for dryness and cleanliness prior to fitting the sleeve over the ends.

Completed splices are accepted or rejected according to the criteria described in the following:

Accept

a. Sound metal visible at both ends of the splice sleeve and at the tap hole in the center of the splice sleeve

b. Filler metal may be recessed 1/8 in. to as much as 1/2 in. from end of sleeve. Recessing is due to "bulging" of packing material

c. Presence of a single shrinkage bubble below riser

d. Radial pencil lines with "stars" or dendritic gas "pipes" when not combined with other indications

e. Splice sleeve not concentric and/or rebars not in axial alignment

f. Compression-only splices with solid metal in the tap hole may have voids to a maximum of 1 in. either as spot voids or complete circumferential low fill.

Reject

a. Presence of slag and the absence of solid metal in tap hole

b. Absence of filler at one end of horizontal splice

c. Absence of filler metal at top end of vertical splice

d. Porous metal in tap hole (general porosity).

Randomly selected cadweld splices based on position, size of rebar, and operator are removed from the structure and tensile tested, or a combination of production and companion splices is tested. Testing is in accordance with the following schedule if only production splices are tested:

a. One production splice of the first 10 splices

b. One production splice of the next 90 splices

c. Two production splices of the next and subsequent groups of 100 splices.

If combinations of production and companion splices are tested, the sample frequency is as follows:

a. One production splice of the first group of 10 production splices

b. One production and three companion for the next 90 production splices

c. Three splices, either production or companion splices, for the next and subsequent groups of l00 splices. At least one-fourth of the total number of splices tested are to be production splices.

When companion splice only is required, the following schedule

a. One companion splice of the first group of 10 splices (the companion splice is included in the group count)

b. Three companion splices of the next group of 90

c. Subsequent testing to be done at the rate of three companion splices included in each 100 splices made in accordance with the following schedule:

   1. One of the first group of 30 splices

   2. One of the last group of 30 splices

   3. One of the middle group of 40 splices.

The tensile strength of each sample tested equals or exceeds 125 percent of the specified minimum yield strength for the grade of reinforcing bar used. Failure of any splice to achieve 125 percent of the specified minimum yield strength is evaluated in accordance with Section 5 of the Procedure for Sub-Standard Tensile Test Results as given in Regulatory Guide l.l0, Mechanical (Cadweld) Splices in Reinforcing Bars of Concrete Containments.

3.8.4.6.7 Structural Steel

Structural steel material, erection, and fabrication tolerances are in accordance with the l969 AISC Specification. In general, steel used for structural framing conforms to ASTM A36.

Certified copies of mill test reports showing actual chemical and physical properties are furnished for each heat of steel in accordance with ASTM A6.

Welding of structural steel is in accordance with AWS Dl.0-69, AWS D1.1-72, and AWS D1.1 later issues as well.

The material installation and inspection of high-strength bolts, in general, conform to the requirements of the specification for structural joints using ASTM A325 or A490 bolts.

3.8.4.6.8 Summary of Quality Assurance for Construction and Construction Materials

The Quality Assurance Program, implemented with a full and complete field quality control system, has provided documented assurance that the structural work at the site, including all concrete, reinforcing steel, miscellaneous steel, structural steel, and all ingredients and special processes used in producing the aforementioned items, is in accordance with the project specification requirements and the applicable ACI, ASTM, and AISC standards.

The results of the continuous concrete and reinforcing bar testing program, carried out at the site laboratory, have confirmed the effectiveness of the controls. All reinforcing has met or exceeded the design tensile strength requirements, and the evaluation program for monitoring the concrete cylinder compression test results shows a continuous average strength well above the project specification requirements.

3.8.4.7 Testing and Inservice Surveillance Requirements

Secondary containment leak-rate testing is discussed in Subsections 6.2.1.4.2, 6.2.3.3.2, and 14.1.3.2.51.

Some cracking of the reactor building exterior walls may occur during an SSE, but large, predominantly open cracks are not expected. Therefore, the leakage rate from the reactor building will not change significantly subsequent to an SSE.

No other preliminary structural integrity or performance tests are conducted on the reactor/auxiliary building or RHR complex structures. However, rigorous inspection techniques and QC procedures are adopted throughout their construction, as indicated in Subsection 3.8.4.6.

3.8.5 Foundations and Concrete Supports

3.8.5.1 Description of Foundations and Supports

The reactor/auxiliary building is supported by a reinforced-concrete basemat (Figure 3.8-39), approximately 4 ft thick. A 77-ft-diameter by l9-ft-high reinforced-concrete pad, integral with the base and centered under the RPV, supports the biological shield, drywell, reactor support pedestal, and all other structures internal to the containment (Figures 3.8-40 and 3.8-41). The RHR complex is supported by a reinforced-concrete basemat approximately 4 ft thick.

The RHR complex and the reactor/auxiliary building foundation mats bear on bedrock at approximately Elevations 551.0 and 536.0 ft, respectively.

The dead weight of the RHR complex is designed to offset the remote and unlikely occurrence of building flotation. Therefore, anchoring of the reservoir bottom is not necessary.

Category I equipment is adequately anchored to and/or supported by concrete supports. The mass of the concrete supports is generally a minimum of 2-1/2 times the mass of the supported equipment. The concrete supports and anchorages for the following Category I machinery and equipment are discussed:

a. HPCI pump and turbine

b. RCIC pump turbine and barometric condenser

c. RHR pumps

d. Core spray pumps.

The HPCI pump and turbine foundation (Figure 3.8-42) is located in the subbasement of the auxiliary building at Elevation 540.0 ft. The pump and turbine foundations consist of reinforced-concrete pads poured monolithically with each other and connected integrally with dowels to the auxiliary building basemat. The HPCI turbine concrete pad is approximately 13 ft 1-1/8 in. by 6 ft 2-1/2 in. in plan and 2 ft 8 in. high; the HPCI pump concrete pad is approximately 16 ft 5 in. by 6 ft 2-1/2 in. in plan and 3 ft 11 in. high.

The RCIC pump and turbine and barometric condenser foundations (Figure 3.8-43) are located in the subbasement of the auxiliary building at Elevation 540.0 ft. The foundations consist of reinforced-concrete pads poured monolithically with each other and integrally connected with dowels to the auxiliary building basemat. The RCIC pump pad is approximately 5 ft 5 in. by 4 ft 8 in. in plan and 2 ft 1 in. high; the RCIC turbine pad is 7 ft 1 in. by 4 ft 8 in. in plan and 2 ft 11/l6 in. high; and the barometric condenser pad is 3 ft 4 in. by 4 ft 4 in. in plan and 6 in. high.

Foundations for four RHR pumps (Figure 3.8-44) are provided at the west end of the reactor building subbasement floor at Elevation 540.0 ft. Each pump is supported by a circular steel sole plate 2-1/2 in. thick and 7 ft 6 in. in diameter; this plate is directly anchored to the reactor building base mat by 24 anchor bolts (2 in. in diameter and 2 ft 3 in. long) equally spaced along a 7-ft-diameter bolt circle. The underside of the sole plate contains a rectangular grid pattern of grout grooves 1 in. wide and 3/8-in. deep. The sole plates rest on a 1-1/2-in. grout pad; the final elevation of the top of the sole plate is 540.0 ft. Leveling screws are provided in the plates to facilitate leveling before the plates are grouted in. The sole plates are drilled and tapped for 16 bolts, 1-3/4 in. in diameter, equally spaced along a bolt circle, about 2 ft 8 in. in diameter, to receive the RHR pumps.

Foundations for four core spray pumps (Figure 3.8-45) are provided in the auxiliary building subbasement floor at Elevation 540.0 ft. Each pump is supported by a steel sole plate that is 2 in. thick and 5 ft 5 in. in diameter; this plate is anchored directly to the auxiliary building basemat by 16 anchor bolts (1-3/4 in. in diameter and 2 ft long) equally spaced along a bolt circle that is 4 ft 10 in. in diameter. The undersides of the sole plates contain a rectangular grid pattern of grout grooves 1 in. wide by 3/8 in. deep. Leveling screws are provided in the sole plate to facilitate leveling prior to placing a 2-in. grout pad under the sole plates. The sole plates are drilled and tapped for 16 bolts, 1-5/8 in. in diameter, equally spaced along a bolt circle, 2 ft 8 in. in diameter, to receive the core spray pumps.

Figure 3.8-46 shows typical reinforcing patterns at the junction of reinforced-concrete walls and the foundation basemat. Typical anchor bolt details for Category I equipment are shown in Figure 3.8-47.

3.8.5.2 Applicable Codes, Standards, and Specifications

This section lists the codes, specifications, standards of practice, regulatory guides, and other accepted industry guidelines that have been adopted to the extent applicable in the design and construction of foundations and anchorages for Category I structures and equipment. To eliminate repetitious listing, the codes, standards, and specifications are described in Table 3.8-4 and given a specification reference number. The following are the specification reference numbers for the foundations:

a. 1 through 9 inclusive

b. 11 through 21 inclusive

c. 23 and 28

d. 33 through 35 inclusive

e. 38, 39, and 41.

3.8.5.3 Loads and Loading Combinations

The load combinations and load factors given in Tables 3.8-19 and 3.8-20 have been applied in the design of reinforced-concrete foundations and supports for Category I structures and equipment. The following is a brief description of the loads for which the RHR complex and reactor/auxiliary building basemats and foundation walls have been designed:

a. Dead load

b. Live load (the live load on the reactor building basemat is 350 lb/ft^2)

c. Equipment load

d. Wind load (Subsection 3.3.1)

e. Tornado load (Subsection 3.3.2)

f. Seismic load - Horizontal and vertical accelerations are applied for both OBE and SSE

g. Lateral pressure on subsurface walls - The lateral pressures due to soil and water under static and dynamic conditions are as shown in Figures 3.8-48 and 3.8-49

h. Hydrostatic loads - Foundation walls and basemats are designed for the following water levels:

   1. Design water levels at Elevation 576 ft

   2. Maximum design flood level at Elevation 588 ft (for wave forces, see Subsection 2.4.5).

i. Hydrodynamic loads - Foundation walls are designed for the hydrodynamic forces associated with ground water in motion under both OBE and SSE. For a complete discussion of this effect, refer to Section 3.7

   The RHR complex reservoir walls are designed for the hydrodynamic forces of water in the reservoir due to ground motions during both OBE and SSE

   The reactor building basemat has been designed for torus uplift loads that occur during earthquake, accident and safety/relief valve loading conditions (Reference 19)

j. Surcharge loads - The surcharge load of 500 lb/ft^2 was investigated

k. Thermal loads - The following thermal gradients were applied to the foundation walls:

   1. A 70°F ambient inside temperature under normal operating conditions and a 50°F ambient rock/soil temperature outside

   2. A 170°F ambient inside temperature under accident conditions and a 50°F ambient rock temperature outside. This applies to the reactor building subbasement.

All loads interior and exterior to the building are transferred to the basemat through elastic deformation of the slabs, supporting walls, and columns. Differential settlements of the mat foundations are not anticipated, because they are supported by rigid bedrock.

The foundation mats are properly sized and reinforced to accommodate the total overturning moments caused by winds and tornadoes without exceeding the allowable rock bearing stress at the toe of the mat while keeping the resultant upward soil reaction within the middle third of the mat area. Passive resistance of the soil acting against the foundation walls was neglected in computing the resisting overturning moments. Moreover, any uplift resistance that may be provided by bond of the concrete to the bedrock was neglected.

Horizontal translation of the mat foundations caused by wind loading is resisted by the frictional force between the concrete mat and the bedrock. Passive resistance of the soil acting against the subgrade walls was neglected. In computing the frictional resistance, the resultant uplift force caused by the hydrostatic pressure at the base of the mat was deducted from the building dead load.

The ability of the buildings to resist torsional rotation when engulfed by a tornado is provided by the adhesive forces between the building subgrade walls and soil, and the frictional resistance between the concrete basemats and bedrock.

In general, Category I concrete equipment supports and anchorages are designed for the following loads:

a. Dead load of the equipment

b. Seismic loads - Horizontal and vertical accelerations for both OBE and SSE

c. Operating live loads - This includes overturning moments and base shears caused by rotating or reciprocating type equipment, including short circuit or seizure moments and reactions from piping connected to the machinery

d. Impact loads - To account for the effects of impact and vibration, all centrifugal and rotating equipment support reactions were increased by 20 percent.

All equipment supports and anchorages are designed to behave elastically.

3.8.5.4 Design and Analysis Procedures

The design and analysis of the mat foundations and concrete supports for all Category I structures and equipment are in accordance with conventional elastic techniques. The mat foundations have been analyzed as a "mat on a rigid foundation." The boundary conditions selected for all structural models are determined by evaluating the stiffness (flexural, torsional, and axial) of all the members connected at a boundary point and represent (to the extent practicable) the actual restraint conditions. Loads are transferred from the foundation mats to the bedrock by direct bearing contact pressure. Because the rock provides a rigid support for the basemats, concentrated loads acting on the mats are not uniformly distributed over the area of the mat, and this effect is accounted for in the design of the mat. The analysis procedures for the reactor/auxiliary building and RHR complex mats neglect any uplift resistance (negative bearing pressure) that may be afforded by the bonding of the concrete to the bedrock.

To determine the seismic forces acting on the mat, the supported structure was analyzed by means of the computer programs DSASS and DYNAS (Section 3.13). To analyze the mat foundations for hydrostatic uplift pressures and thermal loads, the computer programs SOR-III and TEMCO-III, respectively, were used (Section 3.13).

