e. Finally, the loop selection is made. If loop A pressure is greater than that of loop B, then loop B is broken and injection will occur in loop A. If the pressure at loop A is not greater than that at loop B, the 0.5-sec timer will run out, causing loop B to be selected. The 0.5-sec time delay allows the loop selection logic to function. The ΔP is measured from each recirculation loop riser pipe to the corresponding riser pipe on the other recirculation loop. The taps are located as close to the reactor vessel as possible. This arrangement provides a one-out-of-two-twice logic

   Loop selection differential pressure trip comparator set-points are adjusted to a value that gives the earliest valid indication of a break. The differential pressure comparator output contact is closed when the pressure in the recirculation pump A riser is approximately 1.0 psi higher than the pressure in the B recirculation pump riser

f. Once the specific recirculation loop is selected for injection and the reactor pressure is below about 500 psig, the RHR outboard and inboard valve circuits for that loop receive an "open" permissive and a "close" block.

Because of the design of the logic circuitry, all cases except when a loop B break is detected cause injection through loop B. The interconnecting line between both RHR loop discharge lines permits total injection to either recirculation loop. In the accident mode, the core is flooded to an adequate height and the level is maintained by the LPCI operating alone with three of four pumps operating. The design basis requires 30,000 gpm (three of four pumps). Injecting into both loops simultaneously would produce some loss of inventory due to a postulated break in one of the loops.

A complete description of the sensors and trip units is the main subject of NEDO-21617, Analog Transmitter/Trip Unit System for Engineered Safeguard Sensor Trip Inputs.

7.3.1.3 Analysis of the Emergency Core Cooling System

7.3.1.3.1 Conformance To General Functional Requirements

In Chapters 6 and 15, the individual and combined capabilities of the ECCS are evaluated. Consideration of failure in plant instrument air and loss of cooling water to vital equipment is presented in Chapter 15. The safety design bases mentioned below are given in Subsection

7.1.2.1.3. The control equipment characteristics and trip settings are described in Subsection 7.3.1.2 and were considered in the analysis of ECCS performance. For the entire range of nuclear process system break sizes, the cooling systems are effective both in preventing fuel-cladding failure and in preventing more than a small fraction of the reactor core from reaching the temperature at which a gross release of fission products can occur. This conclusion is valid even with significant failures in individual cooling systems because of the overlapping capabilities of the ECCS. The instrumentation and control for the ECCS satisfies the requirements of safety design basis Item a.

Safety design basis Item b. requires that instrumentation for the ECCS respond to the potential inadequacy of core cooling regardless of the location of a breach in the nuclear system process barrier. The RPV low water level initiating function, which alone can actuate HPCI, LPCI, and core spray, meets this safety design basis because a breach in the nuclear system process barrier inside or outside the primary containment is sensed by the low water level trip channels. Because of the isolation responses of the CRVICS to a breach of the nuclear system outside the primary containment, the use of the RPV low-water signal is satisfactory as the only emergency cooling system initiating function that is completely independent of breach location.

The other major initiating function, primary containment high pressure, is provided as a diverse backup to water level to ensure isolation of all NSSS breaches inside the primary containment. This second initiating function is independent of the physical location of the breach within the drywell. The method used to initiate the ADS, which employs RPV low water level and primary containment high pressure, requires that the nuclear system breach be inside the drywell because of the required primary containment high pressure signal. For breaks outside primary containment, or for breaks inside primary containment which do not result in primary containment high pressure, the primary containment high pressure permissive is bypassed after a time delay following a low reactor water signal. This control arrangement is satisfactory in view of the automatic isolation of the RPV by the CRVICS for breaches outside the primary containment, and because the ADS is required only if the HPCI fails. This meets Safety design basis Item b.

An evaluation of ECCS controls shows that no operator action is required to initiate the correct responses of the ECCS.

The alarms and indications provided to the operator in the main control room allow interpretation of any situation requiring ECCS operations, and verify the response of each system. Manual controls are illustrated on functional control diagrams. The main control room operator can manually initiate every essential operation of the ECCS.

The degree to which safety is dependent on operator judgment and response has been appropriately limited by the design of the ECCS control equipment. Therefore, safety design bases Items c.1., c.2., and d. of Subsection 7.1.2.1.3 are satisfied.

The redundancy provided in the design of the control equipment for the ECCS is consistent with the redundancy of the cooling systems themselves. The arrangement of the initiating signals for the ECCS which come from common sensors is the same as that provided by the dual trip system arrangement of the RPS. No failure of a single initiating trip channel can prevent the start of the cooling systems.

The numbers of control components provided in the design for individual cooling system components are consistent with the need for the controlled equipment. An evaluation of the control schemes for each ECCS component shows that no single control failure can prevent the combined cooling systems from providing the core with adequate cooling.

In performing this evaluation, the redundancy of components and cooling systems was considered. The functional control diagrams provided with the descriptions of cooling systems controls were used in assessing the functional effects of instrumentation failures. In the course of the evaluation, protection devices that can interrupt the planned operation of cooling system components were investigated for the results of their normal protective action as well as the effect of maloperation on core cooling effectiveness. The only protection devices that can act to interrupt planned ECCS operation are those that must act to prevent complete failure of the component or system. Examples of such devices are the HPCI turbine overspeed trip, HPCI steam line break isolation trip, pump trips on low suction pressure, and automatically controlled minimum flow bypass valves for pumps. In every case the action of a protective device cannot prevent other redundant cooling systems from providing adequate cooling to the core.

The minimum number of trip channels and sensors, as given in Tables 7.3-5 through 7.3-8, is sufficient to ensure correct functional performance of the ECCS. In determining the minimum number of trip channels needed to ensure functional performance, the use and redundancy of sensors in control circuitry and the redundancy of the controlled equipment in any individual cooling system were considered.

Where no redundancy of trip channels is available in the controls of a cooling system component required to function if the system is to operate, functional performance is not possible unless the trip channels are operable. Where two or more sensors of a monitored variable are arranged in parallel in control circuitry, inoperability of one parallel branch does not compromise performance of the system.

It should be noted that the various degrees of redundancy in control circuitry for the components of the ECCS reflect considerations for the integrated performance of the systems. The tables referenced in this subsection consider only the functional performance of each individual cooling system. To determine the proper state in which an inoperable sensor or trip channel should be placed, the functional effect of the channel and the proper action of the controlled equipment in a LOCA are considered. The condition given in the tables for inoperable sensors provides assurance that the essential functions of each individual ECCS are not degraded in a LOCA situation.

Because the control arrangement used for the ADS is designed to avoid spurious actuation, the information in Table 7.3-6 is worthy of special consideration. The relief valves are controlled by two trip systems, either one of which can initiate automatic depressurization. Each trip system has two trip logics, both of which must trip to initiate depressurization. Table 7.3-6 shows the minimum number of functional trip channels necessary for automatic depressurization.

The conditions indicated by Table 7.3-6 result in both trip systems always remaining capable of initiating automatic depressurization. If an inoperable sensor is in the tripped state or if a synthetic trip signal is inserted in the control circuitry, automatic depressurization can be initiated when the other initiation signals are received. The prohibition against simultaneously inoperative RPV low water level and primary containment high pressure trip channels in any one trip logic is necessary to prevent situations where a trip logic is continuously in the tripped condition. If the trip logics containing the timers are affected, the planned delay in automatic depressurization is eliminated. The trip channel conditions indicated in Table 7.3-6 avoid these undesirable situations.

The LPCI system logic arrangement for the injection valves and recirculation loop valves warrants special consideration in the evaluation of conditions affecting LPCI system performance. The LPCI system sensing circuit for break detection and valve selection is arranged so that failure of a single device or circuit to function on demand does not prevent correct selection of a loop for injection. The system is effective in providing the proper amount of coolant flow into the undamaged recirculation loop under all combinations of recirculation loop pumping conditions, break sizes, and break location.

The conditions represented by Tables 7.3-5 through 7.3-8 are the result of a functional analysis of each individual ECCS. Because of the redundancy in methods of supplying cooling water to the fuel in LOCA situation, and because it is the cooling of the fuel that must be ensured in such a situation, the minimum trip channel conditions in these tables are in excess of those required operationally to ensure core cooling capability. Operational requirements for the ECCS will be determined from the reliability aspects of the integrated performances of the systems when the specific characteristics of core cooling system components are known.

The locations of controls where operation of ECCS components can be adjusted or interrupted have been surveyed. Controls are located in areas under the surveillance of operations personnel.

The environmental capabilities of instrumentation for the ECCS are discussed in the descriptions of the individual systems. Components located inside the primary containment that are essential to ECCS performance are designed to operate in the environment resulting from a LOCA.

7.3.1.3.2 Conformance To Specific Regulatory Requirements

Conformance to Regulatory Guide 1.22 is discussed in Subsections 7.3.1.2.1 through 7.3.1.2.4. Conformance to the requirements of General Design Criteria (GDC) 13, 35, 36, and 37 of 10 CFR 50, Appendix A, is discussed in Subsections 7.3.1.2.1 through 7.3.1.2.4. The requirements of 10 CFR 50, Appendix B, are met as described in Chapter 17.

7.3.1.3.3 Conformance To IEEE 279-1971

The provisions of the HPCI, ADS, core spray, and LPCI systems design that fulfill the general requirements of IEEE 279-1971 are given, for the most part, in the GE Topical Report, Compliance of Protection Systems to Industry Criteria; General Electric BWR Nuclear Steam Supply System, NEDO-10139, Subsections 3.4.3, 3.5.2, 3.2.2, and 3.3.2, respectively.

The HPCI, ADS, core spray, and LPCI interlock no control systems; therefore, no failure or combination of failures in the control systems can have any effect on the HPCI, ADS, core spray, or LPCI system.

The ECCS equipment cabinets are identified by means of colored nameplates, in conformance with the 1971 identification requirements. Controls for each subsystem are grouped in one area of the control panel. Relays are located in separated panels for each division and subsystem.

7.3.1.3.4 Industry Standard IEEE 338-1971

The ECCS conforms to IEEE 338-1971.

7.3.1.3.5 Industry Standard IEEE 323-1971

Conformance to IEEE 323-1971 is described in NEDO-10698. See also Section 3.11.

7.3.1.3.6 Industry Standard IEEE 344-1971

Conformance to IEEE 344-1971 is described in NEDO-10678. See also Section 3.10.

7.3.2 Containment and Reactor Vessel Isolation Control System

7.3.2.1 Design-Basis Information

The design-basis information for the CRVICS, as required by Section 3 of IEEE 279-1971, is provided in Subsection 7.1.2.1.2 and is supplemented by the following:

a. To limit the uncontrolled release of radioactive materials to the environs, the CRVICS shall initiate, with precision and reliability, timely isolation of penetrations through the primary containment structure, which could otherwise allow the uncontrolled release of radioactive materials whenever the values of monitored variables exceed preselected operational limits

b. To provide assurance that important variables are monitored with a precision sufficient to fulfill safety design basis Item a., the CRVICS shall respond correctly to the sensed variables over the expected range of magnitudes and rates of change

c. To provide assurance that important variables are monitored with a precision sufficient to fulfill safety design basis Item a., an adequate number of spatially independent sensors are provided for monitoring essential variables that have spatial dependence

d. To provide assurance that conditions indicative of a gross failure of the nuclear system process barrier are detected with sufficient timeliness and precision to fulfill safety design basis Item a., CRVICS inputs shall be derived, to the extent feasible and practical, from variables that are true, direct measures of operational conditions

e. The time required for closure of the main steam isolation valves (MSIVs) shall be short, so that the release of radioactive material and the loss of coolant as a result of a breach of a steam line outside the primary containment are minimal

f. The time required for closure of the MSIVs shall not be so short that inadvertent isolation of steam lines causes a more severe transient than that resulting from closure of the turbine stop valves coincident with failure of the turbine bypass system. This basis ensures that the MSIV closure speed is compatible with the ability of the reactor protection system (RPS) to protect the fuel and nuclear system process barrier

g. To provide assurance that closure of Class A and Class B automatic isolation valves is initiated (Subsection 7.3.2.2.1) when required, with sufficient reliability to fulfill safety design basis Item a., the following safety design bases are specified for the systems controlling Class A and Class B automatic isolation valves:

    1. Any one failure, maintenance operation, calibration operation, or test to verify operational availability shall not impair the functional ability of the isolation control system to respond correctly to essential monitored variables, assuming no other single active failure

    2. The system shall be designed for a high probability that when any essential monitored variable exceeds the isolation setpoint, the event shall either result in automatic isolation or shall not impair the ability of the system to respond correctly as other monitored variables exceed their trip points

    3. Where a plant condition that requires isolation can be brought on by a failure or malfunction of a control or regulating system, and the same failure or malfunction prevents action by one or more isolation control system channels designed to provide protection against the unsafe condition, the remaining portions of the isolation control system shall meet the requirements of safety design bases Items a., b., c., and g.1.

    4. The power supplies for the CRVICS shall be arranged so that loss of one supply cannot prevent automatic isolation when required

    5. The system shall be designed so that, once initiated, automatic isolation action goes to completion. Return to normal operation after isolation action requires deliberate operator action

    6. There shall be sufficient electrical and physical separation between trip channels monitoring the same essential variable to prevent environmental factors, electrical faults, and physical events from impairing the ability of the system to respond correctly

    7. Earthquake ground motions shall not impair the ability of the CRVICS to initiate automatic isolation.

h. To ensure that the timely isolation of main steam lines is accomplished, when required, with extraordinary reliability, at least one of the isolation valves in each of the steam lines does not rely on continuity of any variety of electrical power for the motive force to achieve closure

i. To reduce the probability that the operational reliability and precision of the CRVICS are degraded by operator error, the following safety design bases are specified for Class A and Class B automatic isolation valves:

   1. Access to all trip settings, component calibration controls, test points, and other terminal points for equipment associated with essential monitored variables shall be under the physical control and supervision of the main control room operator

   2. The means for bypassing trip channels, trip logics, or system components is under the control of the main control room operator. If the ability to trip some essential part of the system has been bypassed, this fact shall be continuously indicated in the main control room.

j. To provide the operator with a means independent of the automatic isolation functions to take action in the event of a failure of the nuclear system process barrier, it shall be possible for the main control room operator to manually initiate isolation of the primary containment and RPV

k. The following bases are specified to provide the operator with the means to assess the condition of the CRVICS and to identify conditions indicative of a gross failure of the nuclear system process barrier

   1. The CRVICS is designed to provide the operator with information pertinent to the status of the system

   2. Means are provided for prompt identification of instrument channel and trip system responses.

l. It shall be possible to check the operational availability of each trip channel and trip logic during reactor operation.

7.3.2.2 System Description

7.3.2.2.1 Identification

Class A isolation valves are in lines that communicate directly with the RPV and penetrate the primary containment. These lines generally have two isolation valves in series, one inside the primary containment and the other outside the primary containment.

Class B isolation valves are in lines that do not communicate directly with the RPV, but penetrate the primary containment free space. These lines have two isolation valves in series, both of which are outside the primary containment.

Class C isolation valves are in lines that penetrate the primary containment, but do not communicate directly with the RPV, the primary containment free space, or the environs (closed systems). These lines require one isolation valve located outside the primary containment. The CRVICS includes the sensors, trip channels, switches, and remotely activated valve-closing mechanisms associated with the valves, which, when closed, effect isolation of the primary containment and/or the RPV.

It should be noted that the control systems for the Class A and Class B isolation valves, which close by automatic action pursuant to the safety design bases, are the main subjects of this section.

However, Class C remotely operated isolation valves are included because they add to the operator's ability to effect manual isolation. Testable check valves are also included because they provide the operator with the ability to ensure that the check valve disk can respond to reverse flow.

7.3.2.2.2 Power Supply

The two power supplies for the trip systems and trip logics are fed from the same two electrical buses that supply the RPS trip systems. Each of the buses has its own motor-generator set. Either bus can receive alternative power from a bus that can be energized by standby power. The buses cannot be simultaneously supplied from the same power source.

Isolation valves receive electrical power from buses that are reliable, in that power would be available from standby power sources except those isolation valves that are powered from the RPS. These valves automatically isolate on loss of offsite power. Power for the operation of the two valves in a line comes from different divisional sources. The MSIVs use ac, dc, and air or nitrogen pressure in the control scheme.

7.3.2.2.3 Physical Arrangement

Table 6.2-2 lists the lines that penetrate the primary containment and indicates the types and locations of the isolation valve(s) installed in each line. Lines that penetrate the primary containment and are in direct communication with the RPV generally have two Class A isolation valves, one inside the primary containment and one which is outside the primary containment. Lines that penetrate the primary containment and that communicate with the primary containment free space, but which do not communicate directly with the RPV, generally have two Class B isolation valves located outside the primary containment.

Class A and Class B automatic isolation valves are considered essential for protection against the gross release of radioactive material in the event of a breach in the nuclear system process barrier. Process lines that penetrate the primary containment but do not communicate directly with the RPV, the primary containment free space, or the environs, have at least one Class C isolation valve located outside the primary containment. This Class C valve may close either by process action (reverse flow) or by remote manual operation.

Table 6.2-2 presents information about all piping penetrations in the primary containment. Only the controls for the automatic isolation valves are discussed in this subsection. The valves that are the subject of this text are specially identified in the detailed descriptions that follow.

Power cables are run in conduits from appropriate electrical sources to the motor or solenoid involved in the operation of each isolation valve. Valve position switches are mounted on the valve for which position is to be indicated. Switches are enclosed in cases to protect them from environmental conditions.

The control arrangement for the MSIVs includes pneumatic piping and an accumulator for each valve. Pressure and water-level sensors are mounted on instrument racks in either the reactor building or the turbine building. Cables from each sensor are routed in conduits and cable trays to the trip unit racks located in the reactor building. All signals transmitted to the main control room are electrical; no pipe from the nuclear system or the primary containment penetrates the main control room. Pipes used to transmit level information from the RPV to sensing instruments terminate inside the secondary containment (reactor building). The sensor cables and power supply cables are routed to cabinets in the control center where the logic arrangements of the system are formed.

To ensure continued protection against the uncontrolled release of radioactive material during and after earthquake ground motions, the control system required for automatic closure of Class A and Class B valves is seismic designed as Category I equipment as described in Subsection 7.1.2.1.2. This meets safety design basis Item g.7.

7.3.2.2.4 Logic

The basic logic arrangement is one in which an automatic isolation valve is controlled by redundant trip systems. In cases where many isolation valves close on the same signal, two trip systems control the entire group. Where just one or two valves must close in response to a special signal, two trip systems may be formed from the instruments provided to sense the special condition. Valves that respond to the signals from common trip systems are identified in the detailed description of isolation functions.

Each trip system has two trip logics, each of which receives input signals from at least one trip channel for each monitored variable. Thus, two trip channels are required for each essential monitored variable to provide independent inputs to the trip logics of one trip system. A total of four trip channels for each essential monitored variable is required for the trip logics of each trip system. The trip actuators associated with one trip logic provide inputs into the trip actuator logics for either one or two isolation trip systems. The two automatic trip logics associated with each trip system can produce a redundant isolation valve closure. For main steam line isolation valves only, both trip systems are used to actuate closure of inboard and outboard isolation valves. The logic is "one-out-of-two taken twice" arrangement for each variable.

The basic logic arrangement described above does not apply to Class C isolation valves and testable check valves. Exceptions to the basic logic arrangement are made in several instances for certain Class A and Class B isolation valves. The reasons for this are explained in Subsection 7.3.2.1.

7.3.2.2.5 Operation

During normal operation of the isolation control system, when isolation is not required, sensor and trip contacts essential to safety are closed; trip channels, trip logics, and trip actuators are normally energized. Whenever a trip channel sensor contact opens, its auxiliary relay deenergizes, causing contacts in the trip logic to open. The opening of contacts in the trip logic deenergizes its trip actuators. When deenergized, the trip actuators open contacts in all the trip actuator logics for that trip system. If a trip then occurs in any of the trip logics of the other trip system, the trip actuator logics for the trip system are deenergized. With both trip systems tripped, appropriate contacts open or close in valve-control circuitry to actuate associated valve-closing mechanisms. Automatic isolation valves that are normally closed also receive the isolation signal.

The control system for each Class A isolation valve is designed to provide closure of the valve in time to prevent uncovering of the fuel as a result of a break in the pipeline which the valve isolates. The control systems for Class A and Class B isolation valves are designed to provide closure of the valves with sufficient rapidity to restrict the release of radioactive material to the environs below the guideline values of published regulations.

All automatic Class A and Class B valves and remotely operable Class C valves can be closed by manipulating switches in the main control room, thus providing the operator with a means independent of the automatic isolation functions to take action in the event of a failure of the nuclear system process barrier. This meets safety design basis Item j.

Once isolation is initiated, the valve continues to close, even if the condition that caused isolation is restored to normal. The operator must manually operate switches in the main control room to reopen a valve that has been automatically closed. Unless manual override features are provided in the manual control circuitry, the operator cannot reopen the valve until the conditions that initiated isolation have cleared. This is the equivalent of a manual reset and meets safety design basis Item g.5.

A trip of an isolation control system trip channel is annunciated in the main control room so that the operator is immediately informed of the condition. The response of isolation valves is indicated by "open-closed" lights. All motor-operated Class A and Class B isolation valves have a set of "open-closed" lights. The lights for each valve are located on the main control room panel at the manual control switches that control the valve. A second set of valve group displays that indicate status of the eighteen (18) containment isolation valve groups and individual valve status is available on the Integrated Plant Computer System (IPCS) as part of SPDS.

Inputs to annunciators, indicators, and the computer are arranged so that no malfunction of the annunciating, indicating, or computing equipment can functionally disable the system. Signals directly from the isolation control system sensors are not used as inputs to annunciating or data-logging equipment. Isolation is provided between the primary signal and the information output. The arrangement of indications pertinent to the status and response of the CRVICS satisfies safety design bases Items k.1. and k.2.

7.3.2.2.6 Isolation Valve Closing Devices

Table 6.2-2 itemizes the type of closing device provided for each isolation valve intended for use in automatic or remote manual isolation of the primary containment or RPV. In order that automatic Class A valves be fully closed in time to prevent the RPV water level from falling below the top of the active fuel as a result of a break of the line the valve isolates, the valve-closing mechanisms are designed to give the maximum closing times specified in the Technical Requirements Manual. In many cases a standard closing rate of 12 in./minute is adequate to meet isolation requirements. Using the standard rate, a 12-in. valve is closed in 60 sec. Because of the relatively long time required for fission products to reach the containment atmosphere following a break in the nuclear system process barrier inside the primary containment, a 1-minute closure time is adequate for the automatic closing devices on most Class B isolation valves.

Motor-operators for Class A and Class B isolation valves are selected with capabilities suitable to the physical and environmental requirements of service. The required valve-closing rates were considered in selecting motor-operators. Appropriate torque and limit switches are used to ensure proper valve seating. Handwheels, which are automatically disengaged from the motor-operator when the motor is energized, are provided for local-manual operation.

Direct solenoid-operated isolation valves and solenoid air-pilot valves are chosen with electrical and mechanical characteristics that make them suitable for their services. Appropriate water- tight or weather tight housing is used to ensure proper operation under accident conditions.

The pneumatic actuator used for testable check valves is designed to allow for the opening of the valve at near zero psi differential pressure across the valve. The actuator cannot close the valve against forward flow, or prevent the closing of the valve against reverse flow. Thus, the check valve will neither hinder forward fluid flow nor fail to stop reverse flow regardless of the condition of the actuator.

The MSIVs are spring-closing, pneumatic, piston-operated valves designed to close on loss of pneumatic pressure to the valve operator. This is a fail-safe design. The control arrangement is shown in Figure 7.3-10. Closure time for the valves is adjustable between 3 and 10 sec. Each valve is piloted by two, three-way, packless, direct-acting, solenoid-operated pilot valves, one of which is powered by ac and the other by dc. An accumulator is located close to each isolation valve to provide pneumatic pressure for valve closing in the event of failure of the normal gas supply system.

The valve pilot system and the pneumatic lines, as shown in Figure 7.3-11, are arranged so that when one or both solenoid-operated pilot valves are energized, normal gas supply provides pneumatic pressure to the gas-operated pilot valve to direct gas pressure to the main valve operator. This overcomes the closing force exerted by the spring and keeps the main valve open. When both pilots are deenergized, as would be the result when both trip systems trip, or when the manual switch is placed in the closed position, the path through which gas pressure acts is switched so that the opposite side of the valve operator is pressurized. This assists the spring in closing the valve. In the event of gas-supply failure, the loss of gas pressure causes the gas-operated pilot valve to move by spring force to the position resulting in main valve closure. Main valve closure is then effected by means of the gas stored in the accumulator and by the spring.

Gas pressure and the force exerted by the spring, acting together, are both required to close the valve. The isolation valves inside the primary containment (inboard) are designed to close with pneumatic pressure and spring force with the vented side of the piston operator at the containment peak accident pressure. The outboard valve is exactly the same design, although it will be subjected only to atmospheric pressures.

The accumulator volume holds reserve pneumatic pressure inventory to assist the springs in closing MSIVs when the pneumatic supply to the accumulator has failed. The supply line to the accumulator is large enough to make up pressure to the accumulator at a rate faster than the rate that the valve operation bleeds pressure from the accumulator during valve opening or closing.

A separate, single, solenoid-operated pilot valve with an independent test switch is included to allow manual testing of each isolation valve from the main control room. The testing arrangement is designed to give a slow closure of the isolation valve being tested so that rapid changes in steam flow and NSSS pressure are avoided. Slow closure of a valve during testing requires 50 to 60 sec.

7.3.2.2.7 Isolation Functions and Settings

The isolation trip settings of the CRVICS are listed in Table 7.3-9. The functions that initiate automatic isolation are itemized in Table 6.2-2 in terms of the lines that penetrate the primary containment. Table 6.2-2 includes all lines of concern for isolation purposes. Although this section is concerned with the electrical control systems that initiate isolation to prevent direct release of radioactive material from the primary containment or nuclear system process barrier, the additional information given in Table 6.2-2 can be used to assess the overall (electrical and mechanical) isolation effectiveness of each system having lines that penetrate the primary containment.

Isolation functions and trip settings used for the electrical control of isolation valves in fulfillment of the previously-stated safety design bases are discussed in the following subsection. The role each isolation function plays in initiating isolation of barrier valves or groups of valves is illustrated in the functional control diagrams of Figures 7.3-2, 7.3-12, 7.3-13, 7.3-14, and 7.4-1.

7.3.2.2.7.1 Reactor Vessel Low Water Level

A low-water level in the RPV could indicate that reactor coolant is being lost through a breach in the nuclear system process barrier and that the core is in danger of becoming overheated as the reactor coolant inventory diminishes. Reactor vessel low-water level initiates closure of various Class A valves and Class B valves. The closure of Class A valves is intended to either isolate a breach in any of the lines in which valves are closed, or to conserve reactor coolant by closing off process lines. The closure of Class B valves is intended to prevent the escape of radioactive materials from the primary containment through process lines that are in communication with the primary containment free space.

Three RPV low water-level isolation trip settings are used to completely isolate the RPV and the primary containment. The level signals are defined as follows and are shown in Figure 7.3-12:

a. Level 3 (L3) is the highest of the three and also initiates the level scram and isolates the RHR system

b. Level 2 (L2) is the initiation level for the reactor core isolation cooling (RCIC) and HPCI systems and is selected to be less than the volume resulting from a void collapse occurring in the event of a scram from full power. Level 2 also closes certain containment isolation valves

c. Level 1 (L1) is selected far enough above the top of the active fuel and is selected based on the time required for the RHR and core spray systems to function in the event of a large break. Level 1 also isolates the MSIVs.

Isolation of the following lines occurs when the level reaches L3, which is the highest or most conservative level (Table 6.2-2, signal C):

a. Drywell equipment drain sump discharge

b. Drywell floor drain sump discharge

c. RHR shutdown cooling

d. Traversing in-core probe (TIP) system withdrawal.

The second level (L2) isolates the majority of the nuclear pressure boundary lines and the primary and secondary containment paths. This is also the level that starts the HPCI and RCIC systems, and it has been selected to be lower than the level change resulting from a void collapse following a scram from full power. Specifically, isolation of the following lines is initiated on Level 2 (Table 6.2-2, signal B):

a. Reactor sample lines

b. Reactor water cleanup

c. Drywell air and nitrogen inlet

d. Suppression chamber exhaust

e. Suppression chamber air and nitrogen inlet

f. Drywell exhaust

g. Drywell pressure control

h. Suppression chamber pressure control

i. Purge to standby gas treatment

j. Control center heating, ventilation, and air conditioning (HVAC)

k. Reactor building ventilation

l. Recirculation pump seal purge

m. Torus water management

n. Primary containment radiation monitoring.

The final isolation level is Level 1 (L1). This level setting provides automatic isolation for the following lines, which penetrate the primary containment, if they are open (Table 6.2-2, signal A):

a. RHR containment spray

b. RHR test line

c. Core spray test line

d. Suppression chamber spray

e. Main steam

f. Main steam line drains.

7.3.2.2.7.2 Main Steam Line High Radiation

High radiation in the vicinity of the main steam lines could indicate a gross release of fission products from the fuel. High radiation near the main steam lines initiates isolation of the reactor water sample line (Table 6.2-2, signal D). In addition, main steam line high radiation trips the condenser mechanical vacuum pumps and gland seal exhausters (see Subsection 11.4.3.8.2.3).

The high-radiation trip setting is selected high enough above background radiation levels so that spurious isolation is avoided, yet low enough to promptly detect a gross release of fission products from the fuel. Further information regarding high-radiation setpoint is available in Section 11.4.

7.3.2.2.7.3 Main Steam Line Space High Temperature

High temperature in the space in which the main steam lines are located outside the primary containment could indicate a breach in a main steam line. The automatic closure of various Class A valves prevents both the excessive loss of reactor coolant and the release of significant amounts of radioactive material from the nuclear system process barrier. When high temperatures occur in the main steam line space, all four main steam lines and the main steam line drain are isolated.

The main steam line space high-temperature trip is set far enough above the temperature expected during operations at rated power so that spurious isolation is avoided, yet low enough to provide early indication of a steam line break.

7.3.2.2.7.4 Main Steam Line High Flow

Main steam line high flow could indicate a break in a main steam line. The automatic closure of various Class A valves prevents the excessive loss of reactor coolant and the release of significant amounts of radioactive material from the nuclear system process barrier. On detection of the main steam line high flow, all four main steam lines and the main steam line drain are isolated.

The main steam line high-flow-trip setting was selected high enough to permit the isolation of one main steam line for the test at rated power without causing an automatic isolation of the rest of the steam lines, yet low enough to permit early detection of a steam line break.

7.3.2.2.7.5 Low Steam Pressure at Turbine Inlet

Low steam pressure at the turbine inlet while the reactor is operating could indicate a malfunction of the nuclear system pressure regulator, at which time the turbine control valves or turbine bypass valves open fully. This action causes rapid depressurization of the nuclear system. From part-load operating conditions, the rate of decrease of nuclear system saturation temperature could exceed the allowable rate of change of vessel temperature. A rapid depressurization of the RPV while the reactor is near full power could result in undesirable differential pressure across the channels around some fuel bundles of sufficient magnitude to cause mechanical deformation of channel walls. Such depressurizations, without preventive action, could require thorough vessel analysis or core inspection prior to returning the reactor to power operation. To avoid the time-consuming requirements following a rapid depressurization, the steam pressure at the turbine inlet is monitored. On falling below a preselected value with the reactor in the RUN mode, isolation of all four main steam lines and the main steam drain line is initiated.

The low-steam-pressure isolation setting was selected far enough below normal turbine inlet pressures so that spurious isolation is avoided, yet high enough to provide timely detection of a pressure regulator malfunction. Although this isolation function is not required to satisfy any of the safety design bases for this system, this discussion is included here to make the listing of isolation functions complete.

7.3.2.2.7.6 Primary Containment (Drywell) High Pressure

High pressure in the drywell could indicate a breach of the nuclear system process barrier inside the drywell. The automatic closure of various Class B valves prevents the release of significant amounts of radioactive material from the primary containment. On detection of a high drywell pressure, the following pipelines are isolated:

a. Drywell equipment drain discharge
b. Drywell floor drain discharge
c. TIP tubes
d. Drywell air and nitrogen inlet
e. Suppression chamber exhaust valves
f. Suppression chamber air and nitrogen inlet
g. Drywell exhaust
h. Drywell pressure control
i. Suppression chamber pressure control
j. Purge to standby gas treatment
k. Control center HVAC recirculation mode
l. Reactor building ventilation system isolation
m. Torus water management
n. Primary containment radiation monitoring.
o. Reactor recirculation pumps seal purge supply lines
p. EECW Division 1 and 2 drywell cooling supply lines (Note: isolation signal from ECCS logic, not from RPS logic)

The primary containment high pressure isolation setting was selected to be as low as possible without inducing spurious isolation trips.

7.3.2.2.7.7 Reactor Core Isolation Cooling Turbine Steam Line Space High Temperature

High temperature in the vicinity of the RCIC turbine could indicate a break in the RCIC steam line. The automatic closure of certain Class A valves prevents the excessive loss of radioactive material from the nuclear system process barrier. When high temperature occurs in the RCIC area, the RCIC turbine steam line is isolated. The high-temperature isolation setting was selected far enough above anticipated normal RCIC system operational levels so that spurious operation is avoided, yet low enough to provide timely detection of an RCIC turbine steam line break.

7.3.2.2.7.8 Reactor Core Isolation Cooling Turbine High Steam Flow

Reactor core isolation cooling turbine high steam flow could indicate a break in the RCIC turbine steam line. The automatic closure of certain Class A valves prevents the excessive loss of reactor coolant and the release of significant amounts of radioactive materials from the nuclear system process barrier. The RCIC turbine high-steam-flow trip setting was selected high enough to avoid spurious isolation, yet low enough to provide timely detection of a RCIC turbine steam line break. An electrical time-delay circuit prevents spurious isolations on the turbine startup transient.

The logic arrangement used for this function is shown in Figure 7.4-1, and is an exception to the usual logic requirements since high steam flow is the second method of detecting a RCIC turbine steam line break.

7.3.2.2.7.9 Reactor Core Isolation Cooling Turbine Steam Line Low Pressure

The RCIC turbine steam line low pressure is used to automatically close the two isolation valves in the RCIC turbine steam line so that steam and radioactive gases do not escape from the RCIC turbine shaft seals into the reactor building after steam pressure has decreased to such a low value that the turbine cannot be operated. The isolation setpoint is chosen at a pressure below that at which the RCIC turbine can operate effectively.

7.3.2.2.7.10 High-Pressure Coolant Injection Turbine Steam Line Space High Temperature

High temperature in the vicinity of the HPCI turbine could indicate a break in the HPCI turbine steam line. The automatic closure of certain Class A valves prevents the excessive loss of reactor coolant and the release of significant amounts of radioactive material from the nuclear system process barrier. When high temperature occurs in the HPCI turbine area, the HPCI turbine steam supply line is isolated. The high-temperature isolation setting was selected far enough above anticipated normal HPCI system operational levels so that spurious isolation is avoided, yet low enough to provide timely detection of an HPCI turbine steam line break.

7.3.2.2.7.11 High-Pressure Coolant Injection Turbine High Steam Flow

The HPCI turbine high steam flow could indicate a break in the HPCI turbine steam line. The automatic closure of certain Class A valves prevents the excessive loss of reactor coolant and the release of significant amounts of radioactive materials from the nuclear system process barrier.

On detection of HPCI turbine high steam flow, the HPCI turbine steam line is isolated. The high-steam-flow trip setting was selected high enough to avoid spurious isolation, yet low enough to provide timely detection of an HPCI turbine steam line break. An electrical time-delay circuit prevents spurious isolations on the turbine startup transient.

The logic arrangement used for this function is shown in Figure 7.3-2, and is an exception to the usual logic requirement since high steam flow is the second method of detecting an HPCI turbine steam line break.

7.3.2.2.7.12 High-Pressure Coolant Injection Turbine Steam Line Low Pressure

The HPCI turbine steam line low pressure is used to automatically close the two isolation valves in the HPCI turbine steam line so that steam and radioactive gases do not escape from the HPCI turbine shaft seals into the reactor building after steam pressure has decreased to such a low value that the turbine cannot be operated. The isolation setpoint is chosen at a pressure below that at which the HPCI turbine can operate.

7.3.2.2.7.13 Reactor Building Ventilation Exhaust High Radiation

High radiation prior to the reactor building ventilation exhaust fans could indicate a breach of the nuclear system process barrier inside the primary containment, which would result in increased airborne radioactivity levels in the primary containment exhaust to the secondary containment. The automatic closure of certain Class B valves acts to close off release routes for radioactive material from the primary containment into the secondary containment (reactor building). Reactor building ventilation exhaust high radiation initiates isolation of the following pipelines:

a. Drywell air and nitrogen inlet
b. Suppression chamber exhaust
c. Suppression chamber air and nitrogen inlet
d. Drywell exhaust
e. Drywell pressure control
f. Suppression chamber pressure control
g. Purge to standby gas treatment
h. Reactor building supply and exhaust (vent)
i. Control center normal air intake and exhaust.

The high-radiation trip setting selected is far enough above background radiation levels to avoid spurious isolation, yet low enough to provide timely detection of nuclear system process barrier leaks inside the primary containment. Because the primary containment high pressure isolation function and the RPV low-water-level isolation function are adequate in effecting appropriate isolation of the above pipelines for gross breaks, the reactor building ventilation exhaust high-radiation isolation function is provided as a third redundant method of detecting breaks in the nuclear system process barrier significant enough to require automatic isolation.

7.3.2.2.8 Instrumentation

Sensors providing inputs to the CRVICS are not used for the automatic control of the process system. Thus, the functional controls of the protection and process systems are separated. Trip channels are physically and electrically separated to reduce the probability that a single physical event could prevent isolation. Trip channels for one monitored variable that are grouped near each other provide inputs to different isolation trip systems. The sensors are used functionally in the isolation control system, as illustrated in Figures 7.3-2, 7.3-9, 7.3-12, 7.3-13, and 7.4-1. Table 7.3-9 lists instrument characteristics. The sensors are described in the following paragraphs:

a. Reactor vessel low-water-level signals are initiated from eight level transmitters (differential pressure transmitters) that sense the difference between the pressure due to the constant reference column of water and the pressure due to the actual water level in the vessel.

   A backfill system is installed on each level instrument reference leg. The system provides a metered flow of water from the control rod drive system to each leg. The flow is low enough to not affect the performance of the instrumentation. The backfill is designed to prevent the accumulation of dissolved noncondensable gases in the reference legs.

   Four narrow-range transmitters provide an input to individual trip units that provide an isolation signal when the reactor water level drops to the first (highest) water level (L3) trip settings. Each of the four wide-range transmitters provides signals to two trip units. One trip unit provides the isolation signal for the second low water level (L2) trip setting. The other trip unit provides the isolation signal for the third and lowest (L1) trip setting

   Logic channel trips are arranged in one-out-of-two-twice logic. Channels A or C and B or D are required to initiate isolation for both inboard and outboard MSIVs. Two of the four transmitters for each trip level are connected to one pair of taps (A and B). The other two transmitters (C and D) are connected to taps that are 180^{o} around the RPV from the first pair. This physical separation ensures that no single physical event can prevent isolation if it were required. Cables from the transmitters are routed to the trip units in the auxiliary building

b. Main steam line radiation is monitored by four radiation monitors, which are described in Subsection 11.4.3.8.2.3

c. High temperature in the vicinity of the main steam lines is detected by 16 resistance temperature detectors (RTDs) located along the main steam lines between the drywell wall and the reactor building steam tunnel pressure relief doors. Eight additional RTDs sense high temperature in the turbine building steam tunnel. The detectors are located or shielded so that they are sensitive to air temperature and not to the radiated heat from hot equipment. The main steam line space temperature detection system is designed to detect leaks of from 1 percent to 10 percent of rated steam flow

d. High flow in each main steam line is sensed by four differential pressure transmitters that sense the pressure difference across the flow restrictor in that line. The logic is arranged as two trip systems with two trip logics in each system. Any two trip logics can trip the isolation valve. Each trip logic receives an input from a high-steam-flow trip channel for each steam line

e. Main steam line low pressure is sensed by four pressure transmitters that sense pressure downstream of the outboard MSIVs. The sensing point is located at the header that connects the four steam lines upstream of the turbine stop valves. The logic is arranged as two trip systems with two trip logics per system. Any two trip logics associated with each trip system can trip the isolation valves

f. Primary containment pressure is monitored by four pressure transmitters that are mounted on instrument racks outside the drywell. Pipes that terminate in the reactor building connect the transmitters to the drywell interior. Cables are routed from the transmitter to the main control room. The transmitters are grouped in pairs, physically separated, and electrically connected to the isolation control system so that no single event prevents isolation due to primary containment high pressure

g. High temperature in the vicinity of the RCIC turbine is sensed by two ambient and two differential temperature measurements. Only the ambient temperature sensors can initiate RCIC isolation

h. High flow in the RCIC turbine steam line is sensed by two differential pressure transmitters, which monitor the differential pressure across a mechanical flow element installed in the RCIC turbine steam supply pipeline. The tripping of either trip channel initiates isolation of the RCIC turbine steam line. This is an exception to the usual sensor requirement

i. Low pressure in the RCIC turbine steam line is sensed by four pressure transmitters from the RCIC turbine steam line upstream of the isolation valves. The transmitters are arranged as two trip systems, either of which must trip to initiate isolation of the RCIC turbine steam line. Each trip system receives inputs from two pressure transmitters, both of which must trip to trip the system

j. High temperature in the vicinity of the HPCI turbine is sensed by two ambient and two differential temperature measurements. Only the ambient temperature sensors can initiate isolation

k. High flow in the HPCI turbine steam line is sensed by two differential pressure transmitters which monitor the differential pressure across a mechanical flow element installed in the HPCI turbine steam line. The tripping of either transmitter initiates isolation of the HPCI turbine steam line

l. Low pressure in the HPCI turbine steam line is sensed by four pressure transmitters from the HPCI turbine steam line upstream of the isolation valves. The transmitters are arranged as two trip systems, either of which can initiate isolation of the HPCI turbine steam line. Each trip system receives inputs from two pressure transmitters, both of which must trip to trip the trip system

m. Reactor building ventilation exhaust radiation is monitored by two independent redundant monitors. Each monitoring trip channel provides the isolation function as described in Subsections 7.3.2.2.7.13 and 11.4.3.8.2.4. The primary containment high pressure isolation function and the RPV low water level isolation function are adequate in effecting the isolation of the pipelines that could release radioactivity due to breach of the nuclear system process barrier inside the primary containment. The reactor building ventilation exhaust radiation is provided as a third redundant method of detecting breaks in the nuclear system process barrier (significant enough to require automatic isolation).

   In addition to the above, the fuel pool ventilation exhaust radiation monitoring system is provided to detect a high radiation level in the ductwork that could be due to fission gases from a refueling accident. Four fuel pool ventilation exhaust detectors in a redundant "one out of two" logic provide the isolation function as described in Subsection 11.4.3.8.2.11.

n. High temperature in the spaces occupied by the reactor shutdown cooling system piping outside the primary containment is sensed by temperature switches that activate alarms only, indicating possible pipe breaks. Automatic isolation on high temperature is not required since the RPV low-water-level isolation function is adequate in preventing the release of significant amounts of radioactive material in the event that either of these two systems suffers a breach.

Sensor trip channel and trip logic relays are high reliability relays equal to type-HFA relays made by GE. Table 7.3-10 lists the minimum numbers of trip channels needed to ensure that the isolation control system retains its functional capabilities.

7.3.2.2.9 Environmental Capabilities

Special consideration has been given to isolation requirements during a LOCA inside the drywell. Components of the CRVICS that are located inside the primary containment and that must operate during a LOCA are the cables, control mechanism, and valve operators or isolation valves inside the drywell. These isolation components are required to be functional in a LOCA environment.

Electrical cables for isolation valves in the same lines are routed separately. Motor-operators for valves inside the primary containment are of the totally enclosed type; those outside the primary containment have weatherproof type enclosures. Solenoid valves, whether used for direct valve isolation or as an air or gas pilot, are provided with watertight enclosures. All cables and operators are capable of operation in the most unfavorable ambient conditions anticipated for design-basis accident (DBA) conditions. Temperature, pressure, humidity, and radiation are considered in the selection of equipment for the system. Cables used in high radiation areas have radiation-resistant insulation. Shielded cables are used whenever necessary to eliminate interference from magnetic fields. Electrical cables are selected with insulation designed for this service.

Closing mechanisms and valve operators are considered satisfactory for use in the isolation control system only after completion of environmental testing under LOCA conditions or after submission of evidence from the manufacturer describing the results of suitable prior tests.

Verification that the isolation equipment has been designed, built, and installed in conformance to the specified criteria is accomplished through the following series of tests in the vendor's shop or after installation at the plant before startup, during startup, and thereafter, where appropriate, during the service life of the equipment:

a. Material qualification tests
b. Weld qualification tests
c. Metallurgical tests
d. Hydrostatic tests
e. Leakage tests
f. Closing time tests
g. Preoperational tests
h. Startup tests
i. Periodic tests
j. Verification of type of materials used for insulation
k. Environmental testing of electrical equipment under simulated accident conditions.

Control is also exercised through review of equipment design during bid review and by approval of vendor's drawings during the fabrication stage. Purchase specifications require extensive control of materials and of the fabrication procedure.

7.3.2.3 Analysis

The CRVICS is described in Subsection 7.3.2.2. The safety design bases and specific regulatory requirements of this system are stated in Subsection 7.3.2.1. This analysis shows compliance with these requirements.

7.3.2.3.1 Safety Evaluation Analysis

The CRVICS, in conjunction with other safety systems, is designed to provide timely protection against the onset and consequences of accidents involving the gross release of radioactive materials from the fuel and nuclear system process barriers. It is the objective of Chapter 15 to identify and evaluate postulated events resulting in gross failure of the fuel barrier and the nuclear system process barrier. The consequences of such gross failures are described and evaluated in that section.

Design procedure has been to select tentative isolation trip settings that are far enough above or below normal operating levels that spurious isolation and operating inconvenience are avoided. It is then verified by analysis that the release of radioactive material following postulated gross failures of the fuel and nuclear system process barrier is kept within acceptable bounds. Trip-setting selection is based on operating experience and constrained by the safety design and the safety analyses.

Chapter 15 shows that the actions initiated by the CRVICS, in conjunction with other safety systems, are sufficient to prevent releases of radioactive material from exceeding the guide values of published regulations. Because the actions of the system are effective in restricting the uncontrolled release of radioactive materials under accident situations, the CRVICS meets the precision and timeliness requirements of safety design basis Item a.

The CRVICS meets the precision and timeliness requirements of safety design basis Item a. using instruments with the characteristics described in Table 7.3-9. Therefore, it is concluded that safety design basis Item b. is met.

Temperatures in the spaces occupied by various steam lines outside the primary containment are the only essential variables of significant spatial dependence that provide inputs to the CRVICS. The large number of temperature sensors and their dispersed arrangement near the steam lines requiring this type of break protection provide assurance that a significant break will be detected rapidly and accurately. The number of sensors provided for steam line break detection satisfies safety design basis Item c.

Because the CRVICS meets the timeliness and precision requirements of safety design basis Item a. by monitoring variables that are true, direct measures of operational conditions, it is concluded that safety design basis Item d. is satisfied.

Subsection 15.6.4 evaluates a gross breach in a main steam line outside the primary containment during operation at rated power. The evaluation shows that the main steam lines are automatically isolated in time to prevent both a release of radioactive material in excess of the guideline values of published regulations, and to prevent the loss of coolant from being great enough to allow uncovering of the core. The time required for automatic closure of the MSIVs meets the requirements of safety design basis Item e. The shortest closure time of which the MSIVs are capable is 3 sec. The transient resulting from a simultaneous closure of all MSIVs in 3 sec during reactor operation at rated power is considerably less severe than the transient resulting from inadvertent closure of the turbine stop valves (which occurs in a small fraction of 1 sec) coincident with failure of the turbine bypass system. This conclusion is substantiated in Subsection 15.2.3. This meets safety design basis Item f.

The safety design bases Items g., h., and i. must be fulfilled for the CRVICS to meet the design reliability requirements of safety design basis Item a. It has already been shown that safety design bases Items g.5. and g.7. have been met. The remainder of the reliability requirement is met by a combination of logic arrangement, sensor redundancy, wiring scheme, physical isolation, power supply arrangement, and environmental capabilities. These subjects are discussed in the following paragraphs.

Because essential variables are monitored by four trip channels arranged for physical and electrical independence, and because a dual trip system arrangement is used to initiate closure of automatic isolation valves, no single failure, maintenance operation, calibration operation, or test can prevent the system from initiating valve closure. An analysis of the isolation control system shows that the system does not fail to respond to essential variables as a result of single electrical failures such as short circuits, ground, and open circuits. A single trip system trip is the result of these failures. Isolation is initiated on a trip of the remaining trip system. For some of the exceptions to the usual logic arrangement, a single failure could result in inadvertent isolation of a pipeline. With respect to the release of radioactive material from the nuclear system process barrier, such inadvertent valve closures are in the safe direction and do not pose any safety problems. This meets safety design basis Item g.1.

The redundancy of trip channels for all essential variables provides a high probability that whenever an essential variable exceeds the isolation setting, the system initiates isolation. In the unlikely event that all trip channels for one essential variable in one trip system fail in such a way that a system trip does not occur, the system could still respond properly as other monitored variables exceed their isolation settings. This meets safety design basis Item g.2. The sensors, circuitry, and logic channels used in the CRVICS are not used in the control of any process system. Thus, malfunction and failures in the controls of process systems have no direct effect on the isolation control system. This meets safety design basis Item g.3.

The various power supplies used for the isolation control system logic circuitry and for valve operation provide assurance that the required isolation can be effected in spite of power failures. If ac power for valves inside the primary containment is lost, dc power is available for operation of valves outside the primary containment. The main steam isolation valve control arrangement is resistant to both ac and dc power failures. Because both solenoid-operated pilot valves must be deenergized, loss of a single power supply neither causes inadvertent isolation nor prevents isolation if required.

The logic circuitry for each channel is powered from the separate sources available from the RPS buses. A loss of power here results in a single trip system trip. In no case does a loss of a single power supply prevent isolation. This meets safety design basis Item g.4.

The isolation control system can operate under the most unfavorable environmental condition associated with normal operation. The discussion of the effects of rapid nuclear system depressurization on level measurement given in Subsection 7.2.1.1.3.1 is equally applicable to the RPV low-water-level transmitters used in the CRVICS. The temperature, pressure, differential pressure, and level transmitters, cables, and valve-closing mechanisms used were selected with ratings that make them suitable for use in the environment in which they must operate.

The special considerations made for the environmental conditions resulting from a LOCA inside the drywell are adequate to ensure operability of essential isolation components located inside the drywell.

The wall of the primary containment effectively separates adverse environmental conditions that might otherwise affect both isolation valves in a line. The location of isolation valves on either side of the wall decouples the effects of environmental factors with respect to the ability to isolate any given line. The previously discussed electrical isolation of control circuitry prevents failures in one part of the control system from propagating to another part. Electrical transients have no significant effect on the functioning of the isolation control system. Therefore, it is concluded that safety design basis Item g.6. is satisfied.

The design of the MSIVs meets the requirement of the safety design basis in that the motive force for closing each MSIV is derived from both a source of pneumatic or gas pressure, and the energy is stored in a spring. Both pneumatic and spring energy is required to close the valve. None of the valves rely on continuity of any sort of electrical power to achieve closure in response to essential safety signals. Total loss of the power used to control the valves would result in closure. This meets safety design basis Item h.

Calibration and test controls for pressure and level transmitters are located on the transmitters themselves. These transmitters are located in the turbine building and reactor building. To gain access to the setting controls on each transmitter, a cover plate, access plug, or sealing device must be removed by operations personnel before any adjustment in trip settings can be effected. The location of calibration and test controls in areas under the control of supervision or of the main control room operator reduces the probability that operational reliability will be degraded by operator error. This meets safety design basis Item i.1.

Because no manual bypasses (except for those used during a BDBEE) are provided in the isolation control system, safety design basis Item i.2. is met. Because safety design bases Items g., h., and i. have been met, it can be concluded that the CRVICS satisfies the reliability requirement of item safety design basis a. That the system satisfied safety design bases Items j., k.1., and k.2. was shown in the description of the system. The following subsection, covering inspection and testing of the system, demonstrates that safety design basis Item 1. is satisfied.

7.3.2.3.2 Inspection and Testing

All parts of the primary containment isolation control system are testable during reactor operation. Isolation valves can be tested to ensure that they are capable of closing by operating manual switches in the main control room and observing the position lights and any associated process effects. Testable check valves are arranged to verify that the valve disk is free to open and close. The trip channel and trip system responses can be functionally tested by applying test signals to each trip channel and observing the trip system response.

Functional testing and calibration schedules developed using available failure rate data, reliability analyses, and operating experience are presented in the Technical Specifications. The schedules represent an optimization of CRVICS reliability by considering, on one hand, the failure probabilities of individual components, and, on the other hand, the reliability effects during individual component testing on the portions of the system not undergoing tests.

The isolation actuation system instrumentation response times are shown in Technical Requirements Manual Volume I Table 3.3.6.1-1, which is referenced in UFSAR Table 7.3-12. Response time testing is required by the Technical Specifications. Technical Specification Table 3.3.2-3 was deleted from the Technical Specifications and added to the UFSAR as Table 7.3-12 (TRM Table 3.3.6.1-1) in agreement with NRC Generic Letter 93-08 and Amendment Number 100 to the Technical Specifications. The response times information of UFSAR Table 7.3-12 was then relocated to the Technical Requirements Manual Volume I.

The response time testing for the trip functions associated with the diesel start and sequencing of loads is eliminated in agreement with NRC Generic Letter 93-05 and Amendment Number 99 to the Technical Specifications.

The periodic sensors response time testing for the reactor vessel low water level-level 1 and the main steam line flow-high has been eliminated. The BWROG Report NEDO-32291A provides the required analyses as briefly described in 7.2.1.1.3.8.1.

7.3.2.3.3 Specific Regulatory Requirements Conformance

7.3.2.3.3.1 IEEE 279-1971

Conformance to IEEE 279-1971 is demonstrated in Topical Report NEDO-10139, Paragraph 4.2. The 21 subparagraphs of 4.2 cover the 21 subparagraphs of IEEE 279-1968. The following discussion is addressed to IEEE 279-1971, subparagraphs 4.7, 4.17, and 4.22, which are different from those in IEEE 279-1968:

a. Paragraph 4.7.1: Classification of Equipment - There is no control function in the system. It is strictly a protection system

b. Paragraph 4.7.2: Isolation Devices - Since there is no control function, no isolation devices are required

c. Paragraph 4.7.3: Single Random Failure - No single random failure of a control system can prevent proper action of the isolation system channel designed to protect against the condition

d. Paragraph 4.7.4 - Analysis of 4.7.3 applies directly

e. Paragraph 4.17: Manual Initiation - Manual initiation controls are provided and separated in such a manner as to prevent a single failure from inhibiting an isolation.

   The separation of devices is maintained in both the manual and automatic portions of the system so that no single failure in either the manual or automatic portions can prevent an isolation by either manual or automatic means. There are no areas of the system that are common to manual and automatic functions

f. Paragraph 4.2: Identification - Panels and racks that house isolation system equipment are identified with a distinctive color marker plate listing the system name and the designation of the particular redundant portion of the system. Instrument cables are identified in accordance with IEEE 279-1971.

In addition, NEDO-10139 demonstrated conformance with IEEE 279-1971, Paragraph 4.14, by the position that there are no manual controls that bypass the containment isolation control function. This conformance with IEEE 279-1971 is maintained but is modified to note the use of keylock switches added to allow operation of the Hardened Containment Vent System in support of the plant’s response to a BDBEE in accordance with NRC Order EA-13-109.

7.3.2.3.3.2 Industry Standard IEEE 323-1971

Compliance with this standard is discussed in Section 3.11 and NEDO-10698.

7.3.2.3.3.3 IEEE 338-1971

The system is testable during reactor operation. The tests that may be performed will cover the sensors through the final actuators, demonstrate independence of channels, and bare any credible failures while not negating any isolation.

7.3.2.3.3.4 Industry Standard IEEE 344-1971

Compliance with this standard is discussed in Section 3.10 and NEDO-10678.

7.3.2.3.3.5 Regulatory Guide 1.22

Regulatory Guide 1.22 requires periodic testing of protection system actuation functions. The MSIVs and associated logic and sensor devices may be tested from the sensor device to one of the two solenoids required for valve closure. The valve may be exercised closed with either a slow-acting test solenoid or the normal closing solenoid to verify that there are no obstructions to the valve stem at full power. A reduction in power is necessary before performing a valve closure. All the isolation valves, other than the MSIVs, may be tested from sensor to actuator during plant operation. The test may cause isolation of the process lines involved, but their isolation is tolerable.

7.3.2.3.3.6 10 CFR 50, Appendix A

General Design Criterion 13

The integrity of the reactor core and the reactor coolant pressure boundary (RCPB) is ensured by monitoring the appropriate plant variables and closing various isolation valves, as detailed in the various description sections.

7.3.2.3.3.7 10 CFR 50, Appendix B

The guidelines of 10 CFR 50, Appendix B, are met as described in Chapter 17.

7.3.3 Emergency Core Cooling System Auxiliary Systems Instrumentation and Control

7.3.3.1 Design-Basis Information

The design-basis information for the instrumentation and control of the reactor building closed cooling water (RBCCW) system, as required by Section 3 of IEEE 279-1971, is provided in Subsection 7.1.2.1.28.

7.3.3.2 System Description

7.3.3.2.1 Cooling System for Reactor Auxiliaries

The RBCCW system and its backup, the emergency equipment cooling water (EECW) system, provide cooling water for the ECCS auxiliary equipment and area air coolers, as described in Subsection 9.2.2. A discussion of the EECW system is contained in Subsection

7.3.4. A description of the RBCCW system, including instrumentation and control, is presented in Subsection 7.6.1.14.

7.3.3.2.2 Control Circuits

The RBCCW system operates and supplies services during normal operation of the plant. It continues to operate during an accident unless interrupted by some abnormal condition. The system is shut down by the head tank low-level signal using "one-out-of-two taken twice" logic. Each individual RBCCW pump (outside of the RBCCW supplemental cooling loops) shuts down on low pump suction, also using “one-out-of-two taken twice” logic.

In the event that the RBCCW system cannot maintain adequate flow to the EECW loops, the EECW system is automatically started by low differential pressure between the supply and return headers. Logic is "one-out-of-two." A loss of offsite power directly initiates the EECW system to anticipate the loss of power to the RBCCW system. The EECW system is also auto-initiated on high drywell pressure.

7.3.3.3 Analysis

Description of the analysis of the EECW system is found in Subsection 7.3.4.3.

7.3.4 Emergency Equipment Cooling Water System

7.3.4.1 Design-Basis Information

The design-basis information for the instrumentation and control of the EECW system, as required by Section 3 of IEEE 279-1971, is provided in Subsection 7.1.2.1.18.

7.3.4.2 System Description

The EECW system ensures cooling water to remove heat from emergency equipment on loss of offsite power, on high drywell pressure, or failure of the RBCCW system. Since this system is described in Subsection 9.2.2, the following discussion provides additional information on the EECW instrumentation and control. The EECW system is shown in Figures 9.2-3 and 9.2-4.

7.3.4.2.1 Power Sources

Instruments and controls for the EECW system receive electrical power from the redundant 120-V, 60-Hz instrument power systems described in Subsection 8.3.1 and from Division I and Division II 130 V dc Class IE batteries as described in Subsection 8.3.2.1.2. Those instruments and controls requiring pneumatic power receive plant instrument air as described in Subsection 9.3.1.

7.3.4.2.2 Equipment Design

Each of the two redundant and separate EECW loops has electrically and physically separate controls and instruments.

7.3.4.2.3 Initiation and Control Circuits

The EECW system can be started manually from the main control room. Low RBCCW flow to the EECW loops causes loss of EECW header differential pressure, which automatically isolates the RBCCW and starts the EECW loops. If EECW has already been initiated for the purposes of RBCCW heat exchanger cleaning, enhanced drywell cooling, testing, or RHR reservoir freeze protection, the location of the differential pressure sensors inside the EECW system envelope will not sense a RBCCW low flow condition and, therefore, will not cause EECW to automatically reinitiate and reisolate the nonessential loads. This action is not required since this is not a condition requiring protective action as described in Section 7.1.2.1. The EECW system is also automatically initiated by a loss of offsite power or on high drywell pressure. Automatic start of EECW makeup pump is achieved if makeup tank has low pressure or level and makeup tank isolation valve is open, and normal pump suction pressure.

7.3.4.2.4 Logic

The EECW system logic is shown in Figure 7.3-15. These logic schemes are identical for each of the two redundant EECW loops. Level switches are used to alarm when there is insufficient water inventory. If offsite power is available, the EECW pumps start nominally 1.5 seconds after receipt of the initiation signal. If offsite power is unavailable, the EECW pumps are sequenced on the EDG buses by the automatic load sequencer. See Table 8.3-5.

7.3.4.2.5 Testability

Control and logic circuitry can be tested by placing that loop in operation from the main control room. If an auto-initiate signal is received during a test, the manual signal is automatically overridden by the auto-initiate signal, and both loops will be placed into operation as required.

7.3.4.3 Analysis

7.3.4.3.1 Conformance To Specific Regulatory Requirements

The specific requirements of IEEE 279-1971, to which attention has been directed in the design of the EECW system, are itemized below by paragraph number as they appear in IEEE 279-1971.

a. Paragraph 4.1: Automatic Initiation - This requirement is met by incorporating capability in the design for automatic startup of the EECW system on loss of offsite power, on high drywell pressure, or on occurrence of low pressure across the supply and return headers of either cooling loop

b. Paragraph 4.2: Single Failure - The single-failure criterion is met by having an independently controlled EECW loop for each of the two RBCCW divisions

c. Paragraph 4.3: Quality Assurance - This requirement is met as described in Chapter 17

d. Paragraph 4.4: Equipment Qualification - This requirement is met as described in Chapter 3

e. Paragraph 4.5: Channel Integrity - This requirement is met by supplying electrical power to the EECW system from buses backed up by diesel generators. The routings of power, signal, and control circuits take separate paths. The EECW system is designed to withstand seismic accelerations

f. Paragraph 4.6: Channel Independence - This requirement is met by the independent instrumentation and controls provided in the EECW system and separate power feeds that are used

g. Paragraph 4.7: Control Interaction - The requirement of this criterion is met by the complete independence of controls of the two divisions of the EECW system

h. Paragraph 4.8: Direct Inputs - This requirement is met by the provision of separate and independent instrumentation to supply signal inputs for control of the two loops of the EECW system

i. Paragraph 4.9: Sensor Checks - This requirement is met by introducing a test signal (in one channel at a time) sufficient to verify that a logic trip is achievable when the parameter deviates beyond the setpoint. Correct response of each sensor is verified by observing that its output indicates a deviation of the parameter beyond the setpoint value

j. Paragraph 4.10: Testability - This requirement is satisfied by the automatic override of a manual control command if an emergency condition arises during testing

k. Paragraph 4.11: Channel Bypass - This requirement is met by the cooling adequacy of one loop, allowing one loop to be tested during operation without loss of protection

l. Paragraph 4.12: Operation of Bypasses - This requirement is met by the automatic override of manual control, which is provided to automatically initiate operation of the system if an emergency arises during a test

m. Paragraph 4.13: Bypass Indication - This requirement is met by the display provisions in the main control room, which indicate the operational or nonoperational state of the EECW system

n. Paragraph 4.14: Bypass Access - This requirement is met by the administrative control that is imposed on use of the operational controls of the EECW system

o. Paragraph 4.15: Multiple Setpoints - This requirement is not applicable to the EECW system

p. Paragraph 4.16: Action Completion - This requirement is satisfied by the functional characteristics of the automatic controls of the EECW system

q. Paragraph 4.17: Manual Access - This requirement is satisfied by the manual control provisions incorporated in the EECW system controls

r. Paragraph 4.18: Setpoint Access - This requirement is satisfied by the administrative control that is imposed on use of the setpoint adjustments

s. Paragraph 4.19: Identification - This requirement is satisfied by the indicating lamps and sequential recorders that the design incorporates to indicate the state of the EECW system and its valves and pumps

t. Paragraph 4.20: Information Readout - This requirement is satisfied by the readout instruments provided to display temperature, pressure, and flow parameters in the EECW system

   A sequential recorder is provided to register initiation of water pump operation and tripout of the pump motor circuit breaker

u. Paragraph 4.21: System Repair - This requirement is met by the readily identifiable modular design of the instrumentation and control components

v. Paragraph 4.22: Identification - This requirement is met by using appropriate tags and color schemes to enable easy identification of circuits and components that are part of the EECW safeguard system

The following additional IEEE criteria are met by the provisions outlined in the sections or chapters of this UFSAR that are indicated:

a. IEEE 323-( ): Section 3.11 (IEEE 323-1971 for equipment purchased before November 15, 1974; IEEE 323-l974 for equipment purchased on or after November 15, 1974)

b. IEEE 336-1971:Chapter 17

c. IEEE 338-1971:Subsection 7.3.1.3.4

d. IEEE 344-1971:Section 3.10.

The requirements of Regulatory Guide 1.22 are met on the basis of the manual test and control provisions that the EECW system design incorporates.

Evaluation of the EECW system against criteria of 10 CFR 50, Appendix A and Appendix B, is as follows:

a. Criterion 13 - This criterion is met by using qualified differential pressure sensors and operating them in a "one-out-of-two" logic arrangement

b. Criterion 20 - This criterion is met by providing the automatic mode of startup as stated in Subsection 7.1.2.1.18

c. Criterion 21 - The EECW system provides assurance that, through its standby redundancy, each loop has sufficient reliability to fulfill the single-failure criterion. No single component failure, maintenance operation, calibration operation, or test to verify operational availability impairs the ability of the system to perform its intended safety function. There is sufficient electrical and physical separation between channels and between trip logic circuits monitoring the same variable to prevent environmental factors, electrical transients, and physical events from impairing the ability to respond correctly

The EECW system includes design features that permit inservice testing. This enhances the functional reliability of the system by enabling early detection of malfunctioning components in the course of routine tests

d. Criterion 22 - Physical separation, separate power feeds, and separate controls are provided for the two cooling loops. This ensures that the EECW system of each loop, providing necessary cooling capacity, is available for the required safety function. Details of separation criteria and independence are contained in Section 3.12 and Subsection 9.2.2

e. Criterion 23 - Since the two loops are independent, failure of one loop will not affect operation of the other

f. Criterion 24 - Since no signals required for control of the reactor are used for control of the EECW system, this criterion is satisfied

g. Criterion 29 - High functional reliability of the EECW system is achieved through the combination of sensor redundancy, control logic arrangement, functional and physical separation of loops, operating power independence, fail-safe design, and inservice testability. These requirements are discussed in detail in Criteria 21 through 24.

   An extremely high probability of correct system response to anticipated operational occurrences is maintained by a thorough program of inservice testing and surveillance. Active components can be tested or removed from service for maintenance during reactor operation without compromising protective control functions, even in the event of a subsequent single failure. Components important to safety are tested during normal reactor operation. Functional testing and calibration schedules are developed using available failure rate data, reliability analyses, and operating experience. These schedules represent an optimization of system reliability by considering the failure probabilities of individual components, and also the reliability effects during individual component testing on the portion of the system not undergoing test. The capability for inservice testing ensures the high functional reliability of the system should a monitored parameter exceed the corrective action setpoint.

The guidelines of 10 CFR 50, Appendix B, are met as described in Chapter 17.

7.3.5 Control Center Atmospheric Control System Instrumentation and Control

7.3.5.1 Design-Basis Information

The design-basis information for the instrumentation and control of the control center atmospheric control system, as required by Section 3 of IEEE 279-1971, is provided in Subsection 7.1.2.1.

7.3.5.2 System Description

The instrumentation and control for the control center HVAC system functions to ensure the habitability of the control center under all plant operating conditions is described in Section 6.4 and Subsections 9.4.1 and 12.2.2.1.

7.3.5.2.1 Power Sources

Each redundant control center HVAC system is comprised of a supply air fan, return air fan, electric heating coil, and a refrigeration unit. Power supply for these components of each control center HVAC system is from separate essential ac buses that can receive standby ac power. Control power for isolation dampers, instrumentation, and controls comes from the bus that powers the corresponding equipment train.

7.3.5.2.2 Initiating Circuits, Logic, and Sequencing

Various components of each redundant control center HVAC system are initiated as follows:

a. The supply and return air fans are initiated manually by control switches at the main control board

b. The refrigeration unit is provided with a manual/ automatic selector switch on the main control board. While in automatic mode, the refrigeration unit is initiated by the demand signal from the thermostat in the chilled water piping

c. A subsystem of the process radiation monitoring system (PRMS) monitors radiation levels in the main control room air intake. High radiation indication by detectors in the main control room air intake duct downstream of the filter train activates an alarm within the control center. High-high level automatically places the control center HVAC system in full recirculation mode

d. If combustion products are detected in the control center by the smoke (ionization) detectors, one of the following manual actions is initiated via hand switches in the main control room at the discretion of the operator:

   1. The outside air intake and exhaust air damper can be fully opened and the recirculation air damper fully closed to purge the control center air (smoke purge mode)

   2. Route outside air and recirculation air mixture (approximately 7 percent of the total mixture) from the control center HVAC system through normally bypassed odor and smoke-removing filters.

e. If the control center HVAC system is operating in the normal mode and one of the automatic gaseous suppression systems is initiated automatically by the fire detection system, the smoke purge mode is automatically initiated. However, the smoke purge mode is overridden if the recirculation mode is signaled to start.

f. If an automatic isolation occurs due to detection of a potential breach of the primary reactor pressure boundary, as indicated by low reactor water level, high drywell pressure, high radiation level as monitored by the fuel pool ventilation exhaust, or the reactor building ventilation exhaust, the emergency makeup outside air is automatically provided to pressurize the main control room.

7.3.5.2.3 Bypasses and Interlocks

All of the isolation dampers in each control center HVAC system equipment are interlocked with the operation of corresponding supply air and return air fans. Operation of any of these fans opens all the corresponding isolation dampers. The supply-air and return-air fans are operated manually by hand switches.

To prevent short-cycling and a possible freeze-up of the evaporator, the refrigeration machine start is interlocked with the operation of the supply-air fan and corresponding return-air fans, condenser cooling water, and chilled water pump. The operation of the refrigeration machine is further interlocked with safety protection cutout; i.e., low-pressure and high-pressure cutout in refrigerant circuit, and oil failure switch in the compressor lubrication circuit. To guard against overheating, the electric heating coil is interlocked with supply-air fan operation and a thermal cutout switch. Low temperature of the chilled-water line is alarmed.

Zone mixing dampers are controlled by thermostats in each zone. The operation of the refrigeration machine is controlled by a thermostat in the chilled-water return pipe. The electric heating coil is controlled by a thermostat in the hot deck of the air handling unit.

All of the isolation dampers in the outside air intakes and the emergency-makeup-air filter train are appropriately interlocked to serve the required function. The electric heating coil for humidity control in the emergency-makeup-air filter train is interlocked with the emergency-makeup-air fans.

7.3.5.2.4 Redundancy and Diversity

Instrumentation and control equipment for each control center HVAC system is completely independent of one another.

7.3.5.2.5 Actuated Devices

The normal and emergency operation of each control center HVAC system involves the following actuated devices:

a. Supply-air fan

b. Return-air fan

c. Electric heating coil

d. Refrigeration unit

e. Emergency-makeup-air electric heating coil

f. Emergency-makeup-air fan

g. Corresponding isolation and control dampers

h. Chilled water pump.

7.3.5.2.6 Separation

The channels and logic circuits are physically and electrically separated to preclude the possibility that a single event would prevent operation of the control center HVAC system. Electrical cables for instrumentation and control on each control center HVAC system are routed separately.

7.3.5.2.7 Testability

Control and logic circuitry used in the controls for the control center HVAC system can be individually checked by applying test or calibration signals to the sensors and observing trip or control responses. Operation of each redundant HVAC system is periodically rotated to permit on-line checking and testing of performance of the complete system. The automatic control circuitry for the emergency equipment is designed to restore its normal function in response to initiation signals.

7.3.5.2.8 Environmental Considerations

Temperature, pressure, humidity, and radiation dosage are considered in selection of various equipment, instrumentation, and controls for the control center HVAC system. These are described in Section 3.ll and Subsection 9.4.l.

7.3.5.2.9 Operational Considerations

The control center HVAC system is required during normal and abnormal plant operating conditions. The automatic circuitry is designed to start the emergency equipment if the signal for its initiation is received, as described in this section.

7.3.5.3 Analysis

Conformance To General Functional Requirements

The control center HVAC system instrumentation and controls are designed to ensure the habitability of the main control room during and after all the normal and abnormal plant operating conditions. Certain components of the system are required during normal and abnormal plant operating conditions only. The controls for the system provide warning to the operator of any abnormal operating transients in the system, and automatically initiate action that provides protection against the consequences of the release of radioactive material to outdoor environs following any accident.

Chapter 15 identifies and evaluates postulated events that can result in release of fission products due to an accident. The consequences of such an accident are described and evaluated.

Because essential variables are monitored by channels arranged for physical and electrical independence, no single failure, maintenance operation, calibration operation, or test can prevent the system from performing its function. A single active failure in the Halon fire protection system will cause closure of smoke/Halon dampers to the relay room, cable spreading room or computer room. Manual actions are required to reopen these dampers to reestablish airflow.

The sensor circuitry and logic used in the control center HVAC system are not used in the control of any process system. Thus, malfunction and failures in the controls of the process systems have no direct effect on the control center HVAC system.

The power supplies used for the system logic circuitry and controls provide assurance that the required performance cannot be affected by a loss of offsite electric power or loss of instrument air. In no case does the loss of a single power supply prevent function of the control center HVAC system.

Portions of the system required to operate during and following the design basis accident to provide acceptable environments within the control center have been qualified both environmentally and seismically.

Inputs to annunciators and indicators are arranged so that no malfunction of the annunciating and indicating device can functionally disable the system. Direct signals from the control center HVAC system control system sensors are not used as inputs to annunciating or data-logging equipment.

All controls for interrupting any part of the system operation are located in the main control room. All controls and instrumentation essential to the operation of the control center HVAC system meet the IEEE 279-1971 criteria.

7.3.6 Standby Gas Treatment System Instrumentation and Control

7.3.6.1 Design-Basis Information

The design basis information for the instrumentation and control of the standby gas treatment system (SGTS), as required by Section 3 of IEEE 279-1971, is provided in Subsection 7.1.2.1.16.

7.3.6.2 System Description

The instrumentation and control of the SGTS are used to maintain, when necessary, a preset constant flow that will maintain the reactor building at a negative pressure and preclude leakage of radioactive particulates and gases directly to the outdoors. The SGTS is designed to reduce radioactive particulates and gaseous concentration in the exhaust air from the reactor building before exhausting to the outdoors.

The SGTS is described in detail in Subsection 6.2.3 and is shown schematically in Figure 6.2-20.

7.3.6.2.1 Power Sources

Each SGTS exhaust equipment train has an exhaust fan, a standby cooling fan, an electric heating coil, and associated air- operated isolation valves that require power. Power supply for various components of each SGTS equipment train and the instrument air compressor is from separate essential ac buses that can receive standby ac power. Motive power for isolation valves and the controls comes from the bus that powers the corresponding equipment train, except for the isolation valves in the reactor building ventilation system supply and exhaust duct headers. These valves are operated by air cylinders with instrument air being controlled by solenoid valves for each isolation valve. If either control air or electric control power were lost, the isolation valves would be closed by springs mounted on the valves.

7.3.6.2.2 Initiating Circuits

The system is automatically started in response to any one of the following signals:

a. High drywell pressure (Subsection 7.3.2.2.7.6)

b. Low reactor water level (Subsection 7.3.2.2.7.1)

c. High radiation in fuel pool ventilation exhaust (Subsection 11.4.3.8.2.11)

d. High radiation in the reactor building ventilation exhaust (Subsection 11.4.3.8.2.4)

e. Manual activation from the main control room

f. Downscale trip due to loss of offsite power to radiation monitors located in the Reactor Building and fuel pool ventilation exhaust system.

7.3.6.2.3 Logic and Sequencing

The following actions take place simultaneously on receipt of an initiation signal:

a. Closure trip of reactor building isolation valves

b. Trip of reactor building ventilation system

c. Opening of SGTS isolation valves

d. Startup of both SGTS equipment trains and annunciation of an alarm on the main control panel.

When both trains are automatically started, the audible and visual alarm on the main control panel warns the operator to shut down one of the trains. Individual hand switches located on the main control panel for each of the equipment trains permit manual operation.

7.3.6.2.4 Bypasses and Interlocks

All of the air-operated isolation valves pertinent to a SGTS equipment train are interlocked through a relay circuit with the operation of the SGTS unit.

The SGTS cooling fan is interlocked so as not to operate when the SGTS exhaust fan is in operation.

To protect against overheating, the electric heating coil for relative humidity control of the charcoal filters is interlocked with the SGTS exhaust fan operation, and high temperature is indicated by an alarm in the main control room.

Airflow through the SGTS is controlled automatically with a vortex damper on the exhaust fan valve, and flow is recorded on the main control panel. Low flow initiates an alarm to alert the operator to start the redundant SGTS equipment train.

To prevent fire in the charcoal bed, a source of CO_2 will purge air from the charcoal filters if the bed temperature exceeds 310°F. A pressure switch in the discharge line of the CO_2 unit will annunciate an alarm on the main control panel after the purge process begins.

On receipt of an initiation signal, the reactor building ventilation isolation valves close and remain closed unless a manual reset switch is activated.

7.3.6.2.5 Redundancy and Diversity

Each SGTS unit is automatically initiated by independent control systems.

7.3.6.2.6 Actuated Device

Initiation of the SGTS includes starting of the SGTS exhaust fan, energizing electric heating for preheating air, deenergizing charcoal bed heaters, and opening valves on the inlet and outlet sides of the SGTS equipment train.

7.3.6.2.7 Separation

The channels and logic circuits are physically and electrically separated to preclude the possibility that a single event would prevent operation of the SGTS. Electrical cables for instrumentation and control on each SGTS equipment train are routed separately.

7.3.6.2.8 Testability

Control and logic circuitry used in the controls for the SGTS can be individually checked by applying test or calibration signals to the sensors and observing trip or control responses. Operation of the isolation valves and fans from manual switches verifies the ability of breaker and damper mechanisms to operate.

7.3.6.2.9 Environmental Considerations

Temperature, pressure, humidity, and radiation dosage are considered in the selection of the various equipment, instrumentation, and controls for the SGTS described in Section 3.11 and Subsection 6.2.3.

7.3.6.2.10 Operational Considerations

The SGTS is available, if required, during normal plant operating conditions when any division is being tested. The other division is available for operation should it be needed.

7.3.6.3 Analysis

Conformance To General Functional Requirements

The SGTS control system is designed to initiate action that provides timely protection against the consequences of the release of radioactive materials inside the secondary containment following any accident. Chapter 15 identifies and evaluates postulated events that can result in release of fission products due to an accident. The consequences of such an accident are described and evaluated.

Because essential variables are monitored by channels arranged for physical and electrical independence, and because a dual trip system arrangement is used to initiate the SGTS, no single failure, maintenance operation, calibration operation, or test can prevent the system from operating when required. The sensor circuitry and logics used in the SGTS control system are not used in the control of any process system. Thus, malfunction and failures in the controls of process systems have no direct effect on the SGTS control system.

The various motive power supplies used for the SGTS logic circuitry and controls provide assurance that the required initiation can be effected in spite of loss of electric power or loss of instrument air. In no case does a loss of single power supply prevent initiation of the SGTS when required. Required instruments, isolation valve closing mechanisms, and cables of the SGTS can operate under the environmental conditions associated with postaccident operation. Active components of SGTS instrumentation and control can be tested and calibrated during plant operation.

All sensors and associated equipment are designed to meet Category I requirements, and are protected from fire, explosion, missiles, lightning, wind, and flood to preclude functional degradation of the system performance.

Inputs to annunciators and indicators are arranged so that no malfunction of the annunciating and indicating device can functionally disable the system. Direct signals from the SGTS control system sensors are not used as inputs to annunciating or data-logging equipment. Isolation is provided between primary signal and the information output.

7.3.7 Standby Power System

7.3.7.1 Design-Basis Information

The design-basis information for the instrumentation and control of the standby power system, as required by Section 3 of IEEE 279-1971, is provided in Subsection 7.1.2.1.

7.3.7.2 System Description

Four emergency diesel generators (EDGs) provide the power necessary for the ECCS during a loss of system power. A detailed explanation of this system and its corresponding instrumentation and control can be found in Subsection 8.3.1.

A battery system of redundant 130-V dc power-control batteries provides the dc power required during any ECCS function. Full- size battery chargers normally carry the load. However, the capability of the batteries is enough to handle the load for a sufficient amount of time should power to the chargers be lost. A detailed explanation of the battery system can be found in Subsection 8.3.2.

7.3.7.3 Analysis

Conformance To General Functional Requirements

The standby power systems are designed to provide electrical power availability to the ECCS and other safety-related systems at maximum reliability should normal offsite power not be available. Each supply has an independent redundant counterpart, thereby ensuring against single failure (IEEE 279-1971, Paragraph 4.2). The equipment, cabling interconnections, and circuit breakers are all qualified to Class 1E standards and housed in Category I structures.

An explanation of the EDGs and their conformance is found in Subsection 8.3.1. An explanation of the battery systems and their conformance is found in Subsection 8.3.2.

7.3.8 Post-LOCA Combustible Gas Control System

The NRC amended 10 CFR 50.44, “Standards for combustible gas control system in light-water-cooled power reactors” on October 16, 2003 to eliminate the requirements for hydrogen recombiners. The hydrogen recombiner Technical Specification requirements were subsequently removed by License Amendment 159, dated March 15, 2004. Regulatory Guide 1.7 was revised in March 2007 to reflect the amended 10 CFR 50.44. The Combustible Gas Control System (CGCS) has been retired in place with its electrical circuits de-energized and fluid process piping isolated from primary containment with redundant locked-closed isolation valves. Combustible gas control of the primary containment is provided by inerting the primary containment with nitrogen. Gas concentrations inside the primary containment are monitored by the Hydrogen/Oxygen analyzer subsystem of the primary containment monitoring system which is further discussed in Subsection 7.6.1.12.

7.3.9 Residual Heat Removal Service Water System Instrumentation and Control

7.3.9.1 Design-Basis Information

The design-basis information for the instrumentation and control of the residual heat removal service water (RHRSW) system, as required in Section 3 of IEEE 279-1971, is provided in Subsection 7.1.2.1.27.

7.3.9.2 System Description

The RHRSW system provides cooling water to remove heat from the RHR system. The RHRSW system includes a closed-cycle supply of water, pumps, and mechanical draft cooling towers to reject the heat to the environment. The system will operate with or without a loss of offsite power. The RHRSW system is described in Subsection 9.2.5 and the system diagram is provided in Figure 9.2-6. The following discussion provides additional information on the RHRSW instrumentation and control.

7.3.9.2.1 Power Sources

Instrumentation and controls for the RHRSW system receive electrical power from the redundant 120-V, 60-Hz instrument power systems described in Subsection 8.3.1. Part of the control logic is direct current, powered by the Class 1E direct current system described in Subsection 8.3.2. The pressure control valves requiring pneumatic power receive plant instrument air as described in Subsection 9.3.1.

7.3.9.2.2 Equipment Design

Each of the two separate, redundant RHRSW loops has electrically and physically separate controls and instruments.

7.3.9.2.3 Initiation and Control Circuits

The RHRSW pumps, valves, and cooling tower fans are all initiated manually from the main control room.

7.3.9.2.4 Logic

The RHRSW system is a manually initiated system; therefore, there is no automatic initiation logic. The RHRSW pumps automatically trip if they are operating and a LOCA signal is received, as indicated in Figure 7.3-9, Sheet 1. This trip is provided to allow the automatic loading of other emergency safety feature equipment on the emergency diesel generators if a loss of offsite power occurs. The interlock can be bypassed by a keylock switch so that the pumps can be started if there is a long-term LOCA signal present. The cooling tower fan motors automatically load-shed if a loss of offsite power occurs. The motors must be manually reset from the main control room before they will restart.

7.3.9.2.5 Testability

Each RHRSW loop can be tested from the control room by starting the RHRSW pumps and/or cooling tower fans. If an accident signal is received during a test, the system pumps trip off and remain off until the operator manually restarts.

[c] Zero is at the top of the active fuel.

[d] Incident detection circuitry instrumentation.

TABLE 7.3-2 AUTOMATIC DEPRESSURIZATION SYSTEM INSTRUMENT TRIP SETTINGS

System Function	Instrument	Trip Settings[a]	Instrument Range
Reactor vessel low water level (permissive)[d]	Level transmitter	Level 3[b]	160 to 220 in.[c]
Reactor vessel low water level (permissive)[d]	Level transmitter	Level 1[b]	10 to 220 in.[c]
Primary containment (drywell) high pressure[d]	Pressure transmitter	1.68 psig	0 to 5 psig
Primary containment (drywell) high pressure bypass time delay[d]	Timer	7 min	1 to 30 min
Automatic depressurization time delay[d]	Timer	105 sec	10 to 300 sec
LPCI pump discharge pressure[d]	Pressure transmitter	118.5 psig	0 to 500 psig
Core spray pump discharge pressure[d]	Pressure transmitter	143.5 psig	0 to 500 psig

[a] Nominal values are given for information. See Technical Specifications for actual operational settings.

[b] Shown in Figure 7.3-12.

[c] Zero is at the top of the active fuel.

[d] Incident detection circuitry instrumentation.

TABLE 7.3-3 CORE SPRAY SYSTEM INSTRUMENT SPECIFICATIONS

Core Spray Function	Instrument	Trip Settings[a]	Instrument Range
RPV low water level[d]	Level Transmitter	Level 1[b]	10 to 220 in.[c]
Primary containment high pressure[d]	Pressure transmitter	1.68 psig	0 to 5 psig
RPV low pressure	Pressure transmitter	469 psig[e] Decreasing	0 to 1200 psig
Core spray sparger high differential pressure	Differential pressure switch	0.2 psid	-7 to +2 psid
Pump discharge flow	Flow indicator	--	0 to 10,000 gpm
Pump suction pressure	Pressure indicator	--	-30 in. Hg to 30 psig
Pump discharge pressure	Pressure transmitter	143.5 psig	0 to 50 psig

[a] Nominal values are given for information. See Technical Specifications for actual operational settings.

[b] Shown in Figure 7.3-12.

[c] Zero is at the top of the active fuel.

[d] Incident detection circuitry instrumentation.

[e] Approximate setting.

TABLE 7.3-4 LOW PRESSURE COOLANT INJECTION INSTRUMENT SPECIFICATIONS

LPCI FunctionF	Instrument	Trip Settings[a]	Instrument Range
RPV low water level (LPCI loop selection)[d]	Level transmitter	Level 2[b]	10 to 220 in.[c]
RPV water level (LPCI pump start signal)[d]	Level transmitter	Level 1[b]	10 to 220 in.[c]
Primary containment (drywell) high pressure(LPCI initiation)[d]	Pressure transmitter	1.68 psig	0 to 5 psig
RPV low water level (inside shroud)	Level transmitter	Level 0[b]	-150 to +50 in.
Recirculation loop break detection	Differential pressure transmitter	0.63 psid[e] Trip on upscale	0 to 2 psid
LPCI break detection circuit	Timer	1/2 sec	0.15 to 3 sec
LPCI break detection circuit	Timer	2 sec	0.15 to 3 sec
LPCI reactor vessel low pressure	Pressure transmitter	925 psig	0 to 1500 psig
LPCI valve initiation signal cancellation	Timer	10 minutes	3 to 30 minutes
LPCI pump low flow	Flow switch	5000 gpm	0 to 50 in. WC
RPV pressure permissive (loop selection)	Pressure transmitter	469.5 psig	0 to 1200 psig
Recirculation pumps differential pressure transmitter	Differential pressure transmitter	1.63 psid Trip on downscale	0 to 5 psid

[a] Nominal values are given for information. See Technical Specifications for actual operational settings.

[b] Shown in Figure 7.3-12.

[c] Zero is at the top of the active fuel.

[d] Incident detection circuitry instrumentation.

[e] Repeatability of ±0.5 percent on trip point. Return from overrange of 200 psi to 0 psi in 100 msec maximum.

TABLE 7.3-5 HIGH PRESSURE COOLANT INJECTION SYSTEM: MINIMUM NUMBERS OF TRIP CHANNELS REQUIRED FOR FUNCTIONAL PERFORMANCE

Component Affected	Trip Channel	Instrument Type	Number of Trip Channels Provided	Minimum Number of Trip Channels Required To Maintain Functional Performance[a]
HPCI system initiation	RPV low water level	Level transmitter	4	2 per untripped trip system
HPCI system initiation	Primary containment high pressure	Pressure transmitter	4	2 per untripped trip system
HPCI system turbine	HPCI system pump discharge flow	Flow indicator controller	1	1
HPCI system turbine	RPV high water level	Level transmitter	2	1 per untripped sytem
HPCI system turbine	Turbine exhaust diaphragm high pressure	Pressure transmitter	2	1[b]
HPCI system turbine	HPCI system pump low suction pressure	Pressure switch	1	1[b]
Minimum flow bypass valve	HPCI system pump flow	Flow switch	1	1
HPCIS steam supply valve and suppression chamber suction valve	HPCI system steam supply low pressure	Pressure transmitter	4	2 per untripped trip system
Suppression chamber suction valve	Condensate storage tank low level and suppression pool high level	Level transmitter	4[c]	2

[a] Nominal values are given for information. See Technical Specifications for operational requirements.

[b] An inoperable trip channel should be placed in the untripped state.

[c] Two each: condensate storage low, suppression pool high.

TABLE 7.3-6 AUTOMATIC DEPRESSURIZATION SYSTEM: MINIMUM NUMBERS OF TRIP CHANNELS REQUIRED FOR FUNCTIONAL PERFORMANCE

Initiating Function	Instrument Type	Number of Trip Channels Provided	Minimum Number of Trip Channels Required To Maintain Functional Performance[a,b]
RPV low water level (Level 1)	Level transmitter	2 per trip system	2 per untripped trip system
RPV low water level (Level 3)	Level transmitter	1 per trip system	1 per untripped trip system
Primary containment high pressure	Pressure transmitter	2 per trip system	2 per untripped trip system
Time delay (ADS timer)	Timer	1 per trip system	2 per untripped trip system
Time delay (ADS drywell high pressure bypass timer)	Timer	2 per trip system	2 per untripped trip system
ac interlock (RHR or core spray pump running)	Pressure transmitter	1 per pump	1 per pump

[a] One trip logic of each trip system must be fully operable. Both an RPV low water level trip channel and a primary containment high-pressure trip channel should not be inoperable in any one trip logic.

[b] Nominal values are given for information. See Technical Specifications for operational requirements.

TABLE 7.3-7 CORE SPRAY SYSTEM: MINIMUM NUMBERS OF TRIP CHANNELS REQUIRED FOR FUNCTIONAL PERFORMANCE

Component Affected	Trip Channel	Instrument Type	Number of Trip Channels Provided	Minimum Number of Trip Channels Required to Maintain Functional Performance[a]
Core spray system	RPV low water level	Level transmitter	4	2 per untripped trip system
Core spray system	Primary containment high pressure	Pressure transmitter	4	2 per untripped trip system
Core spray discharge valve	RPV low pressure	Pressure transmitter	4	2 per untripped trip system
Core spray sparger leak detection	Core pressure differential	Differential pressure switch	1 per sparger (alarm only)	1 per sparger (alarm only)

[a] Nominal values are given for information. See Technical Specifications for operational requirements.

TABLE 7.3-8 LOW-PRESSURE COOLANT INJECTION: MINIMUM NUMBERS OF TRIP CHANNELS REQUIRED FOR FUNCTIONAL PERFORMANCE

Component Affected	Trip Channel	Instrument Type	Number of Trip Channels Provided	Minimum Number of Trip Channels Required To Maintain Functional Performance[a]
LPCI initiation	RPV low water level	Level transmitter	4	2 per untripped trip system
LPCI initiation	Primary containment high pressure	Pressure transmitter	4	2 per untripped trip system
Containment spray valves	RPV low water level inside shroud	Level transmitter	1	1[b]
Minimum flow bypass valves	LPCI pumps discharge low flow	Flow switch	1, 2[c] (one per loop)	1, 2[c]
LPCI injection valves and recirculation loop valves	Recirculation loop break	Differential pressure transmitter	4	2
LPCI injection valves	RPV low pressure	Pressure transmitter	4	2
Reactor recirculation pumps	RPV low water level	Level transmitter	4	2
Containment cooling valves	Primary containment (drywell) high pressure	Pressure transmitter	4	2

[a] Nominal values are given for information. See Technical Specifications for operational requirements.

[b] An inoperable sensor should be placed in the untripped state.

[c] One channel to open, two channels to close.

7.4 SAFE-SHUTDOWN SYSTEMS

7.4.1 Description

7.4.1.1 Reactor Core Isolation Cooling System Instrumentation and Control

7.4.1.1.1 System Identification

7.4.1.1.1.1 Function

The reactor core isolation cooling (RCIC) system provides core cooling during reactor shutdown by pumping makeup water into the reactor pressure vessel (RPV) in case of a loss of flow from the main feedwater system. It is activated in time to preclude conditions that lead to inadequate core cooling.

7.4.1.1.1.2 Classification

Electrical modules for the RCIC system are classified as Safety Class 2 and Category I.

7.4.1.1.2 Power Sources

The RCIC pump is turbine driven and the RCIC trip system is powered by the Division I 260/130-V dc battery.

7.4.1.1.3 Equipment Design

When actuated, the RCIC system pumps water from either the condensate storage tank or the suppression chamber to the RPV via the feedwater lines. The RCIC system includes one turbine-driven pump, one barometric condenser dc vacuum pump, one vacuum dc condensate pump, automatic valves, control devices for this equipment, sensors, and logic circuitry. The arrangement of equipment and control devices is shown in Figure 5.5-7.

Pressure and level transmitters used in the RCIC system are located on racks in the reactor building. The only operating component of the RCIC system that is located inside the primary containment is one of the two RCIC system turbine steam supply isolation valves.

The rest of the RCIC system instrumentation and control components are located outside the primary containment. Cables connect the sensors to control circuitry in the main control room. The system is designed to allow a full flow functional test of the system during normal reactor power operation. The system will automatically return to normal system operation if called upon to do so during the test.

7.4.1.1.3.1 Initiating Circuits

Reactor pressure vessel low water level is monitored by four level transmitters which sense the difference between the pressure of a constant reference leg of water and the pressure resulting from the actual height of water in the vessel. Two pipelines, attached to taps above and below the water level on the RPV, are required for each of the two reference legs used with the RCIC. The lines are physically separated from each other and tap off the RPV at widely separated points. Two pairs of differential-pressure sensing lines from the two reference legs terminate outside the primary containment and inside the reactor building.

A backfill system is installed on each level instrument reference leg. The system provides a metered flow of water from the control rod drive system to each leg. The flow is low enough to not affect the performance of the instrumentation. The backfill is designed to prevent the accumulation of dissolved noncondensable gases in the reference legs.

The RCIC system is initiated only by low water level. The RCIC initiation circuit is arranged in a "one-out-of-two taken twice" logic.

The RCIC system is automatically initiated after the receipt of an RPV low water level signal, and produces the design flow rate within 50 sec. The controls then function to provide a flow of makeup water to the RPV until the amount of water delivered to the RPV is adequate to restore vessel level. At this time, the RCIC system automatically shuts down by closing the turbine steam supply valve and the steam warmup bypass valve, if it is still open. The system will automatically reinitiate if the water level returns to the low-level trip point. The controls are arranged to allow remote manual startup, operation, and shutdown.

The RCIC turbine is functionally controlled as shown in Figure 7.4-1. Minimizing initial peak speed of the turbine is accomplished by use of a warmup bypass valve. A speed governor limits the turbine speed to its maximum operating level. A control governor receives a RCIC system flow signal and adjusts the turbine steam control valve so that design pump discharge flow rate is obtained. Manual control of the governor is possible in the test mode; however, the governor automatically returns to automatic control on receipt of an RCIC system initiation signal. The flow signal used for automatic control of the turbine is derived from a differential pressure measurement across a flow element in the RCIC pump discharge line. The governor controls the position of the hydraulic operator on the turbine control valve, which in turn controls the steam flow to the turbine. Hydraulic pressure is supplied by the shaft-driven hydraulic oil pump.

The turbine is automatically shut down by tripping the turbine trip and throttle valve closed if any of the following conditions are detected

a. Turbine overspeed

b. High turbine exhaust pressure

c. An RCIC isolation signal from Logic A or B

d. Low pump suction pressure

e. Manual trip.

Turbine overspeed indicates a malfunction of the turbine control mechanism. High turbine exhaust pressure indicates a condition that threatens the physical integrity of the exhaust line. Low pump suction pressure warns that cavitation and lack of cooling can cause damage to the pump which could place it out of service. A turbine trip is initiated for these conditions so that the system can be quickly restored to service if the causes of the abnormal conditions can be found and corrected. The trip settings are selected far enough from normal values so that a spurious turbine trip is unlikely, but not so far that damage occurs before the turbine is shut down. Turbine overspeed is detected by a standard turbine overspeed mechanical device.

Two pressure switches are used to detect high turbine exhaust pressure; either switch can initiate turbine shutdown. One pressure switch is used to detect low RCIC system pump suction pressure.

High water level (Level 8) in the RPV indicates that the RCIC system has performed satisfactorily in providing makeup water to the RPV. Further increase in level could result in RCIC system turbine damage caused by gross carryover of moisture. The RPV high water level setting that closes the RCIC turbine steam supply valve is near the top of the steam separators and is sufficient to prevent gross moisture carryover to the turbine. Two level transmitters that sense differential pressure are arranged so that both transmitters are required to trip in order to halt RCIC operation.

UFSAR Section 7.5.1.4.2.1 describes that the wide-range water level system is uncompensated for variation in reactor water density and is calibrated to be most accurate at operational pressure and temperature conditions. At low reactor coolant temperatures and pressures, the higher water density causes the wide-range instruments to read higher than both the narrow-range instruments and the actual water level. Below approximately 550 psig, this phenomenon results in a wide-range level above the RPV high water level setting (Level 8) when the actual water level is normal. With wide-range level above Level 8, RCIC manual initiation is inhibited by the Level 8 trip signal. RCIC automatic initiation on RPV low water level (Level 2) remains available since the Level 8 signal is automatically reset by the occurrence of a Level 2 actuation signal. For accidents occurring below 600 psig for which RCIC may be effective, analysis has shown that RCIC automatic initiation at Level 2 is sufficient to perform the intended safety function and that the analyses of record from normal reactor pressure are bounding. Amendment 206 revised the Technical Specifications to indicate that the RCIC function of manual initiation is not required to be operable below a reactor pressure of 550 psig.

7.4.1.1.3.2 Logic and Sequencing

Reactor pressure vessel low water level automatically starts the RCIC system, as indicated in Figure 7.4-1.

The RCIC trip is powered by the Division I 260/130-V dc battery.

Instrument settings for the RCIC system instrumentation and control are listed in Table 7.4-1. The water level setting is far enough below normal levels that spurious RCIC system startups are avoided.

To prevent the turbine pump from being damaged by overheating at reduced RCIC pump discharge flow, a pump discharge bypass is provided to route the water discharged from the pump back to the suppression pool. The bypass is controlled by an automatic, dc motor-operated valve whose control scheme is shown in Figure 7.4-2. At RCIC high flow, the valve is closed; at low flow, the valve is opened. A flow switch that measures the pressure difference across a flow element in the RCIC pump discharge line provides the signals.

7.4.1.1.3.3 Bypasses and Interlocks

The RCIC steam supply line is maintained hot to prevent build-up of condensate by utilizing a condensate drain pot, steam line drain, and appropriate valves in a drain line arrangement just upstream of the turbine supply valve. The water level in the steam line drain condensate pot is controlled by a level switch and a solenoid piloted air operator, which energizes to allow condensate to bypass a manually controlled globe valve during periods of high condensate such as warming the steam line. The control scheme is shown in Figure 7.4-1. The controls position valves so that during normal operation, steam line drainage is routed to the main condenser. On receipt of a RCIC initiation signal and subsequent opening of RCIC turbine inlet valve E5150F045, the drainage path is isolated.

During test operation, the RCIC pump discharge is routed to the condensate storage tank. A dc motor-operated valve is installed in the pump-discharge-to-condensate-storage-tank line. The piping arrangement is shown in Figure 5.5-7. The control scheme for the valves is shown in Figure 7.4-1. On receipt of a RCIC system initiation signal, the valve closes and remains closed. The valve is interlocked closed if either of the suppression chamber suction valves is not fully opened. Numerous indications pertinent to the operation and condition of the RCIC system are available to the main control room operator. Figure 7.4-1 shows the various indications provided.

Keylock switches have been added to inboard and outboard steam isolation valve control circuitry, as shown in Figure 7.4-1, to ensure deliberate operator action to manually close these valves. Additionally, a control room annunciator alarms when the F007 and F008 valves are not in the fully open position. This prevents damage from water hammer caused by inadvertent valve reopening. Should either or both of these valves be closed, the outboard isolation valve can be slowly reopened to allow any moisture in the line to drain. Then line pressure across the inboard isolation valve is equalized, and the downstream line is warmed by slowly opening the inboard isolation valve.

7.4.1.1.3.4 Redundancy and Diversity

Four reactor water level sensors in a "one-out-of-two taken twice" circuit supply the signal which results from a loss-of-water inventory condition.

7.4.1.1.3.5 Actuated Devices

All automatic valves in the RCIC are equipped with remote manual test capability so that the entire system can be operated from the main control room. Motor-operated valves are provided with appropriate limit switches to turn off the motors when the fully open or fully closed positions are reached. Logic circuitry that controls valves which are automatically closed on isolation or turbine trip signals is equipped with manual reset devices so that the valves cannot be reopened without operator action. All required components of the RCIC controls operate independently of ac power.

To ensure that the RCIC system can be brought to design flow rate within 50 sec from the receipt of the initiation signal, the following maximum operating times for essential RCIC valves are provided by the valve operation mechanisms:

a. RCIC turbine steam supply valve - 45 sec

b. RCIC steam warmup bypass valve - 10 sec

c. RCIC pump discharge injection valves - 30 sec

d. RCIC pump minimum flow bypass valve - 25 sec

The operating time is the time required for the valve to travel from the fully closed to the fully open position, or vice versa. The two RCIC steam supply line isolation valves are normally open. They are intended to isolate the RCIC steam line in the event of a break in that line. A normally closed dc motor-operated isolation valve and a normally closed dc motor-operated warmup bypass valve are located in the turbine steam supply line just upstream of the turbine stop valve. The control schemes for these valves are shown in Figure 7.4-1. On receipt of a RCIC initiation signal, the valves open. The turbine steam supply valve remains open until closed by operator action or a level 8 trip. The warmup bypass valve remains open for 25 seconds then auto closes if a level 2 signal is not present.

Two normally open isolation valves are provided in the steam supply line to the turbine. The valve inside the drywell is controlled by an ac motor. The valve outside the drywell is controlled by a dc motor. The control diagram is shown in Figure 7.4-1. The valves automatically close on receipt of an RCIC isolation signal.

The instrumentation for RCIC isolation consists of the following:

a. Inside valve

   1. Ambient temperature sensor - emergency area cooler high temperature. Isolation is initiated immediately

   2. Differential pressure transmitter - RCIC steam line high flow or instrument line break. A time delay has been installed to prevent inadvertent system isolation due to pressure spikes associated with pump startup. The delay device setpoints (approximately 3 sec), along with the surveillance intervals, are included in the Technical Specifications

   3. Two pressure transmitters - RCIC turbine exhaust diaphragm high pressure. Both transmitters must activate to isolate

   4. Two pressure transmitters - RCIC steam supply pressure low. Both transmitters must activate to isolate.

b. Outside valve

   A similar set of instrumentation causes the outside valve to isolate with the addition of manual isolation if the low-level initiation signal is present.

Three pump suction valves are provided in the RCIC system. One valve lines up pump suction from the condensate storage tank, the other two from the suppression chamber. The condensate storage tank is the preferred source. All three valves are operated by dc motors. The control arrangement is shown in Figure 7.4-1. On receipt of an RCIC initiation signal, the condensate storage tank suction valve automatically opens. On receipt of a condensate storage tank low level signal, RCIC suction is automatically switched to the suppression pool. This is further discussed in Subsection 7.4.1.1.3.8.

Two dc motor-operated RCIC pump discharge valves are provided in the pump discharge line. The control schemes for these two valves are shown in Figure 7.4-1. Both valves are arranged to open on receipt of the RCIC initiation signal. One of the pump discharge valves closes automatically if a turbine trip occurs. The other valve remains open after RCIC initiation until closed by operator action in the main control room.

7.4.1.1.3.6 Separation

As in the emergency core cooling system (ECCS), the RCIC system is separated into divisions designated I and II (Subsection 7.3.1.2.1.6). The RCIC is a Division I system, but the inside steam line valve is in Division II: therefore, part of the RCIC logic is treated as Division II. The inside valve is an ac powered valve. The rest of the valves are dc-powered valves. Division I logic is powered by a 260/130-V dc Division I battery, and the Division II logic is powered by a 260/130-V dc Division II battery.

7.4.1.1.3.7 Testability

The RCIC may be tested to design flow during normal plant operation. Water is drawn from the condensate storage tank and discharged through a full flow test return line to the condensate storage tank. The discharge valve from the pump to the feedwater line remains closed during the test, and reactor operation remains undisturbed. Design of the control system is such that the RCIC system returns to the operating mode from the full flow test if system initiation is required.

7.4.1.1.3.8 Automatic Switchover of RCIC System Suction

In the original design, the switchover from the condensate storage tank to the suppression chamber as a source of water was to be manually controlled. However, as a result of discussions with the NRC, this was changed to automatically controlled. Automatic RCIC suction transfer occurs when the trip logic is deenergized. The trip logic is developed within the Division II HPCI system from redundant analog CST level transmitters and trip units. The HPCI level trip units provide redundant signals to the Division I RCIC suction transfer circuitry through auxiliary relay contacts. Either of these redundant low level signals will automatically open RCIC valves F029 and F031 (refer to Figures 5.5-7, 7.4-1, and 7.4-2). The RCIC suction transfer then uses the full-open position limit switches on F029 and F031 to initiate the closure of F010, the valve in the pump suction connection to the condensate storage tank. Panel status information is provided for the operator in the form of valve position indication.

The condensate storage tank level instrumentation is designed to meet the position of the NRC's Instrumentation and Controls System Branch with respect to freeze protection.

A single source connection penetrates the tank. This source connection is common to both the analog transmitters that monitor tank level for the purpose of transferring the RCIC/HPCI pump suction and the transmitter associated with the continuous wide- range tank level indication provided in the main control room. This equipment is contained within a large insulated steel cabinet (H21-P492) welded directly to the exterior of the condensate storage tank about 3 ft above ground level. The environment within the cabinet is maintained above freezing by a radiant strip heater and a local-control thermostat. A temperature-sensing device that is independent of the strip heater and its associated control thermostat is also located within the cabinet. This sensor produces a visual and audible alarm in the main control room whenever the temperature in the transmitter cabinet falls below 40°F. The cabinet temperature control and the low-temperature alarm are electrically independent and powered from completely independent and diverse power sources. A failure of either would not affect the ability of the other to perform its function. To guarantee the continued performance of the environmental control and monitoring systems, Edison will perform a yearly functional surveillance of the systems prior to the advent of freezing weather.

Edison has based its justification of the nonseismic location of the transmitters used in the suction transfer system primarily on the degree of conservatism in instrumentation seismic design. The level transmitters used in this transfer application were seismically qualified as described in the licensing topical report NEDO-21617.

Fermi site ground response spectra applicable to a transmitter mounting on the tank located at grade level would fall well below the values used for qualification of the transmitters in the reference document. As a result, the transmitters are expected to operate properly during and after a seismic event. As an added degree of conservatism, a failure of the tank which results in a loss of inventory and/or loss of the current signal from either transmitter will cause trip units (E41-N661 B and D) and associated trip relays to transfer the RCIC and HPCI suction valves to the suppression pool. These trip units and relays are located on the fourth floor of the reactor building in panel H21-P081. These devices and cabinet are located within the seismically qualified portion of the plant and meet the environmental and seismic qualification requirements for Class 1E electrical equipment.

All of the equipment that accomplishes the automatic suction valve transfer on low condensate tank level is classified as Quality Level 1. The transmitters were purchased as qualified instruments along with the balance of the transfer system and are included with the trip units and relays in the Technical Specifications because the surveillance requirement includes the entire measurement loop.

7.4.1.1.4 Environmental Considerations

The only RCIC control component located inside the primary containment that must remain functional in the environment resulting from a LOCA is the control mechanism for the inside isolation valve. The environmental capabilities of this valve are discussed in Subsection 7.3.2.2.9. The RCIC instrumentation and control equipment located outside the primary containment is selected in consideration of the normal and accident environments in which it must operate. Refer to Subsection 7.4.1.1.3.8 for information on the environmental considerations for the HPCI/RCIC instruments on the condensate storage tank.

Level sensing instrumentation used as inputs to the RCIC logic from residual heat removal (RHR) is discussed in Subsection 7.3.1.2.4.

7.4.1.1.5 Operational Considerations

7.4.1.1.5.1 General Information

Core cooling is required in the event that the reactor becomes isolated from the main condensers during normal operation by a closure of the main steam isolation valves (MSIVs). Cooling is necessary because of the core fission product decay heat. Steam is vented through the pressure safety/relief valves to the suppression pool. The RCIC system maintains reactor water level by providing the makeup water. Initiation and control are automatic.

The provisions taken in accordance with General Design Criterion (GDC) 19 of 10 CFR 50, Appendix A, to provide the required equipment outside the main control room for hot and cold shutdown, are described in Subsection 7.5.1.5.1.

7.4.1.1.5.2 Setpoints

A list of setpoints for the RCIC system can be found in Table 7.4-1.

7.4.1.2 Standby Liquid Control System Instrumentation and Control

7.4.1.2.1 System Identification

7.4.1.2.1.1 Function

The instrumentation and control system for the standby liquid control system (SLCS) is designed to inject water-soluble neutron-absorber solution well above saturation temperature.

7.4.1.2.1.2 Classification

The SLCS is a backup method of manually shutting down the reactor to cold subcritical independently from the control rod drive system. Thus, the system is considered a control system and not a safety system. The standby liquid control process equipment, instrumentation, and control essential for injection of the neutron-absorber solution into the reactor are designed to withstand Category I earthquake loads. Nonprocess equipment and instrumentation and control are designed as a nonseismic system. The SLCS has been reclassified to identify that it was not originally intended, procured, designed, or classified as safety related, but it will be maintained and tested as a safety-related system after completion of its preoperational tests.

7.4.1.2.2 Power Sources

The power supply to explosive valve F004A and injection pump C001A is from automatically restored MCC 72B-4C. The power supply to explosive valve F004B and injection pump C001B is from automatically restored MCC 72E-5B. The location of these pumps and valves is shown in Figure 7.4-3. The power supply to the tank heaters and heater controls can also be connected to an engineered safety feature (ESF) bus. The 120-V ac power supply to the main control room benchboard indicator lights is powered from an inductive BOP MPU, and the level and pressure transmitters are powered from restorable instrument MPU 1.

7.4.1.2.3 Equipment Design

7.4.1.2.3.1 Initiating Circuits

The standby liquid control is initiated in the main control room by turning a keylocking switch to either system A or system B. The key is removable in the center OFF position. When either system is initiated, both explosive valves (F004A and F004B) are fired, and the selected pump C001A or C001B is started. Should the selected pump fail to start, the key switch may be turned to the alternate pump.

7.4.1.2.3.2 Logic and Sequencing

When the SLCS is initiated, both the explosive valves fire and the pump that has been selected for injection starts.

7.4.1.2.3.3 Bypasses and Interlocks

There are no bypasses. When the SLCS is initiated to inject soluble neutron absorber into the reactor, the outboard isolation valve of the reactor water cleanup (RWCU) is automatically closed.

7.4.1.2.3.4 Redundancy and Diversity

The redundancy exists in duplicated pumps, explosive valves, and power supply as outlined in Subsection 7.4.1.2.2.

7.4.1.2.3.5 Actuated Devices

When the SLCS is initiated to inject soluble neutron absorber into the reactor, one of the two injection pumps and each of the two explosive valves are actuated.

7.4.1.2.3.6 Testability

The instrumentation and control system of the SLCS is tested when the system test is performed as outlined in Subsection 4.5.2.4.4.

7.4.1.2.4 Environmental Considerations

The environmental considerations for the instrumentation and control portions of the SLCS are the same as for the active mechanical components of the system. This is discussed in Section 3.11 and Subsection 4.5.2.4.3.

7.4.1.2.5 Operational Considerations

7.4.1.2.5.1 General Information

The control scheme for the SLCS can be found in Figure 7.4-3. The standby liquid control is manually initiated in the main control room by inserting the proper key into the keylocking switch and turning it to either system A or system B. The time it takes to complete the injection is between 50 and 125 minutes. When the injection is completed, the system is manually turned off by returning the keylocking switch to the OFF position.

7.4.1.2.5.2 Operator Information

The SLCS indicators are as follows:

a. The system pressure is indicated with an indicator that has a range of 0-1800 psig in the main control room

b. The storage tank level is indicated with an indicator that has a range of near empty to near full, calibrated to read in inches of liquid storage in the main control room

c. The continuity of the explosive valve dual primer ignition circuit is monitored by measuring a trickle current through the primers. If either of the dual primer or the primer ignition circuit becomes open-circuited, the continuity meter reads downscale

d. Indicator lights in the main control room show if either pump is running, stopped, or tripped

e. Indicator lights in the main control room show whether or not the explosive valve firing circuitry has continuity

f. Indicator lights in the main control room show if service valve F008 is open or closed, as shown in Figure 7.4-3

g. Indicator lights in the main control room show if the F006 check valve disk is open or closed

h. Indicator lights on the local panel show if the manually controlled high-power storage tank heater is on or off

i. Indicator lights on the local panel for the low-power storage tank heater have been de-energized and abandoned in place.

The SLCS main control room annunciators annunciate when

a. There is a loss of continuity of either explosive valve primers

b. The standby liquid storage temperature becomes too hot or too cold

c. The standby liquid tank level is too high or too low.

7.4.1.2.5.3 Setpoints

The SLCS has setpoints for the various instruments as follows:

a. The loss of continuity meter is set to activate the annunciator just below trickle current that is observed when the primers of the explosive valves are new

b. The high and low standby liquid temperature switch is set to activate the annunciator at temperatures of approximately 110°F and 48°F, respectively

c. The high and low standby liquid storage tank level switch is set to activate the annunciator when the volume is approximately 2975 gal net and 2618 gal net of the storage tank capacity, respectively

7.4.1.3 Reactor Shutdown Cooling System Instrumentation and Control

7.4.1.3.1 System Identification

The shutdown cooling mode is a function of the RHR system and is placed in operation during a normal shutdown and cooldown.