The drywell pedestal (77 ft in diameter and 23 ft high, including the 4-ft-thick mat) for the support of the RPV, drywell, and biological shield was analyzed and designed in connection with the biological shield. The horizontal base shears and overturning moments from these structures induced by OBEs and SSEs and normal and operating accident conditions (including jet impingement forces from the complete and instantaneous severance of one of the largest connecting pipes) were applied at the top of the concrete pad. The critical section for the pad is at its base; the pad was designed taking special precautions to consider the net overturning moment at the base. Figure 3.8-41 shows the reinforcing plan at the top of the drywell pedestal.

3.8.5.5 Structural Acceptance Criteria

The allowable stresses and strains for the reinforced-concrete mat foundations and supports are in accordance with the provisions of ACI 318-71 for the RHR complex and ACI 318-63 and/or ACI 318-71 for the reactor/auxiliary building.

Serviceability checks are made in accordance with the above codes to ensure adequate crack control for the mat foundations and to limit deformations of the concrete supports within the limits prescribed by ACI 318-71 (for the RHR complex) and ACI 318-63 (for the reactor/auxiliary building) or the manufacturers' recommendations for equipment supported by the concrete supports.

A study by Dames & Moore (D&M) for the RHR complex foundation (see Reference 18) showed that the bedrock is permeable because of its fragmented nature and the presence of interconnected solution cavities (vugs). An evaluation of the rock quality based on measurements from core recovery indicated that the upper 15 to 20 ft is fractured. Based on results of compression tests on core samples and applying a reduction factor to account for the rock fractures, it was estimated that the ultimate bearing capacity of the rock is on the order of 300 ksf. In the design of the mat foundations, an allowable bearing capacity of 25 ksf was adopted, thereby providing a safety factor of 12 against bearing failure.

Furthermore, as specified in the Uniform Building Code, the minimum safety factor to be adopted against overturning is 1.5. In determining the safety factor (ratio of resisting moments to overturning moments), the resisting moment of the passive soil pressure against the subgrade walls was neglected. Also, the resultant of the base bearing pressure was kept within the middle third of the basemat.

The safety factor against base sliding (ratio of the resisting forces to driving forces) was taken as a minimum of 1.5. Moreover, the passive pressure of the soil against the subgrade walls was neglected in determining the resisting forces.

Differential settlements of the mat foundations are not expected, because they rest on essentially rigid bedrock. The load and load combinations, and the resulting factors of safety, are shown in Table 3.8-22.

3.8.5.6 Materials, Quality Control, and Special Construction Techniques

The construction materials used for the mat foundations, concrete supports, and machinery and equipment anchors conform to the standards set forth in Subsection 3.8.4.6, which contains a discussion of the QC procedures adopted (including the frequency and location of sampling and test requirements for the materials). Cadwelding is also described in detail.

A description of the construction procedures for the RHR complex mat is included here. A small amount of bedrock was removed prior to the placement of the structure's foundation. This rock was removed by a controlled and monitored program of blasting.

The blasting criteria and monitoring program ensured a minimal impact on the environment, including nearby residents. The excavation was dewatered by sump pumps, which included backup pumps in case of pump failure or other system malfunctions. Observation wells both on and off the site were used to monitor the ground-water level during construction to ensure that an unacceptable lowering of the adjacent ground-water level did not occur. Dewatering in the area of the RHR complex has been discontinued.

Pressure grouting of 15 to 20 ft of the upper rock layers was carried out to provide assurance that no zones of excessive fracturing or highly vugged material are horizontally continuous across the site. In consideration of the high sulfate content of the natural ground water, sulfate-resistant cement (Type V) is used for all cement grout and subsurface concrete that is in contact with the ground water. Grouting was accomplished in two stages, extending to depths of about 6 and 20 ft below the foundation level, respectively. Initial or primary holes within each zone were spaced 30 ft on centers, and final closure was achieved by grouting intermediate holes as required. The grout holes were drilled under qualified engineering supervision. The drilling methods permitted any zones of excessive fractures, vugs, or soil seams to be detected, and particular attention was given to these zones in subsequent grouting operations.

The foundations of the RHR complex are installed on the Bass Islands dolomite and are designed to limit the bearing pressures to values much less than the safe bearing capacity of 50,000 lb/ft^2.

As the foundations of the reservoirs are below the natural ground-water level, they are subject to uplift pressures when the reservoir is empty. The reservoir could be totally empty for possible maintenance. Flotation of the reservoirs has been prevented by using a 4-ft basemat.

Site fill is crusher-run rock material, predominantly dolomite 1-1/2 in. and smaller in diameter. It is placed in loose horizontal lifts approximately 12 in. deep. Each lift is compacted with a vibration roller similar to that used in the compaction test area. Dames & Moore conducted a seismic investigation of the compacted crushed rock (see Reference 20) and measured both compression and shear waves. These data were incorporated into the design of the Category I buildings. The RHR complex, being a Category I facility, was designed by applying the seismic design criteria used for the reactor/auxiliary building.

3.8.5.7 Testing and Inservice Surveillance Techniques

Preliminary field explorations were conducted to evaluate the soil and rock conditions at the Fermi 2 site. The field investigation consisted of the following:

a. Geologic test boring program - All geologic borings were logged in detail, and a general description of the soils and rocks encountered at the site was recorded (Subsection 2.5.1.2)

b. Water pressure tests - Pressure tests were performed during the drilling of representative borings to evaluate the bedrock (Subsection 2.5.1.2)

c. Piezometer observations - Piezometers were installed in several borings to study the seasonal fluctuations of the ground-water table; periodic ground-water level measurements were taken (Subsection 2.4.13.2)

d. Geologic reconnaissance - A geologic reconnaissance of the quarry that serves as a source of fill material for the site area was carried out to assist in the interpretation of subsurface conditions (Subsection 2.5.1.2).

In addition to the field explorations, the following laboratory tests were performed on undisturbed soil samples extracted from the borings to evaluate the physical properties of the soil and fill materials at the site (Subsection 2.5.1.2):

a. Unconfined compression tests - The purpose of this test was to determine the stress-strain characteristics of the soil. In addition, laboratory unconfined compression tests were performed on representative rock samples to determine the strength of the rock

b. Pulsating triaxial load tests - The pulsating triaxial load tests yield the dynamic moduli of elasticity and the shear moduli for the soils. The shear moduli of the bedrock were computed using the elastic relationships between the shear modulus, the modulus of elasticity, and Poisson's ratio. The moduli of subgrade reaction for the bedrock were computed by using the relationship between the subgrade modulus, the modulus of elasticity, Poisson's ratio, and the size of the loaded area used for the pulsating triaxial load specimen

c. Consolidation tests - The consolidation tests indicate the load-settlement properties of the soils

d. Moisture and density tests.

Routine observations are made of the mat foundations and concrete supports to determine the existence, if any, location, and extent of cracking. Representative equipment anchor bolts are tested periodically for tightness.

Rigorous inspection was carried out during construction in conjunction with the QC procedures outlined in Subsection 3.8.4.6 for the structural materials.

[a] In design and operation, inspection, etc. of structures and other components for Fermi 2, it has been the practice to specify the use of code(s) and the related design guides applicable at the initiation of the design activity. In the course of design process, the use of later editions of the code and/or any supplements issued thereto has been allowed.

[b] Appendix A adopted for seismic design.

[c] Official building code of Frenchtown Township.

TABLE 3.8-7 LOADS AND LOADING COMBINATIONS FOR THE DRYWELL VENT PENETRATIONS

Design Category	Load Combination	Stress Comparison[a]
I	E_s	$P_m \leq S_m$ @ T_d
		$P_1 + P_b \leq 1.5\ S_m$ @ T_d
II	$R_p + R_t$	$P_m \leq S_m$ @ T_a
		$P_1 + P_b \leq 1.5\ S_m$ @ T_a
III	$R_p + P_t + E_s$ + Design	$P_1 \leq 1.1\ S_m$ @ T_a
		$P_1 + P_b \leq 1.5\ S_m$ @ T_a

E_s = Maximum seismic reaction due to SSE "g" loads on vent header

R_p = Piping reaction due to maximum accident pressure expansion between drywell and suppression pool.

R_t = Piping reaction due to maximum accident thermal expansion between drywell and suppression pool

Design = Maximum general stresses calculated at vent penetration in Table 3.8-5

T_d = Design temperature

T_a = Temperature associated with design accident

---

[a] Stress nomenclature in accordance with the ASME B&PV Code Section III.

TABLE 3.8-8 LOADS AND LOADING COMBINATIONS FOR THE DRYWELL SPHERICAL EMBEDMENT

Design Category	Loading Combination	Stress Comparison[a]
I	Design + P_a + T_a	$P_1 \leq 1.5\ S_m$ @ T_a
		$P_1 + P_b + Q \leq 3.0\ S_m$ @ T_a

P_a = Pressure loading due to design accident

T_a = Temperature corresponding to design accident

Design = Maximum general shell stress due to loading in Table 3.8-5 for the specific location of the spherical embedment

[a] Stress nomenclature in accordance with the ASME B&PV Code Section III.

TABLE 3.8-9 LOADS AND LOADING COMBINATIONS FOR THE DRYWELL KNUCKLE REGION (ACCIDENT LOADS)

Design Category	Loading Combinations	Stress Comparison[a]
I	Design + P_a	$P_1 \leq S_m$ @ T_a
		$P_1 + P_b \leq 1.5\ S_m$ @ T_a

P_a = Operating pressure associated with design accident condition

Design = Maximum general shell stress in the knuckle region calculated from Table 3.8-5 for condition 8

T_a = Temperature associated with design accident

[a] Stress nomenclature in accordance with the ASME B&PV Code Section III.

TABLE 3.8-10 LOADS AND LOADING COMBINATIONS FOR THE DRYWELL CONE AND TOP HEAD

Design Category	Loading Combinations	Stress Comparison[a]
I	Design P_a	$P_1 \leq S_m$ @ T_a
		$P_1 + P_b \leq 1.5\ S_m$ @ T_a

P_a = Operating pressure associated with design accident condition

T_a = Temperature associated with design accident

[a] Stress nomenclature in accordance with the ASME B&PV Code Section III.

TABLE 3.8-11 LOADS AND LOADING COMBINATIONS FOR THE TOP DRYWELL FLANGE

Design Category	Loading Combination	Stress Comparison[a]
Operating		
I	$D_b + P_o + W_s$	$P_m \leq S_m$ @ T_d
II	$D_b + P_v + W_s$	$P_1 + P_b \leq 1.5\ S_m$ @ T_d
Refueling		
I	$D_b + W_s$	$P_m \leq S_m$ @ T_d
II	Ws	$P_1 + P_b \leq 1.5\ S_m$ @ T_d
Accident		
I	$D_b + P_a$	$P_m \leq S_m$ @ T_a
II	$D_b + P_v$	$P_1 + P_b \leq 1.5\ S_m$ @ T_a

D_b = Design bolting load calculated for gasket seating and for internal pressure

P_o = Design pressure during normal operation

P_v = Design vacuum pressure

P_a = Design accident pressure

W_s = Design loads due to the weight of the water seal, together with loads imposed by the expansion bellows

T_d = Design temperature

T_a = Temperature associated with design accident

---

[a] Stress nomenclature in accordance with the ASME B&PV Code Section III.

TABLE 3.8-12 LOADS AND LOADING COMBINATIONS FOR THE EQUIPMENT HATCH

PRESSURE-RETAINING PARTS

Design Category	Loading Combination	Stress Comparison[a]
I	P_a	$P_m \leq S_m$ @ T_a
		$P_l + P_b \leq 1.5\ S_m$ @ T_a
II	$P_a + R_a$	$P_m \leq 0.9\ S_y$ @ T_{jet}

P_a = Accident pressure load

R_a = Jet force associated with pipe rupture

T_a = Temperature associated with design accident

T_{jet} = Temperature at the jet

STRUCTURAL PARTS

Design Category	Loading Combination	Stress Comparison[a]								
		Tension		Bending		Bearing		Shear		Weld
		P_L	Bolt	P_L	Bolt	P_L	Bolt	P_L	Bolt	
I	$D + L + P_a$	S_m	S_m	1 1/2 S_m	1 1/2 S_m	1.6 S_m	1.6 S_m	.4 F_y	.8 S_m	.8 S_m
		(17.5)	(25)	(26.25)	(37.5)	(28)	(40)	(14.5)	(16)	(14)

		11	$F = 1.0(D + L + R_o + W_t + T_o)$
		12	$F = 1.0(D + L + C + R_o + T_o + H)$
VII	Abnormal/severe environmental	13	$F = 1.0(D + L + C + R_a + E_o + T_a + P_a + Y_r + Y_j + Y_m)$
VIII	Abnormal/extreme environmental	14	$F = 1.0(D + L + C + R_a + E_s + T_a + P_a + Y_r + Y_j + Y_m)$

[a] Loads not applicable to a particular system under consideration may be deleted. If for any load combination the effect of any load other than D reduces the load, it will be deleted from the combination. For both E_s and E_o, the resultant effects (resultant stresses) at both horizontal and vertical earthquake components shall be determined by combining the individual effects by the square root of the sum of the squares. This procedure also applies when combining the dynamic effects of W_t, M, R_a, and P_a.

[b] F = Working load.

[c] See Table 3.8-21 for definition of terms.

[d] For allowable stresses, see Table 3.8-19.

TABLE 3.8-19 ALLOWABLE DESIGN STRESSES

	Loading Condition	Structural Steel F_y = 36,000 psi: Tension (F_t) and Bending (F_b)	Structural Steel F_y = 36,000 psi: Compression (F_a)	Concrete* f'_c = 4000 psi, n = 8: Basic Design Stress	Concrete* f'_c = 4000 psi, n = 8: Compression Stress	Reinforcing Bars F_y = 60,000 psi: % F_y	Reinforcing Bars F_y = 60,000 psi: Tensile Stress F_s
A	Dead load (D.L.) + live load (L.L.)	F_t and F_b from Section 1.5, Appendix A, 1969 AISC Specification	F_a from Table 1-36 of 1969 AISC Specification	From ACI 318-63	$f_c = 0.45\ f'_c$	0.4 F_y	24,000 psi
B	D.L. + L.L. + OBE	F_t and F_b from Section 1.5, Appendix A, 1969 AISC Specification	F_a from Table 1-36 of 1969 AISC Specification	From ACI 318-63	$f_c = 0.45\ f'_c$	0.4 F_y	24,000 psi
C	D.L. + 0.50 L.L. + OBE + forces due to thermal expansion and snubber loads	F_t and F_b from Section 1.5, Appendix A, 1969 AISC Specification	F_a from Table 1-36 of 1969 AISC Specification	From ACI 318-63	$f_c = 0.45\ f'_c$	0.4 F_y	24,000 psi
D	Case B, except SSE instead of OBE	$F_t = F_b = F_y$	1.67 x Case A	1.67 x Case A	$f_c = 0.85\ f'_c$ maximum	1.67 x Case A	0.9 F_y maximum = 54,000 psi
E	Case C, except SSE instead of OBE	$F_t = F_b = F_y$	1.67 x Case A	1.67 x Case A	$f_c = 0.85\ f'_c$	1.67 x Case A	0.9 F_y maximum = 54,000 psi
F	D.L. + L.L. + basic design wind	1.33 x Case A	1.33 x Case A	1.33 x Case A	$f_c = 0.60\ f'_c$	1.33 x Case A = 0.53 F_y	31,800 psi
G	D.L. + L.L. + tornado wind design or maximum	$F_t = F_b = F_y$	1.67 x Case A	1.67 x Case A	$f_c = 0.85\ f'_c$ maximum	1.67 x Case A	0.9 F_y maximum = 54,000 psi

D.L. = Dead load of structure and equipment plus any other permanent loads, such as soil or hydrostatic loads or operating pressure.

*Concrete with 4000 psi specified compressive strength (f'_c) is generally used in Fermi 2. The use of other grades of concrete or use of higher strength for the same grade of concrete based on the time-strength relationship has been noted in corresponding design document package.

TABLE 3.8-20 LOADING COMBINATIONS FOR REINFORCED CONCRETE STRUCTURES, ULTIMATE STRENGTH DESIGN[a]

Load Combination Category		Load Condition No.	Overall Loading Equation[b,c,d,e]
I	Construction	1	$u = 1.3(D + L + C + W + T_o)$
II	Normal	2	$u = 1.4(D + R_o) + 1.7(L + C) + 1.3T_o$
III	Test	3	$u = 1.1(D + R_o) + 1.3(L + C + T_o)$
IV	Severe environmental	4	$u = 1.4(D + R_o) + 1.7(L + C + W) + 1.3T_o$
		5	$u = 1.2(D + R_o) + 1.7W + 1.3T_o$
		6	$u = 1.4(D + R_o) + 1.7(L + C) + 1.9E_o + 1.3T_o$
		7	$u = 1.2(D + R_o) + 1.9E_o + 1.3T_o$
		8	Deleted
V	Abnormal	9	$u = 1.0(D + L + C + R_a + T_a) + 1.5P_a$
		10	$u = 1.0(D + L + C + R_o + T_o + M)$
VI	Extreme environmental	11	$u = 1.0(D + L + C + R_o + Es + T_o)$
		12	$u = 1.0(D + L + R_o + W_t + T_o)$
		13	$u = 1.0(D + L + C + R_o + T_o + H)$
VII	Abnormal/severe environmental	14	$u = 1.0(D + L + C + R_a + T_a + Y_r + Y_j + Y_m) + 1.25(E_o + P_a)$
VIII	Abnormal/extreme environmental	15	$u = 1.0(D + L + C + R_a + E_s + T_a + P_a + Y_r + Y_j + Y_m)$

[a] Loads not applicable to a particular system under consideration may be deleted. If for any load combination the effect of any load other than D reduces the load, it will be deleted from the combination. For both E_s and E_o, the resultant effects (resultant stresses) at both horizontal and vertical earthquake components shall be determined by combining the individual effects by the square root of the sum of the squares. This procedure also applies when combining the dynamic effects of W_t, M, R_a, and P_a.

[b] u = Ultimate load.

[c] See Table 3.8-21 for definition of terms.

[d] Allowable stresses shall be according to ACI 318-71.

[e] Allowable loads shall be according to ACI 349-01 & RG 1.142, Rev. 2 for the second set of Category I underground ductbanks, manholes and above ground cable vaults.

TABLE 3.8-21 NOTES FOR TABLE 3.8-18 AND TABLE 3.8-20

C = Crane-lifted load.

D = Dead load of the structure plus any other permanent load except prestressing forces, including vertical and lateral pressures of liquids, piping, cable pan, self weight of crane, and weight of permanent equipment and its normal contents under operating and test conditions.

E_o = Operating-basis earthquake (OBE) including dynamic lateral soil pressure and hydrodynamic ground-water pressure

Horizontal ground acceleration = 0.08g

Vertical ground acceleration = 66-2/3 percent of the horizontal acceleration where g = 32.2 ft/sec^2.

E_s = Safe-shutdown earthquake (SSE) including dynamic lateral soil pressure and hydrodynamic ground-water pressure

Horizontal ground acceleration = 0.15g

Vertical ground acceleration = 66-2/3 percent of the horizontal ground acceleration where g = 32.2 ft/sec^2.

H = Forces associated with the maximum probable flood or seiches (see Section 3.4).

L = Conventional floor and roof live loads, movable equipment loads, and other loads that vary in intensity, such as lateral soil pressure. Live load intensities may vary from zero to their maximum values to determine the most critical effect upon the structure for the load combination under consideration.

Note: Reduced intensities of live loads such as conventional floor loads may be associated with accident or extreme environmental conditions.

TABLE 3.8-21 NOTES FOR TABLE 3.8-18 AND TABLE 3.8-20

M = Loads associated with both internal and external missiles (see Section 3.5).

$P_a^{(a)}$ = Pressure load caused by a postulated pipe break accident. Containment design accident pressures based upon peak calculated pressure with appropriate margin provided for uncertainties are:

Internal pressure	56 psig
External pressure	2 psig

P_o = Design pressure during normal operating condition. Containment design normal pressures are:

Internal pressure	2 psig
External pressure	atmospheric

P_t = Containment test pressure:

Internal pressure	70 psig
External pressure	atmospheric

R_a = Pipe reactions due to postulated break accident including R_o.

R_o= Normal operating reactions of piping at supports or anchor points.

S = Stability load.

$T_a^{(a)}$ = Thermal loads generated by postulated break accident including T_o. Containment temperatures associated with a design accident are:

Internal temperature of the suppression chamber	281°F
Internal temperature of the drywell	340°F
Minimum external temperature	50°F

TABLE 3.8-21 NOTES FOR TABLE 3.8-18 AND TABLE 3.8-20

T_o= Thermal effects associated with normal, construction, and test conditions:

(a) Climatic temperature ranges:

Maximum outside temperature	102°F
Minimum outside temperature	-18°F

(b) Operating temperature ranges:

Ambient temperature inside the reactor/auxiliary building and RHR complex	70°F

u = Ultimate load capacity as defined by ACI 318-71 [b]

W = Design wind load (see Subsection 3.3.1)

W_t = Tornado load (see Subsection 3.3.2)

Y_j = Jet impingement equivalent static load.

Y_m = Missile impact equivalent static load.

Y_r = Equivalent static reaction load from high-energy line break

---

[a] Since these loads are time dependent, their effects will be superimposed accordingly.

[b] Use ACI 349-01 for the second set of Category I underground ductbanks, manholes and above ground cable vaults.

TABLE 3.8-22 FACTORS OF SAFETY FOR CATEGORY I FOUNDATIONS

Category I Structure	Load Combinations				
	D+H+E	D+H+W	D+H+E’	D+H+W_t	D+F'
Reactor and aux. bldg.	1.92	26.70	1.32	2.85	1.76
RHR complex	1.78	22.20	1.43	2.43	1.10*

*The factor of safety for flotation of the RHR complex is computed based on the reservoirs totally empty

where

D = dead loads or their related internal moments and forces, including any permanent equipment loads and hydrostatic loads

E = loads generated by the operating-basis earthquake

W = loads generated by the design wind specified for the plant

E’ = loads generated by the safe-shutdown earthquake

W_t = loads generated by the design tornado specified for the plant; tornado loads include loads due to the tornado wind pressure, the tornado-created differential pressure, and tornado-generated missiles

H = lateral earth pressure

F’ = buoyant force of the probable maximum flood (PMF)

GENERAL DESIGN INSTRUCTIONS—(SEE SKETCH).

1. INDICATE ON DESIGN DRAWING THE LOCATION, ELEVATION OF TOP OF BOLT, DIAMETER LENGTH & TYPE OF ANCHOR (ALSO SLEEVE LENGTH FOR TYPE "CC" & BAR SIZE FOR TYPE "AA").
2. REFER TO THIS STANDARD DRAWING NO.
3. INDICATE ANY SPECIAL CONSIDERATIONS, IF OTHER THAN SHOWN IN TABLE, SUCH AS SLEEVE LENGTH, THREAD LENGTH EACH END, ETC.
4. KEEP LENGTH OF BOLT TO NEAREST ½" WHERE POSSIBLE.
5. THREAD TOP END OF ALL BOLTS TO A LENGTH EQUAL TO 4 x DIAMETER AND OTHER END TO A LENGTH EQUAL TO 1½ x DIAMETER—U.S. STANDARD COARSE THREAD — CLASS 3 (MEDIUM FIT).
6. USE HEAVY HEX NUTS, SEMI FINISHED, WASHER FACED.—CLASS 3 (MEDIUM FIT).
7. USE STANDARD HEX HEAD OR SQ. HD. BOLTS WHEREVER POSSIBLE.
8. ANCHOR BOLTS WILL BE ORDERED BY THE USING DIVISION.

SULPHUR & FLY ASH MIXTURE—
D.E. CO. STOCK #989-0099, IN 10# CANS. MAKES 1¼ QUARTS WHEN MELTED.
PREPARE HOLES IN CONCRETE AS INDICATED ABOVE & SET BOLTS IN PROPER POSITION. MELT PREMIXED MATERIAL IN MELTING POT SET AT 240°-250° F. STIR MELTED MATERIAL IN POT IMMEDIATLY BEFORE PURING AROUND BOLT. AVOID OVERHEATING, AT 270# F. MIX BEGINS TO THICKEN AND BECOMES DIFFICULT TO POUR TOO HIGH A TEMPERATURE WILL CAUSE MIX TO FUME EXCESSIVELY & TO CATCH FIRE. THIS MIXTURE HAS A HOLDING STRENGTH SEVERAL TIMES THAT OF LEAD. (D.E. CO. RESEARCH DEPT. REPORT 51H87.)

* THEORETICAL QUANTITIES, ADD APPROX. 10% WHEN ORDERING SULPHUR MIX.

3.9 MECHANICAL SYSTEMS AND COMPONENTS

3.9.1 Dynamic System Analysis and Testing

3.9.1.1 Piping and Rotating Equipment Test Program

3.9.1.1.1 Test Objectives

The piping of Fermi 2 is designed in conformance with the vibration requirements of the USAS B31.7-1969 Code for Pressure Piping and/or ASME Boiler and Pressure Vessel (B&PV) Code Section III, 1971 issue (including winter addenda). In accordance with the general objectives of this code, preoperational and startup phase vibration inspections will be conducted on piping systems and rotating equipment. These surveys will be performed with the following objectives in mind.

a. Observe that the vibration of the tested piping system is within acceptable limits

b. Provide baseline vibration signatures of rotating equipment which will serve as data for future comparison

c. Reveal potentially significant, equipment-induced resonances or pressure pulsations within the system and the operating modes during which they occur

d. Provide data to verify compliance with manufacturer's standards and tests, or existing Edison standards

e. Verify that the piping and support systems perform properly over the operating temperature range.

Table 3.9-1 lists the piping systems included in this test program and indicates the extent to which each system will be tested. Using the data collected during this testing and the acceptance criteria outlined in Subsection 3.9.1.1.5, each system will be evaluated for compliance with the original intent of the piping design criteria.

If the test results exceed the acceptance criteria for a given piping system, further evaluation will be performed to determine if it is necessary to modify the system. If the system is modified, additional testing of the modified system will be conducted if the modification significantly changes the vibratory behavior of the piping system.

Final design evaluation of safety-related piping systems has been performed in accordance with B&PV Code Section III after all modifications were completed.

Emergency and faulted-type transients, including such events as pump seizure, pipe rupture, etc., are not part of this testing program because these transients cannot be tested or simulated.

3.9.1.1.2 Rotating Equipment Vibration Testing

Vibration testing of the Fermi 2 rotating equipment was conducted during the preoperational and startup phases. The equipment tested is as follows.