7.4.1.3.2 Power Sources

The power sources for the reactor shutdown cooling system instrumentation and control are as described in the ECCS discussion in Subsection 7.3.1.2.

7.4.1.3.3 Equipment Design

The reactor water is cooled by taking suction from one of the recirculation loops as shown in Figure 5.5-13. During the shutdown cooling mode, only one RHR system heat exchanger is required. This allows the remaining RHR system division to be held in standby for use in either the low-pressure coolant injection (LPCI) mode or containment cooling mode. One RHR division's valve alignment is shifted from the standby mode lineup (suction from the torus) needed for LPCI and containment cooling to the shutdown mode lineup (suction from reactor recirculation loop-B) after the reactor is depressurized. One RHR heat exchanger removes enough decay heat, even with declining reactor water approach temperature, so that the proper cooldown rate may be achieved.

If it is necessary to discharge a complete core load of reactor fuel to the spent fuel pool, the cooling capacity of the fuel pool cooling and cleanup system (FPCCS) heat exchangers may be exceeded. A means is provided for making a physical connection between the spent fuel pool and the RHR system. The RHR heat exchangers have greater cooling capacity than the FPCCS heat exchangers, and can maintain the spent fuel pool within its design temperature until the decay heat load is within the capacity of the FPCCS.

7.4.1.3.3.1 Initiating Circuits

The reactor shutdown cooling system is initiated only by manual action. The system cannot be actuated unless certain requirements, described in the following subsections, are met.

7.4.1.3.3.2 Bypasses and Interlocks

To prevent opening the shutdown cooling valves except under proper conditions, interlocks are provided as shown in Table 7.4-2.

The two RHR pumps used for shutdown cooling are interlocked to trip the pumps if the shutdown cooling valves and suction valves from the suppression pool are not properly positioned.

7.4.1.3.3.3 Actuating Devices

All motor-operated valves in the shutdown cooling system are equipped with remote manual switches in the main control room.

7.4.1.3.3.4 Testability

The shutdown cooling system pumps of the RHR system may be tested to full capacity during normal plant operation.

7.4.1.3.4 Environmental Considerations

The only shutdown cooling control component located inside the drywell that must remain functional in the environment is the control mechanism for the (inboard) isolation shutdown cooling suction valve. The environmental capabilities of this valve are discussed in Subsection 7.3.2.2.9. The instrumentation and control equipment located outside the drywell is selected in consideration of the normal and accident environments in which it must operate.

7.4.1.3.5 Operational Considerations

All controls for the shutdown cooling system are located in the main control room. Operator information is provided as described in the RHR discussion of the LPCI mode in Subsection 7.3.1.2.4.

The provisions taken in accordance with GDC 19 of 10 CFR 50, Appendix A, to provide the required equipment outside the main control room for hot and cold shutdown, are described in Subsection 7.5.1.5.1.

7.4.2 Analysis

7.4.2.1 General

Presented below are analyses that show how the safe shutdown systems satisfy their design bases listed in Section 7.1.

7.4.2.2 Reactor Core Isolation Cooling System Instrumentation and Control

7.4.2.2.1 Conformance To General Functional Requirements

For events other than pipe breaks, the RCIC system has a makeup capacity sufficient to prevent the RPV water level from decreasing to the level where the core is uncovered without using the ECCS.

To ensure to a high degree that the RCIC system operates when necessary and in time to provide adequate core cooling, the power supply for the system is taken from reliable sources that are immediately available. Evaluation of instrumentation configuration for the RCIC system shows that no failure of a single initiating sensor either prevents the starting or causes false starting of the system.

A design flow functional test of the RCIC system can be performed during plant operation by taking suction from the demineralized water in the condensate storage tank and discharging through the full flow test return line back to the condensate storage tank.

During the test, the discharge valve to the feed line remains closed and reactor operation is undisturbed. Control system design provides automatic return from the full flow test mode to the operating mode if system initiation is required during testing.

7.4.2.2.2 Conformance To Specific Regulatory Requirements of IEEE 279-1971

7.4.2.2.2.1 Single-Failure Criterion (IEEE 279-1971, Paragraph 4.2)

The RCIC system, by itself, is not required to meet the single- failure criterion. The control logic circuits for the RCIC system initiation and control are housed in a single relay cabinet, and the power supply for the control logic and other RCIC equipment is from a single dc power source.

The RCIC initiation sensors and wiring up to the RCIC relay logic cabinet do, however, meet the single-failure criterion. Physical separation of instrument lines is provided so that no single instrument rack destruction or single instrument line (pipe) failure can prevent RCIC initiation. Wiring separation between divisions also provides tolerance to single wireway destruction (including shorts, opens, and grounds) in the accident detection portion of the control logic. The single-failure criterion is not applied to the logic relay cabinet or to other equipment required to function for RCIC operation.

7.4.2.2.2.2 Quality Components (IEEE 279-1971, Paragraph 4.3)

This requirement is described in NEDO-10139, which applies equally to the core spray and RCIC systems.

7.4.2.2.2.3 Equipment Qualification (IEEE 279-1971, Paragraph 4.4)

Environmental

No components of the RCIC control system are required to operate in the drywell environment. The RCIC steam line isolation valve located inside the drywell is a normally open valve and is required to operate only to isolate the primary containment.

Other process sensor equipment for RCIC initiation is located in the reactor building and is capable of accurate operation in ambient temperature conditions that result from abnormal conditions.

Panels and relay cabinets are located in typical power station control room and/or auxiliary relay room environments. Therefore, environmental testing of components mounted in these enclosures is not warranted.

There are no components in the RCIC control system that have not demonstrated their reliable operability in previous applications in nuclear power plant protection systems or in extensive industrial use.

7.4.2.2.2.4 Channel Integrity (IEEE 279-1971, Paragraph 4.5)

The RCIC system instrument initiation channels meet the single- failure criterion as discussed in Subsection 7.4.2.2.2.1 above, and thus satisfy the channel integrity objective of this paragraph.

By definition (IEEE 279-1971, Paragraph 2.2), a channel loses its identity where single-action signals are combined. Therefore, since instrument channels are combined into a single trip system, this paragraph of IEEE 279-1971 does not strictly apply for the RCIC control system.

7.4.2.2.2.5 Channel Independence (IEEE 279-1971, Paragraph 4.6)

Channel independence for initiation sensors is provided by electrical and mechanical separation. The A and C sensors for RPV level, for instance, are located on one local instrument panel identified as Division I equipment, and the B and D sensors are located on a second instrument panel widely separated from the first and identified as Division II equipment.

The A and C sensors have a common pair of process taps that are widely separated from the corresponding taps for sensors B and D. Disabling of one or both sensors in one location does not disable the control for RCIC initiation.

7.4.2.2.2.6 Control and Protection Interaction (IEEE 279-1971, Paragraph 4.7)

The RCIC system is strictly an off-on system, and no signal whose failure could cause need of RCIC can also prevent RCIC from starting. Annunciator circuits using contacts of sensor relays and logic relays cannot impair the operability of the RCIC system control because of the electrical separation between controls. A short between the annunciator wiring and the RCIC control wiring could result in a single ground on the dc control circuit without affecting circuit operability.

7.4.2.2.2.7 Derivation of System Inputs (IEEE 279-1971, Paragraph 4.8)

The input that starts the RCIC system is a direct measure of the variable that indicates need for core cooling; e.g., RPV low water level.

7.4.2.2.2.8 Capability for Sensor Checks (IEEE 279-1971, Paragraph 4.9)

All sensors are of the pressure-sensing type and are installed with calibration taps and instrument valves so that testing during normal plant operation or during shutdown is permitted.

The reactor low-pressure transmitters can be easily checked for operability during plant operation by observing the analog output of respective transmitters. The RPV level transmitters are also checked for operability in a similar fashion. Refer to Subsection 7.1.3.1.

7.4.2.2.2.9 Capability for Test and Calibration (IEEE 279-1971, Paragraph 4.l0)

The RCIC control system is capable of being completely tested under normal plant operation to verify that each element of the system, active or passive, is capable of performing its intended function. Sensors can be exercised by applying test pressures.

The RCIC system can be manually started in the test mode by opening steam supply valves to the RCIC turbine to pump water from the condensate storage tank through the test return valves back to the condensate storage tank, while the reactor is at pressure.

Motor-operated valves can be exercised by the appropriate control relays and starters, and all indications and annunciations can be observed as the system is tested.

7.4.2.2.2.10 Channel Bypass or Removal From Operation (IEEE 279-1971, Paragraph 4.11)

Calibration of a sensor that introduces a single instrument channel trip will not cause a protective function without the coincident trip of a second channel. There are no instrument channel bypasses in the RCIC system. Removal of a sensor from operation during calibration does not prevent the redundant instrument channel from functioning.

7.4.2.2.2.11 Operating Bypasses (IEEE 279-1971, Paragraph 4.12)

The RCIC system design contains no operating bypasses.

7.4.2.2.2.12 Indication of Bypasses (IEEE 279-1971, Paragraph 4.13)

Indication of bypasses provided is as discussed in Subsection 7.4.2.2.2.11.

7.4.2.2.2.13 Access To Means for Bypassing (IEEE 279-1971, Paragraph 4.14)

Access to motor control centers and instrument valves is controlled. Access to other means of bypassing is located in the main control room and is therefore under the administrative control of the operators.

7.4.2.2.2.14 Multiple Setpoint (IEEE 279-1971, Paragraph 4.15)

This is not applicable because all setpoints are fixed.

7.4.2.2.2.15 Completion of Protective Action Once It Is Initiated (IEEE 279-1971, Paragraph 4.16)

The final control elements for the RCIC system are essentially bi-stable, i.e., motor-operated valves stay open or closed once they have reached their desired position, even though their starter may drop out (which they do when the limit switch is reached). In the case of pump starters, the automatic initiation signal is electrically sealed in.

Thus, once protection action is initiated (i.e., flow established), it must go to completion or continue until terminated by deliberate operator action or automatically stopped on high vessel water level or system malfunction trip signals.

7.4.2.2.2.16 Manual Actuation (IEEE 279-1971, Paragraph 4.17)

Each piece of RCIC actuation equipment required to operate (pumps and valves) is capable of manual initiation electrically from the control panel in the main control room. Failure of logic circuitry to initiate the RCIC system will not affect the manual control of equipment.

However, failures of active components or control circuit failure which produces a turbine trip may disable the manual actuation of the RCIC system. Failures of this type are continuously monitored by alarms.

7.4.2.2.2.17 Access To Setpoint Adjustment (IEEE 279-1971 Paragraph 4.18)

Setpoint adjustments for the RCIC system sensors are integral with the sensors on the local instrument racks and cannot be changed without the use of tools to remove covers over these adjustments. Control relay cabinets are capable of being locked to prevent unauthorized actuation. Because of these restrictions, compliance with this requirement of IEEE 279-1971 is considered complete.

7.4.2.2.2.18 Identification of Protective Actions (IEEE 279-1971, Paragraph 4.19)

Protective actions are directly indicated and identified by annunciator operation or action of the sensor relay, which has an identification tag and a clear glass window front that permits convenient visible verification of the relay position. This combination of annunciation and visible relay actuation is considered to fulfill the requirements of this criterion.

7.4.2.2.2.19 Information Readout (IEEE 279-1971, Paragraph 4.20)

The RCIC control system is designed to provide the operator with accurate and timely information pertinent to its status. It does not introduce signals into other systems that could cause anomalous indications confusing to the operator. Periodic testing is the means provided for verifying the operability of the RCIC components and, by proper selection of test periods, to be compatible with the historically established reliability of the components tested, complete and timely indications are made available. Sufficient information is provided on a continuous basis so that the operator can have a high degree of confidence that the RCIC function is available and/or operating properly.

In addition to the annunciator alarms shown on the functional control diagram in Figure 7.4-1, the following alarms are provided:

a. Failure of control power to the RCIC system

b. Valve overload alarm.

In addition to the annunciators, the other indications on the main control room panel are

a. Valve position lights

b. Pump monitor lights

c. Pump suction/discharge pressure indicator

d. RCIC pump flow indicator

e. Turbine exhaust line pressure indicator

f. Turbine steam inlet pressure indicator

g. Turbine speed indicator

h. Turbine supervisory indicators.

i. Barometric condenser vacuum pump current

j. Barometric condenser condensate pump current

7.4.2.2.2.20 System Repair (IEEE 279-1971, Paragraph 4.21)

The RCIC control system is designed to permit repair or replacement of components.

Recognition and location of a failed component will be accomplished during periodic testing. The simplicity of the logic will make the detection and location relatively easy, and components are mounted in such a way that they can be conveniently replaced in a short time. Sensors that are connected to the instrument piping cannot be changed so readily but are connected with separable screwed or bolted fittings.

7.4.2.2.2.21 Identification (IEEE 279-1971, Paragraph 4.22)

The RCIC system is identified uniquely as a Division I system. All controls and instruments are located in one area of the main control room panel and are clearly identified by nameplates.

Relays are located in one panel for RCIC use only. Relays and panels are identified by nameplates.

7.4.2.2.3 Conformance To Specific Regulatory Requirements

The RCIC system conforms to the following regulatory requirements:

a. IEEE 323-1971 - This is discussed in Section 3.11 and GE Topical Report NEDO-10698

b. IEEE 338-1971 - Only paragraphs of IEEE 338-1971 that apply to the design of the RCIC system will be covered

   Capability for Sensor Checks (IEEE 338-1971, 2.1) is discussed in Subsection 7.4.2.2.2.8. Capability for Test and Calibration (IEEE 338-1971, 2.2) is discussed in Subsection 7.4.2.2.2.9

c. IEEE 344-1971 - This is discussed in Topical Report NEDO-10678

d. 10 CFR 50, Appendix A requirements -

   1. Criterion 13 - Subsections 7.4.1.1.3.1, 7.4.1.1.3.2, 7.4.1.1.3.3

   2. Criterion 37 - Subsection 7.4.1.1.3.7.

e. 10 CFR 50, Appendix B requirements - The requirements of 10 CFR 50, Appendix B, are met as described in Chapter 17

f. Regulatory Guide 1.22 - Subsections 7.4.2.2.2.8 and 7.4.2.2.2.9.

7.4.2.3 Standby Liquid Control System Instrumentation and Control

7.4.2.3.1 Conformance To General Functional Requirements

Redundant positive displacement pumps, explosive valves, and control circuits for these components have been provided as described in Subsection 7.4.1.2. This constitutes all the active equipment required for injection of the sodium pentaborate solution. Continuity relays provide monitoring on the explosive valves, and indicator lights provide indication on the main reactor control panel of system status as described in Subsection 7.4.1.2.5.2. Testability is described in Subsection 7.4.1.2.3.6. Redundant power sources are described in Subsection 7.4.1.2.2.

7.4.2.3.2 Conformance To Specific Regulatory Requirements

Qualification of Class 1E electrical equipment in accordance with IEEE 323-1971 and seismic design of Class 1E electrical equipment in accordance with IEEE 344-1971 are covered in Topical Reports NEDO-10698 and NEDO-l0678, respectively, and Sections 3.11 and 3.10.

The requirements of 10 CFR 50, Appendix B, are described in Chapter 17.

7.4.2.4 Reactor Shutdown Cooling System Instrumentation and Control

7.4.2.4.1 Conformance To General Functional Requirements

The design of the reactor shutdown cooling system instrumentation and controls meets all the functional requirements of Subsection 7.1.2.1.27 as follows:

7.4.2.4.1.1 Valves

Manual controls and position indicators are provided in the main control room. Interlocks are provided to prevent opening of the valves if shutdown conditions are not met. Interlocks are also provided to close the valves if an isolation signal is present or if high reactor pressure exists.

Redundant sensors (N111A and B) are provided for the RHR shutdown cooling pressure interlocks. These sensing loops meet or exceed the EICSB-3 Branch Technical Position. The interlocks are designed as part of the testability option and, therefore, formal diversity of the sensors and trip units has not been provided. Formal test procedures are used to verify operability of the interlocks. It is Edison's position that the accuracy, reliability, testing, and inherent on-line status monitoring of the analog transmitter/trip unit design obviate the need for diverse instruments.

7.4.2.4.1.2 Instrumentation

Shutdown flow indicator is provided. The RHR cooling water and service water temperatures are provided. Head spray flow indication is no longer provided. A permanent modification has removed the head spray piping, disabling this flow path.

7.4.2.4.1.3 Annunciation

The following annunciators are provided:

a. Division I/Division II RHR valves thermal overload

b. RHR heat exchanger cooling water discharge temperature high

c. RHR system overpressure

d. RHR pump motor tripped.

7.4.2.4.1.4 Pumps

Manual controls and stop and start indicators are provided in the main control room. Interlocks are provided to trip the pumps if the shutdown cooling valves are not properly set up.

7.4.2.4.2 Conformance To Specific Regulatory Requirements

Conformances to regulatory requirements are the same as those specified for the ESF systems.

Consideration of failure of plant instrument air and loss of cooling water to safe-shutdown equipment is given in Chapter 15. These systems are not specifically designed for consideration of plant load rejection or turbine trip, but the plant is designed to handle those situations and shut down safely.

TABLE 7.4-1 REACTOR CORE ISOLATION COOLING INSTRUMENT SPECIFICATION

RCIC Function	Instrument	Trip Settings[a]	Range
RPV high water level turbine trip	Level transmitter	Level 8[b]	10 to 220 in.[c]
Turbine exhaust diaphragm high pressure	Pressure transmitter	10 psig	0 to 30 psi
RCIC system pump low suction pressure	Pressure switch	Low - 20 in. Hg vacuum[d]	30 in. Hg vacuum to 10 psig
RCIC system pump high suction pressure	Pressure switch	High - 70 psig	0.5 to 80 psig
RPV low water level[e]	Level transmitter	Level 2[b]	10 to 220 in.[c]
RCIC system steam supply low pressure	Pressure transmitter	50 psig	0 to 200 psig
Turbine overspeed	Centrifugal device	122.3 percent of rated speed	

[a] Nominal values are given for information. See the Technical Specifications for operational limits.

7.5 SAFETY-RELATED AND POWER GENERATION DISPLAY INSTRUMENTATION

7.5.1 Description

7.5.1.1 General

A description of the instrumentation that provides information to the operator to enable him to perform required safety functions is provided in this subsection.

A Human Factors Engineering design review program was established to maintain control room and remote shutdown panel instrumentation in conformance with the general human factors conventions adapted from NRC Human Factors Criteria (NUREG-0700 “Guidelines for Control Room Design Reviews”) as well as plant specific conventions. This program was originally described in section 5.0 of Supplement 2 to the DCRDR “Summary Report for the Fermi 2 Control Room.”

7.5.1.2 Normal Operation

The normal plant process variable indicators and recorders are described in Section 7.6 and are shown on the piping and instrumentation diagrams for the various nuclear steam supply systems (NSSSs). Information channel ranges and indicators are selected on the basis of giving the operator the necessary information, during expected operational perturbations, to perform all the normal plant maneuvers and to be able to track all the process variables pertinent to safety. Description of the control rod position indicating system is given in Subsection 7.7.1.1.5.

7.5.1.3 Abnormal Transient Occurrences

The ranges of indicators and recorders provided are capable of covering the extremes of process variables and providing necessary information to enable the operator to perform required safety functions.

7.5.1.4 Accident Conditions

Information readouts are provided to accommodate events up to and including a LOCA. These readouts are designed from the standpoint of operator action, information, and event tracking requirements, providing assurance that requirements for all other credible events or incidents will be covered.

7.5.1.4.1 Initial Accident Event

The design basis of all engineered safety feature (ESF) systems to mitigate accident event conditions takes into consideration that no operator action or assistance is necessary for the first 10 minutes of the event. This requirement makes it mandatory that all protective action necessary in the first 10 minutes be automatic. Therefore, although continuous tracking of process variables is available, no operator action based on them is required or recommended.

7.5.1.4.2 Postaccident Tracking

After 10 minutes, operator action is optional, based on the information available. Within 30 minutes, however, containment cooling must be initiated.

The process instrumentation described in the following subsections provides information to the operator for his use in monitoring reactor conditions after a LOCA.

This instrumentation was designed to conform to the requirements of Regulatory Guide 1.97 [formerly, Branch Technical Position (BTP) ICSB-23]. A formal type-test seismic qualification based on IEEE Standard 344-1971 was obtained for the strip-chart recorders used in the systems.

Details of the tests performed are available in the General Electric Seismic Summary Report for panel H11-P602, dated December 1977.

7.5.1.4.2.1 Reactor Water Level

Appropriate vessel water level instrumentation described below is operable during and after postulated design-basis accidents.

The emergency core cooling system (ECCS) equipment and reactor protection and containment isolation system initiation is automatic. In addition, 11 level indicators are located in the control room. These instrument designations, their ranges, and control room location are presented in Table 7.5-1. Their ranges vary to cover the active fuel to the top of the reactor vessel so that the required range of the reactor vessel water level is monitored.

Two wide-range water level signals are transmitted from two nuclear boiler system independent differential pressure transmitters and are recorded on two, multi-point recorders in the main control room. One point records the wide-range level and the other point records the reactor pressure on each of the two recorders. The differential pressure transmitters have one side connected to a condensing-type chamber reference leg and the other side connected directly to a vessel nozzle for the variable leg. The water level system is uncompensated for variation in reactor water density and is calibrated to be most accurate at operational pressure and temperature conditions. The range of the recorded level is from the top of the feedwater control range (just above the high level turbine trip point) down to a point near the top of the active fuel. The power sources for the two channels are inverter-fed from the two divisional batteries. Both pressure and level recorders are equipped to automatically switch from a low (normal) speed to high speed when signal levels reach preset values as shown in Figure 7.3-12.

Two fuel-zone water level signals are transmitted from two nuclear boiler system independent differential-pressure transmitters. Signals go to water level recorders (programmable), one in each division. The differential-pressure transmitters have one side connected to a condensing-type chamber reference leg and the other side connected directly to the bottom tap of a calibrated jet pump for the variable leg. The water level system is uncompensated for variation in reactor water density and is calibrated to be most accurate at saturated atmospheric conditions. The programmable recorders perform mathematical conversion of the fuel-zone water level measurements to readings which account for the difference between calibration and off-calibration conditions expected during the accident.

The recorders use reactor vessel pressure signals to calculate the signal conversions. The level range is from near the bottom of the active fuel to over the top of the active fuel, as shown in Figure 7.3-12. The ranges of the wide-range level and the fuel-zone level overlap. Power sources are as stated in the previous paragraph. The feedwater control system has other reactor water level recorders/indicators in the main control room.

Fermi 2 is a BWR/4 design that uses only nonheated reference columns that are maintained full of condensate by the condensing chambers for all of the level measurements. A backfill system is installed on each level instrument reference leg. The system provides a metered flow of water from the control rod drive system to each leg. The flow is low enough to not affect the performance of the instrumentation. The backfill is designed to prevent the accumulation of dissolved noncondensable gases in the reference legs. Yarway reference columns are not used. Reactor vessel taps are divided into two separate divisions to maintain spatial diversity. Fermi 2 has three upper-steam-space taps (one on the head vent line), similar to the BWR/3 design. There are two intermediate (water zone) taps that sense the water variable leg inside the vessel annulus approximately 13 ft above the top of the active fuel. There are two lower taps that sense the water variable leg inside the vessel annulus outside the core shroud at approximately 10 in. above the top of the active fuel. Additionally, two lower taps that sense the water variable leg inside the jet pump above the pump diffuser tap similar to the BWR/3 are provided.

The power for the feedwater system level instrumentation is supplied from a vital instrument bus. Power is supplied to the reactor protection system (RPS) trip system level instruments from the RPS motor-generator sets. Power for the balance of the level instrumentation that is part of the ECCS is supplied by safety-grade inverter power supplies powered by the appropriate divisional battery.

With respect to drywell sensing line routing, Fermi 2 meets the requirements outlined in Figure 2.3.2.2-8 of NEDO 24708A, and, therefore, the level instruments are relatively independent of drywell temperature changes.

All of the level sensors are located on spatially separated divisional safety-grade instrument racks located in the reactor building approximately 15 ft from the drywell wall. All the level instrument channel response times are well within the design criteria.

In response to NRC requests for additional information on water level indication errors, Edison has provided information to further demonstrate the adequacy of the Fermi 2 water-level instrument design in response to high drywell temperatures that may lead to reference-leg flashing. In the unlikely case that flashing occurred, the expected error would be about 4 in. of indicated level. Even if the entire reference-leg portion in the drywell boiled off, the hypothetical error would not seriously impact adversely either manual or automatic actions to safely mitigate the worst-case transient identified.

7.5.1.4.2.2 Reactor Pressure

Two reactor pressure signals are transmitted from two independent pressure transmitters and are recorded on two, multi-point recorders in the main control room (same recorders described in Subsection 7.5.1.4.2.1 above). One point records pressure; the other records the wide-range level. The range of recorded pressure is from 0 to 1500 psig. Additionally, fuel-zone water level recorders (programmable) use reactor pressure signals to correct water level measurements for off-calibration pressure. The feedwater control system has other pressure signals recorded in the main control room. This range is sufficient to include the safety limit pressure.

7.5.1.4.2.3 Shutdown, Isolation, and Core Cooling Indication

The following information furnished to the main control room operator permits him to assess reactor shutdown, isolation, and availability of emergency core cooling following the postulated accidents.

a. Reactor shutdown occurs as one or more process variables exceed their specified setpoint. Operator verification that shutdown has occurred may be made by observing one or more of the following indications:

   1. Control rod status lamps indicating each rod fully inserted. Power source is a battery-powered inverter supply (Figure 7.5-1)

   2. Control rod scram valve status lamps indicating open valves. Power source is a battery-powered inverter supply (Figure 7.5-1)

   3. Neutron-monitoring power-range channels and recorders downscale. Power sources are the RPS motor-generator sets (Figure 7.5-1) and battery-powered inverters

   4. Annunciators for RPS variables and trip logic in the tripped state. Power source is dc from station battery (Figure 7.5-1)

   5. Logging of control rod positions on the Integrated Plant Computer System (IPCS). Power source is computer power supply from uninterruptible power supply (UPS) A and B

   6. Events recorder logging of trips. Power source is from station battery.

b. Reactor isolation occurs after the accident as various environmental and process variables exceed their setpoints. The operator may verify reactor isolation by observing one or more of the following indications:

   1. Isolation valve position lamps indicating valve closure. Power source is the same as for the associated motor operator

   2. Main steam line flow indication downscale. Power source is a battery-powered inverter supply (Figure 7.5-1)

   3. Annunciators for the primary RPS variables and trip logic in the tripped state. Power source is dc from station battery

   4. Events recorder logging of trips.

c. Operation of emergency core cooling following the LOCA may be verified by observing the following instrumentation:

1. Annunciators for high pressure coolant injection (HPCI), core spray, residual heat removal (RHR), and automatic depressurization system (ADS) sensor initiation logic trips. Power source is dc from a station battery
2. HPCI pump discharge pressure and flow indicators (Figure 7.3-1). Power for these instruments is derived from a battery-operated inverter supply
3. ADS valve position status (Figure 7.3-4). Position-indicator power is derived from battery powered inverters
4. Divisional core spray discharge pressure indicators, loop flow indicators, and pump motor ammeters (Figures 7.3-7 and 7.3-8). Power for the respective instruments is derived from the appropriate ESF bus
5. Divisional low pressure coolant injection (LPCI) (RHR) pump discharge header pressure indicators, loop flow indicators, loop flow recorders, and pump motor ammeters (Figure 7.3-9). Power for these instruments is derived from the associated ESF bus
6. Divisional RHR service water loop flow indicators and outlet temperature recorders (Figure 7.3-9). Power for these instruments is derived from the associated ESF bus
7. Injection valve position status. Power source is the same as for the valve motor
8. Events recorder logging of trips in the emergency core cooling network. Power source is the l30-V dc power system
9. Relief valve discharge pipe temperature monitors. Power source is 120-V ac supplied from a 120-V ac instrument bus.

d. Conditions of significant timed interlocks that restrict the flexibility of the ESF systems are indicated by the following devices:

   1. An indicating timer, which displays the amount of time remaining until manual ADS activation is permissive. This device is powered from the ADS logic supply
   2. Four timers, which indicate that the required time has elapsed and the RHR (LPCI) "failed" loop injection valves can be reopened. These devices are powered from their respective divisional logic supply
   3. Two timers, which indicate that the required time has elapsed and the RHR (LPCI) injection valves can be closed manually. These devices are powered from their respective divisional logic supply.

e. The following indicating devices are provided to permit rapid assessment of the standby power system status and to enhance the manual reconnection of loads:

   1. Each of the emergency diesel generator (EDG) automatic load sequencer systems provides visual indication of the exact state of the automatically sequenced loads. These devices are powered by the sequencer system power supply. Specific details of this system are described in Subsection 8.3.1.1.7.

   2. A digital meter that displays remaining generator capacity for each EDG is provided. Power is supplied to these instruments from the respective EDG bus. This system is described more fully in Subsection 8.3.1.1.11.

7.5.1.4.2.4 Primary Containment Indication

The following systems provide the control room operator with necessary information regarding the full range of environmental conditions possible within the primary containment following an accident or incident.

a. Drywell temperature in various locations within the drywell volume is recorded on redundant strip-chart recorders (Subsection 7.6.1.12.2). The power supply for these recorders is derived from the respective ESF bus

b. Drywell pressure is monitored by both narrow-range and wide-range pressure transmitters and recorded on redundant strip-chart recorders (Subsection 7.6.1.12.3). The power supply for these devices is derived from battery-powered inverters

c. Torus temperature is monitored by thermocouples located in both the torus air space and the suppression pool water. Continuous strip-chart recording of these temperatures is provided on redundant recorders (Subsection 7.6.1.12.2). The recorders are supplied with power from the appropriate ESF bus

d. Torus pressure is monitored by both narrow-range and wide-range pressure transmitters and recorded on redundant strip-chart recorders (Subsection 7.6.1.12.3). The power supply for these devices is derived from battery-powered inverters

e. Suppression pool water level is continuously recorded on redundant recorders (Subsection 7.6.1.12.4). Power for this instrumentation is supplied by the battery-powered inverters

f. Radiation level within the drywell is monitored and recorded (Section 11.4). The power for this instrumentation is derived from a 120-V ac instrument bus.

7.5.1.4.2.5 Bypassed and Inoperable Status Indication for Nuclear Safety Systems

In addition to administrative procedures for determining and indicating bypassed or inoperable status of systems, channel bypassed and inoperable status indication is provided for the RPS and ESF systems in accordance with the requirements of IEEE 279-1971, Section 4.13. As stated in Sections 7.1, 7.2 and 7.3, the RPS and ESF systems comply with

IEEE 279-1971, as supported by NEDO-10139, which has been incorporated into the UFSAR by reference. Refer to Sections 7.2 and 7.3 for descriptions of control room indication related to specific RPS and ESF functions.

7.5.1.4.3 Safety Parameter Display System (SPDS)

SPDS is a function of the Integrated Plant Computer System (IPCS) that provides a specific selection of emergency response information. SPDS uses data from selected plant data systems and processes the data for display on the IPCS. SPDS information can be displayed on any IPCS terminal, which includes those specifically located in the control room, the technical support center (TSC), and the emergency operations facility (EOF). The SPDS display in the control room is provided to assist the operators in assessing the safety status of the plant following an accident. The IPCS and SPDS are described in subsections 7.6.1.9.1 and 7.6.1.9.1.2.5.1 respectively.

7.5.1.5 Special Condition: Loss of Habitability of Main Control Room

7.5.1.5.1 Criteria

It is necessary to be able to carry out the reactor shutdown functions from outside the main control room and to bring the reactor to cold condition in an orderly fashion in compliance with General Design Criterion 19 of 10 CFR 50, Appendix A. This requirement applies when the main control room becomes uninhabitable for any reason and is accomplished using the remote shutdown panel discussed in this section.

Appendix R to 10 CFR 50 requires that the plant be safely shut down remote from the control room in the event of a fire in the main control room, relay room, cable spreading room, and other areas containing equipment or cabling of both divisions required for safe shutdown. This capability is provided by the alternative shutdown system described in Subsection 7.5.2.5.

7.5.1.5.2 Remote Shutdown Panel

The remote shutdown panel is located in the Division I switchgear room on the second floor of the reactor building. At this location it cannot be damaged by failure of any other equipment. The remote shutdown system panel is designed to comply with the requirements of Quality Assurance Level I, Seismic Category I. The following systems have instrumentation and controls on the remote panel, as shown in Figures 7.5-2 and 7.5-3.

a. Reactor core isolation cooling (RCIC) system

b. RHR system

c. Recirculation flow control system

d. Nuclear boiler system

e. Control rod drive (CRD) system

f. Residual heat removal service water (RHRSW) system

g. Primary containment monitoring system.

7.5.1.5.3 Conditions Assumed To Exist As the Main Control Room Becomes Inaccessible

a. The plant is operating normally at, or less than, design power

b. Loss of offsite ac power is considered unlikely, but credible. For shutdown outside the control room coincidental with the loss of offsite ac power, the instrumentation and controls of the alternative shutdown system, e.g., dedicated shutdown panel and its associated procedures, will be used as described in UFSAR Section 7.5.2.5.2.

c. No LOCA or transients shall be assumed; therefore, complete control of ESF systems from outside the main control room will not be required

d. Plant personnel evacuate the main control room

e. The main control room continues to be inaccessible during the entire shutdown procedure

f. The event that causes the main control room to become inaccessible is assumed to be such that the operator can manually scram the reactor before leaving the main control room. As a backup, the operator can manually scram the reactor, and if necessary, close the MSIVs from outside the Main Control Room.

g. The main turbine pressure regulators may be controlling reactor pressure via the bypass valves; however, in the interest of simplicity and safety, it is assumed that this function is lost. Therefore, main steam line isolation is assumed to occur, and reactor pressure is relieved through the relief valves to the suppression pool. The feedwater control system is also assumed to be unavailable due to reactor isolation

h. Reactor water is made up by the RCIC system

i. The dc services are supplied from at least one plant dc power system for each essential system or equipment item in the remote shutdown system.

7.5.1.5.4 Description

The system provides remote control for the reactor systems needed to carry out the shutdown function from outside the main control room and to bring the reactor to cold condition in an orderly fashion. This system also provides a variation to the normal system used in the main control room, permitting the shutdown of the reactor when feedwater is unavailable and the normal heat sinks (turbine and condenser) are lost.

Automatic activation of relief valves and the RCIC system brings the reactor to a hot shutdown condition. During this phase of shutdown, the suppression pool is cooled by operating the RHR system in the suppression pool cooling mode. Reactor pressure is controlled and core decay and sensible heat are rejected to the suppression pool by relieving steam pressure through the relief valves. Reactor water inventory is maintained by the RCIC system.

Manual operation of the relief valves cools the reactor and reduces its pressure at a controlled rate until reactor pressure becomes so low that the RCIC system discontinues operation. This condition is reached at 50 to 100 psig reactor pressure. The RHR system is then operated in the shutdown cooling mode wherein the RHR system heat exchanger is connected directly into the reactor water circuit to bring the reactor to the cold low-pressure condition.

7.5.1.5.5 Procedure for Reactor Shutdown From Outside the Main Control Room

a. If evacuation becomes necessary, the operator will scram the reactor by the manual scram switches or reactor mode switch at the main control room panel as he leaves the main control room

b. The main turbine pressure regulator will, under normal conditions, control the reactor pressure while rejecting heat (steam) through the turbine bypass valves. The feedwater control system will control water level

c. As a backup, the operator can manually scram the reactor and close the MSIVs from outside the Main Control Room

d. The remainder of the procedure as described assumes that the automatic pressure regulator is not available from time zero and the main steam isolation valves (MSIVs) are closed, but the actual procedure may be written to utilize any plant equipment that is available as long as this worse case condition is provided for

e. Key-controlled transfer switches at the remote panel are operated to transfer control to the remote shutdown panel

f. Relief valves open automatically and cycle to control reactor pressure. Reactor level starts to drop at a rate depending on prior power level and elapsed time from scram

g. The operator starts the RCIC system manually before Level 2 (Figure 7.3-12) is reached and monitors the water level thereafter. The water level will continue to fall

h. One relief valve opens and closes automatically, by the Low - Low Set Function

i. Reactor level reaches its lowest point at about 80 in. above top of active fuel if the RCIC system was initiated at low level. Level starts to rise as a result of RCIC system flow. Pressure relief is through one relief valve in automatic intermittent operation

j. Water level is returned to normal by operation of the RCIC system

k. One relief valve is still in automatic intermittent operation. The RCIC system turbine automatically shuts down when Level 8 is reached. It starts automatically when the level drops to the initiation level

l. Reduction of reactor pressure is started by manually actuating one relief valve. While activating relief valves, the operator observes the reactor level and suppression pool temperature

m. Relief valves are closed before level drops below Level 3. The reactor cooldown rate will be controlled to not exceed 100°F per hour. Reactor level varies between Level 3 and Level 8

n. The RHR system with one pump, one heat exchanger, and the RHRSW system is used to cool the suppression pool

o. The operator activates two relief valves to maintain reduction of pressure to 250 psig while observing pool temperature, which is not to exceed 140°F unless the reactor pressure decreases to less than 250 psig

p. Reactor pressure is reduced to 100 psig, allowing the suppression pool temperature to reach 170°F if necessary

q. The RHR system is placed in the shutdown cooling mode. The RHR operation continues until the reactor is in the cold/low-pressure condition

r. Normal reactor water level is maintained after being placed in the shutdown cooling mode.

7.5.2 Analysis

7.5.2.1 General

The safety-related and power-generation display instrumentation provides adequate information to allow operators to make correct decisions as bases for manual control actions permitted under normal, abnormal transient, and accident conditions.

Information instrumentation having no direct input to ESF systems, except through the operator as a link, is considered to be outside the scope of existing IEEE Standards. However, insofar as practical, instruments are selected from those types qualified under IEEE 279-1971 and IEEE 323-1971. Redundancy and independence or diversity are provided in all of the information systems used for the basis of operator-controlled safeguards action.

This instrumentation is designed to operate during normal operation, accident, and postaccident environmental conditions. The design criteria that the instrumentation must meet are discussed more fully in Subsection 7.1.2. The specific design qualifications of the instruments referenced in this section are tabulated in Table 7.5-2.

7.5.2.2 Normal Operation

Subsection 7.5.1.2 describes the basis for selecting ranges for instrumentation and, inasmuch as monitoring requirements for abnormal transient or accident conditions exceed those for normal operation, the normal ranges are covered adequately.

7.5.2.3 Abnormal Occurrences

These occurrences will result in conditions lesser in consequence than those defined to be accident conditions in Subsection 7.5.2.4. Proper accident tracking, therefore, qualifies abnormal occurrence tracking.

7.5.2.4 Accident Conditions

The LOCA is the most extreme operational event. Information readouts are designed to accommodate this event from the standpoint of operator action, information, and event tracking requirements, and therefore cover all other design-basis events or incidents requirements.

7.5.2.4.1 Initial Accident Event

The design bases of all ESF systems to mitigate accident event conditions take into consideration that no operator action or assistance is required or recommended for the first 10 minutes of the event. This requirement makes it mandatory that all protective action necessary in the first 10 minutes be automatic. Therefore, although continuous tracking of variables is available, no operator action based upon them is intended.

7.5.2.4.2 Postaccident Tracking

After 10 minutes, operator action is optional. The following process instrumentation provides information to the operator after a design-basis accident (DBA) for his use in monitoring reactor conditions within the primary containment.

7.5.2.4.2.1 Reactor Water Level

Vessel water-level instrumentation described in Subsection 7.5.1.4.2.1 is redundant, electrically independent, and is operable following all credible accident events. Subsection 15.6.2 discusses the postulated instrument line break scenarios. This instrumentation complies with independence and redundancy requirements of IEEE 279-1971.

7.5.2.4.2.2 Reactor Pressure

Pressure instrumentation described in Subsection 7.5.1.4.2.2 is redundant, electrically independent, and is operable following all credible accident events. This instrumentation complies with the independence and redundancy requirements of IEEE 279-1971.

7.5.2.4.2.3 Shutdown, Isolation, and Core Cooling Indication

This information instrumentation will have no direct input to the ESF systems and is considered to be outside the scope of existing 36IEEE Standards. However, insofar as practical, instruments will be selected from those types that are qualified under IEEE-279 and IEEE-323. Redundancy and independence or diversity will be provided in all systems which are used for operator control and ESF status information.

7.5.2.4.2.4 Primary Containment Indication

Primary containment instrumentation described in Subsection 7.5.1.4.2.4 is designed to be redundant, electrically independent, and remain operable following all credible accident events. The ranges have been selected to cover the design conditions of the containment.

7.5.2.4.3 Safety Parameter Display System

See Subsection 7.6.1.9.1.2.5.1 for a discussion of the design analysis of the SPDS.

7.5.2.5 Special Condition: Post-Fire Reactor Shutdown From Outside the Main Control Room

Analysis of reactor shutdown from outside the main control room is included in Subsection 7.5.1.5 for non-fire scenarios requiring control room evacuation. This section discusses the alternative shutdown system, which includes the dedicated shutdown panel, used for post-fire shutdown for fires in the main control room and selected other areas.

7.5.2.5.1 Design Bases

The alternative shutdown system was designed and installed to meet the requirements of 10 CFR 50, Appendix R, Section III, paragraphs G and L. The alternative shutdown system was designed to provide safe-shutdown capability separate and remote from the control center complex (control room, relay room, and cable spreading room, fire zones 03AB, 07AB and 09AB) and other selected auxiliary building fire zones 08AB, 11AB and 13AB when a fire in the complex or these zones is assumed to significantly damage the equipment/cabling in these zones. In the context of the discussion of alternative shutdown design basis, these six fire zones are referred to as the dedicated shutdown areas of concern. The above fire zones are described in UFSAR 9A.4. These zones are not the Fire Detection Zone numbers. UFSAR Figure 9A-1 provides a descriptive table cross-referencing the UFSAR Fire Zones and the Fire Detection Zones used in the abnormal operating procedure.

The objectives of the alternative shutdown system are to

a. Achieve and maintain subcritical reactivity conditions in the reactor

b. Maintain reactor coolant inventory

c. Achieve and maintain hot shutdown

d. Achieve cold shutdown conditions within 72 hr

e. Maintain cold shutdown conditions thereafter.

The reactor is shut down and maintained subcritical by control rod insertion. The portions of the CRD system necessary for reactor scram are designed to fail safely (actuate) if subjected to a fire. The core is kept covered by establishing standby feedwater flow to make up for loss of reactor vessel water inventory. Hot shutdown is achieved and maintained by establishing primary containment cooling and torus cooling. The primary containment fan and cooling unit operation (Subsection 9.4.5) and the torus cooling mode of the system (Subsection 5.5.7) are established prior to exceeding established drywell temperature and suppression pool water temperature design limits, respectively. Cold shutdown is achieved by the shutdown cooling mode of the RHR system.

The alternative shutdown system provides a dedicated shutdown panel located in the radwaste building, second floor*, from which an operator can monitor the reactor and keep the reactor core covered with water. The system design uses appropriate systems already installed, with installation of the panel and necessary control and transfer switches to make it functional.

NOTE:* In past correspondence with the NRC, the dedicated shutdown panel has also been called the 3L panel because it satisfies Paragraph III.L, of Appendix R to 10 CFR 50.

7.5.2.5.2 System Description

The alternative shutdown system consists of one of the four combustion turbine generators (CTGs), the standby feedwater (SBFW) system, a dedicated shutdown control panel and associated instrumentation, a Distributed Control System (DCS), and Division I portions of the following systems: RHR, RHRSW, emergency equipment cooling water (EECW), and emergency equipment service water (EESW). The dedicated shutdown panel is supplemented by local manual operator actions to achieve hot or cold shutdown.

The four CTGs (Subsection 8.2.1.2) are oil-fired turbine generators located onsite, remote from the fire areas of concern. The CTG 11-1 is used to provide emergency power when a fire occurs in the fire areas of concern, or on loss of offsite power should the EDGs be unavailable. CTG 11-1 has black start capability. The CTG starting diesel is located in an enclosed heated compartment and is equipped with a float tank, which provides an initial supply of warm fuel oil, to ensure its operability. Diesel fuel is maintained in the CTG Fuel Oil Tank with a fuel level maintained by plant procedures to ensure nominal fuel availability for 72 hours of operation for a single CTG unit at 10 MW load.

If CTG 11-1 is not available, either CTG 11-2, CTG 11-3 or CTG 11-4 (with AC starting motors) can be established on a standby basis as the black start power source for alternative shutdown power source using a standby starting diesel generator. Cold weather equipment preparation is addressed within the System Operating Procedure during the cold weather season.

The CTGs' control, instrumentation, and power cabling is located, isolated, and/or routed independent from the fire areas of concern, except for the CTG supervisory control circuit, which has transfer and lockout features that ensure that it is isolated from control room CTG circuitry.

Control of the breakers in the Fermi 120-kV switchyard and control of the CTGs is via a supervisory system. The essential elements of the system consist of a Distributed Control System panel (with local I/O) located at the 120-kV switchyard area, fiber optic communication lines, and actuating devices.

The Distributed Control System (DCS) functions as follows: field devices interface with the local DCS I/O panels and processors for 120-kV switchyard & CTGs process the signals and transmit the data via redundant fiber optic lines to a 3L Remote I/O panel in the Dedicated Shutdown Panel area in Fermi 2. The 3L Remote I/O panel interfaces with the Dedicated Shutdown panel for monitoring and control functions for the CTGs and 120-kV switchyard equipment. A block diagram of the CTG DCS control system is presented in Figure 7.5-4.

A dedicated shutdown system transfer pushbutton is provided in the control room, which, when activated, communicates with the DCS to initiate a start signal to CTG 11-1, arm the 120-kV switchyard undervoltage scheme, and inhibit control signals for the 120-kV

Switchyard and CTGs from the Fermi 2 control room. At the same time, 120-kV Switchyard and CTG 11-1 control is transferred to the Dedicated Shutdown Panel (H21-P623). If the control room is abandoned before the transfer pushbutton is activated, transfer can be accomplished at the Dedicated Shutdown Panel H21-P623 and the CTG 11-1 can be started manually after transfer. The possible fire induced spurious equipment actuations before transfer occurs are recoverable at the H21-P623 panel. The undervoltage scheme isolates 120-kV switchyard buses from offsite supplies and aligns breakers to provide power for Dedicated Shutdown from CTG 11-1.

The CTG power is supplied via peaker bus 1-2B through breaker A6 to the 4160-V Class 1E bus or via the main 120-kV bus through transformer SS64 (see Figure 8.3-1). The 4160-V bus provides power for the SBFW pumps; the Division I RHR, RHRSW, EECW, and EESW pumps and associated powered equipment through downstream electrical buses (Figure 7.5-5).

The SBFW system, Figure 7.5-6, described in Subsection 10.4.8, provides an alternative makeup water source for the reactor vessel. After transfer, the SBFW system is manually controlled and operated from the dedicated shutdown panel to maintain level above the top of the core. Control and transfer switches necessary for operating associated feedwater system valves and breakers are installed on the dedicated shutdown panel. Also, SBFW system flow is indicated on the dedicated shutdown panel. Power for the feedwater pump motors is from the CTGs or offsite power via the 4160-V electrical bus.

If the CTG is operating in parallel on the grid at the time offsite power is lost, the CTG output breaker is assumed to trip. However, the CTG turbine will not trip. The plant operator must take steps to isolate the grid, reclose the CTG output breaker and line up the two SBFW buses. If the CTG was not in operation, it could be started from the main control room before abandonment, but in the worst case, it would be started from the dedicated shutdown panel.

The RHR and RHRSW systems, described in Subsections 5.5.7 and 9.2.5, provide cooling capability for the reactor and torus water. The RHR system functional modes (1) torus cooling (Figure 7.5-7) and (2) shutdown cooling (Figure 7.5-8) modes, are described in Subsections 5.5.7.3.1 and 5.5.7.3.2.

The RHRSW system (Subsection 9.2.5) provides the heat sink for the reactor core by providing the cooling medium for the RHR heat exchanger. The EECW system functions as described in Subsection 9.2.2.1 to cool equipment required for reactor shutdown. The EECW is cooled by the EESW described in Subsection 9.2.5; a simplified flow diagram is shown in Figure 7.5-9.

The dedicated shutdown control panel is a local operation station, remote from the fire areas of concern, with instrumentation and control switches and transfer switches necessary for operating the SBFW shutdown system required to keep the reactor core covered with water. Instrumentation, control switches, and transfer switches on the panel are listed in Table 7.5-3.

Hot and cold shutdown can be achieved from the dedicated shutdown panel with manual operator action required locally in the reactor/auxiliary building and RHR complex. Local operation includes controlling equipment at local panels, switchgear, MCCs, distribution panels, and valves. Figures 7.5-7 and 7.5-8 show the flow paths involved for both hot and cold shutdown.

Auxiliary systems required to support the alternative shutdown system are listed below and are described in the sections identified.

The SBFW system requires no auxiliary support system. Both pump and motor have a forced-flow lube-oil system that is driven off the pump shaft. The lube-oil system is cooled by a portion of the pump discharge flow routed to an oil cooler. Motor windings are designed to take a 74°F rise in temperature over a continuous rating of 111°F, which results in a maximum temperature of 185°F in approximately 60 hr. Once in shutdown cooling, the SBFW system will be turned off; inventory makeup will no longer be required. Conditions required for entry into shutdown cooling will be established within 12.5 hours. Space cooler, heat exchanger, and pump/motor cooling for the other systems is supplied either by EECW, EESW, or RHRSW as specified in Subsections 9.2.2 and 9.2.5.

Auxiliary support systems (i.e., heating, ventilation, and air conditioning [HVAC], or other fluid systems) are not required for the EECW system, EESW system, or the Division I switchgear room. This is because of the small heat loads generated (under the scenario very little electric equipment is energized) and because the EECW and EESW pumps require no external cooling or seal water. The dedicated shutdown panel area in the second floor of the radwaste building is provided with a local area cooler as described in Section 9.4.3. The function of the Dedicated Shutdown Air Conditioning Unit is to provide cooling, if needed, to maintain habitability at the Dedicated Shutdown Panel location for the duration of a post-fire shutdown requiring the use of the panel. This cooler is manually restored to the 72M Bus which is powered by dedicated shutdown power sources, including CTG 11-1. Once started using a switch near the Dedicated Shutdown Panel, area temperature is automatically controlled by local thermostat.

The RHR pump requires the support of a room cooler and a pump bearing cooler. Both the bearing cooler and pump room cooler are supplied by the EECW system. The room cooler also requires operation of a fan unit.

Drywell cooling is accomplished by establishing EECW flow to the drywell cooling units and operation of their associated fan units.

If normal communications links are not available, communications between the operators at locations in the plant and the dedicated shutdown panel operator are via hand-held portable radios that operate by either radio-to-radio, or radio-to-portable, repeater-to-radio communication links. Communication between the Dedicated CTG operator and the Main Control Room or local Dedicated Shutdown Panel operator is achieved using the local telephone system.

Eight-hour emergency lighting for safe-shutdown capability is provided for all local operations and for access/egress routes to and from local safe-shutdown areas. Use of local emergency lighting for the CTG area is addressed within the System Operating Procedure.

To implement the alternative shutdown concept, it must be ensured that cabling and required devices are not in, or do not pass through, a fire zone for which the concept is being relied upon, or that an adequate level of protection is provided. To achieve this objective, transfer switches have been installed that completely isolate any cabling that passes through the fire zones of concern from their associated actuating devices. New cable that is required for instrumentation and CTG supervisory control is routed to ensure it does not pass through the fire areas of concern.

Interfaces between Class 1E and non-Class 1E components meet the electrical separation criteria for Section 8.3 and appropriate IEEE criteria for environmental and seismic qualification.

Table 7.5-5 lists the 4160-V switchgear and motor control center (MCC) positions that have the above-described transfer function.

7.5.2.5.3 Procedure

An Abnormal Operating Procedure provides procedural guidance to achieve and maintain safe shutdown in the event that a fire in any of the dedicated shutdown areas of concern warrants post-fire shutdown from outside the main control room using the dedicated shutdown panel. The procedure provides direction regarding conditions upon which the procedure should be entered, actions to be taken in the control room before it is abandoned, as well as immediate and longer-term manual actions at the dedicated shutdown panel and other plant locations. These actions, in the aggregate, assure that the plant is put in a known and analyzed configuration to support the performance of the design basis functions described in Section 7.5.2.5.1 consistent with the safe shutdown analysis described in Appendix 9A.

When the standby diesel generator is utilized, the system operating procedure addresses starting and maintaining the standby diesel generator to power the CTG 11-2, CTG 11-3, or CTG 11-4 480 volt starting motors and auxiliaries. An additional dedicated CTG operator is required at the CTG area whenever the standby diesel generator is used to provide power for the Dedicated Shutdown System.

7.5.2.5.4 Safety Evaluation

Post-fire shutdown outside the control room using the alternative shutdown system and dedicated shutdown panel has been analyzed as described in Section 9A.3. This analysis includes circuit faults including open circuits, shorts to ground and hot shorts that could directly affect safe shutdown systems as well as common shutdown functions, e.g., loss of RPV inventory or spurious SRV operation. The safe shutdown analysis demonstrates that the core will remain covered with the Standby Feedwater System delivering flow to the RPV within 24.4 minutes. The time studies for establishing SBFW flow include allowance for the power supply starting times, breaker and valve operating times and operator transit times. In addition, the analysis demonstrates that establishing suppression pool and drywell cooling functions within approximately 4 hours following reactor scram from full power, ensures operation within the containment design limits.

Therefore, the alternative shutdown system (including the instrumentation and controls located on the dedicated shutdown panel), in conjunction with proceduralized manual actions taken at the panel and at other plant locations, provides the capability required to achieve and maintain safe shutdown following a fire that requires shutdown from outside the control room.

A black start test of an alternate CTG demonstrated that use of an alternate CTG supported the performance goal of the alternative Dedicated Shutdown system which is Standby Feedwater system delivering flow to the RPV within 24.4 minutes.

7.5.2.5.5 Tests and Inspections

Except for where equipment directly interfaces with essential Class 1E components, the alternative shutdown system is considered a BOP system. Quality assurance requirements for the Class 1E portion of the alternative shutdown system will be the same as for the Class 1E equipment it is interfacing with. Quality assurance requirements applied to those portions of the system not interfacing directly with a Class 1E system will be appropriate for the use of that portion of that system. Periodic testing is described in Section 9A.6.

EMERGENCY EQUIPMENT COOLING WATER SYSTEM SIMPLIFIED DIAGRAM

7.6 OTHER SYSTEMS REQUIRED FOR SAFETY AND POWER GENERATION

7.6.1 Description

7.6.1.1 Refueling Interlocks System

7.6.1.1.1 System Identification

The purpose of the refueling interlocks system is to restrict the movement of control rods and the operation of refueling equipment to reinforce operational procedures that prevent making the reactor critical during refueling operations.

7.6.1.1.2 Power Sources

Both channels are powered by the control rod drive (CRD) system power supply. A failure of this power supply will prevent any rod motion.

7.6.1.1.3 Equipment Design

7.6.1.1.3.1 Circuit Description

The refueling interlocks circuitry senses the condition of the refueling equipment and the control rods. Depending on the sensed condition, interlocks are actuated to prevent the movement of the refueling equipment or withdrawal of control rods (rod block). Dual channel Circuitry is provided to sense the following conditions:

a. All rods inserted

b. Refueling platform positioned near or near over the core

c. Refueling platform hoists fuel-loaded (fuel grapple, frame-mounted hoist, trolley-mounted hoist)

d. Fuel grapple not at full-up position.

The indicated conditions are combined in logic circuits to satisfy all restrictions on refueling equipment operations and control rod movement (Figure 7.7-1). A two-channel dc circuit indicates that all rods are in. The rod-in condition for each rod is established by the closure of a magnetically operated reed switch in the rod position indicator probe. The rod-in switch must be closed for each rod position indicator probe. The rod-in switch must be closed for each rod before the "all-rods-in" signal is generated. Both channels must register the "all-rods-in" signal for the refueling interlock circuitry to indicate the "all-rods-in" condition.

During refueling operations, no more than one control rod is permitted to be withdrawn. This restriction is enforced by a redundant logic circuit that uses the "all-rods-in" signal and a rod selection signal to prevent the selection of a second rod for movement with any other rod not fully inserted. The simultaneous selection of two control rods is prevented by the interconnection arrangement of the select pushbuttons. With the mode switch in the REFUEL position, the circuitry prevents the withdrawal of more than one control rod and the movement of the loaded refueling platform over the core with any control rod withdrawn.

Operation of refueling equipment is prevented by interrupting the power supply to the equipment. The refueling platform is provided with two mechanical switches attached to the platform, which are tripped open by a long, stationary ramp mounted adjacent to the platform rail. The switches open before the platform or any of its hoists are physically located over the reactor pressure vessel (RPV) to indicate the approach of the platform toward its position over the core.

The hoists on the refueling platform and the service platform are provided with switches that open when the hoists are fuel loaded.

This circuitry indicates when fuel is loaded on any hoist.

7.6.1.1.3.2 Bypasses and Interlocks

NOTE: Service platform and hoist equipment are permanently removed. However, bypass for the load interlock system will remain in place in order to provide original function.

A bypass for the service platform hoist load interlock is provided. When the service platform is no longer needed, its power plug is removed. This deenergizes the power supply to the hoist. The platform can then be moved away from the core. Deenergizing the hoist power supply opens the hoist load switches and gives a false indication that the hoist is loaded. This indication prevents control rod withdrawal with the mode switch in the STARTUP or REFUEL position. A bypass plug allows control rod movement in this situation. The bypass plug is physically arranged to prevent the connection of the service platform power plug unless the bypass plug is removed. The rod block interlocks and refueling platform interlocks provide two independent levels of interlock action. The interlocks that restrict operation of the platform hoist and grapple provide a third level of interlock action since they would be required only after a failure of a rod block and refueling platform interlock. It is pertinent to note that the strict procedural control exercised during refueling operations may be considered a fourth level of backup.

7.6.1.1.3.3 Redundancy and Diversity

The refueling interlocks are designed such that a single interlock failure will not cause an accident. These refueling interlocks are provided for use during planned refueling operations. Criticality is prevented during the insertion of fuel, provided control rods in the vicinity of the vacant fuel space are fully inserted during the fuel insertion. The refueling interlock system accomplishes this by:

a. Preventing operation of the fuel-loaded refueling equipment over the core whenever any control rod is withdrawn

b. Preventing control rod withdrawal whenever fuel-loading equipment is over the core

c. Preventing withdrawal of more than one control rod when the mode switch is in the REFUEL position.

The refueling interlocks have been carefully designed using redundancy of sensors and circuitry, to provide a high level of reliability and assurance that the stated design bases will be met. Each of the individual refueling interlocks discussed above need not meet the single-failure criterion of IEEE 279-1971 because the four essentially independent levels of protection provide assurance that the design basis is met. For any of the "situations" listed in Table 7.6-1, a single interlock failure will not cause an accident, result in potential physical damage to fuel, or result in radiation exposure to personnel during fuel-handling operations.

7.6.1.1.3.4 Testability

Complete functional testing of all refueling interlocks before refueling outages positively indicates that the interlocks operate in the situations for which they were designed. The interlocks are subjected to valid operational tests by loading each hoist with a suitable test weight, positioning the refueling platform, and withdrawing control rods.

7.6.1.1.4 Environmental Considerations

The refueling equipment is subject to conditions during normal operation that are less severe than those listed in Table 3.11-1. The refueling interlocks are not required to operate under the conditions listed in Table 3.11-1.

7.6.1.1.5 Operational Considerations

The refueling interlocks system is required only during refueling operations.

In the refueling mode, the main control room operator has an indicator light for “refuel mode one rod permissive” whenever all control rods are fully inserted. He can compare this indication with control rod position data from the computer as well as control rod in/out status display. Furthermore, whenever a control rod withdrawal block situation occurs, the operator receives annunciation and computer logging of the rod block. He can compare these outputs with the status of the variable providing the rod block condition.

Both channels of the control rod withdrawal interlocks must agree that permissive conditions exist in order to move control rods; otherwise, a control rod withdrawal block is placed into effect. Failure of one channel may initiate a rod withdrawal block, but does not prevent application of a valid control rod withdrawal block from the remaining operable channel.

In terms of refueling platform interlocks, the platform operator has indicators for the platform x-y position and z position of the fuel grapple. Pushbuttons and rotary control switches are provided for local control of the platform and its hoists. The platform operator can immediately determine whether the platform and hoists are responding to his local instructions. In conjunction with the main control room operator, the local operator can verify proper operation of each of the three categories of interlocks listed previously.

7.6.1.2 Reactor Pressure Vessel Instrumentation

Figure 7.3-12 shows the instrument numbers, arrangements of the sensors, and sensing equipment used to monitor the RPV conditions. Because the RPV sensors used for the reactor protection system (RPS), engineered safety feature (ESF) systems, and control systems have been described and evaluated in other portions of this document, only the sensors that are not required for those systems are described in this subsection.

7.6.1.2.1 System Identification

The purpose of the RPV instrumentation is to monitor the key RPV operating parameters during plant operation.

7.6.1.2.1.1 Function

These instruments and systems are used to provide the operator with information during normal plant operation, startup, and shutdown. They are monitoring devices only and provide no active power control or safety function.

7.6.1.2.1.2 Classification

The systems and instruments discussed in this subsection are designed to operate under normal and peak operating conditions of system pressures and ambient pressures and temperatures. However, no special industry classifications are imposed on these instruments.

7.6.1.2.2 Equipment Design

The instrument sensing lines to the various pressure and level sensors slope downward from the vessel to the instrument rack at a nominal 1/8 in./ft (including allowance for piping sag).

7.6.1.2.3 Circuit Description

Basic design information for this system is given in Table 7.6-2.

7.6.1.2.3.1 Reactor Pressure Vessel Temperature

The RPV temperature is determined on the basis of reactor coolant temperature. Temperatures needed for operation and for compliance with the Technical Specifications operating limits are obtained from one of several sources, depending on the operating condition. During normal operation, either reactor pressure and/or the inlet temperature of the coolant in the recirculation loops can be used to determine the vessel temperature. Below the operating span of the resistance temperature detectors in the recirculation loop, the vessel pressure is used for determining the temperature. Below 212°F the vessel coolant temperature, and thus the vessel temperature, is reasonably well shown by the reactor water cleanup (RWCU) system inlet temperature. These three sources of input are most conveniently available from the Integrated Plant Computer System (IPCS). During normal operation, vessel thermal transients are limited via operational constraints on parameters other than temperature.

Reactor pressure vessel thermocouples are provided as a means of observing vessel metal surface temperature behavior in response to changes in vessel coolant temperature during startup and during power-operation testing. Indications based on the thermocouples are not used for controlling the rate of heating or cooling or limiting the vessel thermal stresses.

7.6.1.2.3.2 Reactor Pressure Vessel Water Level

The reactor vessel water level instrumentation systems are discussed in other sections as follows:

a. Reactor water level instrumentation that initiates reactor scram is discussed in Subsection 7.2.1.1.3.1

b. Reactor water level is maintained by the feedwater control system (Subsection 7.7.1.3).

The reactor water level system that pertains to this section is used to monitor, in the main control room, the reactor water level during the shutdown condition when the reactor system is flooded for maintenance and head removal. The water level design is the condensate chamber reference leg type that is not compensated for change in density. The vessel condition that provides accurate water level information is 0 psig pressure and ambient temperature. The range of the instrument is from the bottom of the feedwater control operating range to a level over the top of the RPV head. Figure 7.3-12 shows specific values at which alarms and safety actions are initiated.

7.6.1.2.3.3 Reactor Core Hydraulics

Figure 7.3-12 shows the flow instruments, differential pressure instruments, and recorders provided so that the core coolant flow rates and the hydraulic performance of RPV internals can be determined.

The differential pressure between the throat of each jet pump and of the core inlet plenum is measured and indicated in the relay room. Four jet pumps, two associated with each recirculation loop, are specially calibrated. They are provided with pressure taps in the diffuser sections. The differential pressure measured between the diffuser tap and the throat tap allows precise flow calibration using the jet pump prototype test performance data for each of the calibrated jet pumps. The flow rates through the remaining jet pumps are calculated from the flows shown by the four calibrated jet pumps. The flow rates through the jet pumps associated with each recirculation loop are summed to provide main control room indication of the core flow rate associated with each recirculation loop (Figure 7.3-12). Total flows for both loops are summed and recorded in the main control room to indicate the total flow through the core. During the operation of a single recirculation loop, total core flow indication is derived by subtracting the reverse flow signal from the forward flow signal of the active jet pumps. This function is provided automatically any time a single recirculation pump is operating.

A differential pressure transmitter indicates core plate pressure drop by measuring the pressure difference between the core inlet plenum and the space just above the core support assembly. The instrument sensing line used to determine the pressure in the core inlet plenum is the same line used for the injection of the standby liquid from the standby liquid control system (SLCS). An instrument sensing line is provided for measuring pressure above the core support assembly. The differential pressure across the core plate is indicated and recorded in the main control room.

A differential pressure transmitter and control room indicator indicate the jet pump developed head by measuring the difference between the jet pump suction pressure (reactor annulus – between vessel wall and core shroud) and the jet pump discharge pressure (pressure below the core plate).

This instrumentation permits the determination of total core flow in two ways. The first method is the readout of the summed flow measurements from all the jet pumps as described in the preceding paragraphs. The second method involves establishing a correlation between drive loop flow rate and core flow rate with reactor power as a parameter. The correlation can then be used to convert the flow in the recirculation pump loops to core flow rate. This correlation is of a temporary nature because it changes with a fixed core arrangement over a period of time as a result of crud buildup on the fuel. The main control room flow rate readouts of the specially calibrated jet pumps can be used to cross check the flow rate readouts of all the other jet pumps. A discrepancy in the cross-checks is reason enough to check local flow indications.

7.6.1.2.3.4 Reactor Pressure Vessel Pressure

Pressure indicators and transmitters detect RPV internal pressure from the same instrument lines used for measuring RPV water level.

The following list shows the subsections in which the RPV pressure-measuring instruments are discussed:

a. Pressure transmitters for initiating scram or for bypassing main steam isolation valve (MSIV) closure are discussed in Subsection 7.2.1.1.3

b. Pressure transmitters used for high-pressure coolant injection (HPCI), core spray, low-pressure coolant injection (LPCI), and the automatic depressurization system (ADS) are discussed in Subsection 7.3.1.2

c. Pressure transmitters and recorders used for feedwater control are discussed in Subsection 7.7.1.4

d. Pressure transmitters used for wide range pressure recordings are discussed in Subsection 7.5.1.4.2.

7.6.1.2.3.5 Reactor Pressure Vessel Head Seal Leak Detection

The pressure between the inner and outer head-seal rings is sensed by a pressure switch. If the inner seal fails, the pressure at the pressure switch is the vessel pressure and the pressure switch trips, sounding an annunciator in the main control room. The plant continues to operate with the outer seal as a backup and the inner seal can be repaired at the next outage when the head is removed. If both the inner and outer head seals fail, the leak is detected by an increase in drywell temperature and pressure. This system is part of the leak detection system (LDS), which is described in Subsection 7.6.1.8.

7.6.1.2.3.6 Safety/Relief Valve Seat Leak Detection

Thermocouples are located near the discharge of the safety/relief valve seat. The temperature signal goes to a multipoint recorder with an alarm. The alarm will be activated by any temperature in excess of a set temperature, signaling that one of the safety/ relief valve seats has started to leak. This system is part of the LDS (Subsection 7.6.1.8).

7.6.1.2.3.7 Other Instruments

a. The steam temperature is measured at the steam manifold and is recorded in the main control room

b. The feedwater temperature is measured and transmitted to the main control room.

7.6.1.2.4 Testability

Pressure, differential pressure, water level, and flow instruments are located outside the drywell and are piped so that calibration and test signals can be applied during reactor operation.

7.6.1.2.5 Environmental Considerations

There are no special environmental considerations for the instruments described in this subsection.

7.6.1.2.6 Operational Considerations

7.6.1.2.6.1 Normal

The RPV instrumentation discussed in this subsection is designed to augment the existing information from the ESF such that the operator can start up, operate at power, shut down, and service the RPV in an efficient manner. None of this instrumentation is required to initiate any ESF.

7.6.1.2.6.2 Operator Information

The following information is available to the operator:

a. Selected RPV thermocouples are recorded on a multipoint recorder at a local rack

b. The shutdown flooding water level is indicated in the main control room

c. The flow for each of the four calibrated jet pumps is indicated in the main control room

d. The differential pressure for all the jet pumps (calibrated and uncalibrated) is indicated in the main control room and relay room

e. The recirculation core flow that is generated by each recirculation loop is indicated in the main control room

f. The total core flow is recorded by one pen of a two-pen recorder in the main control room. The other pen records the core plate differential pressure

g. The jet pump developed head is indicated in the main control room

h. The reactor head seal LDS activates an annunciator when the reactor head inner seal fails

i. The discharge temperatures of all the safety/relief valves (SRVs) are shown on a multipoint recorder in the relay room. Any temperature in excess of setpoint turns on an annunciator indicating that an SRV seat has started to leak.

7.6.1.2.7 Setpoints

The annunciator alarm setpoints for the reactor head seal leak detection, SRV seat leak detection, and feedwater corrosion product monitor are set so the sensitivity to the variable being measured provides adequate information.

Figure 7.3-12 includes a chart showing the relative indicated water levels at which various automatic alarms and safety actions are initiated. Specific level values are shown in Figure 7.3-12. Each of the listed actions is described and evaluated in the subsection of this report where the system involved is described. The following list tells where various level measuring components and their setpoints are discussed:

a. Level transmitters for initiating scram are discussed in Subsection 7.2.1.1

b. Level transmitters for initiating primary containment or vessel isolation are discussed in Subsection 7.3.2.2.8

c. Level transmitters used for initiating HPCI, LPCI, core spray, and ADS, and the level transmitters to shut down the HPCI pump drive turbine, are discussed in Subsection 7.3.1.2

d. Level transmitters to initiate reactor core isolation cooling (RCIC) and the level transmitters to shut down the RCIC pump drive turbine are discussed in Subsection 7.4.1.1

e. Level trips to initiate various alarms and trip the main turbine and the turbine-driven feed pumps are discussed in Subsection 7.7.1.3 and 7.7.1.4.

7.6.1.3 Process Radiation Monitor System

The Process Radiation Monitor system is described in Section 11.4.

7.6.1.4 Area Radiation Monitor System

The Area Radiation Monitor system is described in Subsection 12.1.4.

7.6.1.5 Offsite Environs Radiation Monitor Systems

These systems are described in the Offsite Dose Calculation Manual (ODCM).

7.6.1.6 Rad-Chem Radiation Monitoring Instruments

These systems are described in Section 12.3.

7.6.1.7 Reactor Water Cleanup System Instrumentation and Control

7.6.1.7.1 System Identification

The purpose of the RWCU system instrumentation and control is to provide protection for the system equipment from overheating and overpressurization and to provide the operator with information concerning the effectiveness of operation of the system.

This system is not safety related, and all instrumentation components in the system used only for RWCU operation are nonessential. The instrumentation is a standard industrial type for which performance has been proven by years of service throughout the industry.

7.6.1.7.2 Power Sources

The RWCU instrumentation is fed from the 120-V ac instrumentation bus. No backup power source is necessary since the RWCU system is not a safety-related system. The RWCU instrumentation is arranged in groups or circuits, and each such circuit is protected by a suitable fuse. Thus, a short-circuit within the system will have only a local effect that can be corrected easily without interrupting reactor operation.

7.6.1.7.3 Equipment Design

7.6.1.7.3.1 Circuit Description

The RWCU system is described in Subsection 5.5.8. This subsection describes the circuitry used to protect the resin and the filter-demineralizer. These circuits are shown in Figure 5.5-19 and the operating logic is shown in Figure 7.6-1.

To prevent resins from entering the reactor recirculation system in the event of a filter-demineralizer resin support failure, a strainer is installed on the outlet of each filter-demineralizer unit. Each strainer is provided with a local alarm energized by high differential pressure. A bypass line is provided around the filter-demineralizer units for bypassing the units when necessary.

Relief valves and instrumentation are provided to protect the equipment against overpressurization and the resins against overheating. The system is automatically isolated when signaled by any of the following occurrences:

a. High temperature downstream of the nonregenerative heat exchanger - to protect the ion exchange resins from deterioration due to high temperature (Table 7.6-2)

b. Reactor vessel low water level - to protect the core in case of a possible break in the RWCU system piping and equipment (Subsection 7.3.2.2.7.1)

c. SLCS actuation - to prevent removal of the boron by the RWCU system filter-demineralizers

d. Cleanup system equipment area high ambient temperatures - part of the plant LDS

e. High temperature increase across the system's ventilation ducts - part of the plant LDS

f. High change in system inlet flow in comparison to the system outlet flow - part of the plant LDS.

In the event of low flow or loss of flow in the system, flow is maintained through each filter-demineralizer by its own holding pump. Sample points are provided upstream of the RWCU system and downstream of each filter-demineralizer unit for continuous indication and recording of system conductivity. High conductivity is annunciated in the main control room. The influent sample point is also used as the normal source of reactor coolant samples. Samples analysis also indicates the effectiveness of the filter-demineralizer units.

7.6.1.7.3.2 Testability

Because the RWCU system is usually in service during plant operation, satisfactory performance is demonstrated without the need for any special inspection or testing.

7.6.1.7.4 Environmental Considerations

The RWCU system is not required for safety purposes, nor is it required to operate after the design-basis accident (DBA). The RWCU system is required to operate in the normal plant environment for power generation purposes only.

The RWCU control instrumentation located in the RWCU equipment area is subject to the environment described in Table 3.11-3.

7.6.1.7.5 Operational Considerations

The RWCU system instrumentation and control is not required for safe operation of the plant. It provides a means of monitoring parameters of the system and protecting the system.

7.6.1.8 Leak Detection System

7.6.1.8.1 System Identification

This subsection discusses the instrumentation and controls associated with the LDS. The system itself is discussed in Subsection 5.2.7.

The LDS serves to detect leakage from the nuclear boiler pressure boundary and auxiliary and ESF systems. It also generates isolation signals to systems that are leaking in excess of determined limits.

7.6.1.8.2 Power Sources

Power source separation is applicable to leak detection channels that are associated with the isolation valve system. Two power sources are used to comply with separation criteria so that redundant channels receive power from separate sources. Power is provided by dc/ac inverter A and dc/ac inverter B.

Inboard and outboard isolation valves in the same line are on separate power sources.

7.6.1.8.3 Systems and Components Provided With Leak Detection Systems

The following systems and components include leak detection instrumentation and control:

a. Main steam lines
b. Reactor core isolation cooling
c. High-pressure coolant injection
d. Recirculation pumps
e. Residual heat removal
f. Reactor water cleanup
g. Safety/relief automatic depressurization system valves
h. Reactor vessel head seal
i. Emergency core cooling system suction lines.

7.6.1.8.4 System Design

The LDS detects leaks by use of the following techniques:

a. Sensing excess flow in process piping systems
b. Sensing pressure and temperature changes in the primary containment
c. Monitoring temperatures in areas containing equipment and piping systems (Figure 7.6-2)
d. Monitoring activity of the drain sumps.

Detected leaks are annunciated in the main control room and, in certain cases, isolated from the nuclear steam supply system (NSSS) pressure boundary.

Leaks as small as 5 gpm are detected by either temperature and pressure changes or drain sump activities. Leaks greater than 5 gpm are also detected by changes in reactor water level and by change of flow in process lines.

Temperature detectors are located or shielded such that they are sensitive to air temperature only, and not to heat radiated from the equipment. Temperature sensors have individual alarm setpoints adjustable over a range of flow rates corresponding to leakage of up to 35 gpm.

Reactor coolant leakage of 5 gpm actuates an alarm in the main control room.

Specific information concerning the LDS is given in Table 7.6-2.

7.6.1.8.5 Leak Detection Within the Primary Containment

7.6.1.8.5.1 General

Leaks within the primary containment are detected by the following methods (Figure 7.6-3):

a. Monitoring pressure and temperature in the primary containment

b. Monitoring equipment drain and floor drain sump pump activity

c. Monitoring the drywell floor drain sump level

d. Monitoring the cooling water differential temperature of the closed cooling water system

e. Monitoring reactor water level.

In addition, a second method of leak detection uses recognition of increased containment atmosphere radioactivity as indicative of a system leak.

7.6.1.8.5.2 Pressure Measurement in Primary Containment

The primary containment is pressurized and maintained at a slightly positive pressure during reactor operation. The normal operating pressure is about 0.5 psig. The pressure may fluctuate as a result of barometric pressure changes and outleakages, but a pressure rise above the operating level indicates a process system leak.

Drywell pressure is monitored in the main control room as part of the primary containment monitoring system (Subsection 7.6.l.l2). High drywell pressure activates an alarm in the main control room and initiates automatic response of the RPS and ESF systems (Sections 7.2 and 7.3).

7.6.1.8.5.3 Temperature Measurement in Primary Containment

Drywell atmosphere temperature is maintained at approximately 135°F during reactor operation by heat exchangers of the drywell cooling system. An abnormal temperature rise significantly above 135°F indicates a high-energy process leak. A temperature rise will be detected by monitoring:

a. Drywell temperature at various elevations

b. Differential water temperature of closed cooling water system.

7.6.1.8.5.4 Primary Containment Sump Activity Monitoring

Equipment drain and floor drain sumps are provided with "fill-up" and "pump-out" rate measurements. Excessive rates are annunciated in the main control room.

The equipment drain sump collects only identified leakage and is equipped with high/low-level switches that control the sump drain. A sump filling/pump frequency in excess of the normal rate or excessive pumping time activates an annunciator in the main control room (Figure 7.6-4). Normal leakage (filling/pumping frequency) is to be determined during operational testing. The equipment drain sump receives drainage from pump seal leakoff, RPV head flange vent drain, and valve packing leakoff.

The floor drain sump is provided with the normal level switches for control of the pumps similar to the equipment drain sump. Additionally, an analog level transmitter is installed in the floor drain sump to provide a very sensitive level change measurement. A continuous analog display of sump level is derived from the transmitter and is located in the control center. An operator alarm is activated whenever the level measurement detects a sump inleakage greater than 1 gpm. This level monitor is designed and installed to remain functional following a seismic event and thereby meet the requirements of Regulatory Guide 1.45.

The floor drain sump collects unidentified leakage. This leakage is collected from CRDs, valve flanges, floor drains, the closed cooling water system, drywell cooling unit drains, and other potential sources not already identified. Leakage from the closed cooling water system is detected by decreased levels in the system surge tank.

The unidentified-leakage rate is that portion of the total leakage rate received in the drywell floor drain sump. A leakage rate of 150 gpm has been calculated to be the liquid leakage from a crack large enough to propagate rapidly. An allowance for reasonable leakage that does not compromise barrier integrity and is not identifiable is made for normal plant operation.

The unidentified-leakage rate limit is established at 5 gpm, which is far enough below the 150-gpm leakage rate to allow time for corrective action to be taken before the process barrier is significantly compromised. Normal background leakage will be determined during operational testing.

7.6.1.8.5.5 Reactor Vessel Head Seal Leak Detection

The RPV head is provided with double seals with a pressure switch sensing the pressure between the seals. High pressure (Table 7.6-2) is indicative of leakage past the inner seal and activates an annunciator in the main control room. The RPV head seal leak detection is also described in Subsection 7.6.1.2.3.5.

7.6.1.8.5.6 Recirculation Pump Seal Leak Detection

There are two recirculation pump LDSs, one for each of the pumps in the recirculation loop. Each LDS monitors the flow rate (leakage) past its associated pump's shaft by measuring the pressure within the seal cavity. There are two monitored seal cavities per pump.

The recirculation pump LDS consists of two types of monitoring circuits (Figure 7.6-5). The first of these monitors the pressure levels within the seal cavities, presenting the plant operator with a visual display of the pressure in each cavity. The second type of circuit monitors the rate of liquid flow from the seal cavities.

The pressure levels within seal cavity number 1 and seal cavity number 2 are measured with identical instrumentation (Table 7.6-2).

All condensate flowing past the recirculation pump seal packings and into the seal cavities is collected and sent by one of two drain systems to the drywell equipment sump for disposal. The first system drains the major portion of the condensate collected within the number 2 seal cavity. The condensate flow rate through the drain system is measured (high/low) by a flow switch. The point at which the microswitch closes can be adjusted so that switch actuation occurs only above or below certain flow rates (Table 7.6-2). Excessively high or low flow rates through this drain system activate the "Pump Seal Staging Flow" annunciator in the main control room.

7.6.1.8.5.7 Safety/Relief Valve Automatic Depressurization System Leak Detection

A temperature element (sensor) is used to detect leakage past each relief or safety valve. These temperatures are recorded on a multipoint recorder in the relay room. Normally, all relief and safety valves are in the shut-tight condition and remain at about the same temperature.

Steam passage through the valve elevates the sensed temperature at the exhaust, causing an "abnormal" temperature reading on the recorder. Microswitch contacts on the recorder close on high temperature (Table 7.6-2) to activate the "SRV Open" annunciator in the main control room.

7.6.1.8.6 Reactor Building Sump Activity Monitoring

Instrumentation for monitoring equipment drain sump and floor drain sump activities is the same in design as that described for drywell sump monitoring in Subsection 7.6.1.8.5.4.

7.6.1.8.7 Main Steam Line Leak Detection System

7.6.1.8.7.1 System Function

The main steam lines are continuously monitored for leaks by the main steam line LDS. Steam line leaks will cause changes in at least one of the following monitored operating parameters: sensed temperature, flow rate, or low water level in the RPV. If a leak is detected, the LDS responds by triggering an annunciator in the main control room and, depending upon the activating parameter, initiates steam line isolation action.

7.6.1.8.7.2 Physical Description

The main steam line LDS resistance temperature detectors (RTDs) are located throughout the main steam line tunnel, positioned such that they are screened from direct thermal radiation and yet are still able to respond to the temperature of the ambient air. The RTDs are used to trip the MSIVs closed.

The flow-rate monitoring components of the main steam line LDS consist of a set of four differential pressure transmitters and an associated flow element for each main steam line. The outputs of the differential pressure transmitters are connected to components of the nuclear steam supply shutoff system that give a coincidence signal for main steam line isolation at a flow of approximately 130 percent.

Reactor water level and main steam line tunnel area temperature are monitored by circuits associated with the containment and reactor vessel isolation system to indicate the presence of a steam leak. The coverage of this discussion extends only to the sensing instrumentation and not to circuit arrangement or response. Such information may be found in the description of the primary containment and reactor vessel isolation control system.

Under conditions of normal reactor operation at constant power, reactor water level should remain fairly constant since the rate of steam mass flow leaving the reactor is matched by the feedwater mass flow rate into the RPV. However, given a condition of continued steam leakage from the closed system, the condensate reservoir level and the reactor water level decrease.

Reactor water level is monitored by level transmitters of the containment and reactor vessel isolation control system in addition to the normal complement of process-monitoring instruments. Reactor water level falling below the predetermined minimum allowable level results in switch actuation and subsequent containment and reactor vessel isolation control system responses.

7.6.1.8.8 Reactor Water Cleanup System Leak Detection

Leakage in the high temperature process flow of the RWCU system external to the primary containment is detected by temperature- sensing elements. Temperature sensors are located in the inlet and outlet ventilation ducts to measure the temperature difference. Local ambient-temperature sensors are located in all compartments containing equipment for these systems. Alarms in the main control room annunciate a temperature rise corresponding to excessive leakage. In addition to annunciation, a high cleanup- room temperature rise actuates automatic isolation of the RWCU system.

In addition to the temperature-detection method, leakage is detected by means of a flow comparison between RWCU system inlet and outlet. If the inlet flow exceeds outlet flow by approximately 55 gpm, as governed by the Technical Specifications, an alarm is actuated and the RWCU system is isolated automatically.

7.6.1.8.9 Residual Heat Removal System Leak Detection

The residual heat removal (RHR) leak detection components are divided into two groups, one sensitive to RHR system leaks external to the primary containment, and the other sensitive to system leaks internal to the primary containment. Leak detection instruments of the first group use devices that are sensitive to temperature and that monitor area ambient and differential temperatures. The second group of instruments monitors the pressure level within the drywell. Additionally, liquid leakage from system components contained within the drywell is collected and the rate of accumulation measured. The ambient and differential temperature monitoring circuits consist of thermocouples, switch point modules, and meters.

The thermocouples are mounted in their individual holders which, in turn, are mounted in the RHR equipment area such that they are sensitive primarily to the air temperature. The switch-point modules and meters are mounted on the leak detection panel in the relay room. A high ambient temperature lights the point module alarm indicator on the leak detection panel and activates the high ambient temperature alarm.

7.6.1.8.10 Reactor Core Isolation Cooling and High-Pressure Coolant Injection Systems

Leaks in the RCIC or HPCI systems are detected by differential pressure transmitters and by local temperature detectors that are functionally the same as those described for main steam line leak detection (Subsection 7.6.1.8.7).

Downstream of the differential pressure elements, gross leaks in the system are detected by a set of two differential pressure transmitters sensing differential pressure across an orifice plate. Flow in excess of specified limits isolates the system and activates an alarm in the main control room. A 3-sec time delay has been installed to prevent inadvertent system isolation due to pressure spikes. Gross leaks upstream of the differential pressure elements may be detected by a set of four pressure transmitters. The primary function of these transmitters is to detect low reactor pressure and to provide HPCI or RCIC turbine isolation signal.

The turbine exhaust vent lines of the HPCI system and the RCIC system are monitored for pressure by means of four pressure transmitters. A high-pressure signal isolates the system and activates an alarm in the main control room. Temperature sensors are located in the inlet and outlet of the ventilation duct of the equipment area and in the inlet to emergency coolers for measuring temperature-difference rise and room ambient temperature in the event of steam leakage. High temperature and high temperature difference are annunciated in the main control room. A high area temperature will automatically isolate the respective system.

The power required to operate the logics associated with the RCIC and HPCI LDSs is continuously monitored. Loss of power is identified by the "RCIC LOGIC POWER FAILURE" or "HPCI LOGIC POWER FAILURE" annunciators in the main control room.

7.6.1.8.11 Leak Detection in the Emergency Core Cooling System Piping Routing Area Adjacent to Suppression Pool

Temperature elements are located in the inlet and outlet of the ventilation ducts of the suppression pool area. High temperature and high temperature differences are annunciated in the main control room.

7.6.1.8.12 Emergency Core Cooling System Suction Lines Leak Detection

The purpose of this LDS is to provide information that would allow the closing of the valve in a broken emergency core cooling system (ECCS) line before net positive suction head (NPSH) is lost to the redundant system.

A sump-level alarm contact notifies the operator that a significant leak exists in the torus area. This signal allows the operator to terminate the loss of torus water.

7.6.1.8.13 Feedwater Leak Detection

A separate feedwater LDS is not provided. Leaks from the feedwater lines will be detected by one or a combination of the following methods:

a. Primary containment sumps high flow rate
b. Differential water temperature of closed cooling water system
c. Primary containment high pressure
d. Primary containment high temperatures
e. Reactor building sump high flow rate.

7.6.1.8.14 Testability

The proper operation of the sensors and the logic associated with the LDS are verified for proper operation during the LDS preoperational test and during inspection tests that are provided for the various components as they apply during plant operation.

Each temperature switch, both ambient- and differential-type, is connected to dual thermocouple elements. Each temperature switch can be checked for operation by observing the ambient temperature or differential, and then turning the trip-point adjustment and verifying that the switch operates at the proper temperature. Each temperature switch contains a trip light that lights when temperature exceeds the setpoint. The setpoint is reset manually to its required value by adjusting the setpoint on the meter in the main control room. In addition, keylock test switches are provided so that logic can be tested without sending an isolation signal to the system involved. Thus, complete system check can be confirmed by checking activation of the isolation relay associated with each switch.

The containment drain monitor system can be tested by supplying makeup water to the sump at a sufficient flow rate to bring the water level above the sump high-level pump-actuation point in less than predetermined time.

The RWCU differential-flow leak detection is tested by inputting a mA signal to simulate a high differential flow. Alarm and indicator lights monitor the status of the trip circuit.

7.6.1.8.15 Environmental Considerations

The sensors, wiring, other equipment, and electronics associated with the isolation valve logic are designed to withstand the conditions that follow a LOCA.

7.6.1.9 Plant Computer Systems

7.6.1.9.1 Integrated Plant Computer System (IPCS)

7.6.1.9.1.1 System Description

The IPCS is a computer system that combines various functions of the legacy computer systems that it replaced. The IPCS provides the capability of monitoring, recording and displaying plant parameters via strategically located display devices. The IPCS is designed to be highly reliable and provide current information for selected plant variables. All real-time data displays will update the current field conditions in a timely manner.

The IPCS is not required for safe operation of the plant. Hardwired instrumentation and control allows the operator to safely operate the plant in all modes in the absence of the IPCS. There is no safety objective for the IPCS.

The IPCS consists of several computing nodes interconnected through a local area network (LAN) configuration. These computing nodes work in conjunction with each other to form a single cohesive system.

The IPCS computing nodes have self-checking provisions. It performs diagnostic checks to determine the functionality of certain portions of the system hardware and software. It also performs internal software checks to verify that input signals and selected program computations are within specific limits or reasonable bounds.

The IPCS consists of two redundant computers, operating in parallel, simultaneously monitoring the same field signals. Either of the computers can be designated as the main computer (Master), and the other will be designated as the backup computer (Slave). Under normal operating conditions, both the Master computer and Slave computer perform all the key functions; however, only the Master computer is allowed to output data and calculation results. In the event the Master computer fails, the Slave computer will become the Master computer, and automatically assume control of all functions. The operating personnel will be informed of the fail-over. If the Slave computer fails while the Master computer is operating normally, the operating personnel will be informed and the Master computer will continue to function normally.

The operating personnel use display consoles to enter information into the IPCS, and to request various functions. Diagnostic messages on the display consoles, together with printer outputs and annunciator outputs permit the IPCS to communicate plant and system status to the operating personnel.

The IPCS has the capability for on-line storage and retrieval of historical data, which are to be used for time-history displays and other data analysis functions. These analysis functions include, but are not limited to, determining the plant steady-state operating conditions prior to an initiating event and evaluating the transient conditions producing the event and the post-event equipment performance.

The IPCS has on-line storage for pre-event and post-event data. The declaration of an event is signaled to the system from the display consoles or automatically for a scram. Additional post-event data can be stored at the operator’s request. The historical data storage and recovery are performed by the IPCS without interrupting the other functions of the system, such as data acquisition and console display. The IPCS has the capability of transferring the historical data onto magnetic media.

The IPCS consolidates the following functions into a homogenous computer system. Separate legacy computers provided these functions during the initial licensing of the plant:

- a. Scan, Log and Alarm (SLA)
- b Man-Machine Interface (MMI)
- c. Nuclear Steam Supply System (NSSS) Function
- d. Balance of Plant (BOP) Function
- e. Emergency Response Functions
    - 1. Safety Parameter Display System (SPDS) Function
    - 2. Emergency Response Data System (ERDS) Function
- f. Meteorological (MET) Function
- g. Transient Recording and Analysis (TRA) Function
- h. Data Archival Function
- i. Special Functions

In addition to the function consolidation listed above, the IPCS provides external interfaces with the digital processor/computer equipment associated with each of the following systems, which are further described in Section 7.6.1.9.1.3:

GE 3D-Monicore Computer System (3DM) Interface

GE NUMAC LINK Interface (PRNM and RWM Interface)

Eberline SS-1 Radiation Monitor System

Radiological Dose Assessment Application Interface

Meterological Data Acquisition System (MDAS) Interface

Visual Annunciator System (VAS) Interface

7.6.1.9.1.2 System Functions

7.6.1.9.1.2.1 Scan, Log and Alarm (SLA) Functions

The SLA function gathers data from selected plant data systems, provides the signal conditioning for conversion to engineering units, provides out-of-scale checking of each data point, and keeps a live database of all the current values of the data points.

The IPCS has the capability to alarm the main control room annunciator system in the event of abnormal IPCS operation.

7.6.1.9.1.2.2 Man-Machine Interface (MMI)

The IPCS generates displays and data summaries for use in the control room, technical support center (TSC), and emergency operations facility (EOF). The IPCS also retains a history of each data point. The current value or the historical values of a data point are accessible from the display consoles.

The MMI, the display consoles, and the form of the display on these consoles are designed considering human factors engineering. The system has predesigned displays that are called onto the screen by the operator.

7.6.1.9.1.2.3 Nuclear Steam Supply System (NSSS) Function

The NSSS functions provided are based on Fermi 2 requirements and General Electric recommendations for BWR heat balance and interface support to core monitoring software 3DM.

MMI screens and reports are provided in support of the NSSS performance calculations.

7.6.1.9.1.2.4 Balance of Plant (BOP) Function

The BOP function provides calculations that are based on Fermi 2 requirements, General Electric recommendations, industry recognized practices, and an analysis of the Fermi 2 BOP cycle arrangement and operation.

Accumulation calculations are provided for the determination of BOP related accumulated data. These accumulated data values are primarily associated with the plant electrical generation data and require the determination of both daily and monthly accumulated totals.

7.6.1.9.1.2.5 Emergency Response Functions

The Emergency Response Functions include the Safety Parameter Display System (SPDS) and the Emergency Response Data System (ERDS). When the plant was originally licensed, various capabilities to support the Emergency Plan were implemented on a dedicated computer system called the Emergency Response Information System (ERIS). These capabilities have been incorporated into the IPCS and are referred to as the Emergency Response Function.

7.6.1.9.1.2.5.1 Safety Parameter Display System (SPDS) Function

Description

An IPCS display with continuous SPDS status indication is provided in the control room, the TSC, and the EOF.

The SPDS function of the IPCS was added to the Fermi 2 design to aid operating personnel in assessing the safety status of the plant. The SPDS function display is accessible and visible to operating personnel and is distinguishable from other displays. The SPDS function display does not inhibit physical or visual access to operator interfaces with other systems located in the control room.

The SPDS design provides for the validation of parameters associated with the function. Operating personnel are alerted to any unsuccessful validation.

Interfaces between the SPDS function and safety-related systems are through isolation means. Interfaces between the SPDS function and non-safety-related systems are designed to ensure the integrity of the SPDS function.

The SPDS functional design includes the consideration of the following human engineering criteria:

a. Presenting information in directly usable form
b. Designing displays for quick identification of unsafe conditions
c. Easy selection of the display required
d. Minimizing reflection and glare.

The SPDS function presents the value or status of the primary variables of the following safety parameters:

a. Core cooling
b. Fuel integrity
c. Reactivity
d. Reactor coolant system integrity
e. Containment integrity

f. Radioactivity effluent to the environment.

A primary variable is defined as the monitored variable that provides the most direct indication needed to assess the status or value of a safety parameter. Secondary variables are those monitored variables that provide additional information about the safety parameters.

The primary variable associated with each safety parameter is shown in Table 7.6-3 and is discussed below:

a. Core cooling. The primary method to assess adequate cooling in BWRs is by a direct measurement of the reactor water level. Natural circulation capability is an inherent BWR feature. There are no traps that might block the natural circulation. Steam and noncondensibles rise to the top during normal operation and during accident conditions. As long as there is adequate water level, there is assurance of adequate core cooling

b. Core and fuel integrity. When the containment is isolated, the presence of fuel damage is determined by taking a sample of reactor coolant and performing a spectral analysis of the sample. During normal operation, the presence of fuel damage is determined by offgas radiation readings

c. Reactivity. The neutron instrument is the primary variable for determining this parameter

d. Reactor coolant system integrity. This parameter is assessed by monitoring reactor pressure, drywell pressure, drywell sump collection rate, and RPV isolation

e. Containment integrity. This parameter is assessed by measuring drywell and torus pressure, containment isolation, combustible gas level, torus temperature, torus level, and drywell temperature

f. Radioactivity effluent to environment. This parameter is assessed by monitoring the radioactivity at planned plant release points.

The parameters associated with the SPDS displays are listed in Table 7.6-4.

Emergency procedure guidelines (EPGs) have been developed by the BWR Owners Group; they are symptom based and designed to improve the operator's ability to mitigate the consequences of a broad range of initiating events and subsequent multiple operator errors. The Fermi 2 Emergency Operating Procedures (EOPs) are based on the EPGs. The EOPs identify entry conditions and contain parameter versus parameter limit curves. The emergency response function includes the EOP limit curves and parameter information that is supportive of determining entry conditions.

The SPDS function displays are comprised of an overview display, critical safety function displays (generally a bar and/or trend), and the EOP limit curves.

Design Analysis

The graphics provided to the operator by the SPDS function are one of the man-machine interfaces to the IPCS. The IPCS acquires both digital and analog inputs from field sensors and computer data links with monitoring and control systems throughout the plant.

Existing signal loops of monitoring and control systems were tapped to provide inputs for the SPDS function. The isolation requirement for analog safety-related circuits was provided by using a qualified isolator for each circuit which provides input to the data acquisition system. Dry contact inputs were provided for digital inputs. Engineering was completed in accordance with applicable design criteria to ensure that the SPDS function cannot adversely affect safety-related systems.

Signals to the IPCS for the SPDS function are processed and validated to prevent misleading the operator. Redundant input signals are used for selected parameters and comparison limits are performed for validation. Additional information processing is performed for analog, digital, and derived parameters and includes the following:

a. Sensor range limit checks

b. Conversion to engineering units

c. Validation routine processing

d. On-line diagnostics for transmission

e. Time tagging of data.

The SPDS function incorporates human factors engineering guidance. The operator's interface with the displays and keyboard have been designed to provide easily accessed and readily understood displays. The BWR Owners Group Control Room Improvements Committee developed the initial Graphic Display System (GDS) in a program which had extensive human factors evaluation. The program included development and dynamic screening of the GDS and later a simulator evaluation of the displays by operators. The Fermi 2 SPDS function includes many features of the GDS, and has incorporated most of the recommendations from the findings of the simulator evaluation. Some of the human factors criteria that were considered in the SPDS function are listed in the Description subsection above.

The SPDS design requirements with regard to parameter selection, isolation, signal validation, and human factors engineering have been analyzed. The critical safety function based, and EOP-related, selected parameters are sufficient to assess the safety status of the identified functions for a wide range of events, which include symptoms of severe accidents.

7.6.1.9.1.2.5.2 Emergency Response Data System (ERDS) Function

The Fermi 2 ERDS function provides selected plant parameters from the IPCS computer to the NRC. The ERDS function was developed to provide the NRC accurate and timely data on four types of plant parameters, namely:

a. Core and coolant system conditions

b. Conditions inside the containment

c. Radioactivity release rates

d. Data from the plant's meteorological tower.

The ERDS function is for use during emergencies to transmit information to the NRC Operations Center. The ERDS function datalink will operate in conjunction with the

Emergency Notification System (ENS), and would be supplemented with voice transmission of essential data not available from the ERDS function.

7.6.1.9.1.2.6 Meteorological (MET) Function

Section 2.3.3.2 describes the Meteorological Data Acquisition System (MDAS) and its interface with the IPCS hardware that replaced the legacy MDAS computer system. The dual-processor IPCS hardware and associated peripherals support the Regulatory Guide 1.23 meteorological function requirements of the orignal system and provide a platform for performing calculations, providing meteorological data for display at various plant locations, and archiving meteorological data.

The following are examples of calculations (based on data obtained from MDAS) done as part of the IPCS meteorological function:

Sigma Phi (measure of wind stability based on the variability of the vertical component of wind direction and and horizontal wind speed)

Pasquill Stability Class

Lake Breeze Status.

In addition, the IPCS MET function uses a Best Value algorithm to determine which value to archive from either the primary or secondary MDAS instrument train data.

7.6.1.9.1.2.7 Transient Recording and Analysis (TRA) Function

The TRA function replaces the legacy General Electric GETARS computer system functionality. The TRA has the capability to process analog and digital points at a scan rate equal to or faster than 100 samples per second, continuously, without degradation of performance of any other IPCS function. The TRA supports auto archiving of data based on data triggers. The ability to utilize both digital states and analog alarm setpoints is provided.

The TRA function plot and report resolution is 10 milliseconds. The TRA function plot and report function provides summary statistics such as mean, minimum, maximum, and standard deviation.

7.6.1.9.1.2.8 Long Term Data Archive (LTA) Function

A computer that is separate from the Master/Slave computers performs the Long Term Data Archive (LTA) function of the IPCS. The LTA computer communicates with the Master computer to receive current plant process data, both analog and digital, at a predefined interval. The LTA computer contains specialized software and a separate I/O database.

Data for points that have been deleted from the IPCS computer database, are retained on the LTA computer, for later retrieval.

7.6.1.9.1.3 External Interfaces

7.6.1.9.1.3.1 GE 3D-Monicore Computer System (3DM) Interface

The 3DM operation requires periodic transmission of live and static plant data to and from the IPCS. All communications with the 3DM are initiated and monitored by the IPCS.

Live plant data transmitted from the IPCS to 3DM includes the following plant inputs and status (represented as individual points):

a. Heat balance input points

b. LPRM and APRM data

c. Control rod data

Live plant data transmitted from the 3DM to IPCS includes the following:

a. RWM messages

7.6.1.9.1.3.2 GE NUMAC LINK Interface

The NUMAC LINK is a data acquisition system interface to the GE NUMAC LINK Power Range Neutron Monitor (PRNM) and the Rod Worth Minimizer (RWM) NUMAC systems. The IPCS NUMAC LINK interface provides the necessary analog and digital points acquired by the PRNM and RWM in support of real-time plant monitoring and application functions. All data received by the NUMAC LINK from the PRNM and RWM is date and time stamped and is accessible by a two-way communication protocol interface.

The IPCS RWM acquired data, through the NUMAC LINK interface, consists of the following signals:

a. Control rod positions and status (including substitute)

b. Control rod movement messages

c. RBM digital points

d. RWM messages

The IPCS PRNM data consists of the following signals

a. LPRM flux and associated digital points

b. APRM flux and associated digital points

c. RBM flux and associated digital points

d. Recirculation flow

e. Oscillation Power Range Monitor Units (OPRM)

7.6.1.9.1.3.3 Eberline SS-1 Radiation Monitor System (SS1) Interface

The SS1 radiation monitor has replaced the legacy Eberline CT2B radiation monitor. The SS1 interface acquires current value/status and historical value/status of various radiation monitoring points and processes them for storage in the real-time and archive database, as appropriate.

The IPCS performs all necessary calculations in support of the SPDS function and Dose Assessment interface, including a complex, best channel selection algorithm.

7.6.1.9.1.3.4 Radiological Dose Assessment Application Interface

The Radiological Dose Assessment program calculates the off-site radiological doses based on meteorological and radiological data available in the IPCS. The Earth Tech Raddose V software has been selected to replace the legacy ERIS dose assessment program.

The Raddose V implementation method runs on IPCS MMI in the control room, EOF, and TSC in two separate modes:

a. Utilizing manually input data
b. Using selected partial (or total) meteorological and radiological data automatically acquired from the IPCS.

Data and control files, necessary for sharing information between multiple dose assessment nodes, reside in multiple locations within the IPCS.

7.6.1.9.1.4 Power Sources

The IPCS has a reliable AC UPS power source. In the event of a complete loss of offsite power, data will be retained by the IPCS during the outage for display once power is restored. Non-essential peripheral devices are supplied from a reliable AC source with an automatic throw-over switch between normal and standby sources.

7.6.1.9.1.5 Environmental Considerations

All the IPCS equipment are capable of withstanding the service conditions to which they will be subjected to with respect to temperature, humidity, precipitation, etc.

7.6.1.9.1.6 Human Factors Engineering

Industry-accepted human factors considerations are followed in designing the man-machine interface. These considerations include, but are not limited to, the following:

a. Simplicity of entering commands
b. Feedback recognition of operator commands
c. Operator input error prevention and error detection
d. Flexibility of display access
e. Flexibility of data entry

7.6.1.9.2 3D-Monicore Computer System (3DM)

7.6.1.9.2.1 System Description

The objectives of the 3DM are to provide a quick and accurate calculation of core thermal performance and to facilitate data reduction, accounting, and logging functions.

The 3DM is not required for safe operation of the plant. Hardwired instrumentation and control allows the operator to safely operate the plant in all modes in the absence of the 3DM. There is no safety objective for the 3DM.

The 3DM consists of two redundant computers. Either of the computers can be designated as the main computer (Normal), and the other will be designated as the backup computer (Standby). Under normal operating conditions, the Normal computer performs all the functions and outputs data and calculation results. The Normal computer also updates the Standby computer at predefined intervals. In the event the Normal computer fails, the Standby computer will become the Normal computer after manual intervention by operating personnel, and assume control of all functions. If the Standby computer fails while the Normal computer is operating normally, the Normal computer will continue to function normally. Either computer can be placed in Failover mode for off-line activities without affecting the operating computer.

3DM receives plant process data from the IPCS via a high speed datalink. The IPCS gathers, formats and transmits the plant process data at predefined intervals. In addition, LRPM calibration flux data is received directly from the TIP system via a fiber optic NUMAC link.

The key 3DM features and capabilities are:

a. Adaptation of 3D diffusion theory solution to measured TIP and LPRM data

b. Use of full or partial TIP measurements of LPRM calibration

c. PANACEA 11 diffusion theory based substitute for non-functional TIPs and LPRMs

d. Calculating core performance parameter distributions and supplying gain corrections for each of the 172 LPRMs based on TIP data measurements

e. Calculating core margins based on LPRM and thermo-hydraulic readings

f. Providing displays and printouts of core thermal margins and core performance parameters automatically and on demand

g. Providing predictive capability to study and evaluate potential impact of operational changes

h. Providing a digital interface between the Power Range Neutron Monitor (PRNM) system and the IPCS. The interface is provided by the GE NUMAC LINKs as described in Section 7.6.1.9.1.3.2. The NUMAC LINKs also transmits calibration data to the PRNM from 3DM

i. Receiving and displaying RWM messages.

7.6.1.9.2.2 Operational Considerations

The local power density of every 6-in segment for every fuel assembly is calculated, using plant inputs of pressure, temperature, flow, LPRM levels, control rod positions, and the calculated fuel exposure. Total core thermal power is calculated from a reactor heat balance. Iterative computational methods are used to establish a compatible relationship between the core coolant flow and core power distribution. The results are subsequently interpreted as local power at specified axial segments for each fuel bundle in the core.

The core power distribution calculation sequence may be completed periodically or on demand. The computer has the capability to automatically print a periodic log for record purposes.

Flux level and position data from the plant are processed and formatted by the TIP system Automatic TIP Control Units (ATCU) and subsequently transmitted to 3DM. 3DM evaluates the data and determines gain adjustment factors by which the LPRM amplifier gains can be altered to compensate for exposure-induced sensitivity loss. The LPRM amplifier gains are not physically altered except immediately prior to calibration of the affected LPRM using the traversing in-core probe (TIP) system. The gain adjustment factor computations help to indicate to the operator when such a calibration procedure is necessary.

Using the power distribution data, a distribution of fuel-exposure increments from the time of the previous power distribution calculation is determined and is used to update the distribution of cumulative fuel exposure. Each fuel bundle is identified by batch and location, and its exposure is stored for each of the axial segments used in the power distribution calculation.

Exposure increments are determined periodically for each section of each control rod. The corresponding percent boron depletions are periodically updated. The exposure increment of each LPRM is determined periodically and is used to update both the cumulative ion chamber exposures and the correction factors for exposure-dependent LPRM sensitivity loss.

3DM provides on-line capability to determine monthly isotopic composition for each fuel bundle in the core. This evaluation consists of computing the weight of one isotope of neptunium, three of uranium, and five of plutonium, as well as the total uranium and total plutonium content. The isotopic composition is calculated for each segment of each fuel bundle and summed accordingly by bundles and batches. The method of analysis consists of relating the computed fuel exposure and average void fraction for the fuel to computer-stored isotopic characteristics applicable to the specific fuel type.

All functions and reports can be executed on demand by the operating personnel.

7.6.1.9.2.3 Power Sources

The 3DM has a reliable AC source with an automatic throw-over switch between normal and standby sources.

7.6.1.9.2.4 Environmental Considerations

All the 3DM equipment are capable of withstanding the service conditions to which they will be subjected to with respect to temperature, humidity, precipitation, etc.

7.6.1.10 (Deleted)

7.6.1.11 Sequence of Events Recorder

The sequence of events recorder function provides the basic alarm detection management, reporting and real-time display of all sequence of events input signals to the annunciator system. The inputs include NSSS and balance-of-plant (BOP) data.

The input signals are independent of the IPCS and are electrically isolated from it. An outage of the computer would not affect operation or reliability of the sequence of events recorder.

The sequence of events recorder displays the time and alarm type of each event and can resolve the time of occurrence with a resolution approaching 1 msec.

7.6.1.12 Primary Containment Monitor System

The primary containment monitor system consists of the following five monitor subsystems:

a. Primary containment radiation monitor

b. Primary containment temperature monitor

c. Primary containment pressure monitor

d. Pressure suppression pool water level indicator

e. Hydrogen/oxygen monitor.

Division II AOVs T5000F420B and T5000F421B are designed to be reopened in the event of an extended AC power failure, using DC solenoid valves T50F459B and T50F468B respectively, as show in Figure 7.6-11.

The primary containment radiation monitor subsystem supplements the LDS. The primary containment radiation monitor is not designed to operate following the DBA. The radiation monitor designed to monitor post-DBA containment radiation is the containment area high range monitor discussed in Section 11.4. The other four primary containment monitor subsystems, namely, the primary containment temperature monitor, primary containment pressure monitor, the pressure suppression pool water-level indicator, and the hydrogen/oxygen monitor, are required to operate after a LOCA, and are designed to meet the redundancy and separation requirements listed in Subsection 7.6.2.12. Under normal plant operation, however, these subsystems provide display of the monitored parameters for additional information on the operating conditions of the plant.

Descriptions of the five subsystems that compose the primary containment monitor system are presented in Subsections 7.6.1.12.1 through 7.6.1.12.4.

7.6.1.12.1 Primary Containment Radiation and Hydrogen/Oxygen Monitor Subsystem

7.6.1.12.1.1 System Identification

The primary containment radiation monitor subsystem is incorporated for monitoring the radioactivity of the atmosphere within the primary containment to provide additional information related to primary coolant leak detection. This provision improves the total drywell leak-detection diversity and enhances the sensitivity of leak detection beyond that which is available with the drywell sump system. An alarm and annunciator are actuated when the radiation level reaches a predetermined setpoint level. This subsystem has no control function (Table 7.6-2).

The primary containment radiation monitor uses a beta scintillation detector viewing a sample flow of primary containment atmosphere as it passes through a gaseous detector chamber. The sample is drawn from the primary containment, through the filters, past the gaseous sample detector, and returned to the containment by a sample pump. The piping and valve arrangement for sample flow are illustrated in Figure 7.6-11. Remotely controlled valves are used to select either all the drywell atmosphere sampling points, selected locations within the drywell, or the suppression chamber atmosphere for radiation monitoring.

The main sample flow loop supplies both the primary containment radiation monitor subsystem and the hydrogen/oxygen monitor subsystem in parallel. The hydrogen/oxygen monitor subsystem operates continuously to provide indication in the main control room of the concentration of hydrogen/oxygen in the containment. Levels of hydrogen and oxygen in excess of preset limits are alarmed in the main control room (Table 7.6-2).

The total time lag from intake of drywell atmosphere sample loop manifold to the monitoring instrument sampling point is designed to be less than 5 minutes. Within the primary containment radiation monitor are particulate and halogen filters to collect integrated samples for subsequent analysis.

Associated with each beta scintillation detector is a logarithmic count rate circuit, power supply unit, and meter readout. A recorder is provided in the main control room for display of radiation level. A flowmeter is provided in the sample line, with local display of flow rate, and means for actuation of the alarm and annunciator associated with the primary containment radiation monitor on loss of sample flow.

7.6.1.12.1.2 Classification

The primary containment hydrogen/oxygen monitor subsystem is seismically and environmentally qualified to meet the requirements of Regulatory Guide 1.97, Rev 2, Category 3 and 2, respectively. The radiation monitor has not been qualified environmentally or seismically.

7.6.1.12.1.3 Supporting Systems

Electrical Power

The electrical power required for operation of the primary containment radiation and hydrogen/oxygen monitor subsystems is supplied from the 480-V ESF motor control centers (MCCs) and the 120-V ac instrument bus as described in Subsection 8.3.1.

Pneumatic Power

The pneumatic power required for operation of valves in the sample lines will be supplied by an uninterruptible air system for the primary containment monitoring system isolation valves and an interruptible air system for the primary containment radiation monitoring system isolation valves as described in Subsection 9.3.1.

7.6.1.12.1.4 Equipment Design

Initiating Circuits

Control of the primary containment radiation and hydrogen/oxygen monitor subsystems for normal operation, test, and calibration is manual. The hydrogen/oxygen monitor subsystem is normally operated continuously from plant startup to shutdown.

Logic

The primary containment radiation monitor subsystem incorporates trip logic circuits for alarm and annunciator operation. A low mode alarm trip is provided to indicate instrument failure on loss of normal background reading, and a high mode trip to indicate a radiation level exceeding a predetermined normal background level. The hydrogen/oxygen monitor has alarms as defined in Table 7.6-2.

Actuated Devices

The primary containment radiation monitor and hydrogen/oxygen monitor subsystems have no control function. Devices actuated by the primary containment radiation monitor are an alarm and an annunciator on high radiation and on loss of background signal, the latter being indicative of instrument failure.

Testability

The primary containment radiation monitor and the hydrogen/oxygen monitor subsystems are fully testable during normal plant operation.

7.6.1.12.1.5 Environmental Considerations

The primary containment hydrogen/oxygen monitor subsystem is designed to operate reliably under normal and postulated abnormal environmental conditions in the equipment area. The local environmental conditions are defined in Table 3.11-1.

The oxygen monitors provide verification of the status of the inerted atmosphere of containment and oxygen levels in the containment atmosphere following a significant beyond design-basis accident for combustible gas control and accident management, including emergency planning.

The hydrogen monitors provide diagnosis of the course of significant beyond-design-basis accidents for accident management, including emergency planning.

7.6.1.12.1.6 Operational Considerations

Normal

During power operation, startup, or hot shutdown of the reactor, the primary containment radiation monitor subsystem is in continuous operation to detect and alarm a high level of radiation in the monitored atmosphere. The hydrogen/oxygen monitor subsystem is normally operated continuously from plant startup to shutdown.

Safety Function

On occurrence of radiation above the alarm setpoint level, the abnormal condition will be alarmed and annunciated in the main control room. High levels of hydrogen and/or oxygen are alarmed in the main control room.

Operator Information

The primary containment radiation monitor subsystem has provisions in the main control room for indicating the radiation count rate per unit volume of sample, for checking the setpoint at which the high radiation alarm is actuated, and for alarming low sample flow rate. A chart recorder is provided to record the monitored radiation levels. By the actuation of an alarm and annunciator, the operator is informed of high radiation level, instrument failure as evidenced by loss of normal background reading, or loss of sample flow. A number of functional alarms are provided in the hydrogen/oxygen monitors to ensure proper system operation.

Setpoints

The setpoint for actuation of the alarm and annunciator on high radiation will be established after the normal background is determined. The setpoint is adjustable over the instrument range. The alarm setpoints for the hydrogen/oxygen monitors can be found in Table 7.6-2.

7.6.1.12.2 Primary Containment Temperature Monitoring Subsystem

7.6.1.12.2.1 System Identification

The primary containment temperature monitor subsystem uses thermocouple detectors to measure drywell atmosphere temperature, pressure suppression pool chamber atmospheric temperature, and pressure suppression pool water temperature. To achieve representative temperature measurements in the primary containment, 16 sensors in the drywell, four sensors for suppression pool atmosphere, and four sensors for suppression pool water are used. The monitored temperatures are continuously recorded on two stripchart recorders. The primary containment temperature monitor subsystem has no control function; its purpose is that of data acquisition. Because of the importance of securing these temperature data on postulated accident (LOCA) conditions and other abnormal plant conditions, two redundant temperature monitors are provided.

In parallel with the primary containment temperature monitor subsystem (PCTMS), and in response to additional design requirements, two additional temperature monitoring systems have been installed to monitor the drywell air temperature and the suppression pool temperature, during normal mode of plant operation and transient condition, as discussed below.

The additional drywell air temperature monitoring subsystem uses 28 thermocouples (which are independent of the PCTMS) installed at six elevations. The temperature information is recorded in the main control room and is used by the operators to compute the volumetric average temperature for determination of the Technical Specifications operating limit. The additional suppression pool temperature monitoring subsystem uses a recorder and eight thermocouples (which are all independent of the PCTMS). These eight thermocouples in the torus are used by operators to compute the suppression pool water bulk average temperature for determination of the Technical Specification operating limit. The thermocouples are placed so that each thermocouple monitors the discharge of two SRVs. The recorder is located in the main control room and will alarm on bulk average water temperature ≥95.0°F or detection of an open T/C. The technical specifications allow the maximum average temperature of the suppression pool to be 95°F during operational conditions 1 or 2 unless the thermal power is less than or equal to 1%, or a test is being performed which adds heat to the suppression chamber. To alert an operator of this limit, an alarm will be set at approximately 95.0°F (increasing).

The additional thermocouples in the drywell and torus and the associated recorders which are used during normal mode of operation to monitor the drywell volumetric average and suppression pool bulk average temperature are classified as quality assurance (QA) level 1M and seismic category II/I. This classification means that these components are maintained like a QA level 1 component, and they will maintain their structural and mounting integrity during a seismic event.

The torus water temperature recorder and Division I drywell air temperature recorder are powered from a non-class IE distribution cabinet that is fed by a bus which is automatically restored by the emergency diesel generators (EDG) on a loss-of-offsite power. Thus, in the event of loss-of-offsite power, these recorders can be powered from the EDGs by closing a breaker. The Division II drywell air temperature recorder is powered from a class IE power bus.

7.6.1.12.2.2 Classification

The primary containment temperature monitor subsystem is not a fully qualified system. The set of 24 primary containment monitoring thermocouples have been installed seismically. Two thermocouples in the drywell, two in the suppression pool air space, and two in the suppression pool water have also been qualified environmentally for postulated accident conditions.

7.6.1.12.2.3 Power Sources

Operating power for the two identical temperature monitors of the primary containment temperature monitor subsystem is supplied from separate 120-V ac instrument buses to prevent total loss of monitoring capability on interruption of an instrument bus.

7.6.1.12.2.4 Equipment Design

Initiating Circuits

Both monitors are in service when the reactor is operating in order to provide necessary backup monitoring.

Redundancy

Two identical monitors are provided in the primary containment temperature monitor subsystem.

Separation

Instrument control and power feed circuits of the two monitors comprising this subsystem are separate. Routing of thermocouple and power circuits by separate paths and penetrations precludes total loss of temperature monitoring capability by a single destructive event.

Testability

To facilitate test and calibration, the temperature detectors are removable from their working locations. The recorders are tested and checked for calibration by the standard technique of using a millivolt box after disconnection of the thermocouple circuits.

7.6.1.12.2.5 Environmental Considerations

The thermocouples, associated thermocouple lead circuits, and recording instrumentation are of a design that provides reliable operation under normal and postulated abnormal environmental conditions. The environmental conditions of specific plant areas are defined in Tables 3.11-1, 3.11-3, and 3.11-4.

7.6.1.12.2.6 Operational Considerations

Normal

The primary containment temperature monitor subsystem operates continuously during operation of the reactor, and secures recordings of the monitored temperatures. Should a LOCA occur, obtained recordings provide essential information about the temperatures monitored by the primary containment temperature monitor subsystem.

Operator Information

Monitored temperatures are displayed on the recorder chart in the main control room, making this information directly available to the operations personnel when the plant is in operation.

7.6.1.12.3 Primary Containment Pressure Monitor Subsystem

7.6.1.12.3.1 System Identification

The primary containment pressure monitor subsystem monitors the atmospheric pressure of the drywell and the pressure suppression chamber and records on redundant chart recorders in the main control room. The instrumentation for the drywell uses two pressure ranges, -5 to +5 psig and 0 to 250 psig. The instrumentation for the pressure suppression chamber uses two ranges also, -5 to +15 psig and 0 to 80 psig. The low range of the pressure monitoring instrumentation enables detection of a change in drywell and or pressure suppression chamber pressure resulting from a primary containment leak and containment sprays, and provides for sensitive monitoring during normal operation of the plant and during shutdown and LOCA conditions. In order to provide continued monitoring of the drywell pressure during an extended loss of AC power, T5000F420B can be reopened using the DC solenoid valve T50F459B, as shown in Figure 7.6.11. The low range pressure monitoring instrumentation may also provide a means of detecting degradation of the containment pressure boundary. The high pressure ranges provide the capability to measure a pressure transient arising from a LOCA. Pressure is displayed on a multipoint recorder. Two complete and independent pressure monitors comprise the primary containment pressure monitor system. This subsystem has no control function; its purpose is that of data acquisition and advisory information.

Pressure transmitters used to initiate ECCSs or to provide inputs to the RPS are described in Subsection 7.3.1 and Section 7.2.

7.6.1.12.3.2 Classification

The primary containment pressure monitor subsystem is designed and installed as Category I. The pressure transmitters incorporated in this subsystem are also environmentally qualified for postulated accident conditions.

7.6.1.12.3.3 Power Sources

The electrical power for the powered equipment of the two pressure monitors in this subsystem is supplied from separate battery-powered inverters.

7.6.1.12.3.4 Equipment Design

Initiating Circuits

Control of operation of the pressure detector equipment is manual. Operation of this monitoring subsystem is continuous when the reactor is in operation.

Redundancy

Two identical monitors are provided in the primary containment pressure monitor subsystem.

Separation

Electrical circuits of the two identical pressure monitors comprising this subsystem are routed separately to minimize vulnerability to total impairment of the monitor subsystem by a single destructive event.

Testability

To facilitate periodic checks of operation of this subsystem, provisions are incorporated to allow for in-place testing of the detectors and convenient removal for testing when the reactor is shut down.

7.6.1.12.3.5 Environmental Considerations

The equipment of the primary containment pressure monitor subsystem is designed to operate reliably under the normal and postulated abnormal conditions of the equipment areas. The environmental conditions of these areas are defined in Table 3.11-1.

7.6.1.12.3.6 Operational Considerations

Normal

The primary containment pressure monitor subsystem operates continuously during operation of the reactor, securing recordings of the pressures within the primary containment.

Safety Function

Should a LOCA occur, secured recordings provide information sought about transients in the pressures monitored by the primary containment pressure monitor subsystem.

Operator Information

Monitored pressures are displayed on the recorder chart in the main control room as they are being recorded, making this information directly available while the plant is in normal operation. The pressure may fluctuate for a variety of reasons including changes in barometric pressure. A pressure rise above normal could indicate a process system leak as described in Subsection 7.6.1.8.5.2. The low range pressure monitoring instrumentation may also provide a means of detecting degradation of the containment boundary depending on the magnitude of the degradation. Unexplained changes in pressure during normal operation would therefore result in an investigation to determine the cause using the Corrective Action program as appropriate. If the drywell pressure increases above the trip value, the chart recorder increases chart speed to obtain better transient resolution. Peak pressure is also obtained by a peak-pressure indicator.

7.6.1.12.4 Pressure Suppression Pool Water Level Indicator Subsystem

7.6.1.12.4.1 System Identification

The pressure suppression pool water-level indicator subsystem continuously monitors and records on a chart recorder in the main control room the water level in the pressure suppression chamber. The principal function of this monitor subsystem is to obtain data on water level in the pressure suppression chamber on occurrence of a LOCA. The subsystem also serves to indicate and record the water level in the course of normal operation of the plant and during shutdown and LOCA condition. In order to provide continued monitoring of the suppression pool level during an extended loss of AC power, T5000F421B can be reopened using the DC solenoid valve T50F468B, as shown in Figure 7.6.11. This is a supplementary function because the pressure suppression chamber water level is maintained, and the level indication is necessarily provided in the main control room as part of the torus water management system.

7.6.1.12.4.2 Classification

The pressure suppression pool water level indicator subsystem is designed and installed as Category I. The transmitters are qualified to meet the environmental conditions of postulated accidents.

7.6.1.12.4.3 Power Sources

Operating electrical power for the pressure suppression pool water level indicator subsystem is supplied from separate battery-powered inverters.

7.6.1.12.4.4 Equipment Design

Initiating Circuits

Control of operation of the pressure suppression pool water level indicator subsystem is manual. Operation of the subsystem is continuous during reactor operation and when the reactor is shut down.

Redundancy

Two identical level-indicator instrumentation provisions comprise the pressure suppression pool water level indicator system.

Separation

The two independent level-indicator provisions comprising this subsystem have signal and power lines routed separately to minimize vulnerability to impairment of both subsystems by a single destructive event.

Testability

The pressure suppression pool water level indicator subsystem incorporates means to allow for complete testing of the subsystem during periods when the reactor is shut down.

7.6.1.12.4.5 Environmental Considerations

The equipment of the pressure suppression pool water level indicator subsystem is designed to operate reliably under the normal and postulated abnormal conditions to which the equipment would be exposed. The environmental conditions of the equipment areas are defined in Tables 3.11-1, 3.11-3, and 3.11-4.

7.6.1.12.4.6 Operational Considerations

Normal

The pressure suppression pool water level indicator subsystem is in continuous operation during operation of the reactor as well as during periods of shutdown, unless the equipment is taken out of service for test or maintenance purposes.

Safety Function

Should a LOCA occur, the recordings obtained provide essential information about the pressure suppression chamber water level during the abnormal conditions.

Operator Information

The water level in the pressure suppression pool is continuously indicated as well as recorded on a chart in the main control room.

7.6.1.13 Neutron Monitoring System Instrumentation and Control

The neutron monitoring system (NMS) consists of six major subsystems which are

a. Source range monitor

b. Intermediate range monitor

c. Local power range monitor

d. Average power range monitor

e. Rod block monitor

f. Traversing in-core probe.

7.6.1.13.1 System Identification

The purpose of this system is to monitor neutron flux levels of the core over the range from shutdown to full power, and to provide signals to the RPS (Section 7.2). It also provides information for operation and control of the reactor. Basic system information is given in Table 7.6-2.

Certain portions of the intermediate range monitor (IRM) and average power range monitor (APRM) systems provide a safety function, and portions of the rod block monitor (RBM) have been designed to meet IEEE 279-1971. All other portions of the NMS have no safety function.

7.6.1.13.2 Power Sources

The power supplies for each system are discussed in the individual circuit description.

7.6.1.13.3 Source Range Monitor System

7.6.1.13.3.1 Equipment Design

Circuit Description

The source range monitor (SRM) provides neutron flux information during reactor startup and low-flux-level operations. There are four SRM channels. Each includes one detector that can be physically positioned in the core from the main control room (Figures 7.6-12 through 7.6-14). The detectors are inserted into the core for a reactor startup. They can be withdrawn if the indicated count rate is between preset limits or if the IRM is on the third range or above.

The power for the monitors is supplied from the two separate +24 V dc buses. Two monitors are powered from each bus. The detector drives are powered by a 208-V ac three-phase bus.

Each detector assembly consists of a miniature fission chamber and a low-loss, insulated transmission cable.

The sensitivity of the detector is 1.2 x 10^{-3} cps/nv nominal. The detector cable is connected underneath the RPV to shielded coaxial cable. This shielded cable carries the pulses to a pulse current preamplifier located outside the primary containment.

The detector and cable are located inside the RPV in a dry tube sealed against reactor vessel pressure. A remote-controlled detector drive system moves the detector along the dry tube.

Vertical positioning of the chamber is possible from above the centerline of the active length of fuel to approximately 2-1/2 ft below the reactor fuel region, as shown in Figure 7.6-13. When a detector arrives at a travel endpoint, detector motion is automatically stopped. The SRM/IRM drive control logic is presented in Sheet 6 of Figure 7.6-16. The electronics for the SRMs, their trips, and their bypasses are located in one cabinet. Source-range signal-conditioning equipment is designed so that it can be used for open-core experiments.

A charge-sensitive preamplifier provides amplification and impedance matching for the signal conditioning electronics (Figure 7.6-17). The signal conditioning equipment converts the current pulses to analog dc voltages that correspond to the logarithm of the count rate. The equipment also derives the period. The output is displayed on front panel meters and is provided to remote meters and recorders.

The logarithmic count rate meter displays the rate of occurrence of the input current pulses. The period meter displays the time in seconds for the count rate to change by a factor of 2.72. In addition, the equipment contains integral test and calibration circuits, trip circuits, power supplies, and selector circuits.

The trip outputs of the SRM operate in the fail-safe mode. Loss of power to the SRM causes the associated outputs to become tripped (Figure 7.6-16, Sheet 2).

The SRM provides signals indicating SRM upscale, downscale, inoperative, and incorrect detector position to the RMCS to block rod withdrawal under certain conditions. Any SRM channel can initiate a rod block. These rod blocking functions are discussed in Subsection 7.7.1.1.3.5. Appropriate lights and annunciators are also actuated to indicate the existence of these conditions (Table 7.6-5). One in one group of four SRM channels can be bypassed at any one time by the operation of a switch on the operator's console.

Testability

Each SRM channel is tested and calibrated. Inspection and testing are performed as required on the SRM detector drive mechanism. The mechanism can be checked for full insertion and retraction capability. The various combinations of SRM trips can be introduced to ensure the operability of the rod blocking functions.

7.6.1.13.3.2 Environmental Considerations

The wiring, cables, and connectors located within the drywell are designed for the environmental conditions identified in NEDO 31558A per References 7 and 8 in Appendix A.

7.6.1.13.4 Intermediate Range Monitor System

7.6.1.13.4.1 Equipment Design

Circuit Description

The IRM monitors neutron flux from the upper portion of the SRM range to the lower portion of the power range monitoring subsystems. The IRM system has eight IRM channels, each of which includes one detector that can be positioned in the core by remote control. The detectors are inserted into the core for a reactor startup and are withdrawn after the reactor mode selector switch is turned to the RUN position and the LPRM is operative.

Power Supply

Power is supplied separately from the two 24-V dc sources. The supplies are split according to their use so that loss of a power supply results in the loss of only one trip system of the RPS.

Physical Arrangement

Each detector assembly consists of a miniature fission chamber attached to a low-loss, insulated transmission cable. When coupled to the signal conditioning equipment, the detector produces a reading of approximately 30 percent on the most sensitive range with a neutron flux of 10^8 nv. The detector cable is connected underneath the RPV to a shielded cable that carries the pulses generated in the fission chamber through the primary containment to the preamplifier.

The detector and cable are located in the drywell. They are movable in the same manner as the SRM detectors and use the same type of mechanical arrangement (Reference 1) and power supply.

Signal Conditioning

A voltage amplifier unit located outside the primary containment serves as a preamplifier. This unit converts the current pulses to voltage pulses, modifies the voltage signal, and provides impedance matching. The preamplifier output signal is coupled by a cable to the IRM signal conditioning electronics as shown in Figure 7.6-18.

Each IRM channel receives its input signal from the preamplifier and operates on it with various combinations of preamplification gain and amplifier attenuation ratios. The amplification and attenuation ratios of the IRM and preamplifier are selected by an operator's console-mounted range switch that provides 10 ranges of increasing attenuation acting on the signal from the fission chamber (the first six ranges are called low range and the last four ranges are called high range). As the neutron flux of the reactor core increases from 1×10^8 nv to 1.5×10^{13} nv, the signal from the fission chamber is attenuated to keep the input signal to the inverter in the same range. The output signal, which is proportional to neutron flux at the detector, is amplified and supplied to a locally mounted meter. Outputs are also provided for a remote meter and recorder.

Trip Functions

The IRMs are arranged in the core as shown in Figure 7.6-12 and are divided into two groups of IRM channels. Each group is associated with one of the two trip systems of the RPS. Two IRM channels and their trip auxiliary are installed in each bay of a four-bay cabinet. Full-length side covers isolate the cabinet bays. The arrangement of IRM channels allows one IRM channel in each group to be bypassed without compromising intermediate range neutron monitoring.

Each IRM channel includes four trip circuits as standard equipment. One trip circuit is used as an instrument trouble trip. It operates on when the high voltage drops below a preset level, when one of the modules is not plugged in, or when the OPERATE-CALIBRATE switch is not in the OPERATE position. Each of the other trip circuits can be specified to trip when preset downscale or upscale levels are reached.

The trip functions actuated by the IRM trips are indicated in Table 7.6-6. The reactor mode switch determines whether IRM trips are effective in initiating a rod block or a reactor scram (Figure 7.6-16, Sheet 1). Subsection 7.7.1.1 describes the IRM rod block trips. With the reactor mode switch in REFUEL or STARTUP, an IRM upscale or inoperative trip signal actuates a NMS trip of the RPS. Only one of the IRM channels must trip to initiate an NMS trip of the associated trip system of the RPS.

Testability

Each IRM channel is tested and calibrated using the appropriate Checkout and Initial Operations, Preoperational, or Surveillance Procedures. The IRM detector drive mechanisms and the IRM rod blocking functions are checked in the same manner as for the SRM channels. Each IRM channel can be checked to ensure that the IRM high flux scram function is operable.

7.6.1.13.4.2 Environmental Considerations

The wiring, cables, and connectors located in the primary containment are designed for the environmental conditions identified in NEDO 31558A per References 7 and 8 in Appendix A.

7.6.1.13.5 Local Power Range Monitor System

7.6.1.13.5.1 Equipment Design

Description

The LPRM consists of fission chamber detectors, signal conditioning equipment, and trip functions. The LPRM also provides outputs to the APRM, RBM, and Integrated Plant Computer System (IPCS).

Power Supply

Detector polarizing voltage for the LPRMs is supplied by eight pairs of redundant-dc power supplies, adjustable from 75 to 200 V dc. The 75-200 V dc power supplies can supply up to 3 milliamperes for each LPRM detector which ensures that the chambers can be operated in the saturated region at the maximum specified neutron fluxes. Each dc power supply pair powers approximately one-eighth of the LPRMs. Power for the dc power supplies comes redundantly from the two 120 V ac Reactor Protection System buses via intermediate dc power supplies. These intermediate dc supplies also provide power for the LPRM amplifiers.

Physical Arrangement

The LPRMs include 43 LPRM detector strings having detectors located at different axial heights in the core. Each string contains four fission chambers. These assemblies are distributed to monitor four horizontal planes throughout the core. Figure 7.6-12 shows the LPRM detector radial layout scheme that provides a detector assembly at every fourth intersection of the water channels around the fuel bundles. Thus, every location has either an actual detector assembly or a symmetrically equivalent assembly in some other quadrant.

The detector assemblies (see Figure 7.6-19) are inserted in the core in spaces between the fuel assemblies. They are inserted through thimbles mounted permanently at the bottom of the core lattice and penetrate the bottom of the RPV. These thimbles are welded to the RPV at the penetration point. They extend down into the access area below the RPV where they terminate in a flange. The flange mates to the mounting flange on the in-core detector assembly. The detector assemblies are locked at the top end to the top fuel guide by means of a spring-loaded plunger. Special water-sealing caps are placed over the connection end of the assembly and over the penetration at the bottom of the vessel during installation or removal of an assembly. This prevents loss of reactor coolant water on removal of an assembly, and also prevents the connection end of the assembly from being immersed in the water during installation or removal.

Each LPRM detector assembly contains four miniature fission chambers with an associated solid sheath cable. The chambers are vertically spaced in the LPRM detector assemblies in a way that gives adequate axial coverage of the core, complementing the radial coverage given by the horizontal arrangement of the LPRM detector assemblies. Each fission chamber produces a current that is coupled with the LPRM signal conditioning equipment to provide the desired scale indications.

Each miniature chamber consists of two concentric cylinders that act as electrodes. The inner cylinder (the collector) is mounted on insulators and is separated from the outer cylinder by a small gap. The gas between the electrodes is ionized by the charged particles produced as a result of neutron fissioning of the uranium-coated outer electrode. The chamber is operated at a polarizing potential of approximately 100 V dc. The negative ions produced in the gas are accelerated to the collector by the potential difference maintained between the electrodes. In a given neutron flux, all the ions produced in the ion chamber can be collected if the polarizing voltage is high enough. When this situation exists, the ion chamber is considered to be saturated. Output current is then independent of operating voltage and is reasonably linear over the design operating range (Reference 1).

Each assembly also contains a calibration tube for a traversing in-core probe (TIP). The enclosing tube around the entire assembly contains holes that allow circulation of the reactor coolant water to cool the fission chambers. Numerous tests have been performed on the chamber assemblies, including tests of linearity, gamma sensitivity, and cable effects (Reference 1). These tests and experience in operating reactors provide confidence in the ability of the LPRM system to monitor neutron flux to the design accuracy throughout design lifetime.

Signal Conditioning

The current signals from the LPRM detectors are transmitted to the LPRM amplifiers in the main control room. The current signal from a chamber is transmitted directly to its amplifier through shielded cable. The amplifier is a linear current amplifier whose voltage output is proportional to the current input and therefore proportional to the magnitude of the neutron flux. The amplifier output is "read" by the digital processing electronics. The digital electronics applies hardware gain corrections, performs filtering and applies the LPRM gain factors. The digital electronics provides suitable output signals for the computer recorders, annunciators, etc. The LPRM amplifiers also isolate the detector signals from the rest of the processing so that individual faults in one LPRM signal path will not affect other LPRM signals.

The LPRM signals are indicated on the reactor console. When a central control rod is selected for movement, the LPRM values associated with the nearest 16 LPRM detectors are displayed on console readouts. Each of the four axially spaced LPRM detector signals from each of the four LPRM assemblies are displayed. The operator can readily obtain readings of all the LPRM amplifiers by selecting the control rods in the correct order or by selecting summary LPRM screens on digital operator displays. Subsection 7.7.1.1 describes in greater detail the indications on the reactor console.

Trip Functions

The trip functions for the LPRM provide trip signals to activate displays and annunciators. The outputs for the trip functions are designed to go to the "tripped" state on loss of power to the processing electronics. Table 7.6-7 indicates the trips.

The trip levels can be adjusted to within ±0.1 of full-scale deflection, and the expected error is approximately ±1 percent of full scale.

Testability

LPRM channels are calibrated using data from previous full power runs and TIP data and are tested.

7.6.1.13.5.2 Environmental Considerations

Each individual chamber of the assembly is a moisture-proof, pressure-sealed unit. The chambers are designed for the environmental conditions identified in NEDO 31558A per References 7 and 8 in Appendix A.

7.6.1.13.6 Average Power Range Monitor System

7.6.1.13.6.1 Equipment Design

Description

The APRM system has four APRM channels, each of which uses input signals from a number of LPRM channels. Each of the four APRM channels provide inputs to four two-out-of-four voter channels. Two of the voter channels are associated with each of the trip systems of the Reactor Protection System. All four APRM channels are associated with both of the Reactor Protection System trip systems in that they provide inputs to each of the four voter channels.

Each APRM also includes an Oscillation Power Range Monitor (OPRM) Upscale Function which monitors small groups of LPRM signals to detect thermal-hydraulic instabilities. The OPRM Upscale function is enabled in the intended region on the plant power/flow map. The OPRM Upscale Function receives input signals from the LPRMs within the reactor core, which are combined into cells for evaluation by the OPRM algorithms. An OPRM Upscale trip function is generated from an APRM channel when the period based detection algorithm (basis for the safety analysis) in that channel detects oscillatory changes in the neutron flux, indicated by the combined signals of the LPRM detectors in a cell, with the period confirmations and relative cell amplitude exceeding specific setpoints. One or more cells in a channel exceeding the trip conditions will result in a channel trip. An OPRM Upscale trip is also issued from any channel if either the growth rate or amplitude based algorithms detect growing oscillatory changes in the neutron flux for one or more cells in that channel.

Power Supply

The APRM channels receive power redundantly from the 120-V ac supplied RPS buses. Each APRM two-out-of-four voter channel receives power from the same 120 V ac power as the Reactor Protection System trip system with which it is associated.

Signal Conditioning

The APRM channel uses digital electronic equipment which averages the output signals from a selected set of LPRMs, generates trip outputs via the two-out-of-four voter channels, and provides signals to readout equipment. Each APRM channel can average the output signals from up to 43 LPRM channels. Assignment of LPRM channels to an APRM is shown in Figure 7.6-20. The letters at the detector locations in Figure 7.6-20 refer to the axial positions of the detectors in the LPRM detector assembly. Position A is the bottom position, position B and C are above position A, and position D is the topmost LPRM detector position. The pattern provides LPRM signals from all four core axial LPRM detector positions throughout the core. Some LPRM detectors may be bypassed, but the averaging logic automatically corrects for these by removing them from the average. The APRM value calculated from the LPRM inputs is adjusted by a digitally entered factor to allow calibration of the APRM.

Each APRM channel calculates a recirculation flow signal which is used to determine the APRM's flow-biased rod block and scram setpoints. Each signal is determined by summing the flow signals from the two recirculation loops (Figure 5.5-2). These signals are sensed from two flow elements, one in each recirculation loop. The differential pressure from each flow element is routed to four differential pressure transducers (eight total). The signals from two differential pressure transducers, one from each flow element, are routed to two inputs to the APRM digital electronics. Table 7.6-8 indicates the flow function trips.

The APRM Channel Check surveillance will include a step to confirm that an APRM self-test is still running. It will also include a step to confirm that the RBM self-test is still running since the RBM hardware performs the recirculation flow comparison checks, however, the alarm is bypassed when the reactor mode switch is not in the “RUN” position. A surveillance (channel check) finding that the self-test is not operating in both RBMs (means the recirculation flow comparison function is not available) will not automatically result in any APRM/OPRM channel being declared inoperable, but will result in an increased rate of "flow comparison" manual surveillances. The flow comparison surveillance will be performed at nominally hourly frequencies to correspond to the self-test frequencies assumed in the unavailability analysis for the PRNM system.

All APRM channels are powered redundantly, via intermediate low voltage dc power supplies, from both the "A" and "B" Reactor Protection System 120 V ac power buses. The LPRM signal processing equipment is powered by the same sources as their associated APRM channels.

Trip Function

The digital electronics for the APRM channel provides trip signals directly to the Reactor Manual Control System and via the APRM two-out-of-four voter channels to the Reactor Protection System (RPS). Any two unbypassed APRM channels, via the APRM two-out-of-four voter channels, can initiate an RPS trip in both RPS trip systems. Any one unbypassed APRM can initiate a rod block. Table 7.6-9 lists the APRM trip functions. A simplified circuit arrangement is shown in Figure 7.6-21.

The APRM simulated thermal power upscale rod block and scram trip setpoints are varied as a function of reactor recirculation flow. The slope of the upscale rod block and scram trip response curves is set to track the required trip setpoints with recirculation flow changes. Subsection 7.7.1.1.3.5 discusses the thermal power monitor and the APRM in greater detail.

At least two unbypassed APRM channels must be in the upscale or inoperative trip state to cause an RPS trip output from the APRM two-out-of-four voter channels. In that condition, all four voter channels will provide an RPS trip output, two to each RPS trip system. If only one unbypassed APRM channel is providing a trip output, each of the four APRM two-out-of-four voter channels will have a half-trip, but no trip signals will be sent to the RPS. The trips from one APRM can by bypassed by operator action in the control room. Trip outputs to the RPS are transmitted by removing voltage to a relay coil, so loss of power results in actuating the RPS trips. A simplified APRM/RPS interface circuit arrangement is shown in Figures 7.2-3a and 7.2-3b.

In the startup mode of operation, the APRM "fixed" upscale trip setpoint is set down to a low level. This trip function is provided in addition to the existing IRM upscale trip in the startup mode. The trip settings are listed in Table 7.6-9.

The trip functions are performed by digital comparisons in APRM electronics. The APRM flux value is developed by averaging the LPRM signals and then adjusting the average to be APRM power. The APRM power is processed through a first order filter with a six second time constant to calculate simulated thermal power. These calculations are all performed by the digital processor and result in a digital representation of APRM and simulated thermal power. For each RPS trip and rod block alarm, the APRM power or simulated thermal power, as applicable (see Table 7.5-4), is digitally compared to the setpoint (which was previously entered and stored). If the power value exceeds the setpoint, the applicable trip is issued.

Testability

The APRM channels are calibrated using data from previous fullpower runs and are tested by procedures in the applicable instruction manual. Each APRM channel can be tested individually for the operability of the APRM scram and rod blocking functions by introducing test signals.

7.6.1.13.6.2 Environmental Considerations

All APRM equipment is installed and operated in the main control room environment as described in Table 3.11-4.

7.6.1.13.7 Rod Block Monitor System

7.6.1.13.7.1 Equipment Design

Circuit Description

The RBM has two channels; each channel uses input signals from a number of LPRM channels. A trip signal from either RBM channel initiates a rod block. One RBM channel can be bypassed without loss of subsystem function. The minimum number of LPRM inputs required for each RBM channel to prevent an instrument inoperative alarm is four when using four LPRM assemblies, three when using three LPRM assemblies, and two when using two LPRM assemblies (Figures 7.6-22 and 7.6-22(a)).

Power Supply

The RBM power is supplied by two pairs of redundant dc power supplies, one pair for each RBM. Each dc supply in a pair is supplied by one of the two 120-V ac RPS buses, one RBM per bus.

Signal Conditioning

The RBM signal is generated by averaging a set of LPRM signals. The LPRM signals used depends on the control rod selected. Upon selection of a rod for withdrawal or insertion, the conditioned signals from the LPRMs around the rod will be automatically selected by the two RBM channels. (Figure 7.6-22 shows examples of the four possible LPRM/selected rod assignment combinations.) For a typical non-edge rod, each RBM channel averages LPRM inputs from two of the four B-position and D-position detectors, and all four of the C-position detectors. A-position LPRM detectors are not included in the RBM averages, but are displayed to the operator. When a rod near, but not at, the edge of the core is selected, where there are fewer than four, but at least two, LPRM strings around the rod, the number of detectors used by the RBM channels is either six or four depending on how many LPRM strings are available. If a detector has been bypassed in the LPRM system, that detector is automatically deleted from the RBM processing and the averaging logic is adjusted to average only the remaining detectors.

After selection of a control rod, each RBM channel calculates the average of the related LPRM detectors and calculates a gain factor that will adjust the average to 100. Thereafter, until another rod is selected, the gain factor is applied to the LPRM average to obtain the RBM signal value. The RBM signal value is compared to RBM trip setpoints.

When a peripheral rod is selected, or if the APRM value from the RBM’s associated APRM is below the automatic bypass level (approximately 30% power), the RBM function is automatically bypassed, the rod block outputs are set to "permissive", and the RBM average is set to zero.

Each RBM channel receives the total recirculation flow and status from all four APRMs using high-speed fiber optic communication links to provide circuit isolation. The RBM channel provides a trouble alarm (flow compare) when the difference between max and min values for total recirculation flow exceeds a user defined setpoint (typically 10%), however, the alarm is bypassed when the reactor mode switch is not in the “RUN” position.

A surveillance (channel check) finding that the self-test is not operating in both RBMs (means the recirculation flow comparison function is not available) will not automatically result in any APRM/OPRM channel being declared inoperable, but will result in an increased rate of "flow comparison" manual surveillances. The flow comparison surveillance will be performed at nominally hourly frequencies to correspond to the self-test frequencies assumed in the unavailability analysis for the PRNM system.

Trip Function

The RBM supplies a trip signal to the Reactor Manual Control System to inhibit control rod withdrawal. The trip is set whenever the RBM signal value exceeds the RBM setpoint.

There are three different setpoints, each a percentage above the RBM initial value of 100. Figure 7.6-22(b) illustrates the trip setpoints. The particular setpoint that is applied is selected based on the simulated thermal power value from the RBM's associated APRM channel (an alternate APRM channel is assigned and is automatically used for inputs if the primary APRM channel is bypassed or inoperative). Higher APRM simulated thermal power values select a lower setpoint. That is, at higher power levels, the percentage increase in the RBM value allowed is less than at lower power levels.

Below 30 percent power, fuel damage cannot occur for any single rod withdrawal; hence, the RBM system is automatically bypassed. The low trip setpoint (LTSP) is enforced between 30 percent and 65 percent power, the intermediate trip setpoint (ITSP) is enforced between 65 percent and 85 percent power, and the high trip setpoint (HTSP) is enforced between 85 percent and 100 percent power. The core power input used to automatically select the applicable RBM trip is provided by the APRM. The RBM system is automatically bypassed if the control rod has one or more adjacent fuel bundles comprising the outer boundary of the core. The operator can bypass one of the two RBMs at any time. Either RBM can inhibit control rod withdrawal (Figure 7.6-16, Sheet 1). Table 7.6-10 indicates the trips.

Isolation Separation and Redundancy - The RBM channels A and B are redundant, separate, and isolated. The only exception is the sharing of LPRM C level detectors by both RBM channels. The impact on the availability of the RBM system due to the sharing of the C level detectors is small (Reference 9) and the benefits of the improved signal response far outweigh any perceived loss in signal redundancy; some other salient features are:

a. Redundant, separate, isolated rod selection information (including isolated contacts for each rod selection push button) provided directly to each RBM channel.

b. Independent, isolated RBM level readouts and status displays from the RBM channels.

c. Independent, isolated rod block signals from RBM to the RMCS circuitry.

Testability

The RBM channels are tested and calibrated. The RBMs are functionally tested by introducing test signals into the RBM's channels.

7.6.1.13.7.2 Environmental Considerations

See the description for the APRM.

7.6.1.13.8 Traversing In-Core Probe System

7.6.1.13.8.1 Equipment Design

Circuit Description

The TIP system includes five TIP machines. Each TIP machine includes the following components:

a. One TIP

b. One drive mechanism

c. One indexing mechanism

d. Up to 10 in-core guide tubes

e. One chamber shield

f. One guide tube valve.

The subsystem allows calibration of LPRM signals by correlating TIP signals to LPRM signals as the TIP is positioned in various radial and axial locations in the core. The guide tubes inside the reactor are divided into groups. Each group has its own associated TIP machine.

Physical Arrangement

A TIP drive mechanism uses a fission chamber attached to a flexible drive cable. The cable is driven from outside the drywell by a gearbox assembly. The flexible cable is contained by guide tubes that penetrate the reactor core. The guide tubes are a part of the LPRM detector assembly. The indexing mechanism allows the use of a single detector in any one of ten different tube paths. The tenth tube is used for TIP cross-calibration with the other TIP machines.

The control system provides both manual and semiautomatic operation. Electronics on the TIP panel amplifies and displays the TIP signal. Core position versus neutron flux is provided to the computer. A block diagram of the drive system is shown in Figure 7.6-23.

The heart of each TIP machine is the probe (Figure 7.6-24). It consists of a detector (fission chamber) and the associated signal drive cable. The body of the fission chamber is made of titanium with a neutron-sensitive inner coating of uranium-235. The chamber can operate in a neutron flux level of greater than 10^{14} nv. The saturation voltage is approximately 150 V dc (Reference 1).

The signal current from the detector is transmitted from the TIP to amplifiers and readout equipment by means of signal cable, which is an integral part of the mechanical drive cable. The cable drive mechanism contains the drive motor, the cable takeup reel, a mechanical counter, and an absolute encoder. The absolute encoder provides digital pulses to the control unit for positioning the TIP at specific locations along the guide tube.

The drive mechanism inserts and withdraws the TIP and its cable from the reactor and provides detector position indication signals. The drive mechanism consists of a motor and drive gearbox that drives the cable in the manner of a rack and pinion. A two-speed motor provides a high speed for insertion and withdrawal (approximately 60 fpm) and a low speed for scanning the reactor core (approximately 7.5 fpm). A takeup reel is included in the cable drive mechanism to coil the drive cable as it is withdrawn from the reactor. This reel makes it possible to connect the TIP and its cable to the amplifier through a connector rather than slip rings. This reduces possible noise and maintenance problems.

The absolute encoder and mechanical counter are driven directly from the output shaft of the cable drive motor. The absolute encoder position signal and a flux amplifier output are used to plot neutron flux versus TIP position. The TIP position signal is also available to the 3D-Monicore Computer System (3DM). The absolute encoder is used to position the TIP in the guide tube with a linear position accuracy of ±1 in. The absolute encoder can control TIP positions at the top of the core for initiation of scan and at the bottom of the core for changing to fast withdrawal speed.

A circular transfer machine with 10 indexing points functions as an indexing mechanism. One of the 10 locations is available for access to the guide tube common to all the TIP machines. Indexing to a particular tube location is accomplished manually at the control panel by means of a position selector switch that energizes the electrically actuated rotating mechanism.

The tube transfer mechanism is part of the indexing mechanism and consists of a fixed circular plate containing 10 holes on the reactor side that mate to a rotating single-hole plate. The rotating plate aligns and mechanically locks with each fixed-hole position in succession. The indexing mechanism is actuated by a motor-operated rotating drive. Electrical interlocks prevent the indexing mechanism from changing positions until the probe cable has been completely retracted beyond the transfer point. Additional electrical interlocks prevent the cable drive motor from moving the cable until the probe cable has been completely retracted beyond the transfer point. Additional electrical interlocks prevent the cable drive motor from moving the cable until the transfer mechanisms have indexed to the preselected guide tube location (Figure 7.6-16, Sheet 7).

A valve system is provided with a valve on each guide tube entering the primary containment. These valves are closed except when the TIP system is in operation. A ball valve and a cable shearing valve are mounted in the guide tubing just outside the primary containment. They prevent the loss of containment integrity. A guide tube ball valve is opened manually prior to TIP insertion. The shear valve is used only if containment isolation is required when the TIP is beyond the ball valve and when power to the TIP system fails. The shear valve, which is controlled by a manually operated keylock switch, can cut the cable and close off the guide tube. The shear valves are actuated by detonation squibs. The continuity of the squib circuits is monitored by indicator lights in the main control room.

A guide tube ball valve is normally deenergized and is in the closed position. When the ball valve is manually opened, it actuates a set of contacts which gives a signal light indication at the TIP control panel (Figure 7.6-16).

Signal Conditioning

The readout instruments and electrical controls for the TIP machines are mounted in a cabinet in the relay room. Because there are several groups of guide tubes, each with an associated TIP machine, there are also several groups of readout equipment controls mounted in the cabinet. Each set of readout equipment consists of a dc amplifier and a dc power supply for the TIP polarizing voltage. Each TIP control unit records the flux variations of each scan and provides the results to 3DM for operations.

Testability

The TIP system equipment is tested and calibrated using heat balance data and by use of the common channel.

7.6.1.13.8.2 Environmental Considerations

The equipment and cabling located in the primary containment are designed for the environmental conditions identified in NEDO 31558A per References 7 and 8 in Appendix A.

7.6.1.13.9 Thermal Power Monitor (TPM)

The thermal power monitor (TPM) typically involves the flow-weighted APRM scram in conjunction with a 6-sec time constant circuit.

The APRM has two output signals. The APRM neutron flux signal is representative of the core average neutron flux. The APRM-simulated thermal power (STP) signal represents the fuel surface heat flux. This signal is obtained by passing the neutron flux signal through a nonadjustable, 6-sec first order ("RC") filter to represent the fuel dynamics. A scram signal occurs when

a. The APRM neutron flux signal exceeds a setpoint that is independent of the recirculation flow rate or

b. The APRM STP signal exceeds a setpoint that is dependent on the recirculation flow rate.

If the time constant, which affects scram initiation by the TPM, is less than the effective time constant for the fuel for this type of transient, the TPM should provide a conservative measure of the time variation in surface heat flux. However, if the time constant is appreciably larger than that for the fuel, the fixed APRM trip without a time constant would provide the scram protection. The resulting maximum critical power ratio (MCPR) would then be less than that predicted for the TPM scram, which has a lower setpoint.

A General Electric analysis reported in the Supplemental Reload Licensing Report indicates that with a 6-sec time constant, the TPM scram occurs before the high-neutron-flux scram, because of its lower setpoint of 117 percent nuclear boiler rated (NBR). Therefore, it was appropriate to take credit for TPM scram for the loss of feedwater heater event. Assuming the APRM neutron-flux scram occurs first, the surface heat flux will be below the 117 percent setpoint, and the result will be even less severe.

The TPM used in Fermi 2 is safety grade and is designed to be single-failure proof.

7.6.1.14 Plant Cooling Water Systems Instrumentation and Control

7.6.1.14.1 System Identification

7.6.1.14.1.1 Reactor Building Closed Cooling Water System

The reactor building closed cooling water system (RBCCW) contains three 50 percent-capacity water pumps, two 50 percent-capacity heat exchangers, a makeup tank, a bypass valve for regulating the differential pressure across the supply and return water headers, motorized isolation valves, and a service water supply for discharge of heat from the heat exchangers. During normal operation(with or without RBCCW supplemental cooling in operation), two heat exchangers and two pumps are in service, and one pump is retained in standby. Automatic controls are provided in the RBCCWS to maintain within their operational range the demin water level in the makeup tank, the water temperature at the outlet of the heat exchanger, and the differential pressure between the supply and return water headers.

When the GSW temperature is 60°F or greater, operators have the option of placing the RBCCW supplemental cooling loops in service. Each loop is furnished with two 100 percent-capacity pumps and a plate and frame heat exchanger. Each RBCCW-SC loop takes suction from the RBCCW return header downstream of the RBCCW/EECW system interface, passes this water through a plate and frame heat exchanger in that loop to cool the RBCCW supplemental cooling water with chilled water from the supplemental cooling chilled water (SCCW) system, and discharges the cooled water to the RBCCW supply header just upstream of the RBCCW/EECW interface. When the RBCCW supplemental cooling pumps are in operation, each RBCCW supplemental cooling loop alone provides RBCCW flow to its respective division of EECW; thus the RBCCW supplemental cooling loops operate in parallel with the two 50 percent-capacity RBCCW pumps that service the nonessential loads outside of the EECW loops. Further details of the RBCCW supplemental cooling loops are described under Section 9.2.2.2.

7.6.1.14.1.2 Turbine Building Closed Cooling Water Systems

The TBCCWS contains three 50 percent-capacity water pumps, two 100 percent-capacity heat exchangers, a makeup tank, a bypass valve for regulating the differential pressure across the supply and return headers, and a service water supply for discharge of heat from the heat exchangers. One pump and one heat exchanger are retained on standby. Automatic controls are provided to maintain condensate level in the makeup tank and the water temperature at the outlet of the heat exchanger outlet to the supply header, and to regulate the differential pressure across the supply and return headers.

7.6.1.14.1.3 Classification

The RBCCWS is classified by regions, as indicated in Subsection 9.2.2. In the regions of the RBCCWS pumps, heat exchangers, makeup tank, and service water system, (including the RBCCW supplemental cooling loops), the classification is Quality Group D. In the regions of the drywell and the emergency equipment cooling water system (EECWS) components, the classification is Category I, Quality Group B and C, respectively. Elsewhere the classification is Quality Group D. The turbine building closed cooling water system (TBCCWS) and the supplemental cooling chilled water (SCCW) system are classified Quality Group D.

7.6.1.14.2 Supporting Systems

7.6.1.14.2.1 Electrical Power

The electrical power for the instrumentation and control of the RBCCWS and TBCCWS is from the 120-V ac circuit which is stepped down from the 480 bus supplying power to the pumps. Power for operating the coils of the pump circuit breakers and associated condition-indicating lights is 130 V dc. A detailed description of the ac and dc power system is contained in Subsection 8.3.1.

7.6.1.14.2.2 Pneumatic Power

In the RBCCWS and TBCCWS, pneumatic power is used for operation of the makeup tank level controller, heat exchanger outlet temperature controller, and water header differential pressure controller. In the RBCCW supplemental cooling loop, pneumatic power is used for operation of the temperature control valves. The pneumatic power is supplied by the air system described in Subsection 9.3.1.

7.6.1.14.2.3 Service Water

Cooling water for the RBCCWS and TBCCWS heat exchangers is taken from the general service water (GSW) system of the plant. Details of the GSW system are contained in Subsection 9.2.1.

GSW also provides the source of condenser cooling water for the supplemental cooling chilled water auxilliary support system to the RBCCW supplemental cooling loops. Details of the SCCW system are contained in Subsection 9.2.9.

7.6.1.14.3 Equipment Design

7.6.1.14.3.1 Initiating Circuits

Normal initiation of pump operation and shutdown in the RBCCWS and TBCCWS is by manual control. Selection of one or two pumps to be operational is made by the operator in response to bypass-valve position indications that are activated by two position switches, one closing at the 10 percent valve open position and the other at the 85 percent open position. Auxiliary controllers within the RBCCWS and TBCCWS function automatically to regulate the demin water level in the makeup tank, temperature at the process outlet of the heat exchanger, and the differential pressure across the supply and return headers.

Separate controls automatically regulate the bypass of RBCCW flow around the RBCCW supplemental cooling plate-and-frame heat exchangers to regulate the temperature of the water supplied by the RBCCW supplemental cooling loops when they are in operation. Manual operation of the temperature control valve is described in section 9.2.2.2. When RBCCW supplemental cooling is not in service, the RBCCW differential pressure controller functions to maintain EECW differential header pressure. With RBCCW supplemental cooling in operation, EECW differential header pressure is maintained by operation of the RBCCW supplemental cooling pumps themselves. In this mode of operation, the RBCCW differential pressure controller does not function to maintain EECW header differential pressure; however, it functions to allow two RBCCW pump operation outside of the RBCCW supplemental cooling loops.

7.6.1.14.3.2 Logic and Sequencing

The control logic diagrams for the RBCCWS and TBCCWS pumps are illustrated in Figures 7.6-25(1) (excluding RBCCW Supplemental Cooling) and 7.6-26, respectively. Operation of the pumps is prevented if the level in the associated makeup tank or the suction pressure at the pump inlet is at or below the lower limit of the established control range (Table 7.6-2). The control logic diagram for the RBCCW supplemental cooling loops is illustrated in Figure 7.6-25(2). RBCCW supplemental cooling pump operation is prevented on the same RBCCW makeup tank low level level signal. The RBCCW supplemental cooling pumps are not equipped with low pump suction trips. Equipment protection is provided instead with low flow trips. An EECW start signal initiates closure of the RBCCW/EECW system isolation valves; a low flow condition in the RBCCW supplemental cooling loops results, which trips the RBCCW supplemental cooling pumps. The low flow trip is not required to assure the operation of the EECW during or after receipt of the initiation signal.

Four sensors for each of the two parameters (demin water level and suction pressure) supply inputs to a "one-out-of-two taken twice" logic arrangement to inhibit pump operation if these parameters are below normal. Activation of the logic for low suction pressure trips only the pump at which the low pressure is sensed.

Activation of the logic for low demin water level in the makeup tank trips all the pumps in that system.

7.6.1.14.3.3 Bypasses and Interlocks

Loss of offsite power, high drywell pressure, or drop in differential pressure across the supply and return headers of the RBCCWS results in isolation of coolant circuits that are not essential in an emergency and in automatic initiation of EECWS operation.

Restoration of RBCCWS operation after power becomes available is by manual control. On loss of offsite power, the TBCCWS is deactivated. Initiation of system operation after power becomes available is by manual control.

7.6.1.14.3.4 Redundancy and Diversity

The RBCCWS contains two divisions of flow, one of which is a redundant division. Under normal conditions both divisions are operational. On loss of offsite power, high drywell pressure, or drop in differential pressure across the supply and return headers, the EECWS automatically takes over the function of supplying cooling water to vital equipment served by the two divisions (Section 7.3).

7.6.1.14.3.5 Testability

The controls of the RBCCWS and TBCCWS are fully testable during normal operation of the plant as well as during shutdown periods.

7.6.1.14.4 Environmental Considerations

The instrumentation and control of the RBCCWS and TBCCWS is designed to function with reliability under the environmental conditions that would be encountered under normal or postulated abnormal conditions. These conditions are defined in Tables 3.11-3 and 3.11-4.

7.6.1.14.5 Operational Considerations

7.6.1.14.5.1 Normal

Under normal plant conditions, the RBCCWS and TBCCWS are operated with one or two pumps, initiated manually, to meet the cooling needs as they arise. In the event of a malfunction of a pump or heat exchanger, operation of the standby unit is manually initiated, and the malfunctioning unit is deactivated by manual action or by automatic trip. When the GSW supply temperature exceeds 60°F, the operators have the option of initiating the RBCCW supplemental cooling loop(s) to provide additional RBCCW cooling capacity.

7.6.1.14.5.2 Operator Information

Attention of the operator is secured when the need arises for an increase or decrease of pumping capacity in the RBCCWS or TBCCWS by control room annunciators which indicate the near-open or near-closed positions of the bypass valve. Readout instruments are provided locally to display the demin water level and gas pressure in the makeup tanks and the pumps discharge pressure. Control room annunciators also alert operators to abnormal demin water level or gas pressure in the makeup tanks Readout instruments provided in the main control room display process outlet temperature of the heat exchangers and supply/return header pressure. With the RBCCW supplemental cooling loops in operation, the supply temperature to the EECW loops is indicated by the EECW divisional supply temperatures to the drywell. High and low demin water level, low gas pressure in the makeup tanks, and drop in differential pressure or in the supply and return headers of either EECW division are alarmed. Recorders register the initiation, shutdown, or tripout of the pumps in each system.

7.6.1.15 Fuel Pool Cooling and Cleanup System Instrumentation and Control

7.6.1.15.1 System Identification

7.6.1.15.1.1 Function

The purpose of the fuel pool cooling and cleanup system (FPCCS) instrumentation and control is to provide protection for the system from overheating and to provide the operator with information concerning the effectiveness of operation of the system.

7.6.1.15.1.2 Instrumentation Classification

The FPCCS is not a safety-related system. Therefore, the instrumentation is classified as nonessential. The instrumentation is a standard industrial type for which performance has been proven by years of service throughout the industry.

7.6.1.15.2 Power Sources

The FPCCS instrumentation is fed from the plant instrumentation bus. No backup power source is necessary since the FPCCS is not a safety-related system. The system wiring is protected against short circuit by appropriate fuses. Thus, a short circuit within the FPCCS wiring has only a local effect, which can be corrected without shutting down the FPCCS.

7.6.1.15.3 Equipment Design

The equipment for the FPCCS system is comprised of circulating pumps, heat exchangers, filters, surge tanks, and required piping, valves, instrumentation and controls. The spent fuel pool water is continually circulated in a closed loop except when the FPCCS is used to drain the reactor well and dryer-separator pit. The FPCCS functions and description are explained in Section 9.1.3.

The operating configurations for the FPCCS are obtained by means of manually operated valves and weir gates. The system operation is monitored by instrumentation that provides the operator with a means of evaluating system performance and also provides alarms in the event of a malfunction.

Irradiated components and spent fuel require cooling in addition to the shielding provided by the spent fuel pool. The cooling is provided on a continuous basis during normal operation of the FPCCS. The instrumentation of the FPCCS measures conductivity, temperature, system flow rate, level, and leakage. Indications of the system performance are furnished to the plant operators.

7.6.1.15.3.1 Conductivity

The ionic concentration in the water leaving each demineralizer unit is monitored by a conductivity-measuring system consisting of a conductivity cell, indicating transmitter, and a recorder.

7.6.1.15.3.2 Pump Discharge Pressure

The discharge pressure of each FPCCS pump is monitored by its pressure-indicating switch. If the pump discharge pressure falls below the switch setpoint, a contact set of the switch actuates a local indicator lamp. Another flow switch contact set opens in the actuating path of the alarm annunciator “Fuel Pool Cooling Trouble.”

7.6.1.15.3.3 Temperature

The temperature of the liquid in the piping system associated with the FPCCS pumps, heat exchangers, and valves is monitored by individual temperature elements, and the observed temperatures are recorded by a multipoint recorder. Temperature elements monitor the operation of the FPCCS. In each instance, the temperature levels observed by the temperature monitoring circuits are recorded on a multipoint recorder in the main control room.

7.6.1.15.3.4 Leakage

The leakage rates past the refueling bellows and the gate seal or drywell-to-reactor-well seal are monitored by circuit arrangements consisting of a flow switch and alarm annunciator (Figure 9.1-23). Liquid leakage past the refueling bellows is caught and routed past the flow switch before being piped to the drywell equipment drain sump. When the leakage liquid flow rate through the flow switch exceeds the high flow setpoint, flow switch contact sets energize an indicator lamp and initiate the alarm annunciator, "Fuel Pool Cooling Trouble."

7.6.1.15.3.5 Level

The water levels in both the spent fuel pool and the skimmer surge tank are monitored by alarm annunciator circuits. The spent fuel pool water level is monitored by a level sensor switch assembly that trips if the water level rises above the high level setpoint. On the high-level trip, the alarm annunciator activates and a local indicator lamp lights. Lowered water level automatically resets the level-sensing alarm circuitry.

The skimmer surge tank water level is monitored for both high and low water level. A high-water condition trips a level switch, which activates the alarm annunciator and lights a white indicator lamp. Subsequent lowering of the water level below the high trip setpoint automatically resets the alarm circuitry. Excessively low water levels in the skimmer surge tank cause a trip in the low water level sensor level switch. An alarm annunciator actuates and a white indicator lamp lights on the trip. The alarm circuit automatically resets with normal water level restored in the tank.

All annunciator alarms are located in the main control room panel with their attendant instrumentation located at local panels. The sensors are located at their respective monitoring positions. Specific alarm points are listed in Table 7.6-11.

To comply with NRC Order EA 12-051, spent fuel pool levels are monitored by Primary and Backup instrument channels. Each channel consists of a seismically installed level probe in the spent fuel pool, a signal processor with battery backup, and a remote level indicator. Primary and backup indicators are located in the main control room and reactor building second floor which are capable of supporting the following spent fuel pool actual water levels:

Level 1: Level that is adequate to support operation of the normal fuel pool cooling system, i.e. the surface of the water is maintained at Elevation 683’6” by scuppers that act as skimmers and wave suppressors.

Level 2: Level that is adequate to provide substantial radiation shielding for a person standing on the spent fuel pool operating deck, i.e. 18’ above the top of the fuel in the storage racks (el. 679’ 1/8”)

Level 3: Level where fuel remains covered and actions to implement make-up water addition should no longer be deferred, i.e. <12 in. above the top of the fuel in the storage racks (el. 661’ 1/8”)

7.6.1.15.4 Testability

Because the FPCCS is usually in service during plant operation, satisfactory performance is demonstrated without the need for any special inspection or testing beyond that specified in the manufacturer's instructions.

7.6.1.15.5 Environmental Considerations

The FPCCS is not required for safety purposes, nor is it required to operate after the DBA. The FPCCS is required to operate in normal plant environment only.

7.6.1.15.6 Operational Considerations

The FPCCS instrumentation and control is not required for safe operation of the plant. It provides a means of monitoring parameters of the system and protecting the system.

7.6.1.16 Deleted

7.6.1.17 Control Air System

7.6.1.17.1 System Function

The station air system normally provides control air for operation and control of various plant systems that are safety related as well as those that are nonsafety related. If the control air system pressure drops to 85 psig, indicating an abnormal loss of air pressure, the control air compressors will automatically start for the purpose of supply to its associated division and the control air system will be isolated from the station air system and also the nonsafety related plant systems. See Subsection 9.3.1 for a more detailed discussion of the control air system.

7.6.1.17.2 Classification

The noninterruptible portion of the control air system, including the compressors, filters, dryers, afterfilters, and receivers, is classified as Category I. The interruptible portion of the control air system, including its filter, dryer, afterfilter, and receiver, is classified as nonseismic.

7.6.1.17.3 Supporting Systems

7.6.1.17.3.1 Electrical Power

The electrical power required for operation of the control air system is supplied from the 480-V ac bus as described in Subsection 8.3.1.

7.6.1.17.3.2 Service Water

The cooling water required for operation of the control air system is supplied from the RBCCW or EECW system as described in Subsection 9.2.2.

7.6.1.17.4 Equipment Design

7.6.1.17.4.1 Initiating Circuits

Initiation of the noninterruptible control air system compressors occurs automatically on detection of low control air header pressure (85 psig), loss of offsite power, or a level 2 LOCA signal. In addition, isolation of the noninterruptible control air system from the station air and interruptible control air systems occurs automatically on detection of low noninterruptible control air header pressure (85 psig) or a loss of offsite power. Normally, the interties between the station air system and control air systems are open and the noninterruptible control air compressors are in auto standby.

7.6.1.17.4.2 Logic and Sequencing

Pressure sensors are provided to detect low control air system pressure. Activation of the logic for low control air header pressure causes isolation of the control air system and startup of the control air compressor.

7.6.1.17.4.3 Bypasses and Interlocks

A drop in control air header pressure results in isolation to prevent the use of noninterruptible control air by nonessential control air users. If offsite power is available, the control air compressors start prior to system isolation. On loss of offsite power, the control air compressors are started by the automatic load sequencer when diesel generator power becomes available. See Subsection 8.3.1.1.7 for a more detailed discussion of the automatic load sequencer.

7.6.1.17.4.4 Redundancy and Diversity

The noninterruptible control air system consists of two divisions for redundancy. Under normal operating conditions both divisions are supplied from the station air system. On loss of noninterruptible control air pressure, the control air compressors automatically take over the function of supplying control air to the vital equipment served by the two divisions of the control system. The interruptible control air system is supplied separately from the station air system. A normally closed tie from this system can be opened to provide air supply (if available) to the Division II noninterruptible control air system in the event of loss of its normal and control air compressor supply.

7.6.1.17.4.5 Testability

The controls for the control air system are fully testable during normal plant operation as well as during shutdown periods.

7.6.1.17.5 Environmental Considerations

The instrumentation and control of the control air system is designed to function with reliability under the environmental conditions that would be encountered under normal or postulated accident conditions. These conditions are defined in Table 3.11-4.

7.6.1.17.6 Operational Considerations

7.6.1.17.6.1 Normal

Under normal operating conditions, station air is the supply to both control air systems through their respective dryers. Under these conditions, the noninterruptible control compressors are normally in standby. In the event of low control air header pressure, the noninterruptible control air system divisions are isolated from the interruptible air users. The control air compressors will start automatically at the isolation setpoint.

7.6.1.17.6.2 Operator Information

Readout instruments are provided in the main control room to display and record the Division I and II control air pressures.

Recorders register the automatic initiation of the control air system compressors.

7.6.1.18 Alternate Rod Insertion

7.6.1.18.1 Equipment Identification

The alternate rod insertion (ARI) components of the CRD system are designed to mitigate the potential consequences of an anticipated transient without scram (ATWS) event. The ARI components are redundant to the RPS.

7.6.1.18.2 Equipment Design

7.6.1.18.2.1 Initiating Circuits

There are three initiating signals used for the ARI logics, namely:

a. Reactor dome high pressure

b. Reactor low water level 2

c. Manual initiation in the main control room

Any one of the above signals can initiate the divisional ARI logics as shown in Figure 7.7-3, Sheet 4. Additional immediate response to the initiation signals includes the recirculation pump motor generator field breaker trip (see Subsection 7.7.1.2.3.1).

7.6.1.18.2.2 Logic

Two divisional ARI logic systems are provided: Division I, consisting of logic channels A and C, and Division II for logic channels B and D. The signal to insert the control rods is generated in two separate divisions on two-out-of-two logic channels in a given division.

The ARI logic receives reactor dome pressure and water level signals from the nuclear boiler system. The logic causes automatic energization of the ARI solenoid valves when either the reactor high-pressure trip set point or low-water level 2 set point is reached. The ARI logic can also be initiated manually from the main control room. Each ARI logic channel is provided with a disarmed/armed pushbutton switch. Both pushbutton switches in a given division must be depressed to energize the ARI logic and initiate control rod insertion. The ARI initiation signals are designed to seal in the initiation logic to ensure completion of the ARI function until it is reset manually. A reset pushbutton per division is provided in the main control room to clear the ARI logic. A timer is used in each of the ARI logic channels to inhibit the reset function for approximately 30 seconds after the initiation signal is received. A 30-second time delay is selected to ensure completion of the ARI function before the logic can be reset.

The initiation of the two separate ARI logics results in the energization of eight Class 1E dc solenoid valves (four per division). Two of these, F160A and B, vent the scram air supply line just downstream of the F110A and B backup scram valves. (Refer to Figure 7.6-36). These ARI valves also act to block the supply of air to the scram header. Check valves F161A and B provide an air-flow path around the F160 valves in the event one or more of them fails. Four additional ARI valves, F162A, B, C, and D, vent the A and B scram header to the atmosphere. As the header depressurizes, the scram valves at each hydraulic control unit will spring open scramming the rods. Two ARI valves, F163A and B, vent the scram air header to the scram discharge volume drain and vent valves, closing these valves and isolating the scram discharge volume. All eight ARI valves are normally deenergized.

7.6.1.18.2.3 Annunciation and Indication

The manual initiation pushbutton switch in the main control room activates an annunciator window whenever it is placed in armed position. A separate annunciator window is activated upon initiation of the ARI logic circuits. The open and close position of the ARI solenoid valves are also indicated in the main control room.

7.6.1.18.2.4 Testability

Four separate ARI initiation logic channels are provided to permit maintenance, repair, test, or calibration of all circuit devices (at power) up to but not including the final trip devices (ARI solenoid valves). Each ARI logic channel is provided with a test jack and indicating lights to verify logic activation in any given division.

7.6.1.19 Safety/Relief Valves

7.6.1.19.1 System Identification

The nuclear pressure relief system is designed to prevent over-pressurization of the nuclear system that could lead to the failure of the reactor coolant pressure boundary.

7.6.1.19.2 Safety/Relief Valve Equipment Design

Safety/relief valves (SRVs) are dual-functioning types: automatic self-actuating and solenoid operated. The valves are self-actuated when reactor pressure exceeds spring set pressures that are adjustable in range. The SRVs are divided into three spring-set-pressure groups. The first group consists of five valves set to open when vessel pressure exceeds 1135 psig, the second group consists of five valves set to open when vessel pressure exceeds 1145 psig, and the third group consists of five valves set to open when vessel pressure exceeds 1155 psig. The solenoid-operated air pilot valves permit remote manual or automatic opening. The pilot valve controls the pneumatic pressure applied to an air cylinder operator that controls valve opening and closing. Each valve associated with ADS has an accumulator to store pneumatic energy with sufficient capacity for several relief valve operations. The valves are capable of remote manual opening at any pressure above 100 psig and staying open, once opened, until pressure decreases to 50 psig. Five of the SRVs are used for ADS (Subsection 7.3.1.2.2). Two SRVs are used for low-low setpoint relief (Subsection 7.6.1.19.9).

7.6.1.19.3 Initiating Circuits

Reactor pressure exceeding the setpoint actuates the SRV. The SRV can also be manually actuated (by remote manual switch) or automatically by the ADS and low-low setpoint relief logic.

7.6.1.19.4 Logic and Sequencing

No automatic logic is involved in the overpressure safety function of the SRVs. (See Subsection 7.6.1.19.9 for low-low setpoint relief logic and Subsection 7.3.1.2.2 for the ADS logic.)

7.6.1.19.5 Bypasses and Interlocks

Bypasses are not used in the normal SRV function. An arming circuit is used as an interlock to prevent the low-low setpoint valves from prematurely actuating during normal plant operation. The interlock is required because the reopening setpoint of the low valve is near the normal reactor operating range.

7.6.1.19.6 Redundancy and Diversity

Seven of the SRVs and their respective monitoring system pressure switches are powered by Division I. The other eight SRVs and their respective monitoring system pressure switches are powered by Division II. The SRVs are designed to meet ASME Boiler and Pressure Vessel Code Section III, and therefore diversity is not provided.

7.6.1.19.7 Actuated Devices

Relief valves are actuated by the following two means:

a. Self-actuation by reactor pressure exceeding the spring set pressure setpoint

b. Solenoid pilot operation by remote manual control or automatically by ADS (Subsection 7.3.1.2.2) or low-low set relief logic.

7.6.1.19.8 Separation

Logic circuitry, controls, and instrumentation are designed to maintain physical and electrical separation between Division 1 and Division II.

7.6.1.19.9 Low-Low Setpoint Relief Logic

Two of the 15 SRVs are provided with lower opening and closing setpoints that override the normal setpoints following initial opening of one or more SRVs using the normal setpoint. Logic for this low-low setpoint consists of reactor pressure transmitters that are enabled (armed) by a separate reactor high-pressure (scram) signal and a signal that one or more

SRVs are open. The two low-low set SRVs have slightly different opening and closing setpoints, thus ensuring that only one SRV at a time will reopen on increasing pressure after initial SRV actuation and closure. This arrangement serves to damp reactor pressure surges.

The low-low set logic automatically seals itself into control of the two selected valves and actuates an annunciator in the control room. This logic remains sealed in until manually reset by the operator.

Since the two valves will already have opened when reactor pressure exceeded the original (normal) overpressure safety setpoint, the low-low set logic acts to hold the valves open past their normal reclose points until the pressure decreases to a predetermined "low-low" setpoint. Thus, the valves remain open longer than the other SRVs.

The low-low set logic is designed with redundancy and single-failure criteria; that is, no single electrical failure will(1) prevent any low-low set function from operating, and (2) cause inadvertent seal-in of low-low set logic.

The two valves associated with low-low set are arranged in two independent secondary setpoint groups or ranges (low and high). The low- and high-pressure groups consist of one valve each, having both reopen and reclose setpoints independently and uniquely adjustable. These are set considerably lower than their normal SRV setpoints.

Each SRV valve has its own set of two tailpipe pressure switches. These pressure switches are arranged in two divisions for each low-low set valve so that opening of a single SRV will result in arming of both divisions of low-low set logic. The single-failure criterion is thus met for this function.

The operability of the low-low function is dependent on the operability of the instrumentation channels providing inputs to the low-low set logic. Besides the reactor steam dome pressure-high and low-low set pressure setpoint signals, each division of the low-low set logic normally receives at least five SRV pressure switch inputs from one group of SRVs with the same pressure setpoint. The low-low set logic is capable of performing its function (i.e., preventing multiple actuations of the SRVs) even if both pressure switches associated with one SRV tailpipe become inoperable. The loss of SRV position indication in this case will not challenge the assumptions of the safety analyses for a stuck-open SRV event (see Section 15.1.4).

7.6.1.19.10 Low-Low Setpoint Relief Logic Testability

The SRV system has two low-low setpoint logics, one in Division I and one in Division II. Either one can perform the low-low set function. Each valve has its own set of pressure switches. The sensors are arranged in two separate channels per each division and two-out-of-two logic is used to open the valves. Thus, the sensors and logic of each channel can be tested separately without actually actuating the valves. Indicator lights are provided to facilitate logic testing.

7.6.1.19.11 Environmental Considerations

The solenoid valves and their cables, pressure switches for indication, and the SRV operators are the only SRV controls located inside the drywell. All equipment will meet applicable environmental requirements.

7.6.1.19.12 Operator Information

A temperature element is installed on the SRV discharge piping several feet from the valve body. The temperature element is connected to a multipoint recorder in the control center to provide a means of detecting SRV leakage during plant operation. When the temperature in any SRV discharge piping exceeds a preset value, an alarm is sounded in the control room. The alarm setting is far enough above normal (rated power) drywell ambient temperatures to avoid spurious alarms, yet low enough to give early indication of significant SRV leakage.

Valve actuation is monitored by the SRV open/closed monitoring system (SRVOCMS) pressure switches connected to the SRV discharge line. An open SRV pressurizes the discharge line, which actuates the pressure switch that provides the input to the SRV monitor circuit. The monitor circuit provides inputs to SRV annunciators in the control room, to the Integrated Plant Computer System (IPCS), to the open-close indicators in the control room, and to the low-low setpoint relief logic. The SRVOCMS setpoint is selected so the pressure switch will actuate when the SRV opens in the expected operating range but will not respond to a leaking SRV. The expected operating range of the SRVOCMS is from 200 psig to the SRV safety function actuation point. The SRVOCMS uses Class 1E power and has a power supply monitor with annunciation upon loss of power. If a pressure switch becomes inoperable, SRV position indication relies on monitoring the SRV tail-pipe temperature recorder in the relay room as a backup means for determination of an open SRV.

7.6.1.20 Rod Worth Minimizer (RWM)

7.6.1.20.1 System Identification

7.6.1.20.1.1 Function

The objective of RWM is to provide backup to the operator for control rod pattern control in reactor startup and for control rod manipulation during low power operations. The nuclear measurement analysis and control RWM function is described in Reference 7.

7.6.1.20.1.2 Classification

The RWM is used for power generation only.

7.6.1.20.2 Power Source

The RWM receives its power from the 120V AC uninterruptible power supply.

7.6.1.20.3 Description

The RWM microcomputer system is a stand-alone microcomputer-based system with an RWM operator display and a continuous operating self-test feature that enforces adherence to established startup, shutdown, and low power level control rod procedures. The RWM microprocessor prevents the operator from establishing control rod patterns that are not consistent with prestored RWM sequences by initiating appropriate rod withdrawal block and rod insert block signals to the reactor manual control system rod block circuitry. The RWM sequences stored in the microprocessor memory are based on control rod worth at acceptable levels as determined by the design basis rod drop accident analyses.

7.6.1.20.3.1 RWM Inputs

Sequence

Up to four sequences are simultaneously stored for sequence control operation.

The operator is permitted to switch between sequences when all rods are in or when above the low power alarm point (LPAP).

The operator is permitted to switch between sequences at any power level, when both sequences conform to the present rod configuration within a single insert or withdraw error, not exceeding two notches.

Sequence selection is accomplished under keylock control with insert and withdraw blocks applied.

Bypass/Operate/Test

A keylock switch is provided for selection of operate or alternately bypass during sequence control operation.

During reactor shutdown, the test mode provides a single rod permissive function and a shutdown margin test facility.

Control Rod Selected

The input is a binary coded identification of the control rod selected by the operator.

Control Rod Position

The input is a binary coded identification of all rod positions.

Control Rod Drive Selected and Driving

The RWM uses the rod selected and driving input to identify the envelope of rod motion for the selected rod.

Control Rod Bypass

A maximum of eight control rods can be bypassed under keylock control.

Reactor Power Level

Feedwater system signals are used to implement two digital inputs to permit automatic bypass of the RWM function.

The low power set point (LPSP) identifies the power level at which the RWM is automatically bypassed on reactor startup and automatically initiated on reactor shutdown.

The low power alarm point (LPAP) identifies the approach to the LPSP on reactor shutdown.

Select Insert and Select Withdraw

The select insert and select withdraw inputs identify the direction of intended rod motion to permit termination of insert or withdraw motion at the respective insert or withdraw limit.

Insert Bus and Withdraw Bus

The reactor manual control system insert and withdraw bus is monitored to permit timing of rod drive motion.

7.6.1.20.3.2 RWM Outputs

Isolated contact outputs provide RWM Block and Annunciator functions.

RWM insert block and withdraw block are applied for each rod selection to inhibit rod motions which would result in insert or withdraw error.

RWM rod drive block and settle functions are used to terminate continuous rod motion at the respective insert or withdraw limit or if the RWM senses Multiple Rod Motion (See Section 7.6.1.20.3.4).

RWM annunciation draws operator attention to the RWM message log which identifies the reason for the action taken. RWM Annunciation is not systematically applied with insert or withdraw block since these are routinely applied to limit and inhibit rod motion.

7.6.1.20.3.3 RWM Indications

The RWM operator display panel provides indications of operating status including

a. Selected Rod

   Identification of the coordinate of the selected rod along with

   Position of the selected rod

   Select error status

   Insert block status

   Withdraw block status

b. Insert Error

   Identification of control rod coordinate and rod position for up to three insert error rods. Insert error is corrected as the next rod motion.

c. Withdraw Error

   Identification of control rod coordinate and position identification for one withdraw error. Withdraw error is corrected as the next rod motion.

d. Latched Step

   Identification of the current RWM sequence step number.

e. Selected Sequence

   Identification of the selected sequence.

f. Power Level

   Identification of power level is identified as "Below LPSP", "Transition Region", "Above LPAP", or "Unknown". When power level is indicated to be below LPSP and above LPAP, the power level is identified as "Unknown" and the RWM defaults to below LPSP operation.

7.6.1.20.3.4 Additional Functions

In addition to enforcing adherence to established control rod sequences, the RWM performs additional functions. These additional functions, with the exception of the multiple rod motion (MRM) rod drive block and display, are “utilities” which are used to record and display rod position/time data.

a. Single Rod Scram Timing

Single rod scram timing is selected by the operator to record rod position/time data during single rod scram testing.

b. Full Core Scram Timing

Full core scram timing is automatically initiated by a reactor scram signal and records the rod position/time data during a reactor scram.

c. Rod Drive Timing

Rod drive timing is selected by the operator to record rod position/time data for the rod being driven/tested.

d. Single Rod Scram Data Display

Single rod scram data display is selected by the operator during single rod scram testing to display the actual scram time for the rod under test, the average Technical Specification scram time, and margin of the scram time of the tested rod to the Technical Specification time. The display is available at the RWM operators display and RWM computer.

e. Shutdown Verification Display

The Shutdown Verification display is automatically initiated by a reactor scram signal and immediately displays if all rods are full-in, if all rods are inserted to or beyond the shutdown margin limit, and how many rods are not full-in. The shutdown verification screen is displayed at the RWM operators display.

f. Multiple Rod Motion (MRM) Rod Drive Block and Display

The multiple rod motion (MRM) rod drive block and display are initiated when the RWM senses that a rod (or rods) other than the selected rod is moving. MRM is defined as a movement of an unselected rod (or rods) that has resulted from a failure in the reactor manual control system (RMCS) when a valid rod is selected and being moved by the operator. The purpose of the MRM rod drive block is to terminate and limit rod motion of both the selected and any unselected rods to one notch, if an MRM were to occur. The MRM firmware will actuate the existing RWM rod drive block and settle relays to the RMCS and automatically initiate the MRM display at the RWM operator display if the RWM senses that an unselected rod (or rods) is moving. If the RWM is bypassed (keylock switch on the operator display), the MRM screen is automatically selected, but the MRM rod drive block is inhibited by the RWM bypass relay.

7.6.1.20.4 Environmental Considerations

The RWM is not used for credit in the safety analysis, nor is it required to operate during or after any design basis accidents. The RWM is employed to operate in the normal plant environment for power operation.

7.6.1.20.5 Operational Considerations

The RWM function does not interface with normal reactor operation, and in the event of its failure does not cause new rod patterns. The RWM function may be bypassed and its rod block function disables only by specific procedural control initiated by the operator, in accordance with the Technical Specifications.

With the RWM inoperable, a second licensed operator or other technically qualified member of the unit technical staff who is present at the reactor control console verifies the control rod movement compliance with the prescribed control rod pattern. The requirements for a rod motion verifier and the specified actions expected of the operator and verifier are proceduralized including:

Procedural guidance for control of Rod Pull Sheets to ensure correct pullsheets are used

Explicit instructions to the operator and verifier are contained in a Rod Pull Cover Sheet

Each operator and verifier reviews the cover sheet prior to pulling rods.

Explicit instructions are included to the verifier as to how and where to verify proper rod selection and positioning.

7.6.2 Analysis

7.6.2.1 Refueling Interlock System Instrumentation and Control

7.6.2.1.1 Conformance To General Functional Requirements

a. Safety Evaluation

The refueling interlocks, in combination with core nuclear design and refueling procedures, limit the probability of an inadvertent criticality. The nuclear characteristics of the core ensure that the reactor is subcritical even when the highest-worth control rod is fully withdrawn. Also, refueling procedures are written to avoid situations in which inadvertent criticality is possible. The combination of refueling interlocks for control rods and the refueling platform provides redundant methods of preventing inadvertent criticality even after procedural violations. The interlocks on hoists provide yet another method of avoiding inadvertent criticality.

Table 7.6-1 illustrates the effectiveness of the refueling interlocks. This table considers various operational situations involving rod movement, hoist load conditions, refueling platform movement and position, and mode switch manipulation. The initial conditions in situations 4 and 5 appear to contradict the action of refueling interlocks, because the initial conditions indicate that more than one control rod is withdrawn, yet the mode switch is in REFUEL. Such initial conditions are possible if the rods are withdrawn when the mode switch is in STARTUP and then turned to REFUEL. In all cases, correct operation of the refueling interlock prevents either the operation of loaded refueling equipment over the core when any control rod is withdrawn or the withdrawal of any control rod when fuel-loaded refueling equipment is operating over the core. In addition, when the mode switch is in REFUEL, only one rod can be withdrawn; selection of a second rod initiates a rod block.

7.6.2.1.2 Conformance To Specific Regulatory Requirements

No specific regulatory requirements apply to refueling interlocks. The refueling interlocks are designed to be normally energized (fail-safe).

IEEE standards do not apply because the refueling interlocks are not required for any postulated DBA or for safe shutdown. Furthermore, the interlocks are required only for the refueling mode of plant operation.

The requirements of 10 CFR 50, Appendix B, are met in the manner set forth in Chapter 17.

7.6.2.2 Reactor Pressure Vessel Instrumentation and Control

7.6.2.2.1 Conformance To General Functional Requirements

The RPV instrumentation and systems are designed to augment the existing information from the ESF systems such that the operator can start up, operate at power, shut down, and service the reactor systems in an efficient manner. None of this instrumentation is required to initiate an RPS or ESF system.

7.6.2.2.2 Conformance To Specific Regulatory Requirements

There are no specific regulatory requirements imposed on the RPV instruments and subsystems discussed in Subsection 7.6.1.2 because of the reasons stated in Subsection 7.6.2.2.1 above.

The requirements of 10 CFR 50, Appendix B, are met in the manner set forth in Chapter 17.

7.6.2.3 Process Radiation Monitor Systems

The process radiation monitor systems are described in Section 11.4.

7.6.2.4 Area Radiation Monitor System Instrumentation and Control

See Subsection 12.1.4.

7.6.2.5 Offsite Environs Radiation Monitor Systems

See the Offsite Dose Calculation Manual (ODCM).

7.6.2.6 Rad-Chem Radiation Monitoring Instruments

See Section 12.3.

7.6.2.7 Reactor Water Cleanup System Instrumentation and Control

7.6.2.7.1 General

The RWCU system is not a safety-related system. Therefore, the instrumentation supplied is for the plant equipment protection only.

7.6.2.7.2 Conformance To General Functional Requirements

The RWCU system is protected against overpressurization by relief valves. The ion exchange resin is protected from high temperature by temperature switches upstream of the filter-demineralizer unit. One switch activates an alarm when the water temperature reaches 130°F. A second switch provides a signal at 140ºF to close a motor-operated valve in the suction line to the RWCU pumps, which subsequently trips the pumps on low discharge flow.

Three motor-operated isolation valves close automatically on a reactor low water level signal. The outermost isolation valves G33F004 and G33F220 also close automatically when the standby liquid control system is activated. The isolation valves provide a pump trip when the valves close.

A high differential pressure across the filter-demineralizer or its discharge strainer automatically closes the unit's outlet valve after sounding an alarm. The holding pump starts whenever there is low flow through a filter-demineralizer. The precoat pump does not start when the level in the precoat tank is low.

Sampling stations are provided to obtain reactor water samples from the entrance and exit of both filter-demineralizers.

The system instrumentation and control for flow, pressure, temperature, and conductivity is recorded and/or indicated on a panel in the main control room. Instrumentation and control for backwashing and precoating the filter-demineralizers is on a local panel in the reactor building. Alarms are sounded in the main control room to alert the operator to abnormal conditions.

The RWCU system is controlled by the operator from the main control room.

A list of the RWCU system annunciators is given in Table 7.6-14.

7.6.2.7.3 Conformance To Specific Regulatory Requirements

Since the RWCU system is not a safety-related system, no specific regulatory requirement is applicable.

7.6.2.8 Leak Detection System Instrumentation and Control

7.6.2.8.1 General

The part of LDS instrumentation that is related to the system isolation circuitry is designed to meet requirements of the ESF system.

7.6.2.8.2 Conformance To General Functional Requirements

There are at least two different methods of detecting abnormal leakage from each system within the nuclear system process barrier and in each area as shown in Table 5.2-11. The instrumentation is designed so that it may be set to provide alarms at established leakage rate limits and isolate the affected system,if necessary. The alarm points are determined analytically based on design data and on measurements of appropriate parameters made during startup and preoperational tests. This satisfies the power generation design basis and safety design basis.

The unidentified leakage rate limit is based, with an adequate margin for contingencies, on the crack size large enough to propagate rapidly. The established limit is sufficiently low so that even if the entire unidentified leakage rate were coming from a single crack in the nuclear system process barrier, corrective action could be taken before the integrity of the barrier is threatened with significant compromise.

The limit on total leakage rate is established so that in the absence of normal ac power and feedwater, and without using the ECCSs, the leakage loss from the nuclear system could be replaced. The limit on total leakage also allows a reasonable margin below the discharge capability of either the floor drain or equipment drain sump pumps. Thus, the established total leakage rate limit allows sufficient time for corrective action to be taken before either the nuclear system coolant makeup or the drywell sump removal capabilities are exceeded.

7.6.2.8.3 Conformance To Specific Regulatory Requirements

Compliance With Regulatory Guide 1.22

The portion of the LDS that provides outputs to the system isolation logic is designed so that complete periodic testing of the isolation system actuation function is provided. This is accomplished by tripping the LDS one channel at a time from the leak detection panel in the main control room. An indicator lamp is provided to show that the particular channel is tripped.

Compliance With General Design Criteria 13 and 19-24 of 10 CFR 50

The leak detection sensors and associated electronics are designed to monitor the reactor coolant leakage over all expected ranges required for the safety of the plant. Automatic initiation of the system isolation action, reliability, testability, independence, and separation have been factored into leak detection design as required for isolation systems.

Compliance With IEEE 279-1971

Compliance of the LDS with IEEE 279-1971 is included in the IEEE 279-1971 compliance discussion of the CRVICS (Subsection 7.3.2.3.3.1) for which this system provides logic trip signals.

Compliance With IEEE 323-1971 - Leak detection compliance is shown in Topical Report NEDO-l0698. See also Section 3.11.

Compliance With IEEE 338-1971 - Leak detection compliance with IEEE 338-1971 is shown. All active components of the LDS associated with the isolation signal can be tested during plant operation.

Compliance With IEEE 344-1971 - Leak detection compliance with IEEE 344-1971 is shown in Topical Report NEDO-10678. See also Section 3.10.

7.6.2.9 Integrated Plant Computer System (IPCS)

The IPCS, exclusive of the meteorological and emergency response functions, is designed to provide the operator with certain information as defined in the equipment description in Subsection 7.6.1.9. The system augments existing information from other systems such that the operator can start up, operate at power, and shut down in an efficient manner. There are no specific regulatory requirements associated with this portion of the IPCS capabilities.

See Subsection 7.6.1.9.1.2.5.1 for a discussion of the design analysis of the IPCS Safety Parameter Display System (SPDS) function. NRC guidance on safety parameter systems is contained in Supplement 1 to NUREG-0737.

The IPCS, inclusive of all its functions, is not required to initiate any ESF or safety-related system.

7.6.2.10 (Deleted)

7.6.2.11 Sequence Recorder

The sequence recorder is designed to provide the necessary data and information systems to permit diagnosing the causes of unscheduled reactor shutdowns and determine the proper functioning of safety-related equipment. The requirements of generic letter 83-28 are met for post-trip review. The power source is reliable and non-interruptible. The system meets the requirements to record, recall, and display data and information to permit post-trip review.

7.6.2.12 Primary Containment Monitor Systems

7.6.2.12.1 Primary Containment Radiation and Hydrogen/Oxygen Monitor System

Conformance To Specific Regulatory Requirements

The primary containment radiation monitor subsystem is designed to monitor the primary containment for determination of radiation level during reactor operation or shutdown periods. The rate of flow of drywell atmosphere sample is sufficiently high to provide readings representative of the radiation level in the drywell in less than 5 minutes. Filters are provided in the sample supply line to the primary containment radiation monitor to collect particulates and halogens, on separate filters, for analysis. Monitored radiation level above a predetermined level is alarmed and annunciated in the main control room.

The diversity requirement of Regulatory Guide 1.45 is met by the noble gas activity monitor alarm; activity (cpm) is not required to be correlated with leak rate (gpm) per an exemption granted in NUREG 0798, Section 5.2.5.

The requirements of General Design Criterion (GDC) 30 of 10 CFR 50, Appendix A, are met in that the primary containment radiation monitor system provides means, as required, for monitoring the reactor primary containment atmosphere radioactivity.

In addition, the primary containment is monitored for hydrogen/oxygen with indication and high alarms in the main control room in compliance with Regulatory Guide 1.7 and Regulatory Guide 1.97, Rev 2, Category 3 and 2 requirements, respectively.

The design of the primary containment radiation monitor system incorporates provisions for indicating activity level of noble gases, and collecting particulates and halogens on filter papers for laboratory analysis. Also provided are trip logic provisions for actuating an alarm and an annunciator to inform operations personnel of low-scale conditions that would be indicative of instrument failure.

7.6.2.12.2 Primary Containment Temperature Monitor Subsystem

7.6.2.12.2.1 Conformance To General Functional Requirements

The primary containment temperature monitor subsystem is designed to fulfill the safety and power generation design bases and industry standards that are stated under Subsection 7.1.2.1.22.

7.6.2.12.2.2 Conformance To Specific Regulatory Requirements

The primary containment temperature monitor subsystem is designed to monitor continuously the temperature of the drywell atmosphere, drywell walls, drywell cap atmosphere, pressure suppression chamber atmosphere, and pressure suppression chamber water pool.

The requirements of GDC 13 of 10 CFR 50, Appendix A, are met in that the primary containment temperature monitor system provides instrumentation to obtain temperature measurements in the designated areas during normal operation, as well as postulated abnormal conditions of a LOCA.

The requirements of 10 CFR 50, Appendix B, are met in the manner set forth in Chapter 17.

The design of the primary containment temperature monitor subsystem includes multipoint recorders in the main control room, on which the temperatures monitored by the subsystem are continuously recorded and displayed.

7.6.2.12.3 Primary Containment Pressure Monitor Subsystem

7.6.2.12.3.1 Conformance To General Functional Requirements

The primary containment pressure monitor subsystem is designed to fulfill the safety and power generation design bases and industry standards stated in Subsection 7.1.2.1.22.

7.6.2.12.3.2 Conformance To Specific Regulatory Requirements

The primary containment pressure monitor system is designed to continuously monitor atmospheric pressure in the drywell and in the pressure suppression chamber.

The requirements of GDC 13 of 10 CFR 50, Appendix A, are met in that the primary containment pressure monitor subsystem has instrumentation that is provided, as required, for measurement and recording of pressure during normal operation, as well as postulated abnormal conditions of a LOCA.

The requirements of 10 CFR 50, Appendix B, are met in the manner set forth in Chapter 17.

The design of the primary containment pressure monitor subsystem includes chart recorders in the main control room, on which the pressure monitored by the subsystem is continuously recorded and displayed.

7.6.2.12.4 Pressure Suppression Pool Water Level Indicator Subsystem

7.6.2.12.4.1 Conformance To General Functional Requirements

This system is designed to fulfill the safety and power generation design bases and industry standards stated in Subsection 7.1.2.1.22.

7.6.2.12.4.2 Conformance To Specific Regulatory Requirements

The design of the pressure suppression pool water level indicator subsystem provides continuous monitoring of the water level in the pressure suppression chamber.

The requirements of GDC 13 of 10 CFR 50, Appendix A, are met in that the pressure suppression pool water level indicator system constitutes instrumentation that is provided, as required, to monitor the pool water level during normal operation as well as postulated abnormal conditions of a LOCA.

The requirements of 10 CFR 50, Appendix B, are met in the manner set forth in Chapter 17.

The pressure suppression pool water level indicator subsystem design includes chart recorders in the main control room on which the monitored level of the water pool is continuously recorded and displayed.

7.6.2.13 Neutron Monitoring System Instrumentation and Control

7.6.2.13.1 Source Range Monitor System

7.6.2.13.1.1 Conformance To General Functional Requirements

The arrangement of the source range monitors (SRM) in the reactor is shown in Figure 7.6-12. This arrangement and irradiated fuel produce at least three counts per second in the SRM using the sensitivity noted in Subsection 7.6.1.13.3. If the discriminator setting is adjusted to produce the specified sensitivity, the signal-to-noise count ratio is well above the 2:1 design basis for cold startup.

If the multiplication of one section of the core increases to put that section of the reactor on a 20-sec period, the nearest SRM chamber shows an increase in count rate. In general, at least one detector indicates the change in multiplications.

Normal startup procedures ensure that withdrawal of control rods is distributed about the core to prevent excessive multiplication in any one section of the core. Hence, each SRM chamber can respond in some degree during the initial rod withdrawal.

Examination of the sensitivity of the SRM detectors and their operating ranges of 10^6 counts per second indicates that the IRM is on scale before the SRM reaches full scale (Figure 7.6-15). Further overlap is provided by partial retraction of the SRM chambers. Such retraction is possible only if the indicated SRM count rate remains above the rod block trip level (approximately 100 counts per second), or if the IRM has been set to the third or any less sensitive (higher) IRM range.

7.6.2.13.1.2 Conformance To Specific Regulatory Requirements

There are no specific regulatory requirements of the SRM system.

7.6.2.13.2 Intermediate Range Monitor System

7.6.2.13.2.1 Conformance To General Functional Requirements

Subsection 7.2.1.1 evaluates the arrangement of redundant input signals to the RPS. The NMS trip input to the RPS and the trip channels used in actuating a NMS trip are of equivalent independence and redundancy to other RPS inputs.

The number and locations of the IRM detectors have been analytically and experimentally determined to provide sufficient intermediate range flux level information under the worst permitted bypass or detector failure conditions. To verify this, a range of rod withdrawal accidents has been analyzed. The most severe case assumes that the reactor is barely subcritical. One-fourth of the control rods plus one more rod have been removed in the normal operating sequence (Figure 7.6-37). The error or malfunction is removal of the control rod adjacent to the last rod withdrawn. This rod has been chosen to maximize the distance to the second nearest detector for each trip system. It is assumed that the nearest detector in each RPS trip system is bypassed.

A scram signal is initiated when one IRM detector in each RPS trip system reaches its scram trip level. The neutron flux versus distance resulting from this withdrawal is shown in Figure 7.6-38. Note that the second nearest detector in trip system B is farther away than the second nearest detector in trip system A. The ratio of the neutron flux at this point to the peak flux is l:4l00. This detector reaches its high scram trip setting of 95 percent of full scale at a local flux approximately 3.3 x 10^8 nv. At that time the peak flux in the core is 1.35 x 10^{12} nv or 2.7 percent rated average flux. The core average power is 0.07 percent when scram occurs. For this scram point to be valid, the IRM must be on the correct range. To ensure that each IRM is on the correct range, a rod block is initiated any time the IRM is both downscale and not on the most sensitive (lowest) scale. A rod block is initiated if the IRM detectors are not fully inserted in the core unless the reactor mode switch is in the RUN position.

The IRM scram trips and the IRM rod block trips are automatically bypassed when the reactor mode switch is in the RUN position.

The IRM detectors and electronics have been tested under operating conditions and verified to have the operational characteristics described. They provide the level of precision and reliability required by the RPS safety design bases.

The IRM is the primary source of information as the reactor approaches the power range. Its linear steps (approximately a half decade) and the rod blocking features on both high flux level and low flux level require that all the IRM'S are on the correct range as core reactivity is increased by rod withdrawal. The SRM overlaps the IRM. The sensitivity of the IRM is such that the IRM is on scale on the least sensitive (highest) range with approximately 15 percent reactor power.

7.6.2.13.2.2 Conformance To Specific Regulatory Requirements

Compliance With Regulatory Guide 1.22

The portion of the IRM system that provides outputs to the RPS is designed to provide complete periodic testing of protection system actuation function as desired. This provision is accomplished by initiating an output trip on one IRM channel at any given time, which will result in tripping one of the two RPS trip systems. Details are provided in Topical Report NEDO-10139, Subsection 2.2.8 (Reference 8).

Operator indication of IRM bypass is provided by indicator lamps as described in NEDO-10139, Subsection 2.2.8.13 (Reference 8).

Compliance With General Design Criteria 13 and 22-24 of 10 CFR 50

The IRM detectors and associated electronics are designed to monitor the in-core flux over all expected ranges required for safety of the plant.

Automatic initiation of RPS action, reliability, stability, independence, and separation has been factored into the IRM design as required for protection systems.

Compliance With IEEE 279-1971 - The IRM design is shown to comply with the design requirements of IEEE 279-1971 in Subsection 2.2.8 of Reference 8.

Compliance With IEEE 323-1971 - IRM compliance is shown in Topical Report NEDO-10698. See also FSAR Section 3.11.

Compliance with IEEE 338-1971 - IRM compliance with IEEE 338-1971 is shown in Subsections 2.2.8.9 and 2.2.8.10 of Reference 8.

Compliance With IEEE 344-1971 - IRM compliance is shown in Topical Report NEDO-10678. See also FSAR Section 3.10.

Compliance with 10 CFR 50, Appendix B - The requirements of 10 CFR 50, Appendix B, are met in the manner set forth in Chapter 17.

7.6.2.13.3 Local Power Range Monitor System

7.6.2.13.3.1 Conformance To General Functional Requirements

The LPRM provides detailed information about neutron flux throughout the reactor core. The number of LPRM assemblies and their distribution is determined by extensive calculational and experimental procedures. The division of the LPRM into various groups for ac power supply allows operation with one ac power supply failed or in service without limiting reactor operation.

Individual failed chambers can be bypassed. Neutron flux information for a failed chamber location can be interpolated from nearby chambers. Also, a substitute reading for a failed chamber can be derived from an octant-symmetric chamber, or an actual flux indication can be obtained by inserting a TIP to the failed chamber position. Each output is electrically isolated so that an event (grounding the signal or applying a stray voltage) on the reception end does not destroy the validity of the LPRM signal. Tests and experience attest to the ability of the detector to respond proportionately to the local neutron flux changes (Reference 1).

7.6.2.13.3.2 Conformance To Specific Regulatory Requirements

There are no specific regulatory requirements of the LPRM subsystem. Because they form inputs to the APRM system, however, a minimum number of LPRMs must be operable for each APRM as defined in the APRM safety design basis.

7.6.2.13.4 Average Power Range Monitor System

7.6.2.13.4.1 Conformance To General Functional Requirements

Each APRM derives its signal from LPRM information. The assignment, power separation, cabinet separation, and LPRM signal isolation are in accord with the safety design bases of the RPS. There are four APRM channels with the Reactor Protection System trip outputs from each routed to each of four APRM two-out-of-four voter channels. Two voter channels are associated with each Reactor Protection System trip system. This configuration allows one APRM channel to be bypassed plus one failure while still meeting the Reactor Protection System safety design basis.

Above a plant power level defined by Technical Specifications, the APRM power (and simulated thermal power) is adjusted periodically based on heat balance to match true reactor power. This adjustment is made regularly at a rate sufficient to compensate for LPRM burnup and the related change in APRM values. However, coolant flow changes, control rod movements, and failed or bypassed LPRM inputs can also affect the relationship between APRM measured flux and true reactor power. These predictable APRM variations are included in the analysis performed to determine minimum number of LPRM inputs required to be operable in order for the APRM channel to be operable. The analysis is performed considering worst case combinations of failed LPRM inputs, at rated conditions by assuming both continuous withdrawal of the maximum worth control rod and reduction of recirculation flow to 40% of rated flow. The minimum number of LPRM inputs for an APRM is determined such that the average of the remaining operable LPRM inputs still allows the APRM to track power excursions within the acceptance criteria assumed in plant safety analysis. If the number of operable LPRMs is less than the required minimum, the APRM channel is declared inoperable.

The flow-referenced APRM scram setpoint is adequate to prevent fuel damage during an abnormal operational transient, as demonstrated in Chapter 15.

The APRM also includes an OPRM Upscale function to provide compliance with GDCs 10 and 12, thereby providing protection from exceeding the fuel MCPR safety limit due to anticipated thermal hydraulic induced power oscillations. The OPRM utilizes three algorithms for detecting thermal-hydraulic instability related neutron flux oscillations: the period based detection, the amplitude based, and the growth rate based algorithms. All three are implemented in the OPRM Upscale function, but the safety analysis takes credit for the period based algorithm. The remaining algorithms provide defense in depth and additional protection against unanticipated oscillations. The OPRM Upscale function receives input signals from the LPRMs within the reactor core, which are combined into cells for evaluation by the OPRM algorithms. The OPRM Upscale function is enabled in the intended region on the plant power/flow map. The plant power level and recirculation drive flow conditions are defined by Technical Specifications.

7.6.2.13.4.2 Conformance To Specific Regulatory Requirements

a. Compliance With Regulatory Guide 1.22

The portion of the APRM subsystem that provides outputs to the RPS is designed to provide complete periodic testing of protection system actuation functions as desired. This provision is accomplished by initiating an output trip of one APRM channel at any given time, which will result in tripping one of the two RPS trip systems. Details are provided in Subsection 2.2.8 of Reference 8.

Compliance With General Design Criteria 10 and 12

The OPRM Upscale Function provides compliance with GDC 10 and GDC 12 by providing a hardware/software system that detects and acts to suppress thermal-hydraulic instabilities, thereby providing protection from exceeding the fuel MCPR safety limit due to thermal hydraulic induced power oscillations.

Compliance With General Design Criteria 13 and 20-24 of 10 CFR 50

The APRM detection and associated electronics are designed to monitor the in-core flux over all expected ranges required for safety of the plant.

Automatic initiation of protection system action, reliability, testability, independence, and separation has been factored into the APRM design as required for protection systems.

The requirements of 10 CFR 50, Appendix B, are met in the manner set forth in Chapter 17.

Compliance With IEEE 279-1971 - The APRM design is shown to comply with the design requirements of IEEE 279-1971 in Subsection 2.2.8 of Reference 8 and Subsection 4.4.1.1 of Reference 10.

Compliance With IEEE 323-1971 - APRM compliance is shown in Topical Reports NEDO-10698 and NEDC 32410P-A. See also FSAR Section 3.11.

Compliance With IEEE 338-1971 - APRM compliance with IEEE 338-1971 is shown in Subsections 2.2.8.9 and 2.2.8.10 of Reference 8.

Compliance with IEEE 344-1971 - APRM compliance is shown in Topical Reports NEDO-10678 and NEDC 32410P-A. See also FSAR Section 3.10.

7.6.2.13.5 Rod Block Monitor System

7.6.2.13.5.1 Conformance To General Functional Requirements

Motion of a control rod causes the LPRMs adjacent to the control rod to respond strongly to the change in power in the region of the rod in motion. Figure 7.6-41 illustrates the calculated responses of the two RBMs to the withdrawal of a selected control rod. The RBM setpoints may be selected such that the rod withdrawal error (RWE) is not the limiting transient. Figure 7.6-42 shows the relationship between MCPR and the RBM setpoint. It also shows that for an example operating limit MCPR (OLMCPR) requirement of 1.28, there is a 0.08 margin with 108 percent RBM setpoint (0.03 for 111 percent RBM setpoint). These margins are more than adequate to protect against any RWE events. The RBM setpoints conservatively assume a probability of 15 percent that any given LPRM has failed. The RBM setpoints are also valid for peripheral cells with less than four LPRM strings (the RBM cells near the core periphery may possess fewer than four control rods and have one, two, or three LPRM strings). In some peripheral cases, the responses are actually improved because the missing strings are the weaker signal inputs in a standard RBM cell.

7.6.2.13.5.2 Conformance To Specific Regulatory Requirements

Compliance With General Design Criterion 24 of 10 CFR 50, Appendix A

The RBM provides an interlocking function in the control rod withdrawal portion of the CRD RMCS. This design is separated from the protective functions in the plant to ensure their independence.

The RBM is designed to prevent control rod withdrawal error, given an imposed single failure within the RBM. One of the two RBM channels is sufficient to provide an appropriate control rod withdrawal block.

Compliance with 10 CFR 50, Appendix B

The requirements of 10 CFR 50, Appendix B, are met in the manner set forth in Chapter 17.

7.6.2.13.6 Traversing In-Core Probe Subsystem

7.6.2.13.6.1 Conformance To General Functional Requirements

An adequate number of TIP machines is supplied to ensure that each LPRM assembly can be probed by a TIP and that one LPRM assembly (the central one) can be probed by every TIP to allow intercalibration. Typical TIPs have been tested to prove linearity (Reference 1). The system has been field tested in an operating reactor to ensure reproducibility for repetitive measurements. The mechanical equipment has undergone life testing under simulated operating conditions to ensure that all specifications can be met. The system design allows semiautomatic operation for LPRM calibration and 3DM TIP processing function use. The TIP machines can be operated manually to allow pointwise flux mapping.

7.6.2.13.6.2 Conformance To Specific Regulatory Requirements

There are no specific regulatory requirements of the TIP subsystem.

7.6.2.14 Plant Cooling Water Systems Instrumentation and Control

Conformance To General Functional Requirements

The instrumentation and control of the RBCCWS and TBCCWS is designed to permit reliable operation and testing for each instrument loop or subsystem. Controls for the essential portion of the RBCCWS are described in Subsection 7.3.4

The nonessential portions of the RBCCWS and the TBCCWS are designed to shut down upon loss of offsite ac power. These systems can be restarted manually from the main control room. These systems are designed for manual startup, shutdown, and testing. Automatic controls are provided for maintaining condensate level in the makeup tank, gas pressure in the makeup tank, heat exchanger outlet temperature, and differential pressure across the supply and return headers. Indications, alarms, and/or warning lights for these variables are provided in the main control room. Deviations from normal conditions are thereby brought to the attention of the main control room operator who subsequently can take the appropriate action.

7.6.2.15 Fuel Pool Cleanup System Instrumentation and Control

7.6.2.15.1 General

The FPCCS is not a safety-related system. Therefore, the instrumentation supplied is for the plant equipment protection and for operator information about the system.

7.6.2.15.2 Conformance To General Functional Requirements

The FPCCS is monitored for conductivity, temperature, pool level, flow rate, and leakage.

The conductivity measurement provides the operator with information required to ensure that impurities in the water are limited to acceptable levels.

The low flow (pump discharge pressure) and temperature monitoring provide the operator with information required to ensure that the desired temperature is not exceeded and that filtering is maintained. Pool level and leakage monitoring provide the operator with information assuring the maintenance of adequate shielding and cooling.

Interface

The FPCCS is an independent system during normal operations. Evaporative losses in the system are replaced by the condensate storage system. If the heat load should become excessive, the shutdown cooling portion of the RHR system is operated in parallel with the FPCCS to remove the excess heat load.

7.6.2.15.3 Conformance To Specific Regulatory Requirements

System analysis shows that none of the regulatory requirements are applicable to the FPCCS.

7.6.2.17 Control Air System

Conformance To General Functional Requirements

The instrumentation and control of the control air system is designed to permit reliable operation and testing of each divisional loop of the control air system. The control air system is designed to fulfill the safety and power generation design bases stated in Subsection 7.1.2.1.31.

7.6.2.18 Alternate Rod Insertion

Conformance To General Functional Requirements

The sensors, transmitters, trip units, associated logic, and ARI valves are Class 1E, redundant to and diverse from the reactor protection system, are seismically and environmentally qualified to meet IEEE 323-1974 and IEEE 344-1975, and are supplied with Class 1E dc power.

The ARI equipment is physically separated into two redundant divisions. Either division will be automatically energized to actuate and scram the reactor upon receipt of high reactor pressure or vessel low-water-level 2 signals. The ARI logic may also be initiated manually from the main control room. (See Subsection 7.6.1.18.2 for further details).

7.6.2.19 Safety/Relief Valves Analysis

7.6.2.19.1 Conformance To General Functional Requirements

The SRVs furnished meet requirements of the ASME Boiler and Pressure Vessel Code Section III, Article 9. The valves are operable in two modes: self-actuated or power-actuated solenoid pressure relieving mode. The automatic mode is independent of the power-actuated mode. Failure of the power-actuated mode does not affect the self-actuated mode.

7.6.2.19.2 Conformance To Specific Regulatory Requirements

Compliance With Regulatory Guide 1.22

The logic channels up to the SRV solenoid operators are designed to enhance periodic testing.

Compliance With IEEE 279-1971

A demonstration of the single-failure withstand capability of the generic low-low set design was presented in the BWR Owners Group letter to the NRC, D. B. Vassallo, dated November 19, 1982, titled "Low-Low Set Logic/Lowered MSIV for Mark I Plants."

Compliance With IEEE 323-1974

System components are environmentally qualified as described in Section 3.11.

Compliance With IEEE 344-1975

System components are seismically qualified as described in Section 3.10.

7.6.2.20 Rod Worth Minimizer System

7.6.2.20.1 Conformance to General Functional Requirements

The RWM protects against the existence of a rod worth which could result in the damage to the reactor coolant pressure boundary in the unlikely event of a control rod drop accident.

7.6.2.20.2 Conformance to Specific Regulatory Requirements

There are no specific regulatory requirements for the RWM. The Fermi 2 RWM has been designed to enforce operator adherence to the predetermined sequence of control rod motions during operation at low power levels.

7.7 CONTROL SYSTEMS NOT REQUIRED FOR SAFETY

7.7.1 Description

This subsection discusses control systems whose functions are not essential for the safety of the plant. These systems are the reactor manual control system (RMCS), recirculation flow control system (RFCS), feedwater control system, pressure regulator and turbine-generator controls, and the radwaste processing system controls.

7.7.1.1 Reactor Manual Control System Instrumentation and Control

7.7.1.1.1 Identification

The RMCS instrumentation and control consists of the electrical circuitry, switches, indicators, and alarm devices provided for operational manipulation of the control rods and the surveillance of associated equipment. This system includes the interlocks that inhibit rod movement (rod block) under certain conditions. The RMCS does not include any of the circuitry or devices used to automatically or manually scram the reactor; these devices are discussed in Sections 7.2 and 7.6. In addition, the mechanical devices of the control rod drive (CRD) and the CRD hydraulic system are not included in the RMCS. The latter mechanical components are described in Subsection 4.5.2.

7.7.1.1.1.1 Function

The objective of the RMCS is to provide the operator with the means for changing reactor power by manipulating the control rods.

7.7.1.1.1.2 Classification

This system is a power generation system, nonessential for safety, and is classified in Chapter 3.

7.7.1.1.2 Power Sources

7.7.1.1.2.1 Normal

The RMCS receives its power from the 120-V ac instrumentation and control power buses, either bus A or bus B. Each of these buses receives its normal power supply from the appropriate 480-V ac engineered safety feature (ESF) bus as described in Subsection 8.3.1. One subsystem, the control rod position indication system, is powered by the 120-V ac instrument bus, as described in Subsection 8.3.1.

7.7.1.1.2.2 Alternate

On loss of normal auxiliary power, the station diesel generator provides backup power to the 480-V ac ESF bus and the 120-V ac instrument bus.

7.7.1.1.3 Equipment Design

7.7.1.1.3.1 General

Figure 4.5-15 shows the layout of the CRD hydraulic system. Figure 7.7-1 shows the functional arrangement of devices for the control of components in the CRD hydraulic system. Although the figures also show the arrangement of scram devices, these devices are not part of the RMCS.

Control rods are moved by admitting water, under pressure, from a CRD water pump into the appropriate end of the CRD cylinder. The pressurized water forces the piston, which is attached by a connecting rod to a control rod, to move.

Three modes of control rod operation are used: insert, withdraw, and settle. Four solenoid-operated valves are associated with each control rod to accomplish the actions required for the operational modes. The valves control the path the CRD water takes to the cylinder. The RMCS controls the valves.

The settle mode of control rod operation is provided to decelerate the control rod at the end of either an insert cycle or a withdraw cycle. The settle action smooths out the control rod movement and prolongs the life of the CRD hydraulic system components. During the settle mode, the withdraw valve associated with the settle operation is opened or remains open while the other three solenoid-operated valves are closed. During an insert cycle, the settle action vents the pressure from the insert drive water supply line to the exhaust header, thus gradually reducing the differential pressure across the drive piston of the selected rod. During a withdraw cycle, the settle action holds open the discharge path for withdraw water while the withdraw drive water supply is shut off. This also allows for a gradual reduction in the differential pressure across the control drive piston. After the control rod has slowed down, the collet fingers engage the index tube and lock the rod in position.

The arrangement of control rod selection pushbuttons and circuitry permits the selection of only one control rod at a time for movement. A rod is selected for movement by depressing a button for the desired rod on the reactor control benchboard in the main control room (Figure 7.5-1).

The direction in which the selected rod moves is determined by the position of a switch, called the "rod movement" switch, which is also located on the reactor control benchboard. This switch has "rod-in" and "rod-out-notch" positions and returns by spring action to the "off" position. The rod selection circuitry is arranged so that a rod selection is sustained until the movement cycle of the selected rod has been completed. Reversion to the no-rod-selected condition is not possible, except for loss of control-circuit power until any moving rod has completed the movement cycle.

7.7.1.1.3.2 Insert Cycle

The following is a description of the detailed operation of the RMCS during an insert cycle. The response of a selected rod when the various commands are transmitted has been explained in Subsection 7.7.1.1.3.1. Figure 7.7-1 can be used to follow the sequence of an insert cycle.

A three-position rod movement switch is provided on the reactor control benchboard. The switch has a "rod-in" position, a "rod-out-notch" position, and an "off" position. The switch returns by spring action to the "off" position. When a control rod is selected for movement, the operator places the rod movement switch in the "rod-in" position and then releases the switch. This action energizes the insert command for a limited time. Just before the insert command is removed, the settle command is automatically energized for a limited time. The insert command time setting and the rate of drive water flow provided by the CRD hydraulic system determine the distance traveled by a rod. The time setting results in a one-notch (6 in.) insertion of the selected rod for each momentary application of a "rod-in" signal from the rod movement switch. Continuous insertion of a selected control rod is possible by holding the rod movement switch in the "rod-in" position.

A second switch can be used to initiate insertion of a selected control rod. This switch is the "rod-out-notch-override" switch and is called the RONOR switch. The RONOR switch has three positions: "emergency-in," "notch override," and "off." The switch returns to the "off" position by spring action. By holding the RONOR switch in the "emergency-in" position, the logic maintains the insert command in a continuously energized state to cause continuous insertion of the selected control rod.

7.7.1.1.3.3 Withdraw Cycle

This subsection describes the detailed operation of the RMCS during a withdraw cycle. The response of a selected rod when the various commands are transmitted has been explained in Subsection 7.7.1.1.3.1. Figure 7.7-1 can be used to follow the sequence of a withdraw cycle.

When a control rod is selected for movement, the operator places the rod movement switch in the "rod-out-notch" position, which energizes the insert commands for a short time. Energizing the insert command at the beginning of the withdraw cycle is necessary to allow the collet fingers to disengage the index tube.

When the insert command is deenergized, the withdraw and settle commands are energized for a controlled period of time. The withdraw command is deenergized before the settle command; this tends to decelerate the selected rod. When the settle command is deenergized, the withdraw cycle is complete. This withdraw cycle is the same whether the rod movement switch is held continuously in the "rod-out-notch" position or is released. The timer that controls the withdraw cycle is set so that the rod travels one notch (6 in.) per cycle. Provisions are included to prevent further control rod motion in the event of timer failure.

A selected control rod can be continuously withdrawn if the rod movement switch is held in the "rod-out-notch" position at the same time that the RONOR switch is held in the "notch-override" position. When both switches are held in these positions, the withdraw and settle commands are continuously energized.

7.7.1.1.3.4 Control Rod Drive Hydraulic System Control

A motor-operated pressure control valve, two air-operated flow control valves, and four solenoid-operated stabilizer valves are included in the CRD hydraulic system to maintain smooth and regulated system operation. These devices are shown in Figure 4.5-15. The motor-operated pressure-control valve is positioned by manipulating a pushbutton in the main control room. The pushbuttons for this valve are located close to the pressure indicator that responds to the pressure changes caused by the movements of the valve. The air-operated flow control valves are automatically positioned in response to signals from an upstream flow measuring device. The stabilizer valves are automatically controlled by the energization of the insert and withdraw commands. The control scheme is shown in Figure 7.7-1.

There are two drive-water pumps, one of which is a spare. They are controlled by switches in the main control room. Each pump automatically stops on indication of low suction pressure.

7.7.1.1.3.5 Rod Block Interlocks

General

Figure 7.7-1 shows the general functional arrangement of the rod block interlocks used in the RMCS.

To achieve an operationally desirable performance objective where most failures of individual components would be easily detected or would not disable the rod movement inhibiting functions, the rod block logic circuitry is arranged as two similar logic circuits. These circuits are energized when control rod movement is allowed. Each logic circuit receives input trip signals from a number of trip channels, and each logic circuit can provide a separate rod block signal to inhibit rod withdrawal.

The rod block circuitry is effective in preventing rod withdrawal, if required, during both normal (notch) withdrawal and continuous withdrawal. If a rod block signal is received during a rod withdrawal, the control rod is automatically stopped at the next notch position, even during a continuous rod withdrawal.

The components used to initiate rod blocks in combination with refueling operations provide rod block trip signals to these same rod block circuits. These refueling rod blocks are described in Subsection 7.6.1.1.

Rod Block Functions

The following discussion describes the various rod block functions and explains the intent of each function. The instruments used to sense the conditions for which a rod block is provided are discussed in Subsection 7.6.1.13. The rod block functions provided specifically for refueling situations are described in Subsection 7.6.1.1.

With the mode switch in the SHUTDOWN position, no control rod can be withdrawn. This enforces compliance with the intent of the shutdown mode.

The circuitry is arranged to initiate a rod block, regardless of the position of the mode switch, for the following conditions:

a. Any average power range monitor (APRM) upscale rod block alarm. The purpose of this rod block function is to avoid conditions that would require reactor protection system (RPS) action if allowed to proceed. The APRM upscale rod block alarm setting is selected to initiate a rod block before the APRM high neutron flux scram setting is reached

b. Any APRM inoperative alarm. This ensures that no control rod is withdrawn unless the average power range neutron monitoring channels are either in service or are correctly bypassed

c. Either rod block monitor (RBM) upscale alarm. This function is provided to stop the erroneous withdrawal of a control rod so that local fuel damage does not result. Although local fuel damage poses no significant threat in terms of radioactive material released from the nuclear system, the trip setting is selected so that no local fuel damage results from a single control rod withdrawal error during power range operation

d. Either RBM inoperative alarm. This ensures that no control rod is withdrawn unless the RBM channels are in service or are correctly bypassed

e. Any APRM indicating recirculation flow upscale. This ensures that no control rod is withdrawn unless the recirculation flow functions, which are necessary for the proper operation of APRM rod block function, are operable

f. Deleted

g. Scram discharge volume high water level. This ensures that no control rod is withdrawn unless enough capacity is available in the scram discharge volume to accommodate a scram. The setting is selected to initiate a rod block earlier than the scram that is initiated on scram discharge volume high water level

h. Scram discharge volume high water level scram trip bypassed. This ensures that no control rod is withdrawn while the scram discharge volume high water level scram function is out of service

i. The rod worth minimizer (RWM) can initiate a rod insert block and a rod withdrawal block. The RWM limits the worth of any control rod that could be dropped by regulating the withdrawal sequence. This system prevents the movement of an out-of-sequence rod in the 100 percent control rod density to the preset low power level, the RWM will allow only BPWS mode withdrawals or insertions. The rod block trip settings are based on the allowable control rod worth limits established for the design-basis control rod drop accident. Additional information on the RWM function is available in Subsection 7.6.1.20

j. Rod position information system malfunction. This ensures that no control rod can be withdrawn unless the rod position information system is in service

k. Rod movement timer malfunction during withdrawal. This ensures that continuous withdrawal of a control rod does not result from failure of the normal rod timer during the withdrawal portion of the timing sequence.