Component	Quantity
Residual heat removal (RHR) and core spray pumps and motors (four each)	8
High pressure coolant injection pump and turbine	1
Reactor core isolation cooling pump and turbine	1
Reactor recirculation pumps and motors	2

The specific conditions for which vibration data has been obtained on each piece of equipment are as follows:

a. Design flow rate

b. Minimum normal flow rate

c. Maximum normal flow rate

d. Startup

e. Shutdown

To obtain vibration data for the rotating equipment, instrumentation has been installed temporarily on the various pumps and motors at locations that, based on the experience of Edison and the manufacturers, provide significant data. This instrumentation is used to measure bearing vibration or relative motion of the shaft, with respect to the case, in the axial and radial directions. Where possible, the vibration instrumentation is fastened to the machines using magnetic bases or some other temporary means. Instruments of an adequate type, number, and location already installed on machines can be used for testing.

Data is recorded on a multichannel, magnetic tape recorder. Narrow-band frequency spectrum analysis has been performed on these data to permit comparison of each frequency component with applicable criteria. The magnetic tape recording and its analysis is retained as permanent baseline data to permit identification of the deterioration of equipment performance.

In I&E Bulletin 79-15, the NRC identified concerns over the long-term operability of deep-draft pumps. In response to this, Edison described the steps being taken to ensure long-term operability of the pumps. These steps are

a. Quality verification of the pump and motor assembly during manufacture

b. Construction verification of the foundation and sump

c. Verification of proper installation and alignment of the pump assembly

d. Startup testing sufficient to verify pump capability and condition for long-term operability

e. Inservice surveillance testing using sophisticated vibration-measuring techniques to determine any degradation of internal components.

Inservice surveillance testing takes two forms: operational monitoring and diagnostic testing. Operational monitoring is performed by the operating instrumentation installed locally or in the control room. Thrust bearing temperature, on-off-auto control switches, and pump running status are all operationally monitored.

Surveillance testing consists of the following:

a. Determination of the total head developed by the pump

b. Measuring the flow from the pump

c. Measuring vibration of the pump-motor assembly using readings in velocity units.

These tests are aimed at providing the earliest possible detection of pump problems which exhibit the following symptoms:

a. Degradation of capacity or developed head

b. Excessive vibration

c. Excessive thrust bearing temperature.

Following repair and/or reassembly of a pump/motor unit, and/or during the Section XI inservice test, vibration base data will be taken prior to returning the unit to service.

The only safety-related deep-draft pumps used at Fermi 2 are the service water pumps.

3.9.1.1.3 Piping System Vibration Testing

Vibration surveys will be conducted on the piping systems listed in Table 3.9-1 during the preoperational and startup phases. For the majority of these systems, the system and plant conditions existing during the preoperational phase will be adequate to obtain vibration data representative of the piping vibration experienced during normal system operation.

Table 3.9-1 indicates the extent of vibration testing that will be performed on the piping systems and their supports. Normally, vibration data will be taken during steady-state operation of the system. Data will be taken also on portions of selected systems during specific transient events. These systems and the events are

a. Feedwater system piping from the feedwater pump discharge to the containment penetration, following a trip of a feedwater pump

b. High-pressure coolant injection (HPCI) system piping from the HPCI pump discharge to the feedwater system tee connection, after a rapid start of the HPCI turbine

c. Main steam piping from the turbine stop valve to the reactor vessel, after a turbine stop valve and control valve fast closure

d. Selected main steam safety/relief valve (SRV) discharge piping during SRV operation

e. Recirculation piping for a pump trip at 100 percent rated flow.

The vibration surveys will entail monitoring the overall system for indications of unacceptable vibratory response. Where appropriate, deflections, pressure pulsations, restraint forces, or accelerations will be monitored. The points that will be selected for monitoring will be, typically, those points which are predicted, either by experience or analysis, to undergo the highest deflections, pressure surges, operating stresses, or vibrations during system operation. Using the criteria of Subsection 3.9.1.1.5, the vibration data will be evaluated to determine the acceptability of the piping system design.

In addition to the piping systems listed in Table 3.9-1, safety- related small-bore piping and instrument lines will be included in the vibration surveys. Test, branch, bypass, and instrument lines attached to the piping systems in the areas selected for monitoring will be observed to ascertain that there will be no danger to personnel and no potential damage to the system under investigation.

Special attention will be given to ensure that these small lines are not in resonance with operating equipment or flow-induced vibrations of the attached large-bore lines.

Based on those observations, instrumentation and other lines 2 in. and smaller attached to the test system piping and to the system components in the piping areas selected for monitoring will be inspected visually for the following specific reasons:

a. To eliminate danger to personnel

b. To ensure that there will be no damage (such as fatigue failure) to the primary system at junctions with large piping and equipment.

Therefore, safety-related small-bore piping and instrument lines will be included in the test program, subject to the above considerations and, in general, covering only the junction points (taps, tees, etc.) with the main system piping under test as listed in Table 3.9-1. Such junction points are assumed to be the worst case for fatigue failure of the small-bore piping instrument lines. If the piping system itself is small-bore piping, as in the case of the control rod drive (CRD) lines, then the test program covers small-bore piping and instrument lines in its entirety (as limited by accessibility and personnel safety) at the system level.

For instrumentation lines that because of accessibility or personnel safety cannot be inspected during system operation, an inspection of the lines' routing and supports was completed prior to operation. The inspection verifies that the instrumentation lines have been adequately supported to resist vibrations caused by the header piping or equipment to which the lines are attached (as there is no flow in instrumentation lines, vibrations from header piping or equipment are the source of excitation). If it was determined that the lines were not adequately supported or routed, the routings were modified or supports were added to obtain an appropriate design.

3.9.1.1.4 Thermal Expansion Testing

The thermal expansion movements of piping systems identified in Table 3.9-1 will be monitored when these systems are heated initially to their normal operating temperatures. This testing will normally take place during the startup phase.

Prior to the heatup of a system, points of potential contact with other equipment will be identified. During heatup of the system, these points will be monitored to verify that free movement of the piping is not hindered.

The thermal expansion deflections of selected points of the piping systems will be monitored either visually or with test instrumentation. Normally, the points to be monitored will be those points that are predicted by the stress analyses to exhibit relatively large, thermally induced deflections. During heatup, data will be taken at temperature intervals that will allow abnormal conditions to be identified before specified limits are exceeded. An additional set of data will be taken when the monitored system returns to ambient temperature to verify that piping is free to contract during cooldown. The criteria of Subsection 3.9.1.1.5 will be used to evaluate the thermal expansion performance of the tested systems.

3.9.1.1.5 Acceptance Criteria for Piping Vibration and Thermal Expansion Testing

These vibration criteria apply only to the systems being monitored as part of the Vibration and Dynamic Effects Test Program (See Table 3.9-1). All piping systems are subject to various dynamic forces caused by fluid flow, some transient, some steady-state. Each piping system, because of its unique configuration, will vibrate at its own fundamental frequencies. These criteria are developed to detect any vibratory deflections of sufficient amplitude to cause the intent of the original design criteria to be violated.

Thermal expansion occurs as a result of any system heatup. When a piping system is designed, a flexibility analysis is performed that verifies analytically that the system configuration is not overstressed while undergoing the thermal growth expected to result from the change in system temperatures. The purpose of the thermal expansion testing is to verify that the actual thermal growth is reasonable and unrestricted and is within the parameters of the acceptance criteria contained herein.

3.9.1.1.5.1 Level 1 and Level 2 Criteria

When applicable, Level 1 and Level 2 acceptance criteria will be established. Violation of Level 1 acceptance criteria for those systems and locations being monitored indicates that the design limits of the piping may be exceeded during the tests. Further operation of the system in the offending mode of operation will be avoided. The system response will be evaluated and the violation will be resolved by analysis and/or corrective action.

Violation of Level 2 criteria indicates that stress levels exceed long-term operating criteria but that a short-term threat to the piping system integrity does not exist. Violations of Level 2 criteria will not require the halting of the test but will require post-test evaluation to be performed to ascertain if the apparent violation was of significance and to determine what, if any, system modifications may be necessary to bring the system into acceptable limits.

3.9.1.1.5.2 Steady-State Vibration Acceptance Criteria

The following allowable stress amplitude, S_a, will be used for steady-state piping vibration:

S_a = 7690 psi for carbon steels with UTS <80 ksi

S_a = 12,000 psi for stainless steels

These stress amplitudes represent values based on 80 percent of the alternating stress intensity at 10^6 cycles for carbon steels and 60 percent of the alternating stress intensity at 10^6 cycles for stainless steels divided by a factor of safety of 1.3. The values of alternating stress intensity are taken from Figures I-9.1 and I-9.2 of Appendix I of ASME B&PV Code Section III.

3.9.1.1.5.3 Transient Vibration Acceptance Criteria

Analyses have been completed for the piping systems that are expected to experience significant operational transients (main steam piping, main steam SRV discharge piping, and feedwater piping). For these systems the calculated responses are the basis of the acceptance criteria for the measured transient response.

For other systems which transient testing is to be completed, the piping will be instrumented and/or visually inspected during the transient. If the acceptance criteria are exceeded, the source of the transient will be eliminated, the piping or restraints will be modified, or it will be proved by detailed measurement or analysis that the stresses are acceptable.

3.9.1.1.5.4 Thermal Expansion Acceptance Criteria

The piping and its appurtenances will not be constrained from expanding or contracting. All interferences will be resolved. During heatup, actual expansion movements will be within the greater of a specified tolerance of the calculated values or ±0.25 in. Calculated or actual displacements of ±0.25 in. or less will be ignored. At steady-state operating temperatures, the actual movements will be within a specified tolerance of calculated values. Discrepancies from these criteria will be resolved.

3.9.1.2 Dynamic Testing Procedures

A description of the tests or analyses used in the design of safety-related mechanical equipment (e.g., pumps, valves, and heat exchangers) to withstand seismic loadings is given in Subsections 3.7.2 and 3.7.3.

Most of the safety-related mechanical equipment is situated in the secondary containment and isolated from the reactor coolant pressure boundary (RCPB) by two or more isolation valves. Fluid dynamics and associated vibrations generated in the RCPB cannot propagate beyond closed isolation valves and their rigid anchorages at the point of containment penetration. Consideration of dynamic hydraulic transients generated within an emergency core cooling system (ECCS) subsystem is provided by establishing the following design criteria.

a. Piping and components not designed to withstand the dynamic effects of pipe whip, must be part of redundant, physically separated subsystems so that single failure of one subsystem does not affect the operability of the redundant subsystem

b. Where systems are subjected to potential vibratory loadings due to the dynamic effects of fluid momentum changes (i.e., water hammer), the following measures are taken to avoid the causes of such changes:

    1. Motor-operated valves in the ECCS are not capable of closing or opening at speeds greater than 1.0 in./ sec. Catastrophic failure is improbable for motor- operated valves. Where exception to the above is probable (such

as a break occurring in the feedwater line and the instant flow reversal causing the check valves to slam closed), a detailed analysis was made, and the valves and piping have been designed to withstand such an event

2. The ECCS and feedwater pumps are not capable of fast starts under normal operating conditions, because the lines are filled with fluid. Seizure of the prime mover (motor or turbine) is considered a single failure in the ECCS and renders the complete subsystem inoperative. Pressures and fluid velocities in the ECCS systems, except HPCI and reactor core isolation cooling (RCIC), are such that a water hammer stemming from pump motor seizure can be tolerated within the ASME Code faulted limits. For the feedwater system, the circumferential pipe rupture is identified to be the controlling event. The feedwater flow reversal and check-valve-closure transient resulting from this event were analyzed and the pressure surges, or peak pressure, for this transient were calculated to be less than 2.8 times the system design pressure. Accordingly, a faulted design pressure transient of 2.8 times the system design pressure is used in the ASME B&PV Section III NB-3656 analysis of the Class 1 portion of the feedwater systems

   Transient pressure surges, or peak pressures, associated with pump seizure are less than those associated with pipe rupture and are, therefore, not limiting. Similarly, the calculated transient pressure surges, or peak pressures, associated with pump seizure in the HPCI and RCIC systems are less than 2.5 times the system design pressure. Thus, a faulted design pressure transient of 2.5 times the system design pressure is used in the NB-3656 analysis of these systems

3. Air and steam voids that may develop in a stagnant system due to leakage are prevented in the RHR and core spray systems by providing pump discharge check valves and automatic condensate or demineralized water charging on the pump discharge piping. The HPCI pump discharge piping, up to the normally closed injection valve, is kept charged with condensate water. See section 6.3.2.2.5 for further discussion of the HPCI keep fill system. The RCIC pump lines do not need a charging system because the condensate storage tank provides the same function. The pump suction piping is pressurized by the condensate storage tank. RCIC discharges to the feedwater line from the pump. Thus, the water in the discharge piping cannot leak into the higher pressure feedwater line

   Although system vents are located at the piping high points, air pockets resulting from poor or inadequate system drainage, filling and venting during and after maintenance or prior to startup, could result in severe water hammer. To preclude this, Edison has included appropriate cautions in the applicable system operating procedures

4. The dynamic effects of rapid check valve closure in the feedwater piping due to feedwater line break have been analyzed. The frequency of this transient is so much higher than the natural frequency of the system that vibratory amplification of the equipment responses will not occur.

c. The piping systems have been designed and analyzed to accommodate thermal expansion due to system operational transients. Procedures will be instituted during the preoperational testing phase to verify the validity of the analytical predictions of pipe displacements by measuring pipe movement and comparing the field data to analytical predictions (see Subsection 3.9.1.1.4). It will also be verified that pipe supports and restraints are loaded within their design range.