With the mode switch in the RUN position, any of the following conditions initiates a rod block:

a. Any APRM downscale alarm. This ensures that no control rod will be withdrawn during power range operation unless the average power range neutron monitoring channels are operating correctly or are correctly bypassed. All unbypassed APRMs must be on scale during reactor operations in the RUN mode

b. Either RBM downscale alarm. This ensures that no control rod is withdrawn during power range operation unless the RBM channels are operating correctly or are correctly bypassed. An RBM which reads downscale (downscale alarm) and not automatically bypassed by the APRM low power feature is considered to have failed. This results in the rod withdrawal permissive not being given unless this RBM is bypassed.

With the mode switch in the STARTUP or REFUEL position, any of the following conditions initiates a rod block:

a. Any source range monitor (SRM) detector not fully inserted into the core when the SRM count level is below the retract permit level and any IRM range switch is on either of the two lowest ranges. This ensures that no control rod is withdrawn unless all SRM detectors are correctly inserted when they must be relied on to provide the operator with neutron flux level information

b. Any SRM upscale level alarm. This ensures that no control rod is withdrawn unless the SRM detectors are correctly retracted during a reactor startup. The rod block setting is selected at the upper end of the range over which the SRM is designed to detect and measure neutron flux

c. Any SRM downscale alarm. This ensures that no control rod is withdrawn unless the SRM count rate is above the minimum rate prescribed for low neutron flux level monitoring

d. Any SRM inoperative alarm. This ensures that no control rod is withdrawn during low neutron flux level operations unless neutron monitoring capability is available in that all SRM channels are in service or are correctly bypassed

e. Any intermediate range monitor (IRM) detector not fully inserted into the core. This ensures that no control rod is withdrawn during low neutron flux level operations unless proper neutron monitoring capability is available in that all IRM detectors are correctly located

f. Any IRM upscale alarm. This ensures that no control rod is withdrawn unless the intermediate range neutron monitoring equipment is correctly upranged during a reactor startup. This rod block also provides a means to stop rod withdrawal in time to avoid conditions requiring RPS action (scram) in the event that a rod withdrawal error is made during low neutron flux level operations

g. Any IRM downscale alarm except when range switch is on the lowest range. This ensures that no control rod is withdrawn during low neutron flux level operations unless the neutron flux is being correctly monitored. This rod block prevents the continuation of a reactor startup if the operator upranges the IRM too far for the existing flux level. Thus, the rod block ensures that the IRM is on scale if control rods are to be withdrawn

h. Any IRM inoperative alarm. This ensures that no control rod is withdrawn during low neutron flux level operations unless neutron monitoring capability is available in that all IRM channels are in service or are correctly bypassed.

Rod Block Bypasses

To permit continued power operation during repair or calibration of equipment for selected functions that provide rod block interlocks, the limited number of manual bypasses that are permitted are:

a. One SRM channel

b. Two IRM channels (one on bus A and one on bus B)

c. One APRM channel

d. One RBM channel.

The permissible IRM bypasses are arranged in two groups, each having an equal number of channels. One manual bypass is allowed in each group. The groups are chosen so that adequate monitoring of the core is maintained when one channel is bypassed in each group. The arrangement allows the bypassing of one IRM in each rod block logic circuit.

These bypasses are effected by positioning switches in the main control room. A light in the main control room indicates the bypassed condition.

An automatic bypass of the SRM detector position rod block is effected as the neutron flux increases beyond a preset low level on the SRM instrumentation. The bypass allows the detectors to be partially or completely withdrawn as a reactor startup is continued.

An automatic bypass of the RBM rod block occurs when the power level is below a preselected level or when a peripheral control rod is selected. Either condition indicates that local fuel damage is not threatened and that RBM action is not required.

The RWM rod block function is automatically bypassed when reactor power increases above a preselected value in the power range.

Arrangement of Rod Block Trip Channels

Half of the total neutron monitoring equipment (SRM, IRM, APRM, RBM) provides input to one of the two rod block logic circuits and the other half provides input to the other logic circuit. Two of the flow functions from each of the two recirculation loops provides a rod block signal to one logic circuit and the other two flow functions for each recirculation loop provides an input to the other logic circuit. Scram discharge volume high water level signals are provided as inputs into both of the two rod block logic circuits. Both rod block logic circuits sense when the high water level scram trip for the scram discharge volume is bypassed. The rod withdrawal block from the RWM trip affects both rod block logic circuits. The rod insert block from the RWM function prevents energizing the insert bus for both notch insertion and continuous insertion.

The APRM rod block settings are varied as a function of recirculation flow. The RBM rod block settings are power dependent. Analyses show that the selected settings are sufficient to avoid both RPS action and local fuel damage as a result of a single control rod withdrawal error. Mechanical switches in the SRM and IRM detector drive systems provide the position signals used to indicate that a detector is not fully inserted. Additional detail on all the neutron monitoring system (NMS) trip channels is available in Subsection 7.6.1.13.

The rod block from scram discharge volume high water level uses one nonindicating float switch installed on the scram discharge volume. A second float switch provides a main control room annunciation of increasing level.

7.7.1.1.3.6 Inspection and Testing

The RMCS can be routinely checked for correct operation by manipulating control rods using the various methods of control. Detailed testing and calibration can be performed by using standard test and calibration procedures for the various components of the reactor manual control circuitry.

7.7.1.1.4 Environmental Considerations

The RMCS is not required for safety functions, nor is it required to operate after the design-basis accident (DBA). The RMCS is required to operate in the normal plant environments for power generation purposes only.

The hydraulic control units are located in the reactor building. The logic, control units, and instrumentation readouts are located in the main control room. The control rod position detectors are located beneath the reactor pressure vessel (RPV) in Zone 3 of the primary containment. The normal design environments encountered in these areas are listed in Table 3.11-5.

7.7.1.1.5 Operational Consideration

7.7.1.1.5.1 Normal

The RMCS is totally operable from the main control room. Manual operation of individual control rods is possible with a jog switch to effect control rod insertion, withdrawal, or settle. Rod position indicators, described in Subsection 7.7.1.1.5.2, provide the necessary information to ascertain the operating state and position of all control rods. Conditions that prohibit control rod insertion are alarmed by the rod block annunciator.

7.7.1.1.5.2 Operator Information

Instrumentation

Table 7.7-1 gives information on instruments for the RMCS. A large rod information display on the vertical portion of the reactor control benchboard is patterned after a top view of the reactor core, as shown in Figure 7.5-1. The display allows the operator to acquire information rapidly by scanning. Colored windows provide an overall indication of rod pattern and allow the operator to quickly identify an abnormal indication. The following information for each control rod is presented in the display:

a. Rod fully inserted (green)

b. Rod fully withdrawn (red)

c. Rod identification (coordinate position, white)

d. Accumulator trouble (amber)

e. Rod scram (blue)

f. Rod drift (red).

Also available on digital operator display assemblies (ODAs), one for each two APRM channels, are local power range monitor (LPRM) readings as well as indications of LPRM low flux level and LPRM high flux level.

A separate, smaller display is located just below the large display on the vertical part of the benchboard. This display shows the positions of the control rod selected for movement and the positions of the other rods in the rod group. For display purposes, the control rods are considered in groups of four adjacent rods centered around a common core volume monitored by four LPRM strings. Rod groups at the periphery of the core may have less than four rods. The small rod display shows the positions, in digital form, of the rods in the group to which the selected rod belongs. A white light indicates which of the four rods is selected for movement. On either side of the four-rod position display are indicated (on RBM ODAs - one for each RBM) the readings of the 16 LPRM channels (four LPRM strings) surrounding the core volume common to the four rods of the group. The four-rod display allows the operator to easily focus his attention on the core volume of concern during rod movements. This arrangement eliminates the problems inherent in larger, full core displays where the operator must concentrate his attention on a small portion of a large display. The four-rod display also allows the operator to quickly investigate any volume of the core by simply selecting a control rod located in that volume.

The position signals of selected control rods, together with a rod identification signal, are provided as hardwired digital signals to the rod worth minimizer (RWM). These signals are then provided by the RWM as digital data to the Integrated Plant Computer System (IPCS) via a GE NUMAC LINK component of the 3D-Monicore Computer System (3DM).

Control rod position information is obtained from reed switches in the CRD that open or close as a magnet attached to the rod drive piston passes during rod movement. Reed switches are provided at each 3-in. increment of piston travel. Because a notch is 6 in. long, indication is available for each half-notch of rod travel. The reed switches located at the half-notch positions for each rod are used to indicate rod drift. Both the rod selected for movement and the rods not selected for movement are monitored for drift. A drifting rod is indicated by an alarm and red light in the main control room.

The rod drift condition is also monitored by the IPCS. Reed switches are provided at locations that are beyond the limits of normal rod movement. If the rod drive piston moves to these overtravel positions, an alarm is sounded in the main control room. The overtravel alarm provides a means to verify that the drive-to-rod coupling is intact because the drive cannot be physically withdrawn to the overtravel position when the coupling is in its normal condition. Coupling integrity can be checked by attempting to withdraw the drive to the overtravel position.

The following main control room lights are provided to enable the operator to be aware of the conditions of the control rod drive hydraulic system and the control circuitry:

a. Stabilizer valve selector switch position

b. Insert command energized

c. Withdraw command energized

d. Settle command energized

e. Withdrawal not permissive

f. Notch override

g. Pressure control valve position

h. Flow control valve position

i. Drive water pump low suction pressure (alarm only)

j. Drive water filter high differential pressure (alarm only)

k. High pressure of charging water to accumulator (alarm only)

l. CRD temperature

m. Scram discharge volume not drained (alarm only)

n. Scram valve pilot air heater high/low pressure (alarm only).

7.7.1.2 Recirculating Flow Control System Instrumentation and Control

7.7.1.2.1 System Identification

7.7.1.2.1.1 Function

The objective of the RFCS is to control reactor power level, over a limited range, by controlling the flow rate of the reactor recirculating water (Figure 5.5-2). The control involves varying the speed of the recirculation pumps by varying the voltage and frequency of the ac supply to each pump motor. The ac supply is provided by a motor-generator set for each pump. Each motor-generator set consists of a squirrel-cage induction motor driving a variable-frequency generator through a variable-speed converter. The generator output is varied by varying the slip within the converter. Since flow rate is directly proportional to pump speed which is proportional to generator speed, generator speed is considered the controlled variable of the system. Manual input to the individual loop controllers is the reference input to the system.

The RFCS is also designed to limit the range and rate of change of pump speed, and to otherwise ensure proper operation and equipment protection.

7.7.1.2.1.2 Classification

This system is a power generation system, nonessential for safety, and is classified in Chapter 3.

7.7.1.2.2 Power Sources

The RFCS consists of Remote Distributed Control System – Reactor Recirculation (Remote DCS-RR) and Remote Input/Output – Reactor Recirculation (Remote I/O-RR). The RFCS has redundant power supplies and redundant processing units. Both the flow loops A and B are controlled by Remote DCS-RR. The Remote DCS-RR is powered by 120 V ac instrument and control bus and 125 V dc power and Remote I/O-RR is powered by 120 V ac Bus A and Bus B for redundancy.

7.7.1.2.3 Equipment Design

7.7.1.2.3.1 General

Reactor recirculation flow is changed by adjusting the speed of the two reactor recirculating pumps by adjusting the frequency and voltage of the electrical power supplied to the recirculation pump motors.

Control of pump speed, and thus core flow, is such that at various control rod patterns, different power level changes can be accommodated. Refer to Section 4.4.3.5 for a discussion of BWR operation with recirculation flow control.

An increase in recirculation flow temporarily reduces the void content of the moderator by increasing the flow of coolant through the core. The additional neutron moderation increases the reactivity of the core, causing the reactor power level to increase. The increased steam generation rate increases the steam volume in the core with a consequent negative reactivity effect, and a new steady-state power level is established. When recirculation flow is reduced, the power level is reduced in the reverse manner.

Figure 7.7-2 is a simplified illustration of the RFCS. Figure 7.7-3 shows the system functional control diagram (FCD).

Each recirculation pump motor has its own motor-generator set for a power supply. A variable-speed converter is provided between the motor and generator of the motor-generator set. To change the speed of the reactor recirculation pump, the variable-speed converter varies the generator speed, which changes the frequency and magnitude of the voltage supplied to the pump motor so that the desired pump speed is attained. The RFCS uses a demand signal from the operator.

The RFCS is a digital microprocessor based distributed control system (DCS). The DCS features modular design consisting of input/output, redundant processor and communication. The DCS equipment is located in the relay room, control room and reactor building 4th floor.

The operator interface consists of manual/automatic (M/A) controllers, bar graph indicators, recorders, pushbuttons, control switches, indicating lights and video display. The controls permit the operator to operate in manual or automatic mode. An individual, independent M/A controller will provide speed control for each reactor recirculation pump. The manual mode of operation bypasses closed loop speed control. The M/A controller is placed in AUTO for control loop regulation by the feedback signal of generator speed, subject to the limiters. A manual runback indicating pushbutton is provided in the control room to manually runback the recirculation pumps. The M/A controller display includes speed setpoint, generator speed, and speed demand signal. A flat panel display with a touch screen is provided in the control room to access various system parameter data.

The system locks up the scoop tube on fault conditions. The system has the capability to monitor the initiation and clearance of the fault condition.

Each MG set has three magnetic pick-up speed sensors for redundancy, which provide speed feedback inputs into the Remote DCS-RR. The system transfers the M/A controller to MANUAL mode on either loss of two speed signals or communication failure with DCS processors.

A provision has been included in the Fermi 2 design to trip the recirculation pump motor-generator field breakers and drive motor breakers on receipt of ATWS initiation signals. The Fermi 2 RPT design employs two trip coils in each recirculation system motor generator set field breaker and drive motor breaker. This design provides redundant trips of both motor-generator sets following the transient and failure-to-scram. To minimize the possibility of breakers being tripped inadvertently, the automatic trip signals are arranged in two-out-of-two logic.

The breaker automatic trip signal is a combined ARI/RPT logic. That is, a low reactor vessel water level (level 2) or high reactor vessel pressure signal will initiate the trip of both sets of field breakers. (Refer to Figure 7.7-3, sheet 4).

The RPT may be manually initiated by the same two pushbuttons in the control room (on a divisional basis) as ARI, the difference being that initiation of one division will trip both sets of breakers.

The RPT logic delays MG set field breaker trip on low reactor vessel water level for 9 seconds. This time delay was provided to account for the difference in the pump coastdown time if the field breaker is tripped rather than the motor-generator set drive motor, as was assumed in the LOCA analysis. The manual reset of the generator field breaker trip seal-in circuit does not have any time delay due to the rapid operation of the circuit breaker. The manual reset of the drive motor breakers will have a time delay because the reset logic is ARI logic.

7.7.1.2.3.2 <u>Motor-Generator Sets</u>

Each of the two motor-generator sets and its controls are identical; therefore, only one description is given of the motor-generator set. Figure 5.5-2 shows the general arrangement and rating of the motor-generator set. The motor-generator set can continuously supply power to the pump motor at any speed between approximately 19 percent and 96 percent of the drive motor speed. The motor-generator set is capable of starting the pump and accelerating it from standstill to the desired operating speed when the pump motor thrust bearing is fully loaded by reactor pressure acting on the pump shaft.

The main components of the motor-generator set are

a. <u>Drive motor</u> - The drive motor is an ac induction motor that drives the input shaft of the variable speed converter

b. <u>Generator</u> - The variable-frequency generator is driven by the output shaft of the variable-speed converter. During normal operation, the generator exciter is powered by the drive motor. The excitation of the generator is provided from an auxiliary source during pump startup

c. <u>Variable-speed converter and actuation device</u> - The variable-speed converter transfers power from the drive motor to the generator. The variable-speed converter actuator automatically adjusts the slip between the converter input shaft and output shaft as a function of the signal from the speed controller. If the speed controller signal is lost, the actuator causes the speed converter slip to remain "as is." Manual reset of the actuation device is required to return the speed converter to normal operation.

7.7.1.2.3.3 Speed Control Configuration

The speed control system (Figure 5.5-2) controls the variable speed converters of both motor-generator sets. The micro-processor-based scoop tube positioner directly interfaces with the speed control system. The motor-generator sets can be manually controlled individually. The control system configuration for each motor-generator set consists of a manual automatic transfer station, a speed control function, a signal failure alarm, a startup mode function and a speed limiter. Components in the new speed control system contain I/O modules feeding the redundant main processing units. The control system is comprised of an arrangement of discrete modules which run the main processing unit. The operator interface is manual/automatic setpoint stations.

Speed Control

There is one speed control for each motor-generator set. The speed control system transmits the signal that adjusts the motor-generator set variable-speed converter. The speed control for each motor-generator set compares the setpoint signal from the operator station to the feedback signal from triple redundant magnetic speed sensors for each motor-generator set. The control system adjusts its output to the speed converter so that the speed feedback signal is made to equal the setpoint signal. The speed controller setpoint signal is received during automatic operation and during motor-generator set manual operation or during pump startup from the startup signal generator.

System Trouble Alarm

There is one system trouble alarm for each motor-generator set. The system trouble alarm actuates an alarm in the main control room and acts to prevent any change of slip within the variable-speed converter.

Startup Mode

There are triple redundant magnetic speed sensors for each motor-generator set. The triple redundant speed sensors supply the setpoint signal to the speed control system. This function sets the motor-generator set variable speed converter for approximately 50 percent recirculation pump speed.

Speed Limiter

There are four speed limiter functions for each motor-generator set. Number 1 limiter is an adjustable high limit. The speed control setpoint signal is automatically limited by the Number 1 limiter if the recirculation pump main discharge valve is not fully open or if the feedwater flow is less than 20 percent of rated flow. Number 2 or 3 limiter acts on the position demand to the scoop tube positioner and is actuated when a feedwater pump is tripped and level is below the low alarm setpoint (Number 2 limiter) or when both heater drain pumps are not pumping forward to the suction of the feed pumps (Number 3 limiter).

A manual defeat of runback 2 and 3 logic is used during startups, shutdowns and single loop operation. Number 4 limiter limits speed controller setpoint signal of operating pump following a trip of a single recirculation pump. The limiters are enabled during manual operation of the operator station. A manual runback indicating pushbutton is provided in the control room to manually runback the recirculation pumps.

7.7.1.2.3.4 Recirculation Loop Starting Sequence

Each recirculation loop is independently put into operation by operating the controls of each recirculation loop as follows:

a. Whenever the generator field breaker is open, the control system is automatically placed in startup mode. Startup mode bypasses the normal speed control circuits to position the variable-speed converter for startup. The minimum speed of the recirculation pumps is 20 percent as established by the mechanical stops. Startup operations of the plant are normally carried out with the recirculation pumps operating at approximately 30 percent speed. The power-versus-flow operating state for the reactor follows the 30 percent speed line for the normal control rod withdrawal sequence. (See Section 4.4.3.3.1 and Figure 4.4-3)

b. The starting sequence is manually initiated by placing the drive motor control switch for one motor-generator set in the start position.

c. Once the variable-speed converter has achieved its startup position, the following events occur:

    1. The auxiliary source of field excitation is engaged after a time delay

    2. The generator field breaker is closed after a time delay.

d. When the generator field breaker is closed, the manual/automatic setpoint station is automatically transferred to give the desired initial generator speed (typically <30 percent of rated speed) after the startup sequence is complete.

e. Deleted

f. After recirculation pump start is sensed by a combination of field breaker position and generator output current, the generator is automatically transferred to self-excitation

g. Recirculation flow is increased during startup by manually increasing recirculation pump speed

h. Deleted

7.7.1.2.3.5 Inspection and Testing

The motor-generator set, and the speed control system are functioning during normal power operation. Any abnormal operation of these components can be detected during operation. The components that do not continually function during normal operation can be tested and inspected for calibration and operability during scheduled plant shutdowns. All the RFCS components are tested and inspected according to the component manufacturer's recommendations. This can be done during scheduled shutdowns.

7.7.1.2.4 Environmental Considerations

The RFCS is not required for safety purposes, nor is it required to operate after the DBA. The system is required to operate in the normal plant environment for power generation purposes only. The following normal design environments are encountered by parts of the RFCS. The recirculation flow-control equipment in Zone 4 of the primary containment is the pump motor, which is subject to the environment specified in Table 3.11-5 under environmental conditions.

The control system hardware, operator controls, and instrumentation terminals are located in the main control room, relay room and reactor building (remote I/O) and are subject to the normal environments of these areas.

7.7.1.2.5 Operational Considerations

Indicators and alarms are provided to keep the operator informed of the status of the system so that he may quickly determine the location of malfunctioning equipment.

Temperature monitoring of equipment is recorded and alarmed if safe levels are exceeded. Indicators are provided to show pumping power requirements, motor-generator set speed, recirculation loop flow, valve positions, and analog control signal, all of which determine system status. Alarms are provided to alert the operator of malfunctioning control signals, excessive cooling water temperatures, inability to change pump speed, and the status of the motor-generator circulating lube-oil supply.

7.7.1.3 Feedwater Control System Instrumentation and Control

7.7.1.3.1 System Identification

7.7.1.3.1.1 Function

The feedwater control system automatically controls the flow of feedwater into the RPV so that the water in the vessel is maintained within predetermined levels during all modes of plant operation. The range of water level is based on the requirements of the steam separators, including limiting carryover and carryunder, which affects turbine performance and recirculation pump operation. The range of water level is also based on the need to prevent exposure of the reactor core. The feedwater control system uses water level, steam flow, and feedwater flow as a three-element control. Single-element control, based on water level only, is also available.

Normally, the signal from the feedwater flow is equal to the steam flow signal; thus, if a change in the steam flow occurs, the feedwater flow follows. The steam flow signal provides anticipation of the change in water level that would result from change in load. The level signal provides a correction for any mismatch between the steam and feedwater flow, which causes the level of the water in the RPV to rise or fall accordingly. Figure 7.7-4 shows the system IED.

7.7.1.3.1.2 Classification

This system is a power generation system, nonessential for safety, and is classified in Chapter 3.

7.7.1.3.2 Power Sources

The feedwater control system power is supplied by two (2) redundant uninterruptible power supplies. Interruptible instrument air and power is supplied to certain feedwater system (N21) control valves and operators.

7.7.1.3.3 Equipment Design

7.7.1.3.3.1 General

During normal plant operation, the feedwater control system automatically regulates feedwater flow into the RPV. The system is a distributed control system (DCS) using redundant processors and communication links. This system can be manually operated from the main control room.

The feedwater flow control instrumentation measures the water level in the RPV, the feedwater flow rate into the RPV, and the steam flow rate from the RPV. During automatic three-element operation, these measurements are used for controlling feedwater flow.

The optimum RPV water level is determined by the requirements of the steam separators. The separators limit water carryover in the steam going to the turbines and limit steam carryunder in water returning to the core. The water level in the RPV is maintained within ±2 in. of the setpoint level. This control capability is achieved during plant load changes by balancing the mass flow rate of feedwater to the RPV with the steam flow from the RPV. The feedwater flow is regulated by adjusting the speed of the turbine-driven feedwater pumps to deliver the required flow to the RPV.

7.7.1.3.3.2 Reactor Pressure Vessel Water Level Measurement

Reactor pressure vessel water level is measured by two independent sensing systems. Two (2) redundant differential pressure transmitters in each system sense the difference between the pressure caused by a constant reference column of water and the pressure caused by the variable height of water in the RPV. A backfill system is installed on each reactor water level instrument reference leg in compliance with the requirements of USNRC Generic Letter 92-04 and Bulletin 93-03. The system provides a metered flow of water from the control rod drive system (CRD) to each leg to prevent the accumulation of the noncondensable gases in the reference legs and assure a high reliability of the water level indication. The backfill flow rate is low enough to not affect the performance of the instrumentation. The differential pressure transmitters are installed on lines that serve other systems (Subsection 7.6.1.2). The differential pressure signals are used for level indication and control. The amplifier transmits the level signal for indication and control. The RPV water level signals from each sensing system are indicated in the main control room. The level signal from either sensing system can be manually selected by the operator as the signal to be used for feedwater flow control.

The redundant level signals in the operator selected sensing system and both level signals from the nonselected sensing system are applied to a median signal selector. The median signal is compared against the operator selected level and will automatically assume the lead level control signal if the operator selected sensing system fails. The water level for control is continuously recorded in the main control room.

7.7.1.3.3.3 Steam Flow Measurement

Steam flow is sensed at each main steam line flow restrictor by differential pressure transmitter. These steam flow signals are indicated in the main control room. The signals are summed to produce a total steam flow signal for indication and feedwater flow control. The total steam flow signal is recorded in the main control room.

7.7.1.3.3.4 Feedwater Flow Measurement

Feedwater flow is sensed at a flow element in each feedwater line by differential pressure transmitters. Each feedwater signal is summed to provide a total mass flow signal for the feedwater control system. The total feedwater flow signal is also recorded and integrated in the main control room. In addition, feedwater flow is sensed by an ultrasonic flow meter in each feedwater line and processed in the associated central processing unit to provide mass flows to the Integrated Plant Computer System (IPCS) for the sole purpose of the IPCS heat balance calculation and is not used for any direct control function.

7.7.1.3.3.5 Feedwater Control Signal

The level control system produces the feedwater control signal through digital control logic, the master level controller and the reactor feed pump manual/automatic control stations. The signal can be controlled either manually or automatically.

The master level control and the reactor feed pump manual/automatic stations contain a setpoint meter, level indicator, and a manual output control indicator.

The master manual/automatic setpoint station contains a setpoint meter, level indicator and a manual output control with an indicator. Input to the control system is derived from either the single-element signal (level only) or the three-element signal. The three-element signal is the summation of steam flow, feedwater flow, and the selected reactor water level. Single-element or three-element level control is manually selected by the operator. When three-element level control is selected, automatic transfer to single-element level control will occur if one of the feedwater flow signals or two of the steam flow signals should fail. Manual level control is automatically initiated if the control system cannot provide automatic level control. During automatic operation of the feedwater control system, the level control system output is proportional to the level error in the system. During manual operation, output is set and indicated at the manual/automatic setpoint station.

The level demand signal from the master control is applied to the input of two manual/automatic stations that have capabilities to add or subtract a bias signal from the master level demand, when in automatic. The bias capabilities allow independent adjustment of the speed demand signals to the turbine-driven feedwater pumps during automatic operation. During manual operation of the bias stations, the speed demand signal is manually adjusted by the operator.

Selection of automatic or manual control is made by the operator at a master manual/automatic setpoint station.

Normal Automatic Operation

The feedwater control system provides function block through the I/O modules to compute the three-element control signal to maintain RPV water level within a small margin of optimum water level during plant load changes. The total steam flow signal and the total feedwater flow signal are subtracted from each other to derive a flow error signal. When steam flow exceeds feedwater flow, the error signal is positive in polarity from its normal zero value. The flow error signal is multiplied by a gain factor referred to as mismatch gain. The mismatch gain determines how much level effect the flow error signal has when the error is 100 percent. The mismatch gain is used as a dynamic control system adjustment. The flow error signal is limited for +/-20 percent multiplied by the mismatch gain. The flow error signal is then subtracted from the selected level signal to provide the three-element control signal. When feedwater flow exceeds steam flow, the error signal is negative polarity. The three-element signal is modified further by a lead/lag function before being used for level control. The control system compares this signal against the level setpoint adjusted by the operator.

Following a reactor scram, the RPV water level controller setpoint is capable of being automatically lowered so that the Reactor Feed Pump Turbines do not overfill the reactor vessel. On receipt of a scram signal via a contact of an RPS auxiliary relay, the Post-Scram Reactor Water Level Setdown Logic lowers the level controller setpoint after the time delay. A momentary actuated switch in the control room allows the operator to reset the Post-Scram Reactor Water Level Setdown Logic after the scram signal is cleared.

Optional Automatic Operation

A single-element control signal (RPV water level) can be used to replace the above three-element signal. The operator manually transfers the level controller input to the "1 element control" signal. In the event of failure of the three-element signal, the control system will automatically transfer to single element. Reactor water level is then controlled in accordance with the controller setpoint.

Auxiliary Functions

The level control system also provides interlocks and control functions to other systems. When one of the reactor feed pumps is lost and coincident or subsequent low water level exists, reactor recirculation flow is reduced to within the power capabilities of the remaining reactor feed pumps. This reduction aids in avoiding a low-level scram by reducing the steaming rate.

Reactor recirculation flow is also reduced on sustained low feedwater flow to ensure that adequate net positive suction head (NPSH) is provided for the recirculation system.

Interlocks from steam flow and feedwater flow are used to initiate insertion of the RWM block. An alarm on low steam flow indicates that the RWM insertion interlock setpoint is being approached. The same steam flow and feedwater flow interlocks are used to bypass the gland seal exhauster trip on main steam line high radiation above the low power setpoint. Alarms from the control system are also provided for high and low water level, reactor high pressure and failures. High reactor water level (L-8) from the nuclear boiler system trips the turbine driven feedwater pumps, see subsection 7.6.1.2.7.

7.7.1.3.3.6 Turbine-Driven Feedwater Pump Control

Feedwater is delivered to the RPV through turbine-driven feedwater pumps arranged in parallel. The turbines are driven by steam from the RPV. During normal operation, the feedwater control signal from the level controller is fed to the turbine control mechanisms. The turbine control mechanisms adjust the speed of their associated turbines so that feedwater flow is proportional to the feedwater control signal. Each turbine can be controlled by its manual/automatic transfer station. The master manual/automatic setpoint station and the manual/automatic station associated with each turbine speed controller are configured to have "bumpless transfer". The turbine-driven feedwater pump control has speed limiters to restrain maximum feedwater flow to 117 percent.

7.7.1.3.3.7 Inspection and Testing

All feedwater control system components can be tested and inspected according to the manufacturers' recommendations. This can be done prior to plant operation and during scheduled shutdowns. Reactor pressure vessel water level indications from the two water level sensing systems are compared during normal operation to detect instrument malfunctions. Steam mass flow rate and feedwater mass flow rate can be compared during constant load operation to detect inconsistencies in their signals.

7.7.1.3.4 Environmental Considerations

The feedwater control system is not required for safety purposes, nor is it required to operate after the DBA. This system is required to operate in the normal plant environment for power generation purposes only. The reactor feed pumps in the turbine building experience the normal design environments listed in Table 3.11-5.

7.7.1.3.5 Operational Considerations

7.7.1.3.5.1 Normal

All control stations are located in the main control room where, at the operator's discretion, the feedwater control system can be operated either manually or automatically. Manual control of the individual turbine-driven feedwater pumps is available to the operator in the main control room. Manual control of the individual turbine-driven feedwater pumps is used during control of the startup level control valve. The startup level control valve is used to supply feedwater during periods of low reactor pressure and/or flow demand. The startup control system will automatically hold reactor water level to an operator selected setpoint as a single-element unmodified control system. It can also be operated manually.

Subsequent to a scram, the feedwater flow demand is very low. To ensure adequate control at this low flow, the feedwater control system automatically diverts feedwater flow through the startup control valve when a scram occurs. A minimum flow recirculation line valve automatically opens to maintain flow through each feedwater pump so that the pump is protected from overheating.

7.7.1.3.5.2 Operator Information

Indicators and alarms, provided to keep the operator informed of the status of the system, are discussed in Subsection 7.7.1.3.3.

7.7.1.4 Pressure Regulator and Turbine-Generator Instrumentation and Control

7.7.1.4.1 System Identification

7.7.1.4.1.1 Function

Power Generation - The pressure regulator system maintains constant main turbine inlet steam pressure.

7.7.1.4.1.2 Classification

The main turbine pressure regulator and bypass system is a conventional analog/hydraulic control system and is classified in Chapter 3.

7.7.1.4.2 Normal Power Sources

The main turbine pressure regulator control system is supplied by two independent 120-V ac instrument buses.

7.7.1.4.3 Equipment Design

7.7.1.4.3.1 System Description

Control and supervisory equipment for the turbine generator is conventional and arranged for remote operation from the main control room. Normally, the initial pressure regulator controls steam throttle valve position to maintain constant reactor pressure. The ability of the plant to follow system load demands is accomplished by adjusting reactor power level, either by changing flow in the reactor recirculation system (manually) or moving control rods (manually). However, the turbine speed governor, which is supplied by the turbine supplier, can override the initial pressure regulator. The steam valves close when an increase in system frequency or a loss of generator load causes the speed of the turbine to increase. In the event that the reactor is delivering more steam than the admission valves pass, the excess steam is automatically and directly bypassed to the main condenser by pressure-controlled bypass valves. Figure 7.7-5 is a simplified control diagram.

7.7.1.4.3.2 Steam Pressure Control

During normal plant operation, steam pressure is controlled by the turbine control valves. These control valves are positioned in response to either the pressure regulation signal or the turbine speed-load signal as selected by a "low value gate" circuit in the BOP turbine control system. The change in steam production is sensed by the pressure regulator, which signals the turbine control valves to adjust position to accept the change in steam flow, thereby regulating steam pressure.

A main steam line resonance filter is included in the pressure regulator circuits to prevent cycling from false pressure signals. These false pressure signals could be caused by sonic resonances in the main steam lines.

7.7.1.4.3.3 Steam Bypass System

The steam bypass equipment is designed to control steam pressure when reactor steam generation exceeds turbine requirements such as during startup (speed raising and synchronizing), sudden load reduction, and cooldown. Capacity of the system is 23.5 percent of 105 percent of nuclear steam supply system (NSSS) rated steam flow, and sudden load reductions of up to 25 percent of rated power can be accommodated without reactor scram.

Normally, the bypass system valves are held closed while the pressure regulator controls the turbine control valves, directing all steam flow to the turbine. If the speed governor or the load limiter restricts steam flow to the turbine, the regulator controls system pressure by opening the bypass valves. If the capacity of the bypass valves is exceeded while the turbine cannot accept an increase in steam flow, the system pressure rise and RPS action causes shutdown of the reactor.

The bypass valves are the automatically operated, regulating type. They are proportionately controlled by the NSSS pressure regulator which compares the steam pressure signal with the turbine control valve signal to bypass excess steam to the main condenser.

Bypass valves and controls are designed so the valves close on loss of control system electric power or hydraulic pressure.

7.7.1.4.3.4 Turbine Speed/Load Control System

The turbine control system is discussed in Chapter 10.

7.7.1.4.3.5 Turbine Generator to Reactor Protection System Interface

The RPS initiates reactor scram when it is required by the particular monitored plant conditions (Section 7.2). Two such conditions are turbine stop valve closure and turbine control valve fast closure when reactor power is above 29.5 percent.

The turbine stop valve closure signal is generated before the turbine stop valves have closed more than 10 percent (opened less than 90 percent). This signal originates from position switches that sense stop-valve motion away from fully open. The switches are closed when the stop valves are fully open, and the switches open within 10 msec after the setpoint is reached. The switches are electrically isolated from each other and from other turbine plant equipment.

The control-valve-fast-closure signal is generated by the relay logic that initiates the fast control valve closure. Separate circuits are associated with each of the control valves. Relay contacts are closed whenever the control valves are not being closed in the fast mode, and these relay contacts open when the fast closure mode is initiated.

To avoid reactor scram due to turbine stop or control valve fast closure when power is below 29.5 percent of rated power, two independent sensing lines are provided from the turbine first-stage pressure transmitter/trip units, which supply power level logic contacts to the RPS. The pressure taps are located to provide a pressure signal proportional to turbine steam flow. The pressure taps are shared with other instrumentation sensors. All sensors have individual isolation or root valves.

7.7.1.4.3.6 Inspection and Testing

Testing controls for testing the turbine valve RPS interface signal switches are provided to:

a. Actuate each stop valve individually to the 10 percent closed point with no interaction with other valves
b. Actuate one stop valve to the ten percent closure point and simulate another stop valve at the 10 percent closure point in the following combinations: valves 1 and 2; valves 1 and 3; valves 2 and 4; valves 3 and 4
c. Actuate one control valve at a time in the fast closure mode with no interaction with other valves.

7.7.1.4.4 Environmental Considerations

The pressure regulator and turbine-generator control system is not required for safety nor is it required to operate after the DBA. This system is required to operate in the normal plant environment for power generation purposes only.

Instrumentation and control on the turbines that experience the turbine building normal design environment is listed in Table 3.11-1. The logic, remote control units, and instrument terminals located in the main control room experience the environment listed in Table 3.11-1.

7.7.1.4.5 Operational Considerations

7.7.1.4.5.1 Normal

Two pressure control channels (A and B), operating redundantly, receive inputs from the pressure reference unit and from independent pressure transducers in the main steam lines upstream of the main steam stop valves. Main steam pressure is indicated on meters on the turbine control panel.

The pressure setpoints for the pressure reference circuit are produced by tandem potentiometers driven by a common motor. The motor is controlled by use of pushbuttons on the PRESSURE SETPOINT SELECTOR section of the main control panel. Desired setpoints for Channels A and B are indicated on meters on the main control panel. Pressure setpoint adjustment is limited to a maximum of 1 psi/sec by motor speed. In the event of failure of both regulators, alarm communication is provided in the main control room. Pushbutton operation is provided to remove the system from operation.

7.7.1.4.5.2 Operator Information

Nuclear Steam Supply System Control and Display

The NSSS pressure regulator has the following controls and information displayed in the main control room:

a. Main steam pressure regulator setpoint A

b. Main steam pressure regulator setpoint B

c. Individual bypass valve position indicators

d. Bypass valve test controls

e. Pressure regulator selection control.

Balance of Plant Control and Display

A list of the conventional turbine-generator control and supervisory instrumentation provided for operational analysis and malfunction diagnosis is described in Section 10.2.

7.7.1.5 Gaseous Radwaste System Instrumentation and Control

7.7.1.5.1 System Identification

7.7.1.5.1.1 Function

The objective of the gaseous radwaste system is to process and control the release of gaseous radioactive wastes to the site environs so that the total radiation exposure to persons outside the controlled area is as low as practicable, and does not exceed applicable regulations.

7.7.1.5.1.2 Classification

This system is required for power generation only.

7.7.1.5.2 Power Sources

The 120-V ac instrument bus normally provides power for the gaseous radwaste system instrumentation.

7.7.1.5.3 Equipment Design

7.7.1.5.3.1 General

The radiation levels at the offgas delay pipe and at the discharge of the offgas system are continuously monitored by detectors described in Section 11.4. This system is also monitored by flow and temperature instrumentation and by a hydrogen analyzer to ensure correct operation and control and to ensure that hydrogen concentration is maintained below the flammable limit. Table 7.7-2 lists process instruments that cause alarms and whether or not they are indicated or recorded in the main control room.

7.7.1.5.3.2 Catalytic Recombiner Instrumentation

The catalytic recombiner vessel temperatures are monitored by thermocouples and are then recorded. High or low temperature is annunciated in the main control room. The standby recombiner is temperature controlled, maintained, monitored, and recorded. Any low temperature is annunciated in the main control room. Inlet process gas is monitored for pressure and temperature. If abnormal measurements are obtained, they are annunciated in the main control room.

7.7.1.5.3.3 Offgas Condenser Condensate Level Control

The offgas condenser condensate level is maintained at a given level within the condenser shell. A level control system is used to provide drainage of condensate from the condenser shell. High level is annunciated in the main control room.

7.7.1.5.3.4 Offgas System Flow Measurements

Offgas system flow measurements are made between the charcoal adsorbers and the absolute filter downstream of the ring water buffer tanks before discharge into the reactor building ventilation stack.

7.7.1.5.3.5 Hydrogen Analyzer Measurement System

One hydrogen analyzer is used to measure the hydrogen content of the offgas process stream in the delay pipe. The hydrogen concentration percentage output from the analyzer is indicated and recorded in the main control room along with alarm annunciation for high hydrogen concentration percentage in the offgas process stream.

The hydrogen analyzer system continuously withdraws a sample of the process offgas, analyzes the hydrogen content, and returns the sample gas to the delay pipe. A loss of ac power to the analyzer system stops the analyzer.

7.7.1.5.3.6 Charcoal Vessel and Vault Temperature and Flow Monitoring and Control

Each charcoal vessel is temperature monitored. High vessel temperature is alarmed and annunciated at 100°F in the main control room. The charcoal vessel vault is also temperature monitored and recorded in the main control room along with high temperature alarm and annunciation. Three refrigeration units maintain the vault at a nominal temperature of 70°F.

The charcoal vessel train is flow monitored at the outlet and is indicated and recorded in the main control room along with highflow alarm and annunciation.

7.7.1.5.3.7 Differential Pressure Measurements

Differential pressure measurements are made across the precoolers, the sandfilter, the chillers, the charcoal vessel train, and the absolute filters. High differential pressure is annunciated in the main control room.

7.7.1.5.4 Environmental Considerations

The offgas control system is not required for safety purposes, nor is it required to operate after the DBA. The offgas control systems are required to operate in the normal plant environment for power generation purposes only.

Radwaste instrumentation and controls located in the offgas equipment area are subject to the environment under design conditions listed in Table 3.11-5. The control circuitry, remote control units, and instrument terminals in the main control room experience the normal design environment also listed in Table 3.11-5.

7.7.1.5.5 Operational Considerations

7.7.1.5.5.1 General

No operator action is required on the equipment described unless an alarmed condition occurs. The offgas signal to trip the HWC System is taken from the relay room panel H11-P913. Employing contact-to-coil separation prevents HWC System operation from affecting the Offgas system. Operator indicators and alarms are described in Subsection 7.7.1.5.3.

7.7.1.5.5.2 Setpoints

Hydrogen Analyzer

A hydrogen level of ~1.5 percent alarms and annunciates in the main control room.

Flow

A high flow of approximately 70 scfm alarms and annunciates in the main control room.

7.7.1.6 Liquid Radwaste System Instrumentation and Control

7.7.1.6.1 System Identification

7.7.1.6.1.1 Function

The objective of the liquid radwaste system is to control the release of liquid radioactive waste material to the environs and to package these wastes in suitable containers for offsite shipment and burial.

7.7.1.6.1.2 Classification

Since this system is required for power generation only, it does not include any Quality Class 1 or Category I components with the exception of the drywell drain isolation valve controls. The closure of these valves is necessary for sealing the primary containment under postulated accident conditions. The initiating signal is from the containment and reactor isolation control system (Subsection 7.3.2.2).

7.7.1.6.2 Power Sources

The 120-V ac instrument power is used for the liquid radwaste system.

7.7.1.6.3 Equipment Design

7.7.1.6.3.1 General

The liquid radwaste system is designed to process liquid waste water to remove particulates, impurities, and other materials, and to return the processed water for plant usage. The resulting solid wastes are then packaged in suitable containers for offsite burial.

Only those portions of the liquid radwaste system related to safety are described herein.

7.7.1.6.3.2 Instrumentation and Control

The radiation levels of the waste materials packaged for burial are monitored by plant personnel and are not part of this control system. Wastewater is collected in various sumps throughout the plant and is pumped into the radwaste collection tanks where it is processed. Excess processed liquids that are discharged from the plant are radiation monitored, flow controlled, and recorded. The instrumentation and control system of the radwaste process is typical of a standard chemical and water treatment process. Tank levels are indicated and recorded in the radwaste control room and high tank levels are annunciated in the radwaste control room.

Radiation from the liquid releases is monitored and recorded with high and low/inoperative alarms in the radwaste control room and alarms only in the main control room.

7.7.1.6.3.3 Drywell Sumps Control

There are two sumps within the containment that collect waste water which is pumped out to the liquid radwaste system collector tanks. Each sump is equipped with two pumps that automatically start and stop on high and low sump levels, respectively. The pumps are alternately started on each high level signal. Each pump is equipped with a separate float switch in a separate float well and is electrically connected to provide level backup for the other pump if one float device should fail. A high-high level is provided by each float switch which will start both pumps and annunciate an alarm in the main control room. The liquid discharge lines to the radwaste collector tanks are provided with two isolation valves. When either isolation valve is closed, the sump pumps are interlocked to prevent their operation. The sumps are automatically isolated on high drywell pressure or low reactor water level (L3).

7.7.1.6.3.4 Reactor and Turbine Building Sumps

These sumps collect waste water from their respective areas and automatically pump out the sumps on level control. These are not safety systems. An alarm and annunciation in the radwaste control room will occur on a high-high sump level to allow the operator to take corrective action.

7.7.1.6.3.5 Tank Level and Process Control

All tanks containing waste liquids throughout the radwaste liquid processing system are provided with liquid level indicators or recorders and alarms, and annunciators in the radwaste control room for high liquid level to inform the operator that corrective action is to be taken. The process control is by an operator from the radwaste control room panel. The control system is designed for manual startup and automatic stop when a process is completed (i.e., tank liquid contents have been emptied to next process). Since this is a batch system, the operator has full control and responsibility for the system control process.

The Side Stream Liquid Radwaste Processing System (SSLRPS) operation is controlled from the local control panel in the Radwaste Building Basement. Tank liquid level indicators, recorders and alarms are provided in the local control panel. Radwaste Control Room is provided with a trouble indicating alarm, as a backup, to alert the Radwaste Control Room Operators when the system operation drifts from the normal range.

7.7.1.6.4 Environmental Considerations

The radwaste control systems are not required for safety purposes, nor are they required to operate after the DBA. The radwaste control systems are required to operate in the normal plant environment for power generation purposes only. This environment is listed in Table 3.11-1.

7.7.1.6.5 Operational Considerations

7.7.1.6.5.1 General

The operator is in full control of the process system batches. Indicators and recorders are provided for all liquid tanks to inform the operator of the status of the system. Alarms and annunciation are provided to inform the operator either that a tank must be emptied or processed, or that a particular piece of equipment has malfunctioned so that corrective action may be taken.

7.7.1.6.5.2 Setpoints

All tank levels are set to alarm and annunciate in a timely manner in order to avoid overflow. This allows sufficient time for the operator to take corrective action in the process control.

7.7.2 Analysis

7.7.2.1 General

This subsection demonstrates that the protection systems are capable of coping with all failure modes of the control system.

7.7.2.2 Reactor Manual Control System Instrumentation and Control

7.7.2.2.1 Conformance To General Functional Requirements

The circuitry used in the RMCS is completely independent of the circuitry controlling the scram valves. This separation of the scram and normal rod control functions prevents failures in the reactor manual control circuitry from affecting the scram circuitry. The scram circuitry is discussed in Section 7.2. Because each control rod is controlled as an individual unit, a failure that results in the energizing of any of the insert or withdraw solenoid valves can affect only one control rod. The effectiveness of a reactor scram is not impaired by the malfunctioning of any one control rod. Therefore, no single failure in the RMCS can result in the prevention of a reactor scram. Repair, adjustment, or maintenance of RMCS components does not affect the scram circuitry.

The RMCS is an operational system used for regulating power level and power distribution. This system is self-monitoring with the automatic rod blocks, operator annunciators, and operating status lights (such as the rod position indicators) as part of the system design. The rod blocks are an internal subsystem of this nonsafety system. As such they are designed to be single- failure-proof, but are not designed to stringent safety standards.

The RMCS receives rod block signals from the NMS to prevent improper rod motion that could result in reactor scram. Common LPRM, IRM, and SRM detectors are used, but the signal is physically and electrically isolated before use in the RMCS. This isolation is achieved through two separate relay trip units that prevent any feedback from the RMCS to the RPS. Subsections 7.6.l and 7.6.2 describe this interface.

The performance of the RMCS is monitored by the RPS. If a variable, such as the neutron flux, which is controlled by the RMCS, exceeds specific limits, the RPS takes independent action to cause reactor shutdown.

It is thus seen that the RMCS is not required for safety nor for reactor shutdown, but only for changing plant power.

Accident analyses in Chapter l5 show that failures in the RMCS, such as continuous withdrawal of a control rod, do not result in any fuel damage. No fuel damage results from any single operator error or single equipment malfunction.

7.7.2.2.2 Conformance To Specific Regulatory Requirements

The RMCS meets the requirements of GDC 24 of l0 CFR 50, Appendix A.

No part of the RMCS is required for scram. The rod block functions provided by the NMS and the scram discharge volume high water level trip bypass signal interlocks are the only instances where the RMCS uses any instruments or devices used by the RPS. This includes relay contacts to the reactor mode switch and the scram discharge volume high level bypass switch. The rod block signals received from the NMS prevent improper rod motion before limits causing reactor scram are reached. Common LPRM, IRM, and SRM detectors are used, but physically and electrically separate trip signals are supplied to the RMCS and RPS systems. A description of this interface is contained in Subsections 7.6.l and 7.6.2. The scram discharge volume high water level trip bypass signal interlocks with the RMCS to initiate a rod block. The interlock is performed using isolating relay contacts so that no failure in the control system can prevent a scram.

7.7.2.3 Recirculating Flow Control System Instrumentation and Control

7.7.2.3.1 Conformance To General Functional Requirements

The RFCS is designed so that coupling is maintained between a motor-generator set drive motor and its generator even if the ac power or a speed controller signal fails. This ensures that the drive motor inertia contributes to power supplied to the recirculation pump during the coastdown of the motor-generator set after loss of ac power, and also ensures that the generator continues to be driven if the speed controller signal is lost.

Transient analyses described in Chapter l5 show that no malfunction in the RFCS can cause a transient sufficient to either damage the fuel barrier or exceed the nuclear system pressure limits as required by the safety design basis.

7.7.2.3.2 Conformance To Specific Regulatory Requirements

Except for the recirculation pump trip function, there are no specific regulatory requirements for the RFCS. The RFCS is not a safety-related system and is not required for safe shutdown of the plant, nor is it required during or after accident conditions. The recirculation pump trip function meets the requirements of IEEE 323-1974 and IEEE 344-1975.

7.7.2.4 Feedwater Control System (Turbine-Driven Pumps) Instrumentation and Control

7.7.2.4.1 Conformance To General Functional Requirements

The feedwater is a power generation system for the purposes of maintaining proper RPV water level. Should the RPV water level rise too high, the feedwater pumps and plant main turbine would be tripped. This is an equipment protective action which would result in reactor shutdown by the RPS as outlined in Section 7.2. Lowering of the RPV water level would also result in action of the RPS to shut down the reactor. Further decrease would actuate the emergency core cooling system (ECCS). Loss of feedwater is analyzed in Chapter 15.

7.7.2.4.2 Conformance To Specific Regulatory Requirements

The feedwater control system is not a safety-related system and is not required for safe shutdown of the plant, nor is it required during or after accident conditions. The Feedwater Control System Contains QA Level 1 transmitters classified as NUREG-0588 Category 2B (mechanical) for pressure boundary integrity and Category 2C (electrical).

There is no interface with safety-related systems, with the exception of the Reactor Protection System which provides a Post Scram Signal to the Feedwater Control System.

7.7.2.5 Pressure Regulator and Turbine-Generator Instrumentation and Control

7.7.2.5.1 Conformance To General Functional Requirements

The pressure regulator and turbine-generator instrumentation and control is designed to maintain constant reactor pressure, to follow system load demand fluctuations, and to control turbine speed. Excessive reactor pressure swings caused by failure of this system would be dealt with by the RPS (Section 7.2) and/or the safety/relief valves.

7.7.2.5.2 Conformance To Specific Regulatory Requirements

The pressure regulator and turbine-generator instrumentation and control is neither safety-related nor required for the safe shutdown of the plant. It is also not required during or after accident conditions.

7.7.2.6 Gaseous Radwaste System Instrumentation and Control

7.7.2.6.1 Conformance To General Functional Requirements

The objectives of the gaseous radwaste system instrumentation and control are to indicate and alarm the level of radioactivity within offgas process lines, to provide a record of all radioactive plant site releases, and to initiate appropriate action that would prevent the release of radioactive materials to the environs that exceed the operational limits established in 10 CFR 20 and Regulatory Guide 1.21.

The flow recorder is provided to keep a record of all discharge volumes. The flow measurements and recording accuracies are within 5 percent of indication for the flows measured.

7.7.2.6.2 Conformance To Specific Regulatory Requirements

The gaseous radwaste system instrumentation and control is neither safety-related nor required for the safe shutdown of the plant. It is not required to operate after a DBA. The gaseous radwaste system instrumentation and control is required to operate in the normal plant environment for power generation purposes only.

7.7.2.7 Liquid Radwaste System Instrumentation and Control

7.7.2.7.1 Conformance To General Functional Requirements

The liquid radwaste effluent for discharge to the circulating water blowdown is flow controlled and monitored for activity level. The discharge flow shutoff valve is operated by a keylock switch that requires plant supervisory control of any releases. The flow is recorded in the radwaste control room.

The packaged wastes are stored in the plant in a storage area set aside for this purpose. The radioactivity and quantity is the responsibility of plant supervisory personnel. This complies with Regulatory Guide 1.21, Revision 0.

7.7.2.7.2 Conformance To Specific Regulatory Requirements

Section 11.2 discusses the conformance of the liquid radwaste system to specific regulatory requirements.

TABLE 7.7-1 REACTOR MANUAL CONTROL SYSTEM INSTRUMENT SPECIFICATIONS

Measured Variable	Instrument Type	Instrument Range	Accuracy[d]	Trip Setting[a]
Drive water header pressure	Pressure indicator	0 to 2000 psig	±1/2 percent full scale	-
Drive water pump discharge pressure	Pressure indicator	0 to 2000 psig	±1/2 percent full scale	-
Drive water pump suction pressure	Pressure indicator	30 in. Hg to 60 psig	±1.5 percent full scale	-
Drive water filter differential pressure	Differential pressure switch (indicating)	0 to 75 psig	±1/2 percent full scale	25 psid, increasing
Cooling water header pressure	Pressure indicator	0 to 2000 psig	±1/2 percent full scale	-
Exhaust water header pressure	Pressure indicator	0 to 2000 psig	±1/2 percent full scale	-
Charging water accumulator header pressure	Pressure indicator	0 to 2000 psig	±1/2 percent full scale	-
Charging water header pressure	Pressure indicator	0 to 1800 psig	±1 percent full scale	-
Drive water pump suction Pressure	Pressure switch	30 in. Hg to 10 psig	±1 percent full scale	25 in. Hg, decreasing
Drive water system flow rate	Flow indicator	0 to 100 gpm	±1 percent full scale	-
Drive water header flow rate	Flow indicator	0 to 8 gpm	±2 percent full scale	-
Cooling water header flow rate	Flow indicator	0 to 80 gpm	±2 percent full scale	-
Stabilizing flow rate	Flow indicator	0 to 8 gpm	±0. 5 percent full scale	-

TABLE 7.7-1 REACTOR MANUAL CONTROL SYSTEM INSTRUMENT SPECIFICATIONS

Measured Variable	Instrument Type	Instrument Range	Accuracy[d]	Trip Setting[a]
Control rod drive Temperature	Temperature switch and monitor	0 to 500°F	±1 percent full scale	250°F
Control rod position (normal range)	Reed switches	Full in to full out every 3 in.	NA[b]	-
Control rod drive overtravel (withdraw direction)	Reed switches	NA	NA	2 in. beyond full out position

7.8 EMERGENCY RESPONSE FACILITIES

7.8.1 Introduction

DTE has a technical support center (TSC), an operational support center (OSC), and an emergency operations facility (EOF) onsite; an alternative EOF is located offsite. The TSC is in the office building annex. The command and control area of the primary OSC is an area within the TSC ventilation boundary. Additional areas adjacent or remote to this location are used for support, briefings, and for personnel musters. An alternate OSC is in the machine shop. The EOF is in the basement of the nuclear operations center approximately 6000 ft southwest of the reactor building outside the protected area. The alternative EOF is at the DTE Western Wayne Center, 22 miles northwest of the Fermi 2 site. See Figure 7.8-1 for the location of the facilities within the owner controlled area.

7.8.2 Technical Support Center

7.8.2.1 General

The TSC has been established to provide the capability to display and transmit plant status information to individuals knowledgeable and responsible for engineering and management support of reactor operations in the event of an emergency condition. The TSC building is sited inside the protected area to lessen the time needed by personnel working in the plant to reach the building during an emergency condition. Other key factors considered in the selection of the TSC location included (1) the time needed by personnel working in the control room, in other plant areas, and at offsite locations to reach the TSC; (2) the availability of shielding to minimize exposure to direct radiation from the primary containment for personnel traveling to the TSC from the control room and other plant areas; and (3) the radiation protection (shielding) provided by existing plant structures to personnel arriving from offsite locations. The site chosen for the TSC also supports the efficient routine staffing of the building by plant operations and support groups who will provide added assurance that the systems and equipment necessary for TSC functioning will be maintained in a state of readiness.

The TSC is the emergency operations work area for designated DTE technical, engineering, and management personnel; other DTE personnel required to provide any needed technical support; and a small staff of NRC personnel. The TSC personnel will provide guidance and technical support for the Shift Manager in the control room. However, all control operations will be performed by licensed operators.

7.8.2.2 Design Basis

Information on plant status is provided to the TSC for use by technical and management personnel in support of command and control functions executed from the control room. The TSC does not affect the reliability or availability of the power plant and its safety systems.

The design bases for the TSC are as follows:

a. Function. The onsite TSC will have the following functions:

1. Provide plant management and technical support to plant operations personnel during emergency conditions
2. Relieve the reactor operators of peripheral duties and communications not directly related to reactor system manipulations
3. Prevent congestion in the control room
4. Perform EOF functions until the EOF is activated.

b. Activation time. The TSC is activated according to the RERP Plan and is made functional within prescribed times

c. Information availability. The TSC is equipped with Integrated Plant Computer System (IPCS) displays that provide information on plant status to support control room operations and emergency management. The IPCS also provides sufficient data for the assessment of offsite radiological and meteorological conditions. See Subsection 7.6.1.9.1.2.5.

d. Communications. The TSC is provided with the capability to communicate with all emergency facilities and locations to implement the Radiological Emergency Response Preparedness Plan

e. Habitability. The TSC is habitable during postulated radiological emergencies to the same degree as the main control room. Special shielding and heating, ventilation, and air conditioning (HVAC) systems are provided to minimize personal exposure and to ensure that NRC limits for whole-body exposure and airborne concentrations are satisfied

f. Size and layout. Adequate space is provided for proper functioning of the TSC emergency organization. Adequate space is also provided for equipment necessary for operation of the TSC. (See Figure 7.8-2)

g. Security. Normal plant security measures are maintained during the activation of the TSC

h. Access. The TSC is readily accessible to members of the TSC emergency organization arriving from both onsite and offsite locations. The exposure of personnel manning the TSC to potential direct radiation from the primary containment has been minimized by the selection of an appropriate TSC site and of appropriate access routes to the TSC

i. Fire protection. The TSC construction minimizes the use of combustible materials. Appropriate portable and permanent fire-extinguishing equipment is provided for the TSC and for the HVAC system. Fire-detection instrumentation is provided for automatic shutdown of the building's HVAC system

j. Record storage. Adequate space is provided within the TSC for permanent storage of records, diagrams, and design drawings that are considered necessary to support the functioning of the TSC during emergency conditions

k. Protection against natural phenomena. The TSC is sited and constructed to withstand the maximum postulated 100-year winds and 100-year floods.

7.8.2.3 Codes and Standards

The TSC building is designed and constructed according to the following codes and standards:

a. ACI-318-77 - American Concrete Institute, Building Code Requirements for Reinforced Concrete

b. AISC-1978 - American Institute of Steel Construction, Specification for the Design Fabrication and Erection of Structural Steel for Buildings

c. ANSI A58.1-72 - American National Standards Institute, Building Code Requirements for Minimum Design Loads in Buildings and Other Structures, with

   1. Seismic Loadings conforming to Uniform Building Code (UBC) requirements for Zone 1

   2. Wind loads based on 100-year mean recurrence intervals for exposure type C.

d. UBC-79 - Michigan Uniform Building Code, Seismic Zone 1

e. ACI-531-79 - American Concrete Institute, Building Code Requirements for Concrete Masonry Structures.

The TSC is not classified as a nuclear safety-related facility. Its mechanical and electrical design bases are as follows:

a. Mechanical systems: Quality Group D (includes mechanical system supports) design governed by the codes listed in Tables 7.8-1 and 7.8-2

b. Electrical systems: Non-Class 1E.

7.8.2.4 Description

The TSC is located within the protected area of the Fermi 2 site, approximately 3-1/2 minutes walking time from the control room, as shown in Figure 7.8-3. It is located on the ground floor of the two-story office building annex, partially steel framed, with a 12-in.-thick reinforced-concrete ceiling slab on metal decking. The exterior walls, including labyrinths, are 12-in.- thick reinforced hollow-core concrete block filled with grout. The foundation incorporates spread footing under columns and strip footing under concrete block walls. There is a forced-air supply system, but no forced-air exhaust system; therefore, under normal operating conditions, the TSC will be under slight positive pressure with all entrance doors closed.

The site for the TSC was chosen to optimize the trade-off between travel time from the control room to the TSC and the radiation exposure of personnel enroute from onsite and offsite locations to the TSC. The Fermi 2 plant design was essentially completed at the time of TSC site selection, with the location of the primary containment and control room on the northwest side of the plant, as shown in Figure 7.8-3. To satisfy the NRC guidelines for a 2-minute transit time from the control room to the TSC, it would have been necessary to locate the TSC to the north or west of the plant, which would increase the exposure of personnel traveling to the facility to radiation from the primary containment. Because the TSC could be activated at any time of day, the final site was selected so that members of the TSC emergency organization have access to the TSC from several locations, including the control room, offsite locations, and the plant supervisory offices located in the office building annex. The structures adjacent to the site offer the advantage of maximum shielding to the TSC and its access routes, thus providing acceptable, safe travel time from the control room, should this route have to be traveled.

The TSC, as shown in Figure 7.8-2, covers about 5000 ft^2 including an area devoted to the primary OSC command and control function. Approximately 2075 ft^2 of this area is devoted to occupancy by TSC and designated OSC personnel. The remaining space consists of rooms for records storage, toilets, HVAC equipment, telephone and communications equipment, and electrical equipment. Status boards and marking boards are conveniently located within the monitor room. Telephone jacks and electrical outlets are in the floor.

The NRC has defined four emergency action levels (see Subsection 7.8.2.13) to categorize the severity of various operational emergencies. Additional guidance is published in NUREG-0654, Appendix 1 (Reference 1). The TSC will be activated for events at or beyond the "alert" level. Upon activation, the TSC will be placed in operation after occupancy by a specified number and type of personnel (staffing of the TSC is described in the Fermi 2 Radiological Emergency Response Preparedness Plan) and after TSC communication, monitoring, and occupancy support systems have been energized.

7.8.2.5 Habitability

The TSC occupants are protected from radiological hazards, including exposure to direct radiation and airborne contaminants. Specific design features and administrative procedures ensure that the radiation dose received by TSC personnel does not exceed the limits and guidelines of General Design Criterion (GDC) 19 of 10 CFR 50, and NRC Standard Review Plan, Section 6.4 (Reference 2).

The contributions of several radiation sources are considered in calculating the dose equivalent to TSC personnel. Radiation exposure may derive from immersion in or inhalation of radioactivity in the TSC atmosphere as well as direct shine from sources outside the TSC shield envelope (e.g., reactor building, standby gas treatment system [SGTS] exhaust plume, TSC makeup filters). Shielding is used to reduce the dose equivalent from any single external source to a negligible level; that is, less than one-tenth of the allowable dose equivalent. The radiation shield design considers all shield penetrations, as well as potential radiation sources within the habitable area.

The HVAC system has been designed to facilitate the occupation of all necessary personnel for winter and summer environmental and radiological accident conditions. It is designed to maintain a habitable environment of the same quality as the control room, even though it is not rated safety related, seismic, or redundant. The HVAC system is capable of the following:

a. Maintaining room temperature by removing all heat released by equipment, lights, occupants, and thermal transmission

b. Maintaining room temperature by replacing all heat loss due to thermal transmission, with no credit for lighting, occupants, or equipment

c. Limiting the thyroid radioiodine dose received by personnel inside the TSC

d. Introducing outside air into the TSC envelope will result in a slight positive pressure with respect to the outdoors.

Simplified process flow diagrams for the TSC HVAC system are provided as Figures 7.8-5, 7.8-6, and 7.8-7. The HVAC equipment consists of the following:

a. Air-handling unit: a three-zone, multizone air-handling unit with an air delivery of 5500 cfm. The unit is equipped with a direct-expansion cooling coil with a cooling capacity of 15 tons. Pressure-equalizing baffles are provided in the hot deck, as each zone shall have its own electric heating coil

b. Supply air filter: bag filters that are 80 to 85 percent efficient. The filter-element efficiency is based on the National Bureau of Standards' dust spot test

c. Purge fan: a ceiling-mounted, vane-axial, 4900-cfm purge fan

d. Steam generator: a self-contained, all-electric steam generator. The unit is capable of generating 20 lb/hr of steam for humidification

e. Steam humidifiers: Each zone is provided with a steam humidifier. The steam for humidification is provided from the steam generator

f. Air-cooled condensing unit: a floor-mounted, air-cooled condensing unit with a cooling capacity of 15 tons

g. Electric heating coils: Duct-mounted heating coils for each zone are provided and are rated for their respective zones

h. Toilet room exhaust fan: an air-line, duct-mounted exhaust fan with a 400-cfm capacity

i. HVAC and electric equipment room air-handling unit: This unit has a capacity of 3600 cfm

j. Duct-mounted electric heating coils and unit heaters are also provided for HVAC and electric equipment rooms.

The HVAC system for the TSC has an emergency makeup air system to filter a combination of outside makeup air and recirculation air for pressurization and to maintain the TSC dose within allowable limits. The emergency makeup air system consists of the following components:

a. Prefilters capable of no less than 85 percent filtration efficiency based on the ASHRAE dust spot test

b. A single-stage electric heating coil, capable of raising the air temperature and reducing the relative humidity of the airstream to 70 percent, or less, for the worst inlet condition

c. High-efficiency particulate air (HEPA) filters capable of removing 99.97 percent of particulate matter 0.3 μm and larger in size based on a hot dioctyl phthalate (DOP) test. The HEPA filters are provided upstream and downstream of the charcoal adsorber. The HEPA filters need not be tested as specified in Regulatory Guide 1.52 and need not meet the quality assurance requirements of 10 CFR 50, Appendix B

d. Two charcoal adsorbers (total charcoal thickness of 4 in.) that are capable of removing radioactive and nonradioactive forms of iodine are provided. The charcoal adsorbers are of the drawer type, filled with impregnated coconut shell where the depth of charcoal is 2 in. These adsorbers together have the iodine removal efficiency of not less than 99 percent. The charcoal adsorbers meet the requirements of Regulatory Guide 1.52, and of Table 7.8-3

e. A belt-driven centrifugal fan located upstream of the filter unit is provided to maintain the filter unit at a positive pressure

f. Each charcoal adsorber bank is provided with a two-stage continuous thermistor located across the discharge air path from each adsorber

g. Each charcoal adsorber bank includes a fire protection system for extinguishing a charcoal fire

h. The makeup air unit is provided with instrumentation as required in Table 4.2 of ANSI N509

i. The makeup air unit is provided with drain connections for each compartment of the housing, which are piped to the side of the unit, valved, and drain to the sanitary sewer.

The filter train for the emergency makeup air system is designed to remove radioactive particulates and absorb radioactive iodine. Circulated air consists of a mixture of recirculated air and sufficient outside air to maintain the TSC at a positive pressure of ≥ 1/8-in. water gage. TSC doses will be maintained within allowable limits provided the introduction of outside air does not exceed 1000 cfm.

An area radiation monitor is provided to continuously measure and indicate the general area radiation levels in the TSC. Friskers are available at the entrance to the TSC to provide radiological access control of persons entering the TSC. The TSC has provisions for monitoring iodine by using specific cartridges that can detect iodine levels as low as 1×10^{-7} $\mu Ci/cm^3$. The TSC radiation monitoring equipment is calibrated according to Health Physics procedures and to manufacturers' recommendations.

Sufficient protective clothing is stored in the TSC for personnel. If additional clothing is required, it is available from various designated locations in the plant.

Stationery supplies and duplicating equipment are also available in the TSC.

7.8.2.6 Staffing

Staffing of the TSC is described in the Fermi 2 Radiological Emergency Response Preparedness Plan. The TSC emergency organization is activated for conditions involving an alert, site area emergency, and general emergency.

7.8.2.7 Communications

The communications system is discussed in detail in the Radiological Emergency Response Preparedness Plan.

The plant intercom (HiCom) system used for general plant operations also has extensions in the TSC and other site emergency facilities. There is a public address system within the TSC for general announcements to all TSC personnel.

The communications systems have been tested and their performance evaluated during practice drills and a full-scale exercise. The systems have been found satisfactory for implementing the emergency plan.

7.8.2.8 Instrumentation and Power Supplies

Electric power is furnished to the TSC via two independent non-Class 1E 480-V ac feeders derived from separate offsite sources, each sized to carry the entire TSC load. The feeders are connected to the TSC power distribution system through an automatic transfer switch. On complete loss of offsite power, combustion turbine generators (not associated with the emergency diesel generators) located at the site are capable of providing power. Since the TSC is powered from non-Class 1E sources, TSC loads or faults in the TSC power distribution system will not affect the plant's safety-related power distribution system.

The TSC power distribution system consists of a single motor control center that provides power to the HVAC equipment, lighting and instrumentation power supply transformers, and other TSC auxiliary loads, such as copying machines and microfilm viewers. A separate instrumentation power supply transformer protects the solid-state TSC IPCS data display equipment from power-line disturbances.

Lighting for the TSC consists of recessed ceiling fixtures. Emergency battery-pack lighting is also furnished.

7.8.2.9 Information Systems

The TSC data display system, documentation, plant drawings, control room records, plant chemistry data, plant historical data, analytical data, verbal and recorded information provided by plant operations personnel, radiological assessment and other analyses available from offsite sources, and data provided by the radiological monitoring teams enable the TSC staff to determine the following:

a. The plant status and dynamics before and during the accident

b. The performance of accident mitigation functions

c. The nature and trend of the accident

d. The damage to the plant and equipment

e. The status of the operation (including personnel activity in the plant)

f. The amount of radioactive release to the environment

g. The prevailing meteorological conditions

h. The radiation and radioactivity level of the environs

i. The offsite dose assessment.

A computer-based data handling system, IPCS (see Subsection 7.6.1.9.1), is provided to supply emergency response information for display in the TSC. The IPCS is of high quality and reliability, and is non-Class 1E and nonseismic.

The IPCS displays emergency response information in the control room, TSC, and EOF. Recording, trending, and time-history plotting capabilities are provided within the system. In the event of a complete loss of offsite power, data will be retained by the IPCS during the outage for display once TSC power is restored.

Six workstations for data display are located in the TSC.

7.8.2.10 Records Storage

A file of copies of the following documents is maintained for use in the TSC:

a. General arrangements

b. Process and instrumentation diagrams

c. Piping drawings

d. Logic diagrams

e. Electrical schematics

f. Operating procedures

g. Emergency procedures

h. Technical Specifications

i. Master instrument lists (retrieval by computer)

j. Updated Final Safety Analysis Report

k. Plant operating records

l. Radiological Emergency Response Preparedness Plan and its implementing procedures

m. Radiation exposure histories (retrieval by computer)

n. Other documents sufficient to diagnose potential plant operating problems at the system level.

Other plant documents, or copies, are available for use by the TSC as needed during the course of an emergency. Such documents include those normally stored in other locations at the plant site, such as in the technical staff offices or in the records storage center next to the

TSC. A conventional office copy machine and microfilm viewing and copying devices are located in the TSC for the purpose of copying documents likely to be used during an emergency.

7.8.2.11 Fire Protection

The TSC is constructed using the following noncombustible materials:

a. Exterior: reinforced concrete block walls, reinforced concrete roof, and hollow metal doors. Exposed structural steel has been fireproofed

b. Interior: stud drywall-type partitions and suspended acoustical ceiling. All floor areas except the electrical equipment room, the HVAC room, and the monitor and rest rooms are carpeted. The monitor area has a computer floor with vinyl asbestos tile.

The following fire-protection equipment is provided:

a. Portable carbon dioxide units

b. A water deluge system for the charcoal filters in the emergency makeup filter unit

c. Smoke detectors in the fresh air intake and in the return-air duct of the TSC HVAC system.

7.8.2.12 Evaluation

DTE has provided for a TSC separate from but near the control room. The location in the office building annex ensures operating personnel familiarity with the facility. The TSC has the capability to display and transmit plant status to individuals knowledgeable of and responsible for engineering and management support of plant operations in the event of an accident.

The overall data handling system is the IPCS. The emergency response capability of the IPCS includes measurements that permit assessment of reactivity control, reactor core cooling, reactor coolant system integrity, containment integrity, meteorology, and dose assessment. The IPCS incorporates features and recommendations from NUREG-0696 (Reference 3).

Upon activation, the TSC will provide the initial main communications link between the plant, the OSC, the NRC, and the offsite emergency response organizations until the EOF is available. The TSC will be habitable to the same degree as the control room during postulated accident conditions in accordance with the requirements of NUREG-0578 (Reference 4).

Records pertaining to as-built conditions and layout of structures, systems, and components are available to personnel in the TSC.

In summary, the TSC provides the integrated emergency response capability required by the NRC.

7.8.2.13 Emergency Action Levels

a. Notification of unusual event: Events are in process or have occurred that indicate a potential degradation of the level of the safety of the plant

b. Alert: Events are in process or have occurred that involve an actual or potential substantial degradation of the level of the safety of the plant

c. Site area emergency: Events are in process or have occurred that involve actual or likely major failures of plant functions needed for the protection of the public

d. General emergency: Events are in process or have occurred that involve actual or imminent substantial core degradation or melting with imminent potential for loss of containment integrity.

7.8.3 Operational Support Center

The function of the OSC is to provide an onsite area where licensee operations support personnel will assemble in an emergency. The OSC will:

a. Provide locations where plant logistic support can be coordinated during an emergency

b. Restrict control room access to those support personnel specifically requested by the Shift Manager.

The OSC is an area within the TSC ventilation boundary. Additional areas adjacent or remote to this location can be used for support, briefings, and for personnel musters. These areas can include:

- A designated assembly point near the Control Room (Turbine Building 3rd floor)
- Normal work areas near the TSC
- The machine shop are in the Office Services Building
- Additional areas that may be used when directed by the Emergency Director

The OSC provides areas for the coordination of shift and maintenance personnel to support emergency response operations without causing congestion in the Control Room. Personnel reporting to the OSC include the Fire Brigade, Damage Control and Rescue Teams, Onsite Radiological Emergency Teams, Chemistry personnel, instrument control technicians, and general maintenance personnel.

The OSC is activated for an alert, site area emergency, or general emergency condition. The emergency organization is described in the Radiological Emergency Response Preparedness Plan. The machine shop is an alternate OSC, but any or all the designated OSC areas may serve as an alternate OSC. The designated assembly point near the control room and the area designated in the machine shop are equipped as necessary with supplies and equipment to ensure continued support of the OSC emergency organization. These areas are located such that it would be highly improbable that the different locations would not be habitable at the same time.

The OSC areas are equipped with communications systems and supplies, including protective clothing and equipment. Portable Health Physics equipment is provided to monitor radiological conditions in the OSC. Procedures have been established for control and for periodic inventories, recalibrations, and replenishments of perishable items. Communication to the OSC is via the emergency telephone communications network, radio communications using hand-held radio transmitters, and the plant intercom system.

The OSC also has radiation monitoring capabilities, though its habitability requirements are not the same as those of the control room. The monitoring equipment consists of friskers, dose rate meters, and high range dosimeters. The OSC personnel also have available the use of self-contained breathing apparatus and partial sets of protective clothing. At the direction of the Emergency Director, the OSC leadership shall relocate the command and control of the OSC to the alternate OSC as warranted. Additional muster and staging areas can be established as needed based on plant conditions.

The OSC emergency organization, equipment, and communications systems have been evaluated during a full-scale exercise and have been found acceptable.

7.8.4 Emergency Operations Facility

7.8.4.1 General

The EOF functions as an operational support center with capabilities for the following:

a. Management of overall licensee emergency response

b. Coordination of radiological and environmental assessment

c. Determination of recommended public protective actions

d. Coordination of emergency response activities with federal, state, and local agencies

Facilities are provided in the EOF for the acquisition, display, and evaluation of radiological, meteorological, and plant system data pertinent to determining offsite protective measures. These facilities are used to evaluate the magnitude and effects of actual or potential radioactive releases from the plant and to determine offsite dose projections. The EOF is used to coordinate emergency response activities with those of local, state, and federal agencies, including the NRC. DTE personnel in the EOF will make protective action recommendations for the public to the state emergency response organization.

The EOF is located in the basement of the nuclear operations center (NOC), approximately 6000 ft southwest of the Fermi 2 reactor building, and has been designed for habitability in the event of a postulated accidental radioactive release from Fermi 2. Shielding and HVAC system design ensure that NRC regulations for personnel exposure are satisfied.

The EOF is activated for conditions involving an Alert or higher emergency classification. Emergency plan implementing procedures define the transition of responsibility from the control room to the TSC and the EOF until the latter facilities become functional. The NOC also provides space for managing recovery operations and media briefings.

An alternative EOF is located at the Western Wayne Center, 22 miles northwest of the Fermi 2 site. The facility has adequate communications equipment and sufficient space to accommodate the additional personnel required for continuity of dose projection and decisionmaking capability, including coordination of the offsite teams. Portable equipment is provided for the personnel to perform their assigned functions.

7.8.4.2 Description

The primary EOF is located in the NOC building. Besides housing the EOF, the NOC provides room for supporting personnel required for assistance to Fermi 2 operations. This includes licensing, data control, administrative support, and training personnel. Also contained in the NOC will be the recovery center, a media briefing area, and a food processing and service area. Over 60,000 ft^2 of space will be provided in the NOC for these support personnel. Detailed information about staffing and the emergency organization is contained in the Fermi 2 Radiological Emergency Response Preparedness Plan.

The EOF is located about 6000 ft southwest of the power plant, just west of Quarry Lakes, within the DTE-controlled property boundary (see Figure 7.8-1). The facility can be reached from two directions via roads under the control of DTE. Electrical power is available from either one of two major power substations. An emergency generator is also available to automatically restore power in the improbable event of the loss of both power supplies.

The NOC building has been designed for the following:

a. Roof snow load: 40 lb/ft^2 minimum, plus provisions for drifted snow

b. Floors: 150 lb/ft^2 for entire second floor and for first floor at EOF

c. Stairs: 100 lb/ft^2

d. Wind load: conforms to ANSI A58.1-72, based on 100-year mean recurrence interval for exposure type C

e. Seismic: conforms to UBC for Zone 1.

The construction is standard except for special concrete shield walls surrounding the EOF that provide a protection factor of approximately 20. The internal layout of the EOF is shown in Figure 7.8-10 and consists of space allocated for records, counting facilities, offices, NRC office space, communications equipment, and emergency power (batteries) for communications equipment.

Habitability of the EOF is provided by an HVAC system, which includes a HEPA filter.

Radiation detection alarms are set at approximately three times the background levels to provide an early visual and audible warning to the EOF occupants. Air sampling capability is also provided in the EOF, with the capability to detect iodine concentrations as low as 1×10^{-7} $\mu Ci/cm^3$.

The EOF also has available friskers, dose rate meters, dosimeters of legal record (DLRs), iodine air sampler/detectors, and dosimeters to monitor radiation levels. The quality and quantity of this instrumentation has been determined by surveys, data research, and professional experience. The radiation monitoring equipment used in the EOF is calibrated according to Health Physics procedures and to manufacturers' instructions.

The EOF backup laboratory is equipped with a high-resolution gamma spectroscopy system and other equipment required to perform chemistry and radiochemistry.

Emergency supplies and equipment are stored and maintained in the EOF in accordance with the implementing procedures for the Radiological Emergency Response Preparedness Plan. These are periodically inventoried and calibrated to ensure their availability if needed. These supplies include protective clothing, stationery supplies, and duplicating equipment.

The EOF communication network is described in detail in the Radiological Emergency Response Preparedness Plan.

7.8.4.3 Information Systems

The EOF information systems are commensurate with the EOF functions of:

a. Coordination of offsite response

b. Coordination of radiological, meteorological, and environmental assessment

c. Recommendations for protective actions.

The information required to perform the above functions includes:

a. Assessment of plant status

b. Radiation releases

c. Meteorological data

d. Atmospheric dispersion models

e. Field monitoring for offsite radioactivity.

In addition to the information included in Subsections 7.8.2.9 and 7.8.2.10 for the TSC, the following are available for use in the EOF:

a. Offsite population data

b. Environmental radiological monitoring records

c. State and local emergency response plans

d. Evacuation plans.

7.8.4.4 Staffing

Staffing of the EOF is described in the Radiological Emergency Response Preparedness Plan.

7.8.4.5 Emergency Response Facilities Integration

During emergency conditions, it is essential that there be a continuous high level of interaction and communication among key personnel in the control room, emergency response facilities, and the NRC to ensure that all emergency actions are fully understood and coordinated.

The emergency response facilities are developed to function as an integrated system. DTE's emergency response facilities are designed to provide coordinated support to the control room during emergency operating conditions. These facilities are integrated into the Radiological Emergency Response Preparedness Plan to facilitate coordination with state and local emergency response facilities.

The system design of the emergency response facilities has the following functional criteria:

a. The operation of any system or subsystem within the emergency response facilities does not degrade the performance or reliability of any reactor safety or control system or of any safety-related displays in the control room

b. The operation of any system or subsystem in the emergency response facilities does not degrade or interfere with the functional operation of other systems in those facilities

c. The data acquisition hardware and software are protected against unauthorized manipulation or interference with input signals, data processing, data storage, and data output.

The emergency response function of the IPCS provides a fully integrated data processing system serving all emergency response facilities and systems.

The equipment to be used in the control room during an emergency is identified in Subsection 7.6.1.9. Subsection 7.6.1.9 also addresses the primary variables to be displayed.

CHAPTER 8: ELECTRIC POWER

8.1 INTRODUCTION

Fermi 2 has a net electrical capacity of approximately 1170 MWe generated by a single turbine generator at 22 kV, and stepped up to 345 kV by two parallel transformers. These transformers are connected on the high side to the Fermi 2 345-kV station. This station is interconnected by two double circuit 345-kV lines to the Edison system (Figure 8.2-1). When Fermi 2 becomes operational at full power, the total capacity of the Edison system will be approximately 10,429 MW. When operating in conjunction with the Consumers Power Company, with whom a coordinated system has been established having four interconnections at 345 kV, the total integrated system capacity will be approximately 16,709 MW. Edison also has strong 345-kV interconnections with Ontario Hydro (two interconnections) and Toledo Edison (three interconnections).

Also on the Fermi site is the permanently shutdown Enrico Fermi Atomic Power Plant, Unit 1 (Fermi 1).

Fermi 1 also includes four gas turbine peaking units, each generator having a name plate capacity of 18.8 MVA. These units, as limited by turbine design ratings, have a net electrical output of 62.2 MW (summer) and 75.9 MW (winter). One of these units has the ability to be started by a diesel without the need for an external source of power.

The output of the gas turbine peaking units is connected to the 120-kV station, and this station is connected to the Edison system by three 120-kV lines (Figure 8.2-2).

All lines at both 120 kV and 345 kV are run on a common right-of-way; however, the right-of-way is of such a width that a 345-kV tower falling cannot interrupt all the lines on the right-of-way. The 120-kV and 345-kV transmission lines leave the plant in a common right of way for approximately 5 miles before diverging into different rights-of-way to the final termination at individual stations. Auxiliary power for Fermi 2 comes from both the 120-kV and 345-kV systems. Each system supplies half of the balance-of-plant (BOP) loads and one of the two redundant safety divisions.

Plant auxiliary power for engineered safety feature (ESF) loads for Division I of the two divisions is derived from a 15/20-MVA, 13.2/4.16-kV transformer connected to the secondary of a 120/13.2-kV transformer on bus 101, with an alternate feed from the secondary of the 120/13.8/13.8-kV gas turbine peaking unit transformer. The other division's power is supplied by one secondary winding, 45.32 / 27.99 / 17.33 MVA (ONAF (Oil Natural Air Forced cooling system)), of the 345/4.16/4.16-kV transformer. It should be noted that Fermi 2 has no unit auxiliary transformer. All plant auxiliaries are fed in normal operation from the 120-kV and 345-kV systems indicated above.

The principal voltage for auxiliary power is 4.16 kV, with smaller loads being supplied from 480-V ac load centers and motor control centers (MCCs).

In case of a total loss of offsite power, the unit requirements for power for safe shutdown are supplied by four 2850-kW diesel generators, two per division. Within a division, the two diesel generators are not run in parallel; each supplies a load group comprising about half of the division's emergency power requirements.

The dc power is supplied from three 260-V batteries, two batteries for ESF loads and one battery for BOP loads, to supply dc motors and motor-operated valves. Each battery is center tapped to provide 130-V dc power for control functions (Figures 8.3-9 and 8.3-11). There are two 48-V center-tapped batteries to supply source and intermediate range nuclear instrumentation and radiation monitoring equipment (Figure 8.3-10).

The ESF loads that require electric power to perform their safety function, the function that is performed, and the type of power that is required (ac/dc) are listed in Tables 8.1-1 and 8.1-2.

The design of the Fermi 2 electric power system is up to date with respect to the state of the art for nuclear plants and takes into account all NRC regulations, guides, and design criteria, including General Design Criteria 17 and 18. Regulatory Guides 1.6, 1.9, 1.30, 1.32, and 1.63, and IEEE Standards 308-1971, 279-1971, 323-1971, 317-1972, and 334-1971 are followed, except as noted in Subsection 8.3.1.2.2.2 and Appendix A.1.9. IEEE 323-1974 was taken into account on equipment for which the purchase specification was executed on or after November 15, 1974.

TABLE 8.1-1 ENGINEERED SAFETY FEATURE, AC LOADS

Engineered Safety Feature, AC Loads	Safety Function Performed
Core spray system (including pump motors, controls, and supporting devices)	Provides emergency core cooling by spraying water directly on the core
Residual heat removal (RHR) system (including pump motors, controls, and supporting devices)	Provides emergency core cooling by restoring and maintaining the water level in the reactor core at an adequate height; provides containment cooling using the containment spray mode of operation; removes residual heat from the reactor core during shutdown for refueling or servicing
RHR service water system and ultimate heat sink (including pumps, motors, fans, controls, and supporting devices)	Provides cooling to the essential features of the RHR complex, backup core flooding, and ultimate heat sink for all vital cooling systems
Main steam line monitoring system	Provides indication of gross fuel failure
Containment inboard isolation valves	Isolates the primary containment
Emergency equipment closed cooling water system (including pump motors, controls, and supporting devices)	Provides cooling water to the equipment needed for emergency shutdown
Diesel generator cooling water pumps, vent fans, and associated devices necessary for the operation of the standby power supply	Allows operation of the standby power supply
Main control room ventilation and air conditioning system	Ensures operation of safety-related control and instrumentation devices within their rated temperature
Standby gas treatment system	Reduces the consequences of off-site radiation doses resulting from a postulated accident
Engineered safety feature ventilation cooling system	Ensures operation of safety-related equipment

TABLE 8.1-2 ENGINEERED SAFETY FEATURE, DC LOADS

Engineered Safety Feature, DC Loads	Safety Function Performed
Automatic depressurization system	Relieves the pressure of the reactor pressure vessel to the containment pressure suppression pool
High-pressure coolant injection system accessories only (valves, pumps)	Maintains sufficient reactor water inventory for a small-break area LOCA
Containment outboard isolation valves	Isolates the primary containment
Control power for Class 1E switchgear and other devices included in the safety systems	Provides reliable control of the safety equipment

8.2 OFFSITE POWER SYSTEM

8.2.1 Description

8.2.1.1 Offsite Power Sources

Offsite power is available for the auxiliary power requirements of Fermi 2 at two different voltage levels, 345 kV and 120 kV.

Fermi 2 exports its net generation capability of approximately 1170 MWe at 345 kV after transformation by two parallel transformers from the generation level of 22 kV. The unit is interconnected with the 345-kV transmission system by two circuits or lines with one line per single tower, as shown in Figure 8.2-1. Each circuit is installed on a single tower and the two lines run to the Brownstown Station located about 16 miles away. These lines run over generally flat farmland. Each 345 kV line is protected by two identical and independent line differential schemes (A and B) using digital relays and fiber optic communication paths to provide high speed fault clearing. Each of these digital relays also provides additional time coordinated line protection, as a supplement to the differential schemes. Breaker failure protection is provided as part of the Backup (B) relaying and provides input to the (A) and (B) transfer trip logic. There are two independent fiber optic paths that link Fermi 2 to Brownstown Station. Each digital relay receives a fiber pair from each path as a normal and hot standby input. All four line protection schemes (A and B for each line) provide transfer tripping to Brownstown Station using the fiber optic communication paths as part of the breaker failure protection scheme. Both lines are equipped with time delayed automatic breaker reclosing to restore service to the line in the event of a momentary line fault (e.g., lightning).

The Fermi 2 to Brownstown lines leave the plant on opposite sides of a 500-ft right-of-way with three 120-kV lines routed between them. A plan view of the transmission corridor is shown in Figure 8.2-2; a sectional view of the transmission corridor appears in Figure 8.2-3. The spacing of the lines is such that collapse of either of the 345-kV towers would not interrupt the other 345-kV line, although it can interrupt two of the three 120-kV lines. The Fermi-Brownstown circuits will run to Brownstown Station via 345-kV towers located on the 500 ft out-of-plant transmission corridor to the east side of the Detroit-Toledo Expressway (I-75) and then via 345-kV towers on the Monroe-Brownstown corridor. Angle towers are used for all turns. The towers and lines have been designed for a simultaneous wind loading of 8 lb/ft^2 with a 1/2-in. ice load or, equivalently, a 1-in. ice load without wind load.

Although Fermi 2 does not generate power at 120 kV, it has strong interconnections with the 120-kV system (Figure 8.2-4). There are three 120-kV lines on separate towers running into the plant along the same right-of-way as the 345-kV lines. One line terminates at the Custer substation 13.9 miles away passing through the Shoal substation, the second at Radka 21.7 miles away, and the third at Brownstown 16.3 miles away after passing through the Swan Creek Substation and the Berlin Substation. (These line lengths are historical data and may not reflect the current line lengths.) These lines all terminate at the Toll Road substation located outside of the Fermi 2 owner controlled area. From the substation, the power enters the Fermi 2 120 kV switchyard on lines designated as Toll Road #1, #2, and #3. The 120-kV lines separate from the 345-kV Brownstown line at various points of the right of way and therefore do not follow the 345-kV lines the entire distance to the Brownstown Station but may share right of ways with additional lines (see Figure 8.2-2). These lines run through generally flat farmland with no unusual terrain features. These lines are protected with current differential and timed step distance first-line relaying, with redundant current differential and timed step distance relay backup. All three lines have automatic reclosing after a time delay to restore service in case of transient faults.

The 120-kV switchyard at Fermi 2 is tied to the 120-kV system through the Toll Road substation with three lines. The 120-kV Toll Road-Swan Creek line to the Brownstown station has a strong 345/120-kV source at Brownstown, in addition to two other 120-kV lines. The line to Custer Station ultimately ties to the Consumers Power Company's 120-kV system (Whiting A-1). The Radka line is ultimately tied to Superior Station, which has five additional lines at 120 kV, including two strong ties to the 345-kV transmission system at Wayne.

In March 2003, ownership of the Edison transmission system, including both switchyards, transferred to an independent purchaser, ITC Holdings. Edison and ITC Holdings are members of the East Central Area Reliability Council (ECAR), which also includes other utilities located in the midwestern region of the United States. The total peak load served by ECAR members is about 100,000 MW, and the ECAR members have about 108,000 MW of installed generating capacity.

ECAR members are required to maintain a minimum level of contingency reserves totaling 3 percent of their daily peak load projection, to protect against the unexpected loss of generating sources or other contingencies. An additional 1 percent of the daily peak load projection for each day is required to be maintained by the ECAR members as Load and Frequency Regulation Reserve, for load and frequency regulation. Some of the reserves are available immediately upon request, to meet the contingencies like unit trip and all reserves are required to be available within 10 minutes.

ECAR members are also required to share their reserves in the event of a unit trip, or some other type of system emergency that jeopardizes firm load, under a process referred to as Automatic Reserve Sharing. Thus, there will always be sufficient reserves available to maintain reliability for customers on the Detroit Edison system, even in the event of a trip of the largest unit.

The interconnection capability of Michigan Electric Coordinated System (MECS) study area, which includes Detroit Edison, will conservatively be approximately 3000 MW. ECAR studies show that adverse conditions outside the MECS study area may at times limit the capability to 2500 MW. This capability is sufficient to allow the forced outage of Edison's largest unit while its second largest unit is out of service.

Edison has the following interconnections with other utilities:

a.	Consumers Power	four 345-kV circuits five 120/138-kV circuits
b.	Ontario Hydro	two 345/230-kV circuits* two 230-kV circuits

c. Toledo Edison three 345-kV circuits

* The 230-kV portion of these circuits is located in Ontario.

8.2.1.2 Switchyards

The 345-kV switchyard is located approximately 150 yards from the plant. Its physical configuration is shown in Figure 8.2-5 and its electrical configuration is shown in Figure 8.3-1. The 345-kV switchyard is arranged in a nominal double breaker-double bus configuration. Transformer SS65, the auxiliary transformer serving Division II engineered safety feature (ESF) buses, is fed from the east bus (bus 301) of the switchyard. Switchyard circuit breakers are opened automatically by the associated line or bus relaying. Each breaker has two independent trip coils. The switchyard circuit breakers CM and CF are controlled in the Fermi 2 main control room. Switchyard circuit breakers BT, BM, DM and DF are controlled by transmission company, ITC Holdings. The switchyard has two control batteries, one for each of the two channels of protection (including trip coils) so that a battery or associated protection system failure will not prevent tripping and resultant isolation of faults. Transfer tripping of backup or remote terminal circuit breakers is accomplished through redundant fiber optic links.

The only switchyard fault that could lead to a sustained loss of power to transformer SS65 is a fault affecting bus 301 or transformer SS65 or an open phase condition on the SS65 high voltage side. In this case, the feed from the 120-kV switchyard to transformer SS64 will still be available for Division I power and safe shutdown. Failure of circuit breakers CF, DF or BM will cause a shutdown of bus 301.

If circuit breaker CF should fail, service to bus 301 can be restored in the following manner. Bus 301 would be deenergized with circuit breakers DF, BM and CM open due to backup protective relaying operation which isolated the faulted breaker. Visual inspection of relaying operation indicators would be made along with visual breaker inspection. If it is determined that a breaker failure caused the backup protective relaying to operate, permission would be obtained from the Central System Supervisor to restore service.

The defective circuit breaker CF would be isolated by opening the two sets of manual disconnects associated with circuit breaker CF. This is done at the control pedestal located at the base of the disconnects. Once the disconnects have been opened and tagged for safety purposes, circuit breaker DF and/or BM may be closed to energize bus 301, restoring service to system service transformer 65. The circuit breaker operations required to complete such an alignment is controlled by ITC Holdings. The time required to complete such an operation could vary from a minimum of 1 hr to a maximum of 8 hr.

Similarly, if circuit breaker DF should fail, bus 301 would be deenergized with circuit breakers DM, BM and CF open due to backup protective relaying operation which isolated the faulted breaker. Circuit breaker CM would be opened due to loss of the main machine on loss of system service transformer 65. The defective circuit breaker DF would be isolated by opening the manual disconnects associated with circuit breaker DF. Once the disconnects have been opened, the circuit breaker BM can be closed to energize bus 301, restoring service to system service transformer 65. Alternatively, circuit breakers CF and CM can be closed to energize bus 301, restoring service to system service transformer 65, after opening the intermediate switchyard motor-operated disconnect switches to disconnect the main unit transformers from the circuit breakers CF and CM. The time required to complete such an operation could vary from a minimum of 1 hr to a maximum of 8 hr.

Similarly, if circuit breaker BM should fail, bus 301 would be deenergized with circuit breakers DF, BT and CF open due to backup protective relaying operation which isolated the faulted breaker. Circuit breaker CM would be opened due to loss of the main machine on loss of system service transformer 65. The defective circuit breaker BM would be isolated by opening the manual disconnects associated with circuit breaker BM. Once the disconnects have been opened, the circuit breaker DF can be closed to energize bus 301, restoring service to system service transformer 65. Alternatively, circuit breakers CF and CM can be closed to energize bus 301, restoring service to system service transformer 65, after opening the intermediate switchyard motor-operated disconnect switches to disconnect the main unit transformers from the circuit breakers CF and CM. The time required to complete such an operation could vary from a minimum of 1 hr to a maximum of 8 hr.

The 120-kV switchyard, located at Fermi l about 1/4 mile from Fermi 2, is arranged as a radial-fed double bus as shown in Figure 8.3-1. The switchyard is arranged in such a way that any line fault will not interfere with the ability to energize transformer 1 and, therefore, Division I power. The only circumstance that could result in a sustained loss of power to transformer 1 is a fault affecting the 120-kV switchyard bus 101 or an open phase condition on the transformer 1 high voltage side. In this case, offsite power would be available from the 345-kV switchyard to Division II, which meets minimum safety-feature power requirements. Failure of circuit breakers GH or GD to interrupt a fault will cause a loss of bus 101. However, the power to Division I can be restored by one of two alternatives: the defective breaker can be isolated by use of disconnect switches and the bus reenergized or the source to Division I can be transferred to transformer CTG-11 secondary, thus feeding from 120-kV switchyard bus 102 (Figure 8.3-1).

The l20-kV switchyard was originally built to service the Fermi 1 liquid metal fast breeder reactor which has been permanently shut down. Four 18.8-MW gas turbine peaking units are installed near Fermi l on the Fermi site. Peaking units are of GE heavy-duty industrial design, rated at 18.8 MVA each.

These units may be started individually from the local panels in the combustion turbine generator control rooms. They may also be started from the Fermi 2 control room by a supervisory control system.

The peaker units are located approximately 200 ft south of the 120-kV switchyard, and are enclosed in a separate, fenced-in area. Electrically, there are two units to a peaker bus (buses 1-2A and 3-4A). These buses in turn are connected to the CTG-11 transformer via direct, buried, 25-kV insulated cables. These units operate at 13.8 kV, but the cables to the CTG-11 transformer were replaced with more conservatively rated 25-kV cables to improve the overall reliability of the CTG-11 transformer and the peaking unit block. However, any one of them has sufficient capacity to supply all plant ESF loads connected to Division I buses. One of the gas turbine peaking units is diesel-cranked and can be started without offsite power. The output of this generator can be used to start the other three.

8.2.1.3 Offsite Power Supply to the Plant from the Switchyards

There are five transformers supplying offsite power to Fermi 2. Two of the transformers, SS66 and SS68, provide power to the circulating water pump house and the general service water pump house, respectively, and both are located near their respective pump houses. The third transformer, SS69, provides power to both the circulating water pump house and the general service water pump house. See Subsection 8.3.1.1.1.

The other two transformers, SS64 and SS65, are located on the west side of the turbine building. Transformer SS65 is a three winding 345/4.16/4.16-kV, 34 / 21 / 13 MVA (ONAN (Oil Natural Air Natural cooling system)) 45.32 / 27.99 / 17.33 MVA (ONAF) cooled, outdoor transformer. One secondary winding supplies power to the recirculation pump motor-generator sets. The other winding supplies approximately half of the balance-of-plant (BOP) loads and all of the Division II Class 1E loads. Transformer 65 is equipped with an automatic online load tap changer on each of the 4.16 kV windings to accommodate a maximum switchyard voltage of 105% on down to a minimum switchyard voltage of 92% following a single grid contingency. Transformer SS65 is connected to bus 301 of the 345-kV switchyard via overhead lines.

Transformer SS64 is a 13.2/4.16-kV, 15/20-MVA, OA/FA outdoor transformer. It supplies Division I Class 1E power requirements and BOP loads. It receives its power from the 13.2-kV bus 11 via a buried bus duct. Bus 11 in turn receives its power from transformer 1, a nominal 120/13.2-kV, 24/32-MVA, oil-cooled outdoor transformer. Transformer SS64 is equipped with a +/- 15 percent automatic acting Load Tap Changer and a fixed tap setting of -5 percent which maintains adequate Division 1 voltages with 120 kV voltage variations between -10 percent and +20 percent which envelopes the +5 percent to -6.7 percent range. Without action from the Load Tap Changer, the Division 1 voltages would not remain adequate for the entire range of 120 kV voltages. The Load Tap Changer has a 20 second delay before movement and is set to maintain 121.8 V ac +/1 V ac. After the 20 second time delay the Load Tap Changer is capable of moving one tap approximately every two seconds resulting in a voltage change of approximately 0.9375 percent for each movement. Transformer 1 is located within the 120-kV switchyard and is connected to bus 101 of that switchyard. An alternate feed has been supplied to transformer SS64 from bus 1-2B. Bus 1-2B in turn receives power via an overhead enclosed bus duct from transformer CTG-11, a 120-kV to 13.8-kV, three winding, 60/68-MVA, oil-filled transformer. This transformer also serves as the step-up transformer for the four gas turbine peaking units located near Fermi 1. Transformer CTG-11 is located within the 120-kV switchyard and is connected to bus 102 of that switchyard.

CTG 11-1 is utilized as the alternate ac source for a Station Blackout event and to support response by the Dedicated Shutdown Panel to an Appendix R fire. An alternate CTG started with the standby diesel generator can also be utilized as an alternate source of this ac power.

The feeders from transformers SS64 and SS65 are run into the plant in completely separated systems to preserve the independence of the two offsite supplies. Transformer SS64 is run in underground ducts and in nonsegregated cable bus. Transformer SS65 is run in nonsegregated cable bus only.

Fermi 2 has installed open phase detection and isolation systems on the high voltage side for the system service transformer 1 and SS65 that powers Division I & II ESF and BOP buses to ensure that plant safety-related structures, systems and components perform their intended functions under postulated open phase conditions.

8.2.1.4 Design Capabilities for Periodic Inspection and Testing

The protective equipment on the 345-kV offsite power system is in itself redundant. Each of the two 345 kV lines have two identical and independent relay schemes utilizing fiber optic communications. There are two independent fiber communication paths between Fermi 2 and Brownstown Station, which serve each relay. The redundant relay schemes for each line operate from separate ac current and potential sources and the dc control is fed from separate batteries. The control for each line relay scheme operates separate redundant trip coils at each breaker. Breaker failure protection is provided as part of the backup (B) line relaying and provides input to (A) and (B) relaying schemes as available, to provide tripping of adjacent breakers and transfer trip for remote breakers.

The use of two relaying schemes with the redundant batteries and trip coils, along with current shorting switches and potential throwover switches, allows for the inservice shutdown of any one relay and control scheme for testing while maintaining one relaying scheme in service. The use of the double breaker-double bus scheme allows for the shutdown of one breaker without shutdown of the line itself. The breaker may then be tested with the relaying schemes as desired.

The 345-kV bus 301 has two protective bus differential relaying schemes, either one of which may be shut down for testing while maintaining the other in service. All control operations except actual tripping of the breakers can be done while maintaining bus 301 in service. Associated breaker operations may be completed one at a time to maintain service to the bus.

The 120-kV offsite system allows for periodic testing in the following manner. In addition to the combustion turbine generators, the 120-kV switchyard, which ultimately supplies Division I ESF buses, has three sources of power, composed of three 120-kV lines. Any of the lines may be shut down for complete periodic testing and still maintain two sources of power to the switchyard.

The design of the Edison system and the excellent reliability and percentage of correct operations are a result of this design and the effort to give maximum service and reliability. This design is in full conformance with General Design Criterion 18.

8.2.1.5 Conclusions

It is concluded that the design and configuration of the offsite power system conform to the requirements of IEEE 308-1971, Regulatory Guide 1.32, except for Parts 1d, 1e, and 2b, and General Design Criteria 17 and 18 of 10 CFR 50, Appendix A. These sections required compliance with Regulatory Guides 1.75 and 1.93. For discussions of those guides, see the applicable sections of Appendix A of this UFSAR.

8.2.2 Analysis

8.2.2.1 Loss of Fermi 2

Analysis of the Edison grid and surrounding systems was conducted, assuming the sudden loss of Fermi 2 during a period of maximum system demand and heavy power import. System stability is generally more critical during periods of heavy power import. A study was conducted using a digital computer program that models the Edison power system and those systems with which it has strong interconnections. The model treats large generators in both the Edison system and surrounding systems as discrete entities.

The analysis of the Edison offsite power grid stability, assuming a sudden trip of Fermi 2, indicates that the grid is stable.

The studies also indicate that the grid is capable of supplying the necessary offsite power if Fermi 2 is lost. This conclusion is based on the following analysis of the studies:

a. There is no evidence of cascading resulting from either high circuit loadings or depressed network voltages, because:

    1. Transient and steady-state postfault network voltages are at or near prefault conditions

    2. Transient and steady-state postfault network line flows are within emergency ratings.

b. Based on generator rotor angle changes, no machines tend toward instability

c. Transient and steady-state postfault Fermi auxiliary supply voltages are near prefault conditions.

A series of studies that consider a large Edison import have been made to examine the consequence of a system fault combined with a circuit breaker failure. This study assumed that:

a. The system modeled was that planned by Edison for early 1979 assuming Fermi 2 operational

b. System load was at the peak expected value for that period

c. Edison was importing 1300 MW of power, approximately 15 percent of net demand and roughly half of the system's net import capability

d. One 800-MW unit at the Monroe plant, the large fossil station nearest the Fermi site, was not operating

e. Only the Fermi 2 generator was in service at the Fermi plant

f. The postulated contingency was a three-phase fault on the Fermi-Brownstown 345-kV #3 circuit adjacent to Fermi 2

g. In addition, a circuit breaker failure at the Fermi 345-kV switchyard was assumed, which actuates backup relaying, resulting in disconnection of Fermi 2 from the grid.

The stability evaluation consisted of a prefault load flow, a transient stability study of the fault and immediate postfault system conditions, and a postfault steady-state load flow simulating system conditions after transients have subsided.

The prefault load flow study, which provided the initial conditions for the transient and the posttransient studies, included a detailed representation of the Edison, Consumers Power, Ontario Hydro, and Toledo Edison systems. Other interconnected systems were represented either to a lesser degree, or by an equivalent of the system.

The transient stability study showed the first 2 sec after the contingency occurs. The contingency considered involves a three-phase fault adjacent to the Fermi 345-kV bus on the Fermi-Brownstown #3 circuit and subsequently, backup protection operates in 12 cycles to isolate the faulty circuit breakers BM and BT at the Fermi station. Simulation of generators of 500 MW or greater capacity, which are electrically close to the Fermi plant, included transient saliency and excitation response.

The postfault load flow portrayed system conditions after transients have subsided and prior to automatic tieline and frequency control actuation to recover the Edison generation loss. During this period, the loss of generation is assumed offset by discrete load and generation changes that result from the drop in system frequency.

The transient stability and postfault load flow studies indicated that both the grids at 345 kV and 120 kV are stable and that Edison and its interconnected systems are capable of supplying the necessary offsite power. This conclusion was reached since there was no evidence of cascading, which could have resulted from either high circuit loadings or depressed network voltages. Steady-state postfault network voltages were at or near prefault conditions, and steady-state postfault network line flows were within emergency ratings. There was no apparent reaction of network protective relaying to transient network line currents and voltages. System transient studies are periodically updated, as system loads and configurations change, to verify that Edison's stability criteria are being met.

8.2.2.2 Outages of Transmission Lines Into Fermi

To demonstrate the reliability of the lines supplying the Fermi site, a historical study of unscheduled line outages on the existing 120-kV system was made. The following outages are an actual record of the outages of the 120-kV lines and buses at the Fermi plant. These interruptions are of the unscheduled variety and were recorded anytime the through current was interrupted. A number of these interruptions were of a momentary nature; that is, the current was automatically restored within seconds.

Unscheduled Outages[a]
Lines, 120 kV into Fermi Plant

Line	Length (Miles)[e]	1968	1969	1970	1971	1972	1973	Interruptions Average/Year
Fermi-Custer[b]	9.5	2	2	2	3	2	1	2.16
Fermi-Luzon[c]	21.5	0	0	0	2	1	2	0.83
Fermi-Brownstown[d]	16.1	2	0	1	4	3	3	1.66

a For additional, more current information on outages, see Table 8.2-1

b Line renamed in 1995 to Fermi-Shoal and Shoal-Custer lines. The Fermi-Shoal segment was revised to Fermi-Toll Road and Toll Road-Shoal in 2018.

c Line renamed in late 2003 to Fermi-Radka and Radka-Luzon. The Fermi-Radka segment was revised to Fermi-Toll Road and Toll Road-Radka in 2018.

d Line re-named in 1989 to Fermi-Swan Creek and Swan Creek-Brownstown lines and renamed in 1996 to Fermi-Swan Creek, Swan Creek-Berlin and Berlin-Brownstown lines. The Fermi-Swan Creek segment was revised to Fermi-Toll Road and Toll Road-Swan Creek in 2018.

e These line lengths are historical data and may not reflect the current line lengths.

Buses, 120 kV at Fermi

Bus	1968	1969	1970	1971	1972	1973	Interruptions Average/Year
101	0	0	0	1	0	0	0.166
102	0	0	0	1	0	1[f]	0.33

f This outage was due to a gas turbine peaking unit cable failure, which directly affects the 120-kV system. These cables have been replaced with extra-insulated cables (25 kV) to increase reliability.

A similar historical analysis of the actual 345-kV system was not possible since the lines are relatively new into Fermi 2. Past outages in this region most often have been the result of lightning strikes; however, outages due to gunshots, train derailments, galloping conductors, equipment failure, and unknown causes have also occurred. The average occurrence rate for thunderstorms is 35 per year. Circuit failures causing outages for 5 minutes or longer have occurred at a frequency of 1.0 per 100 circuit-miles per year. Failures causing outages for less than 5 minutes have occurred at a rate of 4.0 per 100 circuit-miles per year.

To achieve a base for viewing reliability of the 345-kV system, transmission performance data published by ECAR and MAIN reliability regions were used to yield estimated circuit unavailabilities for both the 345-kV and 120-kV transmission systems. This outage rate includes both scheduled and unscheduled outages.

Out-of-plant transmission availability can be measured by circuit outage rates and restoration time following an outage. The data are statistical in nature and are, therefore, subject to the number of circuit miles and geographical area for which historical performance data were available to compile the outage rate. Data for 120-kV circuits should be fairly representative because of the considerable number of circuit miles and years for which operating records are available. The data base available for evaluation of 345-kV circuit outage rates is not extensive, and is, therefore, more subject to change. The outage rate and restoration time data in Table 8.2-2 are for this reason based on a mixture of judgment and operating experience.

The stability studies in Subsection 8.2.2.1 lead to the conclusion that the two systems are electrically independent.

Another area of possible susceptibility to common failure is transmission line crossovers. The two Fermi-Brownstown 345-kV circuits are on separate tower lines. The crossovers that exist are

a. Fermi to Brownstown #3, south 345-kV circuit <u>crosses over</u> the Toll Road #1, Toll Road #2, and Toll Road #3 120-kV circuits (three 120-kV Fermi circuits) near the Fermi power plant at Toll Road and again when 345-kV circuit turns north at Highway I-75 at Mentel Road crossing over the Toll Road-Shoal, Toll Road-Radka, and Toll Road-Swan Creek lines

b. Monroe to Brownstown 345-kV (2) circuits <u>cross over</u>

    l. Fermi to Brownstown #3 north of Post Road at I-75

    2. Three 120-kV Toll Road circuits at I-75.

c. Monroe to Wayne and Monroe to Coventry circuits <u>cross</u> <u>over</u>

    1. Toll Road-Shoal 120-kV circuit near I-75

    2. Toll Road-Radka 120-kV circuit near War Road.

d. Majestic to Monroe-Allen Junction tap and the Majestic to Lemoyne circuits near Covell Road <u>cross over</u> the Toll Road-Radka 120-kV circuit

e. Fermi to Brownstown #3 north 345-kV circuit crosses over all three 120-kV lines twice at the Toll Road substation.

Based on the above, the most critical failure would be the collapse of the Fermi-Brownstown 345-kV north or south circuit out of Fermi as they pass over the 120-kV circuits as described in a. or e. above. Although this could cause the loss of all 120-kV circuits, the remaining Fermi-Brownstown 345-kV circuit out of Fermi would remain in service.

Based on this information, it is concluded that even in the case of a major earthquake, tornado, or similar cataclysmic event, the simultaneous loss of all offsite power transmission is improbable. However, should a complete loss of offsite power occur, the ESF buses will be supplied from the standby emergency diesel generators (EDGs).

8.2.2.3 <u>Switchyard Outages</u>

The primary defense against a total loss of offsite power is the complete independence of the two switchyards. The 345-kV and 120-kV switchyards are physically separated by more than a quarter of a mile and have no electrical interties. Therefore, other than a major natural disaster, such as a tornado or an earthquake of unexpected magnitude, no single event could precipitate the simultaneous loss of both switchyards.

The 345-kV switchyard double breaker-double bus design maximizes circuit, unit, and system service transformer availability by allowing terminal equipment maintenance without a complete shutdown of the associated circuit, unit, or system service transformer. On occurrence of a line fault, the provided protective relay schemes will:

a. Open the affected breaker

b. Initiate the breaker failure scheme.

In case the breaker called on to open fails to function or interrupt the fault within a predetermined time, the breaker failure scheme will:

a. Initiate transfer trip to open the breakers at the remote terminal of the line

b. Open all local breakers necessary to isolate the fault and defective breaker.

With the exception of a breaker failure-scheme operation resulting in tripping of all bus 301 breakers, no 345-kV line fault will cause the interruption of power transformer SS65.

Any defective breaker in the switchyard can be isolated with disconnect switches and power restored. The only failures that could cause a sustained outage of power to transformer SS65 are

a. A fault on bus 301 or associated equipment

b. A fault on either transformer SS65, or its feeder on the secondary side, detected by the transformer phase and neutral overcurrent or differential protection relays

c. A sudden pressure rise in the transformer oil

d. An open phase condition on transformer SS65 high voltage side.

As shown in Figure 8.3-1, the 120-kV switchyard is arranged with two buses tied together by a normally closed circuit breaker. On occurrence of a l20-kV line fault, the provided first-line or backup relay schemes will open the affected breaker to isolate the faulted line without interrupting power to transformer SS64. The only failures that could cause a sustained interruption of power to transformer SS64 are

a. When fed from bus 11 (normal feed)

 1. A fault on bus 101 or its associated equipment

 2. A failure of transformer 1 and its associated bus 11

 3. A failure of transformer SS64, its associated feeder cable, or primary breaker

 4. A fault on 120-kV bus 102 with a breaker failure of section breaker GH

 5. An open phase condition on transformer 1 high voltage side.

b. When fed from transformer CTG-11 (alternate feed)

 1. A fault on bus 102 or its associated equipment

 2. A failure of circuit switcher ‘GL’, transformer CTG-11 and its associated buses

3. A fault on circuit switcher ‘GJ’, 13.8-kV transformer SS62 and its associated buses (Fermi 1 equipment)
4. A failure of transformer SS64 or its primary breaker
5. A fault on the 120-kV bus 101 with a breaker failure of section breaker GH.

If an event should occur causing loss of power through transformer 1 and bus 11, transformer SS64 can be immediately restored by closing the feed from transformer CTG-11 via bus 1-2B. The controls for these breakers are on panel H11-P809 in the Fermi 2 control room.

8.2.2.4 Conclusions

Since the feeder to transformer SS64 is run in underground bus ducts and the feeder to transformer SS65 is run overhead, it is evident that no single occurrence except a major earthquake would cause the simultaneous loss of the feeders to both transformers.

It is concluded that the offsite power system is in conformance with General Design Criterion 17 of 10 CFR 50, Appendix A, and complies with the applicable sections of IEEE 308-1971 and Regulatory Guide 1.32, except for Parts 1d, 1e, and 2b. These sections required compliance with Regulatory Guides 1.75 and 1.93. For discussions of those guides, see Subsections A.1.75 and A.1.93.

8.2.2.5 Operation With Degraded Grid

8.2.2.5.1 Analysis

Based on the 1991 Edison grid configuration, generation capability, and predicted load, electrical equipment operating requirement limits were identified for Fermi 2 offsite power sources. These limits ensure satisfactory operability of all electrical equipment during all modes of plant operation, and are listed in the Nuclear Plant Operating Agreement (NPOA) for the Fermi 2 Nuclear Power Plant. The NPOA contains the detailed operating requirements for Fermi 2. The NPOA Transmission System Operating Criteria section contains nominal offsite source voltages, minimum continuous voltage, maximum continuous voltage, minimum frequency and maximum frequency.

These figures are based on results of load flow and stability analyses that calculated the grid response to contingencies designed to be the worst possible and to limitations for operating requirements of Fermi 2 auxiliaries and safety-related equipment.

At the conditions defined above, the voltage limits during continuous operation were calculated for all safety-related buses.

At the voltages specified, all safety-related loads are capable of performing their safety functions. Further load flow and stability analyses were run for a simulated loss of Fermi 2 or a loss of the largest grid load while operating at the limits identified previously.

The Ludington pumped storage plant constitutes the largest single grid load that could be lost at once. Based on the analysis for either situation, the following conclusions were evident:

a. Grid system stability is maintained

b. System frequency fluctuations that occur are insignificant

c. Voltage fluctuations are short lived and, allowing for normal grid voltage operating adjustment, do not exceed the limits previously stated.

No grid operating restrictions for spinning reserve, either real or reactive, within a designated distance from the plant site are required to maintain the offsite power sources within the limits specified.

In the course of the various voltage analyses, all previous transformer tap settings were verified. For the loads fed from the 120-kV system, the voltage regulation setpoint for the +20, -10 percent load tap changer of SS64 transformer was determined. Voltage regulation setpoints were also verified for the 480-V bus ±10 percent induction regulators fed from the 345-kV system via transformer SS65. Operational setpoints were chosen to optimize voltage levels for all modes of plant operation and to ensure that all electrical equipment can function as required when called on.

8.2.2.5.2 Identification of Degraded Grid Condition

Each of the Fermi 2 offsite sources is monitored by indicating voltmeters. In addition to the offsite source voltmeters, a low voltage alarm sensor and an indicating voltmeter are provided for monitoring the Division I 4160-V buses 64B, 64C, 11EA, and 12EB, since they are all at a common bus voltage. Another indicating voltmeter and a low voltage alarm sensor are provided for monitoring the Division II buses 65E, 65F, 13EC, and 14ED. In both cases, the low voltage alarm sensor will initiate alarms in the control room through the annunciator if the voltage on the buses drops below normal. The alarms will actuate at approximately 4.08 kV for the 120-kV source and 4.09 kV for the 345-kV source. These alarms would consist of both audio and visual indication to attract operator attention.

Supplementing the indicating voltmeters are recording voltmeters for each of the reactor building safety-related 4160-V buses. These could be used also to evaluate voltage at the corresponding bus in the residual heat removal complex since the voltage is essentially the same.

Safety-related 480-V buses use one indicating voltmeter per division. The voltmeter may be switched to read the desired bus voltage. Similarly, one 480-V bus within a division may be placed on a recording voltmeter as required. Since continued plant operation is directly dependent on the offsite source voltage, only those voltages would be alarmed.

8.2.2.5.3 Response To Degraded Grid Condition

Under certain unlikely operating conditions, the 120-kV bus voltage could drop below the limit specified in Subsection 8.2.2.5.1. For both the 345-kV and the 120-kV systems, two methods exist to maintain the proper voltage at the safety-related buses.

On receipt of the ESF bus voltage alarm but before the voltage has fallen below the minimum specified in Subsection 8.2.2.5.1, the plant operator, in conjunction with the System Supervisor, will take corrective action to prevent the grid voltage from decaying further. These actions may include, but are not limited to, initiation of the offsite peaking units or offsite switching.

Should the voltage continue to decay, undervoltage relays offer further protection. Two levels of undervoltage protection exist at the 4160-V safety-related buses. The primary undervoltage relays detect complete loss of offsite power and will be set below the allowable motor-starting transient with a brief time delay. The second level of undervoltage protection will prevent the voltage at the safety-related buses from slipping below the minimum required voltage for safety related loads. A moderate time delay provides immunity to grid and starting transients. A more conservative, time delay duration is applied for a degraded grid condition concurrent with a LOCA. Specific features of the second level of undervoltage protection are described below:

a. The undervoltage relays are set in accordance with design calculations to preclude damage to Class 1E equipment. A time-delay setting was chosen to avoid the operation of the relay for motor-starting conditions. The relays are qualified to Class 1E requirements and located in, and connected to, the Class 1E switchgear and fed from bus potential transformers that are also qualified to Class 1E requirements

b. Alarm relaying has been provided to alert the operators that a low-voltage condition exists. The setpoint of the alarm relay is above that of the degraded grid trip setting. This was done to give the operators advanced indication of system degradation. It also eliminates any possibility that setpoint drift would permit the trip function to be actuated ahead of an alarm. It does not in any way affect the time delay of the degraded grid relaying

c. The time delay for the actuation of the degraded grid undervoltage relay has been selected to be as short as possible, without encountering spurious trips from motor starting

d. A second, shorter time delay exists for the actuation of the degraded grid undervoltage relay with a concurrent LOCA. This second time delay was established to support Branch Technical Position (BTP) PSB1 Position B.1.b.1

e. The degraded grid voltage protection system at Fermi 2 meets all applicable requirements of IEEE Standard 279-1971, "Criteria for Protection Systems for Nuclear Power Generating Stations," as outlined in Branch Technical Position (BTP) PSB1

f. If offsite power is lost, the degraded grid relay output is inhibited upon opening of the associated offsite power supply breaker. The emergency diesel generators would start, and, when synchronous speed is achieved, the automatic sequencer would begin to add loads as required. If a safety injection actuation signal is received, the sequencer would automatically shed all loads from the emergency diesel generators. The sequencer would then begin adding ESF equipment as needed to mitigate the consequences of the accident. The degraded grid relaying is not designed to operate during sequencer operation. The diesel generator bus load-shedding feature is automatically bypassed once the diesel generator is supplying power to the bus. This is required so that the voltage drops encountered during load sequencing on the diesel generators will not interact with the load-shedding feature and negate the load sequencing

g. The Class 1E buses have been analyzed for all anticipated operating situations. Section 8.3 provides a description of the Class 1E distribution system

h. Measurements have been made during the preoperational test program to verify the Class 1E bus analysis techniques.

An independent scheme is provided for each division of emergency power. Within a division, both types of undervoltage relays can automatically trip the offsite feeder breaker and initiate load shedding. Upon start of the EDG and the subsequent EDG breaker closure, the diesels would be loaded by the automatic load sequencer.

Limiting conditions for operation, surveillance requirements, and trip setpoints are included in the Technical Specifications.

8.2.2.5.4 Periodic Verification of Grid Adequacy

To ensure that grid configuration changes do not adversely affect the present analyses, Edison constantly reviews the transmission grid system stability and voltage levels. On a yearly basis, an official company 5-year load and generation forecast is made. Based on these forecasts, base grid systems for a 5-year period are established. These base grid systems are tested via computer simulations to meet voltage and stability criteria. From the results of these tests, any grid configuration modification or operating restrictions required to maintain required grid operation are initiated. Verification of voltmeter accuracy and alarm setpoints for the low voltage alarm sensor will be made periodically, either at unit shutdown or at least once every 4 years.

In addition, during preoperational testing, the plant auxiliary system response was determined from actual measurements and these results were compared to the computer-simulated results to confirm the adequacy of the computer program.

Degraded grid voltage adequacy is ensured by the Fermi 2 electrical design basis calculations along with the yearly performed grid analyses.

8.3 ONSITE POWER SYSTEMS

8.3.1 AC Power Systems

8.3.1.1 Description

Figure 8.3-1 shows the auxiliary ac power systems for Fermi 2. The offsite or preferred power for the ac power systems is supplied from the 120-kV and 345-kV transmission system through stepdown transformers. Alternate power for the engineered safety feature (ESF) systems is available through tie breakers that can tie the ESF bus to the opposite system transformer, for maintenance only. The main and tie breakers are interlocked in such a way that in no case can the two offsite power sources be tied together. Transfer to and from a maintenance tie source without interruption is possible, but the emergency diesel generator (EDG) of that particular bus must be used to make the transfer. This is accomplished by paralleling the EDG with the source, removing the source, paralleling with the alternate source, and then securing the EDG. Standby or onsite power originates at the EDGs housed in a physically separate Category I structure near the reactor building, known as the residual heat removal (RHR) complex.

Also available is CTG 11-1 or an alternate CTG 11-2, 11-3, or 11-4 which can be aligned to the 120-kV switchyard to act as the alternate ac source for a Station Blackout event and as a power source for the Dedicated Shutdown Panel.

The ac auxiliary power system as used in the plant has the following voltage levels:

a. 4160 V for loads above approximately 300 KVA

b. 480/277 V for loads below approximately 300 KVA.

8.3.1.1.1 Power Supply Feeders

Power supply feeders are of proven electrical, physical, and thermal qualities. They are sized to carry the load currents, with conductor temperatures remaining within the limits established by IPCEA and IEEE to obtain full expected cable life. The feeders are connected to their respective buses through air circuit breakers which are specified and constructed according to the applicable standards of ANSI, NEMA, and IEEE. These 4160-V circuit breakers are capable of an interruption capacity of 350 MVA. The 480-V breakers are of the following ratings:

	Symmetrical Interrupting Rating	
Breaker Type	Instantaneous amps	Delay amps
K600S	30,000	30,000
K1600S	50,000	50,000
K3000S	65,000	65,000

The calculated phase short circuit current for all feeders is always below the interrupting capacity of the breakers.

The preferred power for Division II is supplied from the system service transformer SS65 to the 4.16-kV buses through a nonsegregated cable bus system. A separate feeder bus section services each of the two 4.16-kV windings of transformer SS65. One feeder bus services switchgear bus 65G, which feeds only the two reactor recirculation pump motor-generator set drives. The other feeder bus is routed independently to Division II ESF buses 65F and 65E in the reactor building and balance-of-plant (BOP) buses 65D and 65W in the radwaste building, as shown in Figure 8.3-1.

Preferred power for Division I ESF buses is supplied from transformer SS64, through a feeder bus consisting in part of underground cable and ducts and nonsegregated cable bus coming off the 4.16-kV winding. In addition to Division I ESF buses 64B and 64C in the reactor building, BOP bus 64A and 64V in the radwaste building is also served by this feed.

A third feeder bus serves BOP loads in the circulating water pump house from transformer SS66. A fourth feeder bus supplies loads located in the general service water pump house, and is fed from transformer SS68.

A fifth feeder from the 345-kV transmission system via transformer SS69 provides an alternate feed to the BOP loads in the general service water pump house and the circulating water pump house. Transformer SS69 is fed from 345-kV bus 302. The feeds to the circulating water pump house BOP loads are split between transformers SS66 and SS69, with manual transfer of the feeds to the buses from the main control room. The feed to the general service water pump house BOP loads are split between transformers SS68 and SS69, with manual transfer of the feeds to the buses from the main control room (refer to Figure 8.3-1).

Bus feeders to and from the system service transformers are not classified Class 1E as defined by IEEE 308-1971. However, those feeder buses that service Class 1E switchgear buses are separate and independent of each other, so that any failure on one bus cannot affect the other.

The four feeders from the four EDG buses are contained in Class 1E underground concrete ducts. This onsite power supply is used as the standby supply to the ESF system buses in the event of the loss of offsite power.

8.3.1.1.2 Busing Arrangements

Switchgear buses are arranged and located to maintain electrical and physical independence between divisions of the safety systems. Separate switchgear rooms ensure the physical independence of safety divisions.

The two redundant ESF divisions include four 4.16-kV buses each. Two buses of each division are located in the RHR complex, and two are located in the auxiliary building (Figures 8.3-2 through 8.3-6). These buses service all 4.l6-kV safety loads, as well as provide a power bus source for lower voltage subdivisions at 480-V ac (Figures 8.3-5 and 8.3-6) and l20-V ac for ESF equipment (Figure 8.3-7). Except as noted below, the two divisions have no interconnections.

Within a division, ac loads are divided into two groups, each supplied by the common system service transformer. A diesel generator is assigned to power each group, when required. The EDGs are connected to a dedicated bus in the RHR complex rather than directly to the ESF buses in the reactor building, so that the cabling is minimized. The ESF bus located in the

RHR complex, the cable between the equivalent 4160-V ac bus in the reactor building, and the feeder breaker are included in a total differential protection scheme, avoiding the problems associated with the use of an overcurrent scheme on a feeder where full load currents are different when the feed direction reverses.

Several BOP loads in the reactor building are serviced by the safety buses. In case of a loss of offsite power, a load- shedding scheme initiates tripping of all breakers on 4160 V and 480 V, except 4160/480-V transformers and ESF-motor control center feeders. After the onsite power source (EDG) reaches normal voltage and frequency, sequential loading follows, in compliance with IEEE 308-1971. Once the diesel generator is supplying power to the bus, the bus load-shedding feature is automatically bypassed.

Figure 8.3-1 shows the overall bus arrangement. A functional logic diagram (Figure 8.3-8) describes the various conditions of operation. A description of the operation of the system is given in Subsection 8.3.1.1.14.

8.3.1.1.3 Loads Supplied From Engineered Safety Feature Buses

Loads supplied from ESF buses of each division are comprised of that equipment pertinent to the division and selected BOP loads. The one-line diagram of the ESF buses is shown in Figures 8.3-1 through 8.3-6. A tabulation of the overall ESF loads by system is listed in Table 8.3-2.

Motors are sized so that they have adequate torque to start with the pump discharge open, accelerate within the time allowed by the plant design, and run with maximum pump load. Torque calculations include voltage dips of the motor's rated terminal voltage.

When running at rated speed and maximum load, the motors have adequate torque to prevent stalling during voltage dips caused by starting other large motors on the same power source.

In general, the motor horsepower rating determines the voltage and the source of the motor feed as follows.

a. 1/2 to 49 hp at 480 V, from a 480-V motor control center (MCC)

b. 50 to 249 hp at 480 V, from 480-V bus switchgear

c. 250 and larger hp at 4160 V, from 4160-V bus switchgear.

Voltage regulation for the buses and equipment fed from the 120-kV system is provided by the +20, -10 percent load tap-changing facilities on the secondary windings of transformers SS64, SS66, and SS68.

Voltage regulation is provided for the 480-V buses fed from the 345-kV system through transformer SS65, which is equipped with an automatic online load tap changer on each of the secondary windings to accommodate a maximum switchyard voltage of 105% on down to a minimum switchyard voltage of 92% following a single grid contingency. The 345 kV system voltage can vary +5, -2 percent for normal operation. Voltage regulation is provided for the BOP buses at bus 65L at 4160 V. Bus 65L voltage is regulated by a ±5 percent, oil-filled, 300-kVA regulator. The 480-V ESF buses (buses 72 EC, ED, E, and F) are regulated by 480-V ±10 percent dry-type induction regulators that are part of the 480-V switchgear-unit substations.

8.3.1.1.4 Engineered Safety Feature Bus Interconnections

A manual bus tie connects the Division I buses to the alternate division transformer SS65, and a manual tie connects the Division II buses to the alternate division transformer SS64. The tie is made through two breakers, one at each end of the bus tie with both breakers normally open and racked out.

If power were not available to an ESF bus through its normal offsite source or through its emergency onsite source, it could be manually energized through the alternate offsite power source, for maintenance use only. The affected breakers are interlocked so that the two divisional transformers SS64 and SS65 cannot be operated in parallel on a common load. Nevertheless, this tie can be used as an alternate source for either one of the ESF buses through manual operation.

There is one area where loads can be powered from either redundant system by automatic throwover. This area involves MCC 72 CF, serving certain RHR valves, operation of which is necessary to the operation of the RHR system in the postaccident core cooling mode. This MCC has feeds from both divisions. Division I is the normal feed with an automatic throwover to the Division II feeder. Each feeder has a breaker and contactor at the source and a contactor at the MCC.

According to Regulatory Guide 1.6, Paragraph 4.C, no automatic load transfers are to be performed between redundant divisions. However, in the AEC Safety Analysis of Brunswick FSAR, Section 8.3, Docket No. 50-324, a throwover for certain RHR-related loads was accepted.

However, due to the special nature of the above auto transfer, all feeds to and from the MCC are run in conduit to maintain divisional integrity. This automatic throwover is provided with positive interlocks, breakers, and series contactors to satisfy the "no single failure" criterion.

Division I 480-V breaker 72C-3C is the normally closed feeder breaker. Division II 480-V breaker 72F-5C is the normally open standby breaker. The contactors will either close or open automatically as a result of the operated status of the associated breaker. This solution provides an open break on both ends of the standby feeder to prevent having both sides or contacts of the standby circuit breaker energized from the two redundant divisions.

The 120-V ac control buses and instrument buses have no direct ties between redundant safety divisions. The buses of each division are energized through three 480/120/120-V ac, single- phase transformers with an automatic throwover switch between the 480-V buses of the same division (Figure 8.3-7).

Engineered safety feature inductive loads such as relays and solenoids are connected to the "inductive load" buses, and signal devices such as transmitters and electronic systems are connected to the "instrument" buses.

8.3.1.1.5 Redundant Bus Separation

The 4160-V switchgear, 480-V switchgear, MCCs, and other load centers of one safety system are physically and electrically separated from the load centers of the other safety system. Separate and independent switchgear rooms are provided for each division. The

Division I switchgear is located generally to the south of the reactor centerline on the second floor, and the Division II switchgear is located in the same location on the third floor. Battery rooms are located on the third floor and separated by a 12-in. concrete wall.

The MCCs, distribution panels, and other load centers, except as described previously, are not necessarily located in a specific room. They are separated from similar safety equipment of the opposite division by a horizontal distance of 20 ft or more. If this distance cannot be achieved, a 6-in.-thick reinforced- concrete wall is placed between the redundant buses.

8.3.1.1.6 Equipment Capacities

The ac power system has its related equipment provided with adequate capacity to meet its intended function under all design conditions. All Class 1E 4.l6-kV switchgear is rated at 350 MVA to ensure proper operation and circuit interruption under the most adverse fault current conditions. Auxiliary load transformers and EDGs have been sized for the worst-case conditions of auxiliary or shutdown loading. Cables are properly sized in accordance with the latest IPCEA requirements.

8.3.1.1.7 Automatic Loading and Load Shedding of Buses

Should a loss of offsite power occur on any ESF bus, the degraded grid relay output to the associated load shed scheme is inhibited. This bus is stripped of loads by a double load-shedding scheme, as indicated on the functional logic diagram (Figure 8.3-8). Automatic load shedding of the buses begins and the associated EDG receives a start signal and accelerates to rated voltage and frequency. The EDG breaker closes and loads are sequenced on. These loads are specified in Table 8.3-3. Conditions imposed after an automatic loading interval may warrant further manual loading for an extended shutdown. These loads are shown in Table 8.3-4.

A LOCA without loss of offsite power will start the diesels without closing the EDG breaker. The EDGs will idle and remain in standby until manually stopped.

Although there are no mechanical limitations on running the diesel generator at full-speed no-load conditions, running in an unloaded condition can result in an accumulation of unburned oil residue in the engine exhaust system. If load is suddenly applied, it could result in a "stack fire." Therefore, the manufacturer has recommended that the engine be loaded with 50 to 75 percent of rated continuous load for 1 hr after any 8-hr period of unloaded operation.

If diesels are operating in an unloaded condition, normal operating procedures ensure that the engine is loaded after extended periods of no-load operation. In the event of an emergency start from a LOCA without a loss of offsite power, such a procedure would be used for running the diesels. Because there are four diesels, the first diesel would be loaded after four (4) hours and run for an hour, after which the next diesel would be loaded. This method would be applicable during initial recovery. A keylock switch to defeat the LOCA start signal is provided to permit the diesels to be shutdown and placed in standby for a possible long term recovery period without a loss of offsite power.

After a postulated design-basis LOCA, the water level is maintained at two-thirds core height by the core spray pumps. This level is below Level 1, or the LOCA initiating level. Also, containment pressure could remain above the LOCA initiating signal level for extended periods until the temperature is reduced. Thus, either LOCA signal could be present for weeks after an accident. With the keylock switch and administrative control, the EDG would still be operable for automatic startup on an undervoltage signal, but an extended period of light-load operation would be avoided.

Should the LOCA occur with or during a loss of offsite power, the buses are first stripped of all loads, except for selected feeds for motor-operated valves, and isolated from the offsite power sources before the loading time sequence begins (Table 8.3-5). Loads that are automatically initiated appear in Table 8.3-3. Conditions imposed after an automatic loading interval may warrant further manual loading for an extended shutdown. These loads are listed in Table 8.3-4. The EDG automatic load sequencing system consists, with the exception of the input and output electromechanical relays, of solid-state components. These automatically initiate the closing of selected circuit breakers or contactors in MCCs.

The automatic load sequencing system consists of two redundant, physically separated, and electrically isolated subsystems, one for each of the two divisions.

Each subsystem functions independently and is associated with the sensors and safety equipment of a particular division. Each EDG has its own automatic load sequencing equipment to load the generator in its own independent time interval. Contained in the control cabinet are an input signal conditioning module, initiation logic, a system clock, counter-decoder and delay logic, output drive, and relay modules.

Devices to provide reset control and test capability and indicators to monitor the system status are provided.

The logic and operating components in this system are manufactured using industrial and military-approved quality materials, discrete components (resistors and capacitors), solid-state semiconductors, and integrated circuits. The equipment is rated Class 1E. Printed circuit (PC) cards are flame retardant and are also keyed to prevent insertion of an incorrect card in the PC card file. Digital integrated circuits used on the PC cards are high-threshold logic.

The automatic load sequencing equipment system is designed to function continuously at ambient temperatures and under humidity conditions much more severe than can be expected in the Fermi 2 control area.

On receiving a signal indicating an emergency situation, the system will commence operation. It will delay output for a preselected time period to permit the shedding of the affected bus load and, if required, for the EDG to start and the EDG breaker to close.

After this delay, the automatic load sequencing equipment will generate an output, in the predetermined time and sequence, to initiate bus loading as per Table 8.3-5.

The automatic load sequencing equipment is periodically tested to ensure availability and correct functioning of this system.

8.3.1.1.8 Standby AC Power System

8.3.1.1.8.1 Description

The standby ac power system for Fermi 2 consists of four diesel-generator units. These units are Colt Industries, Fairbanks-Morse, 38TD8-1/8, 12-cylinder, opposed piston, 3967-hp, 900-rpm diesels, each driving a 4160-V ac, 3250-kW salient pole generator, using a solid-state excitation system and fast-response electrohydraulic governors. The total unit is rated at 2850 kW continuous. The basic unit has a long history of successful use in commercial and marine application and as a standby power source for nuclear power plants. At the time it was purchased it was the largest unit with proven reliability available for this service. Of the units for which bids were received, the model selected showed the best performance in starting the 2000-hp RHR pumps required for postaccident service at Fermi 2.

Each EDG is started automatically on loss of voltage to its respective bus, on low reactor water level, or on high drywell pressure.

The units are capable of being started or stopped (for non-emergency starts) manually from local control stations near the engines as well as from the main control room. For testing purposes, units are started manually, brought to speed, synchronized to the power plant system, and loaded. Normally, voltage is regulated automatically with capability to adjust the set point both locally and in the main control room. Manual speed control is also provided locally and in the main control room. Each unit is capable of operating in parallel with the power plant electrical system.

If offsite power is lost during parallel operation with the electrical system, the diesel breaker will be opened automatically via underfrequency relaying. It was determined that this would be the quickest method of tripping the EDG while it was trying to maintain the system loads. The operation of the underfrequency relaying will open the EDG breaker only, and is interlocked to operate only when the EDG is in parallel operation with the offsite system.

The opening of the EDG breaker causes an undervoltage condition on the affected bus. The EDG breaker will reclose automatically as soon as all designated loads are removed from the bus.

On occurrence of a LOCA and on receipt of an automatic signal from the power plant relays, each unit automatically "fast-starts," comes to rated voltage and synchronous speed, and is capable of operating as an isolated source to start the loads sequentially. Table 8.3-5 shows the loading sequence. If a loss of system power has occurred, the EDG is automatically connected to the bus. If bus voltage is normal, the EDG stands by at synchronous speed and rated voltage.

The EDGs are capable of being started or of being restarted from a hot shutdown condition without outside auxiliary service, except the 130-V dc control source from divisional batteries. They reach rated voltage and synchronous speed (unloaded) within 10 sec after initiation of a starting signal.

The individual rating of each EDG is

a. Continuous 2850 kW

b. Short time (2 hr) 3135 kW

c. 2000 hr 3100 kW

d. 300 hr 3250 kW

e. 30 minute 3500 kW

Inlet and exhaust system pressure drops are considered for determining these ratings. Losses attributable to continuously driven electrical auxiliaries are deducted from the gross output of the EDGs, except for the EDG service water pump. Each generator is designed to operate as an isolated source or, for testing purposes, in parallel with a 4160-V, three-phase, three-wire, 60-Hz, resistor-grounded, 350-MVA electrical system. The system also operates with a high impedance ground system, isolated from the offsite system.

The generators are air-cooled, 80 percent power factor, 4l60 V, 60 Hz, Class F insulated, with a rating of 4063 kVA at a temperature rise not exceeding ANSI Standard MG-I (1972) at ambient temperature of 140°F. The EDG rooms of the RHR complex are designed for 122°F ambient. The generator stator coils are vacuum-pressure impregnated to provide resistance to moisture and contaminants.

The generators and original excitation systems were designed to limit bus voltage dips during sequential starting of motors. Two different system analyses, one by Colt and the other by Detroit Edison, produced results close to the recommended limit of 75% in Regulatory Guide 1.9. As a result, pre-operational testing was utilized to ensure successful operation in lieu of analytical comparison to the Regulatory Guide 1.9 recommended limit. The pre-operational test results, shown in Table 8.3-8, identified that the first voltage dip associated with the RHR pump start did decrease below the Regulatory Guide 1.9 value, but subsequent voltage dips, such as for the CS pump start, did not. Following replacement of the original excitation systems (Portec) with new excitation systems (Basler), voltage dips associated with the RHR pump start have sometimes been below those from the pre-operational test results. Similarly, the voltage dip associated with the CS pump start has at times decreased below the Regulatory Guide 1.9 value. In addition to the older pre-operational test data, Table 8.3-8 also identifies the voltage dips since the excitation system replacements. Continued successful testing during refueling outages with the identified voltage dips ensures the adequacy of the EDG performance during large-motor starting transients. Voltage dips, while not an acceptance criteria, are monitored to identify potential for EDG or other equipment degradation. See Appendix A.1.9 for additional discussion of Regulatory Guide 1.9 conformance.

During preoperational testing, each diesel generator was started and loaded in the desired sequence, thus verifying their capabilities. In addition, the motor and pump torque curves were reviewed to ensure that the motor torque curve did not dip below the pump torque curve.

The EDGs are housed in reinforced-concrete, Category I structures. Each unit is completely enclosed in its own concrete cell and is isolated from the other units.

The units are connected to their respective 4.16-kV switchgear and control equipment by cables in underground ducts. There are two sets of Category I ductbanks between the RHR complex and the Reactor/Auxiliary building, with a Division I and Division II ductbank in each set. These cable duct runs meet necessary seismic design and Class 1E criteria, as explained in the following paragraphs. In each case, the buried cable ducts between the RHR complex and the Reactor/Auxiliary building provide adequate cable separation to maintain independence of redundant circuits.

The first set of ductbanks was installed during plant construction. The physical separation of the two redundant, below-grade circuits is 30 ft at the point the cable ducts leave the southeast corner of the reactor building. The ducts make a sweeping bend with a minimum separation of 20 ft between them. After the bend, the ducts parallel the reactor building in a westerly direction with 24 ft separation. This separation is constant until the ducts pass under the rail car air lock where the separation widens until the ducts enter (still below grade) the RHR complex.

Because of the separation provided, the redundant cables will not be subject to a common mode failure from a tornado missile, or a redundant division cable causing failure in the surviving divisional cable. (See Section 3.5 for a discussion of missile protection.)

Each circuit is separately housed in a cast-in-place rectangular shaped reinforced-concrete duct. The duct is then covered by placing successive layers of compacted-rock fill up to the finished site grade of 583.0 ft. The duct runs vary in elevation from 573.0 ft minimum to 580.0 ft maximum. Since maximum groundwater elevation is 576.0 ft, the cables are not specifically designed for continuous underwater service. For low voltage power, control and instrumentation cables, there is no long term mechanism for water related insulation degradation due to lack of voltage stressor or a credible common mode failure mechanism. Therefore, low voltage cables perform their design functions while their external surface remains continuously wetted due to surrounding water. 4160-V essential power circuits are not routed within these ductbanks.

The minimum elevation for cable termination in either the RHR complex or reactor building is 588.7 ft, which is above the site probable stillwater elevation of 586.9 ft.

The cable duct runs are designed to meet Category I requirements.

The physical separation of the redundant cable duct run provides adequate protection against all of the defined missiles since any single missile could fall within the zone of influence of only one cable at a time. The defined tornado missiles, i.e., the 4-in. by 12-in. by 12-ft-long plank or the 4000-lb passenger automobile, cannot physically impact the zone around both cable duct runs at the same time. Additional protection is provided as the entire cable duct run is buried beneath a layer of compacted rock that varies in depth from 3 ft 0 in. to 10 ft 0 in., placed in layers up to the final site grade elevation.

The second set of ductbanks and associated manholes is installed above the maximum ground water elevation of 576.0 ft with ducts sloped to the manholes, such that circuits contained are not subject to continuous wetting. 4160-V essential power circuits are routed within these ductbanks. These are also cast-in-place, rectangular reinforced concrete ductbanks, but are located with the ductbank top approximately six inches below the surface and manhole covers at grade level. The ductbanks rise above grade at the entrance to the RHR complex and the Reactor/Auxiliary building. The Division I and Division II ductbanks are separated by approximately 25 feet at the Auxiliary building entrance. The separation narrows to approximately 10’-6” at the closest point as they make a sweeping turn and widens to approximately 20 feet at the entrance to manholes 16946A and 16947A. The ductbank separation again narrows to approximately 7’-8” at a top elevation of approximately 580'-6" (three feet below grade) and runs underneath the ISFSI Transfer Pad to manholes 16946B and 16947B. The ductbanks exit manholes 16946B and 16947B with a separation of approximately 15 feet that increases to a separation of greater than 20 feet after approximately 30 feet from the manholes. The separation increases to approximately 115 feet during the run from manholes 16946 B and 16947B to manholes 16946C and 16947C, located near the RHR building. Ductbank separation for the ductbank run between manholes 16946C and 16947C and the RHR building cable vaults is greater than 80 feet.

The 4160-V RHR cable vaults and the manholes and ductbanks between these cable vaults and the Reactor/Auxiliary building cable vaults are designed as tornado missile barriers per the requirements of Regulatory Guide 1.76 Revision 1. Because of the tornado missile barrier design, the redundant cables will not be subject to a common mode failure from a tornado missile and, due to separation provided, a redundant division cable will not cause a failure in the surviving divisional cable. (See Sections 3.5, 3.12.3.2.3, and 9A.4.7.7 for a discussion of tornado missiles, separation, and fire protection, respectively.)

8.3.1.1.8.2 Location

Each diesel generator and its associated excitation system and switchgear are located within separate rooms in the RHR complex. The separating walls between units meet the same requirements as does the exterior of the building. The RHR complex structure serves to contain, protect, house, and support the equipment of the EDG system and protect it from the outdoor environment. In addition, the building is designed to the following requirements:

a. Each EDG is located in a separate compartment, with its own separate fuel-oil day tank and storage tank housed in a separate room

b. The EDGs are at Elevation 590 ft (New York Mean Tide, 1935), about 7 ft above the grade level of 583 ft. The associated switchgear and controls are located in separate rooms above the EDGs. The exciter-voltage regulator panel for each EDG is located in the EDG room

c. The building is protected against flood damage to Elevation 590 ft (New York Mean Tide, 1935)

d. The RHR complex structure is designed so that a turbine missile will not result in the failure of more than one system division

e. The total wind load pressures include positive and negative pressures, gust factor, and shape factor

f. The building is designed for a maximum roof live load of 70 lb/ft^2

g. Sufficient openings are provided in the structure for the combustion air inlet and exhaust piping and for the interior ventilation air

h. The generator end of the EDG is located to permit access to and removal of the generator

i. The EDG system is designed to be operable during and after a design-basis tornado that has the following characteristics:

NOTE: Effects of items i1., i2., and i5. are to be considered as acting simultaneously.

1. External wind forces resulting from the tornado funnel, which have a horizontal peripheral velocity of 300 mph and a transient horizontal velocity of 60 mph
2. Differential pressure between inside and outside of fully enclosed areas - 3 lb/in.^{2}
3. The ability to generate a missile equivalent to a 4-in. by 12-in. by 12-ft-long wood plank traveling end-on at 225 mph or a passenger auto (4000 lb) flying through the air at 50 mph and at not more than 25 ft above ground with a contact area of 20 ft^2
4. For torsional design the structures were considered engulfed in a tornado of a diameter equal to the diagonal dimension of the complex. Positive and negative pressures were applied to each wall proportional to the normal component of the tangential wind velocity
5. All building structures housing equipment necessary for safe shutdown are designed to withstand a tornado-induced depressurization rate of l lb/in.^{2}/sec for 3 sec. The Category I 4160-V RHR cable vaults and the manholes and ductbanks between these cable vaults and the Reactor/Auxiliary building cable vaults are designed to withstand a tornado-induced depressurization rate of 0.5 lb/in.^{2}/sec for 2.4 seconds, in accordance with Regulatory Guide 1.76 Revision 1 (March 2007). (See section 3.3.2.1 for a discussion of tornado protection.)

j. The complex is a Category I structure

k. It is impossible to recirculate the diesel generator exhaust to the diesel generator combustion air intake except under extremely adverse meteorological conditions. The diesel generator exhaust is 25 ft higher than and 50 ft horizontally away from the ventilation and combustion air intakes for the RHR building. Only a small fraction of the exhaust could recirculate to these intakes under extremely adverse conditions. Each ventilation and air intake is approximately 89,000 cfm, of which about 14,000 cfm (16 percent) is combustion air for the diesel generators. The small amount of exhaust that could be recirculated would be thoroughly mixed in the combustion and ventilation air intake system. Therefore, the amount of combustion products in the combustion air intake would be a fraction of the fraction of recirculated exhaust. Recirculation of exhaust products has been used to reduce NOX emissions, and tests have been performed in which there was no deleterious effect on engine capacity and performance for exhaust recirculation over 12 percent. There is no possibility that the diesel generator exhaust could dilute even nearly this much. Therefore, there is no possibility that the diesel generator could not develop full rated power due to exhaust recirculation

l. Abnormal climatic conditions such as heavy rain, freezing rain, dust storms, ice, and snow will not affect the diesel combustion air intake or exhaust

The diesel engine combustion air inlet filter is located inside the RHR complex structure. Combustion air is 14,000 cfm of the 89,000 cfm total (combustion plus ventilation) admitted through a louvered wall opening and a missile shield. Abnormal climatic conditions will not affect the diesel engine combustion air intake

The diesel engine exhaust silencer is located on the roof of the RHR complex and is surrounded by a missile shield enclosure. The exhaust silencer is provided with an open drain to relieve any condensate that may collect through the exhaust pipe

m. All of the critical electrical equipment required for operation of the EDGs, including switchgear, MCCs, and diesel generator control panels, is located within that diesel generator's separate heating, ventilation, and air conditioning (HVAC) system. These independent HVAC systems for each EDG use filtered outside air and maintain the rooms at positive pressure to preclude the infiltration of unfiltered outside air. The HVAC inlet takes air from the upper level of the RHR building at an elevation of 617 ft, while the grade level of the building is 583 ft. The diesel air combustion system, including the inlet and exhaust, is completely separate from the HVAC systems. These features protect the electrical equipment from dust particles

In addition, the diesel generators and the starting systems of associated electrical equipment are inspected and tested periodically to ensure the availability of the diesel generator on demand

The control cabinets are located in the switchgear room. The control voltage on the diesel generators is 130 V dc; this voltage level reduces problems of dust on contacts in the diesel generators control circuits.

All the above features provide protection to the electrical equipment from dust particles.

8.3.1.1.8.3 Emergency Diesel Generator Rating and Sizing

The following general sizing parameters were applied to the EDG:

a. Each unit shall be at rated voltage and frequency within 10 sec

b. Each unit shall be sized to carry the full requirement of postaccident loads

c. Each unit shall be capable of sequentially starting the large RHR pumps (2000-hp motors for pumps A, B, and C and 2250-hp for pump D) and the 800-hp core spray pump motors while maintaining a voltage and frequency as close as possible to Regulatory Guide l.9 recommended limits and still maintain parameter a of this list (See Table 8.3-8).

The Colt Industries Fairbanks-Morse units chosen were extensively tested to prove their ability to achieve rated speed and voltage in less than 10 sec.

Before delivery, each engine was given a wear-in run during which operation was gradually increased from idle speed, no load, to full speed and full-load. Between each step in the wear-in run, the unit was shut down and inspected. The unit was then given a full-load test run, with necessary temperature and pressure measurements to verify performance. After completion of the test run, the unit was given a post-trial inspection. After post-trial reassembly, a final check run was conducted. The generators were given tests in accordance with ASA-C-50. Further testing of the EDGs to start rapidly, accept load, and provide proper voltage response (using actual or simulated Fermi 2 emergency loads) was performed during the preoperational testing program, as described in Subsection 8.3.1.2.2.2.

Colt Industries has demonstrated the ability of the 38TD8-1/8 engine to withstand repeated starts and load pickups (see Reference 1). The engine successfully started, loaded, stopped, cooled down, and repeated the cycle l00 times without adjustment, failure, or excessive engine wear. Further discussion of this test is found in IEEE Conference Paper 69 CP 177-PWR (Reference 2).

Fifteen large-size Colt units had been qualified and were providing standby service at seven operating nuclear plants, as shown in Table 8.3-9. Included in this list is the Duane Arnold Energy Center. The Colt Industries EDGs at this plant have a continuous rating of 2850 kW, the same rating as Fermi 2.

Branch Technical Position EICSB 2 states that the diesel generator reliability qualification is needed for (1) larger capacity machines than previously used, or (2) nonstandard diesel generator arrangements. Since the Fermi 2 Colt EDGs have been qualified previously, since a previous nuclear standby unit of the same size is considered qualified, and since the Fermi 2 onsite power system is a standard design in compliance with Regulatory Guide 1.6, the Fermi 2 EDGs are in full compliance with the reliability qualification requirements of Branch Technical Position EICSB 2.

A demonstration test program, developed and implemented by Edison, confirmed the reliability of the EDGs. This program simulated the number of slow and fast starts that would be expected of an EDG over an 18-month fuel cycle and run time that might be needed to assure safe shutdown of the plant if EDG operation were required following a LOCA. This translated into 20 prelubed slow starts and 10 prelubed fast starts, and included a 7-day continuous run. After each start, the EDG was run under load for a minimum of 2 hr, including 1 hr at a load of 2500- 2600 kW. After each run, the EDG upper crankshaft main bearings were gap checked. The EDGs 11 and 13 were selected for the demonstration test program on the basis of their operating and maintenance histories and because they are in separate divisions. All aspects of the demonstration test were successfully completed on both EDGs and therefore it was concluded that the Fermi 2 EDGs could reliably perform their intended function.

The total loads on each diesel generator are shown in Tables 8.3-3 and 8.3-4. These tables show load requirements for loss of offsite power and LOCA. For all conditions calculated, the loads are within the short-time rating of the diesel generator in compliance with paragraph C.2 of Regulatory Guide 1.9, Revision 2.

The ability to recover voltage and frequency over load increments was the most critical parameter in the selection process for the EDG. The response of the units to the load sequence shown in Table 8.3-5 was analyzed using simulations by Colt Industries and by Detroit Edison. The analysis results shown in Table 8.3-8 were close to the recommended limit of 75% in Regulatory Guide 1.9. As a result, pre-operational testing was utilized to ensure successful operation in lieu of analytical comparison to the Regulatory Guide 1.9

recommended limit. The pre-operational test results, shown in Table 8.3-8, identified that the first voltage dip associated with the RHR pump start did decrease below the Regulatory Guide 1.9 value, but subsequent voltage dips, such as for the CS pump start, did not. Following replacement of the original excitation systems (Portec) with new excitation systems (Basler), voltage dips associated with the RHR pump start have sometimes been below those from the pre-operational test results. Similarly, the voltage dip associated with the CS pump start has at times decreased below the Regulatory Guide 1.9 value. In addition to the older pre-operational test data, Table 8.3-8 also identifies the voltage dips since the excitation system replacements. Continued successful testing during refueling outages with the identified voltage dips ensures the adequacy of the EDG performance during large-motor starting transients. Voltage dips, while not an acceptance criteria, are monitored to identify potential for EDG or other equipment degradation. See Appendix A.1.9 for additional discussion of Regulatory Guide 1.9 conformance.

8.3.1.1.8.4 Emergency Diesel-Generator Fuel System

For a detailed description of the EDG fuel system, refer to Subsection 9.5.4.

8.3.1.1.8.5 Emergency Diesel-Generator Cooling and Heating System

Each diesel unit has a self-contained, jacket-closed cooling water system that consists of an engine-driven pump, a heat exchanger using the RHR service water (RHRSW) as the heat sink, a l5-kW standby heater, and a standby coolant circulating pump. The standby heater and pump maintain a constant water temperature to ensure uniformly fast starts.

Lube oil is maintained at a constant temperature by a 15-kW heater and a standby lube-oil circulating pump to enable the machine to start reliably.

A separate service water pump and separate service water piping system are provided for each diesel engine (Subsection 9.5.5).

8.3.1.1.8.6 Emergency Diesel-Generator Starting System

Two air-operated starting subsystems are furnished for each EDG. Each starting subsystem is of the air- over-piston type supplied from one accumulator. Periodic tests verify the operability of the air start system and its components.

Each starting subsystem includes a separate air header, accumulator, piping, and air start distributor and can independently start the EDG. The fast start feature is ensured by utilizing both starting air subsystems.

Two accumulators are furnished for each unit, and they have the capability to start the unit a minimum of five times without recharging. Each accumulator is furnished with a shutoff cock, pressure gage, drain valve, safety valve, check valve, and sensing element for low-pressure alarm.

One 460-V ac, three-phase, motor-driven air compressor is furnished for each EDG. The compressor recharges the accumulators to normal operating pressure; recharging, when required, is automatic.

Redundant starting solenoid valves with continuous-duty coils are used. All solenoid valves have manual bypass valves for use in case of failure of the solenoid valve.

8.3.1.1.8.7 Emergency Diesel-Generator Control System

Each EDG has a local control panel and annunciator, as well as control and annunciator alarms in the main control room. The control functions provided are listed in Table 8.3-10. The provided metering is given in Table 8.3-11.

Control power for each diesel comes from a highly reliable Class 1E battery. The two diesels providing power for the safety system of Division I receive their control source from the two 130-V dc batteries of that division. The two diesels of the other divisions are supplied, in like manner, by the Division II control batteries.

Table 8.3-12 lists the parameters annunciated at the local EDG control panel. Table 8.3-13 provides a list of the EDG parameters monitored in the main control room.

The diesel generator air intake and exhaust systems do not require the alarming of any parameter except for the differential pressure across the intake filter. An indicator and switch are installed to locally monitor the air intake filter and alarm in the main control room. The combustion air intake and exhaust systems have no interlocks.

Controls and monitoring instrumentation critical to the continued operation of the EDG are protected from engine vibration. The annunciator and other control equipment are mounted on freestanding electric control panels. The engine gage boards are mounted in a cradle on vibration isolation springs. The relays pertaining to operation of skid equipment that were in a skid-mounted relay box have been moved to a wall-mounted panel.

8.3.1.1.8.8 Other Plants Utilizing Colt Emergency Diesel Generators

Table 8.3-9 lists other nuclear plants that use Colt Industries' EDGs of the same type as Fermi 2 for their standby power source.

8.3.1.1.9 Class 1E Instrument 120-V AC Power Supply

The 120-V ac power supply provides power for both Class 1E instrumentation and control and for certain ac control valves and solenoids. The system is shown in Figure 8.3-7 and the loads are tabulated in Table 8.3-14.

There are two Class 1E 120-V ac nominal power supplies, one per division. Each supply is a separate modular power supply unit rated at 45 kVA. A modular power unit consists of an automatic transfer switch with appropriate sensing devices, three single-phase transformers, and two line voltage regulators. Each modular power supply unit has two power sources at 480 V ac, each fed from a different MCC in the same division, which improves reliability. Power is selected from one of the two feeds and will transfer to the other feed on an undervoltage condition of 83 to 85 percent if maintained for 1 sec (nominal), provided that the alternate source is above 90 percent rated voltage and frequency.

The modular power supply unit has three distribution cabinets providing outputs, each 120 V ac nominal, 15 kVA. One is for inductive loads such as solenoid valves and similar applications where minor variations of voltage can be tolerated. Two outputs are 120 V ac nominal, 15 kVA, regulated power for instrumentation loads, the regulated outputs of MPU 1 and MPU 2 are bounded by the electrical design calculations to ensure that the regulated output voltage variations are within the tolerances for proper operation of the instrumentation loads. During the period when the common offsite power for both divisional MCCs is lost, these units will be powered by the respective division EDG within approximately 18 sec after loss of power.

Important, but not safety-related, loads such as feedwater control and the Integrated Plant Computer System (IPCS) are fed from a BOP uninterruptible power supply.

The instrument loads are such that they can tolerate a short power outage without unacceptably degrading plant safety.

8.3.1.1.10 Reactor Protection System 120-V AC Power System

A separate power system is provided for the reactor protection system (RPS) and certain other instrumentation, as described in Subsection 7.2.1.1.2.

The power feeds to the RPS 120-V ac power system are

a.	Motor-generator set A:	480-V MCC72B-4C pos 2C.
b.	Alternate A:	Distribution Cabinet 72C-2D pos 2 via a 480/120-V single-phase transformer feeding a 120-V regulator.
c.	Motor-generator set B:	480-V MCC 72E-5B, pos 1C-R.
d.	Alternate B:	Distribution Cabinet 72F-4B, pos 2 via a 480/120-V single-phase transformer feeding a 120-V regulator.

The alternate RPS feeds serve primarily as maintenance ties. No automatic transfer occurs between the normal and alternate sources because the loss of one motor-generator set will not cause a scram.

8.3.1.1.11 Instrumentation and Control Systems

The instrumentation and control required for the ESFs listed in Tables 8.1-1 and 8.1-2 are powered by the ac control and instrument buses shown in Figure 8.3-7, and by the dc buses shown in Figure 8.3-9. These buses provide the same reliability for control and instrumentation as is afforded by the equipment power supply. The instrumentation provides the operator with complete information on plant conditions. He receives all the information required to base a decision on adjusting loads or manually initiating loads, particularly when shutting down the emergency power supply.

Manual controls necessary for emergency equipment are all located in the main control room. The EDGs and their accessories have local control and instrumentation, in addition to that provided remotely in the main control room. On loss of offsite power and subsequent transfer to the emergency power supply (diesel generator), the following information is presented to the operator:

a. Load on the EDGs as well as the remaining EDG capacity is displayed in the main control room

   A digital "EDG remaining loading capability" instrument is provided for each EDG. With the EDG unloaded, this instrument will indicate the full rated loading capability in kilowatts. As soon as load is applied (automatic or manual), this digital instrument will display the remaining capability of the EDG. This information enables the operator to take appropriate action to avoid the remote possibility of the affected EDG becoming overloaded

b. Emergency core cooling system (ECCS) conditions are indicated as follows:

   1. High-pressure coolant injection - There is main control room indication of pump discharge flow and pressure, and local indication of steam flow

   2. Core spray - There is main control room indication of pump discharge flow and pressure plus current to the motors

   3. RHR - There is main control room indication of pump discharge flow and pressure plus current to the motors

   4. Automatic depressurization system (ADS) - There is main control room indication of valve position

   5. RHRSW - There is main control room indication of RHRSW flow and discharge temperature from the heat exchanger and the current to the pump motors.

c. Automatically initiated loads are connected as outlined in Table 8.3-3. They are adjusted manually for the conditions listed in Table 8.3-4.

8.3.1.1.12 Circuit Protection

8.3.1.1.12.1 Grounding

The general plant ground mass is formed by ringing each structure of the plant with bare copper cables and interconnecting the ground masses of the individual buildings. All connections are made by the cadweld process.

Separate cadwelded risers are used for the following ground systems:

a. Equipment ground system

b. Main turbine generator ground system

c. Instrument ground system.

The equipment ground system consists of multiple bare copper conductors with taps on each floor for equipment grounding. All motors, equipment cabinets, and ground buses are to be connected directly to the risers. The cable tray system is intended to be electrically continuous and is connected to the equipment ground risers.

Each tray or tray run is provided with a copper conductor connected to each section of tray and to the ground mass. All instrument grounds and case grounds are normally connected to the equipment ground. Local instruments are grounded using the equipment ground provided by the cable tray system.

The turbine-generator ground system consists of a double ring of 1/4- by 4-in. copper ground bars linked to the generator by two 500 MCM bare copper cables.

The instrument ground system is designed using an insulated cable connected directly to the station ground mass. This ground system is designed to provide a low noise ground for the computer system. One isolated riser is terminated on a ground bus bar in the relay room area to accommodate unusual field grounding problems.

All stairs and piping systems are grounded.

The 4.16-kV system is normally connected to neutral ground via 4-ohm resistors at the service transformers to limit ground fault current. When the vital system is fed from the EDGs, this ground is removed and the 4.16-kV system is operated as a high impedance ground system, with grounding accomplished through an impedance at the EDG neutral. The EDG high resistance grounding system allows continued operation of the EDG in the presence of a ground fault by limiting the ground fault current to a very low value, thus permitting operation of both the EDG and 4.16 kV loads. This feature provides the Operators with additional flexibility and enhanced equipment availability until an orderly transfer or equipment shutdown can be accomplished. All other power systems are directly grounded through the transformer neutrals..

8.3.1.1.12.2 Circuit Protection

The 4160-V bus feeder circuits have three phases of inverse time overcurrent plus inverse time neutral (ground) fault relay protection. The inverse time ground overcurrent relays, for the most part, monitor the neutral of the current transformers used for the phase overcurrent relays. The protective relays are GE-type IAC. These relays meet the seismic qualifications necessary for Class 1E equipment.

Motors, feeders, and other loads on the 4160-V buses have two phases of inverse time overcurrent relaying plus instantaneous ground fault protection using the ground fault sensor principle. The ground fault sensor is essentially a CT-like device that surrounds the three load conductors and detects any imbalance that occurs. The relays used with the ground fault sensors are GE-type PJC instantaneous overcurrent.

All protective relays are calibrated to provide the proper sequence of operation, which ensures that selective tripping will occur. The feeder circuit phase relays are calibrated to give at least 30 cycles of margin at the associated branch circuit relay calibration trip point. The feeder neutral or ground relays are calibrated to provide a 0.4-sec margin above the branch circuit neutral relay setting.

Devices fed from 480-V ac switchgear have time overcurrent protection that is applied in accordance with the latest industry standards. At Fermi 2 this protection is provided by solid-state devices known as "Power Shield." These devices are supplied as an integral part of the 480-V circuit breakers. The long time, short time, and instantaneous trip elements perform essentially the same protective functions as provided by the electromechanical trip devices, but with greater accuracy and repeatability due primarily to the absence of mechanical moving parts. These devices, being solid state, easily meet the seismic qualifications for the Class 1E equipment. Motor feeders are equipped with phase-instantaneous and time-delay overcurrent relaying, with a neutral solid-state instantaneous ground sensor device.

Each ESF bus located in the RHR complex, the feeder cable to the ESF bus in the reactor building, and the feeder breaker are protected by an overall differential relay scheme. In addition to the superior ability of a differential to detect bus faults, the use of such a scheme avoids the problems associated with an overcurrent relay scheme on a feeder where full load currents are different when the feed direction reverses.

When the EDGs are operating in parallel with offsite power, several protective relay functions are used to protect both the generator and engine. These trips are listed in Table 8.3-12 for both the test condition and emergency condition.

Under conditions that cause pickup of the emergency start relays, all of the trip circuits are blocked, with the exception of overspeed trip, generator differential, low lube-oil pressure, crank-case overpressure, and start failure trip. The low lube-oil pressure and crankcase overpressure trips are each connected in a two-out-of-three logic (one out of three causes an alarm only). Although there is one start failure relay, once the engine is started, either the low speed or running speed relays will inhibit initiation of the start failure relay.

There are two emergency start relays: either of these relays will initiate EDG starting as well as bypass the unnecessary trips. All of the bypassed trip circuits still retain their alarm function to alert the operator to an abnormal condition. Since the trip bypass is achieved with the emergency start relays, the bypass circuitry is directly monitored by the annunciator position "EDG - Auto Start." Surveillance tests on the emergency start relays will also test the status and operability of the bypass circuits. The EDG logic is designed so that the nonemergency trip relay is automatically reset by the emergency start signal. (Nonemergency trips are those other than the emergency-mode trips described above.) This feature prevents the inadvertent lockout of an EDG during standby by a false or real nonemergency-mode trip.

Devices such as motors fed from MCCs are protected by fused disconnect switches and thermal overloads. Non-motor-type loads are protected by circuit breakers. Overload settings are 125 percent or greater of full load current for nonessential items and 140 percent or greater of full load current for ESF loads.

At Fermi 2, the thermal overload devices on the ESF system motor-operated valves (MOVs) were selected to allow at least four times the valve stroke time at full load current and at least one time the valve stroke time at motor current associated with twice running torque. These criteria were used because it is felt that operation of the valve motors when needed supersedes any concern with degradation or failure of the motor due to excess heating.

Additional protection against premature operation is afforded by the thermal overload devices' being located at the MCCs and not at the motors themselves. All thermal overload devices are temperature compensated.

Branch short-circuit protection is provided by dual-element fuses (fusetrons) sized to override starting currents, yet maintain coordination with the thermal overload devices.

Preoperational testing ensured that thermal overload setpoints were calibrated properly. As necessary, full load current measurements were made to verify adequacy of the thermal overload device settings. Periodic tests will serve as verification of the drift of the trip setpoints for the thermal overload devices.

All circuits of the ESF buses are tripped on undervoltage, except feeds to the 4160/480-V transformers and selected MCCs with small load requirements. This allows each bus to be cleared when bringing up the EDG.

8.3.1.1.13 Maintenance and Testing

8.3.1.1.13.1 Auxiliary Electrical Power Systems

The 4160-V ac circuit breaker and associated equipment can be tested by jacking out the breaker to the test position. (The testing of certain systems is not possible during operation.)

The breaker opening and closing circuits can be operated without energizing the circuit in this test position. Test stations are provided for each ESF switchgear room, with the exception of the EDGs, because of the small number of breakers.

The 480-V ac circuit breakers for motor circuits and associated equipment can be tested if they are jacked to the test position. This allows breaker operation checks without energizing the circuit.

Incidents involving the inadvertent disabling of a component by racking out the circuit breaker of its redundant counterpart have occurred in nuclear power plants. At Fermi 2 several steps have been taken to preclude such an occurrence.

The 4160-V and 480-V switchgear (ESF and BOP) incorporate 52H auxiliary switches as applicable as part of the design. These individual cell-mounted auxiliary switches are actuated by the location of the circuit breaker. When the breaker is in either the test or disconnected position, the 52H/a contacts are open and the 52H/b contacts are closed, and vice versa when the breaker is fully racked in and connected. These contacts are wired to bypass the breaker-operated auxiliary contacts, as necessary, when the circuit breakers are in the disconnected or test position. Their specific purpose is to eliminate undesired signals and avoid disabling other equipment due to testing or removal of a circuit breaker.

All systems were checked during design for the presence of disabling interlocks. If an interlock had been inadvertently wired in even after design review was complete, construction testing procedures should have detected this condition. The preoperational tests served as the final test for the presence of disabling interlocks.

The 4160-V and 480-V breaker operating and protective relay tests were performed initially by performing checkout and initial operating (CAIO) tests. These tests were performed after the construction phase and consisted of initial equipment energizing, calibration, and functional testing of components.

Preoperational or acceptance tests and protective relay tests were performed before fuel load.

a. Preoperational or acceptance tests were system operating tests, which verified adequacy of individual components, instruments, interlocks, alarms, etc., to function as a system

b. Protective relay final verification and required retesting were also performed because construction and CAIO testing could and sometimes did alter the required final relay settings.

For CAIO and preoperational testing, instructions meeting the requirements of IEEE 336-1971, IEEE 279-1971, and others as applicable were written to ensure the adequacy of tests to be made on the electrical equipment.

The test package for a particular component included a test procedure, test forms, a check-off list to ensure completion, and an overlay test sheet to indicate, among other things, test equipment certification and approval by a responsible individual.

The test instructions described and indicated the purpose and scope of the tests, the equipment to be tested, the specifications and drawings to be used, the test equipment required, the precautions to be taken, and the prerequisites. Also included were the test procedure itself and the method of handling deviations or variances.

The personnel who performed this testing were engineers or technicians from several divisions of Edison who were qualified with respect to the concerned equipment, the test equipment to be used, and the procedures and precautions to be followed.

Subsequent tests will be performed in accordance with the Preventive Maintenance Program and surveillance program. Scheduled inspections of circuit breakers, contactors, and associated equipment to ensure adequacy of installation, mechanical and electrical clearances, cleanliness, and operability are conducted as specified in approved instructions and the Preventive Maintenance Program.

8.3.1.1.13.2 Standby AC Power System

Because the EDGs are used as standby units, readiness is of prime importance. The testing program is designed to test both the ability to start the system and the ability to run under load long enough to demonstrate that cooling and lubrication are adequate and that auxiliary system functions are satisfactory for an extended period of operation.

Each generator unit is capable of being synchronized manually for parallel operation with the normal plant ac power buses for load test runs. To ensure availability of the systems, one EDG at a time is routinely started and loaded in parallel with the offsite power systems. Tests of the automatic EDG functions are conducted as required to demonstrate proper operation. Details are contained in the Technical Specifications.

Plant operating procedures require application of approximately 30 percent load immediately after synchronization, with subsequent testing performed at loads of 50 percent or greater. To preclude formation of gum and varnish deposits in engine components, extended operation at less than 25 percent load is not required.

An initial system test was performed to demonstrate that the standby power supply can be started and can accept design load within the design-basis time, and that the standby power supply is independent of the offsite power supply.

The surveillance testing of the EDGs is scheduled in accordance with the Technical Specifications.

Component failures of the EDGs are addressed in the plant preventive maintenance program and are identified in the equipment performance evaluation analysis. Component failures are analyzed with respect to frequency, application, design, and manufacturing defects. Component failures are thereby corrected by problem analysis and engineering judgment.

Postmaintenance functional checks, before postmaintenance operability testing, of the individual EDG subsystems and components are specified in the plant procedures. These procedures verify the status of temporary modifications, that is, lifted leads or jumpers; electrical power feeds and switch lineups; valve lineups; and support system operability. The postmaintenance testing verifies the Technical Specifications operability requirements, and the updating of the equipment status board ensures the placement of the EDG in the automatic standby mode by the control room operator.

8.3.1.1.14 Operation of Breakers Associated With Bus 64B

In the following description, only ESF bus 64B will be considered. Breakers on buses 64C, 65E, and 65F operate in a similar manner. The description is typical of any of the vital load groups shown in Figure 8.3-1. Various relays will be referenced by their standard device function identification number as follows:

a. 51 - Time overcurrent relays

b. N51 - Time overcurrent neutral relay

c. 87B - Bus differential relays

d. 27 - Under/voltage relays.

8.3.1.1.14.1 Feed to Bus 64B

Bus 64B normally receives power from transformer SS64 via breaker B6, but it can also receive power from alternate sources, as discussed in Subsection 8.3.1.1.14.3.

8.3.1.1.14.2 Loss of Power to Bus 64B

In an emergency situation, such as loss of power to transformer SS64, EDG ll automatically starts, and the affected buses are cleared of loads. After the EDG reaches rated voltage and speed, EDG breaker EA3 will close automatically, and EDG ll will provide power to bus 64B, via breaker B8.

8.3.1.1.14.3 Maintenance Tie for Bus 64B

During maintenance operations, power can be supplied to bus 64B via breakers 65T and B9. If it is desired to have uninterrupted power to bus 64B during maintenance, EDG ll must be manually started and synchronized with bus 64B via breaker EA3. All of the load on 64B would be manually transferred to EDG-11, breaker B6 would be opened, breaker 65T would be closed, and Division I would be paralleled with Division II via breaker B9. The load would be manually transferred from EDG 11 to Division II, breaker EA3 would be opened and EDG 11 shut down. The reverse of the above would be followed to return bus 64B from a maintenance feed to its normal supply from transformer SS64.

8.3.1.1.14.4 Limitations on Use of Maintenance Tie

The design limitations on the use of the maintenance ties are as follows:

a. When power is provided to Division I from Division II via maintenance tie breaker 65T, the sum of the current through breakers 65T and C9 or B9 should not exceed 1200 amp

b. When power is provided to Division II from Division I via maintenance tie breaker 64T, the sum of the current through breakers E9 or F9 and 64T should not exceed 1200 amps.

8.3.1.1.14.5 Breaker Operation

For operation of breakers B9, B6, B8, EA5, 65T, EA3, and buses 64B and 11EA, refer to the logic diagram in Figure 8.3-8.

8.3.1.2 Analysis

8.3.1.2.1 Auxiliary Electrical Power Systems

8.3.1.2.1.1 Safety Design Basis

The auxiliary electrical power system provides adequate power to operate all auxiliary loads necessary for plant operation and safe shutdown of the reactor. The number of power sources for the plant auxiliary electrical power system is sufficient, and of such electrical and physical independence, that no single event would interrupt all auxiliary power at one time.

The ESF buses may be connected, by appropriate switching operations, to alternative sources of offsite power for maintenance purposes only. In the event of a total loss of external power sources, emergency auxiliary power is supplied from the plant EDG system located on the site. The EDG system sources are physically independent of any normal offsite power system. Each power source, up to the point of its connection to the auxiliary power bus, is capable of complete and rapid electrical isolation to prevent paralleling of power sources.

Duplicate electrical loads are diversified among auxiliary power buses. Plant layout criteria include the separation of switchgear sections, motor feeders, and similar equipment groups, so that no single postulated accident causes total loss of power to critical loads.

The auxiliary electrical power system takes into account General Design Criteria 17 and 18, and is designed accordingly.

8.3.1.2.1.2 Safety Evaluation

Normal power for ESF buses is from the 345-kv and 120-kV transmission systems by means of two system service transformers. One transformer is from the 345-kV station bus 301. The other is from the 120-kV bus 101 via transformer 1. All 345-kV and 120-kV buses have more than one offsite power source.

Redundancy of buses within the plant and the division of critical loads between buses yield a system that has a high degree of reliability and integrity.

Segregation of buses and components limits or localizes the consequences of electrical faults or mechanical accidents occurring at any point in the system.

All breakers and transformers are rated according to standard electrical industry practices and applicable IEEE, NEMA, and ANSI standards.

8.3.1.2.2 Standby AC Power Supply System

8.3.1.2.2.1 Safety Design Basis

The design of the onsite standby ac power supply system is a one ESF bus/one-EDG arrangement (two such arrangements per ESF division) with the redundant loads of each division split among four buses. Each EDG is of sufficient capacity to carry the essential loads of its respective bus. A single failure that could cause the loss of a division pair of EDGs would not prevent safe reactor shutdown.

The EDGs start automatically and reach rated frequency and voltage within a maximum of 10 sec. They either automatically close into the bus and load, if offsite power is lost, or they stand by at rated speed and voltage, if offsite power is still available. The EDG fuel-oil storage tanks are of sufficient capacity to meet the EDG fuel requirements for at least 7 days. The EDG fuel-oil storage tanks are located inside the RHR complex in separate enclosed rooms. Refer to Subsection 9.5.4 for details. Two fuel pumps are provided for each EDG. Either pump is adequate to maintain the proper level in the fuel day tank, thus providing 100 percent redundancy. The EDGs are equipped for manual periodic starting, synchronizing, and loading to permit readiness testing without interrupting normal plant operation.

8.3.1.2.2.2 Compliance With Design Criteria

The design of the standby ac power supply system is based on the requirements of Regulatory Guide 1.6 and IEEE 308-1971, and complies with General Design Criteria 17 and 18. The two redundant ac systems are completely independent except for the one swing bus which has double safety interlocks to ensure against tying divisions together at the bus (Subsection 8.3.1.4). The loads on this bus are the low pressure coolant injection (LPCI) system injection valves and recirculation pump suction and discharge valves.

The standby ac power supply system meets the requirements of Regulatory Guide 1.9 except for certain voltage and frequency requirements. Table 8.3-8 gives an analysis of large-motor starting ability. The two motors considered were the RHR pump motors (2000-hp motors for pumps A,B, and C and 2250-hp for pump D) and the 800-hp core spray pump motor. Depending on the analysis used, the voltage dip when starting the RHR pump and the recovery time when starting the core spray pump exceed the stated limits. A detailed test program has been conducted to ensure the adequacy of the EDG. Continued surveillance testing also ensures the adequacy of the EDG performance during large-motor starting transients. Additional discussion of conformance with Regulatory Guide 1.9 is provided in Appendix A.1.9.

Field tests were performed to prove the Fermi 2 EDG capabilities for the following items:

a. Rapid start

b. Voltage response

c. Load acceptance.

Quantities recorded during these tests included

a. Generator voltage

b. Generator current

c. Generator kilowatts

d. Field voltage and current

e. Motor current

f. Frequency

g. Elapsed time

h. Motor speed

i. Motor-connected load (such as pump flow and pressure)

j. Other quantities as necessary.

Detailed procedures for these tests were developed as part of the Startup (Preoperational) Test Program, to meet the criteria established in Regulatory Guide 1.41.

8.3.1.2.2.3 Safety Evaluation

The primary bases for selecting EDGs are reliability and total independence. Normal sources of power are extremely reliable, and the probability of coincident failures of all sources of offsite power into the plant is very low. The EDGs are provided as onsite power sources to provide backup to the offsite sources of power. It is imperative that the EDGs are not influenced by the same environment that affects the offsite power sources. For these reasons, the diesel generator units, which are selfsustained and require no offsite electrical power sources for operation, were selected as standby auxiliary power sources.

The ability of the EDG to start rapidly on demand is consistent with the concept of maintaining continuity of the ECCS under accident or emergency conditions. A continuous source of auxiliary power for the plant is ensured by the facilities described previously. The reliability demonstration tests are discussed in Subsection 8.3.1.1.8.3.

The following events occur in the order indicated for (a) a LOCA, or (b) a loss of offsite power:

a. The EDGs are started automatically. After reaching rated speed and voltage, they are ready to be loaded. However, the breakers remain open

b. If there has also been a loss of offsite auxiliary power sources, all 4160-V and 480-V feeder breakers on the service buses are tripped open, except for the 4l60/480-V transformers and certain essential breakers for MCCs

   At the same time the divisional EDGs are started, and after reaching rated speed and voltage, the respective EDG breakers will close automatically

c. When the voltage on an ESF bus is restored by the EDG, essential auxiliaries are started automatically in a predetermined sequence. Manual operation from the main control room is also available for all essential auxiliaries. The EDGs can be stopped manually if offsite power is restored.

The control circuits are designed to provide the automatic features described. They allow the reactor operator to take other appropriate action as circumstances require.

Monitoring of automatic functions is provided in the main control room, thereby permitting the reactor operator to observe that proper conditions have been established.

All components of the EDG system are designed, constructed, and enclosed in accordance with the performance objectives for Category I design. Similarly, the entire system as well as the structures surrounding the system are protected against other natural and man-made phenomena.

8.3.1.2.3 Class 1E Electrical Equipment in Hostile Environments

Safety-related equipment required to operate in hostile environments and its environmental qualifications are given in Section 3.11. Section 3.11 defines the environmental conditions for various areas of the plant. Tables 3.11-1 and 3.11-3 give the accident basis environmental envelope. Table 3.11-4 lists the safety equipment and its operating environment both inside and outside the primary containment.

8.3.1.2.4 Loss of Non-Class 1E Instrumentation and Control Power System Bus During Power Operation

IE Bulletin 79-27 addresses a loss of an instrumentation bus, either safety related or not safety related, that could affect the ability to attain cold-shutdown status.

Fermi 2 has redundant systems that can be used to attain a cold-shutdown status. These systems are discussed in Chapter 6.

The instrument power supplies for the following engineered safety systems were reviewed for IE Bulletin 79-27:

a. High-pressure coolant injection (HPCI)

b. Reactor core isolation cooling (RCIC)

c. Automatic depressurization

d. Core spray

e. Residual heat removal (RHR)

f. Reactor protection

For the purposes of the review, a complete loss of the feedwater system was assumed.

The results of the review indicated that no modifications were required at Fermi 2 to ensure the attainment of cold shutdown according to the concerns of IE Bulletin 79-27. This conclusion is based on the following:

a. Instrumentation associated with systems required for a cold shutdown is powered from ac and/or dc sources

   1. The ac instrumentation is fed from 480-V MCC 72B-2A or 72C-3A (Division I) and MCC 72F-2A or 72E-5A (Division II). Each of these feeds a delta-connected transformer bank that, in turn, feeds three instrumentation and control buses. Each of these buses is separately fused, and each bus has only seven loads, all of which are separately fused. Figure 8.3-7 shows this configuration. Each feeder powers a distribution cabinet, and circuits from each distribution cabinet are individually fused. These circuits feed individual instrument loops, which consist of an instrumentation power supply, transmitter, and indicating instrument

   2. The dc instrumentation is powered by 130-V batteries (one per division) or by 24-V batteries (one per division). Each of these dc distribution systems has characteristics similar to those of the ac system described above.

   Thus, the instrumentation power system at Fermi 2 is very diverse.

b. If a main ac power source is lost, such as a 480-V bus, the "bus energized" light will go out on the combination operating panel in the control room, an annunciator window will light, and the sequence-of-events recorder will indicate which breaker(s) operated. Critical instrumentation, such as that for reactor water level and pressure, is maintained via uninterruptible supplies, which are fed from the same division battery. Each uninterruptible supply powers only one or, in a few cases, up to five instrument loops. These supplies are Class 1E and are not physically close to each other. Such critical instrumentation is redundant across divisions

c. If any dc power sources are lost, an alarm and annunciator indication will be initiated in the control room. In this case, sufficient instrumentation associated with systems in the opposite division will be available. In addition, critical instrumentation fed by the failed supply will be maintained, since such instruments are fed by small, qualified, uninterruptible supplies. The alternative source, as mentioned above, is the ac power source in the same division

d. If power to a small group of instruments is lost, through a failure of a distribution cabinet or an individual circuit, the operator will be readily aware that power has been lost. The indicating instrument will drop to zero; the coordinated manual control switch or pushbutton backlight for that instrument or function will go out. However, the system redundant to that which suffered the instrument power loss will be available to achieve cold shutdown. The instrumentation for that system is powered from a totally separate source.

8.3.1.3 Conformance To Appropriate Quality Assurance Standards

The Quality Assurance Program covering design, fabrication, testing, purchase, and shipment of equipment for safety-related systems is discussed in Section 17.1. Quality Assurance procedures to implement the requirements of IEEE 336-1971 (Regulatory Guide 1.30) are used during installation, inspection, and testing of electrical equipment.

8.3.1.4 Independence of Redundant Systems

8.3.1.4.1 System Independence

The cabling criteria for Fermi 2 are established to afford complete independence of redundant safety systems as well as maximum reliability within each safety system. Guidelines for the cabling criteria follow the general criteria for electrical equipment described in Subsection 3.12.3.

The independence of safety systems is achieved primarily by the physical layout of the plant itself. Class 1E electrical equipment is totally redundant. In addition to the general separation achieved by the plant layout, definite separation requirements are imposed between equipment and cables of redundant divisions. Cables for redundant channels of the RPS and ESF are so arranged and installed that no single credible event could cause damage to more than one of the redundant systems. The systems are so designed that the occurrence of such an event on one system can in no way affect the other system.

For trays or conduits crossing a single insulated process steam line, a minimum separation of 12 in. is required. Crossing multiple insulated steam lines or running parallel to a single insulated steam line is avoided. However, if not avoidable, a 4-ft separation is required. Deviations from this criterion are evaluated and resolved on a case-by-case basis.

Non-Class 1E systems do not degrade the separation between redundant systems. In the case where separation distances are compromised by non-Class 1E cable trays, a fire-resistant barrier is used. Barrier use in these cases conforms to the redundant separation requirements.

Protective measures for cables required to meet the identified safe-shutdown path in the fire-protection analysis in Appendix 9A are applied as indicated in that section.

Routing of RPS or ESF control or power cables is avoided through rooms or spaces where there is a potential for the accumulation of large quantities (gallons) of oil or other combustible fluids through leakage or rupture of lube oil or cooling systems. Where such routing is unavoidable, only one division of RPS or ESF cables is allowed.

In the RHR complex, there is no separate BOP cable tray system. The BOP cables on the south side of the building centerline are routed as ESF, Division I; those on the north side are routed as ESF, Division II. This means that no BOP cables can cross safety system divisions, thereby ensuring complete isolation and independence of the redundant safety systems.

In addition to the separation of cables for redundant safety systems, physical separation is provided between cables classified as power, control, and instrument. Each is run in a separate tray system. The definition of each type of cable is as follows:

a. Power cables – Power cables, as described, generally fall into two voltage levels of 600-V and 5000-V insulation. These are the cables that provide electrical energy for motive power or heating to all 4160-V ac, 480-V ac, 208-V ac, and 260-V dc auxiliaries. Cables used to provide electrical energy to switchgear, MCC, and distribution panels also fall into this category. Lighting power and 260-V dc are not run in the cable tray, but in separate trays or conduits

b. Control cables – Control cables are those cables that provide 120 V ac and 125 V dc, for components which affect the automatic or manual control of auxiliary equipment or the 24 V dc for annunciators which provide alarms for indication of the state of those auxiliary components

c. Instrument cables – Instrument cables are those low voltage or low-current cables that carry signals from such analog devices as thermocouples, resistance temperature detectors, transducers, pneumatic-to-electric converters, or low-level digital signals. They generally are sized 16 AWG or smaller. The instrument cables also include the fiber optic cables that carry light pulses rather than current or voltage.

Cable tray design is such that, where practical, the trays containing power cables are the highest level in stacked trays.

In some cases, cables for small 460-V motors may contain both the power and the control for those motors. These cables are routed with other control cables in control cable trays.

Instrumentation cables are installed in separate conduit or in separate nonventilated solid trays with covers to provide electromagnetic shielding. In general, instrument trays occupy the lowest of a stack of cable trays.

The minimum vertical distance between stacked trays of the same safety-related system or between stacked trays of a non-safety-related system is 1 ft from the bottom of the upper tray to the top rail of the lower tray. This provides accessibility to the tray for adding or replacing cables.

Separation of redundant safety systems and power, control, and instrument cables of the same safety or nonsafety systems extend through the primary containment penetrations.

Penetrations are grouped in two separate areas, one to the north and one to the south of the reactor centerline. Penetrations for the divisions of ESF, RPS, and NMS are separated into the two areas by division. Penetrations are divided by division and by class of service as follows:

	Division I	Division II	BOP
5 kV power			6*
480V power	1	1	
120V control	2	2	
Control rod drive			6*

	Division I	Division II	BOP
Thermocouple			2*
Low level signal			2
RPS	1	1	
NMS	2	2	

* Half of these penetrations are located in each divisional area.

8.3.1.4.2 Cable Reliability

All safety related cables and balance of plant cables routed in cable trays utilize materials that are designed to meet the electrical requirements of IEEE/ICC/WG-12-32 after being subjected to 1.8×10^8 rads gamma integrated over a 40-year period. In addition, a fire test was conducted for all cables 14 AWG and larger and a fire retardancy test for cables 16 AWG and smaller. Refer to Section 9A.5.d.3(f) for a description of tests on cables 14 AWG and larger. Temperature and humidity tests were conducted to meet the LOCA BWR requirements, as detailed in Section 3.11.

Cables not subject to these requirements are routed in enclosed raceway (except as otherwise noted) and are as follows:

a. BOP medium voltage underground cables

b. Lighting cables

c. Communication cables (i.e., computers, telephone, data, etc.) will be routed in enclosed raceways unless otherwise approved by engineering.

d. Security system cables

e. BOP vendor supplied wiring and their replacements

f. Internal panel wiring in the control center (not subject to the radiation resistance requirements only)

8.3.1.4.2.1 Ampacities

Power cable values are sized according to criteria mentioned in ICEA Pub. No. P-54-440-1975 for cables in open-top trays and ICEA Pub. No. P-46-426 for cables in conduits and underground ducts. Sizing of cables is controlled via design instructions and engineering calculations in the design process. Ampacities for cables outside the drywell are based on a conductor temperature of 90°C and air ambient temperature of 40°C. To correct for cable diameters, a diameter correction mentioned in the ICEA publication was applied.

Power cables installed inside the drywell are sized at 65°C (149°F) air ambient with the exception of cables used only during cold shutdown where 40°C (104°F) air ambient may be utilized and cables in certain areas inside the drywell where the temperature exceeds 65°C (149ºF). Cables installed in operating environmental conditions above 65°C (149°F) were evaluated. The ampacity tables for 65°C (149°F) were obtained by applying a temperature correction to the cable ampacities at 40°C. The temperature correction formula was obtained from ICEA Pub. No. P-46-426.

Power cable values are selected on the basis of 115 percent bus load amps for bus feeder cables and 125 percent full load amps for cables feeding motors, heaters, etc. These values can be overruled by engineering dispositions.

8.3.1.4.2.2 Fire Protection of Cables

Cables are fabricated with tested, fire-resistant insulating and jacketing materials. Flame tests were conducted by the selected cable vendors with the results certified and submitted to Edison. Cable types were not accepted unless it was proven that a self-sustaining propagating fire did not result under rigid test conditions.

Fire stops are installed in all horizontal and vertical cable tray penetrations through walls and floors except for a few select wall penetrations identified as required for pressure venting from a postulated high-energy pipe break. The high-energy pipe break venting paths are identified in Subsection 3.6.2. For cable tray penetrations that are not fire stopped, fire breaks are provided that do not affect vent area requirements. Walls identified as fire walls are not used for pressure relief and all electrical tray penetrations are fire stopped. Fire breaks have not been added along horizontal and vertical tray runs because of division of the plant into fire zones and the use of cable that was tested and purchased to be nonpropagating.

Although tray penetrations are generally used for convenience where the maintenance of a pressure differential between areas is not required, fire stops are nevertheless provided to prevent the spread of fire from one area to another. Part of the opening provided is taken up by the barrier designed in accordance with the wall structure itself. Derating effects of cable capacity are considered when establishing the depth of the fire-resistant fill in the penetration. When penetrating a floor, the tray section is completely enclosed for a distance of 8 ft above the floor surface.

Cable tray penetrations through secondary containment will be fire stopped and sealed with either the multicable transit manufactured by Nelson Electric Company or an approved silicone foam fire stop.

The multicable transit consists of a steel rectangular frame through which the cables are pulled. The spaces inside the frame around the cable are packed with elastomer inserts of a proprietary formulation. The entire assembly has been fire tested to UL 263 followed by a hose stream test as specified in UL 10B. UL rates the transits for Classification and Follow-up Services of Underwriters Laboratories, Inc., and allows it to be marked:

Underwriters Laboratories, Inc.

Classified

Wall Opening Protective

Multi-Cable Device

Fire Rating: 3 hr minimum

The other cable tray fire penetrations will be sealed using a fire stop made of

a. Dow-Corning Q3-6548 Silicone RTV Foam, or

b. Other material to achieve an ANI approved 3-hr barrier.

At the designated safety-related fire barriers, Edison has provided 3-hr-rated penetration fire stops, tested and qualified in accordance with the NELPIA/MAERP (ANI) standard method of cable and pipe penetration fire stops. The thickness is adequate to meet the test requirements of ASTM E-119. Fire stops at walls not rated as fire barriers are rated for 30 minutes.

If it becomes necessary to breach or repair a completed fire stop, the silicone foam fire stops can be repaired using silicone foam repair procedures and controls.

Edison recognizes the need for periodic surveillance. These surveillances determine the condition of the fire stops and seals and will be conducted in accordance with the Technical Specifications requirements.

Holes and other voids in sleeve penetrations through floors to switchgear, MCCs, and other panels are plugged with a suitable fire-resistant material. In areas of high cable concentration, such as a cable spreading room, smoke-detection devices are provided. The design and configuration of the area determines the actual location of the devices.

The QA procedures to be used to verify that penetration fire stops and seals have been properly installed include

a. Verification by QC personnel that fire stops and seals are made of the specified materials

b. Monitoring of installation by QC personnel (using inspection procedures and checklists) to ensure compliance with identified design requirements.

8.3.1.4.2.3 Environmental Effect on Cables

Cable materials are evaluated for the effects of environmental conditions. Cable insulation temperature ratings consider the effects of ambient temperature and ohmic heat resulting from loads on the cable.

Where possible, adverse environmental effects are reduced by restricting cable passage through affected areas. However, cables within areas such as the primary containment are subjected to small pressure variations and radiation levels over the 40-year operational life of the plant, possibly at normal operating temperature conditions that may exceed the design rating of the cable insulation. The effect of these ambient temperatures on the service life of the cable are evaluated.

An additional requirement of these cables is to operate satisfactorily in the environment during and after the design-basis accident (DBA) outlined in Section 3.11 and Table 3.11-3. Throughout the period indicated, the cables may be subjected to a relative humidity of 100 percent as well as to the temperatures and pressures outlined in Table 3.11-3. The cable manufacturers are required to test samples of cable to demonstrate that they can withstand the conditions of the DBA defined in Section 3.11, and so certify.

8.3.1.4.3 Cable Trays

NOTE: Reduced design loadings for hangers were specified as a result of reverification of hanger loading and design.

The power and control cable trays are prefabricated sheet metal structures consisting of longitudinal channel side rails connected by transverse hat section members spaced on 9-in. centers. Hanger loading is limited to the reduced design loading (cable and tray weight plus firewrap load, tray cover load, and side rail weight). During initial design, the cable trays within the relay room, cable spreading room, and directly below the relay room floor were designed to withstand a dead weight loading of 50 lb./ft.^{2} , in addition to 200-lb. live load anywhere along the 8 foot maximum tray span, with a two-to-one safety factor. All other trays were designed to withstand a dead weight loading of 40 lb./ft.^{2} in addition to the live load with the same safety factor. In cases where a reduced design loading for a hanger was specified, cable trays were designed for such reduced load. An on-going program was later established to monitor the actual weight of cables in the trays and to account for fire wrap, conduit, and air drop loads. Cable tray design load is adjusted to reflect these actual loads. For the trays in the drywell, a concentrated live load of 250 lb was specified. In the design specification for cable trays, deadweight loading did not include the weight of fire wrap material or any other attachments, such as top hat covers, that were subsequently added. Accordingly, hanger modifications were made where necessary, and the structural adequacy of the cable trays was reverified.

Instrument cables are installed in nonventilated solid metal trays with covers to provide adequate electromagnetic and electrostatic shielding. Ladder-type sections are used in the relay room over the cabinets where cable dropouts are required.

All cable tray hangers for RPS and ESF circuits are of Category I design. The trays are adequately supported and braced to withstand maximum horizontal and vertical forces. The transition tray sections are structurally connected to form a tray system.

Tray fills in both the control and instrumentation tray systems are initially limited by a computer program to 60 percent fill by cross-sectional area, but they may exceed 60 percent fill by specific instruction to the computer detailing the route to be taken. No control or instrumentation tray is permitted to exceed the deadweight loading limit of its hangers.

Tray fills in the power cable tray systems are initially limited to 47.1 percent fill by cross-sectional area. This value is equivalent to 3 in. of calculated depth, where depth is calculated according to the formula given in the ICEA-NEMA Standard Ampacity for Cables in Open Top Trays (ICEA P54-440, NEMA WC51-1975). Power trays may exceed 47.1 percent fill by specific instruction to the computer detailing the tray route to be taken.

Power trays that exceed 47.1 percent calculated fill are reviewed to verify that the temperature ratings of the cables are not exceeded. The temperature ratings of safety related cables are not exceeded in power trays greater than 47.1% fill. No power tray is permitted to exceed the deadweight loading limit of its hangers.

8.3.1.5 Physical Identification of Safety-Related Equipment

All safety-related equipment is identified using a color and/or numbering scheme that is both permanent and conspicuous. The purpose of the numerical and color-coding of cable conduits and trays is to uniquely define each cable and routing as to voltage level, service, and channel where appropriate. This provides a sure system for ascertaining the proper installation of each cable. Details of the numbering and color-coding schemes are in the following subsections.

8.3.1.5.1 Cable Identification

Cables are assigned an alphanumeric code number that is used for the purpose of identification. This number denotes the equipment category and tray system to which the cable is assigned. A permanent cable identification tag that indicates the cable number and segregation code plainly and legibly is affixed to each end of the cable. The number also appears on any wiring drawing, intercabling diagram, or plan electrical (electrical installation) drawing on which the cable appears. Cables are color coded in accordance with plant specifications. Cables belonging to ESF Division I have orange jackets; cables belonging to ESF Division II have blue jackets. Cables which are pulled QA 1 with a black jacket are required to have the cable jacket re-identified (phase taped) per plant specifications. Also, in cases where divisional color jacketed cable have been pulled BOP, cable jacket re-identification (phase taping) is required per plant specification. In general, the BOP cables have black jackets except for certain cases, described in plant specifications. Black-, neutral-, and magenta-colored jacket cables are installed in divisional trays in a limited number of cases due to lack of cables having proper jacket colors in that size (e.g., the coaxial cables with a black or magenta jacket and thermocouple leads with a clear neutral jacket to expose the underlying tracers).

8.3.1.5.2 Cable Tray and Conduit Identification

Each cable tray has an alphanumeric identification number applied to its side at 25-ft intervals and at room entrances. This identification reflects the classification, power level, and channel of the tray section and is so coded. The ESF trays are color-coded orange and blue by division every 25 ft. The ESF cables are installed only in tray sections or conduits with a code identical to the code assigned to each cable. The BOP cables, except those in the RHR complex, which are treated (though not identified) as ESF cables, are routed only in BOP-coded cable trays.

Conduits installed for ESF and RPS cables are also assigned number codes that show cable routing. These number codes are affixed to the conduit at appropriate locations, and are color-coded to denote safety function. The RPS and NMS conduits will be uniquely color coded.

8.3.2 DC Power Systems

8.3.2.1 Description

8.3.2.1.1 General

The dc power system consists of two independent Class 1E battery systems, one system per division. Each system supplies dc power at 260 V dc and 130 V dc.

There is also a 260/130-V dc BOP system serving BOP loads. Further, each high-voltage switchyard has its own independent source of dc power for circuit breaker control. There are two batteries and chargers in the 345-kV switchyard and one battery and charger in the 120-kV switchyard.

Certain positions on the ESF 480-V buses supply non-safety-related loads. The control logic power for these positions as well as the safety-related positions is supplied by the Class 1E battery systems. Non-safety-related dc power loads, such as emergency oil pumps, are normally supplied by the BOP battery system. Where non-safety-related power loads exist on the Class 1E battery systems, a Class 1E isolation device will disconnect the non-safety-related load from the Class 1E battery system on receipt of a LOCA signal.

The ESF and BOP systems are protected from voltage variation by an undervoltage and two overvoltage circuits at the charger. One overvoltage circuit deactivates the rectifier bridge when the voltage exceeds 139.5 V for BOP and 138.5 V for Div I and II, while the other alarms to the main control room any voltage surpassing 136 V for BOP and 134 V for Div. I and II. The undervoltage relay alarms in the main control room if the voltage at the main distribution panel drops below 128.5 V for BOP and 124.2 V for Div. I and II.

8.3.2.1.2 260/l30-V DC Class 1E Power System

Two center-tapped 260-V batteries are provided for Class 1E loads. They are designated as 2PA for Division I and 2PB for Division II, and are shown in Figure 8.3-9. The batteries are located in separate rooms in the auxiliary building. The chargers and related equipment for the Class 1E batteries are located outside the battery rooms, in accordance with the separation criteria required for redundant systems.

Each 260-V battery is divided into two 130-V batteries connected in series. Each l30-V battery section has an adequately sized battery charger. These chargers are connected in parallel through fusing to their respective battery. For each 260-V battery, a 130-V spare battery charger is provided that can replace either of the normal 130-V connected chargers. The replacement can be made manually when it has been verified that the charger is connected to the proper 130-V battery, as shown in Figure 8.3-9. Each division's two 130-V batteries and their chargers are the source of dc control power for that respective division.

To maximize the reliability of system control power, the following philosophy is applied:

a. Control power for each of the two load groups within a division is supplied from a separate 130-V dc section of that division's battery

b. Power for control of each division's two diesel generators and their associated switchgear is supplied from the 130-V dc battery section supplied from their respective load group.

The 260-V sources furnish power for the dc motors necessary during shutdown conditions. For 260-V use, the battery is connected directly to dc MCCs through adequate fusing. The two center-tapped 260-V batteries 2PA and 2PB (identical) are redundant and separated according to IEEE Standard 308-1971 and General Design Criterion 17.

The loads supplied from the ESF batteries are shown in Table 8.3-15.

8.3.2.1.3 48/24-V DC Power System

8.3.2.1.3.1 Introduction

A reliable source of isolated low-voltage dc energy must be available to provide power for neutron monitoring instrumentation. The system is designed to be free of electrical noise, and is reliable in that the loads that are the most needed have the highest probability of being served. A failure in any part of the system is isolated so that it does not disable the entire system. The 48/24-V dc system is not required to be Class 1E, but because of physical relationships with the 260/130-V Class 1E batteries, they are Seismic Category II/I.

Figure 8.3-10 shows a one-line diagram of the 48/24-V dc system required to operate the various monitoring instruments. One 48/24-V battery, center tapped with the tap grounded at the instrument ground system, is supplied for each of the two systems. The batteries, designated 2IA and 2IB, are redundant. The batteries are located in the same rooms with the 260/130-V Class 1E batteries as follows: battery 2IA with 2PA and 2IB with 2PB. Each 48-V dc source is provided from two 24-V batteries connected in series charged by two 24-V chargers.

There is a main distribution panel with three buses: positive, neutral, and negative. The neutral bus is grounded to the instrument ground bus. Two 24-V series connected batteries and chargers are connected in parallel to these buses.

Each system has a +24-V dc and a -24-V dc battery charger connected in series with a common ground. The primary source of power is from the battery chargers, with the batteries serving as a backup source of power. A fifth charger that can replace any of the four normal chargers is supplied.

The 24-V dc power system supplies power for all 24-V dc requirements through the use of two independent systems. The systems, identified as system A and system B, are described in Subsections 8.3.2.1.3.2 and 8.3.2.1.3.3.

8.3.2.1.3.2 System A

System A furnishes power to the following instruments:

a. Source range monitor units

b. Trip auxiliary unit--source range

c. Intermediate range monitor units

d. Trip auxiliary units--intermediate range

e. Process radiation monitor units--stack gas

f. Trip auxiliary unit--air ejector offgas

g. Linear amplifier unit--air ejector offgas

h. Miscellaneous instrument loops.

System A has as its primary sources of power a positive (+ to N) 24-V battery charger identified as battery charger 2IA-1, and a negative (N to -) 24-V battery charger identified as battery charger 2IA-2. The primary sources have as a backup a positive (+ to N) 24-V battery, and a negative (N to -) 24-V battery.

The system is protected from voltage variation by one under-voltage circuit and two overvoltage circuits at the charger. One overvoltage circuit opens the charger dc circuit breaker when the voltage exceeds 28.5 V, while the other alarms to the main control room any voltage surpassing 26.9 V. The undervoltage relay alarms to the main control room if the voltage drops below 25 V.

This circuit monitors both the plus and minus sides of the system. A loss of power from the battery chargers does not interrupt service. A loss of ac feed to the battery chargers will also alarm in the control room.

8.3.2.1.3.3 System B

System B furnishes power to the following instruments:

a. Source range monitor units

b. Trip auxiliary unit--source range monitor

c. Intermediate range monitor units

d. Trip auxiliary units--intermediate range monitor

e. Process radiation monitor unit--reactor building closed loop cooling water

f. Process radiation monitor unit--reactor building service water effluent

g. Process radiation monitor unit--radwaste effluent.

h. Miscellaneous instrument loops.

System B also has as its primary sources of power a positive (+ to N) 24-V battery charger identified as battery charger 2IB-1, and a negative (N to -) 24-V battery charger identified as battery charger 2IB-2. The primary sources have as a backup a positive (+ to N) 24-V battery and a negative (N to -) 24-V battery.

The protection and test facilities for system B are the same as those for system A.

The battery chargers are of the full-wave silicon-rectifier type. They are capable of working independently since loads are different on the positive and negative buses.

8.3.2.1.4 Maintenance and Testing

The plant batteries and other equipment associated with the dc system are easily accessible for inspection and testing. Service and testing are accomplished on a routine basis in accordance with recommendations of the manufacturer and requirements of IEEE 450-1972. Typical inspections include visual inspections for leaks and corrosion and the testing of all batteries for voltage, specific gravity, and level of electrolyte. Battery testing will be performed at least once per 24 months to ensure the capacity as described in Section 8.3.2.2.2 is satisfied.

8.3.2.1.5 Balance-of-Plant 260/l30-V DC System

One 260/130-V battery designated 2PC is provided for BOP systems and is located in the radwaste building. There are two dc MCCs fed in parallel from battery 2PC. The 2PC battery system is shown in Figure 8.3-11.

8.3.2.2 Analysis

8.3.2.2.1 Safety Design Basis

The plant safety battery system is a Class 1E system and consists of two 260/130-V dc control and power batteries. Each battery is of adequate size to safeguard the plant until ac power sources are restored. Each battery has its own charger, which is sized to recharge the battery after discharge while carrying its steadystate load within a time compatible with the recommendations of the battery manufacturer. One standby charger is provided for each of the two 260/130-V dc power batteries. The plant safety battery system is arranged so that no single circuit component failure prevents the system from providing power to vital loads. Feeds for the chargers are from critical buses and redundancy is maintained.

The existing 345-kV switchyard is provided with two separate control batteries that also have separate chargers. The 120-kV switchyard has its own battery, normal charger, and spare charger.

8.3.2.2.2 Capacity

Design calculations determined safety related battery capacity by developing load versus time plots of dc power demand for accident and safe- shutdown conditions. The safety related battery capacity was then chosen such that under the worst-case condition with no chargers available, the batteries are able to carry all required loads for 4 hours without battery voltage dropping below the minimum voltage necessary to operate the respective components as designated within the applicable design calculation requirements and component voltage acceptance criteria.

The required safety related 130 V batteries are demonstrated operable at least once per 24 months by verifying that either:

a. The battery capacity is adequate to supply and maintain in operable status all of the actual emergency loads for the design duty cycle (4 hr) when the battery is subject to a battery service test, or

b. The battery capacity is adequate to supply a dummy load for a profile as described within the applicable design calculation while maintaining the battery terminal voltage greater than or equal to the minimum voltage necessary to operate the bounding component as designated within the applicable design calculation requirements.

Design calculations determined BOP battery capacity by developing load versus time plots of dc power demand for station blackout (SBO) and Appendix R dedicated shutdown conditions. The BOP battery capacity was then chosen such that under the worst-case condition with no chargers available, the batteries are able to carry all required loads for 1.5 hours without battery voltage dropping below the minimum voltage necessary to operate the respective components as designated within the applicable design calculation requirements and component voltage acceptance criteria.

The required BOP 130 V batteries are demonstrated operable at least once per 72 months by verifying that the battery capacity is adequate to supply and maintain in operable status all of the actual emergency loads, or an equivalent dummy load, for the design duty cycle (1.5 hr) when the battery is subject to a battery service test.

The chargers were sized so that any charger is able to recharge a totally discharged battery in 24 hr while supplying maximum predicted load.

8.3.2.2.3 Compliance With Design Criteria

The description in the previous subsections and the dc system shown in Figures 8.3-9 and 8.3-10 demonstrate the compliance of this design with all Regulatory Guides and General Design Criteria, as well as with all other applicable design criteria and standards including IEEE 308-1971.

8.3.2.2.4 Safety Evaluation

Each safety related 130-V battery in a division has one designated charger fed on the ac side from an MCC of the same division. One 130-V spare charger is provided per division and is also fed on the ac side from another MCC of the same division.

There are two redundant power and control dc systems for ESF loads. The safety related divisional ESF batteries are of the same size, capable of carrying the load for 4 hr without chargers, although it is highly improbable not to have either offsite or onsite power available.

In case of a safety related charger failure, the spare charger is employed manually.

The safety related batteries are permanently in service and working while the power plant is operating; therefore, any failures are detected and resolved during normal operation.

The two divisions are totally independent as far as ac feeds for the battery chargers, the batteries, and their distribution systems.

The Float and Equalize voltages for the respective Division 1 and 2 batteries are as maintained within the applicable design calculation requirements. The Battery (Final) Discharge voltages are maintained at the minimum voltage necessary to operate the respective components as designated within the applicable design calculation requirements and component voltage acceptance criteria.

Each BOP 130-V battery has one designated charger fed on the ac side from a BOP MCC. One BOP 130-V spare charger is provided and is also fed on the ac side from another BOP MCC. The BOP batteries are of the same size, capable of carrying the load for 1.5 hr without chargers, although it is highly improbable not to have either offsite or onsite power available. In case of a BOP charger failure, the spare charger is employed manually. The BOP batteries are permanently in service and working while the power plant is operating; therefore, any failures are detected and resolved during normal operation.

There is no battery control from the main control room; however, the following abnormal conditions are alarmed or recorded in the main control room:

	<u>DC system alarms</u>
DIV. I	Battery 2A-1 charger (ac power failure)
	Battery 2A-2 charger (ac power failure)
	Battery 2A-1 high voltage
	Battery 2A-2 high voltage
	Battery 2A-1 low voltage
	Battery 2A-2 low voltage
DIV. II	Battery 2B-1 charger (ac power failure)
	Battery 2B-2 charger (ac power failure)
	Battery 2B-1 high voltage
	Battery 2B-2 high voltage
	Battery 2B-1 low voltage
	Battery 2B-2 low voltage
BOP	Battery 2C-1 charger (ac power failure)
	Battery 2C-2 charger (ac power failure)
	Battery 2C-1 high voltage
	Battery 2C-2 high voltage
	Battery 2C-1 low voltage
	Battery 2C-2 low voltage
48/24V	Battery 2IA
	24V battery A1 charger (ac power failure)
	24V battery A2 charger (ac power failure)
	Battery 2IA high voltage
	Battery 2IA low voltage
48/24V	Battery 2IB
	24V battery B1 charger (ac power failure)
	24V battery B2 charger (ac power failure)
	Battery 2IB high voltage
	Battery 2IB low voltage.

TABLE 8.3-8 DIESEL RESPONSE TO LOADING[g]

	Minimum Voltage (percent)[a]			Minimum Frequency (percent)[c]		Recovery Time (sec)		
	Colt Program	Edison Program	Preop Test[b]	Colt Program	Preop Test[b]	Colt Program	Edison Program	Preop Test[b]
Starting of RHR pump (2000 hp)[h]	78 (69.4)[e]	72.5	69-73 (61)[f]	95	90-95[d]	3	2.75	4-5
Starting of CS pump (800 hp) with RHR pump operating	89 (87.2)[e]	87.9	89-91 (71)[f]	98	98-99 (96)[d]	7	6.97	5-7

[a] Minimum voltage specified in Regulatory Guide 1.9: 75 percent.

[b] Preoperational Test Results - Approximate range for the four EDGs. Minimum values are a deviation from the recommended values of Regulatory Guide 1.9, but are momentary. The preoperational test demonstrated the starting and load-accepting capabilities of the EDGs.

[c] Minimum frequency specified in Regulatory Guide 1.9: 95 percent.

[d] Value in parenthesis for CS reflects EDG testing performed with Woodward 2301A based governor control system. Values for RHR with Woodward 2301A based governor control system fell within existing ranges shown and do not indicate any new value.

[e] Value in parenthesis reflects Coltec Study for Basler series boost exciter, which is the current exciter in service. The value before the parenthesis is maintained for historical purposes and is associated with the Portec shunt type static exciter.

[f] Value in parenthesis reflects the minimum value among all EDGs from testing performed during refueling outages since replacement of Portec shunt type static exciter with Basler series boost exciter. The testing demonstrates the starting and load-accepting capabilities of the EDGs.

[g] Regulatory Guide 1.9, Rev. 2 Section C.4 allows testing to justify and validate voltage and frequency dip levels below the stated nominal values as acceptable based on satisfactory motor starting. Additional discussion of conformance with Regulatory Guide 1.9 is provided in Appendix A.1.9.

[h] The two motors considered were the RHR pump motors (2000-hp motors for pumps A, B, and C and 2250-hp for pump D).

8.4 STATION BLACKOUT (SBO)

8.4.1 Introduction

10 CFR 50, Section 50.63 (Station Blackout Rule) (reference 1) requires that each light-water-cooled nuclear power plant be able to withstand and recover from a station blackout (SBO) of a specified duration. Licensees are expected to have the baseline assumptions, analyses, and related information used in their SBO evaluation documented and available for Nuclear Regulatory Commission (NRC) review. Section 50.63 also identifies the factors that must be considered in specifying the SBO duration and requires that, for the SBO duration, the plant be capable of maintaining core cooling and appropriate containment integrity.

The object of the SBO rule is to reduce the risk of severe accidents resulting from SBO by maintaining highly reliable ac electric power systems and, as additional defense-in-depth, assure that nuclear plants can cope with an SBO for a specific period of time.

The governing criteria for SBO are contained in 10 CFR 50.63. The term “Station Blackout” is defined as the loss of offsite ac power to the essential and nonessential electrical buses concurrent with turbine trip and the unavailability of the redundant onsite emergency ac power systems. However, ac power to buses fed by station service batteries through inverters is considered available along with the dc power to buses fed by the batteries.

8.4.2 SBO Coping Evaluation

Regulatory Guide (RG) 1.155, Station Blackout, (reference 2) describes a means acceptable to the NRC for meeting the requirements of 10 CFR 50.63. RG 1.155 states that the NRC has determined that the Nuclear Management and Resource Council (NUMARC) document NUMARC 87-00, Guidelines and Technical Bases for NUMARC Initiatives Addressing Station Blackout at Light Water Reactors, (reference 3) also provides guidance that is in large part identical to the RG 1.155 guidance and is acceptable to the NRC for meeting these requirements. When reference to NUMARC 87-00 is made, it also includes reference to the supplemental NUMARC letter of January 4, 1990 (reference 4).

The reactor core and associated systems have been reviewed to determine that there are sufficient capacity and capability to ensure that the core is cooled, the reactor coolant system is isolated, and appropriate containment integrity is maintained in the event of an SBO for the required duration.

Systems required for decay heat removal have been reviewed to ensure that those portions of the systems which are required to cope with the consequences of an SBO are available. Effects of nonavailability of support systems such as instrument air, HVAC, and ac power are considered. Condensate storage tank and battery capacities have been reviewed for adequacy.

Combustion Turbine Generator (CTG) 11-1 is designated as an alternate ac (AAC) power source for the plant and is available within one (1) hour to the blacked out unit. In the event CTG 11-1 is inoperable, one of the remaining CTG’s can be started using a standby diesel generator. The alternative CTG has the same time availability criteria as CTG 11-1. Plant coping is controlled predominately by class IE dc power and steam driven sources until the

AAC power is available for loading within one hour. The AAC receives its fuel from a fuel tank located near the unit and independent of any fuel tanks for the EDGs.

The Fermi 2 plant has been evaluated against the requirements of the SBO rule using guidance from NUMARC 87-00 except where RG 1.155 takes precedence. The results of this evaluation are detailed as follows.

8.4.2.1 SBO Coping Duration

RG 1.155 and NUMARC 87-00 Section 3 were used to determine an SBO coping duration of four (4) hours for Fermi 2. The specific SBO duration is based on the redundancy of the onsite emergency ac power sources, the reliability of the onsite emergency ac power sources, the expected frequency of loss of offsite power (LOSP), and the probable time needed to restore offsite power. The coping duration is based on the following design characteristics using the NUMARC 87-00 methodology:

1. Offsite power design characteristic group is classified “P2”.
2. Emergency power configuration group is classified “B”.
3. EDG target reliability is “0.95”.

8.4.2.2 SBO Coping Analysis Assumptions

The assumptions used in the coping analysis are as follows:

1. RG 1.155 and NUMARC 87-00 provide general guidance for the SBO coping analysis.
2. The unit is operating at 100 per cent rated thermal power for at least 100 days prior to the event initiation.
3. Initiating conditions will be loss of offsite power and Station Blackout. No design basis accidents, other events, or additional single failures are assumed to occur prior to or during the SBO event.
4. A reactor SCRAM immediately follows an LOSP.
5. Reactor coolant system inventory losses are limited to normal system leakage, losses from blowdown and recirculation pump seal leakages (18 gal/min per pump maximum).
6. Credit is taken for operator actions where appropriate.
7. CTG 11-1 is available for loading within one (1) hour of the SBO event, or CTG 11-2,11-3, or 11-4 is available with blackstart capability using a standby diesel generator, and available for loading within one (1) hour of the SBO event.
8. Equipment needed for the SBO coping duration is available at the site.

8.4.2.3 SBO Coping Capabilities

Applicable plant systems/functions, as identified in RG 1.155 and NUMARC 87-00 guidelines, are available to successfully cope with the SBO event to the extent required by RG 1.155 for the required SBO duration.

The SBO coping evaluation concludes that the various systems and components required for reactor core cooling are available. The CTG 11-1 or alternate CTG with the standby diesel generator in conjunction with the battery capacity has been found to be adequate for the four hour coping duration. The ability to maintain the reactor cooling system (RCS) inventory and containment integrity has been evaluated and confirmed. The effects of the loss of ventilation on equipment needed for SBO has been evaluated. The plant can successfully cope with the SBO event for the required four hour duration with negligible impact on the equipment qualified life and with no impact on the operability of the equipment.

The plant has the capability to cope with an SBO for the coping duration of four hours as discussed below:

1. Capability to provide core cooling is demonstrated by the following:

   a. RCS isolation

      RCS isolation is provided to prevent loss of inventory through normally open lines.

   b. Main steam line isolation

      Main steam line isolation is achieved by automatic closure of the main steam isolation valves (MSIVs) upon loss of offsite power. Manual closure capability of the MSIVs is also available. Controlled steam release capability is available to remove decay heat via the safety relief valves (SRVs) to the suppression pool. The SRVs are self-actuating at the set relieving pressure, but may be operated manually at pressures below the valve setpoint.

   c. High pressure coolant injection (HPCI) system availability

      During SBO, the high injection volume of the HPCI system is not necessary, since loss of coolant accident conditions are not postulated.

   d. Reactor core isolation cooling (RCIC) system availability

      During SBO, a steam flowpath from the reactor and a water flowpath from either the condensate storage tank (CST) or the suppression pool are available to the turbine driven RCIC pump.

      The RCIC system starts and initially feeds to the reactor from the CST until the CST reaches its low level setpoint. Upon reaching this limit, the RCIC suction automatically shifts to the suppression pool. All necessary instrumentation and valves required to assure automatic transfer to the suppression pool are available during an SBO.

   e. CST capacity

Adequate condensate inventory is available for the required coping duration without additional water supply. The inventory in one CST is adequate for the required SBO coping duration of four hours.

f. Batteries and battery charger capacity

To maintain the electrical and instrumentation components needed for core cooling and decay heat removal following SBO, Fermi 2 requires class IE as well as non-IE batteries to support operation of the AAC. A battery capacity calculation has been performed pursuant to NUMARC 87-00, section 7.2.2 to verify that required class IE and non-IE batteries have sufficient capacity to meet Station Blackout loads for one hour. The class IE batteries were determined to be adequate to meet Station Blackout loads for one hour. The non-IE batteries that support the AAC, switchgear and associated functions were determined to be adequate to meet Station Blackout loads for one hour.

The associated battery chargers for the division 1 IE battery and the necessary non-IE station batteries are connected within one hour and power is available to support battery operation in excess of the one hour from the AAC. Therefore the batteries are capable of adequate support of the SBO loads for the four hour coping duration.

g. Compressed air system requirements

No air-operated valves are relied upon to cope with a station Blackout for one hour. The loss of the compressed air system during an SBO would have no impact on maintaining both decay heat removal capabilities and RCS inventory.

The only pneumatic operated valves relied upon to cope with a Station Blackout are the two (2) low-low set relief valves and five (5) ADS Safety Relief Valves (SRVs) that are operated by pressurized nitrogen. Each valve has an accumulator sized to provide five (5) actuations of the valve on loss of the nitrogen supply.

The division 1 Control Air Compressor can be powered by the AAC source and would be available after the AAC is started and connected to the loads within one hour.

h. Instrumentation requirements

Adequate instrumentation is provided to assess the core reactivity, RCS inventory, core cooling capability, decay heat removal capability, and availability of necessary ac and dc power systems.

2. Ability to maintain adequate RCS inventory

As allowed by NUMARC guidelines, recirculation pump seal leakage is assumed not to exceed 18 gpm per pump. A design calculation on CST inventory was performed using the 18 gpm per pump leakage plus the 25 gpm maximum allowable Technical Specification leakage for a total of 61 gpm leak rate. Additionally reactor depressurization was assumed to be required. The results indicate that less than 150,000 gallons are required which is less than the volume of water that must be maintained in the CST while in Modes 1, 2 and 3. The RCIC system is capable of providing sufficient makeup inventory to the reactor pressure vessel to maintain water level. Standby Feedwater system is also available to be powered from the AAC to maintain the reactor water level.

3. Ability to maintain appropriate containment integrity

Appropriate containment integrity is provided during the required duration of the SBO. Valves necessary for containment isolation or which must be operated during the four hour SBO event can be positioned independent of the preferred and blacked out unit class IE emergency power supply. Means of closure include manual operation, dc powered operation, AAC powered operation and air operated valves that fail closed on loss of air, as discussed as acceptable in NUMARC 87-00. Valve position can be determined by either control panel indicating lights or by mechanical valve position indicators at the valves. The system operating procedure on primary containment isolation system has been revised to include actions necessary to verify containment isolation valves are in their appropriate position during an SBO.

4. Effects of loss of ventilation

Those areas of the plant which contain equipment required to operate during an SBO to achieve and maintain safe shutdown have been evaluated to determine their average ambient steady state temperatures occurring during the SBO duration. This evaluation was performed in accordance with the guidelines established in NUMARC 87-00, Appendix F. This evaluation has established reasonable assurance of operability of equipment in these areas during as SBO event.

5. Equipment environmental evaluation

Areas of the plant housing equipment/components required for SBO coping have environmental conditions which are either below the component environmental qualification design limit or are only slightly above the design limit and are well below the minimum generic limit established in NUMARC 87-00.

A plant specific heat up analysis of the primary containment was performed. The analysis is documented in a design calculation and concludes that the containment design temperature of 340 degrees F is not exceeded within the first hour of the SBO event. The HVAC systems for the drywell are not available during the first hour, but will be reestablished when the AAC source is available. The drywell is a dominant area of concern not from an equipment operability concern but to ensure that drywell temperature would not exceed the design limit of 340 degrees F. Fermi 2 has a Mark 1 containment.

The HVAC system for the Control Center Complex which is not identified as a dominant area of concern is not available during the first hour of the SBO event. A design calculation has verified that the Control Room temperature will not exceed 120 degrees F during an SBO event. Since equipment inside instrument and control cabinets are exposed to their own electrical heat loads, doors of cabinets containing energized equipment within the Control and Relay Rooms relied upon to cope with an SBO should be opened within thirty (30) minutes of the SBO event onset, per NUMARC 87-00, Section F.5. An increase in air transfer is provided by opening cabinet doors, thus, keeping the instrumentation inside cooler. Procedures have been revised to include this requirement for an SBO event.

Equipment in the HPCI and RCIC rooms has been evaluated and determined to be operable at the calculated temperatures of 180 degrees F and 158 degrees F respectively. Both the HPCI and RCIC rooms have equipment area high temperature sensors which are capable of causing isolation of the HPCI or RCIC systems. Calculations show that temperatures will exceed the setpoints of 150 degree F. The systems will isolate unless operator action is taken. Procedures have been revised to ensure that the equipment area high temperature signals are disabled for an SBO event.

Weather hazards such as extreme temperatures, wind, and flooding will not impact components required for an SBO event.

6. Emergency lighting requirements

   Emergency lighting is provided in the Control Room to enable station operators to perform the necessary manual actions to cope with the SBO. Adequate emergency lighting is available for those areas of the plant where operator actions and/or ingress or egress is required. Emergency lighting is provided by self-contained battery powered Appendix R lighting and other battery powered lighting provided for the SBO event.

7. Identification of required operator actions and training

   Operator actions and training that are required, inside and outside the Control Room, to cope with the SBO event are identified in plant procedures and the operators are trained as applicable on the procedures.

8. Procedure interface considerations

   RG 1.155 provides the guidance that procedures and training should include all operator actions necessary to cope with an SBO for at least the duration determined according to RG position 3.1 and to restore normal long term cooling/decay heat removal once ac power is restored. Procedures have been integrated with plant-specific technical guidelines and the emergency operating procedure upgrade program.

9. Diesel generator reliability program requirements

   Elements of the EDG program are contained in RG 1.155. An EDG reliability program has been integrated within other existing programs and plant procedures and is consistent with the guidance of RG 1.155, Section 1.2. The target reliability of the EDGs is 95% which is consistent with the plant category and coping duration in the regulatory guide.

10. Quality Assurance

   A quality assurance program consistent with the guidance of RG 1.155 is in place for SBO equipment. Quality Assurance activities have been implemented as were determined appropriate for the existing equipment consistent with the guidance in Appendix A of RG 1.155.