3.9.1.3 Dynamic System Analysis Methods for Reactor Internals

3.9.1.3.1 Forcing Functions and Dynamic Response of Reactor Internals

The major reactor internal components are subjected to extensive testing, coupled with dynamic system analyses, to properly describe the resulting flow-induced vibration phenomena incurred from normal reactor operation and from anticipated operational transients.

In general, the vibration-forcing functions for operational flow transients and steady-state conditions are not predetermined by detailed analysis. Special analysis of the response signals measured from reactor internals of similar designs are performed to predict amplitude and model contributions. Parameter studies useful for extrapolating the results from tests of internals and components of similar designs are performed. This vibration prediction method is appropriate where standard hydrodynamic theory cannot be applied because of the complexity of the structure and flow conditions. Elements of the vibration prediction method are outlined as follows.

a. Dynamic analysis of major components and subassemblies is performed to identify natural vibration modes and frequencies. The analysis models used for Category I structures are similar to those outlined in Subsection 3.7.2, Seismic System Analysis

b. Data from previous plant vibration measurements are assembled and examined to identify predominant vibration response modes of major components. In general, response modes are similar but response amplitudes vary among BWRs of differing size and design

c. Parameters are identified that are expected to influence vibration response amplitudes among the several reference plants. These include hydraulic parameters such as velocity and steam-flow rates, and structural parameters such as natural frequency and significant dimensions

d. Correlation functions of the variable parameters are developed that, when multiplied by response amplitudes, tend to minimize the statistical variability between plants. A correlation function is obtained for each major component and response mode

e. Predicted vibration amplitudes for components for the prototype plant are obtained from these correlation functions based on applicable values of the parameters for the prototype plant. The predicted amplitude for each dominant response mode is stated in terms of a range, taking into account the degree of statistical variability in each of the correlations. The predicted mode and frequency are obtained from the dynamic analysis of Item a. in this listing.

The dynamic model analyses also form the basis for interpretation of the prototype plant preoperational and initial startup test results (Subsection 3.9.1.3.2). Model stresses are calculated and relationships are obtained between sensor-response amplitudes and peak-component stresses for each of the lower normal modes. The allowable amplitude in each mode is that which produces a peak stress amplitude of $\pm$10,000 psi.

3.9.1.3.2 Preoperational Flow-Induced Vibration Testing of Reactor Internals

Fermi 2 reactor internals were tested in accordance with provisions of Regulatory Guide 1.20, Revision 2, for nonprototype Category I plants. The test procedure requires operation of the recirculation system at rated flow with internals installed (less fuel), followed by inspection for evidence of vibration, wear, or loose parts. The test duration was sufficient to subject critical components to at least 10^6 cycles of vibration during two- loop and single-loop operation of the recirculation system. At the completion of the flow test, the vessel head and shroud head were removed; the vessel was drained and major components were inspected on a selected basis. The inspection covered all components that were examined on the prototype design, including the shroud, shroud head, core support structures, the jet pumps, and the peripheral control rod drive and in-core guide tubes. Access was provided to the reactor lower plenum.

Reactor internals for Fermi 2 are substantially the same as the internals design configuration that was tested in prototype BWR/4 plants. Results of the prototype tests are presented in Reference 1. This report also contains additional information on the confirmatory inspection program.

3.9.1.4 Correlations of Reactor Internals Vibration Tests With the Analytical Results

Prior to initiation of the instrumented vibration test program for the prototype plant, extensive dynamic analyses of the reactor and internals were performed. The results of these analyses were used to generate the allowable vibration levels during the test. The results of the data analysis, vibration amplitudes, natural frequencies, and mode shapes were then compared to those obtained from the theoretical analysis.

Such comparisons provided the analysts with added insight into the dynamic behavior of the reactor internals. The additional knowledge gained was used in the generation of the dynamic models for seismic and LOCA analyses for Fermi 2. The models used for Fermi 2 were the same as those used for the vibration analysis of the prototype plant.

The vibration test data were supplemented by data from forced- oscillation tests of reactor internal components to provide additional information concerning the dynamic behavior of the reactor internals.

3.9.1.5 Analysis Method Under Loss-of-Coolant Accident Loading

Annulus pressurization refers to the loading on the sacrificial shield wall, reactor vessel, reactor vessel supports, and reactor internals caused by a postulated pipe rupture at the nozzle safe ends. The assumed break is an instantaneous guillotine rupture that allows mass and energy release into the drywell and annular region between the shield wall and the reactor pressure vessel (RPV).

The mass and energy released during this postulated pipe rupture results in the following:

a. An acoustic asymmetric loading on reactor internals, due to a rapid decompression of the annular region between the vessel and the shroud

b. A transient asymmetric pressurization of the annular region between the shield wall and the RPV

c. A jet stream release of the RPV and pipe inventory

d. A force against the restraint attached to the shield wall due to the impact and constraint of the ruptured pipe

The study was broken into four tasks:

a. Calculation of mass energy release

b. Calculation of annulus pressure distribution history

c. Structural design assessment of the sacrificial shield and pedestal

d. Structural design assessment of the reactor components.

The first three tasks are described in detail in Subsection 6.2.1.3.11. This section is a brief description of these tasks and the results of the assessment of reactor components.

3.9.1.5.1 Mass and Energy Release

The postulated pipe rupture at the weld between recirculation or feedwater piping and the reactor nozzle safe end leads to a high flow rate of water and steam mixture into the annulus between the RPV and the shield wall. Figure 3.9-1 illustrates the location of this break. Calculation of the mass and energy release is performed using the generic method for short-term mass releases. This method is described in Subsection 6.2.1.3.11. As mentioned previously, this mass energy release results in acoustic loads, pressure loads, and jet loads.

3.9.1.5.2 Acoustic Loads

The recirculation suction line break is the most limiting break relative to the generation of asymmetric pressure loads on the shroud. The following pressure loads are used for input to the reactor internals stress analysis. There are two types:

a. Acoustic decompression wave loads that last for less than 5 msec; the method of the modeling of this load is consistent with NEDO-24048, "Evaluation of Acoustic Pressure Loads on BWR/6 Internal Components," September 1978 (Reference 2)

b. Flow-induced pressure loads due to the flow out of the break; these are analyzed by a potential flow theory analysis of the reactor downcomer region.

   Because the BWR is a two-phase system that operates at or close to saturation pressure, the differential pressure across the reactor shroud is of short duration and the structural supports of the system are not subjected to a significant shock-type load. This short-duration acoustic load is confined to a bending moment and shear force on the reactor shroud and reactor shroud support. Typical results of the integrated force acting on the reactor vessel shroud are given in Table 3.9-2. (These typical results apply to the Fermi 2 reactor.)

3.9.1.5.3 Pressure Loads

The pressure responses of the RPV-shield wall annulus for a recirculation suction line and a feedwater line were investigated using the COMPARE computer code. The pressure histories generated by COMPARE were in turn used to calculate the loads on the sacrificial shield wall and the RPV. Time-force histories representing the resultant loads on the RPV in the structural model were generated by taking the product of the pressure in each pressure node and its effective area, and summing these to give the force of the geometric center of each structural node (See Figure 3.9-3).

3.9.1.5.4 Jet Loads

To completely address structural loads on the vessel and internals, jet thrust, jet impingement, and pipe whip restraint loads must be considered in conjunction with the pressure loads. Jet thrust refers to the vessel reaction force that results as the jet stream of liquid is released from the break. Jet impingement refers to the jet stream force that leaves the broken pipe and impacts the vessel. Jet impingement and jet thrust forces are modeled as suddenly applied constant forces rising from a value of zero at time zero to its full value in one time step (0.001 sec). The pipe whip restraint load is the force that results when the energy-absorbing pipe whip restraint restricts the pipe separation to less than one full pipe diameter. These jet loads are calculated as described in ANSI 176 (draft), "Design Basis for Protection of Nuclear Power Plants Against Effects of Postulated Pipe Ruptures," January 1977 (Reference 3).

The jet-load forces used for the recirculation suction-line-break analysis are shown in Figure 3.9-2 and Table 3.9-3. These values were also used for the feedwater load evaluation. This is conservative because the calculation of these jet effects depends largely on the area of the break, and because the recirculation line is about 2.5 times larger in area.

3.9.1.5.5 Structural Dynamic Analysis

The pressure loads and jet loads described in Subsections 3.9.1.5.3 and 3.9.1.5.4 are combined to perform a structural dynamic analysis. Both of these loads are distributed along the horizontal beam model shown in Figure 3.9-3. The force-time- histories are then applied to a composite lump mass model of the pedestal, shield wall, and a detailed representation of the RPV and internals.

In each analysis, a multiple force input time-history is performed. The DYSEA computer program, described in response to La Salle NRC Item 111.61 (La Salle County Stations, NRC Docket No. 50-373-374), was used for the analysis. The maximum forces and moments at each end of the element were calculated for evaluating the RPV and internals at uprated power conditions. Acceleration time histories and the broaden response spectra at all nodes were generated and used for subsystem analysis. Only the horizontal excitations were generated for this analysis, since the AP loads are all horizontal.

The peak loading on the major components used to establish the adequacy of the component design is shown in Tables 3.9-5 and 3.9-6. A new set of time histories from the 12" recirculation discharge line break was provided for uprated power. The new AP analysis was done by using the same model with combined AP and jet loads. The maximum forces and moments at the RPV, shield wall, and pedestal location were obtained. The loads on major components are shown in Tables 3.9-5 and 3.9-6 for power uprate conditions.

3.9.1.5.6 Annulus Pressurization With a Safe-Shutdown Earthquake

A design analysis has been performed to evaluate the effect of such loading on the Fermi 2 RPV and internals. This evaluation accounted for the load combination of normal loads (NL) and annulus pressurization (AP) with a safe-shutdown earthquake (SSE). The AP and SSE are combined by the square-root-sum-of-squares (SRSS) method and added directly to normal loads and internal pressure differentials due to the line break.

The following safety-related RPV components were evaluated:

a. Top guide

b. Shroud

c. Core support

d. Jet pumps

e. Core ΔP line

f. RPV support (ring girder)

g. RPV stabilizer

h. Shroud support

i. Vessel skirt

j. Vessel stabilizer bracket

k. CRD housing

l. Control rod guide tube

m. Fuel assembly.

A comparison of loads resulting from this evaluation and allowable loads and stresses appears in Tables 3.9-7, 3.9-8, and 3.9-9. No allowable stresses are exceeded.

The critical buckling stress in the support skirt is equal to the allowable compressive stress determined in accordance with Article I-1150 of ASME B&PV Code Section III, 1968 Edition. The skirt is treated as a cylinder of radius equal to the largest skirt radius, and thickness equal to the thickness of one support skirt plate.

L_1 = Radius of skirt

t_n = Plate thickness

$$\frac{L_1}{100\ t_n} = 0.415 \qquad (3.9\text{-}1)$$

From Figure 1-1100 (B), factor B for SA-516-Gr70 material at design temperature of 575°F:

B = $S_{critical}$ = maximum allowable compressive stress for design conditions = -11.5 ksi.

According to paragraph N-417-10 of ASME B&PV Code Section III, the allowable compressive stress for emergency and faulted condition is increased by the same ratio as for other conditions.

$$S_{critical}\ (\text{emergency and faulted}) = B\left(\frac{S_y}{S_m}\right) \qquad (3.9\text{-}2)$$

$$= -11.5 * \frac{28.76}{19.15}$$

$$= -17.25\ \text{ksi}$$

The axial stresses in the skirt for original loads are

$$O_x = -\left(v_1 + v_2 + \frac{2M}{L_1}\right)\frac{1}{2\pi L_1 t_n \cos^u} \qquad (3.9\text{-}3)$$

= -8.8 ksi < $S_{critical}$ = -11.5 ksi (design)

= -14.7 ksi < $S_{critical}$ = -17.25 ksi (emergency and faulted)

To show design adequacy of the RPV support skirt, the resultant loads from the combination of responses due to LOCA and SSE are applied to the highest stressed point on the skirt. The skirt knee is the highest stressed portion of the RPV support. In comparing the loads due to the combination of plant-unique LOCA and SSE responses, it was found that the loads calculated for the original design of the vessel skirt are not exceeded. The calculated and allowable stresses for the support skirt are shown in Table 3.9-10.

The load combinations and maximum tensile forces in the RPV pedestal bolts are given in SL-3647 (Reference 4). Table 15 from SL-3647 gives the maximum forces in the RPV anchor bolts.

For new-loads evaluation, effective vertical load on the support skirt ($v_1 + v_2 + 2M/L_1$) is compared with the original load. The faulted-condition values are as follows:

	Original Load	New Load
Load $v_1 + v_2$	5213 kips	5196.5 kips
Moment M	1,344,000 in-kips	530,553 in-kips
Effective vertical load $v_1 + v_2 + \frac{2M}{L_1}$	30,262 kips	15,085 kips

The axial stresses for the new-load faulted condition are less than half the value of design faulted loads.

The efficiency of the dome segment in the penetration region is 43.8 percent.

The fuel assembly is modeled by seven axial nodes. The maximum acceleration occurring at each node is separately determined for the pressure reaction (PR), jet reaction (JR), and SSE loading. This results in three acceleration profiles. The acceleration profiles are then combined by taking the SRSS of the individual PR, JR, and SSE profiles at each axial position along the length of the fuel assembly.

The resulting profile is then compared to the design-basis profile. If the resultant acceleration profile is less than the design-basis profile, the resultant loads, moments, stresses, and deflection will be less than those for the design-basis case and therefore are acceptable. The acceleration components for Fermi 2 are shown in Table 3.9-11. (None of the accelerations exceed the design-basis profile.)