CHAPTER 9: AUXILIARY SYSTEMS

9.1 FUEL STORAGE AND HANDLING

9.1.1 New-Fuel Storage

9.1.1.1 Design Bases

The new-fuel storage racks, as shown in Figure 9.1-1, are designed to maintain sufficient spacing between the new-fuel assemblies under fully loaded conditions to ensure that the array will limit the effective multiplication factor (k_{eff}) to ≤0.90 for the dry condition and to ≤ 0.95 in the event of complete flooding of the storage vault. New-fuel storage racks are supplied for 30 percent of the full core fuel load.

These racks are designed to withstand combined loadings, including impact and seismic disturbance, to ensure against damage to the racks or distortion of the fuel storage arrangement.

The new-fuel storage vault is designed to preclude flooding of the new-fuel assemblies.

9.1.1.2 Facilities Description

9.1.1.2.1 New-Fuel Storage Vault

After receipt, uncrating, and transfer to the operating floor, the new fuel may be placed in dry storage in racks. These racks are contained in a Category I new-fuel storage vault. The new fuel may be placed in the new fuel storage vault, provided criticality concerns are addressed as outlined in letter EF2-61,906. The vault, shown in Figure 9.1-2, accepts 23 new-fuel storage racks, each of which accommodates 10 new-fuel assemblies. The 230-assembly capacity of the vault amounts to 30 percent of the 764 assemblies in the reactor. The vault dimensions are shown in Figure 9.1-2.

The vault is closed at the top by a shield plug 12 in. thick. The shield plug is divided into five sections, each with redundant lifting rings. The openings and shield plugs are steel lined. The plugs extend 4 in. above the refueling floor. The vault floor slopes to an open drain located in the center of the vault floor.

The new-fuel vault is served by the reactor building crane.

9.1.1.2.2 New-Fuel Storage Racks

The new-fuel storage racks provide a place for storing new fuel in the new-fuel storage vault, as shown in Figure 9.1-1. The location of the new-fuel storage vault within the station complex is shown in Figure 9.1-3. Each new-fuel storage rack holds up to 10 channeled or unchanneled fuel assemblies in a row, spaced nominally 6.625 in. apart, center-to-center.

The new-fuel storage racks are designed so that arrangement in rows on a nominal 11.5-in. center-to-center spacing between rows limits the k_{eff} of the array to ≤ 0.90 for the dry condition. The k_{eff} is ≤ 0.95 in the event of complete flooding of the storage vault. The fuel assemblies are loaded into a rack through a hole in the top of each rack. Each hole for a fuel assembly has adequate clearance for the insertion or withdrawal of the assembly while enclosed in a protective plastic wrapping. Guides are provided to guide the fuel element spacers the full length of their insertion into the rack so that damage to the fuel assemblies is precluded. The spacers and the upper tie plate of the fuel element rest against the rack to provide lateral support. The design of the racks prevents accidental insertion of the fuel assembly in a position not intended for the fuel. The weight of the fuel assembly is supported by the lower tie plate which is seated in a chamfered hole in the rack base. The new-fuel racks can withstand an upward force of 6000 lb.

9.1.1.3 Safety Evaluation

Calculations of k_{eff} are based upon the geometrical arrangements of the fuel array, and subcriticality does not depend upon the presence of neutron-absorbing materials. The arrangement of the fuel assemblies in the fuel storage racks results in a k_{eff} below 0.90 in a dry condition or in the absence of moderator. In an abnormal condition, if the fuel array were to be flooded with water, k_{eff} would not exceed 0.95. The criticality analysis for initial licensing of the new-fuel storage vault is provided in Reference 1. Use of the new fuel storage vault is currently restricted as discussed in Section 9.1.1.2.1.

The new-fuel storage racks are designed to meet Category I requirements as described in Section 3.2. Stresses in a fully loaded rack will not exceed stresses specified by ASTM Specifications (B108, B179, B209, and B221) on light-weight metal alloys when subjected to a 1.5g horizontal acceleration.

The storage rack structure is designed to withstand the impact resulting from a falling object possessing 2000 ft-lb of kinetic energy. The structural arrangement is such that no lateral displacement of the fuel occurs; therefore, subcritical spacing is maintained.

The new-fuel racks are designed to be restrained by hold-down bolts in case a stuck fuel assembly is inadvertently hoisted and to ensure that rack spacing does not vary under specified loads. The rack structure and hold-down bolts are designed to maintain the minimum required cell spacing due to forces that might occur if a fuel bundle were to jam in the rack during removal.

The new-fuel storage racks are made from aluminum. All welds are in accordance with GE standards which are based on ASME Section IX and ASTM Standards Part 6. The material choice is based on a consideration of the susceptibility of various metal combinations to electrochemical reaction. When considering the susceptibility of metals to galvanic corrosion, aluminum and 300-series stainless steel are relatively close together, insofar as their coupled potential is concerned. The use of stainless steel fasteners in aluminum to avoid detrimental galvanic corrosion is a recommended practice and has been used successfully for many years by the aluminum industry.

9.1.1.4 Testing and Inspection

The new-fuel storage racks do not require any special periodic testing or inspection for nuclear safety purposes.

9.1.2 Spent Fuel Storage

9.1.2.1 Design Bases

Spent fuel storage space is provided to accommodate 3590 fuel assemblies. Stainless steel high-density fuel storage racks are provided for all fuel assemblies. The spent fuel assemblies are placed in racks designed to ensure a k_{eff} equivalent of $\leq$0.95 with the spent fuel pool filled with unborated water at 68°F for both normal and abnormal storage conditions.

The calculated k_{eff} includes margins for uncertainty in the calculations, including mechanical tolerances, which are statistically combined such that the true k_{eff} will be less than 0.95 with a 95 percent probability at a 95 percent confidence level.

To ensure that the analysis followed a conservative approach, the criticality calculations for the high-density racks were performed with the following criteria:

a. Initial uniform enrichment of 4.9 weight percent ^{235}U with credit for gadolinia burnable poison normally present

b. Maximum reactivity evaluated at the point of peak reactivity over burnup

c. Both unchanneled and channeled fuel with maximum expected distortion

d. Abnormal and accident conditions considered

e. Lattice of storage racks is infinite in all directions; that is, no credit for axial or radial neutron leakage

f. Unborated water at 20°C.

To simplify the analysis, no credit is taken for:

a. Neutron absorption in minor structural members; that is, spacers and Inconel springs are replaced by water in the calculation

As indicated in Section 4.0 of Reference 1 and Section 4.0 of Reference 3, the results of the criticality analysis for the spent fuel racks show that for all normal and abnormal storage conditions, the calculated k_{∞} is below the criterion of $k_{eff} \leq 0.95$.

The spent fuel storage racks (SFSR) are designed such that no fuel assembly can be placed within the rack array in other than a design storage location.

The spent fuel pool and storage racks, containing their full complement of fuel, are designed to meet Category I requirements.

Reference 1 documents the Abnormal and Accident Conditions analyzed for the Holtec High Density Racks. Reference 3 documents similar analyses performed for the Joseph Oat High Density Racks.

Spent fuel storage racks are designed and arranged so that the fuel assemblies can be handled efficiently during refueling operations.

Shielding for the spent fuel storage arrangement is sufficient to protect plant personnel so that exposure to radiation is well within the Occupational Limits of 10 CFR 20.101.

The spent fuel storage facilities provide the capability to limit the potential offsite exposures in the unlikely event of significant release of radioactivity from the stored fuel to a fraction of 10CFR50.67 limits.

9.1.2.2 Facilities Description

9.1.2.2.1 Spent Fuel Pool

The two main functions of the Category I spent fuel pool are to provide a storage place for irradiated fuel and other radioactive equipment requiring shielding and to provide a convenient area for performing work on selected radioactive equipment. The spent fuel pool is shown in Figure 9.1-3. The spent fuel pool has an inside length of 40 ft, an inside width of 34 ft, and a height of 38 ft 9 in. The surface of the water is maintained at Elevation 683.5 ft (New York Mean Tide, 1935) by scuppers that act as skimmers and wave suppressors. This results in a minimum water depth for shielding of 7 ft above the top of the fuel while it is being moved over storage racks. The Technical Specifications require that a minimum of 22 ft of water be maintained over the top of irradiated fuel assemblies in the spent fuel storage pool racks during movement of irradiated fuel assemblies in the spent fuel storage pool. Pool water-level indication is painted on the north and east walls of the spent fuel pool starting at 18 ft above the stored fuel assemblies. Spent fuel pool levels are monitored by primary and backup instrumentation channels and level indication is provided in the main control room and reactor building 2nd floor grid B-11 which are capable of supporting pool actual water levels to comply with NRC Order EA 12-051. Refer to Figure 9.1-23 for details.

The spent fuel pool is of poured reinforced-concrete construction with an all-welded stainless steel plate liner. The water in the spent fuel pool is filtered, demineralized, and cooled as described in Subsection 9.1.3.2.

The stainless steel spent fuel pool liner is designed in accordance with the following codes and standards: ASME Boiler and Pressure Vessel (B&PV) Code Section VIII, Division 1, Subsection B (for welds); and ACI 347, recommended practice for concrete formwork (for tolerances). The liner can withstand thermal loads due to operating temperatures of 125° to 150°F (assume installation temperature of 70°F) and thermal loads due to abnormal temperatures inside the pool of 212° and external temperatures of 150°F. The liner plate is designed based on an acceptance criterion that neither the construction allowable tensile stress (f_t), nor the allowable compressive stress (f_c), exceeds 0.67 yield stress (f_y). The normal allowable compressive membrane strain is 0.003 in./in. and the abnormal allowable compressive membrane strain is 0.005 in./in. All welded seams in the pool liner are backed by channels to collect any possible leakage. All the channels are interconnected to the bottom peripheral drain with four separate outlet drains that are used to monitor leakage. The leaktight integrity of the spent fuel pool liner is verified to be upheld in a postulated fuel assembly drop accident. (Analysis shows that the fuel assembly can be dropped 17 ft 7 in. without penetrating the liner or causing overall slab instability.)

Two self-sealing gates with a monitored drain between them separate the spent fuel pool from the reactor well pool.

Should there be leakage, this arrangement would permit the repair of a gate without disturbing the integrity of the spent fuel pool. Each gate has two solid-rubber seals that seal to the spent fuel pool liner.

Spent fuel assemblies will be stored in thirteen (13) Joseph A. Oat supplied high-density stainless steel racks (designated F1600E002A through H and F1600E002J through N) (See Figures 9.1-4 for the design details of these racks.) These racks have a nominal 6.22-in. center-to-center distance between assemblies (pitch). Each of these racks each contain 169 storage cells. There are nine (9) additional Holtec supplied racks (designated F1600E011A through I) with a nominal 6.23-in. pitch, (See Figure 9.1-15 for the design details of these racks). The spent fuel storage rack description, individual rack size and the number of storage cells are summarized below:

Spent Fuel Pool

Rack and Storage Capacity Summary

Rack Description	Size	Total Number of Cells		
F1600E002A through H	13 X 13	169 X 8	=	1352
F1600E002J through N	13 X 13	169 X 5	=	845
F1600E011A and B	9 X 11	99 X 2	=	198
F1600E011C	19 X 19	361 X 1	=	361
F1600E011D	12 X 17	204 X 1	=	204
F1600E011E	9 X 17	153 X 1	=	153
F1600E011F	9 X 12 minus 28 Cell cutout	80 X 1	=	80
F1600E011G	9 X 13 minus 28 Cell cutout	89 X 1	=	89
F1600E011H	9 X 14	126 X 1	=	126
F1600E011I	13 X 14	182 X 1	=	182
Storage Cell Total				3590

Two of the above cells may be used for Boraflex in-service surveillance program.

The arrangement of the fuel storage modules is shown in Figure 9.1-3 (Sheet 3). Four dual purpose cells in F1600E011F and six dual purpose cells in Rack F1600E011G are provided to store defective fuel assembles, control rods, control guide tubes and other equipment and components.

The spent fuel pool is also used to store 104 control rods that are suspended in a vertical position from 52 hooks. These hooks are mounted on frames located adjacent to the spent fuel shipping cask restraining framework on the west wall and on the south wall of the pool. A total of 114 control rods (104 suspended from hooks plus 10 in the dual-purpose cell racks) can be accommodated in the spent fuel pool. If storage for more than 114 rods should ever be required, the rods can be supported by mounting additional hooks on the equipment lugs on the east wall of the pool or control rod curb hanger(s) may be utilized. Temporary storage racks may also be used, as needed, to store control rod blades.

The area in the vicinity of the north wall of the spent fuel pool is laid out as a working area. In Figure 9.1-3, Sheet 3, two fuel-preparation machines are shown, an outline of which is shown in Figure 9.1-8. The function of the fuel-preparation machines is to remove and replace fuel bundle channels. The fuel preparation machines are used for fuel inspections and new fuel receipt/transfer activities. Strict administrative control on the fuel preparation machine's full-up end stop is required for personnel protection. Holtec high density Racks F1600E011C and F1600E011H are designed to support a specially engineered overhead platforms referred to as "Holtec Overhead Platforms (HOPs)" on top of the rack which permits storage of miscellaneous objects up to five tons total dry weight without interfering with the normal functions of the module. The structural and thermal-hydraulic qualification of these racks includes the appropriate consideration of the overhead platform.

A special storage area is provided on the west wall of the spent fuel pool to accommodate the spent fuel shipping cask. Details of the storage area are given in Subsection 9.1.4.2.1.

The spent fuel pool is supplied with several types of underwater lights; some provide general illumination and others provide specific local illumination.

The spent fuel pool shielding design objectives and design criteria are presented in detail in Subsections 12.1.1 and 12.1.2. Special provisions for ventilation of the fuel pool area are discussed in Subsection 12.1.1.1. Estimates of exposure to plant personnel in the fuel pool area are presented in Subsection 12.1.5.2.2.

9.1.2.2.2 Spent Fuel Storage Racks

Spent fuel storage racks provide a place in the spent fuel pool for storing spent fuel assemblies received from the reactor pressure vessel (RPV). There are two types of high density spent fuel storage racks (Holtec and Oat) being used. Both are full-length top entry racks, designed to preclude the possibility of criticality under normal and abnormal conditions.

The original Oat high-density spent fuel storage racks are of welded stainless steel construction with a neutron absorber sandwiched between the stainless steel sheets. The neutron absorber is marketed under the trade name of Boraflex, supplied by BISCO of Park Ridge, Illinois. The original high-density spent fuel racks are designed and fabricated by the Joseph Oat Corporation of Camden, New Jersey.

The basic philosophy of the high-density spent fuel storage rack design is consistent with the NRC Position Paper (Reference 2), General Design Criteria (GDC) 61 and 62, and Standard Review Plan (SRP) Sections 9.1.1 and 9.1.2. Seismic classification and analysis are in accordance with Regulatory Guides 1.29, 1.61, and 1.92.

The modules of the Holtec high density spent fuel racks are square cross-section boxes. Each box is equipped with Boral neutron absorber panels on its sides to form a composite box.

Reference 3 contains a detailed discussion of various aspects of the Oat high-density fuel rack design, analysis, and fabrication.

The high-density spent fuel storage racks provide for a total of 3590 storage locations arranged in 22 racks. All the racks are freestanding; that is, they are not anchored to the pool floor or connected to the pool wall through snubbers or lateral restraints. For the new racks, the minimum gap between adjacent racks is 1.0 in. at all locations, and the nominal gap between the fuel pool wall and storage rack is 2.39 in. The respective gaps for the Oat racks are 3.625 and 24 to 28 inches.

Of the 3590 storage locations, 3588 locations are intended for the storage of spent fuel assemblies. Two locations are designated for the Boraflex neutron absorber material surveillance program. This program is described in plant procedures. An additional 53 locations are inaccessible due to interferences. This will reduce the available storage locations to 3535. If the two Holtec Overhead Platforms (HOPs) are installed, an additional four cells per HOP will be unavailable.

The Oat high-density fuel storage racks are constructed from SA-240, type 304, austenitic stainless steel sheet material; SA-240, type 304, austenitic stainless steel plate material; and SA-182, type F304, austenitic stainless steel forging material. Boraflex, a patented brand name product of BISCO, serves as the neutron absorber material in the Oat high-density racks. Boraflex material has been tested in a fuel-pool-like environment to a minimum of 1.03×10^{11} rad and found to perform satisfactorily. Boraflex has been observed, however, to shrink and develop gaps. These effects have been evaluated in Reference 7. Alterations in physical properties and offgassing due to irradiation and material chemical or galvanic interactions with the rack structure have been considered in the design of the rack.

The Holtec high density racks are constructed from SA-240, type 304L, austenitic stainless steel sheet and plate material; and male spindles (lower part of support feet) of SA-564-630; age hardened at 1100°F. The storage cells are 6.035 ± 0.04 in. square cross-section. Modules F1600E011E-I are 3 inches shorter than the other Holtec racks with the result that the bale handle is exposed. This is for ease of fuel handling operations. They employ Boral as the neutron absorber material. Boral is a thermal neutron poison material composed of boron carbide and 1100 alloy aluminum. The composite boxes containing the Boral panels and enveloping sheathing are arrayed in a vertical fixture over a solid monolithic baseplate. Boron-10 is the neutron-absorptive agent in both Boraflex and Boral. The boron carbide and aluminum materials in Boral do not degrade as a result of long-term exposure to radiation.

The Oat high-density fuel storage rack contains storage cells that have a 6-in. minimum (+0.125 in., -0 in.) internal cross-sectional opening. These cells are straight to within ± 1/8 in. These dimensions ensure that fuel assemblies with maximum permissible out-of-straightness can be inserted into the storage cells without interference.

To illustrate the elements that make up a typical Oat rack, Figure 9.1-10 shows a horizontal cross section of an array of 3 x 3 cells. (A typical Oat high-density fuel storage rack has an array of 13 x 13 cells.)

The construction of the Oat racks may be best described by the basic building blocks of the design, namely the "cruciform," "ell," and "tee" elements, shown in Figure 9.1-11. The cruciform element is made of four angular subelements, "A" (Figure 9.1-12), with the neutron absorber material tightly sandwiched between the stainless steel sheets. The long edges of the cruciform are welded using a 0.070-in.-thick stainless steel backing strip as shown in Figure 9.1-13. The bottom of the cruciform assembly has a 4-1/4-in.-high stainless steel strip that prevents slippage of the poison material downward due to gravitation loads or operating conditions. The top of the cruciform is also end welded, using a spacer strip as shown in Figure 9.1-13. Skip welding at the top ensures proper venting for off-gassing.

The "ell" and "tee" elements are constructed similarly using angular subelements “A” and “B” and flat subelements "C" (Figures 9.1-12 and 9.1-14). Having fabricated the required quantities of the "cruciform," "tees," and "ells," the assembly is welded in a specially designed fixture that serves the vital function of maintaining dimensional accuracy while fillet welding the adjacent spokes of all elements. In this manner, the cells are produced that are bonded to each other along their long edges, thus, in effect, forming an "egg crate." The following manufacturing deviations were detected subsequent to installation in the spent fuel pool: a cruciform was installed upside down in F1600E002J (Module A9), and a tee was installed upside down in F1600E002L (Modules A11). The effects of these manufacturing deviations have been analyzed in Reference 7 and determined to be acceptable for use.

The bottoms of the cell walls are welded to the base plate, which has 4.75-in.-diameter holes concentric with cell center lines. Carefully machined sleeve elements are positioned in the base plate and are fillet welded to the base plate (Figure 9.1-15). The conical machined surface of the sleeve provides a contoured seating surface for the "nose" of the fuel assembly. Thus, the contact stresses at the fuel assembly nose bearing surface are minimized.

The central hole in the sleeve provides the coolant flow path for heat transport from the fuel assembly cladding. Lateral holes in the cell walls (Figure 9.1-15, Sheet 1) provide the redundant flow path in the unlikely event that the main coolant flow path is clogged.

The composite box assemblies of the Holtec high density racks are arrayed in a vertical fixture over a solid monolithic baseplate which is machined with an array of equispaced cylindrical holes containing tapered crowns (Figure 9.1-15, Sheets 2 and 3). These tapered holes serve as the seating surface for the nose of the fuel assembly.

The high-density fuel storage rack assembly is supported at four corners. The supports elevate the rack base plate 7.5 in. above the pool floor level, thus creating the water plenum for coolant inventory (Figures 9.1-4 and 9.1-5).

The high-density fuel storage racks are designed to meet Category I requirements, in accordance with Regulatory Guide 1.29. They are required to remain functional during and after a safe-shutdown earthquake (SSE). As noted previously, these high-density fuel storage racks are neither anchored to the pool floor nor attached to the side walls. The individual rack modules are not interconnected. Furthermore, a high-density fuel storage rack may be completely loaded with fuel assemblies (which corresponds to greatest rack inertia), or it may be partially loaded so as to produce maximum geometric eccentricity in the structure.

Dynamic simulation analyses involving nine Holtec high density and thirteen Oat high density spent fuel storage racks have been performed to establish the structural margins of safety. Six simulations modeled 22 high density fuel racks (13 Oat and 9 Holtec) in the pool for campaign II with a comprehensive Whole Pool Multi Rack (WPMR) model. References 1 and 3b presents the incorporation of all relevant physical data into the computer code

DYNARACK which then handles simultaneous simulation of all racks in the pool as a WPMR 3-D analysis. Some classical single rack runs were also performed. Parameters varied were interface coefficients of friction and extent of storage locations occupied by spent nuclear fuel, ranging from nearly empty to full. A WPMR run was also performed with four Holtec racks installed in the SFP for the same scenario that resulted in the greatest displacement from among the parametric runs. The results show that all stresses are well below their corresponding ASME Section III, Subsection NF limits and there is no rack-to-rack or rack-to-wall impact. Results also show that rack overturning is not a concern.

Nonlinearities of fuel-to-rack impact and, if appropriate, rack-to-rack impact are included. The racks are designed as freestanding and the effects of rack slide are addressed. Hydrodynamic effects are also included. No additional credit for structural damping is taken unless substantiated by testing or detailed analysis.

Synthetic time-histories in three orthogonal directions (N-S, E-W, and vertical) are generated in accordance with the provisions of SRP 3.7.1. The SRP calls for both the response spectrum and the power spectral density corresponding to a generated acceleration time-history to envelop their target (design basis) counterparts with only finite enveloping infractions. The time-histories for the pool have been generated to satisfy this preferred (and more rigorous) criterion. The seismic files also satisfy the requirements of statistical independence mandated by SRP 3.7.1. Time-history accelerograms were generated for a 20-sec duration of OBE and SSE events, respectively. These artificial time-histories are used in all the non-linear dynamic simulations of the racks.

The time-history data were generated from the floor response spectra given in Section 3.7. These spectra are enveloped with a smooth design spectra. For a complete time-history analysis of the equipment situated on the pool floor, artificial time-history accelerations in three orthogonal directions were generated so that their corresponding response spectra will envelop the smoothed design spectra mentioned above. These artificial time-history series were also verified to be statistically independent.

Figure 9.1-16 displays the dynamic model for the high-density fuel storage racks. Features of the dynamic model are as follows.

a. The fuel rack structure motion is captured by modeling the rack as a 12 degree-of-freedom structure. Movement of the rack cross-section at any height is described by six degrees-of-freedom of the rack base and six degrees-of-freedom at the rack top. In this manner, the response of the module, relative to the baseplate, is captured in the dynamic analyses once suitable springs are introduced to couple the rack degrees-of-freedom and simulate rack stiffness

b. Rattling fuel assemblies within the rack are modeled by five lumped masses located at H, .75H, .5H, .25H, and at the rack base (H is the rack height measured above the baseplate). Each lumped fuel mass has two horizontal displacement degrees-of-freedom. Vertical motion of the fuel assembly mass is assumed equal to rack vertical motion at the baseplate level. The centroid of each fuel assembly mass can be located off-center, relative to the rack structure centroid at that level, to simulate a partially loaded rack

c. Seismic motion of a fuel rack is characterized by random rattling of fuel assemblies in their individual storage locations. All fuel assemblies are assumed to move in-phase within a rack. This exaggerates computed dynamic loading on the rack structure and, therefore, yields conservative results

d. Fluid coupling between rack and fuel assemblies, and between rack and wall, is simulated by appropriate inertial coupling in the system kinetic energy. Inclusion of these effects uses the methods of References 3c and 3d for rack/assembly coupling and for rack-to-rack coupling

e. Fluid damping and form drag are conservatively neglected

f. Sloshing is found to be negligible at the top of the rack and is, therefore, neglected in the analysis of the rack

g. Potential impacts between the cell walls of the new racks and the contained fuel assemblies are accounted for by appropriate compression-only gap elements between masses involved. The possible incidence of rack-to-wall or rack-to-rack impact is simulated by gap elements at the top and bottom of the rack in two horizontal directions. Bottom gap elements are located at the baseplate levation. The initial gaps reflect the presence of baseplate extensions, and the rack stiffnesses are chosen to simulate local structural detail

h. Pedestals are modeled by gap elements in the vertical direction and as "rigid links" for transferring horizontal stress. Each pedestal support is linked to the pool liner (or bearing pad) by two friction springs. The spring rate for the friction springs includes any lateral elasticity of the stub pedestals. Local pedestal vertical spring stiffness accounts for floor elasticity and for local rack elasticity just above the pedestal. Details of the derivation and computation of the element stiffnesses are given in Reference 4

i. Rattling of fuel assemblies inside the storage locations causes the gap between fuel assemblies and cell wall to change from a maximum of twice the nominal gap to a theoretical zero gap. Fluid coupling coefficients are based on the nominal gap in order to provide a conservative measure of fluid resistance to gap closure

j. The model for the rack is considered supported, at the base level, on four pedestals modeled as non-linear compression only gap spring elements and eight piecewise linear friction spring elements; these elements are properly located with respect to the centerline of the rack beam, and allow for arbitrary rocking and sliding motions.

The high-density spent fuel storage racks are designed to withstand the most severe environmental, loading, and seismic conditions assumed to occur simultaneously. Load combinations are in accordance with SRP Section 3.8.4.

The structural acceptance criteria are in accordance with ASME B&PV Code Section III, Subsection NF.

The breakdown of the load combinations and acceptance limits is as follows:

D + L	Normal limits of NF 3231.1a

$D + L + E$	Normal limits of NF 3231.1a
$D + L + T_o$	The lesser of 2 S_y and S_u
$D + L + T_o + E$	The lesser of 2 S_y and S_u
$D + L + T_a + E$	The lesser of 2 S_y or S_u
$D + L + T_a + E^1$	Faulted condition limits of NF 3231.1c

where

D = dead loads of racks, buoyant rack weight

L = live loads, buoyant fuel weight

E = operating-basis earthquake (OBE) seismic loads including impact of fuel due to clearance within rack

T_o = operating thermal load

T_a = accident thermal load based on pool temperature of 212°F

E^1 = safe-shutdown earthquake seismic loads including impact of fuel due to clearance within rack

In addition to thermal and seismic loads, the high-density spent fuel storage racks are designed to withstand each of the following loadings superimposed on the submerged rack dead weight plus the weight of any stored fuel:

a. A 1200-lb uplift force applied at the top of the rack in the "weakest" storage location. The force is assumed to be applied on one wall of the storage cell boundary as an upward shear force. The damage, if any, is limited to the affected storage locations

b. Fuel assembly dropped on top of the rack with an impact energy of 2000 ft-lb. The impact energy is assumed to correspond to a buoyant mass of 600 lb dropped from a height of 40 in. The impact is assumed to occur on the top ridge of the rack

c. A horizontal force of 1000 lb applied at the most vulnerable location on the top of the rack. The load is assumed to act over the width of one storage cell. The subcriticality of all fuel assemblies is to be maintained with a $k_{eff} \leq 0.95$

d. A fuel assembly (assumed buoyant weight = 600 lb) dropping 16 ft 9 in. through a storage location and impacting the base. Local failure of the base plate is acceptable; however, an impact with the pool liner is not allowed. The subcriticality of all fuel assemblies is to be maintained with a $k_{eff} \leq 0.95$.

The allowable stress criteria are in accordance with ASME B&PV Code Section III, Subsection NF. The high-density spent fuel storage racks were checked for normal operating conditions, severe environmental conditions (OBE), extreme environmental conditions (SSE), and abnormal plant conditions (pool temperature = 212°F), and were found to be satisfactory.

The design of the Fuel Pool Cooling and Cleanup System (FPCCS) is described in Subsection 9.1.3. The decay heat load generated by the stored spent fuel is calculated in accordance with NRC Branch Technical Position ASB 9-2 (BTP ASB 9-2) (Reference 23). Where noted, heat up analyses are performed using the corrected form of the BTP decay heat model (References 24 and 25).

The spent fuel pool capacity expansion mentioned in Subsection 9.1.2.2 will occur over a series of campaigns, with the storage capacity increasing after each campaign. The bounding configuration from a thermal-hydraulic standpoint is the final, maximized configuration. This involves the largest number of stored assemblies and therefore the highest SFP decay heat load and lowest net SFP thermal capacity. All analyses discussed in this section are performed for the final configuration and thereby bound all intermediate configurations.

Thermal-hydraulic qualification analyses for the modified rack array are as follows:

a. Evaluation of the maximum bulk temperature. The bulk temperature is limited to 150°F for all conditions where forced cooling is available

b. Evaluation of loss-of-forced cooling scenarios, to establish minimum times to perform corrective actions and maximum makeup water requirements

c. Determination of the maximum local temperature in the pool to establish that localized boiling in the SFSRs is not possible

d. Evaluation of the maximum temperature difference between the fuel rod cladding and the local SFP water, to establish that nucleate boiling is not possible while SFP forced cooling is operating.

For each of the above analyses, evaluation is performed for an analytically bounding scenario as detailed below.

During normal SFP operation, the maximum normal bulk temperature of 150°F is based on the Fuel Pool Cooling and Cleanup System with the SFP gates installed.

In the scenario as addressed in support of the Amendment 141 spent fuel pool re-rack (Reference 7c), an emergency full core discharge comprised of 764 assemblies is discharged into an SFP that already contains 4016 previously discharged assemblies. This analyzed fuel inventory (4780) conservatively exceeds the maximum licensed capacity of 4608 assemblies. The minimum decay time of the previously discharged fuel assemblies for this scenario is 12 months. In addition to those mentioned above, the following conservative framework is applied in the maximum pool bulk temperature calculation:

a. The decay heat load is based on a discharge schedule with bounding parameters (i.e., maximum irradiation time and batch size) for all projected discharges.

b. Design temperatures are used for the coolant water flow inlet to the FPCCS and RHR System heat exchangers.

For evaluating the minimum time-to-boil and corresponding maximum boiloff rate, the following conservatisms are applied:

a. Loss of forced cooling is assumed to occur coincident with the SFP peak decay heat generation.

b. The thermal capacity of the SFP is based on the net SFP water volume only. The energy storage capability of the fuel racks, fuel assemblies and pool structure is neglected.

c. Makeup water supplied to maintain the SFP water level is assumed to be at the coincident SFP bulk temperature. No credit is taken for the difference in enthalpy between the SFP and the cooler makeup water, maximizing the boiloff rate.

For the same pool inventory described above for the maximum pool temperature case, the results of the analysis show that, in the extremely unlikely event of a complete failure of both the FPCCS and RHR System, there would be sufficient time available for corrective actions. The maximum water boiloff rate is less than the minimum available makeup capacity of 100 gpm available from the condensate storage tanks. Additional sources of makeup are also available.

In order to determine an upper bound on the maximum local water temperature, a series of conservative assumptions are made:

a. The walls and floor of the SFP are modeled as adiabatic surfaces, neglecting conduction heat loss through them.

b. Heat losses by thermal radiation and natural convection from the SFP surface are neglected.

c. The rack-to-wall gaps are modeled as 2 inches wide. The actual rack-to-wall gaps are larger.

d. The bottom plenum gap used in the model is approximately 50 percent of the actual gap.

e. No downflow is assumed to exist between the rack modules.

f. The hydraulic resistance of every SFSR cell is determined based on the most hydraulically limiting fuel assembly type.

g. The hydraulic resistance of every SFSR cell is determined based on the most restrictive water inlet geometry of the cells over the rack support pedestals.

h. The hydraulic resistance of every SFSR cell includes the effects of blockage due to an assumed dropped fuel assembly lying horizontally on top of its rack. This condition bounds the effects of contemplated overhead platforms, which add little extra flow resistance because of the large (~16 in.) spacing between the cell exit and the platform. Blockage due to a dropped assembly also bounds that of a vertically blocked gate, because the width of a channeled assembly is larger than the gate thickness.

i. With a full core discharged into the SFP racks and placed approximately equidistant from the coolant water inlet and outlet, the remaining cells in the spent fuel pool are postulated to be occupied with previously discharged fuel.

j. The in-pool sparger piping is modeled as truncated above the elevation of the racks.

k. In the evaluation of local water temperatures in dual-purpose rack cells containing loaded damaged fuel containers, only two of the cell baseplate holes are credited. This conservatively neglects the two additional baseplate holes and the eight cell side holes, thereby yielding greater than 100 percent redundancy in these cells.

The maximum local water temperature is substantially lower than the local boiling temperature at the top of the SFSRs and nucleate boiling does not occur anywhere within the Fermi 2 SFP.

Dose calculations (Subsection 9.1.3.3) performed based on the boiling condition indicate that the spent fuel pool cooling and cleanup system is adequate to provide reasonable assurance that the plant can be operated without undue risk to the health and safety of the public, consistent with the requirements of Criterion 2 of 10 CFR 50, Appendix A.

9.1.2.2.3 ISFSI Storage Pad

The function of the Independent Spent Fuel Storage Installation (ISFSI) storage pad is to provide a level resting surface for dry fuel storage casks. The pad is a 141' by 141' square reinforced concrete structure that is two feet thick designed to accommodate sixty four dry storage casks. The pad is compliant with ACI 349, "Code Requirements for Nuclear Safety-Related Concrete Structures," 2001, and designed in accordance with 10CFR Part 72-Licensing requirements for the independent storage of spent nuclear fuel, high-level radioactive waste, and reactor-related greater than Class C waste. The pad includes a surrounding fence with signage indicating that the pad is a radiologically controlled area. There is a subsurface drainage system surrounding the pad to help prevent the soil under the pad from being displaced as a result of freeze and thaw cycles. The subsoil in the area to the north of the pad has also been prepared for possible future expansion of the pad to allow additional placement of up to thirty two dry storage casks.

9.1.2.3 Safety Evaluation

The design of the spent fuel pool and storage racks meets the requirements of Regulatory Guide 1.13, except as noted in Appendix A of the UFSAR. Moreover, the spent fuel storage racks are designed to meet Category I requirements as described in Section 3.2.

The SFP will contain original Oat racks and Holtec racks introduced in Subsection 9.1.2.2.1. A wide range of conditions has been addressed in the design validation of all the racks. Examples relevant to the Oat racks include SFP water temperature increase to 212°F, the effect of manufacturing deviations (inverted cruciform and tees) and Boraflex panel degradation. Every Boraflex panel is assumed to have experienced an 8-10 in. gap (or reactivity equivalent) randomly distributed in the axial direction and losses in width and areal B-10 density due to thinning within the reactivity margin that is provided in the criticality analysis (see References 7 and 22). References 7 and 22 provide a discussion of the techniques and assumptions used in the criticality analysis of the Oat racks. The K_{eff} for the existing spent fuel storage racks, including an allowance for uncertainties is shown in the above references to be less than or equal to the 0.95 limit.

The criticality analyses for the high density fuel storage racks were performed with the MCNP code. MCNP (Monte Carlo N-Particle Transport) is a continuous energy Monte Carlo code. See Section 3.13.3.17.

As the SFP capacity expansion progresses, a greater and greater percentage of the pool will be occupied by Holtec high-density racks. Neutronic coupling between the Oat Boraflex racks and the Holtec Boral racks is precluded by the water gap between modules and by the absorber panels on both sides of the gap. Accordingly, to ensure that the design of the spent fuel storage racks provides for a $k_{eff} \leq 0.95$, the following normal and abnormal conditions are addressed in References 7b and 22 for the new racks:

a. The nominal design case, normal positioning of spent fuel assemblies in the spent fuel storage rack to act as a baseline

b. Temperature and water density effects: analyses are performed for a temperature decrease to 4°C (maximum water density), boiling (giving rise to voids) at various levels in the SFP. The calculations confirm that the reference temperature of 4°C is most conservative

c. Abnormal location of a fuel assembly was shown to have a negligible reactivity effect, while the nominal case was shown to yield a higher reactivity than a case with the fuel assembly moved to the corner of the storage rack cell (a four assembly cluster at closest approach)

d. The drop of a fuel assembly on a spent fuel storage rack. Such event was found to result in an insignificant increase in the calculated k_{eff}

e. The effect on reactivity of tolerances with respect to rack manufacture (stainless steel thickness, lattice spacing), B-10 loading, Boral width, fuel (enrichment and depletion) uncertainties has also been assessed.

The maximum calculated reactivity, including allowance for all uncertainties, was below 0.95.

Consideration has been given to various objects that might be dropped into the spent fuel pool and impact with the spent fuel storage racks. The spent fuel storage racks are designed to withstand the dropping of a fuel assembly as documented in Reference 1 for Holtec Racks and Reference 3 for Joseph Oat racks. A pool gate drop is evaluated to assess damage to the stored fuel assemblies in a fuel rack, the drop of an overhead platform during installation onto the top of a rack is evaluated, and an additional evaluation was also performed to consider the ability of the rack to withstand the uplift force from a stuck fuel assembly. The drop accident events postulated for the Fermi 2 fuel pool were analyzed and found to produce localized damage well within the design limits for the racks. Consequently, the spent fuel storage racks have a very large margin of safety.

The materials of the high-density spent fuel storage racks are described above in Subsection 9.1.2.2.2.

Provision is made to limit potential offsite exposures in case of significant release of radioactivity from the spent fuel. This would be done by using the standby gas treatment system (SGTS), when necessary, to control the release rate of radioactivity from the fuel storage area.

By maintaining the minimum spent fuel pool water level and the use of the normal reactor building ventilation, the exposure to plant personnel is maintained below the limits of 10 CFR 20.

Subsection 9.1.3.3 discusses the radiological consequences of loss of cooling to the spent fuel pool.

9.1.2.4 Testing and Inspection

A detailed and rigorous inspection of the Holtec high-density spent fuel storage modules is carried out at the fabrication facility prior to their release. The racks are also receipt inspected at the site before the racks are installed in the pool.

The design incorporates provisions for periodic testing of the Boraflex poison material throughout the life of the plant to verify the continued presence of a sufficient amount of neutron absorber in the spent fuel storage racks to maintain a $k_{eff} \leq 0.95$.

In situ verification of the poison material was performed at initial installation for the Oat racks to confirm the presence of the neutron absorber (Boraflex) in the spent fuel storage racks.

9.1.2.5 Reactivity of Fuel in Storage

The basic criterion associated with the storage of both irradiated (spent) and new fuel is that the effective multiplication factor of fuel stored under normal conditions will be ≤ 0.90 for the low density racks and ≤ 0.95 for the high density racks. Abnormal storage conditions are limited to a k_{eff} of 0.95 for both high and low density racks.

For the low density racks removed from the Spent Fuel Pool during Cycle 12, these storage criteria were satisfied if the uncontrolled lattice k_∞ calculated in the normal reactor core configuration met the following condition:

$k_\infty \leq 1.31$ for 20°C to 100°C. (Reference 7a)

For the Oat high density racks, these storage criteria will be satisfied if the uncontrolled lattice k_∞ calculated in the normal reactor core configuration (standard cold core geometry) is less than or equal to 1.3113 (Reference 7). For the Holtec racks, the design-basis hypothetical bundle has a k_∞ of 1.3392 in standard cold core geometry. These values reflect the more limiting of the GE14 (References 7 and 7b) and GNF3 (Reference 22) criticality analyses. The net result is the k_∞ condition to meet the storage criteria is higher for the Holtec racks than for the Oat and the original low density racks. Thus, the Oat and low density racks are more limiting. The maximum k_∞ in the normal reactor core configuration at cold conditions for fuel assemblies in the spent fuel storage racks is 1.31, based on the Technical Specifications.

The peak uncontrolled lattice k_∞ in normal reactor core configuration is calculated by the fuel fabricator for each bundle type.

9.1.3 Fuel Pool Cooling and Cleanup System

9.1.3.1 Design Bases

The fuel pool cooling and cleanup system (FPCCS) is designed to remove the decay heat produced by stored spent fuel assemblies during all anticipated conditions of plant operation and during plant refueling outages 18 days after reactor shutdown. This includes refueling using either a full-core offload or core shuffle method. The system consists of two identical trains, which include pumps, heat exchangers, and filter-demineralizers.

The heat load in the spent fuel pool is anticipated to increase subsequent to each progressive refuel outage until the pool is filled to the maximum capacity where all of the storage locations are filled. The spent fuel pool temperature is maintained at or below 125°F during normal operation and 150°F during refuel outages. In anticipation of installing additional storage locations in the pool, the spent fuel pool and the FPCCS have been evaluated for a normal operating temperature of 150°F. However, additional engineering evaluation is required if the spent fuel pool is to be maintained at a temperature greater than 125°F during normal operating conditions.

The Amendment 141 spent fuel pool re-rack criteria for the FPCCS design analysis were as follows:

a. The originally installed spent fuel pool storage capacity was, nominally, 3.0 cores (2383 assemblies), plus room for removing a full core. EDP-27387 (Campaign I) and EDP-34306 (Campaign II) placed additional racks in the pool, increasing the installed capacity to 3588 locations, with a maximum licensed capacity to 4608 locations.

b. The original Amendment 141 re-rack licensing analysis considered both one-quarter core 12-month and one-third core 18-month fuel discharges; plant operation began at Cycle 1 with one-third core 18-month fuel discharge cycles. The spent fuel pool and the FPCCS have been analyzed assuming a maximum spent fuel population composed of the following:

    1. 6.25 cores composed of 20 groups of spent fuel assemblies, each of the first 19 groups containing from 176 to 228 assemblies discharged approximately every 18 months, ending with a full core discharge 30 years after the first cycle.

c. The spent fuel assemblies have a power history giving the discharge batch an average irradiation less than or equal to 50,000 MWd/MTU

d. The system heat load removal capacity is based on heat exchangers sized for a design heat load of 16.66 x 10^6 Btu/hr with a 55°F hot-to-cold side inlet temperature differential and two trains operating. The system is managed to maintain the spent fuel pool bulk temperature at or below 125°F during normal plant power operation with up to 3.0 cores of spent fuel stored in the spent fuel pool.

e. The decay heat was calculated assuming a bounding 4780 assemblies, exceeding the actual number of licensed storage locations (4608), based on the uncorrected BTP ASB 9-2 (Reference 23) decay heat model. The original Amendment 141 spent fuel pool re-rack evaluation (Reference 7c) was subsequently updated to consider both the impact of a 3486 MWth GNF3-based 24-month equilibrium fuel cycle as well as the effect of the assumed EDP-80016 installation of BORALCAN inserts to address historical Boraflex degradation associated with the original Joseph Oat racks. This more recent evaluation was performed using a corrected form of the BTP ASB 9-2 decay heat model (Reference 24 and 25) that predicts lower calculated decay heat loads, even though the actual GNF3 equilibrium core has a higher exposure (5.74 years at 3486 MWth) and corresponding real higher relative decay heat. In addition, whereas the original re-rack analysis considered 4780 loaded pool locations the analysis updated for GNF3 is based on the licensed capacity of 4608 locations (6.03 cores). The effect of these updates is a net reduction in calculated pre and post offload pool decay heat such that the original analysis remains bounding. Except as noted, the description of the more limiting original Amendment 141 analysis results are retained below. The following assumptions are made to calculate decay heat load to the spent fuel pool.

    1. Each discharged assembly has been irradiated for 5.2 years

    2. During the irradiation period, the reactor is operating at 100 percent power

    3. After shutdown, the RHR cooling system is used as the primary decay heat removal system for up to 18 days while the reactor head is off and refueling/maintenance operations are proceeding, including full-core offload when scheduled

    4. In applying BTP ASB 9-2, the uncertainty factor K for irradiation time $t > 10^7$ sec is taken to be 0.1

f. Refer to Table 3.2-1 for seismic and quality group for FPCCS system.

g. The FPCCS is designed to achieve the following additional functions.

    1. Minimize corrosion product buildup and control water clarity, through filtration and demineralization so that the fuel assemblies can be efficiently handled underwater

    2. Minimize fission product concentration in the water that could be released from the spent fuel pool to the reactor building environment

    3. Monitor spent fuel pool water level and maintain a water level above the fuel sufficient to provide shielding for normal building occupancy

    4. Maintain the bulk water temperature at less than 150°F, with the heat loading resulting from the removal of a full core either during plant

refueling (greater than 18 days cooling) or in a plant outage following a normal refueling. This may be achieved by being able to interconnect the RHR system and the FPCCS to supplement spent fuel pool cooling.

5. Preclude siphoning the spent fuel pool by providing siphoning breakers on all lines penetrating the spent fuel pool.

9.1.3.2 System Description

The FPCCS cools the spent fuel pool by transferring decay heat through heat exchangers to the reactor building closed cooling water system (RBCCWS), as shown in Figure 9.1-23. Water purity and clarity in the spent fuel pool, reactor well pool, and dryer-separator storage pool are maintained by filtering and demineralizing the pool water as shown in Figure 9.1-24.

The FPCCS is composed of two trains. Each train is designed to remove 8.33 x 10^6 Btu/hr with a 55°F (FPCCS to RBCCW inlet flows) temperature differential, 550 gpm tube flow and 800 gpm (RBCCW) shell flow (Table 9.1-1). The system consists of two fuel pool cooling pumps; two heat exchangers; two filter-demineralizers; two skimmer surge tanks; and associated piping, valves, and instrumentation. The two fuel pool cooling pumps are connected in parallel, as are the two heat exchangers. The pumps and heat exchangers are located in the reactor building below the level of the bottom of the spent fuel pool.

The filter-demineralizer units are located in the radwaste building in separate shielded cells, with enough clearance to permit removing filter elements from the vessels. Each cell contains only the filter-demineralizers and piping. All air-operated valves (such as inlet, outlet, recycle, vent, and drain) are located on the outside of one shielding wall of the cell, together with necessary piping and headers, instrument elements, and controls. Penetrations through shielding walls are located so as not to compromise radiation shielding requirements (Subsection 12.1.2).

The pumps circulate the spent fuel pool water in a closed loop, taking suction from the skimmer surge tanks through the heat exchangers, circulating the water through the filter-demineralizers, and discharging nominally 7’ -6” below the normal water level in the fuel storage pool. The cooled water traverses the pool, picking up heat and debris before starting a new cycle by discharging over the skimmer weirs and scuppers into the skimmer surge tanks. The normal makeup water source for the system is provided from the condensate storage tank to the skimmer surge tanks.

Backup cooling is provided to the spent fuel pool by means of a permanently piped cross tie to the RHR system. In this mode of operation, one RHR pump and the corresponding RHR division heat exchanger will provide the means to cool the spent fuel pool. This cooling circuit is established by opening cross-tie valves V8-3264, G4100F016 and V8-3029, G4100F036 and closing FPCCS valves V8-3006, G4153F004 and V8-3253, G4100F011 (Figure 9.1-23). For the designed piping configuration, the RHR pump flow is throttled with valve G4100F231 to a maximum of 3500 gpm. If the fuel pool gates are removed and the reactor cavity is flooded up, the RHR discharge may be configured to split the flow between the reactor cavity and fuel pool by opening G4100F036. The RHR suction will be from the operating SDC loop, therefore G4100F016 is closed. During this split flow configuration, the FPCC is operated in parallel with RHR SDC as FPCC is discharging to the reactor cavity, G4153F004 and G4100F039 are open and G4100F011 is closed. An RHR heat exchanger will remove the total spent fuel pool decay heat load of approximately 42.22 x 10^6 Btu/hr of a full-core offload, completed at 156 hrs decay cooling since reactor shutdown, with about a 49°F temperature differential (Table 9.1-1). To ensure the availability of backup cooling via the RHR system, the cross-tie piping, the FPCCS piping from the skimmer tanks to the first anchor downstream of valve V8-3006, and the FPCCS piping from the first anchor upstream of valve V8-3253 to the spent fuel pool are Seismic Category I.

Both FPCCS heat exchangers operating in parallel are designed to remove the maximum heat load produced by various combinations of spent fuel discharged from the equilibrium fuel cycle at the time the RHR system is isolated from the spent fuel pool, plus the heat being released by batches discharged at previous refueling (see Subsection 9.1.3.1). The maximum heat load 18 days after a reactor shutdown with about 4276 fuel bundles in the spent fuel pool is 14.29 x 10^6 Btu/hr. The maximum heat load 18 days after reactor shutdown with 9 1/3 core off loads in the spent fuel pool is approximately 11.9 x 10^6 Btu/hr. This load is within the capacity of the FPCCS heat exchangers with a temperature differential of about 39°F. Re-evaluated for the GNF3 equilibrium cycle with 4088 pool locations filled, the 18 day heat load is predicted to be 11.54 x 10^6 Btu/hr.

During refueling outages (up until mode change for plant restart), when spent fuel pool circulating flow is interrupted to drain the reactor well and the dryer/separator storage pool or when the FPCCS becomes incapacitated, either of the RHR system heat exchangers may be used to supplement spent fuel pool cooling in the event the pool bulk temperature cannot be maintained below 150°F. During refueling outages, the RHR system can provide necessary supplemental cooling of the spent fuel pool until the RHR system is isolated from the spent fuel pool to restore low-pressure coolant injection (LPCI) standby mode. After RHR is isolated, the spent fuel pool decay heat is managed to remain within the FPCCS duty capability. Table 9.1-1 also lists the characteristics of an RHR subsystem in the fuel pool cooling assist mode.

The design of the spent fuel pool is such that the top of the stored fuel is at a lower elevation than the bottom of the gate between the reactor well and spent fuel pool. There are no connections to the spent fuel pool that could drain the pool below the elevation of the bottom of the gate when the gate is removed for refueling, or below the normal spent fuel pool level when the gate is in place. To prevent water from being siphoned out of the pool, the piping entering the spent fuel pool is fitted with normally submerged vents which will break a siphon before the minimum required water coverage over the stored fuel is lost. A level indicator, mounted at the valve rack, monitors reactor well water during refueling. A high rate of leakage through the refueling bellows assembly, drywell to reactor seal, or the spent fuel pool gates is indicated on the operating floor instrument racks.

Spent fuel pool water is continuously recirculated during normal FPCCS operation. The circulation patterns within the reactor well and spent fuel pool are established by the placement of the diffusers and skimmers to sweep particles dislodged during refueling operations away from the work area and out of the pool.

For refueling operations, the reactor well and dryer-separator storage pools are filled by transferring water from clean stored condensate. After the vessel head is removed, the fill water is transferred through the reactor vessel by flooding vessel level up into the reactor well. Clarity and purity of the pool water are maintained by a combination of filtering and ion exchange. The cleanup system has sufficient capacity to ensure pool water clarity and purity. The water purity is maintained by monitoring the demineralizer conductivity and differential pressure with periodic sampling and analysis of spent fuel pool water. The filter-demineralizers maintain water purity within the chemical limits specified below.

	Fuel Pool Chemical Limits	Demineralizer Effluent
Conductivity	≤ 3 μmho/cm at 25°C	≤ 1 μmho/cm at 25°C
Chloride	≤ 500 ppb	≤ 50 ppb
pH	5.3-7.5 at 25°C	6.0-7.5 at 25°C
Total insolubles	≤ 1 ppm	

Demineralizer differential pressure operating limit is 30 psi, and an alarm is provided at 25 psi. No radiochemical limits are needed to monitor the spent fuel pool water and initiate corrective action for the following reasons:

a. Crud buildup that would contribute to gross gamma activity is minimized by the filter-demineralizer

b. Iodine-131, with an assumed concentration of 64 μCi/g, is the most radiologically significant nuclide; doses from the other nuclides, by comparison, are relatively negligible

c. The assumed concentration of 64 μCi/g of ^{131}I is almost 10^{-6} of the specific activity if its solubility limit is attained. Therefore, assuming a partition factor of 10 and a removal efficiency of 99 percent by the SGTS, ^{131}I would not be a problem.

The system flow rate is larger than that required for two complete water changes per day of the spent fuel pool, or one change per day of the fuel storage, reactor well, and dryer-separator pools.

The maximum system flow rate is twice the flow rate needed to maintain the specified water quality. Particulate matter is removed by powdered ion-exchange resin-fiber mixtures. Alternatively, a combination of powdered resin and precoated material such as cellulose may be used as the disposable filter medium. The filter elements are stainless steel mesh elements mounted vertically in a tube sheet and replaceable as a unit. The filter vessel is constructed of carbon steel and coated with a phenolic resin material.

Spent fuel pool water and demineralizer effluent are sampled and analyzed once per week.

Instrument readings for conductivity and differential pressure are taken once per shift. Alarms sound in the control room if demineralizer conductivity, flow, or differential pressure limits are attained so that corrective action may be initiated. Backwashing and precoating operations are controlled from a local panel in the radwaste building. The spent filter medium is removed from the elements by backwashing with air and condensate and then is flushed to the phase separator tank.

A poststrainer in the effluent stream of the filter-demineralizer limits the migration of filter material. The filter-holding element can withstand a differential pressure greater than the developed pump head for the system.

System instrumentation is provided for both automatic and remote manual operations. A low-low level switch stops the circulating pumps when surge tank reserve capacity is low. Manual control for the circulating pumps is either from local panels or the control room panel. Pump low suction pressure automatically turns off the pumps.

The FPCCS has alarm functions for cooling pump low discharge pressure, refueling bellows seal leakage, spent fuel pool gate reactor well seal leakage, skimmer surge tank high level, spent fuel pool high level, and skimmer surge tank low level. All of these functions give a common alarm signal to the main control room; for example, spent fuel pool cooling system trouble. Each function also has a light, located on local control panels, which determines the cause of the common alarm in the main control room. In addition, there are specific alarms in the control room for spent fuel pool high temperature, spent fuel pool low level, and spent fuel pool demineralizer trouble.

The local control panels receive power from a standby source if normal power is not available. Circulating pump motor loads are considered nonessential loads and will be operated as required under accident conditions.

9.1.3.3 Safety Evaluation

The FPCCS maintains the peak spent fuel pool bulk temperature below 150°F with the maximum design decay heat load during an outage and at or below 125°F during normal plant power operation. Although the spent fuel pool and the FPCCS are evaluated for a normal operating temperature of 150°F, additional engineering evaluation is required if the spent fuel pool is to be maintained at a temperature greater than 125°F during normal operating conditions. The FPCCS and RBCCW pumps are powered from redundant buses; this ensures continued normal cooling operation. The RHR system provides a safety source of emergency makeup water and redundant heat removal capability.

No inlets, outlets, or drains are provided that would permit the spent fuel pool to be drained below a safe shielding level. Lines extending below this level are equipped with siphon breakers, check valves, or other suitable devices to prevent inadvertent pool drainage. The line draining the space between the two gates is sufficiently high to preclude draining excessive water above the spent fuel storage racks.

Except during refueling operations, the spent fuel pool will be isolated from the reactor head cavity and dryer-separator storage pool by two redundant watertight gates that close the opening through which spent and new fuel is transported to and from the spent fuel pool. The bottom of the gate opening is above the top of the fuel storage racks in the bottom of the spent fuel pool to ensure that the stored fuel can never be uncovered.

The only interconnection between the cooling and cleanup subsystems is the spent fuel pool itself. The FPCCS return lines to the spent fuel pool are provided with siphon breakers.

The decay heat load in the spent fuel pool may vary widely because of various possible combinations of the following:

a. The number of groups and the respective irradiation periods of spent fuel assemblies in the racks (see Subsection 9.1.3.1.b. and e.)

b. The duration of time-after-shutdown for each of the spent fuel groups.

The original Amendment 141 re-rack decay heat calculated for the bounding case of an emergency full core offload using the assumptions of Subsection 9.1.3.1 resulted in a maximum calculated spent fuel pool heat load of 42.65 x 10^6 Btu/hr (12.5 MWt). Re-evaluated for GNF3 based on the corrected BTP decay heat model (References 24 and 25), Reference 7c predicts a maximum pool heat load is 40.7 x 10^6 Btu/hr (approx. 12 MWt). In either case, the FPCCS does not have the heat removal capacity to maintain the pool temperature to less than 125°F. Engineering evaluation is required to operate with this heat load in the spent fuel pool.

The FPCCS is normally capable of maintaining the spent fuel pool temperature at or below its maximum normal design temperature of 125°F. Under full-core offload with spent fuel pool decay heat load above the system design capacity, the required differential temperature across the FPCCS heat exchangers exceeds the nominal design temperature differential. In the event of other system abnormal conditions of decay heat load higher than available FPCCS removal capacity due to other refueling outage activities and/or FPCCS capacity restriction (e.g., due to maintenance), the heat load may also result in higher temperature differential across the operating FPCCS heat exchanger(s). This would cause the temperature of the spent fuel pool to rise. Should FPCCS not be able to maintain spent fuel pool temperature below 150°F, then an RHR loop would be aligned to take suction from, and discharge to, the spent fuel pool. If the fuel pool gates are removed and the reactor cavity is flooded up, then the suction remains from the shutdown cooling line and the discharge may be split between the recirculation loop and the fuel pool. The use of the RHR system in the fuel pool cooling assist mode makes both low pressure coolant injection (LPCI) subsystems inoperable.

FPCCS and natural circulation have been analyzed to be capable of serving as an alternate method of decay heat removal to enable RHR Shutdown Cooling to be taken out of service for maintenance during refueling. When operating in this alternate shutdown cooling mode, the fuel pool gates are removed and the RPV cavity is flooded. Entry into this mode requires satisfying the refuel technical specification associated with high RPV water level. FPCCS is normally operated with two pumps and two heat exchangers in service. In this capacity, FPCCS and natural circulation maintain FPCCS suction temperature less than 140°F, cooling both the old and freshly off-loaded assemblies in the fuel pool as well as those remaining in the RPV. RWCU may also be placed in operation with the regenerative heat exchanger bypassed to provide additional cooling and in-vessel mixing. This ability to enter this mode of FPCCS operation for RHR maintenance activities is evaluated on a per cycle basis using the expected vessel and spent fuel pool heat loads. The activity is managed such that normal shutdown cooling can be restored within 8 hrs. This is an arbitrary time frame that conservatively assures cooling can be restored prior to the onset of pool and core boiling. In addition, the operation of this mode restricts the operation of temporary auxiliary pool water filtration units such that the flow discharge does not interfere with the core exit flow and thereby impede natural circulation cooling.

The heat load to the spent fuel pool is caused by the decay heat of the fission products and the activated heavy elements (^{239}U and ^{239}Np) contained in the spent fuel assemblies stored in the racks, including those temporarily stored for a refueling outage. Since different combinations of assemblies are reinserted into the core than were originally removed (possibly including some reinserted assemblies that were removed at prior refuelings), the decay heat load will vary from cycle to cycle. The original Amendment 141 design analysis conservatively assumed a higher number of assemblies in the spent fuel pool storage racks than there are actual storage locations as presented in Subsection 9.1.2.2.2 above. Table 9.1-2a presents the fractional decay heat as a function of time after shutdown for this bounding case determined with the method given based on the uncorrected BTP ASB 9-2 decay heat model. Pool decay heat corresponding to a 24-month GNF3 fuel cycle is presented in Table 9.1-2b.

The data in the table for the prior discharges are based on a full-power operating period of 5.2 years that is conservatively consistent with an approximately one-third core, 18-month equilibrium fuel cycle. The number of fuel assemblies and the decay heat contribution for each discharge are also given in Table 9.1-2a and Table 9.1-2b. The decay heats in MW for fuel assemblies discharged in normal refuelings for the entire plant cycle, ending with a normal partial core unload of 260 assemblies, are presented in Tables 9.1-3a and 9.1-3b are computed as follows:

$$\text{QDKP}\ (t_s) = \text{RTP MWt} \times \frac{P}{P_o}(t_o, t_2) \times \frac{N}{764}$$

where

$\text{QDKP}\ (t_s)$ = decay heat of fuel assemblies that have been stored in spent fuel pool racks for t_s sec, MW_t

RTP MWt = 100 percent of the rated thermal output of core

$\frac{P}{P_o}(t_o, t_2)$ = fractional decay heat

$\frac{N}{764}$ = fraction of full core discharged per Refueling/Unload

Tables 9.1-3a and 9.1-3b give the cumulative spent fuel pool heat load and quantity of spent fuel stored in the racks versus time after the initial discharge to the spent fuel pool for 18-month and 24-month fuel cycles, respectively. To develop a conservative maximum spent fuel pool heat load, the case of a complete operating cycle followed by an emergency full core offload is considered. Under the original heat load analysis, the total number of assemblies in the spent fuel pool was taken as 4780. This maximum heat load case includes 19 approximately one-third core discharges from previous refuelings plus a full-core offload of the last operating cycle started at 2-1/2 days decay cooling from reactor shutdown. The maximum spent fuel pool heat load in this case would be 12.50 Mwt (~42.65 x 10^6 Btu/hr; see Table 9.1-1). In this case, one loop of the RHR system would be needed in the fuel pool cooling assist mode to maintain bulk temperature below 150°F.

Upon completion of refueling activities, FPCCS is evaluated to determine that it is capable of maintaining the spent fuel pool temperature below 125°F. Insufficient decay heat removal capability may occur due to FPCCS performance degradation, capacity limitation due to insufficient temperature differential from high RBCCW service water temperature, larger than normal core discharge, and/or less than design cooling time from reactor shutdown. If this situation should exist, then one loop of RHR would continue to be employed to control the spent fuel pool temperature until the FPCCS decay heat removal capacity is sufficient to allow plant restart (RHR LPCI is considered inoperable and Technical Specifications limits with RHR LPCI inoperable apply to plant operations).

Should two active components in the spent fuel pool cooling system be unavailable and the RHR system be unavailable for cooling, the spent fuel pool water temperature would be inherently limited to 212°F, on boiling.

An analysis has been performed to determine the radiological doses at the site boundary which might result as a consequence of a complete loss of cooling of the spent fuel pool (see Reference 15). Such a complete loss of pool cooling is not considered a Design Basis Accident, and it is not considered a design basis for the fuel pool or for the FPCCS. The subject radiological analysis is currently included in the UFSAR for information only, and is not part of the basis for NRC acceptance of the FPCCS design. Details of the analysis are as follows:

a. Heat released from the spent fuel is conservatively assumed to have a constant value for a period of 30 days after the assumed loss of the FPCCS. For purposes of evaluating the radiological dose consequences only, it is conservatively assumed that no other heat removal method is available except for spent fuel pool boiling and that the time to achieve pool boiling is zero. Makeup water is assumed to be provided at a rate equal to that of boiling and thus maintains the spent fuel pool water volume at a constant value of approximately 48,000 ft^3. Potential makeup sources are the RHR service water, condensate storage, and fire protection system.

b. There is 1.3×10^{-2} μCi/g of ^{131}I in the reactor water during power production (see Table 11.1-3). The temperature, pressure, and flow rate of the spent fuel pool water are much lower than those of the water in the reactor under full-power conditions. Spent fuel in the spent fuel pool storage racks should not cause a water iodine concentration greater than the reactor water concentration, even assuming the spent fuel pool begins to boil. Notwithstanding the above, a ^{131}I concentration of 64 μCi/g was assumed and used. This concentration is more than 5000 times the ^{131}I concentration in the spent fuel pool water during full-power operation and adequately accounts for an "iodine spike."

c. The variation of iodine concentration in the spent fuel pool as a function of time is calculated realistically to account for decay, boiling, and the addition of makeup water. Two cases are considered: one assumes the makeup water to contain no radioactivity, and the other assumes an unlimited supply of makeup water at an initial concentration of 64 μCi/g.

d. The spent fuel pool water volume is about 48,000 ft^3. Based on a concentration of 64 μCi/g, there would be about 87,300 Ci of ^{131}I in the spent fuel pool water. Doses were calculated from other nuclides (gas and particulate) and it was concluded that ^{131}I is the most radiologically significant radionuclide, the others by comparison being negligible.

e. Iodine in the spent fuel pool water is assumed to be released from the pool at a rate that corresponds to the initial concentration and boiling rate with the application of a partition factor of 10.

f. The use of a partition factor of 10 is justified as follows: the solubility limit for iodine in hot water is 0.078 g/100 ml of water. If this amount of ^{131}I were to be dissolved in water, the specific activity would be 9.9 x 10^7 μCi/ml. The iodine concentration used in this analysis was 64 μCi/g. However, assuming the spent fuel pool water contained an amount of stable iodine equal to the radioiodine that would exist in the water during this postulated accident, the spent fuel pool water would still be able to accept almost one million times more iodine before the solubility limit was reached. On the basis of solubility, therefore, a partition factor of 10 is justified.

g. Iodine removal efficiency credit for the SGTS is assumed to be 99 percent, consistent with Regulatory Guide 1.52. The SGTS is designed to accommodate an inlet relative humidity of 100 percent; that is, the secondary containment is conservatively assumed to be filled with saturated air.

h. The meteorological condition assumed for the accident is the fifth percentile short-term (accident) χ/Q's for actual site meteorological data provided from Edison's 60-m tower and as reported to, and accepted by, the NRC staff (NRC letter dated April 26, 1976, G. W. Knighton to H. Tauber, Reference 8). These data are presented in Table 2.3-27.

i. The calculations estimate the 2-hr thyroid (inhalation) dose at the site boundary to be 0.17 rem for both radioactive and nonradioactive makeup water. The 30-day thyroid (inhalation) dose at the low-population zone for radioactive makeup is 0.186 rem; whereas for nonradioactive makeup, the 30-day dose is 0.134 rem.

Results indicate that the dose from this postulated accident would not exceed a fraction of 10 CFR 100 limits.

Thermal-hydraulic calculations confirm that the peak clad temperature for the hottest assembly, offloaded after 2-1/2 days of decay heat cooling from reactor shutdown, will remain below the local saturation temperature assuming a bundle inlet temperature at the maximum spent fuel pool temperature of 150°F. In addition, the calculations confirm that at the time of maximum spent fuel pool decay heat loading, with surface temperature approaching boiling (bulk temperature approximately 200°F), the hottest assembly peak clad temperature would still not exceed local saturation temperature. Should the spent fuel pool water temperature increase to the surface boiling point, the peak fuel cladding temperature would be slightly higher than the local saturation temperature ($T_{sat[racks]} \approx 240°F$). This fuel cladding temperature is a fraction of the fuel cladding temperature during normal plant operation. The physical characteristics of the fuel and the integrity of the fuel cladding would not experience changes that could cause an activity concentration in the spent fuel pool water in excess of the activity in the reactor water during full-power operation. Dose calculations performed by Edison, based on the above, indicate that the design criteria applied to the spent fuel pool cooling system are adequate to provide reasonable assurance that the plant can be operated without undue risk to the health and safety of the public, consistent with the requirements of Criterion 2 of Appendix A to 10 CFR 50.

In summary, the spent fuel pool cooling system's design, siphon-breaking piping arrangement, redundant transfer gates, emergency makeup water supply from the RHR service water system, and RHR backup capability provide a completely reliable system for the storage and cooling of spent fuel.

9.1.3.4 Testing and Inspection

Prior to power operation following a refueling outage, a determination will be made that the heat generation rate in the spent fuel pool is within the current capacity of the FPCCS with both trains in normal operation at a spent fuel pool bulk temperature less than or equal to 125°F.

No special tests are required for instrumentation on the FPCCS. The instrumentation will be subjected to routine testing. The FPCCS Preoperational Test program is discussed in Chapter 14.

9.1.4 Fuel Handling System

9.1.4.1 Design Bases

The fuel handling system provides a safe and effective means for transporting and handling fuel from the time it reaches the plant until the time it leaves the plant after postirradiation cooling.

9.1.4.2 Equipment Description

Table 9.1-5 is a listing of tools and servicing equipment supplied with the nuclear system. The following paragraphs briefly describe the use of some of the major tools, servicing equipment, spent fuel shipping cask, and reactor building crane. Where applicable, safety aspects of the design are discussed. For a historical discussion of the reactor building crane and spent fuel cask-handling details, see Reference 9. The procedure for load testing at 125 percent rated load described in Section 2.3.2 of Reference 9 has been modified in accordance with the guidelines established in NUREG-0554, ANSI B30.2, and NRC BTP ASB 9-1.

9.1.4.2.1 Independent Spent Fuel Storage Installation (ISFSI)

ISFSI program description

Under 10CFR72.210, Fermi is issued a general license for the storage of spent fuel in an Independent Spent Fuel Storage Installation (ISFSI). An ISFSI is a facility designed, constructed, and licensed for the interim storage of spent nuclear fuel and other radioactive materials associated with spent fuel storage in accordance with 10CFR72.

Upon approval of the Final Safety Analysis Report (FSAR) for the HI-STORM 100 Cask System, the NRC issued Certificate of Compliance (CoC) Docket No. 72-1014 and Safety Evaluation Report (SER) Docket No. 72-1014 for use of the HI-STORM 100 Cask System.

As a General Licensee, Fermi is authorized to use the HI-STORM 100 Cask System in accordance with appropriate documents and procedures.

Fermi selected the HI-STORM 100 Cask System to maintain adequate on-site spent fuel storage capacity which comprises of three discrete components: The Multi-Purpose Canister (MPC), the Holtec International Transfer Cask (HI-TRAC) and the Holtec International Storage Module (HI-STORM).

The MPC is a confinement system for the stored fuel. It is a welded, cylindrical canister with a honeycombed fuel backet, a baseplate, a lid, a closure ring, and a canister shell. All MPC components that come into contact with spent fuel pool water or ambient environment are made entirely of stainless steel or passivated aluminum/aluminum alloys such as neutron absorbers.

The HI-TRAC transfer cask provides shielding and structural protection of the MPC during loading, unloading and movement of the MPC from the spent fuel pool to the storage overpack. The transfer cask is a multi-walled (carbon steel/lead/carbon steel) cylindrical vessel with a neutron shield jacket attached to the exterior.

The HI-STORM 100 storage overpack provides shielding and structural protection of the MPC during storage. The overpack has four air inlets at the bottom and four air outlets at the top to allow air to circulate naturally through the cavity to cool the MPC inside. The inner shell has supports attached to its interior surface to guide the MPC during insertion and removal, provide a medium to absorb impact loads, and allow cooling air to circulate through the overpack. The side wall consists of plain (un-reinforced) concrete that is enclosed between inner and outer carbon steel shells.

The use of ISFSI Systems Structures and Components (SSCs) for storage and handling of spent fuel shall be in accordance with Fermi's 10CFR72.212 Evaluation Report and ISFSI related procedures.

9.1.4.2.2 Reactor Building Crane

An overhead traveling (reactor building) crane is utilized in the Fermi 2 reactor building to handle heavy objects, including the spent fuel shipping and transfer casks. The essential design bases applicable to Fermi 2 spent fuel cask handling are:

a. To minimize, to the maximum extent practical, the probability of dropping heavy objects into the fuel storage pool resulting in damage to fuel or compromising the integrity of the pool

b. To prevent a spent fuel shipping cask drop from exceeding the design limits for the cask as set forth in 10 CFR 71

c. To minimize the probability and the effect of dropping heavy objects, including the spent fuel shipping and transfer casks, during movement through the reactor building, so that damage is prevented to structures, systems, and components important to safety.

In order to obviate the possibility and to minimize the probability, to the greatest extent practical, of occurrence of events a, b, or c above, the special crane design features and improvements that have been incorporated are the following:

a. A completely redundant hoisting system

b. An upgrading of the crane for SSE and design-basis tornado

c. Upgrading of the crane quality assurance criteria

d. Crane control redundancy

e. A crane surveillance and test program

f. Administrative control of crane movements.

Crane operations over the spent fuel storage pool when fuel assemblies are stored therein are not allowed when either of the following conditions occur:

a. less than 22 feet of water over the top of irradiated fuel assemblies seated in the spent fuel storage pool racks.

b. less than the Technical Specification required ac electrical power sources operable, when in modes 4, 5 and when handling irradiated fuel in the secondary containment.

Prior to suspending crane operations, fuel assemblies shall be placed in a safe condition.

The reactor building crane is of the single trolley top running type, carried on two main girders. The girders have a rated lifting capacity of 125 short tons and a span of 113 ft 9 in. Power is applied by twin hoist motors through two gearboxes to the two drum gear rings, located on each end of the drum. In this manner, the hoist mechanism is duplicated. In normal operation, the twin hoist trains share the load, but each is separately able to carry the rated load at allowable code stresses, thus providing adequate safety should one gear train fail. Both hoist trains are provided with electrical and electromechanical type brakes; each of the latter is capable of sustaining the load should a mechanical failure occur in a gear train. Each mechanical brake is sized for 150 percent motor torque or 300 percent for redundant systems. (This is based on a required brake torque of 277.5 ft-lb, and a rating of each of the two 13-in. brakes of 550 ft-lb. The required brake torque, B_T, is calculated by using

$$B_T = 1.5 \times 33{,}000\ {}^{P_{hp}}/_{2\pi N}$$

where P_{hp} is the motor horsepower of 20, and N is equal to 570 rpm.)

The electrical brakes complement the mechanical brakes. The electrical brakes can limit the hoist-lowering speed to 1.6 fpm at rated load in the event of failure of both the redundant mechanical brakes. If there should also be a loss of normal power to the electrical brakes, an integrated alternator generates enough power to the units to prevent the lowering speed from exceeding the fully rated load speed.

For the main hoist, this speed is 4.7 fpm at rated load. The reactor building floor and the floor under the equipment hatch have sufficient strength to withstand the impact of a fully rated load at this speed.

The redundant wire rope system consists of two balanced reeving systems utilizing two individual wire ropes. These two wire ropes are reeved side by side from double-scoured drum groovings at each end of a single drum through the upper and lower block sheaves and to the double-sheave-type equalizer. Breakage of one cable system would reduce the factor of safety, but since each system is reeved to both sides of the bottom block and upper block system, there is no swinging or pendulum action of the block upon failure of one system. Equalizer sheaves are used in preference to equalizer bars so that ropes may more readily adjust to differences in length without the need for physical maintenance. Each of the equalizers is hung from a main pivot mechanism which is designed to be redundant within itself.

For the Fermi 2 crane, the wire rope safety factor for each single wire rope is a minimum of 10. This is determined by dividing the design rated load (125 tons) by the number of load-carrying parts (l6) and the efficiency factors (0.933) and comparing the result with the published breaking strength of 102 (nominal) tons for the 1-1/4 in. (nominal) diameter rope. The design of the dual reeving system is consistent with paragraph 3.f of BTP ASB 9-1.

In both the lower and upper blocks, the sheaves are mounted in a structural cage system having supporting plates on each side of each sheave. Thus, the load being carried by the sheave pin is shared by each of these support plates. Should a pin fail on any one particular sheave group, the adjacent sheave still maintains its integrity. This allows either reeving system to take over the entire load.

The main hook block is provided with a conventional hook, and the redundant feature is provided by two smaller hooks, each capable of sustaining 50 percent of the rated load at code stresses. The two additional hooks are individually mounted on their own pins and supported directly in the main block frame. They are intended for use only when handling the fuel cask.

To ensure against damage due to a tornado, the crane is provided with electrically operated locking bars that effectively connect the unloaded crane to the runway when it is not in use. These locking bars are capable of withstanding a tornado windforce of 410 lb/ft^2 intensity at a maximum of 90 percent of the yield strength of the crane components.

Earthquake protection is provided by restraints on the crane and trolley to prevent either from leaving its respective rails due to horizontal and/or vertical displacement. Seismic responses of the crane, based on its fundamental frequency in the vertical and two horizontal directions (perpendicular and parallel to the girder), have been calculated for the SSE and are 0.65g.

The crane is designed to accommodate SSE forces and deflections with the rated load suspended in the cask-hoisting position. Crane accelerations for the vertical SSE in the unloaded condition were also determined and found in all cases to be less than 1.0g. Seismic uplift forces are therefore not encountered.

The crane responses to the SSE, as determined above, are well below the design limits of the reactor building crane. Thus, the crane will remain within its restraints if subjected to an SSE.

Crane control can be either from the cab or by radio control. In the event that the crane cab becomes uninhabitable, control may be continued by means of the remote radio control provided. The only crane components that are actuated by the crane electrical control system and are an integral part of the mechanical load-retaining hoist system are the two shoe-type hoist holding brakes. The two electrical control components that actuate the hoist holding brakes are either the raise or lower hoist reversing contactors. If either the raise or lower hoist reversing contactor fails to open when called upon, the backup is the stop button in either the cab or in the radio control, which will interrupt the main power to the crane, causing the two independent hoist holding brakes to set and thereby stop the load.

To ensure that crane control can only be executed from one position at a time, a master control transfer switch is situated on the bridge. This switch must be manually operated by the operator and thus interrupts all of the control circuits so there can be no simultaneous operation of the crane from both the radio control and the cab control.

The crane control system is protected from actuation by signals from an outside source by use of a Security Start circuit. With this feature, the control system cannot be enabled until multiple conditions have been met which are unique to each receiver and its companion transmitter. To activate the equipment under control, the specific companion transmitter must be used. With this security start feature, there is no possibility of an outside source radio transmitter interfering with this system or causing inadvertent actuation since these foreign signals could not match the security circuit's multiple enabling conditions.

The crane test and surveillance programs include both preoperational tests and periodic testing, surveillance, and inspection programs.

Preoperational tests include crane hook certification to 100 percent overload, gear train no-load running tests, and complete functional tests after final crane assembly.

Periodic testing, surveillance, and inspection programs will be performed no more than 1 year prior to any usage of the crane. However, these tests and inspections will be performed just prior to each major refueling outage. Periodic testing will be conducted not more than 1 month prior to lifting of the first cask for a spent fuel transfer. The programs include magnetic particle or liquid penetrant examination of all hook surfaces; inspection of wire ropes for wear or damage, and measurements of wire rope diameters; other periodic testing, maintenance, and surveillance conducted in accordance with Occupational Safety and Health Administration (OSHA) requirements as set forth in 29 CFR 1910.179, Paragraphs (j), (k), (m), and (n); and periodic inspections as recommended by the crane manufacturer. Testing prior to refueling also includes a full test run of all motions of a typical fuel cask unloading and loading sequence.

The spent fuel cask-handling operation is performed under strict procedural control and under the direct supervision of the Shift Manager or his designated operator. The crane operator receives his instructions from the flagman by verbal communication. All operations that cannot be visually observed by the crane operator from his cab are transferred to radio control.

Personnel carrying out cask- and fuel-handling operations are qualified to meet the guidelines set forth in Regulatory Guide 1.8.

The reactor building crane is designed in accordance with the requirements of:

a. EOCI No. 61, Class A Service, and the structural guidelines of CMAA Specification No. 70

b. Seismic response spectra for Fermi 2

c. Material Specifications: ASTM; AISI; SAE; ASA

d. Electrical Specifications: N.E.C.; NEMA; IEEE; NBFU

e. Welding: AWS

f. Federal, State, and local codes, including OSHA.

Welding specifications used in the crane fabrication are as follows:

a. Manual shielded metal-arc welding (SMAW) in accordance with AWS D1.1 and AWS D14.1 for welding of structural steel of unlimited thickness and base metals of ASTM-A36, ASTM-A242, ASTM-A441, and ASTM-A572. The required preheat and interpass temperatures are as follows:

Plate Thickness (in.)	Minimum Preheat and Interpass Temperature (°F)		
Up to 3/4	50	50	
3/4 to 1-1/2	150	70	For FCAW
1-1/2 to 2-1/2	225	150	
Over 2-1/2	300	225	

(Reference: P&H welding procedure WP-SC of September 1972)

b. Flux cored arc welding (FCAW), same application as above

c. Submerged arc welding (SAW), same application as above, with preheat and interpass temperatures as for FCAW

d. Joint welding procedure classification tests were performed for all welding processes, including groove and fillet type welds

e. No postweld heat treatment was performed.

Girders, trolley frame, and general structures are constructed of ASTM, A-36 steel. The end ties are of ASTM, A-514 material.

9.1.4.2.3 Fuel Servicing Equipment

Two fuel-preparation machines are used to remove the channels from fuel assemblies and to reinstall the channels on fuel bundles. Additionally, the fuel preparation machines are used for fuel inspections and new fuel receipt/transfer activities. Strict administrative control on the fuel preparation machine's full-up end stop is required for personnel protection. These machines are designed to be removed from the pool for servicing.

The new-fuel transfer crane is a 1500 lb, wall-mounted, traveling-hinged boom crane which services the area (B, E, 15, 17) in Figure 9.1-3.

A new fuel uprighting stand is used to hold the steel shipping box in a vertical position while the fuel assembly is removed. A new-fuel inspection stand is used to restrain the fuel bundle in a vertical position for inspection. The inspection stand can hold two bundles. The new fuel uprighting stand and the inspection stand are approximately designated by point C,15 in Figure 9.1-3.

The general-purpose grapple is a small, hand-actuated tool used generally with the fuel. The grapple can be attached to the Reactor building auxiliary hoist and the auxiliary hoists on the refueling platforms. The general-purpose grapple or approved equivalent is used to remove new fuel from the vault, place it in the inspection stand, and transfer it to the fuel storage pool. It also can be used to shuffle fuel in the pool and to handle fuel during channeling.

A channel-handling boom with a spring-loaded takeup reel is used to assist the operator in supporting a portion of the weight after the channel is removed from the fuel assembly. The boom is set between the two fuel-preparation machines. With the channel-handling tool attached to the reel, the channel may be conveniently moved between fuel-preparation machines.

9.1.4.2.4 Servicing Aids

General area underwater lights are provided with a suitable reflector for downward illumination. Suitable light support brackets, independent of the platform, are furnished to support the portable lights in the reactor pressure vessel (RPV) to allow the light to be positioned over the area being serviced. Local area underwater lights are small-diameter lights for additional downward illumination. Drop lights are quartz lamps with no reflector and are used for intense radial illumination where needed. These lights are small enough in diameter to fit into fuel channels or control blade guide tubes. Portable underwater cameras and monitor are part of the plant optical aids. The transmitted image can be viewed on a monitor. This assists in the inspection of the vessel internals and general underwater surveillance in the RPV and fuel storage pool. A general-purpose clear plastic viewing aid that floats is used to break the water surface for better visibility.

Portable underwater vacuum/filter units are provided to assist in removing crud and miscellaneous particulate matter from the pool floor or from the RPV. These units may be completely submerged for extended periods. Fuel pool tool accessories are also provided to meet servicing requirements.

9.1.4.2.5 Reactor Vessel Servicing Equipment

Reactor vessel servicing equipment is supplied for safe handling of the vessel head and its components, including nuts, studs, bushings, and seals.

The head strongback is used for lifting the drywell head and for backup lifting of RPV head. The strongback is designed to keep the head level during lifting and transport. It is cruciform in shape with four equally spaced lifting points. The strongback is designed so that no single component failure can cause the load to drop or to swing uncontrollably. The head strongback meets the requirements of NUREG-0612. The strongback, including hook pins and turnbuckles, has been load tested to three times its rated capacity of 93 tons in accordance with ANSI N14.6-1978, Paragraph 6.3.

The RPV head strongback carousel combines the functions for stud tensioning/detensioning operations, closure stud nut and washer handling and storage (by supporting the Nut Rack), and the head strongback previously used for reactor pressure vessel head lifting and transport. The carousel meets the requirements of NUREG-0612. The carousel including hook pins and turnbuckles, has been load tested to three times its rated capacity of 117.3 tons in accordance with ANSI N14.6-1978, Paragraph 6.3.

A vessel nut-handling tool is provided. This tool handles four nuts and features a spring device to lift the nut and clear the threads.

The head-holding pedestals are designed to properly support the vessel head and permit seal removal and replacement, seal surface cleaning, and inspection. The mating surface between vessel and pedestal is selected to minimize the possibility of damaging the vessel head.

The RPV ventilation equipment consists of a portable unit that is attached to the RPV head for the purpose of removing trapped radioactive gases under the head during removal. After the head nuts and washers are removed, the RPV ventilation system is attached. As the head is raised, the trapped gases are drawn from the area under the head, passed through chemical filters, and exhausted. This eliminates possible inhalation doses to personnel during RPV head removal.

9.1.4.2.6 In-Vessel Servicing Equipment

The instrument strongback is attached to the reactor building crane auxiliary hoist and is used to lift replacement in-core detectors from their shipping containers.

The auxiliary hoist on the refueling platform is used with appropriate grapples to handle control rods, flux monitors, sources, and other internals of the reactor. Interlocks on both the grapple hoist and auxiliary hoist are provided for safety purposes. The refueling interlocks are described and evaluated in Subsection 7.6.1.1.

The Reactor Cavity Work Platform is used during the In-service Inspection of the vessel and other refueling outage related activities. This platform remains on the Reactor Building Fifth Floor during normal operation, secured safely to the reactor cavity concrete shield blocks. During refueling outages the platform will be installed in the reactor cavity, supported by eight (8) legs resting freely on the refueling deck. The leak-tight work area of the platform remains partially submerged in the flooded reactor cavity. The jib crane associated with this platform can be used to handle objects weighting up to 500 pounds.

The Reactor Cavity Work Platform is considered Seismic Category II/I since it is not required to ensure the three requirements of Category I system as discussed in Section 3.2.1. This Work Platform is designed to accommodate safe-shutdown earthquake (SSE) forces and deflections. Dynamic analysis using the Fermi 2 site characteristics for the refueling floor of the reactor building verifies that the Reactor Cavity Work Platform can withstand the SSE for the Fermi 2 site and will remain supported by the eight legs resting on the refueling deck.

The lifting lugs for the Reactor Cavity Work Platform are designed so that no single component failure can cause the load to drop or to swing uncontrollably. The lifting devices meet the requirements of NUREG-0612. The lift and handling system, including hook, pins and turnbuckles, has been load tested to three times its rated capacity of approximately 28 tons, in accordance with ANSI N14.6-1978, Paragraph 6.3.

9.1.4.2.7 Refueling Equipment

The refueling platform is used as the principal means of transporting fuel assemblies between the reactor well and the fuel storage pool. The platform travels on tracks extending along each side of the reactor well and the fuel storage pool. The platform supports the refueling grapple and auxiliary hoists. The grapple is suspended from a trolley system that can traverse the width of the platform. Platform operations are controlled from an operator station on the trolley. The platform contains a position-indicating system that indicates the position of the fuel grapple over the core.

The refueling platform is designed to accommodate safe-shutdown earthquake (SSE) forces and deflections. It has been designed to withstand a 1.5g horizontal and a 0.14g vertical acceleration based on static analysis. Dynamic analysis using the Fermi 2 site characteristics for the refueling floor of the reactor building verifies that the refueling platform can withstand the SSE for the Fermi 2 site and will remain on the rails. However, the refueling platform is considered Seismic Category II/I since it is not required to ensure the three requirements of Category I system as discussed in Subsection 3.2.1.

To ensure access to the drywell for inspection and maintenance during spent fuel transfer, a refueling shield bridge is utilized. A U-shaped trough lined with a nominal 6 in. of lead is placed across the gap between the RPV flange and the inner edge of the fuel transfer canal. When in place, the refueling shield bridge provides sufficient shielding to ensure continuous access to the drywell during spent fuel transfer.

9.1.4.2.8 Storage Equipment

Specially designed fuel storage racks are provided. For a description of fuel storage racks and fuel arrangement, see Subsections 9.1.1 and 9.1.2.

If sipping indicates a fuel assembly with defects of a large enough magnitude, the defective-fuel assembly is placed in a defective-fuel storage container. The defective-fuel storage containers (containing defective fuel) are stored in the Dual Purpose cells of the fuel storage racks. These are used to isolate leakage of defective fuel while in the fuel storage pool and during shipping. A defective-fuel storage container containing a fuel bundle may be moved.

The channel is removed from the defective-fuel assembly before it is placed in the container.

9.1.4.2.9 Under Reactor Vessel Servicing Equipment

The necessary equipment to remove several control rod drives (CRDs) during a refueling outage is provided. An equipment-handling platform with a rectangular open center is provided. This platform can rotate to provide space under the vessel so that a CRD can be lowered and removed. If a control rod guide tube must be removed, the thermal sleeve within the CRD housing must be rotated to disengage the guide tube. A thermal sleeve tool that permits installation or complete removal at the thermal sleeve is provided for this purpose. Special tools and instruments to service and test individual control rod hydraulic units are also provided.

Miscellaneous tools are provided to install and remove the neutron detectors. A drain can be opened after in-core insertion to drain any residual water. Correct seating of the in-core string is indicated when drainage ceases.

Additional tools and servicing equipment not covered in these paragraphs are listed in Table 9.1-5.

9.1.4.2.10 Dry Storage Cask Servicing Equipment

A variety of ancillary equipment is used to lift, move, and prepare the dry storage transfer cask and MPC as discussed in the HI-STORM 100 System FSAR. This includes such items as lifting devices, (e.g., lift yoke, lift links, and slings), draining, drying, and backfill equipment, and welding equipment. After a dry storage cask loading campaign is completed the ancillary equipment is either removed from the site or stored in the dry cask equipment storage building near the ISFSI.

9.1.4.3 Description of Fuel Transfer

The fuel handling system provides a safe and effective means for transporting and handling fuel from the time it reaches the plant until it leaves the plant after postirradiation cooling. The previous subsection described the equipment and methods utilized in fuel handling. The following paragraphs describe the integrated fuel transfer system.

9.1.4.3.1 Arrival of Fuel on the Fermi Site

Fuel arrives on the Fermi site by truck. The fuel elements are shipped in steel boxes that support the fuel element along its entire length. The stainless steel box is contained in a stainless steel overpack. Cushioning material and a support frame positions the stainless steel box in the overpack. Two fuel assemblies are contained in each shipping container. Each shipping container is designed to ensure subcritical geometry in handling as required by 10 CFR 71.

A specific criticality safety analysis, as identified in reference 12 herein, was performed for safe storage, handling and transport of GE BWR nuclear fuel shipping containers during new fuel receipt for Fermi 2. A new generic criticality evaluation, identified as reference 16 herein, has been performed for the new stainless steel shipping container. The updated analysis provides assurance that an inadvertent criticality is highly improbable during onsite storage, handling and transportation of new fuel within shipping containers. This meets the criterion of GDC 62, "Prevention of Criticality in Fuel Storage and Handling." The former safety analysis provided is the bases for Fermi 2's exemption from the requirements of 10 CFR 70.24, as granted by the Nuclear Regulatory Commission and identified by reference numbers 13 and 14 herein. The exemption requires criticality monitoring in areas where fuel is handled outside the inner metal shipping containers (the refuel floor). In contrast, the exemption allows administrative controls, such as the use of geometrically safe configurations as bound by the aforesaid former safety analysis for areas in which the new fuel remains in the inner metal shipping containers (the yard and the reactor building up to the refuel floor). The updated criticality evaluation provides for similar controls. Therefore, monitoring for an inadvertent criticality while handling or transporting new fuel is not required in the yard or during transport to the refuel floor.

The fuel can be handled by wearing gloves and other protective clothing. The containers are lifted to the refueling floor through the equipment hatch using the reactor building crane. Once the fuel is removed from the inner shipping containers on the refuel floor, criticality monitoring is required. Monitoring for an inadvertent criticality event on the refuel floor, is provided by two redundant detectors (D21-N115 and D21-N117). These detectors are high sensitivity gamma ray detectors (GM tubes) and are located on the east wall approximately 9 ft to 12 ft in the air. The alarm trip setting on these detectors is in the proscribed range of 5-20 mR/hr, which is adequate to detect the minimum accident of concern as described in 10 CFR 70.24 and ANSI/ANS 8.3-1986. The alarm circuitry of these detectors is arranged in a fail safe mode such that any malfunction of the detectors or a loss of power results in an alarm condition. Additionally, the detectors have a meter pegging circuit which precludes a downscale low reading (no foldover) during saturation of the GM tube due to high intensity radiation fields. Periodic performance tests are conducted to confirm instrument response to radiation and the operability of the alarm signal generator.

The aforementioned design meets the criterion of GDC 63, "Monitoring Fuel and Waste Storage." Additionally, Fermi 2 personnel are instructed to evacuate areas in which radiation or criticality alarms are activated. Evacuation of plant areas is periodically tested by the conduct of emergency response drills.

Depending on the laydown area, the metal containers can be placed in the new fuel uprighting stand using the auxiliary hoist, the new-fuel transfer crane, or a mobile crane. Any of these cranes can be used to transfer fuel from the new fuel uprighting stand to the inspection stand and to the fuel pool. Transfer of fuel from the new fuel storage vault can be done only with the auxiliary hoist. However, due to the lack of criticality detector redundancy, Fermi 2 does not strictly comply with 10 CFR 70.24 with regard to the new fuel storage vault. Accordingly, the spent fuel pool is used for storage of new fuel rather than the new fuel storage vault.

9.1.4.3.2 Refueling Procedure

Figure 9.1-28 defines, in general, the steps that make up a refueling outage. The heavy lines on the chart define the critical path in a normal outage. Deviations from this path may be encountered under normal circumstances for various reasons, such as scheduling and convenience. The reactor shall be determined to have been subcritical for at least 60 hours by verification of the date and time of subcriticality prior to movement of irradiated fuel in the reactor pressure vessel.

9.1.4.3.3 Departure of Fuel From the Fermi Site

Spent fuel assemblies may be shipped off-site in two different ways: 1) directly from the spent fuel pool into a shipping cask or 2) after a period of storage at the ISFSI and then in a shipping cask. For direct shipping, fuel assemblies from the spent fuel pool are conveyed by the fuel-handling bridge crane into the spent fuel cask located in the fuel storage pool. After insertion into the spent fuel cask, the cask head is replaced, and the flooded container with fuel is raised out of the pool by the reactor building crane for transfer to the cleaning station. The cleaning station is a depression in the floor adjacent to the pool and is designed for 1000 pounds per square foot load. The cask head is bolted down, and the cask is thoroughly cleaned. Final transfer from the cleaning station down the shaft to the vehicle-loading station is by crane. The cask is laid on its side on a flatbed, one to a flatbed, for return to the off-site fuel processing/storage facility.

For fuel to be stored at the ISFSI before shipping off-site, fuel assemblies from the spent fuel pool are conveyed by the fuel-handling bridge crane into the multi-purpose canister (MPC) while inside a HI-TRAC transfer cask. The HI-TRAC containing the fuel-loaded MPC will be removed from the spent fuel pool and moved to a location in the Dryer-Separator Storage Pool for additional processing activities. The HI-TRAC with the fuel-loaded MPC is then transferred to the Cask Transfer Facility (CTF) outside the Reactor Building. At the CTF, the fuel-loaded MPC will be transferred from the HI-TRAC to the storage overpack (HI-STORM). The HI-STORM with the fuel-loaded MPC is moved by a Vertical Cask Transporter (VCT) to the ISFSI pad, which is described in Section 9.1.2.2.3. The fuel will remain at the ISFSI pad until it is ready to be shipped off-site in an NRC-licensed transportation cask pursuant to 10 CFR 71.

9.1.4.4 Control of Heavy Loads in Close Proximity to Irradiated Fuel or Safety Systems

The NRC in Reference 10 concluded that Fermi 2 meets the guidelines of NUREG-0612 for the handling of heavy loads near spent fuel. Travel paths for the handling of these loads have been graphically described, and the procedures controlling adherence to these travel paths have been identified.

The reactor building crane, Subsection 9.1.4.2.2, main hoist is single-failure proof. There are no heavy-load handling applications at Fermi 2 other than those that can be handled by the main hoist, that require handling within single-failure-proof guidelines. In order to meet NUREG-0612 guidelines, the reactor building crane auxiliary hoist has a load-limit feature that restricts the hoist from handling heavy loads (greater than 2000 lb) over the spent fuel pool and open reactor vessel.

The training and qualification of crane and hoist operators are in accordance with NUREG-0612 guidelines. The testing, inspection, and maintenance of these cranes and hoists also conform to these guidelines. Hoisting of all heavy loads around critical equipment will be covered by written procedures.

Cranes, hoists, and slings used to handle heavy loads around critical equipment are in conformance with the standards specified in NUREG-0612. The matrix analysis performed on all heavy load hoist combinations has identified all potentially affected safety system components and has defined the hazard elimination category under the NUREG-0612 guidelines for each of these components.

The special lifting devices at Fermi 2 include the head strongback, the dryer/separator lifting device, the spent fuel transfer cask lifting yoke and the RPV head strongback carousel. These special lifting devices, except for the lifting yoke, were found acceptable by the NRC in Reference 10. All lifts of the spent fuel transfer cask are made with a single-failure-proof lifting system to ensure the likelihood of a drop of either load is so low as to be considered not credible. A single-failure-proof lifting system consists of the crane, lifting devices (e.g., lifting yoke, lift links or brackets, slings, etc.), and interfacing lift points (e.g., cask lifting trunnions and MPC lift cleats). The design of the RB crane lifting system for lifts of a spent fuel transfer cask or canister inside the power plant meets the guidelines for a single-failure-proof lifting system in NUREG-0612, Section 5.1.6.

Periodic testing of these special lifting devices meets the guidelines of NUREG-0612 by following ANSI N14.6-1978 and the NRC's interpretation of the NUREG-0612 guidelines provided with Reference 11. Testing and/or inspection of the RB crane lifting system components used to lift and move dry spent fuel storage cask equipment inside the power plant is performed in accordance with NUREG-0612, Section 5.1.6.

TABLE 9.1-1 FUEL POOL COOLING AND CLEANUP SYSTEM

Total pool, well, and pit volume	107,000 ft^3	
Fuel storage pool net water volume[c]	42.030 ft^3	
Operating heat load	9.12 x 10^6 Btu/hr	
Design heat load[c]	16.66 x 10^6 Btu/hr	
Maximum heat load (core offload)[c]	42.65 x 10^6 Btu/hr	
	Fuel Pool Cooling Water Pumps	
Quantity	2	
Type	Horizontal, centrifugal	
Design flow/TDH (each)	550 gpm/300 ft	
Motor hp	60 hp	
	Fuel Pool Cooling Heat Exchangers	
Quantity	2	
Design code	ASME B&PV, Section VIII	
	Shell Side	Tube Side
Fluid circulated	RBCCW[a]	Spent fuel pool water
Sizing Temperature	95 °F	125 °F
Sizing Fluid flow	800 gpm	550 gpm
Number of passes	1	2
Material	CS, SA-106B	SS-304, SA-249
Design system pressure	150 psig	200 psig
Design system temperature	150 °F	150 °F
Spent Fuel Pool Cooling Capacity of FPCCS		
FPCCS to RBCCW Inlet temperature differential	30 °F	55 °F
Cooling Capacity, Btu/hr:		
1 pump/1 H-X, design service rated	4.56 x 10^6	8.33 x 10^6
2 pump/2 H-X, design service rated	9.12 x 10^6	16.66 x 10^6

Fuel Pool Filter-Demineralizers

Type	Pressure precoat
Quantity	2
Design filter area	270 ft^2
Filter capacity	550 gpm
Maximum pressure drop	30 psi
Design code	ASME B&PV, Section VIII

TABLE 9.1-1 FUEL POOL COOLING AND CLEANUP SYSTEM

Holding pump flow	150 gpm
Precoat flow	>400 gpm

Spent Fuel Pool Cooling Capacity of RHR[b]

RHR to RHRSW Inlet ΔT	36 °F	49 °F	61 °F
Cooling capacity, Btu/hr			
RHR/FPC-Assist @ 3,500 gpm	30.72×10^6	42.22×10^6	52.51×10^6
RHR/SDC @ 10,000 gpm	41.6×10^6		

---

[a] Maximum design temperature of RBCCW is 95°F at 85°F lake water temperature. When lake water temperature is 60°F or below, the RBCCW is controlled to 70°F.

[b] All RHR design capacity values assume 9,000 gpm RHR Service Water flow and fully fouled (service rated) heat exchanger tubes.

[c] These values assume additional storage locations are added in the spent fuel pool to be consistent with Tables 9.1-2 and 9.1-3.

PLANT REFUELING OUTAGE – FLOW DIAGRAM

9.2 WATER SYSTEMS

9.2.1 General Service Water System

9.2.1.1 Design Bases

The general service water (GSW) system is designed to remove various plant heat loads principally from the reactor, turbine, and radwaste buildings during normal station operation. Cooling water is drawn directly from Lake Erie, passed through traveling screens, pumped throughout the plant, and is then returned to the circulating water system where the heat is ultimately rejected to the atmosphere via the plant's natural draft cooling towers.

The GSW system is designed to operate at a higher pressure than the systems it cools, to provide protection against potential outleakage of radioactive contaminants to the environment.

The GSW system is classified as a nonnuclear system and is constructed in compliance with standards for Quality Group D components. This criterion is met by designing the system to ASME Section VIII and ANSI B31.1.0 code requirements. The system is nonseismic, except that portion of the system within the reactor building, auxiliary building, and RHR complex which is designated as Seismic Category II/I.

9.2.1.2 System Description

The GSW system, as shown in Figure 9.2-1, Sheet 1 is designed to remove heat from or provide water to the following equipment on a continuous basis:

a. The reactor building closed cooling water system (RBCCWS) heat exchangers

b. The turbine building closed cooling water system (TBCCWS) heat exchangers

c. The turbine oil coolers

d. The generator hydrogen coolers

e. The radwaste evaporator condenser

f. Reactor building and turbine building room coolers

g. Circulating water pump bearing cooling water and lubricating water.

h. GSW biocide injection system

i. Supplemental cooling chilled water system

The GSW system also provides, on an intermittent basis, water for the following systems or functions:

a. Circulating water biocide injection system

b. Traveling water screen backwashing and deicing

c. Fire protection system (FPS) makeup (via the FPS jockey pump or the GSW to FPS cross-tie line)

d. Residual heat removal (RHR) reservoir makeup

e. Lawn sprinklers

f. Sump flushing.

g. The Sanitary Sewage Treatment Facility (outside protected area)

h. Side Stream Liquid Radwaste Processing System (SSLRPS)

GSW system pump data is shown in Table 9.2-1.

The GSW system takes its water from Lake Erie. The lake water is drawn into an intake canal, passed through a trash rack and a traveling screen, and enters the GSW pump pit. The five GSW pumps take suction from the intake pit and discharge the water into a common header. The GSW pumps operate continuously, maintaining pressure in the GSW header. Minimum pump flow protection is provided by relief valves at each pump's discharge to prevent overheating in the event that the pump is inadvertently run deadheaded. Relief valves are provided in the system piping to prevent overpressurizing the system.

The GSW pump house is located on the existing intake canal serving Fermi 1. It houses the five 25 percent-capacity GSW pumps, two 100 percent-capacity circulating water reservoir makeup pumps, and two 100 percent-capacity fire pumps. The two stage GSW pumps are of the vertical wet-pit type, rated for 7700 gpm flow, and a tested head between 241 and 270 ft. Since the flow demand varies seasonally, the pumps are manually started and stopped by the operator from the main control room. Each pump has a basket strainer located in its discharge line to remove suspended material that has been carried through the traveling screens at the pump house inlet. The strainers are provided with automatic self-backwashing feature.

The GSW system is treated with a biocide to inhibit slime and algae growth and to control organic and inorganic fouling of heat exchanger and piping surfaces. The biocide injection system is shown in Figure 9.2-1, Sheet 2.

Traveling screens and stationary racks are provided to keep floating debris from entering the GSW intake pit. A line from the GSW supply header automatically provides high-pressure water to each screen for backwashing whenever the differential pressure across the screens rises above a predetermined value. A screen deicing line, tapped off the GSW discharge header just prior to its connection into the main condenser circulating water line, provides warm water to keep ice from forming around the screens.

The majority of GSW flow to equipment being cooled is controlled by temperature control valves. Each valve is modulated in response to the exit temperature of the process equipment that the GSW is cooling. The flow to remaining GSW loads is modulated by manual flow valves.

A cross connection is provided from the HPCI Test Line piping to the GSW piping to be used as part of the Flexible and Diverse Coping Strategy (FLEX) to mitigate Beyond Design Basis External Events (BDBEE) in response to NRC Order EA-12-049.

9.2.1.3 Safety Evaluation

The GSW system is not required to be operable in order to effect the safe shutdown of the reactor. Thus, the GSW system is not designed for a single active or passive failure as required of a safety or safety-related system, but sufficient redundancy and automatic protective features are provided to ensure efficient plant operation and availability. Since the GSW system is not an engineered safety feature (ESF), it is not powered by an essential power bus.

The only portion of the GSW system directly involved in reactor operation and shutdown is the section serving the RBCCWS (via the RBCCW shell and tube heat exchangers and the supplemental cooling chilled water system chiller condensers). If the GSW system becomes inoperative, the emergency equipment service water system (EESWS) takes over to serve the equipment essential to safe reactor shutdown through the emergency equipment cooling water system (EECWS) (described in Subsection 9.2.2). The EECWS and the EESWS are powered off the essential buses. No failure in the GSW system can prevent a safe shutdown of the reactor.

The GSW intake structure is designed for operation during low lake levels by drawing water through a 54-in. line from the circulating water reservoir. On low lake level, an alarm alerts the operator of the condition. If necessary, the operator can supply GSW from the circulating water reservoir by opening the normally closed valve in the 54-in. connecting line between the circulating water reservoir and the GSW pump intake pit, and simultaneously closing the sluice gates to isolate the intake canal from the intake pit. The GSW and circulating water systems can be operated for a limited period of time in this mode to support plant load reduction and shutdown. Subsection 2.2.3.1 further discusses the low water considerations.

Radioactive contamination of GSW is avoided by using closed heat exchangers between the service water and the closed cooling water systems. The GSW remains uncontaminated by operating at higher pressure than the cooled system, and any leakage would be from the GSW system to either the TBCCWS or the RBCCWS. In addition, further protection is provided by activity detection equipment located in the circulating water discharge line downstream from the GSW system discharge connection so that both systems are monitored for radioactive contamination.

The cross connection between the HPCI Test Line (at the orifices) and the GSW System is designed to prevent cross contamination during normal plant and under DBA conditions. Double isolation valves are used in the cross connection piping to avoid any potential cross contamination. A tell-tale drain is provided between the two isolation valves to monitor potential leakage or failure of either isolation valve.

9.2.1.4 Tests and Inspections

Initial construction tests such as hydrostatic leak tests were conducted per ASME Section VIII and ANSI B31.1.0 code requirements. Initial system flow distribution, valve operability, instrumentation and control loop checks, and alarm setpoints were done in accordance with the Preoperational Test program. After plant startup, heat exchanger operating performance is observed using actual system heat loads.

Periodic testing of the GSW pumps is done during normal system operation by utilizing each pump's test lines and orifice. Each pump's head and flow point is then compared to its initial flow characteristic curve, and an assessment is made for any deterioration to determine the need for any corrective pump maintenance. Instruments and controls are inspected periodically. No periodic leak tests are planned since the system is continuously operating. Periodic visual inspection of the system will detect minor leakages, such as those from valve stems, flanges, and instrument tubing connections.

9.2.1.5 Instrumentation

Sufficient instrumentation is provided to allow the plant operator to assess the status of the GSW system. The GSW pumps are manually started and shut down from the control room operating panel via coordinated manual control (CMC) switches. Pump status and motor amperage readouts are provided in the control room.

The discharge from each GSW pump flows through an automatic self-cleaning strainer and a discharge isolation valve. GSW system pressure is regulated by changing the number of pumps in service, adjusting the GSW flow through heat exchangers, and/or bypassing some flow back to the pit as necessary. The discharge header pressure is indicated with high and low pressure alarms in the control room.

Water levels in the GSW pump house are measured on each side of the traveling screens to provide additional pump operating intelligence to plant operators. This level instrumentation controls traveling screens and alarms the control room operator of abnormal inlet water levels.

The GSW flow to the major GSW users, turbine oil-coolers, generator hydrogen coolers, TBCCW coolers, and RBCCW coolers, are modulated by temperature control valves. The process temperatures are also provided with a high and low temperature alarm in the control room. The other GSW loads are modulated by manual controls.

9.2.2 Cooling System for Reactor Auxiliaries

9.2.2.1 Design Bases

The RBCCWS is designed to remove heat from the auxiliary equipment housed in the reactor building and auxiliary building during normal plant operation. The RBCCWS is cooled by the GSW system, and makeup is supplied by the demineralized makeup water system. The supplemental cooling chilled water system provides a source of chilled water for cooling the water supplied to each division of EECW serviced by the RBCCW supplemental cooling loops. The GSW system provides service water for condenser cooling of the SCCW chillers. The RBCCW supplemental cooling loops are intended for operation when the GSW supply temperature is greater than 60°F.

In the event of a mechanical failure of the RBCCWS, high drywell pressure, or upon loss of offsite electrical power, the EECWS will start automatically (or may be manually initiated) to cool equipment needed for reactor shutdown. In addition, the EECWS may be used to augment RBCCW for the purpose of assisting in equipment cooling. The EECWS is cooled by the EESWS which is supplied by the RHR reservoir.

To provide for reactor shutdown under severe natural environmental conditions, as well as upon loss of normal offsite power and failure of the RBCCWS, two full-capacity Emergency Equipment Cooling Water loops are provided.

Motor-operated isolation valves are provided to isolate the nonessential loads on the RBCCWS from each EECW loop.

The RBCCW system is operated at a pressure lower than the GSW system to prevent leakage of potentially radioactive water to the environment. Continuous surveillance of the quality and activity level of the RBCCWS is maintained to detect inleakage of GSW or inleakage from the cooled reactor building auxiliary components.

During emergency situations when EECW is in operation, the EECW pressure is slightly greater than the EESW pressure at the EECW heat exchangers. It would take multiple equipment failures to create a situation where radioactive contamination would enter the EESW. First a component being cooled by EECW would have to leak contaminated water into EECW. This would have to be accompanied by a failure in the EECW heat exchanger in order to release radioactive material into the RHR reservoir. If this were to happen, drift losses from the cooling towers could cause a radioactive release to the environment. Given the fact that it would take multiple equipment failures and that monitoring and sampling provisions exist (as described in Subsections 11.4.3.9.2.3 and 11.4.3.9.2.4), the potential for an unmonitored radioactive release is minimal.

The makeup line between the EECW makeup tank and the EESW system for each division is furnished with a check valve and a normally closed air-operated isolation valve. The test return line is provided with two isolation valves that are closed during normal operation. These valves would minimize the potential of radioactively contaminated water leaking into the EESW system during normal operation. The check valve in the makeup line and the closed test return line isolation valves would also minimize the potential for radioactively contaminated water leaking into the EESW system during a design basis accident. The check valves installed as boundary valves on the nitrogen inerting (T48) and demineralized makeup water (P11) systems would minimize the potential for radioactively contaminated EECW water leaking into these systems.

System construction for cooling the essential equipment necessary for reactor shutdown is in compliance with standards for Quality Group C or Quality Group B. Components and equipment not essential to reactor shutdown are built as a minimum to Quality Group D standards. The EECWS is Category I, and is designed in accordance with ASME Section III, Class 2 and Class 3 requirements. The RBCCWS is Seismic Category II/I and is designed to ASME Section VIII and ANSI B31.1.0 code requirements.

9.2.2.2 System Description

The RBCCWS, as shown in Figure 9.2-2, is designed to remove heat from reactor auxiliaries that fall into two categories: those that are essential to reactor shutdown and those that are non-essential to reactor shutdown. Table 9.2-2 lists RBCCWS component design parameters.

The RBCCWS outside of the RBCCW supplemental cooling loops consists of two RBCCW heat exchangers and three 50 percent-capacity pumps. The two, divisional RBCCW supplemental cooling loops are each designed with one RBCCW supplemental cooling (plate-and-frame) heat exchanger and two 100 percent-capacity RBCCW supplemental cooling pumps (see Figure 9.2-2(2)). During normal operation, two heat exchangers and two pumps operate to provide cooling to all the essential and nonessential heat loads. The third pump is in standby and is designed to be started manually on low RBCCWS pressure. When the RBCCW supplemental cooling loops are in operation, one RBCCW supplemental cooling pump will operate for each EECW division. The second pump in each division is in standby and is designed to automatically start on loss of the operating pump. The RBCCW supply header temperature is maintained nominally at 70°F by a temperature control valve modulating the GSW flow through the RBCCW heat exchanger. During the summer season, the RBCCW temperature may be higher. When these higher temperature conditions occur, the RBCCW supplemental cooling loops may be used to cool the water that is supplied to EECW. The water temperature exiting each RBCCW supplemental cooling heat exchanger will be maintained by a temperature control valve which may be operated in automatic or manual mode. Both divisional loops of RBCCW supplemental cooling exchange heat with the supplemental cooling chilled water (SCCW) system. SCCW may be placed in operation when the GSW supply temperature exceeds 60°F. The system thermal capacity is based on a nominal 85°F RBCCW temperature. System pressure is controlled by a differential PCV located in the bypass line between the suction and discharge headers of the RBCCW pumps. Makeup to the system as well as system expansion and contraction resulting from load changes are provided by a makeup tank. Makeup water is automatically supplied via a level control valve. Normal makeup is from the demineralized water system and alternatively from the condensate storage system.

Reactor auxiliaries impose a maximum cooling load on the RBCCW heat exchangers of approximately 68 x 10^6 Btu during normal operation. This requires approximately 10,000 gpm of GSW, assuming a maximum service water temperature of 85°F. Circulation on the RBCCW side of the heat exchanger is approximately 8000 gpm; heat exchanger rate is based on temperatures of 112°F in and 95°F out.

The GSW is not used directly because the relatively high impurity level in this system might result in fouling of equipment heat transfer surfaces. Furthermore, the intermediary loop between contaminated reactor auxiliaries and the GSW system provides additional protection against radioactive water leakage into the environment.

The EECW section of the RBCCWS consists of two redundant full-capacity loops, each with two (2) 100 percent capacity heat exchangers, pump, and makeup pump and tank, as shown in Figures 9.2-3 and 9.2-4. One heat exchanger is manually aligned for service. The second heat exchanger is provided as a backup. The twin systems designated as Division I and Division II are cooled by the EESWS. The EESWS, described in Subsection 9.2.5, is powered off the essential buses and is designed to be redundant throughout. Upon loss of offsite power, high drywell pressure, or failure of the RBCCWS, both divisions of the EECWS are automatically activated; that is, pumps start, makeup tanks isolation valves open, and valves isolate the nonessential portion of the RBCCWS. The makeup tanks isolation valves do not start to open until the divisional isolation valves are closed. Upon loss of RBCCWS differential pressure between the supply and return headers, either Division I and/or Division II EECW loops will start automatically, depending on the portion of the

RBCCWS affected. The EECWS may also be manually initiated. Component design parameters of the EECWS are shown in Table 9.2-3.

The EECW heat exchangers are designed for a maximum heat load of 13.6 mBtu/hr. This requires approximately 1450 gpm of EESW, assuming a maximum service water inlet temperature of 89°F. Circulation on the EECW side of the heat exchanger is approximately 1700 gpm; heat exchanger rate is based on temperatures of 111.1°F in and 95°F out. The EECWS temperature is maintained nominally at 70°F in a similar manner as the RBCCW heat exchanger by modulating the heat exchanger exit cooling water flow.

The replacement of the original shell-and-tube EECW heat exchangers with a plate-and-frame design increased nominal heat transfer capability, but reduced the minimum flow channel dimension from 0.78-in. diameter tubes to 0.0732 inch plate spacing; thus, making the new units potentially more susceptible to plugging. The design analyses that define minimum EECW heat exchanger thermal performance consider the potential effects of initial plugging and plugging rate to establish the thermal performance and heat exchanger differential pressure vs. flow test criteria necessary to ensure the accident mission can be accomplished with credit for only one of the two identical units provided in each division. Once the maximum allowed normal operating plugging limit on a unit is reached, the EECW and EESW flows may be aligned to the clean spare heat exchanger in each division; thereby facilitating maintenance without interrupting normal plant operation.

The RBCCW makeup tank and the EECW makeup tanks are supplied with demineralized water and pressurized with nitrogen during normal plant operation. Normal makeup to the tanks is supplied automatically from the demineralized makeup water system by a level control valve. The pressure regulating valve of the normal nitrogen supply system maintains a nitrogen blanket in the tank at a pressure which will keep the EECW loop full to the upper elements. Nitrogen is provided to prevent leakage of oxygen into the system, thereby retarding corrosion of the closed cooling water system.

The EECW (Division I and Division II) system makeup tank is connected with a makeup line to the EESW system to provide an alternate makeup supply for each division when the normal makeup supply to this tank is lost during and after the design basis accident. The isolation valves for the alternate makeup supply consist of a check valve and an air-operated valve which opens automatically on a makeup pump start, a loss of air or a loss of electrical power. This valve is normally closed to prevent EESW, low quality water from entering the EECW, high quality water system during winter operation when TCV F400A/B is nearly closed. Each makeup pump auto starts and provides the makeup water to the tank. A check valve is installed in this makeup supply line to prevent a reverse flow from the EECW makeup tank to the EESW system. The test return line is provided with two isolation valves that are closed during normal operation and accident conditions to minimize the potential for radioactively contaminated water leaking into the EESW system. Inadvertent injection to the EECW system is minimized by system initiation setpoints and permissives. Inadvertent injection of EESW water into the EECW system during testing is minimized by isolation of the tank during testing. The makeup tank for Division I is also provided with the emergency backup nitrogen supply cylinders which automatically provide nitrogen to the makeup tank whenever the normal nitrogen supply is lost and/or the nitrogen supply pressure is reduced below approximately 26 psig. The check valves are added as the boundary valves between the makeup tank and nonsafety-related nitrogen inerting and demineralized water makeup systems to reduce the potential loss of the makeup tank inventory or pressure due to the loss of the nonsafety-related systems. The backup nitrogen supply cylinders are sized to maintain nitrogen pressure in the makeup tank until the makeup tank has refilled the EECW loop during an Appendix R fire. This will maintain a positive suction head on the EECW pump and provide protection against momentum transients when the EECW pump experiences a delayed start during the dedicated shutdown scenario.

The following equipment, considered essential to reactor shutdown, can be cooled either by the RBCCWS or, in an emergency, by at least one division of the EECWS:

a. RHR pumps (two out of four)

b. Core spray pumps (two out of four)

c. Reactor auxiliary space coolers (three in Division I or four in Division II)

d. Standby control air compressor, aftercooler, and space cooler (one out of two sets)

e. Deleted

f. Switchgear room space coolers (two out of four)

g. Standby gas treatment room space cooler (one out of two)

h. Control center air conditioning equipment (one out of two)

i. Auxiliary building battery charger area space coolers (one out of two).

The nonessential components of the RBCCW that are connected to the EECWS piping have automatic isolation valves installed in their supply lines. The following equipment, considered nonessential to reactor shutdown, is cooled only by the RBCCWS:

a. Two in-series reactor water cleanup nonregenerative heat exchangers

b. Water sample station cooler

c. Twin reactor water cleanup pump seals and bearings

d. Twin fuel pool heat exchangers

e. Twin recirculating pump motor-generator coupling cooler heat exchangers

f. Recirculating pump motor-generator ventilation cooling coils

g. Steam tunnel cooler

h. Drywell equipment sump heat exchanger

i. Reactor building equipment sump heat exchangers (two)

j. Control rod drive (CRD) pumps

k. Battery room space cooler

l. Drywell penetration cooling (eight)

m. High-pressure cask-washdown pump heat exchanger

n. Instrument rack H21-P284.

NOTE: All twin units are sized for 100 percent redundancy.

Two additional loads, drywell coolers (seven per division) and the reactor recirculation pumps, are normally cooled by RBCCW. Flow to this equipment is maintained upon activation of the EECWS. Should EECWS activate in conjunction with a high drywell pressure signal, the supply valve to the drywell will close, thus ensuring cooling of the essential loads.

9.2.2.3 Safety Evaluation

The EECW Division I and Division II portions of the RBCCWS are designed to provide cooling to equipment required for reactor shutdown in spite of a single active or passive failure. Division I and Division II loops are completely isolable from each other. Each loop of the EECWS is operable from a separate emergency bus. Single-failure analysis for the RBCCW and EECW systems is presented in Table 9.2-4. Upon activation of the EECWS, all nonessential loads of the RBCCWS will be isolated except for the drywell coolers and the reactor recirculation pumps. These loads can be manually isolated from the control room and the supply valve will be automatically closed if a high drywell pressure occurs.

The EESWS cooling the EECWS is also completely redundant and powered off separate emergency buses. This system is discussed in Subsection 9.2.5.

The EECWS components of Division I and Division II are located in different areas of the reactor building to preclude failure of both systems due to pipe whip, jet forces, and generated missiles. Physical separation also provides protection against common failure induced by fire, as described in Appendix 9A.

To detect leakage from the RBCCW and EECW systems, the makeup tanks are provided with low-level alarms and an alarm on the makeup valve stem position. Excessive opening of the makeup valve will be indicative of a substantial system leak. Inleakage of GSW or SCCW will be indicated by a high-level alarm in the RBCCW makeup tank. The RBCCWS is continuously monitored for radioactivity. Leakage to GSW and SCCW is minimized by operating the RBCCW at a relatively low pressure.

The use of demineralized water for makeup and nitrogen capping of the makeup tanks gives reasonable assurance against long-term degradation caused by impurities in the circulating loops. Additionally, corrosion inhibitors are added for pH and oxygen control. Alternatively, the cooling water system may be maintained with pure demineralized water only, with no chemicals added.

The makeup line between the EECW makeup tank and EESW system in each division provides emergency makeup water to the makeup tank by automatically starting the makeup pump and opening the air-operated valve. This makeup system is initiated on either low makeup tank pressure or low makeup tank level when the makeup tank isolation valve is open, and normal pump suction pressure is achieved. In Division I the backup nitrogen supply system to the EECW makeup tank is automatically actuated, based on the makeup tank pressure, upon loss of the nonsafety-related nitrogen inerting system and maintains the nitrogen pressure throughout a dedicated shutdown fire scenario. The check valves installed in the nonsafety-related water and nitrogen supply lines will protect the makeup tank from the potential loss of water inventory or nitrogen pressure.

Both EECW loops are automatically started on high drywell pressure or upon loss of normal offsite power. Upon failure of the RBCCWS, such as pipe rupture, redundant differential pressure switches automatically start the EECW pump(s), depending on the location and severity of the break, and initiate appropriate loop isolation consistent with the operating EECW pump(s).

EECW may be manually initiated with the nonessential loads subsequently restored to facilitate RBCCW heat exchanger cleaning, to enhance drywell cooling during high lake water (GSW) temperature, for testing, or to provide RHR Reservoir freeze protection during extreme cold weather. EECW auto-start on high drywell pressure (i.e., a LOCA) or on a loss of offsite power is unaffected by this mode of operation; therefore, these signals will initiate the automatic protective action of reisolating the nonessential portions of RBCCW piping located inside the EECW system envelope. A loss of RBCCW while EECW is operating in this mode will not reinitiate EECW or reisolate the nonessential loads. This action is not required, however, since this is not a condition requiring protective action as described in Section 7.1.2.1 and EECW remains capable of supporting the safe shutdown of the plant in this configuration.

9.2.2.4 Tests and Inspections

Initial construction tests such as hydrostatic leak tests were conducted per applicable code requirements for the RBCCW and EECW systems. Initial system flow distribution, valve operability, instrumentation and control loop checks, and alarm setpoints were done in accordance with the Preoperational Test program as discussed in Chapter l4. Heat exchanger operating performance will be observed during plant operation. Availability of the RBCCW standby pump and automatic start of the EECW pumps and makeup pumps are tested periodically. Periodic inspections and testing will be performed to monitor heat exchanger performance and cleanliness. Individual pump performance will be assessed in regularly scheduled inspections that can be performed without interruption of plant operation. Isolation of the EECWS will be tested periodically by simulating the initiating events that automatically bring the EECW and EESW systems into operation.

No periodic leak tests will be performed because the system is under continuous pressure during operation. Periodic visual inspection of the system will detect minor leakages such as those from valve stems, flanges, and instrument tubing.

9.2.2.5 Instrumentation

The RBCCW pump motors are equipped with standard controls and protective devices, and are monitored from the main control room. Readouts to observe pressure and inlet and outlet temperatures in the RBCCW and EECW systems are also provided in the main control room. Interlocks are provided on the RBCCW pumps to prevent their starting upon low makeup tank level and/or low suction pressure. High/low pump differential pressure and high/low makeup tank level are alarmed for the RBCCW and EECW systems. Low suction pressure is alarmed only on the EECW pumps. Individual components are equipped with local temperature indicators to periodically monitor performance. The temperature of the RBCCWS (or the EECWS) during operation is controlled by modulating the discharge flow of tube-side cooling water through the respective heat exchangers.

High- and low-level alarms and alarms for low system pressure are provided on the makeup tanks to alert the operator of system leakage and EECW makeup pump failure.

The RBCCW supplemental cooling pumps will be controlled and monitored from a control panel located in the basement of the turbine building. When one or more of these pumps trip, a common trouble alarm will be generated in the main control room. An interlock is provided to trip the RBCCW supplemental cooling pumps on low flow to the RBCCW header. A trip of the operating pump will automatically start the standby pump supplying the same division. A low level in the RBCCW makeup tank will prevent operation of all RBCCW supplemental cooling pumps. During the normal mode of operation when both loops of supplemental cooling are in operation, an interlock is provided to prevent these pumps from operating without the SCCW chillers in operation. Should no SCCW chillers be in operation, none of the pumps will start and all operating RBCCW supplemental cooling pumps will be tripped.

During the normal mode of operation one of the following two (2) modes are applicable. These two (2) modes of operation are dependent upon a single SCCW chiller's Full Load Amps (FLA) reading. Mode 1 allows the operation of any one single chiller and two (2) chilled water pumps to provide cooling to both RBCCW-SCS loops SCS-1 and SCS-2 when GSW inlet temperature is low. Mode 2 requires the operation of two (2) chillers and two (2) chilled water pumps to provide cooling for both RBCCW SCS loops.

If it is desired to operate only the supplemental cooling pumps or chilled water pumps for the purpose of maintaining water quality, a maintenance switch is provided which permits operation of the pumps without the chillers running.

The water temperature exiting each RBCCW supplemental cooling heat exchanger is maintained at the required value by a temperature control valve that controls the bypass of RBCCW flow around the heat exchanger.

9.2.3 Demineralized Water Makeup System

9.2.3.1 Design Bases

The demineralized water makeup system is designed to deionize water and store it for makeup to the reactor coolant system and plant auxiliary system and services, and is designed as a direct source of water for flushing and cleaning operations.

The raw water is supplied from the potable water system. The influent and effluent water qualities are shown in Tables 9.2-5 and 9.2-6, respectively.

The demineralized water makeup system is nonseismic, and is constructed in compliance with standards for Quality Group D components. This criterion is met by designing the system to ASME Section VIII and ANSI B31.1.0 code requirements.

9.2.3.2 System Description

The demineralized water makeup system consists of a 300-gal potable water holding tank, a packaged skid-mounted reverse osmosis unit, and two raw water booster pumps with associated distribution piping.

Normal operation of the make-up demineralizer is manually initiated from the reverse osmosis (RO) unit control panel. The booster pump takes suction from the raw water holding tank and sends it to the RO water treatment system. The RO system consists of three separate skid mounted units. The first skid is the pretreatment unit which contains the media filters, carbon filters and the softeners. The second skid is the main RO unit which includes both passes of the reverse osmosis system and the cleaning pump. The last skid, the post treatment unit, contains the transfer pump, ultraviolet light and deionization (DI) bottles.

The normal operation of the RO units is in series. The system operated in the series mode, will provide approximately 25 gpm of purified water. Only one of the two booster pumps needs to operate to supply water to the RO unit. The purified water is stored in the demineralizer make-up water storage tank. The concentrate which is the reject water of this system is simply concentrated potable water and is discharged into the boiler blowdown sump.

Potable water flow into the holding tank is controlled automatically by a level control inlet valve. Operation of the system depends on the water level in the makeup demineralized water storage tank. Makeup demineralized water storage tank level indication with a low-level alarm is provided in the main control room.

Connections are provided to recycle the contents in the demineralized storage tank through the makeup demineralizer to upgrade the quality of the water as it deteriorates due to CO_2 absorption during storage.

9.2.3.3 Safety Evaluation

The demineralized water makeup system is not required for reactor shutdown and as such is not a safety-related system. Redundancy to ensure continuity of design function is not required. Because of the processes involved in this facility, only high-purity water is handled, and no long-term degradation of equipment is anticipated.

9.2.3.4 Tests and Inspections

Initial system flow checks, valve operability, instrumentation and control loop checks, and alarm setpoints were performed in accordance with the Preoperational Test program as discussed in Chapter 14. Flow meters are provided to ascertain pump performance as are on-line conductivity monitors to determine water quality. Grab samples will be taken periodically to confirm water quality and to verify instrument accuracy.

Visual inspection will detect minor leakages such as those from valve stems, flanges, and instrument tubing. Potable water booster pumps will be operated on a rotating basis.

9.2.3.5 Instrumentation

The demineralized water makeup system is operated from the RO unit control panel which is a local panel located in the auxiliary boiler house. Local flow meters provide indication of raw water flow through the system, including the flow through the various skids of the RO unit. On-line conductivity monitors provide information on the various skids of the RO unit performance. The various RO unit trouble alarms and the raw water holding tank low level alarm will shut down the RO unit operation. Any one of these alarms will also initiate the make-up demineralizer trouble alarm in the main control room.

Switchover and operation of the regenerative and backwashing cycle are manual and done from the local RO unit control panel.

All process instrumentation, including that required to maintain temperature, pressure, and flow for the process cycle and the regenerative cycle, is locally indicated.

9.2.4 Potable Water System

9.2.4.1 Design Bases

The potable water system for Fermi 2 is composed largely of existing facilities at Fermi 1, with extended underground distribution lines.

The potable water system is designed to comply with Quality Group D Standards and State of Michigan Health Department code requirements.

9.2.4.2 System Description

The potable water system for Fermi 2 consists of an underground distribution header with branches to the various facilities that require service.

Fermi 2 demand is supplied by the Frenchtown Water System. The 100,000 gallon elevated storage tank on site is abandoned in place. Potable water is used in Fermi 2 to supply the demineralized water makeup system described in Subsection 9.2.3, sanitary plumbing, drinking fountains, washrooms, kitchen facilities, safety showers, and TBHVAC evaporative coolers.

9.2.4.3 Safety Evaluation

The potable water system has no apparent source of contamination. There are no interconnections between the potable water system and any other systems, except that the potable water supplies the demineralized water makeup system and TBHVAC evaporative air coolers. Potential contamination is precluded by an open break in the fill pipe for the demineralized water make-up system and the TBHVAC evaporative air cooler. Because the facility is specifically intended to handle and eliminate impurities, no long-range degradation of equipment is foreseen. Apart from the demineralized water makeup system (which is not critical to the operation or safe shutdown of the reactor), end users of the potable water system are plant personnel. There is, therefore, no requirement for redundancy in order to maintain uninterrupted service. Adequate water supply to the safety showers and eyewash stations is maintained by the tandem booster pumps of the potable water system with one in operation and the other in standby.

9.2.4.4 Tests and Inspections

No special test or inspections are required for the Potable and Sanitary Water System.

9.2.4.5 Instrumentation

Indicating instruments are read out locally in the Potable Water Building.

9.2.5 Ultimate Heat Sink

The ultimate heat sink is provided by the RHR complex, which contains the RHR service water (RHRSW) system, the EESWS, the diesel generator service water system, the mechanical draft cooling towers, the emergency ac power system (diesel generators), and the reservoir. The systems are shown in Figure 9.2-6. The ultimate heat sink design conforms to the requirements of Regulatory Guide 1.27.

9.2.5.1 Design Bases

The RHRSW system is designed for the following functions:

a. With the RHR system, to remove decay heat and residual heat from the nuclear system so that refueling and nuclear system servicing can be performed

b. With the RHR system, to supplement the fuel pool cooling system with additional cooling capacity

c. With the RHR system, to remove decay heat and residual heat from the nuclear system by cooling the suppression pool water, following a postulated LOCA

d. To provide a method to flood the reactor pressure vessel (RPV), acting as a backup in the extremely unlikely event that all RHR (low pressure coolant injection [LPCI] mode) and core spray pumps fail to operate following a postulated LOCA

e. To provide a method to flood primary containment so that the fuel can be removed from the RPV following a postulated LOCA.

The EESWS is designed to provide a cooling water source for the EECWS. The system functions only during a loss of offsite power, high drywell pressure, or upon failure of the RBCCWS.

The diesel generator service water system is designed to provide a cooling water source for the emergency diesel generators (EDGs) during testing and emergency operation.

The ultimate heat sink system structures are designed to comply with Category I requirements. System construction is designed to comply with requirements for Quality Group C components. Piping, valves, and pumps conform to the ASME Section III Class 3 Code requirements.

The ultimate heat sink system is sized to provide sufficient cooling for 7 days following a reactor shutdown without makeup water addition to the RHR reservoir.

The system structures (pump house, diesel generator building, reservoir, and cooling towers) are designed so that the equipment is physically separated or separated by barriers to ensure against multiple damage from missiles, pipe whip, and fire.

The ultimate heat sink is designed to withstand severe natural phenomena (safe-shutdown earthquake, tornado, storm, flood, and freezing). It is designed to withstand any single failure of manmade structures or components. All necessary electrical equipment is served by the essential buses in the event of loss of offsite power.

The RHRSW supply pressure is less than the pressure in the recirculating RHR system during a normal shutdown or under accident conditions. Therefore, radiation detectors are attached to return lines from the RHR heat exchangers to the cooling towers to monitor for leaks in the exchangers.

9.2.5.2 System Description

The RHR complex consists of a single highly reliable water supply (reservoir); a means for heat rejection (cooling towers); a standby power source comprising four EDGs; a makeup and decanting system; and associated pumps, piping, and instrumentation.

9.2.5.2.1 RHR Complex Reservoir

The RHR complex reservoir consists of two one-half-capacity reinforced-concrete structures of Category I construction, each with a capacity of 3.41 x 10^6 gal of water at elevation 583 ft. The reservoirs are connected by redundant QA I, Seismic I, ten-inch penetrations which permit access to the combined inventory of the two reservoirs for either RHRSW, EESW, or EDGSW division usage, which assures that the 7-day supply of water is available.

Normal reservoir water level is at Elevation 583 ft (New York Mean Tide, 1935). Waterproof construction of the walls is provided to Elevation 590 ft (New York Mean Tide, 1935) for protection against flooding from Lake Erie. Subsection 2.4.2.2.3 contains a further discussion of the RHR complex flood protection. Each division of the reservoir is fitted with a floodproof nonsiphon overflow to eliminate excess water. Makeup water delivery ports are designed to prevent siphon losses in the event of a break in makeup water supply piping.

Reservoir water loss due to leaks in the RHRSW, EESW, or diesel generator service water lines is detected by redundant level indicators in each division of the reservoir. Comparison between expected water level due to cooling tower losses and actual indicated level will provide sufficient data to determine any system leakage.

9.2.5.2.2 Cooling Towers

A two-cell induced-draft cooling tower is located over each division reservoir. The towers are of Category I fireproof construction with reinforced-concrete shells, cement board fill, and mist eliminators. Each tower is designed to cool one division of the plant load (one RHR heat exchanger, one EECW heat exchanger, and two EDGs), thus providing complete redundancy. Component design parameters for each tower are given in Table 9.2-7.

Each RHRSW cooling tower cell fan is driven by a 150-hp two-speed motor. The motor is connected to the ESF bus of the EDGs for a redundant power supply, and is manually started and stopped from the main control room.

The towers and fan drives are provided with a reinforced-concrete protective shell for tornado, earthquake, and missile protection.

The fans are provided with a brake system to prevent overspeed from the design-basis tornado. The fan drive shaft is provided with a shield to protect it from tornado missiles.

The cooling tower structure is designed to withstand horizontal and vertical tornado missiles. The cooling fan motor is enclosed in a concrete cubicle designed to repel both types of missiles, and the cooling tower gear hub and shaft are protected by missile shields. Using the guidelines in Standard Review Plan (SRP) Section 3.5.1.4, the only design missile that can be elevated to the top of the towers is the 1-in.-diameter by 3-ft, 8-lb rebar. This missile could damage the cooling tower fan blades if the velocity is sufficiently high. However, analysis has shown that the probability of damaging fans in both cooling tower divisions by rebar tornado missiles is very low (see subsection 3.5.1.3 for more detail). Not withstanding this low probability, two spare sets of two RHR cooling tower fan blades and the necessary tools to install them are stored in the RHR complex building in a location protected from the tornado and tornado missiles. In the event that the cooling tower fan blades are damaged, the blades can be replaced and the fan restored to an operating condition. Plant safe shutdown will not be precluded in the event of tornado missile damage to all four of the RHR cooling tower fans, including assuming a loss of offsite power and a single independent failure. The plant organization estimates that it would take six hours or less to replace a set of cooling tower fan blades. If no fans are available for six hours, reservoir temperature is calculated rise to approximately 100 degrees F. All essential equipment cooled by the UHS is capable of performing its required safety functions at the higher reservoir temperature. One cooling tower fan can maintain hot standby and two cooling tower fans can achieve cold shutdown under these conditions.

In addition to missiles, miscellaneous debris can fall into the tower from the tornado. The debris would not damage the fan blades or other structural components of the towers. The debris would be removed while the blades are being replaced.

9.2.5.2.3 Emergency Diesel Generators

The EDGs are located as a part of the RHR complex. Two divisional pairs of two EDGs are provided; only one divisional pair is required for a safe plant shutdown. The divisional separation is maintained in the EDG system; each EDG division powers only equipment of that same division, and is cooled by that same division. In this manner, no postulated single failure can affect more than one division. A more detailed description of the system is provided in Subsection 8.3.1.1.8 and Subsections 9.5.4 through 9.5.7.

The EDG building is a Category I reinforced-concrete structure. An isolation wall is provided between each EDG for fire and missile protection. Independent fire detection and automatic fire- fighting systems are provided for each EDG.

Diesel generator cooling water is supplied from the RHR reservoirs with each diesel generator supplied by its own pump. Supply lines are also independent for each diesel generator. The diesel generator service water pumps start and stop automatically in conjunction with the diesel generators. The diesel generator service water supplies cooling water to the lube oil heat exchanger, the engine inlet air cooler heat exchanger, and the engine jacket coolant heat exchanger. Demineralized water with corrosion inhibitors is used for the closed loop engine jacket coolant. Makeup is provided by the demineralized water storage tank. The diesel generator service water flows through the tube side of the three-stage heat exchanger. The first stage cools the engine inlet air coolant system, then the second stage cools the lube oil, and finally the third stage cools the jacket coolant.

9.2.5.2.4 Makeup and Blowdown Systems

The makeup system is provided to replace evaporation and blowdown losses during normal shutdown cooling. The makeup system is not designed to withstand accidental and natural phenomena nor to function in the event of a single failure. The system is designed to fill and replenish the reservoir as required, to prevent flooding of the reservoirs, and to prevent siphon losses from the reservoirs in the event of a pipe break. The water makeup and the decanting system are shown in Figure 9.2-7.

Normal makeup water will be supplied by the plant GSW system. Normal water level in each division of the reservoir will be maintained automatically by regulating supply valves.

Five GSW (7700 gpm each) pumps are available to supply makeup water, using installed GSW system piping.

The blowdown system is provided to control the buildup of solids in the reservoir water during normal shutdown cooling. The piping is designed to prevent siphoning from the reservoirs in the case of a line break or other incident. Decanting pumps route blowdown from the reservoir to the main condenser circulating water reservoir. Details of blowdown from the main condenser circulating water reservoir are described in Subsection 10.4.5. Details of effluent monitoring are given in Section 11.4.

9.2.5.2.5 Pumps

Each division of the complex is provided with full-size vertical turbine pumps and a separate reinforced-concrete pump house. All pumps are mounted to ensure adequate net positive suction head (NPSH) under all anticipated operating modes. The pump vendor indicates that a minimum submergence at Elevation 554.6 ft will prevent vortexing of the inlet water to the suction bell of the emergency diesel generator service water (EDGSW) pumps, assuming rated flow at 100°F. The other service water pumps, the EESW and RHRSW pumps, require a minimum submergence at Elevation 554.9 ft and 555.7 ft, respectively. The pump motors and electrical switchgear are located at Elevation 590 ft (New York Mean Tide, 1935), ensuring that the system will continue to operate even if the reservoir is breached during the postulated site high-water event. The pumps and pump houses are Category I construction. Column bracing is provided as required to limit stress to allowable values. All pumps are connected to the essential bus for redundant power supply.

The RHRSW pumps are started and stopped manually from the main control room. Each pair of pumps is capable of delivering 9000 gpm* to the RHR heat exchangers and then to the cooling towers. In the flooding mode, the head of water is sufficient to fill 300,000 ft^3 of air space in the drywell in 1 week, at a rate of approximately 250 gpm. In the event of failure of all four of the 10,000-gpm RHR pumps, the RHRSW pumps in Division II will be capable of backup to the RHR pumps in the LPCI mode at the rate of 3250 gpm.

The 1600-gpm EESW pumps are started automatically on demand of the EECWS. One 800-gpm diesel generator service water pump is provided for each of the four diesel generators.

These pumps start and stop automatically, corresponding to the operation of the respective EDG.

Since the reservoir is covered as shown in Figures 1.2-26 through 1.2-28 and 1.2-31, no automatic backwash strainers are provided on the pump discharge.

NOTE: *RHRSW pump flow reduces below 9000 gpm with time due to the RHR reservoir evaporative and drift losses.

9.2.5.2.6 Piping

The piping system consists of two redundant loops. Each loop serves one division of the system.

Separate piping systems supply the service water from the pumps to the RHR and EECW heat exchangers. The EDG units also have individual cooling water supply lines. The RHRSW and EESW return lines are combined into a single header for each division and are routed to the reservoir via the cooling towers. Diesel generator cooling water return lines for each division also join these two common return headers to the cooling towers. The piping conforms to the following conditions:

a. Piping is Quality Group C and Category I (except for the makeup line and the overflow line). Thermal stress and seismic analysis calculations are made in accordance with the ASME Code Section III, Subsection ND for Class 3 components

b. Pressure indicators are provided on the discharge side of the RHRSW and EDGSW pumps, with PCVs for minimum-flow protection. The PCV air operators are supplied with interruptible air, and the valves fail closed on loss of air

c. Heat removal rate is controlled by a remote manually controlled globe valve on the RHR (for RHRSW), an automatic control valve on the EESW, and a manually controlled globe valve on the diesel generator service water system

d. The cross tie required for primary containment flooding is located in Division II between the discharge side of one pair of RHRSWS pumps and the discharge pipe of the shell side of an RHR system heat exchanger

   Keylock dual isolation valves are provided on the cross tie and are normally closed to prevent the service water from entering the RHR system loop. A testable check valve is provided to prevent the RHR system water from leaking into the service water loop. The cross tie is sized for a flow of 3250 gpm. The two isolation valves are motor operated from the main control room

e. Provision is made for process radiation monitoring on the service water discharge of each RHR heat exchanger division

f. The EESW pumps are provided with spring to close pressure regulating valves for minimum flow protection.

9.2.5.3 Safety Evaluation

The ultimate heat sink consists of a single highly reliable water source with fully redundant cooling towers, pumps, and conduits capable of providing sufficient cooling for 7 days to permit safe shutdown and cooldown of the nuclear unit in the event of a design-basis accident. Procedures for ensuring continued cooling availability after 7 days are available. The RHR complex is designed for a single active or passive failure of any fluid system component without loss of safety function. The ultimate heat sink is capable of withstanding the effects of the most severe natural phenomenon associated with the site. Other applicable site-related events have been analyzed, including a single failure of man-made structural features. System failure analysis is summarized in Table 9.2-8.

9.2.5.3.1 Protection Against Natural Phenomena

The physical separation of RHRSWS Division I and Division II equipment, along with the single highly reliable water source with the two reservoirs cross-connected contributes to the reliability of system performance in the event of damage by natural phenomena (earthquake, tornado, storm, or flood) to provide a sufficient water source for 7 days.

9.2.5.3.1.1 Earthquakes

The RHRSWS is designed to meet Category I requirements. The method used in the seismic analysis of the RHR complex is similar to that of the reactor building as outlined in Section 3.7.

9.2.5.3.1.2 Tornadoes

A design-basis tornado and the missiles it might generate are described in Sections 3.3 and 3.5.

9.2.5.3.1.3 Freezing

The RHR building is designed to protect the reservoirs from direct exposure to winter weather. The floors of the RHR building cover a large portion of the reservoir surfaces and the remaining portion of the reservoirs is covered by floor gratings and tower baffles and is protected by high walls. In addition, 80 to 90 percent of the reservoir water is below the frost line. Drain lines provide passive freeze protection for the Mechanical Draft Cooling Tower (MDCT) spray distribution headers by allowing standing water to drain to the RHR Reservoir subsequent to MDCT operation.

The pump columns below the pump room are protected from freezing by an enclosure which is installed at the two open sides of the area below the pump room floor. The enclosed air volume temperature is locally monitored from the pump room.

During unit operation, the RHR complex reservoirs would receive heat from surveillance testing of plant systems such as the EDG, high pressure coolant injection (HPCI), and reactor core isolation cooling (RCIC) systems, and from other plant activities (such as operating the torus water management system). This heat would go directly to the RHR complex or the torus. Heat sent to the torus is removed by sending it to the RHR complex. During unit shutdowns, the RHR complex would receive reactor decay heat that is sufficient to prevent the reservoirs from freezing. The RHR complex also has cold weather bypasses around the cooling towers that can direct service water to the reservoirs instead of the RHR complex cooling towers. This would help retain the heat sent to the reservoirs.

The reservoir temperatures are monitored by readout in the control room and alarm at 43°F. The heat added to the reservoir during normal operation and testing is expected to be sufficient for this temperature to be exceeded during the winter. If needed, additional heat may be used to increase the reservoir temperatures by operating an EECWS or a temporary system installed for that purpose. Surveillance requirements of the reservoir temperature and required action in the event of low temperatures are contained in the Technical Specifications.

9.2.5.3.1.4 Floods

The reactor/auxiliary building and the RHR complex are designed to withstand the maximum postulated flood-water level and associated wave actions as described in Subsection 2.4.2.2 and Section 3.4.

The reservoir overflow is a nonsiphon floodproof port. Sidewalls are waterproofed to Elevation 590 ft (New York Mean Tide, 1935) and are above the Lake Erie stillwater level at the plant site. All active equipment that could be damaged by water (pump motors, switchgear, diesel generators) is located above the maximum flood-water level. The site flood considerations and plant protective structures are discussed in Subsections 2.4.2, 2.4.3, and 2.4.5.

9.2.5.3.1.5 Snow and Ice

The RHR complex roof structure is designed for the probable maximum snow and ice (including cooling tower drift) loads. The roof structure is capable of supporting a maximum loading of 70 lb/ft^2.

9.2.5.3.2 Protection Against Accident Phenomena

The RHR complex is designed to withstand the effects of the most severe natural phenomena associated with the Fermi plant site, as stated in Subsection 9.2.5.3.1 above. Other applicable site- related events such as river blockage, river diversions, reservoir depletion, or transportation accidents are not applicable to the design or postulated to occur. Flooding of the plant by surface runoff is not possible (Subsection 2.4.3.5). Transportation accidents are expected to have no effect on the complex because

a. The nearest main-line railroad and interstate highway are at least 3 miles from the plant site

b. The nearest ship channel is at least 4-1/2 miles from the plant site; the lake is of insufficient depth for commercial traffic in the plant vicinity; and the RHR complex is approximately 1100 ft inland from the lake shore

c. No significant aircraft operations occur in the plant vicinity.

A single failure of man-made structures such as the cooling tower or the pump house would not result in the loss of capability of the heat sink to accomplish its safety functions, because of the redundancy and separation of these components. A breach in the reservoir retaining wall above grade elevation would not compromise the reservoir's 7-day capacity since the reservoir capacity is contained below grade of 583 ft. A below grade structural failure would only result in a limited degree of water loss since the damaged reservoir(s) would leak only until the ground-water elevation is reached. The 7-day capacity includes allowance for a below grade structural crack in both reservoir basins. Stability of ground-water level is discussed in Subsection 2.4.13.

The RHR complex structures, systems, and components are designed so that the minimum performance requirements of the complex can be met in case the postulated turbine missile strikes the complex.

Typical missiles that could be ejected from the EDGs will be small auxiliary items knocked loose from the engine exterior by blows from within. The maximum velocity of the missiles would be 40 fps, with a maximum mass of 5 lb each. The walls of the EDG rooms are designed to withstand such missiles and contain them within the room. Refer to Subsection 3.5.1 for further discussion of these postulated missiles.

9.2.5.3.3 System Reserve Capacity

The ultimate heat sink system was originally sized to provide sufficient cooling for 30 days following an accident without make-up water addition to the RHR reservoir. Regulatory Guide 1.27 states that a UHS capacity of less than 30 days may be acceptable if it can be demonstrated that replenishment can be effected to ensure the continuous capability of the sink to perform its safety functions, taking into account the availability of replenishment equipment and the limitations that may be imposed on freedom of movement following an accident. In order to provide additional head for the service water pumps, a 7-day reservoir replenishment was reviewed and was found to satisfy the R.G. 1.27 guidelines.

The Fermi 2 UHS design evolved long before the post-TMI improvements in Emergency Preparedness. Those improvements are reflected in the Detroit Edison Radiological Emergency Response Preparedness Plan. One of the objectives of this program is effective and timely implementation of emergency measures. Detroit Edison now has the resources of the Emergency Response Organization to rapidly identify the need for reservoir replenishment and to direct procurement of material and field implementation. This change significantly improves the ability to provide reservoir replenishment within 7 days as it relates to resolving problems associated with freedom of movement following an accident or occurrence of severe natural phenomena.

The 7-day make-up provision for the RHR reservoir is consistent with the 7-day make-up provisions allowed for replenishment of the diesel generator fuel supply. Therefore, this period of time is sufficient to recover from the effects of natural phenomena such as tornado, storm, earthquake or flood and restore site access for replenishment activities.

The reservoir replenishment procedure requires that reservoir make-up be established within 7 days following exceeding the Technical Specification reservoir level limit. Make-up will be provided by the normal make-up system or using RHR Complex fire hoses. If these systems are not available, temporary equipment will be used. The necessary pumps and hoses are commercially available from many sources and 7 days is sufficient time to procure and install the equipment. The procedure requires redundant replenishment equipment so that a single failure will not interrupt make-up. Necessary equipment requirements and vendors are listed to allow rapid procurement. Temporary pumps are located in lower postulated post-accident dose rate areas so that access in available for monitoring and periodic refueling. The water source will be either Lake Erie, the Fermi 1 discharge canal, the circulating water reservoir, the on-site Quarry Lake or Swan Creek. Projected dose for hose installation is below allowable limits. The temperature and quality of make-up water is maintained to ensure that the service water systems and cooling towers perform as required. Siphon of the reservoir is prevented by ensuring that hoses are not placed into the reservoir water.

The reservoir will continue to store approximately 6 million gallons of water which was the previous 30-day supply. However, the level below that needed for 7 days of operation will be used to provide additional service water pump head margin. Therefore, if the level were to go below that required for 7 days of operation, a slow degradation in service water pump performance (discharge head) below design requirements would be possible.

The 7-day supply calculations utilize the Marley design and test data for cooling tower drift and evaporative water losses. In addition, the seven day supply also assumes a below grade structural crack in both reservoir basins and losses for EECW makeup using EESW. To maximize drift and evaporative losses, the reservoir basins are assumed to be cross-connected and both divisions of EDGs, RHR, EECW/EESW, and RHRSW cooling towers are assumed to be operating. The RHR heat exchanger was assumed to be clean (unfouled) to maximize heat loads on the ultimate heat sink. Constant historical worst-case meteorological data is used to compute evaporative water losses. The 7-day supply also assumes initial reservoir level at the technical specification limit of 580’-0” versus the normal operations level of between 582’-0” and 583’-0” which provides additional conservatism.

The RHR reservoirs are sized to provide for the evaporative and drift losses from the RHR cooling towers for 7 days following a design-basis recirculation line break, assuming a total loss of offsite power for the 7-day period. Evaporative losses are calculated as a function of cooling tower range using computer generated curves based on data supplied by the cooling tower manufacturer.

Since the cooling towers are designed to function largely by evaporative heat transfer, water loss due to evaporation is the largest contributor to water consumption. Drift losses (liquid droplet carryover in the air stream) are assumed to be 0.05 percent of liquid flow. Drift losses in combination with the other secondary contributors to water consumption (i.e. reservoir leakage and EECW makeup*) are small compared to evaporative loss.

* The cooling load for the spent fuel pool is not included since the normal burden is insignificant. When all or part of the core is unloaded, the cooling load in the spent fuel pool will increase, and the cooling load imposed by decay heat in the core will decrease proportionately.

The RHR reservoirs are nominally maintained between 583 ft and 582 ft elevation by an automatic makeup system. The Technical Specifications limit is established at 580 ft, or 5,980,000 gal. The 7-day water loss will result in a water level above Elevation 567'-6". This level is above the minimum submergence level required for the service water pumps as indicated in Subsection 9.2.5.2.5.

The heat load into the suppression pool as a function of time for the first 24 hours post LOCA was taken from the suppression pool peak temperature calculations described in Section 6.2.1.3.3. This suppression pool heat load includes decay heat (based on a pre-trip power level of 3499 MWt, which is 102% of 3430 MWt), sensible/blowdown energy, and RHR and core spray pump heat. The heat input to the suppression pool after 24 hours is from decay heat and pump heat. The decay heat after 24 hours is determined using the Standard Review Plan, Section 9.2.5, Branch Technical position ASB 9-2. The fractions of decay heat (as a fraction of operating power) versus time were converted to decay heat using a pre-trip reactor power level of 3499 MWt, which is 102% of 3430 Mwt.

The heat from the station auxiliary systems includes heat from the EECWS, the EDGs, and pump energy. The heat from the EECWS includes the emergency core cooling system (ECCS) pump cooling, control room air conditioning, air compressor cooling, ECCS room coolers, thermal recombiner area coolers, and standby gas treatment system (SGTS) room coolers. The thermal recombiner units are retired in place, de-energized, and isolated from primary containment with redundant locked-closed isolation valves. The associated area coolers are retained and credited as a heat sink for post-accident environmental conditions. The heat rejected by the EDGs is based on loads commensurate with the function required during each stage of the 7-day period. The pump energy created by the work input of the RHR, core spray, RHRSW, EECW, EESW, and EDGSW pumps has been considered.

The LOCA coincident with a loss of offsite power is the worst-case condition for reservoir water usage because:

a. The main condenser is unavailable for removal of any core decay energy or primary system energy

b. The EDGs run at the highest loads, resulting in highest heat rejection to the complex

c. The EECWS is operating (in lieu of RBCCWS)

The reservoir is not sized to supply the water required for flooding the core or primary containment to allow access to the core for accident recovery. Flooding of the primary containment is a long-term action, initiated many days or weeks after an accident, following an administrative decision. Such a decision would not be made until offsite power is available and the makeup water system is restored to service.

9.2.5.3.4 Multiple Water Sources

Two half-sized reservoirs are provided, each with a capacity of 3,410,000 gal of water at elevation 583 ft. Redundant penetrations cross-connect the two reservoirs and permit access to the total UHS water supply in the event of a mechanical failure in one division. Each division of the system has a separate piping system with adequate separation such that a failure of one will not induce failure of the other. The reservoirs are designed to withstand all applicable site-related natural and accidental phenomena, and there is no retaining "dam," as such, to fail. The water in the UHS is stored below site grade level and approximately 90 percent of the total water volume is below site ground-water level. Therefore, it is concluded that there is an extremely low probability of losing the 7-day cooling capability of the UHS.

9.2.5.4 Tests and Inspections

Initial construction tests such as hydrostatic leak tests of the RHRSWS were conducted per applicable code requirements. Initial system flow checks, valve operability, instrumentation and control loop checks, and alarm setpoints were done in accordance with the Preoperational Test program as discussed in Chapter 14. After startup, a test will be run to observe the heat exchanger (including cooling tower) performance. Periodic tests are made to assess continuing pump performance and to demonstrate piping system integrity. The RHRSWS is periodically checked during its normal system function of cooling down the plant, such as during refueling or other outages. The EESWS will be tested in conjunction with the EECWS. The diesel generator service water system is tested in conjunction with the diesel generator testing. The reservoir and cooling tower are periodically inspected for macro and micro biological fouling and are treated, as required. Sampling and surveillance for control of dissolved solids and macro and micro biological fouling are performed by the Chemistry Section.

9.2.5.5 Instrumentation

System temperatures, pressures, and flows are monitored either locally or in the main control room. Pressure, temperature, and flow indicators are provided with local readouts. Pump and fan motors and controls incorporate standard protection devices.

Makeup for the RHRSW reservoir is automatic (except under accident conditions), controlled by level monitors in the two RHRSW reservoir divisions. These level monitors signal low-level alarms in the main control room.

9.2.6 Condensate Storage and Transfer System

9.2.6.1 Design Bases

The condensate storage and transfer system is designed to store and distribute condensate and demineralized water for use throughout the plant during normal and shutdown plant conditions. To provide for high plant availability, two full-capacity 600,000-gal storage tanks are provided, one designed as the normal storage tank and the other as the return tank. Demineralized water is stored in a 50,000-gal storage tank.

The condensate storage and return tanks are located near the turbine building and the auxiliary boiler house. They are arranged to permit gravity feed to condensate supply pumps and to the HPCI, RCIC, CRD, standby feedwater (SBFW), and core spray systems. During normal station operation, hotwell level is raised as necessary by vacuum dragging water to the hotwell from the CST or CRT. When the plant is shutdown, or when a greater flow is required, the normal, or if necessary the emergency, hotwell supply pumps will start and stop automatically depending on hotwell level. The condensate storage tank is designed to deliver its last 150,000 gal only to the HPCI or RCIC system (see Section 6.3.2.6).

A containment wall surrounds the tanks. Surveillance of surface conditions and radioactive content will be performed during plant operation.

The makeup demineralizer storage tank is located near the auxiliary boiler house and gravity feeds to the demineralized water transfer pumps and jockey pump. These pumps provide demineralized water to the service risers and the condensate storage tank.

Collection and distribution piping for the condensate and demineralized water is carbon and stainless steel. A cathodic protection system is supplied for the piping. The condensate tanks are fabricated of corrosion-resistant, high-strength aluminum alloy.

Piping to the HPCI and RCIC systems conforms to Quality Group B standards and is built to ASME Section III, Class 2, requirements. The balance of the condensate storage facilities conforms to Quality Group D standards and is built to ASME Section VIII and ANSI B31.1.0 code requirements. The tanks are designed to withstand a 100-mph wind when empty. They conform to USAS B96.1, "Welded Aluminum-Alloy Field-Erected Storage Tanks," code requirements. A minimum water temperature of 40°F is maintained in the insulated condensate storage tank by steam from the auxiliary boiler.

9.2.6.2 System Description

The condensate storage and transfer system, as shown in Figure 9.2-10, consists principally of two large storage tanks and three pumps, with associated receiving and distribution lines, one demineralized water tank, and three pumps with associated receiving and distribution lines. Component design parameters are given in Table 9.2-9. The condensate return and the condensate storage tanks are 600,000-gal aluminum tanks with open vents. The condensate storage tank is insulated and has sufficient heating capacity to maintain a water temperature of at least 40°F, which is the design limit for thermal shock to the RPV nozzles. Both tanks are located inside a containment wall near the turbine building. The condensate storage tank receives demineralized water from the demineralized water makeup system and may also receive low-conductivity water from the condensate return tank. There is also a normally closed balance line connecting these two tanks to allow gravity transfer from one tank to the other above the 150,000-gal limiting level of the storage tank.

Containment for any condensate loss that might be experienced is provided by a containment wall in the immediate area around the condensate storage tanks, as shown in Figure 9.2-11. All valves associated with either condensate storage tank are located in valve pits at the base of the tank. Any leakage into either valve pit is automatically pumped through a 4-in. drain line to the waste collector tank in the radwaste building.

A single wall, 3 ft high above the normal grade level, encloses both condensate storage tanks. This forms a contained area approximately 109 ft wide by 232 ft long. The contained area is also excavated 3 ft below grade level. The enclosed area has been sealed with a Hypalon liner (waterproof barrier) to contain all spillage of contaminated water from the condensate system and prevent it from entering the soil in the condensate storage tank and condensate return tank diked area.

Relief valves are installed in the condensate return tank valve pit to prevent inlet piping overpressurization. A 30 gpm relief valve discharges directly to the CRT valve pit. Relief valves with 600 and 5000 gpm relief capacities discharge into the lined dike area surrounding the CRT and CST for subsequent cleanup and processing.

Direct access to Lake Erie by lost condensate seeping into the ground is prevented by the clay fill seal beneath the shore barrier. Initial movement of any seepage would be downward to mix and dilute with the ground water from the dolomite aquifer. Thereafter the diluted material would move into and through the aquifer at the same rate of flow and direction of movement as the transient ground water. The direction of movement would be to the east, at a rate of 0.24 ft per day or less. In essence, this would be the same sequence of events as that documented for the loss of all radwaste water to the aquifer in Edison's response to AEC Question 10.2 in the Fermi 2 PSAR, except that the condensate water would be orders of magnitude less radioactive.

The storage tanks are provided with horizontal slots (weirs) in the sides of the tanks with ducting to channel overflow down the side of the tank and eliminate spray. An alarm system is provided that alarms in the control room to indicate that a tank is in the process of overflowing. This alarm system is independent of any other instrumentation or alarms associated with the condensate storage tank or condensate return tank.

Recycle streams are treated and monitored prior to transfer to the condensate return tank. If water in the condensate return tank requires further treatment, it can be transferred to the radwaste system by gravity for processing, or it can be sent through the polishing demineralizer via the hotwell and condensate system.

It is possible for the following water sources to be transferred directly to the condensate tanks:

a. Return from radwaste system

b. Return from CRDs

c. HPCI pump test return

d. RCIC pump test return

e. SBFW pump test return

The inlet valves on the condensate storage tank and condensate return tank are provided with an interlock to prevent the two valves from being simultaneously closed. This interlock provides protection against overpressurization of the tank inlet piping by the CRD, HPCI, RCIC, or SBFW pump.

Treated recycled condensate water is normally routed to the condensate return tank. Typical sources are:

a. Reactor well drain

b. Return from drywell seal rupture

c. Spent fuel storage pool drain

d. Main condenser high-level relief

The demineralized water makeup system supplies only the heated condensate storage tank, the auxiliary boiler, and the demineralized water distribution system.

The condensate storage tank is sized for the following duty:

Fuel pool and reactor well	410,000 gal
Reserve for the HPCI and RCIC pumps (see Section 6.3.2.6)	150,000 gal
Additional reserve	40,000 gal
Total	600,000 gal

The condensate storage tank provides a source of water for the HPCI, RCIC, SBFW, core spray, and CRD pumps. Either condensate tank can supply the low-pressure turbine hood spray pump through a common header.

The condensate return tank is the same size as the condensate storage tank in order to provide operational flexibility so that one tank may be substituted for another for certain functions as described herein. The condensate return tank has sufficient capacity for:

Fuel pool and reactor well	410,000 gal
Additional reserve	190,000 gal
Total	600,000 gal

The primary function, however, of the return tank is to receive condensate from the plant and to store any temporary excess condensate. Excess water from the condenser hotwell is normally relieved to this tank. During normal station operation, hotwell level is raised as necessary by vacuum dragging water to the hotwell from the CST or CRT. When the plant is shut down, or when a greater flow is required, the normal, or if necessary the emergency, hotwell supply pumps will start and stop automatically depending on hotwell level. Makeup to the hotwell is normally supplied by the hotwell supply pump drawing condensate from the condensate return tank. During normal station operation, the hotwell supply pump starts and stops automatically, depending on the hotwell level of the condenser.

Condensate for distribution to other plant areas is supplied from the condensate pump discharge header, downstream of the condensate polishing demineralizers, via a pressure-reducing valve. Condensate at 100 psig feeds the condensate storage system distribution header.

The condensate storage and transfer system distribution pumps are housed in the turbine building and are supplied from the same header, feeding from either condensate tank. The three pumps required for distribution are described as follows:

a. The condensate storage jockey pump (one 100-gpm pump) is used to maintain condensate pressure during startup/ shutdown and supply water to the condensate distribution header whenever the supply from the condensate system is not available. The condensate storage jockey pump has minimum flow protection to provide sufficient pump cooling in the event of low or zero flow in the condensate distribution system. The condensate distribution system supplies the following:

    1. Radwaste building

    2. The turbine building backwash tank

3. A reactor building supply header. This portion of the reactor building supply header is intended for preoperational flushing and fill, and not for makeup.

   It provides RHR system flushing and maintains the RHR keep fill system. As such, the various distribution branches to the following items are normally valved off:

   (a) RBCCW makeup tank

   (b) EECW makeup tank (two).

The reactor building supply header supplies makeup to the following:

   (a) Cleanup phase separators

   (b) Reactor water cleanup filter-demineralizer

   (c) Fuel pool skimmer surge tank

b. The normal hotwell supply pump is a 600-gpm pump discharging to the main condenser hotwell level control station. The normal hotwell supply pump can be used to supply water to the condensate distribution system when either of the other two sources (jockey pump or condensate system supply) are insufficient or out of service. The normal hotwell supply pump has a minimum flow valve which provides flow protection for a limited time. Should plant outage activities require prolonged operation of the pump with minimum flow, a supplemental, temporary flow path is established to provide adequate minimum flow protection.

c. The emergency hotwell supply pump is a 2000-gpm pump with an independent distribution line to the main condenser hotwell and branch to the TBCCWS for flushing. This emergency pump can also discharge into the condensate return line to the storage tanks. In this way, it can be used to transfer condensate water from one tank to the other.

The makeup demineralized water tank supplies demineralized water for the following:

a. Condensate storage tank

b. Auxiliary boiler deaerator makeup

c. TBCCWS makeup

d. RBCCWS makeup

e. EECWS makeup

f. Standby liquid control tank in reactor building

g. Service risers in turbine building, reactor building, auxiliary building, and radwaste building

h. Plant instrument backflush

i. Cask washdown in reactor building

j. Health Physics and chemistry laboratories

k. Deleted

l. Emergency showers in the radwaste building

m. Core spray system charging, and for maintaining the keep fill system.

The demineralized water is distributed to the condensate storage tank and throughout the plant by two 100-gpm transfer pumps and by a 20-gpm jockey pump. Normally the jockey transfer pump operates continuously with bypass flow unloading on low water demand. The jockey pump thereby provides a minimum hydrostatic pressure of 30 psi throughout the system. On increasing flow demand (system pressure decreases), one 100-gpm transfer pump starts automatically. If flow demand is still not satisfied and header pressure continues to drop, the second transfer pump starts.

9.2.6.3 Safety Evaluation

Adequate protection from environmental conditions is provided by designing the tanks to withstand a 100-mph wind when empty. The tanks are designed for -10°F to 95°F ambient temperatures.

Condensate water within the plant is separated from the demineralized water system and confined to areas of limited access. Health Physics surveillance is maintained on this equipment. An exclusion fence surrounds the condensate storage and condensate return tanks. Because of these conditions, personnel injury from radiation is extremely unlikely. Construction materials are corrosion resistant and should serve without failure during the 40-year life of the plant. The tank is constructed of aluminum alloy, and the HPCI and RCIC pump suction lines are stainless steel. Carbon steel piping is provided with cathodic protection.

The design of the demineralized water makeup system precludes radioactive contamination of the storage tank. The transfer line between the uncontaminated demineralized water storage tank and the potentially contaminated condensate storage tank terminates in the condensate storage tank above the normal operating water level. This feature, along with check valves at the transfer pump discharge lines and the normally closed motor-operated isolation valve, provides reasonable assurance against inadvertently contaminating the demineralized water makeup system. Contamination of the potable water system is prevented by an open break between it and the demineralizer water makeup system.

Active functioning of the condensate storage and transfer system is not required during a reactor shutdown. Suction for RCIC (or HPCI) can be manually transferred from the condensate tank to the Category I suppression pool. In addition, on low level in the tank, suction is automatically transferred. Therefore, it is not necessary to install redundant power sources and redundant water sources throughout the condensate system. Nevertheless, the system is designed with certain redundancies (e.g., cross- connections, standby pumps) to reduce, as far as practical, the probability of causing a plant shutdown because of some failure in the condensate storage and transfer system.

Normally, water from the plant is returned to the condensate return tank after treatment and analysis. The water in the return tank will be analyzed to ensure that it is of sufficiently high quality. In the event that water has excessive radioactivity or conductivity readings, it will be transferred to either the polishing demineralizer via the hotwell or to radwaste for further treatment. These operating procedures will ensure a source of high-quality water for station operation.

Leakage is controlled by utilizing welded construction for the storage tanks, and as much as is practicable for the piping. Each penetration on the tank is supplied with an isolation valve. Levels in the two storage tanks are recorded and alarmed in the main control room.

Accidental release of liquids in the condensate storage tank would not result in concentrations in Lake Erie exceeding the limits of 10 CFR 20. Any accidental release that is not retained by the lined containment around the storage tanks will infiltrate the site fill; however, horizontal permeability of the soil will provide sufficient holdup to attain the required decontamination factor by radioactive decay before entering Lake Erie. No credit is taken for filtration or ion exchange through the soil.

9.2.6.4 Tests and Inspections

Initial construction tests such as hydrostatic leak tests were conducted per applicable code requirements for the condensate storage system. Initial system flow tests, valve operability, instrumentation and control loop checks, and alarm setpoint checks were performed in accordance with the Preoperational Test program as discussed in Chapter 14.

Periodic tests are conducted to confirm pump performance and operation of automatic controls. Inspection for system leakage is coincident with pump testing and routine monitoring activities.

9.2.6.5 Instrumentation

Pump motors are equipped with standard controls and protective devices and are controlled and monitored from the main control room. Each pump's flow is indicated locally. The level and temperature of the condensate storage tanks and the demineralized water storage tank are continuously recorded in the main control room. High-and low-water-level and overflow alarms are provided. Level and temperature indicators are provided locally at the tanks.

The storage tank temperature can be manually controlled from the main control room by continuously circulating stored condensate through the condenser hotwell.

9.2.7 Cooling System for Turbine Auxiliaries

9.2.7.1 Design Bases

The TBCCWS is designed to remove heat from auxiliary equipment housed in the turbine building. The TBCCWS is cooled by the GSW system and makeup is supplied by the demineralized water system. The TBCCWS is designed to operate at a lower pressure than the GSW system to prevent leakage to the environs.

The TBCCWS is nonseismic and is constructed in compliance with standards for Quality Group D components. This criterion is met by designing the system to ASME Section VIII and ANSI B31.1.0 code requirements.

9.2.7.2 System Description

The TBCCWS, as shown in Figure 9.2-12, consists of two 100 percent-capacity TBCCWS heat exchangers and three 50 percent-capacity pumps. The TBCCWS component design parameters are listed in Table 9.2-10. During normal operation, one heat exchanger and two pumps operate to remove all the equipment heat loads. The third pump is in standby and is designed to be started manually on low TBCCWS pressure. The TBCCW supply header temperature is maintained by a temperature control valve modulating the GSW flow through the TBCCW heat exchanger. System pressure is controlled by a differential PCV located in the bypass line between the suction and discharge headers of the TBCCW pumps. Makeup to the system as well as system expansion and contraction due to load changes are provided by a makeup tank. Makeup water is automatically supplied via a tank level control valve from the demineralized makeup water system. A pressure-regulating valve maintains nitrogen overpressure in the tank. Nitrogen is provided to prevent the introduction of oxygen into the system, thereby retarding corrosion of the closed cooling water system, and to maintain a positive suction head on the pumps.

Turbine auxiliaries impose a maximum cooling load on the TBCCW heat exchanger of approximately 45 x 10^6 Btu/hr during normal operation. This requires approximately 9000 gpm of GSW, assuming a maximum GSW temperature of 85°F. Circulation on the TBCCW side of the heat exchanger is approximately 6000 gpm; design temperatures are 110°F in and 95°F out. Normal operating temperature is 80°F out. The operating temperature range is 75°F to 88°F as measured at the TBCCW pump suction. The TBCCW header temperature control high-alarm setpoint is 88°F and the low-alarm setpoint is 75°F.

The GSW is not used directly because the relatively high impurity level in this system might result in fouling of equipment heat transfer surfaces. Furthermore, the intermediary loop between potentially contaminated turbine auxiliaries and the GSW system provides additional protection against radioactive water leakage into the environment. The following equipment is cooled by the TBCCWS:

a. First floor:
    1. Station air compressors with associated coolers
    2. Heater feed pump lube oil coolers
    3. Heater drain pump motors
    4. Condenser mechanical vacuum pumps
    5. Oil coolers for each reactor feed pump and turbine drive
    6. Coolers for air conditioning unit serving the Health Physics laboratory and radwaste control room
    7. Cooler for the chemical sampler

b. Second floor:

1. Generator bus duct cooler heat exchangers
2. Hydrogen seal oil coolers
3. Stator winding coolers
4. Excitation equipment area air coolers
5. Offgas system aftercoolers.

c. Third floor:

1. Ring water coolers for the offgas vacuum pumps
2. Adsorber room air conditioner cooler for the offgas system
3. Unitized actuators cooling.
4. Offgas Chiller Refrigeration Unit N6200D010 Condenser.

9.2.7.3 Safety Evaluation

Turbine auxiliaries housed in the turbine building are not considered essential to safe reactor shutdown. An alternative power source for TBCCW pumps and controls is not required. Because a reactor shutdown can be safely executed without depending upon turbine auxiliaries, no alternative water supply to the TBCCWS is required. Redundancy is therefore properly limited to two normally operating pumps and one standby pump to facilitate periodic tests and maintenance and to ensure plant availability.

The design of the TBCCWS avoids direct application of GSW to cooling components and heat exchangers. This excludes impurities from the turbine auxiliaries and service piping and reduces the chances of long-term degradation from fouling or corrosion. Additionally, corrosion inhibitors are added for pH and oxygen control. Alternatively, the TBCCW system may be maintained with pure demineralized water only with no chemicals added.

The TBCCWS operates at a lower pressure than does the GSW system to protect against leakage into the GSW system. Leakage from the TBCCWS into the building is detected by a low-level alarm in the makeup tank and by an alarm on the makeup level control valve stem position. Excessive opening of the makeup valve is indicative of a substantial system leak. Inleakage of GSW will be indicated by a high-level alarm in the makeup tank.

9.2.7.4 Tests and Inspections

Initial construction tests such as hydrostatic leak tests were conducted per applicable code requirements for the TBCCWS. Initial system flow distribution, valve operability, instrumentation and control loop checks, and alarm setpoints were done in accordance with the Preoperational Test program as discussed in Chapter 14. Heat exchanger performance is observed during plant operation using actual system heat loads.

Instruments and controls are inspected periodically. No periodic leak tests are planned since the system is continuously operating and pressurized. Periodic visual inspection of the system will detect minor leakages, such as those from valve stems, flanges, and instrument tubing.

9.2.7.5 Instrumentation

Pump motors are equipped with standard controls and protective devices, and are monitored from the main control room. Readouts to observe pressure and inlet and outlet temperatures in the TBCCW are provided in the main control room. Interlocks are provided on the TBCCW pumps to prevent their starting on low makeup tank level and/or low suction pressure. The temperature of the TBCCWS during operation is controlled by modulating the discharge flow of GSW through the TBCCW heat exchangers. Closed loop pressures are regulated by pump unloading (bypass) valves.

High- and low-level alarms are provided on the makeup tank as are alarms for low system pressure, to alert the operator of system leakage or loss of nitrogen capping.

9.2.8 Torus Water Management System

9.2.8.1 Design Bases

The torus water management system (TWMS) is designed to provide thermal mixing of the torus water, torus water volume inventory control, torus water quality maintenance, and to drain and fill the torus to facilitate inside torus recoating, inspections, and repair work. The TWMS design flow, makeup, and discharge rates are based on draining or filling the 1,000,000 gal of torus water in 48 hr and circulating the torus water at a rate of 500 gpm (maximum). Figure 9.2-13 is the system schematic.

The TWMS pumps (refer to Table 9.2-11) are located in the subbasement of the reactor building in the HPCI room. The interconnected piping required to perform the circulating, cleaning, draining, and filling functions of the TWMS is located in the reactor, turbine, and auxiliary buildings.

The TWMS primary containment penetrations and the associated isolation valves are classified as ASME Section III, Class 2, and designated as Category I. The balance of the TWMS is classified as ASME Section VIII for pressure vessels and ANSI B31.1.0 for piping, and is designated as nonseismic.

9.2.8.2 System Description

The TWMS pumps take suction from two torus connections placed at a 180° angle around the torus from each other. Water is similarly returned to the torus using two different torus connections also at a 180° angle from each other. These torus connections were selected to maximize thermal mixing efficiency to the extent practical.

The TWMS normally maintains torus water quality. The TWMS pumps will transfer torus water to the condensate system at the main condenser continuously or intermittently, as selected by the operator. Clean condensate from the condensate reject line to the condensate storage tank provides return water to the torus. The rate at which torus water is transferred to the condensate system for cleaning and subsequently returned to the torus is regulated by the control room operator to maintain the proper torus water level and desired quality. One facet of the primary containment monitoring system provides the operator with a wide-range torus water level indication and one aspect of the TWMS provides a narrow-range torus level indication.

As required for recoating, inspections, and repair work, the TWMS is used to drain and fill the torus. Torus draining is accomplished by using the TWMS pumps to transfer torus water directly to the main turbine condenser for storage. Torus filling is accomplished using a condensate system pump to transfer water back to the torus through the TWMS return piping. During the filling operation, one of the eight polisher/demineralizers may be placed into service to clean the water returned to the torus.

9.2.8.3 Safety Evaluation

The TWMS is not required for reactor shutdown or accident mitigation and as such is not a safety-related system. However, the availability of the TWMS increases the reliability and availability of the plant. The reliable operation of the TWMS is ensured through the redundancy of the TWMS pumps (two at 250 gpm each) and two 50 percent-capacity suction and discharge lines with required isolation valves.

To ensure that the TWMS will not impair the safety function of the torus, the TWMS primary containment isolation valves automatically close. These valves trip in response to selected primary containment isolation system isolation signals (refer to Table 6.2-2) and to the high-high level alarm of the drywell floor drains or the torus room floor drain sump. The power supplies for containment isolation valves are arranged so that loss of one supply cannot prevent automatic isolation of a TWMS suction or return line when required. Torus water level and temperature limits and alarms are monitored and provided by the primary containment monitoring system, which is designated as a safety-related system.

Administrative controls and other constraints are provided to ensure that the suppression pool is not drained by the TWMS when the need for the ECCSs could be required. The limiting conditions for the draining of the suppression pool are specified in the Technical Specifications. Operational procedures for the TWMS include detailed information on the draining of the suppression pool. The TWMS pumps will automatically trip, preventing a torus water-level decrease, when the torus water level low-low alarm setpoint is reached at an elevation of 556.83 ft (2 in. below normal level) except when in the torus drain mode of TWMS.

Because the TWMS is considered a moderate energy system, flooding and spraying effects from postulated cracks in the system piping have been evaluated. Flooding and spraying effects have been determined to be enveloped by the limiting RHR pump discharge line crack (refer to Subsection 3.6.2.3.4.1.2). System overpressure protection is maintained by pump discharge relief valves.

9.2.8.4 Tests and Inspections

Initial system flow checks, valve operability, and instrumentation and control loop checks were performed in accordance with the test program as discussed in Chapter 14. A flow meter in the TWMS transfer line to the condensate system is provided to indicate the torus water removal rate and establish TWMS pump operability. Conductivity monitors on the discharge side of the polisher/ demineralizers provide continuous monitoring of the water returned to the torus. Minor leakages such as those from valve stems, flanges, and instrument tubing are detected through visual inspection.

9.2.8.5 Instrumentation

The TWMS is operated from the control room. Flow meter indication of the torus water flow to the condensate system is provided in the main control room. Position indication for the TWMS primary containment isolation valves and the control valves on the transfer and return lines are also provided in the main control room. Torus water management system controls and instrumentation are augmented by the containment monitoring functions of the primary containment monitoring system and the water quality monitoring devices in the turbine building.

9.2.9 Supplemental Cooling Chilled Water System

9.2.9.1 Design Basis

The SCCW system is a closed cooling water system which during normal plant operation will provide chilled water that will be used to lower the temperature of the cooling water supply to EECW that is normally cooled by RBCCW. The SCCW system is designed to remove 100 percent of the normal heat produced by the EECW system during normal operation. The SCCW system transfers the heat it has removed to the GSW system via mechanical chillers.

The SCCW system is designed to operate at a higher pressure than the RBCCW system to provide protection against potential outleakage of radioactive contaminants from the RBCCW system.

The SCCW system is classified as a non-nuclear system and is constructed in compliance with standards for Quality Group D components. This criterion is met by designing the system to ASME Section VIII and ANSI B31.1.0 code requirements. The system is nonseismic.

9.2.9.2 System Description

The SCCW system, as shown on Figure 9.2-14, is designed to remove heat from the RBCCW system headers that supply cooling water to the EECW headers and from the fan coil that cools the SCCW chiller area (turbine building basement).

The SCCW system consists of three 50 percent-capacity chillers (two normally operating), only one may be operating during low load conditions, three 50 percent-capacity chilled water pumps (two normally operating), a chilled water expansion tank and associated valves and controls. The system is designed to be started when RBCCW temperature first exceeds its nominal control temperature and left in operation until the RBCCW temperature can be maintained at or below its nominal control temperature. Table 9.2-12 provides SCCW system design parameters.

After a manual startup from the local control panel, system operation does not require operator intervention unless it is desired to rotate equipment that is operating or a trouble signal is annunciated in the control room. In the event a chiller were to trip, the standby chiller would automatically start. A trip of one of the operating chilled water pumps would automatically start the standby pump. The chiller trip logic is tied to the chilled water pump operation to ensure an adequate number of pumps are operating.

An expansion tank is provided to accommodate changes in water volume as the temperature of the chilled water varies. This tank will also maintain a constant chilled water pump suction pressure.

The demineralized water system will provide system make-up water.

9.2.9.3 Safety Evaluation

The SCCW system is not required for the safe shutdown of the reactor or for accident mitigation. Therefore, the SCCW system is not designed for a single active or passive failure as required of a safety-related system, but sufficient redundancy and automatic protective features are provided to ensure efficient system operation and availability. Since the SCCW system is not an engineered safety feature (ESF), it is not powered by an essential power bus.

The SCCW system is involved in normal plant operation. During periods when RBCCW temperature is above its nominal control point, it may be used to cool the cooling water supply to EECW that is normally cooled by RBCCW. If the SCCW system trips off or is removed from service, RBCCW and/or EECW, as required, will perform the cooling function. The RBCCW system is nonsafety and its pumps are not powered by an essential bus. If the RBCCW cooling water temperature is not available, the EECW and EESW systems can be used to provide the required cooling of the drywell and other equipment. The EECW and EESW systems are powered off essential buses. A failure of the SCCW system will not prevent a safe shutdown of the reactor.

The possibility of radioactive contamination of the SCCW system is reduced by using plate heat exchangers between the RBCCW supplemental cooling and SCCW systems. The SCCW system operates at a higher pressure than the RBCCW supplemental cooling system and therefore any leakage would be from the SCCW system into the RBCCW supplemental cooling system. The SCCW system does not contain a radiation monitor. Due to the design of a plate type heat exchanger, any leakage is likely to be to the ambient (auxiliary building) rather than to the SCCW system. The SCCW system is manually sampled to detect any developing problems. Should the barrier between RBCCW and SCCW fail, there is no potential release path to the environment. The SCCW system interfaces with the GSW system via mechanical chillers. The closed refrigerant system which is between the SCCW and GSW systems has a relief valve which exits the turbine building. However, that relief valve setpoint is much higher than any pressure that can be developed in the SCCW system and therefore does not constitute a release path.

9.2.9.4 Tests and Inspections

Initial construction tests such as hydrostatic leak tests were conducted per ANSI B31.1.0 code requirements. Initial system flow distribution, instrumentation and control loop checks and alarm setpoints were performed in accordance with the design change test program.

9.2.9.5 Instrumentation

Sufficient instrumentation is provided to allow the plant operator to assess the status of the SCCW system. Three alarm windows are provided in the main control room to alert the operator to system trouble. The specific details regarding these alarms are provided by control panels located in the vicinity of the chiller units.

In the event a chiller was to trip, the standby chiller would automatically start. A trip of one of the operating chilled water pumps would automatically start the associated standby pump.

During the normal mode of operation when both supplemental cooling loops are in operation, interlocks have been provided to prevent the operation of a chilled water pump should no chillers be in operation. In addition, should all operating chillers trip and the standby unit not start, the operating chilled water pumps will trip.

Design pressure, psig	100
Design temperature, °F	140
Operating pressure, psig	36
Internal volume, gal	600
Liquid volume, gal	300
Pressurizing gas	Nitrogen
Material	Carbon steel SA-515 Grade 70

EECW Makeup Pump

Number provided	Two
Type	Motor driven horizontal centrifugal, vert. disch
Power	480 Vac/3Ph, 3.0 HP
Design pressure	60 ft TDH
Design flow	20 gpm
Material	Stainless steel

EECW Makeup Pressure Regulator Valve

Number provided	Two
Type	Discharge regulator, self-actuated
Size	1-1/2 in.
Setpoint (discharge)	36 psig
Maximum design flow	25 gpm (Div I): 15 gpm (Div II)
Minimum design flow*	10.4 gpm (Div I): 8.3 gpm (Div II)`
Design makeup flow to EECW Head Tank*	2.7 gpm (Div I, or Div II)

* Coincident flows

TABLE 9.2-4 REACTOR BUILDING CLOSED COOLING WATER AND EMERGENCY EQUIPMENT COOLING WATER SYSTEMS FAILURE ANALYSIS

Component	Failure Mode	Consequences on Safety
RBCCW pumps	Loss of pumping due to loss of offsite power	Loss of offsite power automatically starts both EECW pumps and initiates isolation of the nonessential loads.
RBCCW pumps	Trip on low suction pressure or low makeup tank water level	Each EECW pump will start on low differential pressure between its respective supply and return headers. Isolation of nonessential loads is also initiated. (a)
RBCCW piping	Pipe rupture in the RBCCWS	Each EECW pump will start on low differential pressure between its respective supply and return headers. Isolation of nonessential loads is also initiated. (b)
EECW pump	Fails to start due to failure of one set of diesel generators	Redundant full-capacity EECW loop is provided, powered off the second emergency bus.
EECW piping	Piping leak or rupture in the EECWS	Automatic makeup valve will open to maintain tank level. If leak exceeds makeup capacity, the low tank level or low suction pressure will be alarmed. Redundant full-capacity EECW loops are provided that are isolable from each other.
EECW Makeup Tank	Loss of nonsafety-related demineralized water and nitrogen inerting systems	Safety related EESW makeup water to the makeup tank restored by automatic start of EECW makeup pump if makeup tank has low pressure or level and makeup tank isolation valve is open, and normal pump suction pressure is achieved. Nitrogen pressure in the makeup tank will be automatically maintained by the backup nitrogen supply for Division I until the makeup tank Nitrogen leaks off and the Makeup tank is filled and Pressurized with EESW water via the makeup pump

TABLE 9.2-4 REACTOR BUILDING CLOSED COOLING WATER AND EMERGENCY EQUIPMENT COOLING WATER SYSTEMS FAILURE ANALYSIS

Component	Failure Mode	Consequences on Safety
Isolation valve between EECW and RBCCW [P4400F601A(B), P4400F603A(B)]	Fails to close for isolating nonessential loads	Water may be lost from the EECW loop if a break exists in the RBCCWS. Redundant EECW loop available.
Isolation valve on makeup tank outlet line	Fails to open on automatic system initiation	Low suction pressure to the EECW pump may alarm, requiring manual shutdown, but the other redundant EECW division is available. Makeup pump is disabled.
Isolation valve on nonessential load in essential loop	Fails to close on demand	No adverse effects since the heat loads and flow requirements for the nonessential loads affected are small. (c)
Control valves	Loss of control air or instrument power supply	The EESW temperature control valve will fail open. The EECW will continue to operate and provide the necessary cooling water. The Div I controller will continue to operate on a loss of offsite power to fail the TCV open. NIAS is available for Temperature Control Valve (TCV) P44F400A/B.
Isolation valve for Drywell Loads	Fails to close on high drywell pressure/signals	Redundant full-capacity EECW loop is provided plus the valve can be closed manually.

TABLE 9.2-4 REACTOR BUILDING CLOSED COOLING WATER AND EMERGENCY EQUIPMENT COOLING WATER SYSTEMS FAILURE ANALYSIS

Component	Failure Mode	Consequences on Safety

(a) The differential header pressure sensors are located inside the EECW system boundary; thus, if EECW has been manually initiated with the nonessential loads subsequently restored (either for RBCCW heat exchanger cleaning, enhanced drywell cooling during periods of high lake water temperature, testing, or to provide RHR Reservoir freeze protection during extreme cold weather), a loss of RBCCW pumps while EECW is operating in this mode would not reinitiate EECW or re-isolate the nonessential loads. This protective action is not required, however, since this is not a condition requiring protective action as described in Section 7.1.2.1 and EECW remains capable of supporting the safe shutdown of the plant in this configuration. EECW auto-start on high drywell pressure (i.e., a LOCA) or on a loss of offsite power is unaffected by this mode of operation; therefore, these signals will initiate the automatic protective action of reisolating the nonessential portions of RBCCW piping located inside the EECW system envelope.

(b)The differential header pressure sensors are located inside the EECW system boundary; thus, if EECW has been manually initiated with the nonessential loads subsequently restored (either for RBCCW heat exchanger cleaning, enhanced drywell cooling during periods of high lake water temperature, testing, or to provide RHR Reservoir freeze protection during extreme cold weather), a rupture of the RBCCW piping outside of the EECW system envelope while EECW is operating in this mode would not reinitiate EECW or reisolate the nonessential loads. This protective action is not required, however, since this is not a condition requiring protective action as described in Section 7.1.2.1 and EECW remains capable of supporting the safe shutdown of the plant in this configuration.

(c) If a rupture of the RBCCW piping located inside the EECW system envelope were to occur (with EECW either in standby or in operation for RBCCW heat exchanger cleaning, enhanced drywell cooling during periods of high lake water temperature, testing, or to provide RHR Reservoir freeze protection during extreme cold weather), it is unlikely that the loss in differential header pressure would be sufficient to cause an EECW auto-start due to the small bore of these nonessential lines. It is also unlikely that the RBCCW head tank would deplete to the low level RBCCW pump trip setpoint since the normal makeup capacity exceeds the predicted leak rates. These events rely on the normal EECW makeup supply to feed the break until operators locate and isolate the leak. Again, the protective actions of initiating EECW and isolating the nonessential loads are not required since this is not a condition requiring protective action as described in Section 7.1.2.1 and EECW remains capable of supporting the safe shutdown of the plant during the period required to locate and isolate the break.

Consequences default to those of a rupture of EECW piping as described in the table above.

TABLE 9.2-8 ULTIMATE HEAT SINK FAILURE ANALYSIS

Component	Failure Mode	Consequences on Safety
RHRSW, EESW, and DGSW pumps	Loss of pumping due to loss of offsite power	Power is automatically supplied by the emergency buses fed by the diesel generators.
RHRSW, EESW, or DGSW pump	Loss of pumping due to mechanical failure	RHRSW has one-half capacity still available in one division, completely redundant division still intact. A check valve in pump discharge prevents loss of flow through malfunctioning pump. EESW has full capacity pump in redundant division. DGSW pump failure will cause loss of the particular EDG it services. One half of the electrical division plus full redundant electrical division still remain.
RHRSW, EESW, and DGSW pumps	Do not start due to failure of one divisional pair of diesel generators to start on loss of offsite power	Redundant RHRSW, EESW, and DGSW pumps are provided which are powered off the redundant divisional pair of diesel generators.
RHRSW, EESW, and DGSW pumps	Do not start due to failure of one EDG to start on loss of offsite power	The RHRSW pump associated with the particular EDG will not start; 150 percent cooling capacity still provided. The associated DGSW pump will not start but is not needed. The EESW pump is normally run off a particular EDG. Associated EDG failure causes loss of associated EESW pump. Manual throw-over to other EDG within a division is provided to increase reliability during EDG maintenance. Full-capacity redundant division pump intact.
Valve or piping in Division I or Division II	Loss of flow path due to pipe break or failure of valve to open	Fully redundant flow path with separate supply and return lines is provided to redundant RHR heat exchanger, redundant EECW heat exchanger, and redundant diesel generator.

TABLE 9.2-8 ULTIMATE HEAT SINK FAILURE ANALYSIS

Component	Failure Mode	Consequences on Safety
RHR complex structures	Local structural failure due to tornado-borne missiles, turbine missiles, or EDG missiles	Division I and Division II components are physically separated and divided by a divisional barrier wall. Structure will withstand external missiles. Each EDG is protected by interior walls designed to withstand EDG generated missiles.
Cooling tower structure	Collapse or damage from tornado-borne or turbine missiles	Full-capacity redundant cooling tower provided. Physical separation prevents loss of both divisions.
Cooling tower fan motor	Mechanical failure of fan blades or motor	Each cooling tower has two one-half capacity cells. With redundant cooling tower, capacity of 150 percent still available.
	Failure to start due to diesel generator failure to respond upon loss of offsite power	The particular fan motor not needed as service water pump capacity also reduced; 150 percent cooling capacity still available.

9.3 PROCESS AUXILIARIES

9.3.1 Compressed Air System

9.3.1.1 Design Bases

The Fermi 2 station and control air system provides the plant with a reliable source of clean, dry, oil-free compressed air for plant operation. Control air system is designed to provide oil and dirt-free air with a dewpoint of -40°F (at pressure). The control air compressors, aftercoolers, dryers, and receiver tanks are provided to supply air to some of the engineered safety feature (ESF) equipment in the plant when the normal supply of control air is not available. Because the noninterruptible portion of the control air system provides control air to ESF equipment, it is classified as a safety-related system.

The station air and interruptible control air systems are constructed in compliance with standards for Quality Group D components. The criteria are met by designing the systems to ASME Section VIII and ANSI B31.1.0 code requirements. These systems are nonseismic.

The noninterruptible control air system is constructed in compliance with upgraded standards for Quality Group D components. These criteria are met by designing this system to ASME Section III, Class 3 requirements. The system is Category I.

9.3.1.2 System Description

The air system is composed of two subsystems. The first is the supply and distribution of station air and the second is the supply and distribution of interruptible and noninterruptible control air. The station air and interruptible control air supply equipment is located in the turbine building. The non-interruptible control air system is located in the auxiliary building. The station and control air systems are the source of compressed air for use in routine maintenance operations, in equipment process cycles such as demineralizer backwashing, and as an instrument and control media. The compressed air system is shown in Figure 9.3-1.

The station air system consists of three, two stage, nonlubricated compressors equipped with inlet filter-silencers, and intercoolers and aftercoolers. Two 150-ft^3-capacity air receivers and the station air distribution piping, valves, and fittings complete the station air equipment.

In operation, ambient air from the turbine building is drawn into the station air compressors via the inlet filter-silencers. This air is compressed, cooled, and discharged into the station air receivers. Normal practice is to have one compressor running and one lined up in automatic. The running compressor maintains near constant pressure (100 psig) in the air receivers while the compressor in automatic is available to start if more capacity is required. A connection is provided in the 8” inlet line to the west Air Receiver tank (P5001A002) for installing and operating an alternate air source at any time when an additional source of compressed air is desired to supply or supplement the needs of the compressed air system. The use of this tap is administratively controlled and, when not in use, a blank flange is installed.

From the station air receiver, the station air is distributed throughout the plant via the station air header/riser system. The station air system is sized to minimize the pressure loss of air at the point of use.

The noninterruptible control air portion of the system consists of two 100 percent-capacity 100 scfm, single-stage nonlubricated reciprocating air compressors; two 100 percent-capacity parallel strings of oil filters, air dryers, and afterfilters; two control air receivers; and associated piping, fittings, and valves. During normal plant operation, the source of noninterruptible and interruptible control air is through interconnections between the station and control air systems. Compressed air from the station air system is supplied through one of these interconnections to the Division I and II noninterruptible control air compressor discharge headers. The air then flows from each header through its divisional 100 percent-capacity filter and dryer. It is cleaned of all particles of dirt ≥0.5µm (nominal), ≥0.9µm absolute, and then dried by a regenerative desiccant-type dryer which is designed to establish a -40°F dewpoint (at line pressure). After leaving the filter/dryer, the noninterruptible control air flows to its divisional control air receiver from which it eventually flows to its point of use through its divisional noninterruptible control air distribution system.

Another station air connection supplies the interruptible control air system. The interruptible control air system contains two 100 percent redundant dryers. Each dryer has its own prefilter, afterfilter, and instrumentation. Each dryer unit is capable of supplying the same quality of instrument air as the noninterruptible control air system. Redundancy allows for maintenance to be performed on one unit without jeopardizing the system's air quality or quantity. Dryer redundancy improves the reliability of the interruptible control air system. The interruptible control air flows to the interruptible control air receiver, which supplies the interruptible control air distribution system. The station and control air compressors, air receivers, filters, and dryers are designed to operate in an ambient temperature range of 60°F to 100°F, a range of 20 percent to 100 percent relative humidity, and a radiation field of 1mR/hr.

The control air distribution system is divided into two distinct parts: interruptible and noninterruptible. Noninterruptible control air (NIAS) supplies, through two separate distribution systems (Divisions I and II), equipment in the following systems:

a. Standby gas treatment system (SGTS)

b. Control center air conditioning system (CCACS)

c. Primary containment atmosphere monitoring system (PCAMS)

d. Emergency equipment cooling water system (EECWS)

e. Primary containment pneumatic supply system

f. Torus to reactor building vacuum relief system.

g. Railroad bay airlock door seals.

In addition, Division I NIAS provides control air for the following:

a. Primary containment isolation of drywell equipment and floor drain sump pump discharge lines

b. Back-up supply for Division I (N_2) pneumatic supply to the primary containment.

Division II NIAS supplies, in addition, air operated valves in the following systems:

a. High pressure coolant injection system (HPCI)

b. Reactor core isolation cooling system (RCIC).

c. Standby Gas Treatment Primary Containment Isolation Valves which support Torus Venting.

d. Torus Vent Secondary Containment Isolation Valves.

All other control air users are connected to the interruptible control air distribution system. Interruptible control air (IAS) is supplied through its own set of filters, dryer, and receiver tank, which is fed from the station air system.

The station air compressors and their associated coolers are cooled by the turbine building closed cooling water system (TBCCWS). The control air compressors and aftercoolers are cooled by the reactor building closed cooling water system (RBCCWS) or the EECWS.

During normal operation, any one of three installed station air compressors will be in operation. One of the other two will be in "auto" and the third compressor will be in the "off" position. Normal operating pressure from the station air compressors is nominally 100 psig. If the station air header pressure drops below 95 psig, the compressor in "auto" will automatically start.

If the pressure drops to 90 psig, an alarm in the control room will be initiated and the third compressor may be manually started from the control room panel. If the station air header pressure continues to decrease, at 85 psig the station air supply header isolates and only supplies the IAS and NIAS. An alarm is initiated in the control room.

Should station air supply pressure to either division of NIAS decrease to 85 psig, its division's control air compressor automatically starts and the station air supply isolates from the NIAS and alarms. Each division of NIAS is supplied at this point by its own control air compressor.

There is a normally locked closed intertie between Divisions I and II of the noninterruptible control air system. During a maintenance outage on a control air compressor, after cooler, filters, or dryer of one division the intertie may be opened so that the division having the outage may be fed by the other division. Similarly, the normally closed interruptible control air intertie to Division II noninterruptible control air system may be opened during a Division II supply maintenance outage (i.e., Division II compressor, after cooler, filters/dryer outage). In this latter case, loss of offsite power or any other station air failure would render Division II of the noninterruptible control air system inoperable. The intertie auto isolation valve will close on loss of power or low header pressure, thus maintaining Division II noninterruptible air receiver tank integrity. In addition, the isolation valve for the station air supply to the noninterruptible control air system interconnection has a normally locked closed bypass valve and a normally locked open outlet valve. These valves may be unlocked and repositioned (i.e., the bypass valve opened and the outlet valve closed) to provide an alternate lineup for station air supply to the noninterruptible control air system to support normal plant operation in the event the isolation valve is unavailable.

9.3.1.3 Safety Evaluation

The noninterruptible portion of the control air system is required to effect a safe reactor shutdown; it is also required for control during long-term recovery. The station air system and interruptible control air system are not required to effect a safe reactor shutdown. The pneumatic supply to the primary containment is normally fed from the nitrogen inerting system (Subsection 9.3.6). An intertie is provided to permit Division I noninterruptible control air to be used as an emergency backup to the Division I containment pneumatic supply system.

Bottled nitrogen can also be connected to both containment pneumatic supply divisions as an additional backup supply source. Bottled nitrogen can also be used to reopen Division II PCMS isolation valves, T5000F420B and T5000F421B, that go closed in the event of an extended power failure as shown in Figure 7.6-11.

On loss of offsite power, the control air compressors are automatically started with power supplied from the emergency diesel generators (EDGs). Enough receiver capacity is provided to supply compressed air to the air users for the short duration transition period (See Table 8.3-5) before control air compressor load pickup by the diesel generators is required. With normal offsite power available, the control air compressors start immediately on low noninterruptible control air header pressure.

Maximum plant availability and control air system reliability are ensured by providing three station air compressors and two standby control air compressors. Additionally the control air compressors are powered by independent ESF power sources, and each division includes a control air receiver tank sized to supply compressed air to air users for the short duration transition period during a loss of offsite power event until control air compressors are in-service (See Table 8.3-5).

Control air accumulators are located so as to maximize protection for the associated valve and nearby safety-related equipment. Physical separation criteria for the associated system of the valve were also maintained in determining the accumulator location. Inside the drywell, the accumulators have been integrally supported and welded to drywell support steel; outside the drywell, anchor bolts have been used to secure the welded accumulator support structures in position. The accumulator supports and anchor system were analyzed for stressed conditions resulting from seismic excitation, thrust loading from a tank rupture or supply line rupture, and external jet impingement during a LOCA environment. In each of the above loading conditions, the support and anchor designs were found to be adequate to preclude the accumulators from becoming missiles.

9.3.1.4 Tests and Inspections

Initial construction tests such as air leak tests were conducted per applicable code requirements for the station and control air systems. Initial system flow checks, valve operability, instrumentation and control loop checks, and alarm setpoints for the control air subsystem were done in accordance with the Preoperational Test program as discussed in Chapter 14. The station air subsystem was subjected to similar acceptance testing. The quality of the air delivered by the filter/dryer units was also determined.

Periodic examinations of filters and dryers and periodic replacement of filter cartridges are scheduled to ensure control air quality. Periodic inspections are made of compressors to ensure performance of these active units.

Periodic inspections of receiver tanks are performed. Inspection of instruments is made to confirm actuation of relief valves, isolation valves, automatic switchovers, and alarms. Automatic compressor starts are also demonstrated.

9.3.1.5 Instrumentation

Local (turbine building) instrumentation in the station and interruptible control air systems is provided to monitor line and receiver air pressure, pressure drop across filters, compressor airflow rates, and temperature of the compressed air and cooling water. Similar local instruments in the reactor/auxiliary building are provided for the noninterruptible control air system.

Main control room instrumentation consists of pressure indication of station air and control air headers (with low-pressure alarms), selector switches to isolate either division of noninterruptible air, and control switches for the control air compressors.

The station air compressors are started in the main control room and controlled locally.

9.3.2 Process Sampling

Figures 9.3-2, 9.3-3, and 9.3-4 illustrate the sampling systems in the reactor building, turbine building, and radwaste building, respectively. Details of the process radiation monitoring system (RMS) are given in Section 11.4.

9.3.2.1 Design Bases

The Fermi 2 process sampling system is designed to permit samples to be taken for the following purposes:

a. To maintain radiological surveillance

b. To provide analog measurement signals to controls for process equipment

c. To evaluate the performance of system equipment

d. To measure the quality of the process fluid.

Rad Protection supervision is provided where required (some samples will be radioactive). Wherever samples are delivered through shielding walls, backflushing facilities are provided to confine the radioactive material to the shielded area. Where necessary to avoid health hazards to operators, the system is designed with special safeguards, such as one or more remote air-operated block valves with remote position indicators. The system is designed to permit continuous sampling and minimize plate-out or decay that could bias analyses.

Where feasible, the system piping and sample taps are designed to permit mixing and sampling before process inventories are transferred in the process train.

To ensure that the samples taken are representative, the following considerations are provided for in the design:

a. Line lengths are minimized and the smallest practical line diameter is used to reduce lag time and to minimize plating-out of sample

b. Sampling lines avoid traps, deadlegs, and dips

c. The sample flow rates and line sizes are chosen to ensure flow in the turbulent-flow regime.

Sample lines are type 304 stainless steel tubing. After the source or isolation valves, lines connected to Quality Groups A, B, and C systems are constructed to meet Quality Group D requirements. Lines connected to Quality Group D systems are constructed to meet Quality Group D requirements.

All sample tubing or piping, from the point where it connects to a process system to and including the source valve (or if inside primary containment, from the source to the isolation shutoff valve outside primary containment) is the same piping class as the system piping to which it connects. Further, sample lines are either pitched to drain or are equipped with vents and drains, and are designed to prevent damaging water hammer in operation. External lines are heat traced to prevent freezing and all hot lines are stress analyzed to accommodate thermal movement.

9.3.2.2 System Description

Tables 9.3-1 through 9.3-4 describe the process sampling system by listing, for each system sampled, the sample locations, the analyses to be performed, and anticipated pressures and temperatures. Grab samples are taken for laboratory analysis. Grab samples may be taken locally near the process point or remotely at a central sampling station. For remote grab samples, a sample line is routed from the process pipe to the central sampling station. For local grab samples, a sample line is routed from the process pipe to the nearest accessible area for plant personnel. To determine whether a grab sample should be remote or local, the samples are put into the following classification or criteria:

a. Classification or criteria for remote grab sample:

   1. Sample is taken frequently

   2. Sample point is inaccessible during operation

   3. Sample has to be conditioned

   4. Sample may be radioactive

   5. Entrained gases must be vented through a hood.

b. Classification or criteria for local grab samples:

   1. Sample is taken infrequently

   2. Sample point is accessible

   3. Sample taken only during shutdown

   4. Sample tends to form deposits which would cause plugging of longer lines.

Remote grab samples are routed to a central sampling station, where they are temperature conditioned to 120°F or less and are provided with manual flow control. Continuous samples are routed to the central sampling station where the samples are regulated for proper flow and are temperature controlled as required by the instrument manufacturer. Continuous samples are provided with a means for taking grab samples at the central sampling station and are designed so that grab samples do not reduce flow below the design requirements of the continuous analysis instrumentation.

After sample conditioning, except for those samples recovered directly into the process flow, the samples flow through the analysis instrumentation to the radwaste floor drain system.

A special sample drain collection/recovery system has been designed to reduce radwaste burden by collecting and recovering certain sample drains which are of sufficient water quality to allow recovery into the condensate process flow without radwaste processing. The system consists primarily of a single tank with 240 gallon working volume and 20 gpm pump. Normally this system discharges to the condensate pump suction header but defaults to turbine building floor drains.

Central sampling stations are located in the radwaste, turbine, and reactor buildings. This is done to minimize the length of the sample lines and therefore shorten the transport time for the samples. Each central sampling station contains the remote grab and continuous samples as discussed in previous paragraphs, and the temperature conditioning equipment and analysis instrumentation. The central sampling stations are provided with exhaust hoods to draw air from the sample sinks. Airflow is 100 to 150 linear ft per minute.

All remote sample lines, where possible, are pitched 1/4 in./ft in direction of flow. The sample line lengths are as short as possible and the routing avoids traps, deadlegs, and dips upstream from the sample discharge. Sample flow is in the turbulent-flow region to minimize deposition and to ensure representative samples. Local samples are located in well-ventilated accessible areas. Drain funnels are provided to carry sample streams, which are not recoverable, to the floor drain system.

9.3.2.3 Safety Evaluation

Samples that require special handling, and all sample lines that flow continuously, lead to central sampling stations in the reactor building, the turbine building, or the radwaste building. The central sampling stations are equipped with ventilation hoods, backflushing facilities, and pressure and temperature controls. Remote air-operated sample valves are controlled from these central sampling stations.

High-pressure sample lines are required to pass hydrostatic tests with the process units they serve and must conform to the same construction standards.

All sample lines have a shutoff valve located as close as possible to the sample source connection. This valve is manually operated if accessible, and solenoid operated where inaccessible.

Solenoid valves are designed to fail closed. Division II PCMS isolation valves T5000F420B and T5000F421B fail closed following a power failure but can be reopened since these valves are equipped with DC solenoid valves powered from a DC battery and the pneumatic power for these solenoids is provided from bottled nitrogen as shown in Figure 7.6-11. Soft-seated solenoid valves are provided to ensure minimum leakage because leakage could go undetected for long periods of time. Since all samples have a potential for becoming radioactive, the following special precautions are taken to minimize radiation hazards to plant personnel:

a. Sample lines are routed wherever possible in shielded areas where plant personnel have little or no access

b. Equipment that tends to trap activated "crud" is kept behind shield walls

c. Provisions are made for sample line backflushing with demineralized water at the sample stations

d. Ventilated hoods are provided at the sample station

e. Local grab samples are located in well-ventilated areas that are accessible to plant personnel

f. Remote samples are extended through shield walls if located near radioactive equipment or if the sample line creates significant radiation field.

9.3.2.4 Tests and Inspections

During plant operation or shutdown, no special tests or inspections are required for sample lines and sample stations beyond inclusion in the test and inspection programs conducted on the systems they serve. Continuous analysis instrumentation will be periodically checked and recalibrated.

9.3.2.5 Instrumentation

Pressure controls and remotely operated valves are procured to the same specification as the lines they are sampling. The continuous monitors installed in various sample stations are identified by function in Tables 9.3-l through 9.3-4.

9.3.3 Plant Equipment and Floor Drains

9.3.3.1 Design Bases

The plant equipment and floor drainage systems are designed to collect and remove all waste liquids from their points of origin to a suitable disposal area in a controlled and safe manner. Water from radioactive drains is collected for sampling and analysis prior to disposal to the environment in accordance with 10 CFR 20. Drain line penetrations through containment barriers are designed to maintain containment during normal operation and design-basis accidents (DBAs).

In the reactor, auxiliary, turbine, and radwaste buildings, most drain water is considered potentially radioactive and is accumulated for periodic discharge to the radwaste system for treatment. In general, drainage from production equipment is of high purity and high activity relative to floor drain discharge, and is collected separately from the floor drain discharges. In the radwaste process, cleanup of the floor drain accumulations may be more complex and could require more unit separation than do the equipment drain accumulations routed to the radwaste waste collector tank.

Equipment drain water of relatively high purity and high activity is separately collected and discharged to the radwaste waste collector tank and subsequent cleanup train. If the effluent from this cleanup train is of satisfactory quality, the purified stream is normally recycled to the 600,000-gal condensate return tank. Floor drain water of relatively low purity is collected in separate sumps and periodically discharged to the radwaste floor drain collector tank and cleanup train. If this water is of satisfactory quality, the purified stream may also be recycled to the CST or exhausted to the plant circulating water reservoir decanting line that flows into Lake Erie.

The normal equipment and floor drain water in each quadrant of the reactor building sub-basement is collected in the local sump of the respective quadrant. The drain water from the NW and SE quadrant sumps is discharged to the radwaste waste collector tank. The drain water from the SW and NE quadrant sumps is discharged to the radwaste floor drain collector tank.

Equipment drain connections are generally through open funnels (sight drains) at those locations where it is considered desirable to verify performance at a glance, where periodic temperature observations may be required, or where the coolant water system is a high pressure system and might overpressurize drain lines and equipment.

Drain system piping effecting drywell isolation is constructed to meet standards for Quality Group B components. They are designed to ASME Section III, Class 2 code requirements. The balance of the drain system is either Quality Group C designed to ASME Section III, Class 3 code requirements or Quality Group D, designed to ANSI B31.1.0, except for the recirculating sump heat exchangers. Their piping is designed to ASME Section VIII and to ANSI B31.1.0 code requirements.

All the equipment drain piping above the floor in the reactor building sub-basement is designed to ANSI B31.1.0 code requirements.

9.3.3.2 System Description

NOTE: Pump rates are nominal flow rates.

The Fermi 2 drainage system is designed for accumulation of discharges from equipment and floor drains inside the reactor building, auxiliary building, turbine building, and radwaste building, and for periodic transfer of these accumulations to the liquid radwaste system.

Within the reactor building, seven separate drain collection systems operate, each with an independent sump. The reactor and auxiliary buildings drain systems are shown in Figures 9.3-5 and 9.3-6.

An equipment drain collection system from primary coolant components terminates in a 1100-gal nominal capacity sump located in the drywell area under the reactor pressure vessel (RPV) with twin parallel 50-gpm transfer pumps that discharge to the radwaste waste collector tank. The sump is closed and vented, with a recirculating bypass capability from the transfer pump discharge header line returning to the sump. This bypass flows through a heat exchanger cooled by RBCCW. The sump fluid is automatically recirculated on a signal from a temperature sensor in the sump, in order to protect radwaste-system resins from deleterious overheating. The sump liquid setpoint is 135°F. Periodic sump discharge is initiated automatically on a signal from the sump level controller. The discharge header to the radwaste waste collector tank penetrates the primary containment wall. In order to preserve the integrity of primary containment, this line is sealed by the submerged pump suction lines inside primary containment.

These lines are also protected by one air-operated isolation valve and one motor-operated isolation valve installed in tandem in the discharge header; one valve is located inside containment, the other outside. Each valve is fed from a different division. These isolation valves are automatically closed by a rise in pressure inside primary containment and by other primary containment isolation signals (See Table 6.2-2).

Equipment drains from secondary containment spaces in the reactor building and auxiliary building are also collected and discharged to the radwaste waste collector tank. Two drain sumps, each holding 1500 gal (nominal capacity), are provided, each with twin submersible pumps and bypass heat exchangers.

The fourth drain system in the reactor building draws from a trench drain and an undervessel drain and exhausts to the radwaste floor drain collector tank. This system is similar to the equipment drain systems located in the drywell discussed previously. Dual isolation valves ensure the integrity of primary containment, but the bypass cooling heat exchanger is omitted. Sump capacity is 1000 gal (nominal capacity).

The fifth and sixth drain systems in the reactor building collect from the floor drains in secondary containment areas and exhaust through twin parallel pumps to the radwaste floor drain collector tank. These systems, like the other floor drain system, have no sump cooling provision. Each sump has a 1500-gal nominal capacity.

The seventh reactor building drain system consists of a sump in the torus area (with no collection piping). This system discharges through twin parallel transfer pumps and an external water seal to the radwaste floor drain collector tank. This sump has a 900-gal nominal capacity.

Equipment and floor drains in the emergency core cooling system (ECCS) pump rooms, in the subbasement of the reactor building, have been physically separated to prevent possible flooding between ECCS Division I and Division II equipment through the drain lines in the event of an accident that causes one of the rooms to flood.

Equipment and floor drains in the emergency core cooling system (ECCS) pump rooms,in the sub-basement of the reactor building, are collected in each room's sump to prevent possible inter-divisional flooding between ECCS Division I and Division II, with the exception of HPCI room. The floor and equipment drains from the HPCI room are collected in the RHR Division II pump room sump. A motor operated auto-close flood control valve is provided in the floor and equipment drain line to prevent possible flooding between the two rooms in the event of an accident that causes one of the rooms to flood. The flood control valve will normally be open, but will close on high-high sump level to prevent water from backing up into the subbasement floor and equipment drains. The valves will reopen on low sump level. Selected RHR pump and rack H21-P596B drains in the southwest corner room are hard piped to the southeast corner sump, but are isolated by normally closed manual valves.

Flooding of any individual corner room or the HPCI room due to a line break in either room can be confined to that corner room. The configuration of the motor operated flood control valve and its associated sump is shown in Figure 9.3-6. The level switch data for the motor operated flood control valve is given in Table 9.3-5.

The motor-operated flood-control valve and its limit switches are tested periodically to ensure their satisfactory performance. This testing is done as required by the Performance Evaluation Procedures of the overall plant surveillance program. Maintenance procedures cover the testing of the valves. Switches and other pertinent instrumentation are covered by a section of the overall balance-of-plant (BOP) preventive maintenance program.

The turbine building has eight separate radioactive drain collection systems, each with an independent sump. The drain system is shown in Figures 9.3-8 and 9.3-9.

Two equipment drain sumps, with nominal capacities of 400 and 4400 gal, collect oil-free radioactive liquids from equipment and piping systems. Each sump has twin 50-gpm sump pumps that periodically discharge to the waste collector tank in the radwaste building.

A third 2300-gal nominal capacity service water drain sump is provided to collect nonradioactive liquids from such systems as the general service water (GSW) system, and TBCCWS piping. This sump can be emptied into the liquid waste holding pond in the yard.

Two floor drain sumps, with nominal 1600-gal and 4400-gal capacities, are provided to collect oil-free liquids, and each has twin 50-gpm sump pumps discharging to the floor drain collector tank in the radwaste building.

Finally, three sumps, with approximate capacities of 1900, 2200, and 3000 gal, are provided to collect oil-contaminated liquids. These sumps are each provided with two 50-gpm to 64-gpm pumps as well as a 200-gpm or a 250-gpm emergency pump. The discharge is normally routed to an oil-water separator prior to treatment in the radwaste building. The emergency pumps can be used to empty the sumps to the liquid waste holding pond, if desired.

The radwaste building contains an equipment and a floor drain sump, each with a 900-gal nominal capacity. First-floor leakages drain directly into the waste collector tank or into the floor drain collector tank located in the basement. Basement leakages are collected in the appropriate sump and pumped out by twin 50-gpm pumps. The system drains are shown in Figures 9.3-10 and 9.3-11.

The RHR complex drain system is segregated into two types of wastes, oil-free water and oil-contaminated water. Equipment and floor drains that are potentially contaminated with oil drain to a manway which is connected by an overflow line to the liquid waste holding pond. Equipment and floor drains that are oil free drain to another manway which is connected by an overflow line to the circulating water reservoir. The piping pits are provided with sump pumps which discharge to the clear-water manway. The RHR system drains are shown in Figure 9.3-12.

9.3.3.3 Safety Evaluation

All potentially contaminated internal drain water is processed through the radwaste purification trains before release or recycle. The integrity of primary containment is ensured by tandem isolation valves. The drainage system is protected from overpressure by open sight funnel drains at most collection points.

To further ensure performance, the high-temperature drains in the reactor building are cooled by the RBCCWS. This ensures an acceptable net positive suction head (NPSH) at the transfer pumps.

9.3.3.4 Tests and Inspections

The drain lines are all welded and all required tests for joint soundness were carried out in accordance with applicable codes. For this reason, the closing field welds are in accessible positions.

Because spare pumps are installed, no periodic qualifying tests were undertaken. Completed piping has been hydrostatically tested in the field.

9.3.3.5 Instrumentation

Each sump is equipped with a high-high-level alarm to signal automatic initiation of the second pump. The starting of the second pump would be indicative of a system leakage. In addition, temperature controls are provided to cool critical sumps by actuating the flow of sump water through heat exchangers.

All reactor building sumps have leak-detection instrumentation. Timers monitor the operation of the sump pumps both for frequency and for length of operation. Leakage is detected by a pump operating before the timers time out or by a pump operating too long. Leakage is alarmed in the main control room.

9.3.4 Chemical, Volume Control, and Liquid Poison Systems

The only BWR systems that are related to this general class of systems are the standby liquid control system (SLCS) and the reactor water cleanup (RWCU) system.

The SLCS is described in Subsection 4.5.2.4 and the RWCU system is described in Subsection 5.5.8.

9.3.5 Failed Fuel Detection System

In the event of gross rod failure, the increased activity in the coolant would be transferred to the steam and detected by the main steam line RMS. Downstream of the steam line monitors are the offgas RMS and the reactor building exhaust vent RMS. The design bases, system description, safety evaluation, tests and inspections, and instrumentation applications for each of these subsystems are found in Section 11.4.

9.3.6 Nitrogen Inerting System

9.3.6.1 Design Bases

The Fermi 2 nitrogen inerting system provides and maintains a nitrogen atmosphere inside the primary containment and also provides pressurized nitrogen for pneumatic service inside the primary containment and distribution throughout the plant. The system schematic is shown in Figures 9.3-13 and 9.3-14.

The nitrogen inerting system supply is located outside the reactor building on the west side. The components are shown in Figure 9.3-15. The remainder of the system is located in the reactor building. The nitrogen inerting system supplies nitrogen gas at the proper pressure and temperature for inerting the primary containment and for distribution throughout the plant.

The nitrogen inerting system design requirements are the following:

a. To provide nitrogen gas at the proper temperature and pressure to inert the primary containment to a minimum of 97 percent by volume of nitrogen. The nitrogen gas will be injected into the primary containment and the existing atmosphere will be displaced out through the reactor/auxiliary building ventilation system or through the SGTS. Mixing of the injected nitrogen will be accomplished by the use of the drywell cooling system (see Subsection 9.4.5).

b. To provide nitrogen makeup for atmospheric leakage out of the primary containment during normal operation and to ensure that a positive pressure is maintained inside the primary containment with respect to the secondary containment. Makeup requirements to some degree will be taken care of by the bleed-off of nitrogen gas from the pneumatic instrumentation inside the primary containment. Provisions for nitrogen addition to the primary containment atmosphere have been made at the drywell and suppression chamber supply lines through a separate on-line purge system. This system controls the pressure of the drywell and torus through vent/makeup of nitrogen

c. To provide nitrogen gas for the pressurized distribution system for the following services:

    1. To provide pressurized nitrogen for the pneumatic instrumentation inside the primary containment. During normal operation, nitrogen will be supplied to this instrumentation from the nitrogen inerting system. In the event of a loss of nitrogen supply, bottled nitrogen will be available for emergency use for the pneumatic requirements inside the primary containment

    2. To provide pressurized nitrogen to any other remaining services requiring nitrogen throughout the plant.

Air purging of the primary containment to the breathable limit will be accomplished by the use of the reactor/auxiliary building ventilation system or the SGTS.

9.3.6.2 System Design

The nitrogen inerting system primary containment penetrations and the associated isolation valves are classified as ASME Section III, Class 2. The pneumatic supply system inside primary containment is classified as ASME Section III, Class 3. The balance of the nitrogen inerting system pressure vessels are classified as ASME Section VIII, and the piping is classified as ANSI B31.1.0.

The nitrogen inerting system primary containment penetrations and associated isolation valves and the pneumatic supply system inside primary containment are designated as Category I. The remainder of the system is classified as nonseismic.

The nitrogen inerting system has been designed in accordance with the following criteria.

a. Liquid nitrogen requirements are based on the following usage:

   1. To inert the primary containment to less than 3 percent by volume of oxygen

   2. To provide additional nitrogen to the primary containment to compensate for leakage.

   3. To provide nitrogen for the pressurized distribution system.

b. The inerting and air purging procedures for the primary containment will be completed in approximately 6 hr.

c. The minimum distribution temperature of the nitrogen gas for all phases of operation of the nitrogen inerting system is controlled. The vaporizing medium during the primary containment inerting procedure is saturated steam at 15 psig from the plant auxiliary boilers. Heat for the pressurized distribution system will be provided electrically

d. The design capacity of the liquid storage tank is based on the service requirement of the pressurized distribution system for Fermi 2 and the vapor loss from the storage tank during the interval of storage

e. The receiver usable capacity will be designed to allow a system flow rate of 50 cfm for a period of 5 minutes if the liquid nitrogen source should be out of service. A full-capacity standby receiver is available

f. The pressurized distribution system is designed to allow connection of bottles as a backup source of nitrogen

g. The design flow of the nitrogen gas to the primary containment for the inerting procedure is 3000 scfm.

9.3.6.3 Design Evaluation

The system fluid will be commercial 99-percent pure nitrogen. The fluid will not be radioactive. System components for the handling of liquid nitrogen have been constructed of materials suitable for temperatures of -320°F.

The liquid nitrogen storage tank provides the source of supply for pressurized nitrogen distribution. The tank is equipped with a pressure build coil and an auxiliary pressure build vaporizer. The pressure build coil will transfer heat to the liquid nitrogen to generate saturated nitrogen vapor.

The nitrogen inerting system has a steam vaporizer and electric heat exchanger. The steam vaporizer will be used only when nitrogen is required for the inerting of the primary containment. The electric heat exchanger is used to supply gaseous nitrogen for pressurized distribution.

The nitrogen receivers provide temporary storage to meet sudden demands for pressurized nitrogen throughout the plant. One receiver will be in full standby to allow maintenance without disturbing normal plant operation.

The source of system pressure is the liquid nitrogen storage tank. The vapor pressure in the tank will be regulated to provide the required system pressure. All pressure-retaining components of the system are equipped with properly sized pressure relief valves. Piping that is handling liquid nitrogen has pressure relief valves installed in any segment where liquid nitrogen could become entrapped between closed valves. All liquid nitrogen transfer lines are sloped upward in the direction of flow to prevent vapor pocket buildup at the nitrogen source.

The nitrogen inerting system is not required for the safe shutdown of the reactor, and hence is not required to protect the health and safety of the public. However, the continuous operation of the plant is contingent upon the nitrogen inerting system maintaining the required nitrogen atmosphere inside the primary containment. Therefore, to ensure that nitrogen gas is always available to meet the primary containment nitrogen requirements, small amounts of bottled, high-pressure nitrogen will be stored at the site as a secondary source of nitrogen supply.

9.3.6.4 Tests and Inspections

The liquid storage and vaporizing facilities for the nitrogen inerting system are located outside the reactor building and are accessible for inspection. The nitrogen receiver tanks and bottled nitrogen tanks are located in the reactor building and are accessible for inspection during normal plant operation. Initial system checks, valve operability, instrumentation and control loop checks, and alarm setpoints for the nitrogen inerting system were done in accordance with the Preoperational Test program as discussed in Chapter 14. The temperature and pressure of nitrogen delivered by the steam and electric vaporizers have also been determined.

Periodic inspections of receiver tanks and the passive Division II backup nitrogen supply system will be performed. The inspection of instruments will be made to confirm the actuation of relief valves and alarms. The system and its components will be periodically tested and maintained as appropriate for the system safety classification.

9.3.6.5 Instrumentation Requirements

When the primary containment is being inerted, pressure and temperature control will be maintained in the following manner:

a. A pressure control valve located downstream of the liquid storage tank discharge and the steam vaporizer automatically maintains a discharge pressure of approximately 30 psig

b. A temperature indicator is located in the condensate discharge line of the steam vaporizer as is a low-temperature switch that shuts down the nitrogen discharge from the vaporizer at preset temperature.

Pressure and temperature control of the pressurized nitrogen distribution system will be maintained as follows:

a. A pressure control station located between the liquid storage tank and the electric heat exchanger automatically maintains a downstream pressure of approximately 110 psig

b. A variable setpoint temperature controller on the discharge side of the electric heat exchanger maintains a nitrogen discharge temperature

c. A pressure control station located downstream of the receivers maintains a downstream pressure

d. The drywell makeup station will sense the pressure of the primary containment and the secondary containment and with manual action, a positive pressure will be maintained in the primary containment

e. The provision for a bottle backup station will include a manually operated pressure regulator to maintain the receiver pressure when required. However, Division II is backed up by a passive nitrogen supply using bottles in the secondary containment. This capability supports manual operation of Division II SRVs from the control room for certain post-fire shutdowns requiring low pressure makeup systems

f. A pressure indicator is provided to monitor pressure downstream of the receivers. When the pressure of the receiver in operation reaches a setpoint, an alarm is provided to indicate low receiver pressure.

The primary containment isolation valves will automatically isolate on high drywell pressure, low reactor level, or high reactor building radiation.

TABLE 9.3-1 PROCESS SAMPLING SYSTEM

Item No.	Description	Sample tap Location	Purpose of Sample	Type of Analysis	Analysis Mode	Source Operating Temperature (°F)	Source Operating Pressure (psig)
1	TBCCW (2)	E and W heat exchanger outlet	Tube leaks	Conductivity Laboratory	Local grab	95/130	35
2	Condenser	Condenser leak troughs	Spare tap not used				
3	Condensate (3)	Condensate pumps discharge north-center-south	Condensate quality and tube leaks	Laboratory	Grab station	94	213
4	Condensate	Condensate pumps discharge header	Spare tap not used			94	213
5	Condenser (6)	Condenser leak troughs inlet and outlet each quadrant turbine	Spare taps -not used			100	-14
6	Condenser	Condenser leak trough	Spare tap not used			125	147

9.4 AIR CONDITIONING, HEATING, COOLING, AND VENTILATION SYSTEMS

9.4.1 Control Center Air Conditioning System

9.4.1.1 Design Bases

The control center air conditioning system (CCACS) is designed to provide ventilation, heating, and cooling, and to limit the relative humidity in the control center envelope (as described in Subsection 9.4.1.2) during normal operation and following a design-basis accident (DBA).

The CCACS is designed as follows:

a. The system is designed to limit the maximum relative humidity* to 60 percent and the nominal ambient temperature to 75°F dry bulb during normal operation, except for the mechanical equipment room (MER) and SGTS room, to ensure comfort of the operators as well as to obtain an optimum environment for controls and instrumentation. The system is designed to limit the nominal ambient temperature in the MER to 95°F during normal operation and following a design-basis accident, and in the SGTS room to 104°F during normal operation. The system is designed to maintain the above temperatures, assuming an ambient temperature of 95°F dry bulb and 75°F wet bulb during the summer and -10°F dry bulb during the winter

b. The system is designed to detect and limit the introduction of radioactive material into the main control room and to remove airborne radioactivity from the environment therein such that the dose to main control room personnel following a DBA does not exceed the requirements of General Design Criterion 19

c. The system is designed to limit the introduction of chlorine gas into the main control room

d. Redundant components are powered by their corresponding redundant Division I and Division II engineered safety feature (ESF) buses

e. The system is designed to accomplish its design objectives assuming a single active component failure. A single active failure in the Halon fire protection system will cause loss of cooling to the relay room, cable spreading room, or computer room. Redundant smoke/Halon dampers are not provided. Adequate time exists to take manual actions to restore airflow

f. The CCACS is designed to meet Category I requirements.