In addition, GE licensing topical report, "BWR Fuel Assembly Evaluation of Combined SSE and LOCA Loadings," NEDE-21175-P (Amendment 3), July 1982 (Reference 5), provides a bounding evaluation of potential fuel assembly liftoff during such loadings. The evaluation shows the fuel response is within acceptable limits as shown in Table 3.9-12 for the methodology used in the topical report.

Loads on the RPV shroud were studied for asymmetric pressure in addition to SSE, normal loads, and concurrent symmetric pressure differentials. The shroud buckling stresses for this loading combination are approximately 13 percent higher. These are still well below allowable stress limits.

At the request of the NRC, some piping was reanalyzed. These reanalyses confirmed that the piping stress evaluations for the large-bore RCPB piping systems considered faulted condition loadings, including annulus pressurization. This report further indicated that these analyses adequately represent the as-built configurations of these piping systems.

The as-built analysis of the recirculation and drywell RHR piping for combined annulus pressurization and DBE loadings showed that all piping stresses are within code allowable values (3 S_m), and all support component loads are within their Level D component ratings (with one exception where the rating was exceeded by a negligible [4.4 percent] amount). However, Edison has made minor modification (weld size increase) to structural steel for three supports to bring all supports into compliance with code allowable weld stress limits.

In addition, Edison has reviewed the annulus pressurization analysis of all other large-bore (NPS ≥4 in.) RCPB piping systems, comparing the analysis input to the as-built configuration. For these piping systems, the existing analyses were found to adequately represent the as-built configurations.

3.9.1.5.7 Steam Line Break With a Safe-Shutdown Earthquake

The simultaneous occurrence of a steam line break and an SSE also was analyzed. The analysis for core support structures was performed conservatively using the symmetric internal pressure differentials for a steam line break, which are higher than the symmetric internal pressure differentials for a recirculation or feedwater line break. The results are presented in Table 3.9-7.

3.9.1.5.8 Conclusion

In conclusion, a dynamic analysis of the RPV and internals has been performed considering loads due to a LOCA with an SSE. The results of this evaluation show that no RPV and internals allowable stresses are exceeded.

The current practice for such an analysis is to use a high degree of conservatism for each of the key parameters. As these parameters are combined during the evaluation, the degree of conservatism becomes magnified and the final results of the evaluation contain very high total conservatism. The following are some conservatisms for key parameters.

a. Dynamic loads are very conservatively defined in terms of amplitudes, frequencies, and phasing

b. To reduce the number of analysis cases, multiple-load cases are frequently combined into one by enveloping the input response spectra, which are more critical than the worst of individual cases

c. Damping values are conservatively specified

d. Response spectra peaks are broadened by ±15 percent

e. Linear analyses are performed in cases where nonlinear analyses are justifiable. Note that the nonlinear analysis generally results in significantly lower responses because of stress redistribution and higher energy dissipation

f. Allowable stresses used, as specified in the ASME Code, are based on static reserve margins, while for dynamic loads there are considerable additional reserve margins. Instantaneous or brief excursions into the inelastic range are of no or little structural consequences.

In addition to the above, the Fermi 2 evaluation made the following conservative assumptions.

a. The RPV/internals loads and equipment response spectra for the SSE were assumed to be 1.875 times the operating-basis earthquake (OBE) loads, which in effect ignores the higher damping allowed for SSE

b. Dampings used in the AP analysis were the same as those for OBE, although SSE dampings are more appropriate for loads associated with the faulted conditions. The RPV, shroud, and support skirt used 2 percent for OBE, SSE, and AP. Regulatory Guide 1.61 suggests dampings of 2 percent for the OBE and 4 percent for the SSE. Furthermore, in transmittal of structural properties for the reactor building, containment, pedestal, and shield wall, the architect-engineer suggests use of 2 percent damping for the OBE and 5 percent damping for the SSE. General Electric used 2 percent damping for the architect-engineer structures for OBE, SSE, and AP

c. A further conservatism exists in the use of recirculating jet loads in combination with all of the postulated subcompartment histories.

3.9.1.6 Analytical Methods for ASME Code Class l Components

Both elastic and inelastic stress analysis techniques were used in the design of the reactor vessel core support and reactor internal structures to show that stress limits are not exceeded. If an inelastic stress analysis was performed on these components, the elastic (linear) system analysis was checked to see whether the analysis requires modification. The procedure is first to determine the equivalent element stiffness including the inelastic component. The equivalent linear element stiffness is determined by using the method of equivalent linearization of Krylov and Bogoliubov (Reference 6). In this method, the nonlinear differential equation is replaced by an equivalent linear differential equation such that the solutions of the two equations differ from each other by an error of the order of the square of the nonlinear parameter. An alternative method is to determine the equivalent linear system by means of orthogonal polynomials (Reference 7). In either case, the fundamental frequency of the equivalent linear system is then determined. If the fundamental natural frequency of the equivalent linear system deviates less than 15 percent from that of the original linear system, the original linear analysis is considered adequate. A nonlinear dynamic analysis or an equivalent nonlinear dynamic analysis is performed if the natural frequency of the system with reduced stiffness deviates by more than l5 percent from that of the original system.

The l5 percent deviation criterion is applied to the system response for the particular component of interest. This is a realistic approach, since it is difficult, if not impossible, to discuss localized frequencies in dynamic analysis. The whole system must be considered when determining eigenvalues and eigenvectors. The 15 percent deviation criterion was selected in view of the uncertainties in the analytical models of structures and systems. Such uncertainties are normally accounted for in design by introducing conservatisms in the whole analytical process. For example, in the seismic analysis of the structure, floor spectra are generally broadened by 10 to 15 percent to account for uncertainties in the structural models, in the soil structure, and the system modeling. Because of the uncertainties in the dynamic model of the structure and the equipment, it is pointless to refine the analysis beyond the input uncertainty range.

Results for selected RPV internals and associated equipment analyses are provided in Table 3.9-10 and in Tables 3.9-13 through 3.9-15.

3.9.1.6.1 Method of Load Combinations for Class 1 Piping

ASME Code Section III, Class 1 piping systems and components are analyzed by elastic stress analysis techniques. The main computer programs used are PIPSYS or AutoPIPE, described in Subsections 3.13.1.26 and 3.13.3.18, respectively, and the GE in-house verified computer programs PISYS and ANSI7.

Forces and moments in the three normal orthogonal directions are determined for each individual load condition. Forces and moments are then combined in accordance with the rules of the ASME B&PV Code Section III, NB-3652 and NB-3653, in each orthogonal direction. The stress is then calculated on the basis of a single moment after combining the three orthogonal moments by the SRSS such that

$$M_i = \left(M_x^2 + M_y^2 + M_z^2\right)^{1/2} \qquad (3.9\text{-}4)$$

The individual load and operating conditions used in the analysis are as follows:

Condition	Load	ASME Section III Criteria
Operating	Dead weight Design pressure	Primary stress intensity limit, Equation (9), NB-3652 ≤ 1.5 S_m
Upset	Dead weight Design pressure OBE	Primary stress intensity limit, Equation (9), NB-3652 ≤ 1.5 S_m (or 1.8 S_m depending on the code issue used)
	Thermal expansion Thermal displacement OBE	Primary plus secondary stress intensity range, Equation (10), NB-3653.1, or Equations (12) and (13), NB-3653.6
	Other upset occasional loads	Peak stress intensity range, Equation (11), NB-3653.2
	Operating and upset transients	Alternating stress intensity, Equation (14), NB-3653.6
Emergency	Dead Weight Design pressure SSE Other emergency occasional loads	Primary stress intensity limit, Equation (9), NB-3652 ≤ 2.25 S_m
Faulted	Dead weight SSE Other faulted occasional loads Design pressure	Primary stress intensity limit, Equation (9), NB-3652 ≤ 3.0 S_m

A fatigue analysis is performed in accordance with NB-3653.4 considering all cyclic load conditions, including pressure, hydrostatic testing, operating and upset transients, and OBE stress reversals. For some components, NB-3200 analysis is performed instead of the NB-3600 analysis described above. A typical listing of transients applied is given in Table 5.2-2.

The recirculation and main steam piping systems meet the requirements of the ANSI B31.7 Nuclear Power Piping Code Class 1. Other Class 1 piping systems meet the requirements of ASME Section III.

The analysis performed by GE consists of the recirculation loop and those portions of the main steam piping, the steam supply piping to the HPCI and RCIC turbines, the RHR supply and return piping, and reactor water cleanup (RWCU) piping inside the drywell. The analyses performed by GE include the optimization of suspension devices.

Other large bore (NPS ≥ 1-1/4 in.) Class 1 piping systems include the RCPB portions of the following:

a. Core spray system

b. Feedwater system (including HPCI, RCIC, and RWCU lines)

c. Main steam drains system

d. Standby liquid control system

e. RPV vent line

f. Outside containment portions of HPCI and RCIC steam lines, RHR supply and return lines, and RWCU line.

All of the above systems were analyzed to determine the forces and moments acting on each component as a result of thermal expansion, dead weight, and earthquake. In addition to the above, the main steam system was analyzed for relief valve lift and turbine stop valve closure. The moments obtained from these analyses were then used in conjunction with information obtained from an analysis of temperature gradients to determine the stress intensities and fatigue life for each component in the system.

3.9.1.6.2 Combination of Earthquake Response - Piping Systems

Modal responses and spatial components in seismic response analysis are combined using the methods described in Regulatory Guide 1.92, Revision 1.

3.9.1.6.3 Combination of Earthquake Loads With Other Occasional Mechanical Loads

Earthquake loads are combined with other occasional mechanical loads using the SRSS method.

3.9.1.6.4 Valves and Equipment

The requirements of the draft ASME Code for Pumps and Valves or ASME Section III were adhered to in the design of active Code Class 1 valves. Stress intensities were limited to 1.0 S_m for general membrane and 1.5 S_m for general membrane plus bending. These limits ensure that the valve stresses will remain within elastic limits and that no plastic deformation will occur. Representative analyses of Code Class 1 valves are summarized in Tables 3.9-17, 3.9-18, and 3.9-19.

The requirements of Section III of the ASME B&PV Code are adhered to in the design of Code Class 1 manually operated globe valves and check valves 2 in. in size and smaller.

Additional discussion relative to Code Class 1 equipment is provided in Section 5.2. Representative analyses of Code Class 1 pumps are summarized in Table 3.9-20, Recirculation Pumps.

3.9.1.6.5 Structural Supports

Structural supports for Class 1 components were generally designed using the same criteria as for Class 2 and 3 components as described in Subsection 3.9.2.2.4.1.

In the GE design of supplied supports where jet reactions from a break are included with SSE and normal loads, the calculated stress is less than the following:

a. Bending 0.9 yield

b. Tension 0.85 yield

c. Shear 0.50 yield

d. Compression 1.5 times the allowable stress from the AISC Specification Part 1, Paragraph 1.5.1.3.1.

Items that support components such as CRD housing supports and RPV stabilizers were designed using these acceptability criteria.

3.9.1.6.6 Stress Levels for Class 1 Piping Systems

The methods used to analyze Class 1 piping systems are discussed in Subsections 3.9.1.6.1 through 3.9.1.6.3. Typical results are presented here. As-built system data were used as input to the final stress analyses of these systems to ensure that the code- specified allowable stresses are not exceeded.

Piping isometrics, stress levels, and usage factors for the major Category I, Class l, systems are given in the following figures and tables:

System	Figure Numbers	Table Numbers
Main Steam	3.9-6 to 8	3.9-21 and 22
Recirculation – RHR	3.9-9 and 10	3.9-23 and 24
Feedwater	3.9-14	3.9-25
Core Spray	3.9-15	3.9-26

These isometrics and tables show the piping arrangement, stress levels, and usage factors at the high stress points, as well as at the locations of changes of flexibility. They are representative of the analyses and results for all Class 1 systems. The remaining Class 1 systems are not as critical as the previously listed systems, since failure or pipe rupture in these systems does not result in a design-basis LOCA. The Usage values listed in Tables 3.9-21 through 26 are based on original plant design. See FP FERM 310 (Ref. 19) for the fatigue usage accumulated for all monitored locations based on Fermi 2 operating history.

Any detailed information of specific results may be obtained from the certified stress reports for these systems.

3.9.2 ASME Code Class 2 and 3 Components

For Fermi 2 this refers to either ASME Code Class 2 and 3 components or similar non-RCPB safety-related pressure-retaining components designed to earlier codes.

3.9.2.1 Plant Conditions and Design Loading Combinations

These active and inactive components are identified and listed in Table 3.9-27. American Society of Mechanical Engineers Code Class 2 and 3 components of fluid systems were constructed in accordance with Section III of the ASME B&PV Code. Most components (piping, pumps, and valves) were ordered prior to July 1971 and were designed to other industry codes (see Table 3.2-1) when the effective Section III was not applicable. The specific quality group classification for each principal component is provided in Table 3.2-1. Tables 3.9-28 through 3.9-36 list the design loading combinations for the major components of representative safety-related systems.

Definitions of symbols used in the equations in these tables are contained in the applicable code referenced by the table.

3.9.2.2 Design Loading Combinations

The combination of design loadings for the components are categorized with respect to plant conditions identified as normal, upset, emergency, or faulted in Tables 3.9-28 through 3.9-36. The design stress limits associated with each of the plant conditions are specified in the subsections that follow.

3.9.2.2.1 Fluid System Components (Vessels Including Heat Exchangers and Pumps) and Piping Systems

ASME Code Class 2 and 3 safety-related fluid system components were designed considering the following load combinations:

Category	Loads	Pressure Boundary Stress Limits
Normal	Design pressure Design temperature	S = Allowable stress ASME Section III
Upset	Design pressure Design temperature	General membrane = 1.0 S
	Operating-basis earthquake Including nozzle loads	Local membrane/bending = 1.5 S
Emergency*	Design pressure Design temperature	General membrane = 1.2 S
	Safe-shutdown earthquake Including nozzle loads	Local membrane/bending = 1.8 S

* Inactive components may use the smaller of 0.7 S_u or 2.4 S

ASME Section III, Class 2 and 3, piping systems and components are generally analyzed by computerized elastic analysis techniques. The main computer programs used are PIPSYS, AutoPIPE, and NUPIPE, described in Subsections 3.13.1.26, 3.13.3.18, and 3.13.4.1, respectively.

Analysis is based on a single equivalent moment, evaluated as the SRSS combination of the three orthogonal moments generated in the pipe by the various loads, as described in Subsection 3.9.l.6.l. Earthquake response is calculated as described in Subsection 3.9.1.6.2. Earthquake loads are combined with other occasional mechanical loads as described in Subsection 3.9.1.6.3. The combined moments and resulting stresses are evaluated in accordance with the equations and allowable stress criteria of ASME III, Subsection NC-3652, for the various operating categories listed below.

Category	Loads	ASME III Criteria
Normal	Design pressure Dead weight Sustained mechanical loads	NC-3652.1 EQ (8) $\leq$ 1.0 S_h
Upset	Design pressure Dead weight Sustained mechanical loads Operating-basis earthquake OBE displacements* Occasional mechanical loads**	NC-3652.1 EQ (9) $\leq$ 1.2 S_h
Emergency	Design pressure Dead weight Sustained mechanical loads	NC-3652.2
	Safe-shutdown earthquake*** SSE displacements*, *** Occasional mechanical loads**	EQ (9) $\leq$ 1.8 S_h

* The earthquake terminal displacements may be neglected in EQ (9) if they are considered in Equation (10) or (11) as permitted by the Code.
** Such as relief valve blowdown loads.
*** As an alternative to using the SSE response in evaluating stresses under this category, 1.875 times the OBE response may be used.

In addition to the above primary loads, thermal expansion effects are considered by evaluation of Equation (10) or (11) of NC3652.3. The acceptance criteria for allowable stresses are as listed in the code.

Transients, that is, time-varying temperature or pressure changes, are not evaluated for Class 2 or 3 piping as they are for Class l piping. Transient phenomena, such as relief valve blowdown loads on the piping, are considered in the design when these events are specified in the System Design Specification.

The structural analyses for large- and small-bore torus-attached piping, piping supports, and related equipment are described in the Plant Unique Analysis Report and DC-6003 Vol I "Evaluation of New ECCS Suction Strainers on Existing TAP Analysis" for Torus-Attached Piping (Reference 8 & 20). Similarly, the structural analyses for the safety/relief valve discharge piping are described in Volume 5 of the Plant Unique Analysis Report (Reference 9) and in the piping stress reports. The criteria set forth in NUREG-0661 (Reference 10) have been used in the analysis methods and in the evaluation of the results for these systems.

3.9.2.2.2 Containment

Refer to Section 3.7 and Chapter 6.

3.9.2.2.3 Valves

The valve pressure-retaining parts designed to ASME III, Class 2 and 3, were designed to withstand seismic forces and pipe reactions of the SSE. If seismic consideration is necessary for other parts, the following applies:

Operating Condition	Loads
Upset	1. Normal operating 2. OBE
Emergency	1. Normal operating 2. SSE*

* As an alternative to using the SSE response, 1.875 times the OBE response may be used. Maximum horizontal ground acceleration for the SSE is 0.15g; for the OBE it is 0.08g. (see Subsection 3.7.1.1.)

The original design of ASME III, Class 2 and 3, valves is in accordance with MSS-SP-66 or ANSI-Bl6.5. Allowable stress limits are defined by ASME Section I. When more than one allowable stress value was listed in ASME Section I for an austenitic stainless steel material at a temperature, the lower value was used. The pressure-temperature ratings used for the design of valves are either the standard primary service pressure ratings of 150, 300, 400, 600, 900, 1500, or 2500 lb covered by ANSI-B16.5, or are determined by the following formula in compliance with the requirements of MSS-SP-66:

$$P_1 = \frac{PS_1}{S-P(y_1-y)} \qquad (3.9\text{-}5)$$

where

P_1 = maximum allowable pressure at desired temperature, psi

P = maximum allowable pressure at design temperature, psi

S_1 = allowable stress at desired temperature (ASME Section I)

S = allowable stress at design temperature (ASME Section I)

Y_1 = plastic stress distribution factor at desired temperature

Y = plastic stress distribution factor at design temperature

In no case do the pressure-temperature ratings used for a weld- end valve exceed those given for weld-end valves in ASME III, articles NB-3530 and NB-3541. Valves purchased in accordance with more recent editions or Addenda of ASME Section III are designed in accordance with ANSI B16.34.

3.9.2.2.4 Nonpressure Parts

Parts that are not pressure boundary meet the requirements herein for supports and structures (Subsection 3.9.2.2.4.1), provision for anchor bolts (Subsection 3.9.2.2.4.2) and pressure boundary bolting subject to external loads (Subsection 3.9.2.2.4.3) as applicable.

3.9.2.2.4.1 Supports and Structures

Piping and equipment supports are designed for stress levels less than shown below for the loading condition defined for the pressure boundary:

a. Normal and upset

  1. Plate and shells - Primary membrane. 1.0 S; primary membrane plus bending, 1.5 S, where S is the allowable stress limit of the applicable code

  2. Linear supports and bolts - Stress less than the allowable limits of Part I, Section 1.5 through Section 1.10, of the AISC Specifications for the design, fabrication, and erection of structural steel for buildings

  3. Standard support components - Manufacturers' normal and upset condition rated capacity

  4. Concrete expansion anchor bolts - The average ultimate tensile and shear loads established by test divided by the following factors of safety.

     a. Four for wedge-type anchor bolts

     b. Five for self-drilling-type anchor bolts in pipe supports

     c. Four for self-drilling-type anchor bolts in applications other than pipe supports.

b. Emergency

  1. Plates and shells - Stress less than 1.2 times the allowable stress limit values for normal and upset above

2. Linear supports and bolts - Stress less than 1.33 times the allowable stress limit values for normal and upset above

3. Standard support components - Manufacturers' emergency condition rated capacity

4. Concrete expansion anchor bolts - Same as normal and upset above.

c. Load combinations

The load combinations used in the analysis of structural support and anchor bolts for safety-related components are as follows:

1.	Normal and upset conditions active components	Passive components	
	D + E + H + O	D + E + H	(3.9-6)
2	Emergency conditions active components	Passive components	
	$D + E^1 + O + H$	$D + E^1 + H$	(3.9-7)

where

D = dead load (flooded)

H = operating thermal effects

E = operating-basis earthquake

E^1 = safe-shutdown earthquake

O = operational loads (nozzle reactions, pressure, motor torque, pump inertia, etc., as applicable)

In the design of structures and structural components for Fermi 2, it has been Edison's practice to specify the use of codes and related design guides applicable at the initiation of the design activity. In the course of the design process, the use of later editions of the codes and/or any supplements issued thereto has been allowed.

3.9.2.2.4.2 Provision for Anchor Bolts

Equipment mounted on concrete support structures is fastened with anchor bolts (in drilled and grouted holes) or with expansion anchors. Sufficient holes for anchor bolts are provided to limit anchor bolt stress to those allowable per the AISC Code. Equipment anchored to a steel foundation and equipment mounted using expansion anchors follow the provisions of supports and structures (see Subsection 3.9.2.2.4.1).

3.9.2.2.4.3 Pressure Bolting for Component Flanges Subject To External Load

Where appreciable loads can occur on equipment-gasketed pressure joints, the external loads are considered in calculations to determine required bolt area. Code allowable stresses are maintained consistent with the operating conditions associated with the external loads.

3.9.2.2.5 Pipe and Equipment Supports

3.9.2.2.5.1 Equipment Supports

Refer to Subsection 3.9.2.2.4.2 above.

3.9.2.2.5.2 Seismic and Dynamic Effects - Shock Suppressors

Shock suppressors (snubbers) are provided on Category I piping systems, where necessary, to prevent shock forces from causing damaging motion and concurrently to allow for the normal thermal motion of the piping. In general, the snubbers for piping located inside the primary containment (drywell) and inside the steam tunnel, as well as the snubbers for the field run piping described in Subsection 3.9.2.7, are of the mechanical type. The mechanical shock suppressors conform with the requirements of the ASME Code Section III, Subsection NF, 1974 issue up to and including the winter 1976 addendum. Snubbers for the balance of the plant piping are of the hydraulic type and are designed in accordance with the requirements of ANSI B31.7, 1969, and/or ANSI B31.1, 1967, as appropriate for the class of piping being restrained.

As a result of concern about the reliability of the hydraulic and mechanical snubbers used for piping, identified as 10 CFR 50(e), Item 69, Edison reviewed the use of such snubbers. The results of the study included the elimination of about 29 percent of the snubbers, either by replacement with rigid supports or by proving that no restraint was required.

3.9.2.2.6 Relief Valve Operation - ASME III Components

If, during relief valve operation, the pressure exceeds the design pressure, it shall be considered to be an emergency condition and 110 percent of the design stress limit is permitted for Class 2 and 3 components.

3.9.2.2.7 Structural Cast Iron

The following are acceptable allowable stress limits for cast iron used for structures (e.g., bearing housings):

	Unidentified Gray Cast Iron	ASTM Class 20
Tension	3.5 ksi	5 ksi
Shear	3.5	5
Bending	5.25	7.5
Compression	7.0	10

3.9.2.2.8 Nozzle Loads

Nozzles withstand the pipe reactions from dead weight, thermal expansion, earthquake, and relief valve operation.

3.9.2.3 Design Stress Limits

For safety-related non-RCPB pressure retaining components, representative design stress limits are listed in Tables 3.9-28 through 3.9-36. Inelastic methods of analysis are not used for these components.

3.9.2.4 Analytical and Empirical Methods for Design of Pumps and Valves

3.9.2.4.1 General

To ensure the functional performance of Class 2 and 3 active pumps and valves, the design requirements of Subsection 3.9.2.2 were applied. Operability will be further demonstrated by the Operability Assurance Program described in Subsection 3.9.4.

The design methods were a combination of analysis and past testing and operating experience. These methods are the responsibility of the vendor, who is responsible for meeting the requirements of the applicable codes and standards identified in the component specification.

3.9.2.4.2 Valves

Class 2 and 3 (1971 code language) active valves were designed as described in Section 3.9.2.2.3. In addition, an analysis of the extended structure was performed, generally using statically applied acceleration loads from the piping stress analysis, for valves that are required to function during or after an SSE. For this analysis, stresses were limited to values that restrict the maximum stress in the extended structure to within upset condition code stress limits. Deflections of the extended structure will thus be small and operability of the valves will not be impaired.

3.9.2.4.3 Pumps

Active pumps were designed in accordance with the ASME Code for Pumps and Valves or the ASME B&PV Code for Nuclear Power Plants, depending on which code was in effect at the time the purchase order was issued. Forces resulting from seismic accelerations in the horizontal and vertical directions are included in the analysis of the pumps and their supports.

3.9.2.5 Design and Installation Criteria, Pressure-Relieving Devices

3.9.2.5.1 General

All pressure vessels are protected by pressure-relieving devices to meet applicable code requirements, such as ASME Code Sections III and VIII, and ANSI B31.1.

A discussion of the design and installation criteria for Class 1 pressure-relieving devices is given in Chapter 5. The derivation of the forcing functions that govern the fluid thrust during valve operation is presented in Subsection 3.9.2.5.2.

All ASME Code Class 2 and 3 overpressure relief valves and their connecting piping are designed to withstand the maximum load due to the discharge reaction force calculated by the following formula, regardless of the arrangement of the discharge piping:

$$F = 2PA \tag{3.9-8}$$

where

F = reaction force, lbf

P = valve setpoint pressure, lbf/in.^{2}

A = cross-sectional area of the valve inlet nozzle, in.^{2}

The discharge thrust loads so calculated were applied simultaneously with the loads due to internal pressure, dead weight, and seismic (SSE or OBE as applicable). When more than one relief valve is attached to a piping system, the loads due to all relief valves discharging simultaneously were applied to the system along with the above-mentioned primary loads. In addition, the loads from the most critical combination of valves discharging were applied.

3.9.2.5.2 Forcing Functions

The analytical basis for the forcing functions used in the dynamic and static analysis of the relief valves and connected piping is given in the following subsections.

3.9.2.5.2.1 Basic Fluid Flow Equations

One-dimensional flow is assumed in every straight pipe section. The conservation equations used are the following.

Mass

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial t}(\rho v) = 0 \tag{3.9-9}$$

Momentum

$$\frac{\partial v}{\partial t} + v\frac{\partial v}{\partial Z} = \frac{-g_c}{\rho}\left(\frac{\partial P}{\partial Z} + F'''\right) \tag{3.9-10}$$

Energy

$$\frac{\partial S}{\partial t} + v\frac{\partial S}{\partial Z} = \frac{v}{\rho T}F''' \tag{3.9-11}$$

where

ρ = fluid density, lbm/sec

t = time, sec

v = velocity, fps

Z = displacement, ft

g_c = 32.2, lbm x ft/(lbf x sec^2)

P = pressure, lbf/ft^2

S = entropy, ft-lbf/(lbm x °F)

T = temperature, °F

and

$$F''' = \frac{f}{D}\frac{\rho}{2g_c} v\,|v| \qquad (3.9\text{-}12)$$

where

f = Darcy friction factor

D = hydraulic diameter, ft

3.9.2.5.2.2 Reaction Forces

Reaction forces are considered to act longitudinally on each straight section of pipe rather than at each bend or turn, as shown in Figure 3.9-16(a). Consider a general straight section of pipe bounded by two other sections, Figure 3.9-16(b), and consider three fluid volumes from the pipes, Figure 3.9-16(c). Equation 3.9-10 is integrated over the pipe length:

$$\int_0^L \rho\left(\frac{\partial v}{\partial t} + v\frac{\partial v}{\partial Z}\right)\partial Z = -g_c\int_0^L\left(\frac{\partial P}{\partial Z} + F'''\right)\partial Z \qquad (3.9\text{-}13)$$

From Equation 3.9-9,

$$\frac{\partial v}{\partial t} + v\frac{\partial v}{\partial Z} = \frac{\partial}{\partial t}(\rho v) + \frac{\partial}{\partial t}(\rho v^2) \qquad (3.9\text{-}14)$$

so that

$$P_a - P_b - \frac{F_D}{A} = \frac{1}{g_c}\int_0^L \frac{\partial}{\partial t}(\rho v)\,\partial Z + \frac{(\rho v^2)b}{g_c} - \frac{(\rho v^2)a}{g_c} \qquad (3.9\text{-}15)$$

$$\frac{F_D}{A} = \int_0^L F'''\partial Z \qquad (3.9\text{-}16)$$

It is assumed that the turn sections are small in volume (compared to the straight pipe sections), so that no storage terms apply. Furthermore, lossless flow occurs (no friction or other irreversibilities).

Reactions R_1 and R_2 are parallel to pipe section L; R_L and R_R are parallel to the adjoining pipes at the left and right ends. It follows that

$$\rho_a A_a v_a^2 - \rho_1 A_1 v_1^2 \cos\alpha_1 = g_c(R_1 - R_L\cos\alpha_1 + P_1A_1\cos\alpha_1 - P_aA_a) \qquad (3.9\text{-}17)$$

$$\rho_2 A_2 v_2^2 \cos\alpha_2 - \rho_b A_b v_b^2 = g_c(P_bA + R_R\cos\alpha_2 - R_2 - P_2A_2\cos\alpha_2) \qquad (3.9\text{-}18)$$

Equations 3.9-17 and 3.9-18 give momentum conservation at left and right ends parallel to pipe L. Moreover, momentum conservation for the left and right ends in a direction normal to L is

$$-\rho_1 A_1 v_1^2 \sin\alpha_1 = g_c(-R_L\sin\alpha_1 + P_1A_1\sin\alpha_1) \qquad (3.9\text{-}19)$$

$$-\rho_2 A_2 v_2^2 \sin\alpha_2 = g_c(-R_R\sin\alpha_2 + P_2A_2\sin\alpha_2) \qquad (3.9\text{-}20)$$

Equations 3.9-15 and 3.9-17 through 3.9-20 combine to give the net longitudinal force on fluid in section L as

$$R_1 - R_2 - F_D = \frac{A}{g_c}\int_0^L \frac{\partial}{\partial t}(\rho v)\,\partial Z \qquad (3.9\text{-}21)$$

Reactions R_L and R_R are included with longitudinal loads on the adjoining pipe sections. Equation 3.9-21 gives the net force of the pipe walls on the fluid. The pipe load is equal and opposite, or

$$R_{bounded} = -\frac{A}{g_c}\int_0^L \frac{\partial}{\partial t}(\rho v)\,\partial Z \qquad (3.9\text{-}22)$$

Equation 3.9-22 gives the reaction load on a straight pipe section that is bounded at each end by two other adjoining pipes. However, if pipe L is open at the end designated "2," it follows that Equations 3.9-18 and 3.9-20 do not apply, and the pipe reaction load is

$$R_{open} = -AP_b + \frac{\rho_b v_b^2}{g_c} + \frac{1}{g_c}\int_0^L \frac{\partial}{\partial t}(\rho v)\,\partial Z \qquad (3.9\text{-}23)$$

For steady-state flows, Equation 3.9-22 gives zero reaction, whereas Equation 3.9-23 gives

$$R_{open,steady} = -AP_b + \frac{\rho_b v_b^2}{g_c} \qquad (3.9\text{-}24)$$

3.9.2.6 Stress Levels for Class 2 and 3 Piping

Piping isometric sketches, stress levels, and allowable stress limits for selected portions of the below-listed Category I, ASME III, Subsection 2 and 3 subsystems, are given in the following figures and tables.

System	Figure No.	Table No.
EECW system pump suction from heat exchanger	3.9-17	3.9-37
RHR service water return from heat exchanger	3.9-18	3.9-38
RHR containment spray from return header to drywell	3.9-19	3.9-39

These figures and tables indicate the piping system arrangement and stress levels at terminal ends and locations of high change in flexibility. The stress levels given are based upon final analyses and are typical of the stress levels predicted for all Category I, Class 2 and 3 systems. Any detailed information or specific results should be obtained from the specific stress analysis design calculations.

3.9.2.7 Field Run Piping Systems

Piping classified under ASME Code Section III, Classes 2 and 3, size 4 in. and under, with design temperatures of 575°F or less, is analyzed using the computerized stress analysis techniques described in Subsection 3.9.2.2.1, or is analyzed in the field using the simplified approach described in this section. For the field-designed piping, simplified analysis techniques were used for thermal, weight, and dynamic analyses and to determine restraint locations and design loads. These techniques are based on the following criteria.

a. Extreme conservatism is economically practical

b. Uncertainties in manufacturing are present so that a more precise analysis would not be useful

c. The pipe is flexible so that thermal expansion and nozzle movements can be easily accommodated

d. Similarities in the systems allow for use of standard components and design characteristics.

Based on these criteria, simplified analysis techniques pre-sented in Subsections 3.9.2.7.1 through 3.9.2.7.3 are used in the seismic, deadweight, and thermal analyses of field run piping systems. In field run piping systems, the stresses determined by these methods do not exceed the following values.

Stress	Maximum Value (psi)
Thermal expansion	15,000
Anchor movements	15,000
Thermal expansion plus anchor movements	15,000
Weight	3,000
Seismic (OBE)	7,000

Full consideration is given to seismic, weight, and thermal loadings imposed upon equipment and header nozzles to ensure that the imposed loads are within allowable limits.

3.9.2.7.1 Seismic Analyses

Simplified seismic analysis and design procedures are used, treating piping spans between rigid supports and/or restraints as independent simple beams. The span period, maximum mid-span deflection, allowable mid-span deflection, and end restraint forces are determined for a series of span lengths for each pipe size. No restraint credit is taken for hangers or restraints not offering stiffness in the direction of the seismic excitation. The maximum mid-span deflection and restraint forces are a function of the floor response spectra of the building structure in the vicinity of the piping. The spectra used are for the OBE. To predict the effects of the SSE, the responses are doubled.

The resulting data were developed into a set of design curves that are used to

a. Ensure that seismic stresses are not greater than the allowable

b. Ensure that seismic deflections are not large enough to cause damaging contact between pipe and surroundings

c. Provide seismic restraint design loads.

To ensure that seismic stresses are not greater than the allowable, and that seismic deflections are not large enough to cause damaging contact between pipe and surroundings, seismic deflection versus span curves similar to Figure 3.9-20 are used. These curves show the first mode seismic deflection of a simply supported beam representing the pipe span. The response is based upon the most energetic response spectrum expected in the building of interest.

A significant feature of the seismic deflection versus span curves is a line showing the deflection needed to produce a bending stress of 7000 psi in the pipe span. To ensure that code allowable stresses will be met when seismic loading is combined with other appropriate loadings, the seismic deflection due to the OBE is never allowed to exceed that shown by the 7000-psi curve. In addition, to protect against damaging contact between pipe and surroundings, seismic deflections greater than 2 in. are not allowed.

To provide seismic restraint design loads, seismic restraint load versus span curves similar to Figure 3.9-21 are used. These curves give the seismic restraint reactions for a span. Again, the model is a simply supported beam and the response is based on the response spectra curve as used in determining the seismic deflection curves. To account for the continuity of the piping across a restraint attachment point, the reactions from all piping spans supported from a restraint are added.

The following factors are considered in applying the design curves to actual piping systems. The major excitation due to earthquake will be horizontal. However, since it is not known from which horizontal direction the loading will come, all horizontal spans are restrained in the lateral and axial directions. Application of the above criteria requires that the maximum span distance between seismic restraints in the reactor building for the various size pipes does not exceed those spans given below:

	Maximum Span (ft)	
Pipe Size (in.)	Vertical	Horizontal
½	6	9
¾	7	11
1	8	12
1½	10	15
2	12	17
3	14	21
4	16	24

The simplified design curves are based on the accelerations associated with the OBE. The piping design criteria require that Class 2 and those Class 3 piping systems that are designated Category I satisfy normal code stress requirements during an earthquake of this intensity. The 7000-psi seismic stress limit was selected to ensure that normal code stress requirements can always be satisfied. To provide a seismic restraint design that is compatible with the piping design, the Class 2 and 3 system seismic restraints are designed in accordance with the AISC Manual.

A further requirement of the piping design criteria is that the designer must make an assessment of the effect of an earthquake of twice the intensity of the OBE or equal in magnitude to the SSE. The design goal for the SSE is to maintain a safe-shutdown capability for the nuclear energy system. Since the design curves are based on the OBE, all deflections, stresses, and reactions, as determined from the curves, are doubled to obtain SSE values. The allowable seismic stress for the SSE is obviously two times the OBE allowable, or 14,000 psi. The maximum allowable seismic deflection, however, remained at 2 in. The 14,000-psi seismic stress limit ensures that code stress requirements can be met. To provide a seismic restraint design that is compatible with the piping design, the Class 2 and 3 system seismic restraints are designed in accordance with the AISC Manual, except that the restraint stress shall not exceed the AISC allowable by more than 33 percent.

3.9.2.7.2 Weight Analysis

The standard procedure for designing a weight support system involves the use of recommended span lengths, to limit the weight-induced bending stress. The requirements of ASME Code Section III are satisfied by this approach even though the governing equations of NC-3652 do not directly indicate an allowable weight stress level.

In using this method, it is only necessary to determine the fraction of the allowable stress that the weight load should contribute. Recommended spans based on this allowable stress are then calculated by elementary bending theory. The effect of the weight of thermal insulation is also considered. The recommended span length is given by

$$\text{span(ft)} = \sqrt{\frac{2000\text{Z}}{\text{W}}} - 1 \tag{3.9-25}$$

where

Z = section modulus, cubic in.

W = linear weight density, lb/ft

The span recommendations are listed in Table 3.9-40 for pipes filled with water and for gas-filled pipes. This formula is based on the assumption that the pipe element may be represented as a simply supported beam. The maximum bending moment for a continuous beam or for a beam with other end conditions cannot exceed the maximum for the chosen model. Therefore, although the analytical model may not always accurately represent the actual piping, it does establish an upper limit for the bending stress.

To accommodate concentrated weights, the spans are shortened to ensure that the allowable bending stress is not exceeded.

The following rules are used to determine span lengths.

a. A half-span of plain pipe must have a vertical support at one end

b. A half-span that includes an elbow must have a vertical support at both ends

c. The length of a half-span that includes a concentrated weight of less than 10 percent of the normal span load (Table 3.9-40) should not exceed 40 percent of the normal span length. It must have a vertical support on one end

d. A half-span that includes a concentrated weight of from 10 percent to 40 percent of the normal span load must have a vertical support on both ends

e. The length of a half-span that includes a concentrated weight of more than 40 percent but less than 250 percent of the normal span load should not exceed 10 percent of the normal span length and should have a vertical support on both ends. This length does not include the actual length of the concentrated weight

f. A concentrated weight that exceeds 250 percent of the normal span load should be supported directly rather than by the piping to which it is attached

g. The length of a half-span with one free end should not exceed 50 percent of the normal span length

h. A half-span with a concentrated weight should not have a free end

i. Supports not required by these rules should not be used.

3.9.2.7.3 Thermal Analysis

The object of the thermal expansion analysis was to ensure adequate flexibility so that nozzle movements and pipe expansion would not cause stresses in excess of the allowable. This allowable was determined by allocating a percentage of the allowable stress indicated by Equation (10) or (11) of NC-3652, to thermal expansion and anchor displacements.

Flexibility in a given direction is dependent upon the amount of pipe which is perpendicular to that direction. For instance, a component of nozzle movement in the X direction can be accommodated if the nozzle is separated from the first X direction restraint by enough piping in the Y and Z directions (Figure 3.9-22).

The bending stress in the perpendicular legs, B and D, must therefore be examined. These legs are conservatively modeled as a beam with guided ends subjected to a displacement (Figure 3.9-23). This model is conservative since it ignores the flexibility of the elbows and imposes more rigid end conditions than the actual supports.

The allowable stress is limited to 15,000 psi. Therefore the length of perpendicular pipe required to accommodate the component of nozzle movement is

$$\ell = 12\sqrt{\delta r_o} \qquad (3.9\text{-}26)$$

where

ℓ = length of perpendicular pipe required, ft

r_o = outside radius, in.

δ = deflection, in.