---

* The relative humidity in the control room and the computer room is controlled between a minimum of 40 percent and a maximum of 60 percent.

g. The system is designed for accessibility in making adjustments and periodic inspections and for testing principal system components to ensure continuous functional reliability

h. The control center emergency air filtration system design conforms to Regulatory Guide 1.52 except as stated in Subsection A.1.52. The system is redundant only at the active component level.

Environmental design considerations relating to main control room habitability following an accident are discussed in Subsection 6.4.1.

The CCACS is designed to maintain the control center under a positive pressure of approximately 1/4 ± 1/8-in. water gage in the "recirculation mode" in order to minimize inleakage of contaminated air. Such outside contamination could be the result of radioactivity leakage after a LOCA.

Isolation valves and isolation dampers are capable of remote manual operation so that failure of their control system will not render the system inoperable.

Surveillance of airborne radioactivity levels in the main control room is provided by the airborne radiation monitoring system (Subsection 12.2.4).

9.4.1.2 System Description

9.4.1.2.1 System Equipment

The control center envelope encloses a total air volume of approximately 275,960 ft^3 (during normal mode) and 252,731 ft^3 (during emergency modes). The following areas are air conditioned as separate zones as indicated:

Zone	Area Description
1	Relay room
2	Cable spreading room
3	Main control room
4	Computer room
6	Office
7	Conference room
8	Mechanical equipment room and standby gas treatment system (SGTS) rooms (during normal mode). However, the SGTS rooms are not part of the control center envelope during emergency modes (See Subsection 9.4.1.2.3)

The CCACS diagram is shown in Figures 9.4-1, 9.4-2, and 9.4-3, and principal system component design data are listed and described in Table 9.4-1. The CCACS consists of two

100 percent-capacity air-conditioning supply units, an air distribution system, and an emergency filtration system. The control center is heated, cooled, and pressurized by a recirculating air system.

There are four operating modes for the ventilating system, as follows:

a. Normal Mode: A minimum of 2769 cfm outside air mixes with recirculated ventilating air, bypassing the emergency makeup and recirculation filters

b. Purge Mode: 100 percent outside air is circulated through the control center and exhausted to the atmosphere to purge any smoke or fumes within the control center

c. Recirculation Mode: A maximum of 1800 cfm outside air is filtered and mixes with 1200 cfm recirculated air that is filtered again and mixed with recirculating ventilation air to prevent intrusion and to provide continuous removal of contaminants during a radiation-release emergency

d. Chlorine Mode: All outside intakes are closed to prevent ingress during a chlorine-release emergency. Ventilating air is recirculated with 1200 cfm passing through the emergency recirculation filter.

Each of the multizone air-conditioning supply units includes a fail-closed air-operated inlet damper, an electronic air cleaner, a roll filter, a centrifugal fan, and an electrically heated hot deck and a cold deck with a chilled water cooling coil. The supply air temperature for each zone is controlled by a pair of zone dampers that proportion the hot and cold air. Each of the air-conditioning supply units is served by a Category I chiller unit. During normal operation, the condenser section of the chiller is cooled by the reactor building closed cooling water system (RBCCWS). During emergency operation, the chiller condenser is cooled by the emergency equipment cooling water system (EECWS).

The emergency filtration system processes control center air and makeup air through charcoal filters if the control center is subjected to airborne contamination. This system consists of two separate emergency air intakes. Each has a dual set of "bubble tight" dampers in each of two parallel lines.

These dampers are valves with pneumatic piston actuators. The emergency makeup air filter train is sized for a flow rate of 3000 cfm, but is restricted to a maximum emergency intake flow of 1800 cfm. The filter train consists of the following components arranged in the direction of flow:

a. Mist eliminator (prefilter type)

b. Two electric heaters, one each for Division I and Division II

c. High-efficiency particulate air (HEPA) filter with a design filtration efficiency of 99.97 percent for 0.3 μm particles or larger. The filters are installed and field tested such that a 95 percent decontamination efficiency can be assumed for removal of particulate iodine

d. 2-inch deep charcoal adsorber. The carbon is purchased, lab tested, and tested for bypass leakage after installation such that a 95 percent decontamination efficiency can be assumed for removal of all forms of gaseous iodine

e. HEPA filter with a design filtration efficiency of 99.97 percent for 0.3 μm particles or larger.

The emergency intake flow is then combined with 1200 cfm of control center recirculation airflow. This airflow is then processed through the recirculation air filter train.

The emergency recirculation filter train is sized for a flow rate of 3000 cfm and consists of the following filters in the direction of flow:

a. Prefilter

b. HEPA filter with a design filtration efficiency of 99.97 percent for 0.3 μm particles or larger. The filters are installed and field tested such that a 95 percent decontamination efficiency can be assumed for removal of particulate iodine.

c. 4-inch deep charcoal adsorber. The carbon is purchased, lab tested, and tested for bypass leakage after installation such that a 95 percent decontamination efficiency can be assumed for removal of all forms of gaseous iodine.

d. HEPA filter with a design filtration efficiency of 99.97 percent for 0.3 μm particles or larger.

The air is drawn through these emergency filters by one of two redundant emergency recirculation air fans. Redundant air-operated dampers are installed on the intake, upstream of make-up air filter unit, and exhaust side of each of the fans. The fans receive electrical power from ESF buses.

In order to provide adequate makeup air to the control center during normal operation, the intake air damper is provided with a minimum stop to ensure a minimum airflow at all times except while the control center is isolated. The design minimum airflow is 2769 cfm. This minimum airflow is based on the normal airflow to the main control room exhaust vent, the exfiltration from the building, and the ventilation air supplied to the standby gas treatment room, kitchen, and washrooms. A modulating damper in the system exhaust restricts exhaust flow relative to supply airflow rate to maintain approximately 1/4 ± 1/8 in. of water difference between the lower of the outside ambient pressure or the turbine building pressure and control center pressure when the system is in the normal mode.

The two fan-coil cooling units are located in the mechanical equipment room. Each of these units is sized to dissipate the total heat load generated in the mechanical equipment room during an emergency. The units are of the factory-assembled, integral-fan-type with a chilled water cooling coil. One fan-coil unit is for Division I and the other for Division II. Chilled water is supplied to these units from the control center chillers.

The air conditioning system is equipped with alarms annunciated in the main control room for detection of equipment malfunction. Each division has similar alarms. A malfunction in the operating division will annunciate an alarm; if necessary, the entire division will be shut down manually and the standby division will be manually started. Shutoff dampers on the outlet of each unit are interlocked with the fan starter. Chiller starter contacts are held open until verification of chilled water, condenser water flow, supply air, and return airflow. The chiller starter contacts are tripped if oil pressure is not verified after a time delay.

For heat and smoke removal from the control center complex in the event of a fire in either the relay room or the cable spreading room, the fire detection system automatically switches the air conditioning system to a purge mode. Smoke and fire detection systems for the control center are covered in Subsection 9.5.1.

All electrical power for motor operation is supplied by the reactor building ESF buses and the division concept of separation and redundancy is maintained. Power to these buses is supplied from the emergency diesel generator (EDG) system if offsite electrical power is lost. Refer to Subsection 7.3.5 for a discussion of the CCACS instrumentation and controls.

9.4.1.2.2 Normal Operation

During normal operation, the master selector switches in the main control room activate all components in the Division I or Division II system. A mixture of return and outside air is filtered, then cooled, heated, and dehumidified, as required by a multizone air-conditioning supply unit. Each zone thermostat modulates zone mixing dampers to obtain the supply air temperature necessary to satisfy the zone cooling or heating requirements.

Heating is supplied by an electric heating coil and is provided on demand from any one of the zone thermostats. The air temperature leaving the heating coil is maintained at approximately 95°F and reset to lower temperatures on rising outside air temperature. Steam is supplied by the auxiliary boiler and controlled by humidistats located in the control room and computer room. Positive pressure is maintained in the control center by throttling the exhaust air modulating damper. This damper modulates only in the normal mode. It has no essential function and opens upon loss of power to allow "purge" mode operation if required. Exhaust fans are provided in the kitchen and washrooms.

9.4.1.2.3 Emergency Operation

During an emergency, the control center is isolated from all other areas of the plant. All air supplies to the standby gas treatment rooms and the normal operation of air intake and exhaust ducts are dampered closed.

The multizone air-handling unit, the chiller, chilled water pump and the return air fan continue to operate as during normal operation. The return air damper assumes a full open position. Condenser water is supplied from the EECWS. The fan in the mechanical equipment room fan-coil cooling unit is also energized under room thermostat control. Chilled-water flow through the cooling coil of the unit continues unimpeded as during normal operation.

The emergency recirculation air fan is energized and the isolation dampers on the emergency intake air duct are opened. Pressure control dampers, which regulate the proportion of recirculated air to emergency makeup air, modulate to maintain approximately 1/4 ± 1/8-in. water gage positive pressure in the control room. The dampers in the kitchen and washroom exhaust air ducts are closed. In the event that chlorine gas is detected in the control center by control room personnel, manual operator action will place the CCHVAC system in chlorine mode which will cause all system isolation dampers to automatically close. Damper position indications in the main control room allow continuous monitoring of system performance and confirm all remote manual control actions taken.

9.4.1.3 Safety Evaluation

Continued operation of the CCACS during both normal and emergency conditions is ensured by the following:

a. Design of system components to meet Category I requirements

b. Redundancy of components to meet single active failure. Smoke/Halon dampers are not single active failure proof. A system single-failure analysis is presented in Table 9.4-2

c. During loss of offsite power, all active components, such as valve and damper operators, fan motors, controls, and instrumentation, are served by their respective emergency power sources.

d. The unfiltered inleakage into the main control room is limited to a maximum of 173 cfm as evaluated in accordance with the AST methodology in Regulatory Guide 1.183.

Alarms in the control center will alert the operator to any malfunction in the CCACS so that, if necessary, he can manually actuate the standby division. The instrumentation in the main control room is designed to operate without degradation of performance in an ambient temperature of 120°F.

Detection of radioactivity in the main control room environment is provided by radiation monitors, as described in Subsection 12.2.4. Signals generated by high radioactivity in the control center makeup air, the reactor building exhaust, and fuel pool exhaust; low reactor water level; and high drywell pressure will initiate automatic isolation of the control center.

Protection of main control room personnel against an offsite chlorine release can be provided by manual isolation of the main control room and the use of breathing apparatus by the main control room operators as discussed in Section 6.4.

A discussion and analysis of the chlorine accidents considered in the design of the plant and an evaluation of the habitability of the main control room after a chlorine accident are presented in Subsection 6.4.3.4.

An evaluation of the buildup of carbon dioxide in the main control room, with the CCACS isolated, is given in Subsection 6.4.1.2.

A fire outside the plant will not affect control room habitability because the control center will be isolated. The operator will receive an indication of an onsite fire through the control center air inlet smoke detector.

The sources of smoke closest to the control center outside air intake are the system service and main unit transformers approximately 80 to 240 ft from the air intake. Smoke from a fire outside the plant should be detected within 1 minute after the smoke begins to enter the control center. The control center can then be manually isolated in less than 10 sec. The operators will have immediate access to self-contained breathing apparatus for respiratory protection as discussed in Section 6.4.

9.4.1.4 Inspection and Testing Requirements

The CCACS equipment was subjected to a dynamic system test to directly verify the acceptability of the supplied equipment in accordance with the design specifications. At the conclusion of the work, all of the heating, cooling, hydronic, and ventilating systems were tested and balanced to meet the design conditions.

Routine procedures require checking for proper mode of operation, proper positioning of dampers, and proper operation of the system equipment. All those dampers which are required to provide tight shutoff were checked in the closed position by the vendor to verify proper operation of the seals, and those dampers are periodically observed in service to confirm proper functioning of the operating air connections. Design provisions are made so that active components of the air conditioning system can be periodically inspected for operability and required functional performance.

Initial system flow distribution, valve operability, instrumentation and control loop checks, and alarm setpoints were done in accordance with the Preoperational Test program as discussed in Chapter 14.

The control center emergency filtration system has been subjected to shop test, acceptance test, and inservice inspection in accordance with Regulatory Guide 1.52 as delineated in Appendix A. Laboratory testing was also in accordance with Regulatory Guide l.52. The control center emergency filtration system was given a preoperational test as discussed in Chapter 14.

An inservice surveillance program has been implemented in accordance with the Technical Specifications to ensure that the main control room emergency filtration system can perform its design functions.

9.4.2 Reactor/Auxiliary Building Ventilation System

9.4.2.1 Design Bases

The reactor/auxiliary building ventilation system is designed to provide normal ventilation for the reactor and auxiliary buildings and to maintain the temperature in general access areas between 65°F and 104°F. The temperature in potentially contaminated areas is maintained between 65°F and 125°F. To maintain these temperatures, additional room coolers have been added to selected areas. Equipment in the emergency core cooling system (ECCS) pump rooms was originally designed to operate at temperatures below 148°F during emergency conditions. The actual conditions to which this equipment is environmentally qualified under the Fermi 2 EQ program are documented in EQ0-EF2-018. Also see Section 3.11 for discussion of original Fermi 2 design and environmental qualification activities performed for Fermi 2. During normal operation, when the emergency core cooling equipment is not in service, the temperature in these rooms is maintained below 104°F.

The HVAC System for battery rooms controls the temperature at an approximate value of 75°F. The ventilation system is designed to maintain these temperatures when the outside ambient dry bulb temperature is between -10°F and 95°F.

The ventilation system provides a means of purging the drywell of the nitrogen inerting atmosphere, prior to entry by personnel.

The system is designed to maintain airflow from areas of low potential radioactivity to areas of progressively higher potential radioactivity. In addition, the system will maintain the reactor and auxiliary buildings at a negative pressure with respect to the ambient pressure, assuming a maximum wind velocity of 32 mph.

All components, piping, valves, and dampers are designed to meet the criteria of appropriate system quality group classification as listed in Subsection 3.2.2. The reactor/auxiliary building ventilation system is nonseismic, with the exception of ventilation penetrations of the reactor building secondary containment and the engineered safeguard equipment space coolers, which are Category I. The reactor building secondary containment ventilation penetrations consist of the ventilation ductwork and associated isolation valves and actuators. The isolation valves and space coolers receive control and operating power from buses that are connected to the EDGs. The essential battery room ventilation fans are also Category I. The power supplies to these fans are from motor control centers (MCCs) that were installed non-1E, but are automatically restorable from essential power. The MCCs were purchased to the same specifications (except for documentation requirements) as Class 1E, and their installation is seismically qualified. The MCCs will be maintained as 1E equipment.

9.4.2.2 System Description

The reactor/auxiliary building ventilation system is shown in Figure 9.4-4, Sheets 1 and 2. The nominal size and type of principal system components are listed in Table 9.4-3.

Areas in the reactor and auxiliary buildings that have separate ventilation and air conditioning and/or cooling systems are not covered in this subsection. These areas, given in the following listing, are covered in the indicated subsections:

a. Steam tunnel (Subsection 9.4.6)

b. Control center and standby gas treatment system (SGTS) room (Subsection 9.4.1)

c. Drywell cooling (Subsection 9.4.5).

Normal ventilation of the SGTS equipment rooms is handled by the CCACS and is discussed in Subsection 9.4.1. However, ventilation of these rooms is isolated during a DBA. The emergency fan-coil coolers, which are included as part of the reactor/auxiliary building ventilation system, will then handle the cooling requirements for this room.

Air conditioning of the motor-generator set is discussed in Subsection 9.4.11.

The reactor/auxiliary building ventilation system supplies filtered outside air to accessible areas of the reactor and auxiliary buildings through a central fan system consisting of an outside air intake, filters, heating coils, and three 50 percent-capacity fans. The air intake is located midway down the south side of the auxiliary building. The ventilation air is supplied to accessible areas of the buildings through ductwork and is exhausted from areas of high potential contamination through a common vent located on top of the auxiliary building. Three 50 percent-capacity exhaust fans are provided.

Normally, one exhaust and one supply fan are on standby. Gravity backdraft dampers with counterbalancing weights are provided to prevent backflow of contaminated air and permit control of the required differential pressure (approximately 1/4 in. of H_2O) between general access areas and potentially contaminated areas. Backdraft dampers are fitted on the inlets of exhaust ducts that run between general access areas and potentially contaminated areas.

Each of the two battery rooms that are located in the auxiliary building has two 100 percent-capacity exhaust fans. One air-conditioning unit serves both battery rooms. However, safety- related space coolers provide essential cooling at the battery charger location next to each battery room. The exhaust fans draw air into and through the battery room from general access areas and exhaust the air to other general access areas when the air conditioner is off. The main function of the battery exhaust fans is to prevent the buildup of hydrogen from reaching an explosive concentration in the battery room. The fan units are seismically qualified and powered from an automatically restorable ac bus on loss of offsite power. The air-conditioning unit is not considered part of the ESFs in that it is provided only to prolong the life of the batteries. However, battery charger area coolers are capable of maintaining area temperature under 120°F independent of the air-conditioning unit, with or without a loss of offsite power.

The design of the refueling floor area ventilation is sized for a minimum of 7 air changes per hour based on the volume in the lower 15 ft of the refueling area. The supply air outlets are located 15 ft above the refueling floor level. The airflow is directed across the refueling floor toward the pools. The building ventilation system exhaust takes suction from the following refueling areas:

a. Dryer-separator storage pool - 25 percent, 8250 cfm

b. Fuel storage pool - 50 percent, 16,500 cfm

c. The reactor well - 25 percent, 8250 cfm.

During non-refueling periods, the reactor well will not be ventilated; however, the excess air will be exhausted along the wall above the refueling floor.

The ventilation system also serves to purge the primary containment to permit personnel access. This is accomplished through the cross tie between the primary containment purge piping and the building ventilation system. Sufficient airflow (8500 cfm) is provided to purge the drywell and suppression chamber a minimum of three air changes per hour. The purge air is normally processed through the building exhaust system. However, when the drywell atmosphere is contaminated, initiating a reactor building heating, ventilation, and air conditioning (HVAC) shutdown and isolation, the purge air is processed through the SGTS, which is described in Subsection 6.2.3.

The only areas not ventilated in the reactor and auxiliary buildings are stairwells that are fire rated.

Two reactor building isolation dampers are provided in each supply and exhaust duct that penetrates the reactor building. These dampers are closed when there is high radioactivity in the reactor building, high drywell pressure, low reactor water level, or loss of offsite power. When the reactor building is isolated, the ventilation supply and exhaust fans are tripped off and the reactor building is maintained under negative pressure by the SGTS. The same signal that isolates the reactor building ventilation also signals the isolation valve between the reactor building ventilation duct and the SGTS to open. A reactor building isolation pushbutton is provided in the main control room. The fan-coil cooling units are intended primarily to function while the reactor building is isolated, at which time the ventilation system is shut down. The fan-coil cooling units are either automatically controlled by a thermostat located in the room they serve or they are operated in a manual mode where they operate continuously. Thus, the fan-coil units will also aid to cool their respective areas whenever the ventilation system is unable to maintain the designed room temperatures.

During normal plant operation and outages, it sometimes becomes necessary to take a fan-coil unit out-of-service for preventive or corrective maintenance. When this happens, the plant determines the operability of the safety-related equipment that relies on the fan-coil unit for local cooling and then follows the plant's Technical Specifications.

The following fan-coil cooling units are required to operate following a DBA and, as such, are part of the plant ESFs:

a. One unit of 100 percent capacity furnished for each division of residual heat removal (RHR) pumps

b. One unit of 100 percent capacity furnished for each division of core spray pumps. The Division I unit also cools the reactor core isolation cooling (RCIC) pump

c. One unit of 100 percent capacity furnished for the high pressure coolant injection (HPCI) pump room

d. One unit of 100 percent capacity furnished for each division of SGTS filter unit room

e. One unit of 100 percent capacity furnished for each division of EECW pumps

f. Deleted

g. Two units, each of 50 percent capacity, furnished for each division of the switchgear room

h. This item is not used

i. One unit of 100 percent capacity furnished for each division of the control air compressors

j. One unit of 100 percent capacity furnished for each division of the battery charging area.

The fan-coil cooling units recirculate room air to remove heat generated by process equipment. Cooling water is normally supplied to the fan-coil units by the RBCCWS. During malfunction of the RBCCWS or on loss of offsite power, cooling water is supplied by the EECWS. All of the above fan-coil cooling units are physically separated by virtue of their location.

Radiation monitors are provided in the building exhaust to monitor the release of airborne activity. Upon detection of high radioactivity in the exhaust vent, an alarm is sounded in the main control room. Simultaneously, the building ventilation system fans are automatically tripped off and the isolation dampers are closed automatically. A description of the monitoring system is presented in Subsection 12.2.4.

9.4.2.3 Safety Evaluation

The reactor/auxiliary building ventilation system is required to operate only during normal plant operations except the fan-coil cooling units, the battery room exhaust fans, and the reactor building supply and exhaust isolation dampers, which are required to operate after a DBA. To ensure the reliable and safe operation of the ventilation system over the full range of normal plant operations, the portion of the system that is not required to operate after a DBA incorporates the following design features:

a. The ventilation system maintains the building at a negative pressure with respect to the ambient pressure to preclude exfiltration of potentially contaminated air. (The reactor building is maintained at a negative pressure by the SGTS following the isolation of the reactor building)

b. Backdraft dampers are used in the ventilation system to prevent backflow between general access areas and contaminated areas

c. Standby exhaust and supply fans are provided to increase the availability of the ventilation system

d. The ventilation system in the area of the refueling pool is designed to exhaust more air than is supplied. In addition, the supply air is directed across the refueling pool. This method of ventilating the refueling pool area limits the spread of radioactivity from the refueling pool to other parts of the reactor building

e. Potentially contaminated effluent rising from the surface of the refueling pool and the dryer-separator pool is entrained in the normal ventilation air and is drawn into the exhaust openings located above the pool water level. A radiation monitor is provided on the exhaust ducts from the pool areas. The monitors will alarm in the main control room if a high radiation level is detected and will automatically start the SGTS, isolate the reactor building normal air intake and exhaust, and place the CCACS into recirculation mode.

The fan-coil cooling units, the battery room exhaust fans, and the reactor building supply and exhaust isolation dampers, all of which are required to operate after a DBA, incorporate the following design features to ensure their reliable and safe operation following a DBA:

a. Battery room exhaust fans and fan-coil units receive power from the same division as the equipment they protect. The diesel generators are the source of electrical power in the event of a loss of normal offsite power

b. The loss of any of the fan-coil units has the same effect on the safety of the plant as the loss of the equipment being cooled. Therefore, a single failure of the ventilation system affecting the safety-related equipment rooms will not prevent safe shutdown of the plant. Each ECCS subsystem (Division 1 RHR pump room, Division 2 pump room, Division 1 core spray and RCIC pump room, Division 2 core spray pump room, and HPCI pump room) has its own integral area cooling subsystem and fan-coil unit which is supplied from the same essential bus as the ECCS subsystem being cooled and which is an ESF. The loss of a particular ECCS subsystem, its room, or its equipment area cooling subsystem would result in automatic initiation of the redundant ECCS subsystem

c. Each battery room has two 100 percent-capacity exhaust fans. The loss of one of these fans has no effect on plant availability.

9.4.2.4 Inspection and Testing

All equipment is factory inspected and tested in accordance with applicable equipment specifications, quality assurance requirements, and codes. The system ductwork and erection of equipment were inspected during various construction stages, and construction tests were performed on all components of the system. The system was balanced for the design airflow and system operating pressures in accordance with Sheet Metal and Air Conditioning Contractors National Association procedures. Controls, interlocks, and safety devices on each system were adjusted and tested to ensure proper sequence of operation. Initial system flow distribution, valve and damper operability, instrumentation and control loop checks, and alarm setpoints were done in accordance with the Preoperational Test program as discussed in Chapter 14. Periodic tests of all system functions will be performed in accordance with normal operating procedures.

9.4.2.5 Instrumentation and Controls

Each exhaust and supply fan is manually controlled from the main control room. In order to ensure that a negative pressure is maintained in the reactor building while starting a fan combination, a time delay is provided so that the exhaust fan will start first. In addition, the motor starters are interlocked after starting to ensure that the associated fan shuts down when either an exhaust or supply fan is tripped.

The outside barometric pressure is detected on each of the four sides of the building and compared with the pressure being detected on the inside of the building. The difference between the lowest outside pressure and the inside pressure then is used as the control signal for modulating the inlet vanes of the ventilation system exhaust fan in order to maintain the building pressure lower than the outside pressure. Should the pressure in the building become excessively high or low (2.50 in. H_2O above or below the setpoint), the fans are automatically tripped.

The fan-coil cooling units located in a harsh environment are operated in a manual mode where they run continuously. The remainder of the fan-coil cooling units are operated in an automatic mode where the units start when the thermostat in the room being cooled reaches its setpoint.

Tripping of the supply and/or exhaust fans and dampers is indicated by audible and visible alarms in the main control room and audible and visible alarms on the refueling floor.

9.4.3 Radwaste Building Ventilation System

9.4.3.1 Design Bases

The radwaste building ventilation system is designed to maintain a suitable environment that conforms to the equipment and personnel ambient requirements in that area. The specific temperature design criteria used in sizing the system components are as follows:

a. Outside air design temperatures

   1. Dry bulb temperature, -10°F to 95°F

   2. Wet bulb temperature, 75°F maximum.

b. Inside air design temperatures

   1. Radwaste office, control room, and Health Physics laboratory, 75°F ±5°F

   2. Other general access areas, below 105°F

   3. All other areas, below 125°F.

In order to maintain the general access areas as free from potential radioactivity as possible, the system is designed to direct airflow from general access areas to areas of higher potential radioactivity. Exfiltration of potentially contaminated air to the environment is prevented by maintaining the building at a lower pressure than the ambient pressure.

Filters are provided in both the intake and exhaust systems. The intake filters reduce the amount of dust particles that are induced into the radwaste building. The exhaust filters are provided to remove particulate activity from the ventilation exhausts of the radwaste building.

Local hoods are provided to exhaust fumes from selected equipment handling radioactive wastes. Each fume hood exhaust system is designed to maintain a minimum face velocity of 100 fpm across the door opening of the hood.

This system is required to function under normal operating conditions only and therefore is not specifically designed to operate after a DBA. This system is nonseismic.

9.4.3.2 System Description

The radwaste building ventilation system diagram is presented in Figures 9.4-5 and 9.4-6. The nominal size and type of principal system components are presented in Table 9.4-4.

The radwaste building ventilation system consists of two 100 percent supply fans, two l00 percent exhaust fans, one fume hood exhaust fan, and a radwaste control room and laboratory air conditioning system. System fans, including booster fans, take suction through modulating dampers, a prefilter, and either a HEPA or a high-efficiency filter. The intake, exhaust, and fume hood fans all discharge through shutoff dampers. The supply fans take suction through louvers that are located above the radwaste building and supply a total of approximately 22,567 cfm to principal areas of various floor levels of the building. These fans also supply approximately 1650 cfm to the pipe tunnel between the radwaste and turbine buildings. Normally, air is supplied to general access areas and is exhausted from potentially contaminated areas. Wherever an exhaust duct is located between a general access area and an area of higher potential radioactivity, the inlet to the duct is fitted with a backdraft damper. This prevents exfiltration of air from a higher to a lower potential radioactive area. The Drum Conveyor Rooms and a portion of the Drum Conveyor Operating Aisle (DCOA) Room (east of column line S) were converted to a storage area. A 9'x8' opening was installed in the Radwaste Building south wall (just east of column line T), and three openings in the wall between the Drum Conveyor Rooms and the DCOA Room. To isolate this storage area from the Radwaste Building to allow maintaining the design negative pressure in the remainder of the building, fire walls were installed and all perimeter walls, ceiling, and floor penetrations, including drains, were made air tight. In addition, the registers on the supply duct along column line 14 in the DCOA Room were closed, the make up vents on the west wall of Drum Conveyor Room III were sealed, and the return duct routed along column line V was removed and the ceiling penetration sealed. A new return air register was installed in the return air duct in the East Corridor area in order to compensate for the air supply isolated from the Drum Conveyor Room.

Each of the radwaste building exhaust fans discharges approximately 31,818 cfm from the radwaste building. The exhaust fans take suction from all principal areas on the various floor levels of the building and from the vents of the following tanks and equipment:

a. Waste collector tank
b. Waste surge tank
c. Waste sample tanks
d. Floor drain sample tank
e. Floor drain collector tank
f. Waste sludge tank
g. Spent resin tank
h. Centrifuges
i. Condensate phase separators
j. Chemical waste tank
k. Radwaste evaporators.
l. Side Stream Liquid Radwaste Processing System (SSLRPS) Distillation Inlet Batch Tank
m. SSLRPS Post Treatment System Inlet Batch Tank
n. SSLRPS High and Low Rad Side Stream Evaporator Condenser Air Exhausts
o. SSLRPS Sample Batch Tank
p. SSLRPS Granular Activated Carbon Filter Tanks
q. SSLRPS Mixed Bed Filter Tanks

In addition, the hood exhaust fan in the Health Physics area exhausts approximately 6600 cfm from the radwaste laboratory fume hoods. The radwaste exhaust fans and the fume hood exhaust fan discharge air through a common exhaust vent located on top of the radwaste building. A radiation monitor is connected to the common exhaust header.

The radwaste office, radwaste control room, and Health Physics laboratory air conditioning subsystem consists of a double-duct air-handling unit, fan, steam heating coil, evaporator-type cooling coil, and remote water-cooled chiller unit which is cooled by the turbine building closed cooling water system (TBCCWS). Steam to the heating coils is supplied by the auxiliary boilers. The system supply ductwork consists of three decks: hot, cold, and auxiliary. The hot and cold ducts go to mixing boxes that mix the air to the temperature required by each room. The auxiliary air is ducted to the low-level laboratory fume hood through a pressure reducing valve. Return air is ducted to the air-conditioning unit, where it is mixed with fresh air to make up for the air exhausted by the fume hood exhaust fan. The air-conditioning unit consists of a filter, preheat coil, fan, cooling coil, and heating coils with face and bypass dampers.

In addition to the normal ventilation systems, a Dedicated Shutdown Air Conditioning Unit is installed on the second floor of the Radwaste building to support post-fire dedicated shutdown as described in section 7.5.2.5 and Appendix 9A. It is a split system with the air-handling unit (AHU) located inside the room and outside condensing unit located on the adjacent roof. The AHU consists of an inlet filter, fan, evaporator-type cooling coil, condensate collection tank and condensate pump. The discharge ductwork and dampers cool the area in the vicinity of the dedicated shutdown panel. The condensing unit is a split system cooling condenser consisting of two refrigerant circuits that reject heat to the ambient outdoor air. Each circuit consists of a compressor/motor, coil and fan/motor.

Radiation monitors are provided in the building exhaust vent to monitor the release of airborne radioactivity. Upon detection of high radioactivity in the exhaust vent, an alarm is sounded in the main control room. Simultaneously, the building ventilation system fans are tripped off and the isolation dampers are closed automatically. A description of the monitoring systems is presented in Subsection 12.2.4.

9.4.3.3 Safety Evaluation

The radwaste building ventilation system is required to operate only during normal plant operation. However, the system does incorporate features to ensure its reliable and safe operation over the full range of normal plant operation. These features include the installation of standby exhaust and intake fans, and the use of backdraft dampers between general access areas and areas of potentially high radioactivity to prevent general access areas from becoming contaminated. In addition, the system is designed to prevent exfiltration of potentially contaminated air to the environment by maintaining the internal pressure of the radwaste building negative with respect to the ambient pressure.

The Dedicated Shutdown Air Conditioning Unit supports a post-fire shutdown from outside the Main Control Room as described in Section 7.5.2.5.

9.4.3.4 Inspection and Testing

All equipment has been factory inspected and tested in accordance with applicable equipment specifications, quality assurance requirements, and codes. The system ductwork and erection of equipment were inspected during various construction stages. Construction tests were performed on all components of the system. The system has been balanced for the design airflow and system operating pressures. Controls, interlocks, and safety devices on each system were adjusted and tested to ensure proper sequence of operation. Initial system flow distribution, valve operability, instrumentation and control loop checks, and alarm setpoints were done in accordance with the Preoperational Test program as discussed in Chapter 14.

The Dedicated Shutdown Air conditioning Unit is also balanced for its operating conditions. This system and its components will be tested and maintained periodically, as appropriate for the system safety classification.

9.4.3.5 Instrumentation and Controls

Each exhaust and supply fan is manually controlled from the main control room. In order to ensure that a negative pressure is maintained in the radwaste building while starting a fan combination, a time delay is provided to make the exhaust fan start first. In addition, the motor starters are interlocked after starting to make the associated fan shut down when either an exhaust or supply fan is tripped.

The outside barometric pressure is detected on each of three sides of the building and compared with the pressure being detected on the inside of the building. The difference between the lowest outside pressure and the inside pressure then is used as the control signal for modulating the inlet vanes of the ventilation system exhaust fan in order to maintain the building pressure lower than the outside pressure. Should the pressure in the building exceed the alarm setpoints, the fans will be manually tripped.

The balance-of-plant battery room cooling equipment is controlled by a thermostat.

The exhaust air radiation monitoring system will alarm in the main control room in the event of high radioactivity in the exhaust header. A radwaste building isolation pushbutton is provided in the main control room to isolate the exhaust and shut down the supply and exhaust fans.

The instrumentation and controls for the Dedicated Shutdown Air Conditioning System are discussed in Section 7.5.2.5.

9.4.4 Turbine Building Ventilation System

9.4.4.1 Design Bases

The turbine building ventilation system is designed to provide a suitable environment for personnel and to ensure the integrity of equipment and controls located in the turbine building.

The turbine building ventilation system, which has been modified to repitch the fans on the supply and return air, is designed to maintain the temperature in general access areas below 115°F and to ensure that the temperature in all other areas within the turbine building is below 125°F, with the following exceptions:

a. The lube oil room, feedwater heater room, turbine building overhead crane bay, off gas preheater, off gas filter, turbine deck, and the second floor steam tunnel exceed the 115°F and 125°F design temperatures. The maximum nominal temperature for the steam tunnel is 180°F (measured at the ceiling). The maximum nominal temperature for the other specified rooms is less than 150.5°F.

b. The offgas system charcoal adsorber room, which has its own air conditioning system to ensure that the temperature within the room is 70°F (Nominal), and the excitation equipment area, which has its own air cooling system to ensure that the nominal temperature within the area does not exceed approximately 104°F.

The turbine building ventilation system is designed based on the following outside air temperatures:

a. Dry bulb temperature, -10°F to 95°F

b. Wet bulb temperature, 75°F maximum.

To maintain areas within the turbine building as free from potential radioactive contamination as possible, the system is designed to direct the airflow from areas of low potential radioactivity to areas of progressively higher potential radioactivity. The exhaust from the turbine building is monitored to detect and annunciate high radiation levels.

Exfiltration of potentially contaminated air to the environment is prevented by maintaining the building at a negative pressure with respect to the plant environment.

This system is required to function under normal plant operating conditions only and therefore is not specifically designed to operate after a DBA. The system components are designed to nonseismic requirements, with the exception of a few PAS system components located in the Auxiliary Building which are designed to seismic class II/I requirements.

9.4.4.2 System Description

The turbine building ventilation system is shown schematically in Figure 9.4-7. The nominal size and type of principal system components are presented in Table 9.4-5.

The turbine building is heated, cooled, and ventilated during normal and shutdown operation by a circulating air system. The building is heated by the ventilation air intake heating coils, and unit space heaters which are serviced by the auxiliary boiler of the plant. Cooling of the building is accomplished by circulating outside air throughout the ventilation system. All outside air enters the building through an intake located on top of the building and then passes through an evaporative air cooler cooling unit, the fresh air intake dampers, a filter bank, heating coils, a shutoff damper, and two of the three 50 percent-capacity intake fans. The air from these fans is generally distributed to areas of low potential radioactivity through distribution ducts. If the air is discharged into an area of high potential radioactivity, it is exhausted from that area by exhaust ducts and is discharged through the building exhaust enclosure. The air that is discharged into areas of low potential radioactivity is circulated through areas of higher potential radioactivity by the use of propeller fans. The air is then induced into the exhaust ductwork and discharged through the exhaust enclosure by two of the three 50 percent-capacity fans.

A radiation monitor is provided in the building exhaust vent to monitor the release of airborne radioactivity. Upon detection of high radioactivity in the exhaust vent, an alarm is sounded in the main control room. Simultaneously, the building ventilation system fans are automatically tripped off. A description of the monitoring systems is presented in Subsection 12.2.4.

The ventilation system also provides ventilation to the switchgear and exhaust fan rooms of the radwaste building and to the RBCCWS equipment area in the auxiliary building.

The offgas system charcoal adsorber room is provided with one air change per hour. Three cooling coil units are provided in the adsorber room, complete with fan, direct expansion cooling coil, and expansion valve. The compressor/condenser units are located outside the adsorber room. Cooling water is supplied to the condenser by the TBCCWS. The three cooling units are sized to maintain the adsorber room at 70°F during normal operation.

Gravity-type backdraft dampers having adjustable counterbalancing weights are provided on the discharge of propeller fans functioning to exhaust air from general access areas to potentially contaminated areas. This prevents backflow of contaminated air.

The excitation equipment area is provided with a separate air cooling system located on the second floor of the turbine building. Two 100% capacity, water cooled air coolers are provided to maintain the excitation equipment area at a nominal ambient temperature of 104°F during normal operation. Cooling water is supplied by the TBCCW System.

9.4.4.3 Safety Evaluation

The turbine building ventilation system is required to operate only during normal plant operation. However, the system incorporates features to ensure its reliable and safe operation over the full range of normal plant operation. These features include the installation of standby exhaust and intake fans, and the use of backdraft dampers between general access areas and areas of potentially high radioactivity to prevent general access areas from becoming contaminated. With respect to the higher temperature areas in the turbine building (i.e. areas above 115°F/125°F), an evaluation of the impact to equipment and personnel was performed. Results of the review show that the components are fully capable of functioning at the higher temperatures. Plant personnel are not required to access any of the high temperature areas during plant operation or following an accident condition in order to safely shut down and/or maintain the plant in a safe shutdown condition.

The system is designed to prevent exfiltration of potentially contaminated air to the environment by maintaining the internal pressure of the turbine building negative with respect to the ambient pressure.

A radiation monitor in the exhaust vent automatically trips the turbine building ventilating system in the event of a high radiation level.

9.4.4.4 Inspection and Testing

All equipment has been factory inspected and tested in accordance with applicable equipment specifications, quality assurance requirements, and codes. The system ductwork and erection of equipment were inspected during various construction stages. Construction tests were performed on all components of the system. The system has been balanced for the design airflow and system operating pressures. Controls, interlocks, and safety devices on each system were adjusted and tested to ensure proper sequence of operation. Initial system flow distribution, valve and damper operability, instrumentation and control loop checks, and alarm setpoints were done in accordance with the Preoperational Test program as discussed in Chapter 14.

9.4.4.5 Instrumentation and Controls

Each exhaust and supply fan is manually controlled from the main control room and, to ensure that a negative pressure is maintained in the turbine building while starting a fan combination, a time delay is provided to ensure that the exhaust fan starts first. In addition, the motor starters are interlocked after starting to ensure that the associated fan shuts down when either an exhaust or supply fan is tripped.

The outside barometric pressure is detected on each of the four sides of the building and compared with the pressure being detected on the inside of the building. Should the pressure in the building become excessively high or low, both the supply and exhaust fans are automatically tripped.

The adsorber room cooling equipment is controlled by a thermostat.

9.4.5 Drywell Cooling System

9.4.5.1 Design Bases

The cooling system is designed to maintain the average ambient temperature at 135°F. The drywell volumetric average temperature may increase over 135°F and up to 145°F. The area around the primary coolant recirculating pump motors is limited to 128°F during normal operation. During a scram, the system is designed to limit the temperature in the area below the reactor pressure vessel (RPV) to 185°F. The system is not required to operate following a LOCA and is isolated.

The design of the system permits periodic inspection and testing of the principal system components where they are accessible.

The power supply to the drywell cooling unit fans is designed to allow operation from the EDG-fed buses if normal ac power is not available.

The system components, excluding single-speed fan and fan motors but including fan-coil units and ducts, are Category I.

The cooling water supply piping to the fan-coil units in the drywell is provided with a check valve inside containment and one remote, manually actuated isolation valve outside containment. The supply line outboard isolation valves will automatically close on high drywell pressure initiation of EECWS. The cooling water return piping has two remote, manually actuated isolation valves, one on each side of the drywell wall for containment isolation.

Pressure relief valves are provided to relieve hydrostatic pressure caused by water expansion in the cooling water header subsequent to system isolation during and after a LOCA. The system will be operated during nitrogen purging of the containment in order to provide proper mixing of the containment atmosphere.

9.4.5.2 System Description

The system design for drywell cooling is presented in Figure 9.4-8. The nominal size and type of principal system components are listed in Table 9.4-6.

The system design is based on recirculating drywell air and cooling water through fan-coil units to limit the maximum drywell temperature. Cooling water is supplied by the RBCCWS under normal conditions and EECWS during abnormal operating conditions. However, high drywell pressure in conjunction with EECW operation will automatically close the EECW supply line outboard isolation valves.

The cooling system consists of 14 fan-coil coolers. Each unit is furnished with cooling coils, supply air fan, distribution ductwork, air-diffusing devices, and controls. Drywell temperature is maintained by mixing the cool air with the heated air at the heat source.

The fourteen drywell coolers are physically separated into two divisions, each consisting of five single-speed and two two-speed coolers. During normal plant operation, six of seven drywell cooler fans in each division are continuously operating in order to maintain the drywell atmosphere temperatures below the prescribed limits. All of the two-speed fans operate at high speed during normal operation.

All of the fan motors are provided with temperature detectors for the motor windings, a bearing vibration detector, and an integral space heater to maintain motor temperature above ambient during motor shutdown.

All ductwork is fabricated from carbon steel. Each section is galvanized after fabrication.

Electrical power for operation of the Category I cooling units is supplied from ESF buses, maintaining the divisional concept of separation and redundancy. Electrical power for operation of the single-speed fans is supplied from EDG restorable BOP buses. One-half of the fans are supplied from the Division I bus, the other half from the Division II bus. These buses are supplied from the EDG system if offsite electrical power is lost.

Cooling water is supplied to the coolers from two redundant EECWS piping loops during abnormal operation of the system. The loops are designated as Division I loop and Division II loop. Each loop is designed to supply cooling water to one-half of the coolers. Both loops are supplied by cooling water from a single header of the RBCCWS during normal operation.

9.4.5.3 Safety Evaluation

The drywell cooling system is not required for the safe shutdown of the plant. The system incorporates features that ensure its reliable operation over the full range of normal plant operations. These features include the separation of the system into two cooling divisions.

In the event of a postulated design basis accident (LOCA), all of the single-speed drywell cooler fans in AUTO are automatically tripped, and the four two-speed drywell cooler fans then automatically shift to slow speed. Plant procedures provide the necessary guidance for returning any of the drywell coolers to service.

This is done to preclude the possibility of two phase flow phenomenon accompanied by potential water hammer damage due to the initial formation of steam bubbles and their subsequent collapse by the introduction of colder supply water to the drywell cooling system.

Instrumentation is provided to monitor the temperature in various zones in the drywell and to annunciate high temperatures in the main control room.

The equipment and ducts inside the drywell are designed to Category I requirements. Relief valves on the EECWS preclude the possibility of coil rupture inside the drywell as a result of a rise in cooling water temperature and pressure after closure of the isolation valves.

All equipment meets the criteria of the appropriate system quality group classification and codes listed in Subsection 3.2.2.

Upon the loss of offsite power, all fans will trip off. All previously operating units will be restarted automatically using power supplied to the essential and BOP buses from the diesel generators, unless a LOCA signal is also present concurrent with the loss of offsite power.

9.4.5.4 Inspection and Testing

The system will not be accessible during reactor operation. Routine testing and inspection of the system will be accomplished during scheduled reactor shutdowns. However, monitoring devices are provided to determine that the fan-coil units are functioning properly during normal operation.

All equipment has been factory inspected and tested in accordance with the applicable equipment specifications, quality assurance requirements, and codes. System ductwork and the erection of equipment has been inspected for quality assurance during various construction stages. Construction tests were performed on all mechanical components. The system was balanced for the design airflow and system operating pressures. Controls, interlocks, and safety devices on each system were cold checked, adjusted, and tested to ensure proper sequence of operation. Initial system flow distribution, valve and damper operability, instrumentation and control loop checks, and alarm setpoints were done in accordance with the Preoperational Test program as discussed in Chapter 14.

9.4.5.5 Instrumentation and Controls

The drywell cooling system is a "full-on" system in that no modulating controls are installed to automatically reduce or maintain set temperatures. The cooling water flow through the cooling coils and the airflow are constant. Manual balance valves are provided at each air discharge diffuser to adjust the airflow. Cooling capacity can be reduced by shutting down individual unit coolers.

Controls required for remote operation of the system are located in the main control room.

Restart of the cooling units after a loss of offsite power is accomplished automatically on a permissive signal. Restart of the cooling units is initiated within 90 sec after a loss of offsite power, and all cooling units will be in operation within 120 sec after a loss of offsite power.

Thermocouples are provided in various areas in the drywell to monitor the temperature, with alarms and temperature indication provided in the main control room.

9.4.6 Steam Tunnel Cooling System

9.4.6.1 Design Bases

The system is designed to maintain the temperature in the steam pipe tunnel below 130°F and is nonseismic.

9.4.6.2 System Description

A diagram of the steam tunnel cooling system is shown in Figure 9.4-9. Nominal sizes and types of principal system components are listed in Table 9.4-7.

The system consists of two 100 percent-capacity cooling coils and fans that are connected to a common supply plenum. The supply ducts from the plenum deliver the cooled air to various areas within the tunnel. The air is returned to the cooling coils by the induced draft of the fan. Cooling water is supplied to the cooling coils by the RBCCWS.

Balancing dampers are provided in each supply duct downstream of the common supply plenum, and shutoff dampers are provided for each fan.

A pressure equalizing line between the steam tunnel and the reactor building functions primarily to maintain secondary containment negative atmospheric pressure within the steam tunnel in the event of a DBA.

9.4.6.3 Safety Evaluation

The steam tunnel cooling system is required to operate only during normal plant operation. To ensure high reliability of the system and safe operation over the full range of normal plant operation, two 100 percent fan-coil units are provided.

9.4.6.4 Inspection and Testing

All equipment has been factory inspected and tested in accordance with the applicable equipment specifications, quality assurance requirements, and codes. Controls and safety devices on each system have been cold checked, adjusted, and tested to ensure the proper sequence of operation. Initial system flow distribution, valve and damper operability, instrumentation and control loop checks, and alarm setpoints were done in accordance with the Acceptance Test program as discussed in Chapter 14.

Routine maintenance and tests, based on the manufacturer's recommendations and/or operating/maintenance experience, are scheduled in accordance with the plant preventive maintenance program.

9.4.6.5 Instrumentation and Controls

The steam tunnel cooling system is manually controlled from the main control room.

A temperature-sensing element is located inside the steam tunnel and displays the temperature in the main control room. This same element sounds an alarm in the main control room when the steam tunnel air temperature exceeds 160°F.

9.4.7 Residual Heat Removal Complex Ventilation Systems

The RHR complex is composed of two identical divisions. The safety-related equipment in one division is 100 percent redundant to that in the other division. Each RHR division is composed of two diesel generator rooms, two diesel oil storage rooms, two switchgear rooms, and a pump room. The diesel-fuel-oil storage room ventilation system is used to purge the diesel generator room, diesel generator oil storage room, and air receiver room. This system operates continuously for all modes of plant operation. Each division of the RHR complex includes ventilation systems, as described in the following subsection. Failure analysis of the ventilation system for the RHR complex is provided in Table 9.4-8.

A typical ventilation system flow diagram for the RHR complex is presented in Figure 9.4-10. Nominal sizes and types of principal system components are listed in Tables 9.4-9 through 9.4-12.

9.4.7.1 Residual Heat Removal Diesel Generator Room Ventilation System

9.4.7.1.1 Design Bases

The diesel generator room ventilation systems are not required to operate during plant operation unless the ventilation equipment itself is in the manual mode, the diesel generators are running, or the room temperature rises above the room temperature controller setpoint.

The diesel generator room ventilation systems limit the temperature of each diesel room to a maximum of 122°F in conformance with the equipment requirements. The systems are available under all plant operating conditions.

Outside air with a maximum design temperature of 95°F is used to dissipate heat produced by the operation of the equipment in the diesel room.

The systems are designed to Category I requirements.

The fans are powered from ESF buses corresponding to the diesel generators they are serving.

The air intake and exhaust openings are located a sufficient distance apart to preclude reintroduction of exhaust air into the room. The outside air intakes and exhaust openings are protected by missile walls or slabs.

9.4.7.1.2 System Description

Each diesel room is provided with two 50 percent-capacity supply air fans. The operation of the fans induces outside air through a control damper and mixes the recirculation air from the diesel room in order to maintain the minimum air temperature above 65°F during diesel generator operation. The recirculation air path is provided with a control damper.

The mixed air is discharged into the diesel room by the supply fans. A part of the exhaust air is recirculated, depending upon the temperature of the return air. The balance of the exhaust air is forced through gravity dampers provided at the exhaust outlet.

Each division of the RHR complex is redundant to the other, thereby satisfying the need to make the respective equipment redundant.

9.4.7.1.3 Safety Evaluation

The loss of any ventilating fan or damper does not affect the safe-shutdown capability of the plant, since separate ventilation systems are provided for each redundant diesel generator.

To ensure maximum automatic fire-fighting capability, and to minimize potential cold-weather damage to equipment, the outside air damper fails closed upon loss of control power.

9.4.7.1.4 Inspection and Testing

All equipment has been factory inspected and tested in accordance with the applicable equipment specifications, quality assurance requirements, and codes. System ductwork and erection of equipment has been inspected for quality assurance requirements during various construction stages. Construction tests were performed on all mechanical components and the system was balanced for design airflow rates and system operating pressures. Controls, interlocks, and safety devices on each system were cold checked, adjusted, and tested to ensure proper sequence of operation. Initial system flow distribution, valve and damper operability, instrumentation and control loop checks, and alarm setpoints were done in accordance with the Preoperational Test program as discussed in Chapter 14.

Routine maintenance and tests, based on the manufacturer's recommendations and/or operating/maintenance experience, are scheduled in accordance with the plant preventive maintenance program.

9.4.7.1.5 Instrumentation

Each diesel generator room ventilation fan is interlocked to start with the operation of the respective diesel generator set. The ventilation fan will start automatically on high room temperature and can also be manually started by the switches provided in the main control room.

Temperature controllers sense temperature in each diesel generator room to modulate the intake and recirculation air dampers to maintain the room temperature within the design limits.

Indication of room temperature is provided locally. Damper position is indicated locally and in the main control room. An alarm is provided in the main control room for high and low room temperature. Supply fan "no airflow" indication is provided locally and is indicated and alarmed in the main control room.

9.4.7.2 Residual Heat Removal Switchgear Room Ventilation System

9.4.7.2.1 Design Bases

The switchgear room ventilation system is not required to operate during plant operation unless the ventilating equipment is in the manual mode, corresponding essential equipment is running, or the room temperature rises above the room temperature setpoint.

The system dissipates the heat produced by the switchgear room equipment, and limits the inside ambient temperature to 104°F under all plant operating conditions.

The outside air, with a design ambient temperature of 95°F, is used for cooling if necessary.

The system is designed to Category I requirements. Electrical power is furnished from the same ESF buses that supply power to equipment in the room being cooled.

The air intake and exhaust openings are located a sufficient distance apart to preclude reintroduction of exhaust air into the system. The outside air intakes and exhaust openings are protected by missile barriers.

9.4.7.2.2 System Description

Each switchgear room system consists of an intake air duct, high efficiency filter, and two 50 percent-capacity fans in parallel, arranged in the order given. The fan outlets are connected to a common supply air duct that distributes air to the switchgear room.

An outside air control damper is provided on the outside air duct, and a recirculation damper is provided on the mixing box upstream of the supply air filter. The operation of fans induces outside air and recirculated air into the mixing box to maintain the minimum air temperature above 65°F.

The mixed air is discharged in the switchgear room through the supply air duct system. A part of the exhaust air is recirculated, depending upon room temperature, and the balance of the air is forced through gravity dampers provided at the exhaust outlet.

9.4.7.2.3 Safety Evaluation

The loss of any ventilating fan does not affect the safe-shutdown capability of the plant, since a separate ventilation system is provided for each switchgear room.

To ensure maximum automatic fire-fighting capability, and to minimize potential cold-weather damage to equipment, the outside air damper fails closed upon loss of control power.

9.4.7.2.4 Inspection and Testing

All equipment was factory inspected and tested in accordance with the applicable equipment specifications, quality assurance requirements, and codes. System ductwork and the erection of equipment were inspected during various construction stages. Construction tests were performed on all mechanical components, and the system was balanced for the design airflow rates and system operating pressures. Controls, interlocks, and safety devices on each system were cold checked, adjusted, and tested to ensure the proper sequence of operation. Initial system flow distribution, valve operability, instrumentation and control loop checks, and alarm setpoints were done in accordance with the Preoperational Test program as discussed in Chapter 14.

Routine maintenance and tests, based on the manufacturer's recommendations and/or operating/maintenance experience, are scheduled in accordance with the plant preventive maintenance program.

9.4.7.2.5 Instrumentation and Controls

Each switchgear room ventilation system is started automatically on high room temperature or when its corresponding diesel generator sets are started. In addition, manual switches are provided in the main control room. A temperature controller located in the switchgear room modulates the intake and recirculation air dampers to maintain the room temperature within the design limits.

Room temperature and filter high differential pressure are indicated locally. An alarm is provided in the main control room for high and low room temperature. Supply fan "no airflow" indication is provided locally and is indicated and alarmed in the main control room.

9.4.7.3 Pump Room Ventilation System

9.4.7.3.1 Design Bases

The pump room ventilation system is not required to operate during normal plant operation unless the ventilating equipment itself is in the test mode, the corresponding essential pump is running, or the room temperature rises above the room temperature controller setpoint.

The system provides ventilation and limits the temperature of the pump room to 104°F.

The system dissipates the heat produced by the pumps and associated equipment, limiting the inside ambient temperature to 104°F under all plant operating conditions. The outside air, with a design ambient temperature of 95°F, is used for cooling.

The system is designed for Category I requirements. Electrical power is furnished from the same ESF buses that supply power to the equipment in the room being cooled.

The air intake and exhaust openings are located a sufficient distance apart to preclude reintroduction of exhaust air to the system. The outside air intakes and exhaust openings are protected by missile barriers.

9.4.7.3.2 System Description

The pump room ventilation system consists of an intake air duct, high efficiency filter, and two 50 percent-capacity fans in parallel, arranged in the order given. The fan outlets are connected to a common supply air duct that distributes air in the pump room.

An outside air control damper is provided on the outside air duct and a recirculation damper is provided on the mixing box upstream of the supply air filter. The operation of fans induces outside air and recirculated air into the mixing box to maintain a mixed air temperature above 65°F.

The mixed air is discharged to the pump room through the supply air duct system. A part of the exhaust air is recirculated, depending upon the room temperature, and the balance of the air is forced through the gravity dampers provided at the exhaust outlet. The intake and exhaust air openings are protected from missiles.

9.4.7.3.3 Safety Evaluation

The loss of the ventilating system does not affect the safe shutdown capability of the plant, since separate ventilation systems are provided for each redundant pump room.

To ensure maximum automatic fire-fighting capability and to minimize potential cold-weather damage to equipment, the outside air damper fails closed upon loss of control power.

9.4.7.3.4 Inspection and Testing

All equipment was factory inspected and tested in accordance with the applicable equipment specifications, quality assurance requirements, and codes. System ductwork and the erection of the equipment were inspected for quality assurance requirements during various construction stages. Construction tests were performed on all mechanical components, and the system was balanced for the design airflow rates and system operating pressures. Controls, interlocks, and safety devices on each system were cold checked, adjusted, and tested to ensure the proper sequence of operation. Initial system flow distribution, valve and damper operability, instrumentation and control loop checks, and alarm setpoints were done in accordance with the Preoperational Test program as discussed in Chapter 14.

Routine maintenance and tests, based on the manufacturer's recommendations and/or operating/maintenance experience, are scheduled in accordance with the plant preventive maintenance program.

9.4.7.3.5 Instrumentation and Controls

The pump room ventilation system is started automatically on high temperature or when the corresponding EDGs are running. Manual switches are provided in the main control room.

Room temperature and filter high differential pressure are indicated locally. An alarm is provided in the main control room for abnormal high or low room temperature. Supply fan "no airflow" indication is provided locally and is indicated and alarmed in the main control room.

9.4.7.4 Diesel-Fuel-Oil Storage Room Ventilation System

9.4.7.4.1 Design Bases

The diesel-fuel-oil storage room ventilation system is used to pull an adequate quantity of ventilation air through the diesel generator room, CO_2 storage room, fuel-oil storage room, and ventilation equipment room to maintain the temperature in these rooms below 104°F while the diesel is not operating and below 125°F when the diesel is operating. This system is designed to operate continuously for all modes of plant operation.

The outside air, with a design ambient temperature of 95°F, is used for cooling.

The system is designed to Category I requirements. The system is powered from ESF buses corresponding to the respective diesel generator.

9.4.7.4.2 System Description

The system exhausts air through exhaust ducts from the diesel generator room, CO_2 storage room, fuel-oil storage room, and ventilation equipment room. Air is induced through exhaust ducts by an exhaust fan. The exhaust air is discharged to the atmosphere through a missile-protected exhaust opening.

Nominal sizes and types of principal system components are listed in Table 9.4-12. Fire dampers are provided between rooms.

9.4.7.4.3 Safety Evaluation

The loss of any ventilating fan does not affect the safe-shutdown capability of the plant, since a ventilation system for each set of redundant rooms is provided.

9.4.7.4.4 Inspection and Testing

All equipment was factory inspected and tested in accordance with the applicable equipment specifications, quality assurance requirements, and codes. System ductwork and the erection of equipment were inspected for conformance with drawing and specification requirements during various construction stages. Construction tests were performed on all mechanical components, and the system was balanced for the design air and system operating pressures. Controls, interlocks, and safety devices on each system were cold checked, adjusted, and tested to ensure the proper sequence of operation. Initial system flow distribution, valve and damper operability, instrumentation and control loop checks, and alarm setpoints were done in accordance with the Preoperational Test program as discussed in Chapter 14.

Routine maintenance and tests, based on the manufacturer's recommendations and/or operating/maintenance experience, are scheduled in accordance with the plant preventive maintenance program.

9.4.7.4.5 Instrumentation and Controls

Manual switches are provided in the main control room. An indication of the temperature in each room except for the CO_2 storage room, fuel-oil storage room, and diesel generator ventilation equipment room is provided, along with an alarm in the main control room for high room temperature.

9.4.7.5 RHR Complex Heating System

9.4.7.5.1 Design Basis

Electric unit heaters are provided for the following areas:

a. RHR pump room

b. Diesel generator room

c. CO_2 storage room

d. Switchgear room

e. Switchgear ventilation equipment room

f. Diesel generator ventilation equipment room.

The electric unit heaters will maintain the RHR complex equipment rooms at an ambient temperature of 65°F during normal operation and shutdown. The electric unit heaters can be powered from an essential bus. The operation of the heaters inside the diesel generator rooms is required to support the standby readiness of each diesel by ensuring the temperature inside the diesel generator rooms remains above a design minimum value of 40°F. This ensures the initial combustion air inside the EDG intake manifolds remains above the 40°F minimum value necessary to support fast, cold-starting.

9.4.7.5.2 System Description

The electric unit heaters are self-contained with their own fan, heating coil, and thermostat. The heaters recirculate room air to maintain area air temperatures above 65°F. A Control Room Process Computer point alarms if the EDG room temperature begins to approach the 40°F design minimum value so that appropriate corrective action may be taken to restore the room environment.

9.4.7.5.3 Safety Evaluation

The RHR Complex Heating System has no safety design bases. However, the system is relied upon to maintain the temperature of the initial combustion air above the 40°F design minimum required for reliable fast, cold-weather starting. Thus, while the loss of the unit heaters during normal operation does not directly affect the safe-shutdown capability of the plant, EDG operability is compromised if the room is not maintained above the required 40°F.

9.4.7.5.4 Inspection and Testing

All unit heaters were factory inspected and tested in accordance with the applicable equipment specifications. Erection of the heaters was in conformance with drawing and specification requirements. Construction tests were performed on the unit heater system to ensure that the heaters will provide the desired flow distribution. Controls and safety devices for each unit heater were checked and adjusted to ensure proper operation. During the heating season, the heating units are periodically inspected to verify continued proper operation. Operator rounds are performed to verify EDG room temperatures are within the design envelope daily.

9.4.7.5.5 Instrumentation and Controls

Control of the electrical unit heaters is by an individual thermostat built into each unit heater.

9.4.8 Plant Heating System

9.4.8.1 Design Bases

The plant heating system is designed to limit the minimum temperature inside the reactor building, auxiliary building, radwaste building, and other miscellaneous facilities to 65°F. The system is designed to preheat the ventilation air to 65°F and provide perimeter heating to these buildings during the winter. The turbine building heating system is similar. However, the supply air temperature may be controlled in a range of 55°F to 65°F during the heating season.

The system performs its function during normal plant operation and shutdown. The heating steam isolation valves and piping on either side of the secondary containment boundary are seismic I. The remainder of the plant heating system is nonseismic. The system is required to function under normal plant operating conditions. Safety related motor operated isolation valves in the heating steam piping at the secondary containment boundary have been provided to allow the operators to isolate the steam piping in the event of a postulated break in the heating steam piping.

9.4.8.2 System Description

A diagram of the plant heating system is shown in Figure 9.4-11. Nominal sizes and types of principal system components are listed in Table 9.4-13. Steam is used for plant heating in the reactor, auxiliary, turbine, and radwaste buildings. Electrical unit heaters are provided to heat all other buildings. Steam is supplied to heating coils, located in the building ventilation supply system, and to unit heaters from the auxiliary steam boilers via a 15 psig pressure reducing station. To ensure that the steam pressure in the heating system does not exceed 15 psig, the reducing station is equipped with a pressure relief valve. The unit heaters are provided to offset transmission heat loss through exposed walls and roofs. The condensate from the heating coils is returned to a deaerator located in the auxiliary boiler room.

Permanent fuel oil, feedwater, and steam line connections are provided so that a portable boiler can be connected to the existing system to supply steam in a timely manner in the event of failure of the auxiliary boilers.

The system is designed to maintain the building temperature at 65°F, with an ambient temperature of -10°F.

9.4.8.3 Safety Evaluation

The operation of the plant heating system is not required to ensure the safe shutdown of the plant.

The system incorporates features that ensure its reliable operation over a full range of normal plant operations. These features include the installation of control valves on the coil inlet and multiple condensate return pumps.

Instrumentation is provided to monitor the temperature and pressure at various points.

Necessary safety features are provided for the operation of auxiliary boilers.

9.4.8.4 Inspection and Testing

All equipment was factory inspected and tested in accordance with the applicable equipment specifications, quality assurance requirements, and codes. System ductwork and the erection of equipment were inspected for quality assurance during various construction stages. Construction tests were performed on all mechanical components, and the system was balanced for the design water flows and system operating pressures.

Controls, interlocks, and safety devices were cold checked, adjusted, and tested to ensure their proper operation. Initial system flow distribution, valve and damper operability, instrumentation and control loop checks, and alarm setpoints were done in accordance with the Acceptance Test program as discussed in Chapter 14.

Maintenance is performed on a scheduled basis in accordance with the recommendations of the equipment manufacturer and/or operating/maintenance experience.

9.4.8.5 Instrumentation and Controls

The plant heating system works in conjunction with various ventilation systems in the plant. The system is put in service by manually starting the auxiliary boiler. The steam temperature and pressure at various points are monitored and indicated. The capacity control of the coils is achieved by modulating the inlet steam and not by throttling the condensate quantity, thereby precluding the possibility of coil freezeup resulting from low steam flow conditions.

The unit heaters are controlled by locally mounted thermostats with integrated on-off-auto switches.

9.4.9 General Service Water Pump House Heating and Ventilation System

9.4.9.1 Design Bases

The system is designed to maintain the temperature in the pump and switchgear rooms between 50°F and 120°F during all normal modes of plant operation and during plant shutdown periods. The ambient design temperature is between -10°F and 95°F.

The system is nonseismic.

9.4.9.2 System Description

A diagram of the general service water pump house heating and ventilation system is shown in Figure 9.4-12. Nominal sizes and types of principal system components are listed in Table 9.4-14.

The pump room is provided with three propeller-type fans equipped with gravity backdraft dampers. The fans are mounted in the roof of the pump house. A centrifugal blower unit equipped with an air filter and an intake damper is mounted on an outside wall of the switchgear room.

The pump room fans draw outside air into the room through intake louvers located at either end of the pump house. The switchgear room fan supplies outside air to the room and forces the heated air into the pump room.

Five electrical heaters are provided in the pump room and one in the switchgear room. The heating units heat and recirculate room air.

9.4.9.3 Safety Evaluation

This system is not required for the safe shutdown of the plant. An indication of high and low room temperatures, along with an alarm, is provided in the main control room.

9.4.9.4 Inspection and Testing

All equipment was factory inspected and tested in accordance with the applicable equipment specifications, quality assurance requirements, and codes. Controls, interlocks, and safety devices on each system were cold checked, adjusted, and tested to ensure the proper sequence of operation. Initial system flow distribution, valve operability, instrumentation and control loop checks, and alarm setpoints were done in accordance with the Preoperational Acceptance Test program as discussed in Chapter 14.

Routine maintenance and tests, based on the manufacturer's recommendations and/or operating/maintenance experience, are scheduled in accordance with the plant preventive maintenance program.

9.4.9.5 Instrumentation and Controls

Heating and ventilating of each room are controlled by a thermostat located in that room. Each ventilating fan is equipped with a local on-off switch. High and low temperatures for the pump and switchgear rooms are alarmed in the main control room.

9.4.10 Circulating Water Pump House Ventilation System

9.4.10.1 Design Bases

The circulating water pump house ventilation system is designed to limit the temperature in the pump room, switchgear room, and chemical treatment room to a maximum of 104°F.

The ventilation system is nonseismic.

9.4.10.2 System Description

Nominal sizes and types of principal system components are listed in Table 9.4-15.

The circulating water pump house has three separate ventilation systems, one each for the pump room, switchgear room, and chemical treatment room.

9.4.10.2.1 Pump Room

At each circulating water pump location, there is one exhaust fan that draws room air through the pump motor shroud for motor cooling and provides ventilation of the pump area during pump operation. For operation during cold weather, warm air from the pump motor shroud is mixed with a mixture of recirculated room air and outside air to maintain room temperature. During warm-weather operation, outside air is drawn directly into the pump area, through the pump motor shroud, and discharged back to the outside, thereby providing pump area ventilation and adequate cooling for the pump motor. Supplemental electric heating is provided to maintain room temperature well above freezing during cold weather when the circulating water pump is out of service.

9.4.10.2.2 Switchgear Room

Operation of the switchgear room ventilation system is initiated when the switchgear room temperature reaches 80°F. The exhaust fan starts and the outside air damper opens automatically.

9.4.10.2.3 Chemical Treatment Room

The ventilation fan in the chemical treatment room draws in air from the adjacent pump room when the chemical treatment room temperature is below 80°F. Above 80°F, the pump room damper closes and the outside air damper opens. When the chemical treatment room temperature is below 50°F, a room thermostat regulates the electric duct heaters at the ventilating fan.

9.4.10.3 Safety Evaluation

The circulating water pump house ventilation systems are required to operate only during normal plant operation.

9.4.10.4 Tests and Inspections

All equipment was factory inspected and tested in accordance with applicable equipment specifications, quality assurance requirements, and codes. The system ductwork and erection of equipment were inspected during various construction stages. Construction tests were performed on all components of the system. The system was balanced for the design airflow and system operating pressures. Controls, interlocks, and safety devices on each system were adjusted and tested to ensure proper sequence of operation. Initial system flow distribution, valve and damper operability, instrumentation and control loop checks, and alarm setpoints were done in accordance with the Preoperational Acceptance Test program as discussed in Chapter 14.

9.4.10.5 Instrumentation

All rooms are provided with high and low temperature alarms in the main control room. Flow status lights are provided for all rooms and an alarm is provided for a loss of ventilation flow in the pump room.

9.4.11 Motor-Generator Set Cooling System

9.4.11.1 Design Bases

The motor-generator (M-G) set cooling system is designed to provide 104°F cooling air to the reactor recirculating pump M-G sets.

The system is nonseismic.

9.4.11.2 System Description

A diagram of the M-G set cooling system is shown in Figure 9.4-13. Nominal sizes and types of principal system components are listed in Table 9.4-16.

Three 50 percent fan-coil cooling units are provided to cool the two reactor recirculating pump M-G sets located on the fourth floor of the reactor building. The cooling unit fans induce room air to flow through each generator and motor. The air is then drawn through a common exhaust duct system to the fan-coil units. The fan-coil unit cools the air and discharges it back into the room. Two of the three fan-coil units are normally operating, with the third on standby. The standby unit is automatically started if the discharge air temperature in one of the two operating cooling units exceeds 125°F. The cooling coils are cooled by the RBCCWS.

9.4.11.3 Safety Evaluation

The M-G set cooling system is required to operate only during normal plant operation.

In order to ensure that the system has a high reliability during normal plant operation, three 50 percent fan-cooling coil units are provided.

9.4.11.4 Inspection and Testing

All equipment was factory inspected and tested in accordance with the applicable equipment specifications, quality assurance requirements, and codes. Controls, interlocks, and safety devices on each system were cold checked, adjusted, and tested to ensure the proper sequence of operation. Initial system flow distribution, valve and damper operability, instrumentation and control loop checks, and alarm setpoints were done in accordance with the Preoperational Acceptance Test program as discussed in Chapter 14.

Routine maintenance and tests, based on the manufacturer's recommendations and/or operating/maintenance experience, are scheduled in accordance with the plant preventive maintenance program.

9.4.11.5 Instrumentation and Controls

Two M-G set cooling units are selected to operate manually when the M-G sets need to be started. If after 30 sec the chosen fan does not provide airflow, it will be tripped and a standby fan started. Temperature switches are also provided in the discharge of the cooling units to trip above 125°F and automatically start a standby fan. Alarms are provided in the main control room for "motor trip" and "M-G set vent air fan auto start" to alert the operator that the automatic trip has occurred.

TABLE 9.4-1 CONTROL CENTER HVAC SYSTEM MAJOR COMPONENTS DESCRIPTIONS

A. Air Handling Equipment Trains

Type	Built-up
Quantity	Two, 100 percent capacity

1. Air Handling Units

Type		Blow-through
Quantity		Two, 100 percent capacity
Capacity:	cooling, Btu/hr	12×10^5
	heating, Btu/hr	5.3×10^5

2. Supply Air Fans

Type	Centrifugal
Drive	Belt, variable speed
Capacity, scfm	37,000
Total static pressure, in. H_2O	3.6
Motor, hp	40

3. Supply Air Filters

Type	Fiberglass roll filter with electrostatic precipitator
Quantity	Two, 100 percent capacity
Efficiency (NBS Dust Spot Test)	90 percent
Capacity, scfm	37,000
Pressure Drop (Clean), in. H_2O	0.16

4. Return Air Fans

Type	Centrifugal
Drive	Belt
Quantity	Two, 100 percent capacity
Capacity, scfm	35,550
Total static pressure, in. H_2O	2.5
Motor, hp	25

B. Refrigeration Units

Type	Centrifugal packaged chillers (water cooled)
Quantity	Two, 100 percent capacity
Capacity, tons	100
Power, kW	85

TABLE 9.4-1 CONTROL CENTER HVAC SYSTEM MAJOR COMPONENTS DESCRIPTIONS

C. Chilled Water Pumps

Type	Centrifugal, vertically split casing
Total dynamic head capacity, gpm	300
Total dynamic head, ft H_2O	50
Motor, hp	7.5

D. Emergency Makeup Air Filter Trains

Type	Built-up
Quantity	One, 100 percent capacity
Components of emergency makeup air filter trains	

1. Fans

Type	Centrifugal
Drive	Belt
Quantity	Two, 100 percent capacity
Capacity, scfm	3000
Static pressure, in. H_2O	11
Motor, hp	20

2. Makeup Air Filter

a. Prefilter-Moisture Separator

Type	Baffles & fiberglass
Medium	Fiberglass 5 1/2 in.
Efficiency (per NBS Dust Spot Test)	85 percent
Pressure Drop (Clean), in. H_2O	0.80 in. at 1800 cfm flow saturated air at 70 °F

b. Electric Heaters

Type	Resistance, single stage
Quantity	Two
Capacity, kW	12

c. HEPA Filters

Type	High-efficiency particulate dry
Medium	Glass fiber (fire retardant)
Efficiency	Design efficiency of 99.97 percent for 0.3µm particles or larger.

TABLE 9.4-1 CONTROL CENTER HVAC SYSTEM MAJOR COMPONENTS DESCRIPTIONS

c. HEPA Filters (cont.)

	Installed and tested such that an overall decontamination efficiency of 95 percent is assumed for removal of particulate iodine
Pressure drop (Clean) in. H_2O	1.1

d. Charcoal Adsorber

Type	2-in. gasketless
Quantity	One bank
Medium	Impregnated charcoal
Efficiency, percent	Lab tested to ensure a 99 percent removal efficiency for methyl iodide Installed and tested in the adsorber housing such that an overall decontamination efficiency of 95 percent is assumed for removal of all forms of gaseous iodine
Capacity, cfm	3000 by design, 1800 maximum during operation

3. Recirculation Air Filter

a. HEPA Filters

Type	High-efficiency particulate dry
Medium	Glass fiber (fire retardant)
Efficiency	Design efficiency of 99.97 percent for 0.3µm particles or larger. Installed and tested such that an overall decontamination efficiency of 95 percent is assumed for removal of particulate iodine.
Pressure Drop (Clean), in. H_2O	1.1

b. Charcoal Adsorber

Type	4-in. gasketless
Quantity	One bank

TABLE 9.4-2 MAIN CONTROL ROOM AIR CONDITIONING SYSTEM SINGLE-FAILURE ANALYSIS

System	Component Malfunction	Comments
1. Offsite power	Not available	Emergency diesels start and supply electrical load to systems
2. Emergency diesels	One not available	The operative diesel supplies necessary to power one of the System's redundant active components
3. Main control room air conditioning	Rupture of equipment casing and/or ducts	Consideration has been given in the detailed design to withstand the design- basis temperature, pressure, and seismic forces during a postaccident situation. The equipment and components are also inspectable and protected against credible missiles
	Rupture of chiller piping or loss of one of the chiller systems	Rupture is not considered credible since all piping is designed to withstand the design-basis temperature, pressure, and seismic forces during a post accident situation and is inspectable and protected from missiles. 100 percent redundant control center air conditioning systems are provided. The operating division will be shut down and the standby division manually started
	System fan fails	100 percent redundant fans are provided. Loss of a fan will be alarmed in the control room. The operating division must be shut down and the standby division manually started
	Normal intake or exhaust isolation damper fails to close	Two redundant dampers provided in series in each line. Each damper in series receives power from a separate ESF bus. This ensures that at least one damper in each line will close
	One of the emergency filtration intake isolation dampers fails to close during a chlorine accident	Four dampers provided, two per division in each line. The dampers are normally closed and fail closed
	One of the kitchen/washroom exhaust isolation dampers fails to close during a chlorine accident	Four dampers provided, two in each exhaust duct. Each damper in each exhaust duct receives power from a separate ESF bus. This ensures that at least one damper will close in each exhaust duct.
	One of the emergency filtration intake isolation dampers fails to open	Redundant intake lines provided. Two intake isolation dampers provided in each line. Both dampers in series receive power from the same ESF bus. This ensures that two dampers in series will open.
	Smoke/Halon dampers for relay room, cable spreading room or computer room close	Loss of cooling to the respective room. Manual action is required to reopen dampers.

TABLE 9.4-8 RHR COMPLEX HEATING AND VENTILATION SYSTEM FAILURE ANALYSIS

System	Component Malfunction	Comments
Diesel generator room ventilation	One or both the supply air fans for a diesel room fail	Failure of one or both of the supply air fans will actuate a no-flow alarm in the main control room through its associated differential pressure switch, and the temperature in the diesel room will rise. The operator will take the necessary actions in accordance with the alarm response procedures
	Outside air damper fails closed and recirculating air damper fails open	The system will operate at 100 percent recirculation air. The temperature may rise as a result of the outside air damper failing closed. The high temperature in the diesel generator room will actuate an alarm in the control room, and the operator will take the necessary actions in accordance with the alarm response procedures
	Controller memory fails, the outside air and recirculating air dampers fail “as is”	The system will operate at the “as is” damper position at the time of failure. The temperature may rise or drop depending on the damper position and outside temperature. The temperature high or temperature low alarm for the diesel generator room will actuate an alarm in the control room, and the operator will take the necessary actions in accordance with the alarm response procedures
Switchgear room ventilation	Failure of one or both fans for individual switchgear room ventilation	Failure of one or both fans will actuate a no- flow alarm in the main control room through its associated differential pressure switch, and the temperature in the switchgear room will rise. The operator will take the necessary actions in accordance with the alarm response procedures
	Outside air damper fails closed and recirculating air damper fails open	The system will operate at 100 percent recirculation air. The temperature may rise as a result of the outside air damper failing closed. The high temperature in the switchgear room will actuate an alarm in the control room, and the operator will take the necessary actions in accordance with the alarm response procedures
	High pressure differential across the supply air filter	High pressure differential across the filter will illuminate a local indicator light. The operator will take the necessary actions depending upon the room temperature
	Controller memory fails, the outside air and recirculating air dampers fail “as is”	The system will operate at the “as is” damper position at the time of failure. The temperature may rise or drop depending on the damper position and outside temperature. The temperature high or temperature low alarm for the switchgear room will actuate an alarm in the control room, and the operator will take the necessary actions in accordance with the alarm response procedures

9.5 OTHER AUXILIARY SYSTEMS

9.5.1 Fire Protection System

9.5.1.1 Design Basis

9.5.1.1.1 Introduction

The fire protection system is designed to provide adequate fire protection for all potential fire hazards. It provides prompt fire detection, alarm, and suppression. The fire protection system is designed to supplement the other fire protection safeguards incorporated into the plant design, including a low combustible fire loading and adequate separation of fire areas. Included in the total fire protection system are a fire protection water supply and distribution system, a fire detection and alarm system, and gaseous extinguishing systems, as well as fixed water spray and automatic sprinkler systems. Manual fire protection hose connections are provided on all floors, and hydrants are located in the yard. Plant operators are trained on a routine basis in fire-fighting techniques.

The Fermi 2 fire protection system has been developed using the fire hazards analysis, National Fire Protection Association (NFPA) standards, and recommendations made by the Nuclear Energy Liability-Property Insurance Association (NEL-PIA) (now named American Nuclear Insurers (ANI)) after its review of the entire system. This method is equivalent to postulating peak fire intensities due to the fire calculations and experience inherent in the standards and NEL-PIA recommendations.

The entire fire protection system is designed using the NFPA standards and the NEL-PIA recommendations for guidance.

The concrete building materials, the compartmentalization, and fire doors provide the structural features needed to prevent the spread of fires in Category I structures. The concrete used in the walls, floors, and ceilings will not support combustion. The compartmentalization of the plant for shielding purposes also provides fire barriers between equipment areas. The fire zones in the safety-related areas are established in the fire hazards analysis presented in Appendix 9A.

Because of the plant construction using noncombustible materials, the fire protection system is a nonseismic system. The piping is designed to Category II/I criteria (Section 3.7).

9.5.1.1.2 Codes and Standards

The following codes and standards were used for guidance in the design of the Fermi 2 fire protection system:

a. NFPA-10, Portable Fire Extinguishers - 1978

b. NFPA-12, Carbon Dioxide Systems - 1977

c. NFPA-12A, Halogenated Fire Extinguishing Agent Systems – 1977. Guidance in NFPA-12A, Standard on Halon 1301 Fire Extinguishing Systems – 2009, Section 6.7.2.4.2(5), is also used, with supporting justifications identified in FPEE-20-0006.

d. NFPA-13, Installation of Sprinkler Systems - 1980. Certain deviations to NFPA-13 requirements, with supporting justifications, are identified in sections 9.5.1.2.3.3, 9A.4.1.6.1, 9A.4.1.7.1, 9A.4.2.3.1, 9A.4.3.1 and 9.5.1.2.1.

e. NFPA-13A, Care and Maintenance of Sprinkler Systems - 1976

f. NFPA-13E, Fire Department Operations in Properties Protected by Sprinklers and Standpipe Systems - 1973

g. NFPA-14, Standpipe and Hose Systems - 1976

   Certain deviations to NFPA-14 requirements, with supporting justifications, are identified in sections 9.5.1.2.1 and 9A.2.3.5.2.

h. NFPA-15, Water Spray - Fixed Systems - 1979

i. NFPA-20, Centrifugal Fire Pumps - 1970

   Certain deviations to NFPA-20 requirements, with supporting justifications, are identified in section 9.5.1.2.3.2.

j. NFPA-24, Outside Protection – 1970

   Certain deviations to NFPA-24 requirements, with supporting justifications, are identified in section 9.5.1.2.1.

k. NFPA-30, Flammable and Combustible Liquids - 1977

l. NFPA-72D, Proprietary Protective Signaling Systems for Watchman, Fire Alarm, and Supervisory Service - 1975

m. NFPA-72E, Automatic Fire Detectors - 1974

n. NFPA-198, Fire Hose (Including Couplings and Nozzles) - 1972

o. Underwriters Laboratories approved materials for fire protection

p. ANSI Specification B1.1, B18.2.1, Nuts and Bolts

q. ANSI Specification B31.1.0, Power Piping

r. ANSI Specification B16.1 - 1967, Standard Flange

s. 10 CFR 50, Appendix A, Criterion 3, Fire Protection.

9.5.1.1.3 Multiple-Unit Fire Protection

Fermi 2 is not a multiple-unit plant; therefore, no precautions are necessary to protect the operating plant during the construction of multiple units.

9.5.1.2 System Description

9.5.1.2.1 General Description

The FPS is shown in Figures 9.5-1, 9.5-2, and 9.5-3.

The dedicated fire protection water supply is obtained from a 2500-gpm electric-driven fire pump and a 2500-gpm diesel-driven fire pump located in the GSW pump house. Either fire pump will supply the required fire protection water demands. The diesel- and electric-driven fire pumps are normally on standby, since the fire mains are supplied with makeup water and pressurization from the FPS jockey pump which takes suction from the GSW pump header. The FPS jockey pump operates continuously, maintaining pressure in the fire main. If fire header pressure falls below GSW header pressure, makeup water will also be supplied via the cross-tie line between GSW and FPS. The electric fire pump starts automatically when the fire protection system header pressure drops to 130 psig, and the diesel fire pump starts when the fire protection system header pressure drops to 110 psig; both require manual shutdown once started. The fire pumps meet the intent of NFPA Standard 20 (except for certain deviations identified in section 9.5.1.2.3.2) and NEL-PIA recommendations, and are Underwriters Laboratories (UL) approved. The fire main loop is completely isolable from the GSW system, and a check valve is provided to prevent flow from the fire main loop into the GSW system. This design provides flexibility to support the fire main loop while maintaining its integrity with respect to system flow.

The distribution fire main in the yard surrounding the plant is a 12-in. and 14-in. underground header, which is buried below the frost line to prevent freezing. Normally open valves with post indicators are installed in the fire main on each side of every branch and also on every branch leading from the fire main. Those valves, together with individual hydrant shutoff valves, permit isolation of a line break anywhere, with minimum interruption of service to undamaged sections. Hydrants and underground fittings are provided with suitable thrust blocks to prevent blowouts of the system. The underground portion of the system is coated with corrosion-resistant materials and is also protected by cathodic protection, as applicable.

The 12-in. fire main is designed to provide the required water demands for the automatic sprinkler systems and 500 gpm for all hose demands. The hose pipe system is designed as an NFPA Standard 14 Class II hose system. Pressure reducing devices are not installed as required by NFPA-14 at all hose station outlets where the pressure exceeds 100 psig, to reduce the pressure with required flow at the outlet to 100 psig. This is acceptable because the hose stations and fire hose are only used by trained fire brigade members, and adjustable pattern fog nozzles are provided at all hose stations, except for the fifth[h] (refueling) floor of the reactor building where solid stream nozzles are provided. Pressure reducing devices that significantly reduce pressure are provided for hose station outlets on the fifth floor of the reactor building and on floors below the grade floor of 583 ft 6 in., due to excessively high pressure at those hose stations. The reason for utilizing a higher pressure at hose stations is to be able to more effectively fight fires at the ceiling height where cable trays are located. The fuel storage tank for the diesel fire pump holds sufficient fuel to continuously operate the pump for a minimum of 8 hr.

The fire main loop serves the outdoor hydrants, which are spaced in accordance with NFPA Standard 24. Additional hydrants on branches of the main loop are located in the general vicinity of the cooling water towers, in the protected area, and in the vicinity of the warehouses and the CTG fuel storage tank outside the protected area. Underground branches from the fire main loop supply water to the reactor, turbine, radwaste, auxiliary, residual heat removal (RHR) complex, Independent Spent Fuel Storage Installation (ISFSI) equipment storage, FLEX Storage Facility (FSF#1), and warehouse buildings within the protected area. A separate branch with an isolation valve supplies warehouses, fire hydrants and other buildings as shown in Figure 9.5-1, Sheet 2. In addition to the 12-in. steel pipe, this branch includes 12-in., 8-in. and 6-in. portions of transite pipe, 6-in. cement lined ductile iron pipe, 6-in. portions of poly vinyl chloride pipe, as well as 14-in. high density polyethylene (HDPE) pipe, as shown in Figure 9.5-1, Sheet 2. The underground fittings are provided with suitable thrust blocks to prevent blowouts of the system. Valves are provided to isolate this branch in the event of a pipe failure. The underground feeds into the RHR Complex building are embedded in an exterior wall and floor where the two lines are exposed to outdoor temperatures. Freezing is avoided by a combination of exterior wall insulation and by running a continuous amount of water through the lines during the winter season. This is an alternative method of providing freeze protection to the specific requirements of NFPA 13 and 24 and was in a report filed with the NRC in VP-85-0204 (Reference section 9A.1.1.2).

The sprinkler system supplies water to the sprinklers. At a set ambient temperature, the sprinkler system initiates water flow in the sprinkler. An alarm valve and/or flow switch in the line actuates a visible and audible alarm in the main control room for sprinklers in the protected area. Indication for those sprinkler systems in the owner controlled area are located within normally manned security areas. The areas covered by the sprinkler systems are indicated in Table 9.5-1.

The deluge system consists of a system employing open sprinklers attached to a piping system connected to the fire protection water supply through a valve that is opened by the operation of a fire detection system installed in the same area as the sprinklers. Audible and visible alarms are actuated in the main control room for the deluge systems located in the protected area. The deluge valves in the protected area can also be opened by manual switches from the main control room. These deluge valves can be reset only when there is no pressure upstream of the valve. This can be achieved by manually closing the outside screw and yoke valve upstream of the deluge valve. Position-indicating lights for the deluge (and outside screw and yoke) valves of both the sprinkler and the deluge systems in the protected area are provided in the main control room. Provisions for monitoring the electrical control circuits of the deluge valve manual switches are also incorporated into the main control room for valves in the protected area. Indications for those fire protection valves in the owner-controlled area are located within normally manned security areas. Areas with deluge system protection are listed in Table 9.5-1.

Each divisional pair of diesel generators is provided with a low-pressure CO_2 flooding system. The initiation of CO_2 in the diesel generator room does not affect the starting and running of the diesel generators. The diesel-fuel-oil storage tanks are protected by wet-pipe sprinkler systems. The fuel oil storage tanks are contained in their own rooms with elevated doorways that would prevent the fuel oil from flowing into other adjacent areas in the event of a rupture of the tanks. In addition, floor drains are provided in these rooms to drain the oil, and the water from the sprinkler system, to the outside liquid chemical waste holding pond. Diking is also provided around the 150,000-gal auxiliary boiler fuel-oil storage tank.

The standby gas treatment system (SGTS) charcoal filters are provided with a low-pressure CO_2 flooding system.

Fire protection and detection also include provisions of motor-operated dump valves on the reactor feedpump (RFP) turbine-oil reservoir and the emergency diesel generator (EDG) fuel-oil storage tank, fusible-link fire dampers in the supply and return air ducts of the ventilation systems of the reactor and service buildings, control center, and RHR complex, and ionization detectors and/or photoelectric detectors for the detection of combustion products and smoke. The turbine building is provided with 13 heat- and smoke-relief vents in the roof, which open either automatically on high temperature or high pressure in the building or manually from the main control room.

Portable fire extinguishers are deployed throughout the plant, and each unit is selected on the basis of the type of fire anticipated. NFPA Standard 10 was used as a guide for the selection, spacing, location, use, and maintenance of the portable extinguishers. Approximately 200 portable fire extinguishers are distributed throughout all the floors of the reactor, auxiliary, RHR, turbine, and radwaste buildings. These include multipurpose portable dry-chemical extinguishers for Class A, B, and C fires and portable CO_2 and Halon extinguishers. Where necessary, in support of the manual fire suppression systems, masks and portable breathing apparatus are provided for personnel protection.

Temperature, photoelectric, infrared, or ionization detectors are provided throughout the plant and are identified in Appendix 9A. In addition, the activation of any automatic fire-fighting equipment, component, or detector energizes visible and audible alarms in the main control room.

The type of fire-extinguishing equipment provided for each area is as follows:

Type	Area
Yard main and hydrants	Exterior of buildings, yard structures, and storage areas
Deluge and sprinkler systems	Parts of reactor, turbine, radwaste, and service buildings, transformer area, oil storage, reservoirs, diesel-fuel-oil storage tanks in RHR complex, ISFSI equipment storage building, warehouse, and FLEX Storage Facilities #1 and #2
Standpipe system and hose stations	On every floor inside all major plant buildings, except the office building annex (034)
Automatic CO_2 extinguishing systems	Diesel generator rooms, SGTS charcoal filters, cable tunnel (manual only), outside Division II switchgear room, and selected cable tray areas
Portable fire extinguishers	Throughout the plant, especially in critical control areas where general flooding could adversely affect safety-related equipment
Automatic Halon suppression systems	Relay room, cable spreading room, computer room and other selected minor areas
Automatic Clean Agent suppression system	Parts of radwaste building and the Security Diesel Generator enclosures

9.5.1.2.2 Control Room Protection Systems

A potential main control room fire would be extinguished by manual fire-fighting techniques. Portable CO_2 and Halon extinguishers are provided, and if needed, the normal standpipe and hose connections are located outside the main control room. Equipment in the main control room is noncombustible.

The main control room fire detection system covers the main control room, the areas above the false ceiling, inside the COP panels, and under the computer area floor. Main control room habitability in the event of smoke is maintained by the ventilation system as described below.

The exhaust from each zone listed in Subsection 9.4.1.2.1 is either partially recirculated or completely exhausted under normal operating conditions. All of the control center air conditioning system (CCACS) zones are equipped with ionization-type detectors or other approved types of detectors. These areas include the air conditioning system mechanical equipment room, computer/main control room, cable spreading room, and relay room. If smoke is detected by any of the early-warning ionization detectors, an indicating light on the area smoke, fire, and radiation protection panel in the main control room will illuminate, indicating the zone, and an audible alarm will be sounded in the main control room. The control center ventilation will automatically be placed in the smoke purge mode of operation upon confirmed actuation of the Halon system in the cable spreading room or relay room. The ventilation systems for the cable spreading room and relay room automatically isolate when the Halon system initiates in these areas. This prevents dilution of the Halon when the control center ventilation is placed in the purge mode of operation. The purge mode results in once-through ventilation system operation throughout the control center (approximately seven air changes per hour) with no recirculation. This operation clears smoke from the fire area and prevents smoke and Halon from being recirculated into the main control room. The smoke purge mode, however, is overridden by a LOCA signal which places the ventilation system into 100 percent recirculation.

Wherever the control center ventilation supply or return ducts penetrate a fire barrier wall, a 3-hr fire damper installation is provided or a specific fire hazards analysis evaluation has been performed and documented. These fire dampers automatically close either by spring action or by gravity when a fusible link melts on high temperature. In the cable spreading and relay room supply and return ducts, remotely resettable dampers are provided that automatically close when the gaseous system actuates. These dampers can be reset from the main control room. Position indication is provided on the remotely resettable dampers.

In the event of a fire outside the main control room but within the control room complex, the early-warning fire detection system will alert the operators to the problem. The fire detection system includes all areas of the control center. A ventilation equipment room fire will be extinguished by manual fire-fighting means. A relay or cable spreading room fire will be extinguished by manual means or by the automatic Halon suppression system.

A panel is installed outside the main control room that satisfies the requirements of 10 CFR 50, Appendix R, paragraph III.L for alternative or dedicated plant shutdown. The approach to the alternative shutdown design, the analysis, and method used are described further in Subsection 7.5.1.5.

Automatically initiated water systems are not employed on control center complex Class 1E electrical equipment because of the loss of reliability associated with the operation of fire protection equipment. The relay room, selected cable tray areas, and the EDGs are protected with automatic gaseous systems. Class 1E equipment located in other areas is protected by early-warning fire detectors. The above areas are identified in Appendix 9A.

9.5.1.2.3 Design Features

The design features of the Fermi 2 fire protection system equipment are described in the subsections that follow.

9.5.1.2.3.1 Electric Fire Pump

The electric fire pump has the following specifications: 2500 gpm at a discharge pressure of 150 psi, 1780 rpm, and 370-ft total developed head. The motor is 4000 V, 300 hp. The fire pump is UL listed equipment. The controller is not UL listed but does meet the general design and functional requirements of listed controllers. Status alarms indicating the availability of the electric fire pump are provided in the control room.

9.5.1.2.3.2 Diesel Fire Pump

The diesel fire pump has the following specifications, UL listed for 2500 gpm at a discharge pressure of 150 psi, 1775 rpm, and 370-ft total developed head. The engine is a diesel engine, UL listed for 340 hp, 2300 rpm, with a 275-gal fuel-oil tank for 8 continuous hr of operation. This pump and controller are UL listed equipment. Alarms are provided in the control room to indicate pump availability.

The electric fire pump was rebuilt and has replaced the original diesel fire pump. The diesel engine driver, when de-rated in accordance with NFPA 20, cannot develop the required horsepower to operate the diesel fire pump at rated speed to meet NFPA 20 requirements at the 100 percent and 150 percent flow points. The inability of the de-rated diesel driver and pump to meet the NFPA 20 flow and pressure requirements is an acceptable deviation because the diesel fire pump can provide the required flow and pressure demand for simultaneous operation of a suppression system and 500 gpm for hose streams.

9.5.1.2.3.3 Sprinkler Systems

The sprinkler systems are wet- or dry-pipe systems designed to provide a minimum water spray density per square foot of the most hydraulically remote area using NFPA Standard 13 and NEL-PIA requirements as guidelines. The sprinkler alarm check valves have been modified by adding a small bypass line to the trim of each valve to prevent any overpressure developing on the sprinkler system because of temperature changes or other reasons. This trim arrangement differs from the listed alarm check valve trim arrangements required by NFPA 13 but has no adverse effect on the functions of the Fermi sprinkler systems.

Other noncompliances with NFPA 13 have been evaluated in accordance with Generic Letter 86-10 as acceptable. These include the omission of return bend piping on pendent sprinklers, the omission of auxiliary drains on small trapped sections of sprinkler piping, the use of in-place welding to join and modify piping, and the lack of minimum required clearance distance for sprinklers below ceilings, ducts, or other items. The lack of return bends is acceptable based on the periodic change-out of the pendent sprinkler to prevent excessive accumulation of sediment in the sprinkler waterway. The other subject noncompliances are acceptable based on not adversely affecting the required function of the sprinkler systems and based on the administrative controls of the plant Fire Protection Program procedures.

The minimum water spray density used for each sprinkler system was determined by the occupancy classification defined in NFPA Standard 13 listed below:

Sprinkler System	Occupancy Classification
High pressure coolant injection (HPCI) room	Extra hazard, group #1
Reactor core isolation cooling (RCIC) room	Ordinary hazard, group #3
Motor-generator (M-G) set and oil cooler area	Extra hazard, group #1
Torus room	Ordinary hazard, group #3
Equipment unloading area	Ordinary hazard, group #3
2nd floor reactor building area	Ordinary hazard, group #3
Auxiliary building basement area	Ordinary hazard, group #3
Auxiliary building 1st floor mezzanine	Extra hazard, group #1
Cable spreading room (Elevation 630 ft)	Extra hazard, group #1
EDG fuel tank rooms	Extra hazard, group #1
Diesel fire pump room	Ordinary hazard, group #3

The sprinkler heads used in these systems are all fusible-link closed heads.

9.5.1.2.3.4 Deluge Systems

The deluge systems are open directional spray nozzle systems designed to provide density in accordance with NFPA Standard 15 and NEL-PIA requirements.

Deluge valves are solenoid valve operated, controlled automatically by the fire protection system or controlled manually from the main control room.

9.5.1.2.3.5 Gaseous Suppression Systems

A 6-ton low pressure CO_2 storage unit is provided for two EDGs in the same division. A total of two units each serving two EDGs is located in the RHR complex. The CO_2 system for the SGTS provides internal protection for the charcoal beds. Each SGTS division has an independent 1.25-ton CO_2 system. CO_2 systems are provided to protect certain areas of the reactor/auxiliary building, as listed in Table 9.5-1. A low pressure CO_2 storage unit is located outside the reactor building. A distribution system will select the proper zone where the fire is detected. Halon and Clean Agent suppression systems are provided in areas identified in Table 9.5-1.

9.5.1.2.3.5.1 General Design Information for the RHR Complex and Reactor/Auxiliary Building CO_2 Systems

The CO_2 system instrumentation and control equipment detects fires, initiates and terminates fire suppression discharges, and monitors system performance. Detection of fires is accomplished by heat and/or smoke detectors. Detection devices activate alarms to indicate the presence of a fire and activate control equipment to initiate discharge of fire-extinguishing agents. Discharge is delayed for sufficient time to enable personnel to leave the area. Activation of fire suppression equipment is accomplished either manually at local panels or automatically by fire detection devices. The control instrumentation directs the discharge into the selected area and closes ventilation dampers to isolate the fire and contain the discharge. Alarms indicate the operation of the systems.

Controls automatically terminate the discharge after a predetermined time. Instrumentation monitors the system operation and alarms under abnormal conditions. The CO_2 system controls provide for proper operation of the storage tank refrigeration unit.

Wall and floor penetrations for the areas protected by the CO_2 system are sealed to contain the CO_2 discharge. Any CO_2 leakage that may occur after the area is isolated is included in the extended discharge application rate. Further, upon completion of the system, a concentration test was conducted to confirm the design parameters.

Entrance to an area after a CO_2 discharge can be gained by resetting the ventilation dampers to the open position and initiating the exhaust function. To further aid in purging, portable smoke fans can be used as needed. Self-contained breathing apparatus is available and can be used to gain access for manual fire fighting or cleanup.

9.5.1.2.3.5.2 Design Guidance for Reactor/Auxiliary Building CO_2 Systems

a. The CO_2 storage capacity is sufficient to provide two-shot (100-percent redundancy) protection for the hazard area requiring the greatest quantity of CO_2, based on a design concentration of 50 percent. The quantity of CO_2 includes a 50 percent margin for leakage during an extended discharge. This allowance is based on all accesses and ventilation ducts being closed

b. The distribution system pipe sizing and arrangement are based on providing and maintaining an extinguishing concentration of CO_2 in the hazard area for 20 minutes. This is accomplished by applying an initial discharge at a sufficiently high rate to achieve a 30 percent concentration in 2 minutes or less, and the design 50 percent concentration in 7 minutes or less, in conjunction with an extended discharge at a lower rate sufficient to maintain the 30 percent concentration for 20 minutes

c. The design CO_2 concentration is 50 percent for each protected area. Flooding factors are based on the guidelines of NFPA Standard 12 for total flooding systems, assuming dry electrical wiring hazards in general cable areas

d. The storage tank refrigeration unit is sized to maintain the storage tank at 0°F and 300 psig, assuming the highest expected ambient temperature of 105°F. Power is provided as described in item e below

e. Fire detection devices, actuating instrumentation, and control equipment are powered from the 120-V restored ac bus. In addition, the fire detection system for CO_2 actuation is provided with a 4-hr, 24-V dc battery system.

9.5.1.2.3.5.3 Design Guidance for Diesel Generator CO_2 Systems

a. Each division contains two EDGs. The 6-ton storage tank for each division will provide one complete shot to both EDGs or double shot protection for one EDG

b. The design CO_2 concentration is 50 percent for each protected area. Based on guidelines of NFPA 12, the minimum design concentration for diesel fuel is 34 percent

c. Detection devices consist of thermal detectors

d. Fire detection and CO_2 controls are normally powered from the balance-of-plant 130-V dc system. Emergency power for the fire detection and CO_2 controls are powered from a 120-V manual restored ac bus. The power is then rectified to 130-V dc. Power for the refrigeration units and room warning lamps are powered from a 120-V manual restored ac bus

e. The system is designed to maintain the room concentrations for 20 minutes.

9.5.1.2.3.5.4 Design Guidance for the Standby Gas Treatment System CO_2 System

a. When the SGTS charcoal bed temperature reaches 250°F, an alarm sounds, which alerts the control room operator to an overtemperature condition well before there is danger of ignition. If the beds continue to heat up and reach 310°F, the low pressure CO_2 Suppression System will be automatically initiated and 250 lb of CO_2 are injected in the bed over a 10-minute period. This actuation of the CO_2 system is indicated on the fire protection mimic panel and an alarm on the control panel. Based on the alarm response procedure, the SGTS exhaust and cooling fans will be manually shut off if they are running.

   This cycle is repeated as long as the temperature exceeds 310°F. Each of the divisional CO_2 storage tanks holds enough CO_2 for 10 injections

b. Detection devices consist of a continuous thermal fire detection system

c. The detection devices and CO_2 controls are powered from the 120-V restored ac bus.

9.5.1.2.3.5.5 Design Guidance for Halon Systems

a. The Halon storage capacity consists of a main bank and a reserve bank for each system. Each bank will provide sufficient capacity for a complete shot

b. The systems are designed to provide a minimum 5 percent concentration for a 10-minute holding period

c. Emergency power for the fire detection and halon control systems is powered from a 120-V restored ac bus.

9.5.1.2.3.6 Design Guidance for Clean Agent Systems

a. The Clean Agent storage capacity consists of two storage cylinders, a primary and a reserve, for each system. Each will provide sufficient capacity to provide protection for the potential hazard based on concentration, volume of area, and known leakage pathways out of the designated area.

b. The systems are designed for a discharge time to provide a 95 percent minimum design concentration for flame extinguishment based on a 20 percent safety factor and will not exceed 10 seconds.

c. Power for the fire detection and Clean Agent control systems is provided by a separate dedicated 120V, 1 phase 60Hz source that will not be shutdown on system operation.

Use of this system is limited to the Security Diesel Generator enclosures and areas in the Radwaste Building which do not include any systems or circuits credited for reactor shutdown in the event of a fire (i.e. – activation of the Clean Agent fire suppression system will not adversely affect the plant's ability to achieve and maintain shutdown in the event of a fire).

9.5.1.2.3.7 Turbine Room Roof Vents

Thirteen roof vents in the turbine room are opened automatically at 20-psf differential pressure, or at 160°F by fusible link, or manually from the main control room, or locally by pull rings.

9.5.1.2.3.8 Dampers

Fire dampers located in the ventilation ductwork are curtain type with fusible links. Dampers are either spring loaded or rely on gravity to close. The fire damper will close only when high temperature melts the fusible link. Resettable smoke/halon and smoke/CO_2 dampers provided with the gaseous systems have the damper position monitored in the main control room.

9.5.1.2.3.9 Instrumentation

a. Flow Switches

Flow switches are provided in various locations of the fire protection system to detect water flow

b. Thermal Detectors

Thermal detectors are provided as part of the equipment package for the deluge systems, the EDG CO_2 systems, and the Security Diesel Generator enclosures.

c. Ionization Detectors

Ionization detectors are provided in areas requiring early-warning detection. Additionally, a separate ionization detection system was installed to actuate the gaseous systems (except for the CO_2 systems in the EDG rooms in the RHR building, where thermal detectors are used as noted above and the under-floor detectors in the main control room computer room where photoelectric detectors are used along with ionization detectors above the floor).

d. Photoelectric Detectors

Photoelectric detectors are used in areas requiring early-warning detection. These are usually used in place of ionization detectors in areas with difficult access. Photoelectric detectors are used under the floor, to actuate the halon system, in the main control room, computer room.

e. Infrared Detectors

Infrared detectors are utilized on the fifth floor of the reactor building and in the Security Diesel Generator enclosures.

f. Instrumentation and Control

Instrumentation and control of the fire protection systems is fed from various power sources identified in Sections 9.5.1.2.3.5 and 9.5.1.2.3.9. The sprinklers operate independently of ac or dc power. The deluge valves are controlled and fed from the dc power system. The standpipe system, which also supplies the sprinkler and deluge systems, is pressurized in a ready-for- service condition without need for valve operation. The GSW pumps and the electric fire pump operate from the ac system service and are not connected to the onsite power source. On loss of offsite power, the diesel fire pump starts and operates from its own 24-V battery and charger system

g. Fire Detector Location

The types and locations of fire detectors are provided in Appendix 9A.

9.5.1.2.3.10 Fire Detection Circuits

The Fermi 2 early warning only fire detection high-voltage system is a Class B system as defined in NFPA Standard 72D, employing a configuration of two independent detector circuits designated Group A and Group B. Because of the 220-V dc operating voltage, the fire detection circuits are not Class I per NFPA Standard 70. It is not a requirement of Appendix A to BTP APCSB 9.5-1 for the detection circuits to meet NFPA Standard 70, Class I. The Fermi 2 design does meet the Class 3 requirements of this code. However, the danger of a fault-initiated fire is minimized because the current is low (milliamperes) and the power is only about 200 W at each detection panel. Also, the fire detection circuits are routed in non-safety-related trays and are contained in conduits outside the trays.

In the redundant safety division areas, the early warning only fire detection circuits employ a two-circuit configuration of detectors designated Group A and Group B. Each detector group has approximately half the detectors of a given detection area. The two groups of detectors are installed in an interspersed configuration covering the protected region. The detector density in each detection area is such that floor area per detector is within the current NFPA recommendation.

In non-safety-related areas, the early warning only detector circuits are of a single group energized from either of the two main panels. The single group detector circuits are about evenly divided between the two panels to achieve a balanced arrangement. The service building complex has a separate fire detection panel.

The two early warning only fire detector groups are powered from separate non-Class 1E motor control centers (MCCs). Each MCC is fed from opposite divisional Class 1E switchgear. Normal offsite power provides the primary supply for the detectors. Upon loss of offsite power, the detectors are automatically connected to the onsite EDG. This design meets the requirements of Appendix A of BTP APCSB 9.5-1.

The reactor/auxiliary building gaseous suppression systems use a low-voltage smoke detection system. The design is a Class A cross-zoned detection system with a detector required from each zone to actuate the gaseous systems. Power is supplied from a 120-V ac restored bus. Additionally, a 4-hr, 24-V dc battery package provides secondary (backup) power.

For the Security Diesel Generator enclosures, a cross-zoned fire detection system uses both infrared and heat detectors. Should the second heat detector alarm, then the clean agent solenoid activates and, after the thirty second timer expires, the clean agent is released.

All fire detector circuits, flow switch circuits, and alarm bell circuits are electrically supervised in accordance with requirements of the NFPA.

Sensitivity of the ionization smoke detectors is adjustable. Final sensitivity settings are determined after a period of fire detection system operation. The sensitivity used is the highest that is practical and consistent with minimization of false alarms.

In the main control room, annunciator windows are provided for fire alarm (detector actuation or flow switch actuation) and fault in the fire detection/protection circuits. A fault annunciation would occur upon a detector circuit or bell circuit open, ground, or short; detector out of socket (open circuit); power loss; or outside screw and yoke water valve not full open. Other fault conditions, such as low CO_2 pressure, also are covered by an alarm.

On the main control room panel, a display is provided to indicate fire detection zone number in the alarm state, CO_2 release, outside screw and yoke valve closed, power status at panels, and smoke/CO_2 shutoff damper open/closed.

The fire annunciator system, a fire protection system mimic, is combined with the area radiation mimic. The mimic shows the building outlines, with orientation in respect to one another as accurately as possible, within which are color-coded alarm lights for fire, high temperature, smoke, and radiation.

A fire alarm will sound when flow switches indicate flow in the fire protection ring header, or flow in a deluge or sprinkler system, or flow from the electric or diesel fire pump. The alarm will designate the area on the mimic panel. An area indication on the mimic will alarm when any of the outside screw and yoke valves are closed or any deluge valve is opened. The panel will indicate the general area in which a fire detector is indicating the presence of smoke or fire. In the plant, a local panel for each area will display detailed information for each detector. Startup of either the electric or diesel fire pump will be alarmed.

The following remote manual control functions can be performed in the main control room: the deluge valves can be manually initiated by pushbutton. The smoke roof vents in the turbine house can be manually opened, and the smoke dampers can be manually closed. The electric and diesel fire pumps can be manually started from the main control room. The motor-operated dump valves on the EDG fuel-oil storage tank, on the main turbine-oil reservoir, and on the reactor feed pump oil reservoir can be operated from the main control room.

The system diagram of the fire protection system is given in Figure 9.5-1. Table 9.5-1 provides a list of the equipment and devices that make up the fire protection system.

9.5.1.2.3.11 Fire Barriers

The fire hazards analysis has identified the fire barriers and determined the barrier requirements for the floors, walls, and ceilings enclosing separate fire areas and for the doors and other penetrations through these barriers. (See Appendix 9A.) See Subsection 8.3.1.4.2.2 for a discussion of cable tray fire barriers at floor and wall penetrations.

9.5.1.2.3.12 Fire Emergency Lighting and Communications

Fixed emergency lighting with 8-hr battery power supplies is provided in the main control room, in all plant areas where operator action, for safe shutdown in the event of fire, is required within 8 hrs and along access and egress routes for these areas. Emergency communications capability is provided by telephones, public address systems, and radio communications equipment powered from redundant power sources. Repeater stations are installed to improve the quality of radio communication. Loss of a particular repeater will not result in a loss of communication capability in the area adjacent to the repeater.

9.5.1.2.4 Atmosphere Control

To aid in smoke removal, the reactor/auxiliary building ventilation system will continue to operate in the event of a fire in the reactor/auxiliary building except when a loss of offsite power results in initiation of the standby gas treatment system and automatic isolation of RBHVAC. The airflow will generally follow a path from areas of low potential radioactivity to areas of progressively higher potential radioactivity before finally being exhausted to the atmosphere at the roof of the reactor/auxiliary building. Fire dampers are provided where all ventilation ducts penetrate fire barrier walls.

The control center in the auxiliary building is equipped with its own air conditioning system and is not connected with the reactor/auxiliary building ventilation system during emergency mode operation of the CCACS as described in Section 6.4.4.2. Smoke, combustible and explosive gases, and airborne toxic contaminants in the reactor/auxiliary building atmosphere will not enter the control center because the CCACS maintains the atmosphere at a slight positive pressure with respect to the reactor/auxiliary building atmosphere.

The air conditioning zones within the control center can be individually isolated by smoke dampers that are operated from the control room. The detection system and smoke removal process are described in Subsection 9.5.1.2.2. Habitability of the main control room after a chlorine-release accident is discussed in Appendix A, Regulatory Guides 1.78 and 1.95.

Because of the combustible liquids stored in the diesel-oil storage room and the diesel generator room of the RHR complex, a purge ventilation fan will operate continuously (except during an actual fire). The diesel generator room, the CO_2 storage room, diesel-oil storage room, and diesel generator ventilation equipment room will be continuously purged with a 2500-cfm exhaust fan. Each EDG and diesel-oil storage room has a separate exhaust purge fan. Loss of airflow in the purge system is alarmed in the main control room. The exhaust fan will be automatically stopped if a signal is received from the automatic fire protection systems.

The RHR complex is divided into various fire zones, as indicated in Appendix 9A. The ventilation systems for the diesel generator switchgear zone and the EDG zone (two per division) and the pump room zone are entirely separate. Isolation of any of these zones will not affect the ventilation systems in other zones.

The CO_2 system for each EDG requires automatic shutdown of the ventilation system to be effective. The design of the system will allow operation of the remaining EDG in the division as well as the other unaffected division. Other zoned dampers are motor operated and controlled by startup or shutdown of the ventilation fans in the main control room. The ventilation fans for all zones can be manually shut down for fire containment or manually started or left running for smoke purge purposes. The 3-hr-rated fire dampers at ventilation duct penetrations of fire barriers will close only when high temperature melts the fusible link.

9.5.1.2.5 Electrical Cable Fire Protection

The electrical cables are fabricated with fire-retardant insulating and jacketing material. NEL-PIA has approved this design. Fire stops are included in all wall and floor tray penetrations, and fire barriers are installed in areas where a fire could propagate from one area or tray system to another. Details of the fire-resistant wall penetrations are found in Subsection 8.3.1.4.2.2.

Redundant engineered safety feature (ESF) equipment is fed by redundant essential electrical circuits. Physical separation is provided between electrical divisions to prevent loss of more than one division from a fire. As part of the fire hazards analysis, areas were identified that have more than one division in the same fire zone. In these areas, a fire barrier and/or a suppression system was added. The fire hazards analysis shows that any postulated fire will not prevent the ability to initiate or maintain shutdown of the reactor.

Fire protection instrumentation and control circuits are classified as non-safety-related and are not redundant. These cables could be lost and not cause loss of the portable fire extinguishers or loss of the standpipe automatic or manual systems. The electric fire pump and diesel fire pump with its own starting battery are normally on standby since the fire mains are supplied with makeup water and pressurization from the FPS jockey pump which takes suction from the GSW pump header.

These numerous sources of water to the fire protection water header ensure a source of water for extinguishing fires. No motor-operated valves are required to operate. The hose connections and valves are operated manually. Loss of fire protection instrumentation to the main control room would not prevent extinguishing a fire.

9.5.1.3 System Evaluation

9.5.1.3.1 Introduction

A fire hazards analysis of the Fermi 2 fire protection provisions was originally conducted in accordance with BTP APCSB 9.5-1 based on the Fermi 2 design as of April 1977. A point-by-point comparison was made with Appendix A to BTP APCSB 9.5-1. Subsequent minor revisions have been made to keep the analysis current. The results of these fire protection evaluations of Fermi 2 are included in Appendix 9A. Fermi 2 is in compliance with the guidance of Appendix R to 10 CFR 50, Sections III.G, III.J, and III.O. The deviations of Fermi 2 from Appendix R are addressed in Appendix 9A. These deviations provide an equivalent level of protection to the technical requirements of Section III.G of Appendix R.

The possibility of fire is minimized by the use of noncombustible materials in the construction of the plant. The spread of fire from one area to adjacent areas is prevented by high-integrity concrete enclosures and by fire-rated barrier walls where necessary.

The plant design is reviewed by NEL-PIA for potential fire hazards, and recommendations made by NEL-PIA on flame-retardant materials for structures, insulation, and electrical and mechanical equipment have been used.

The fire protection water system is not considered essential to the safe shutdown of the reactor. It is not designed to Category I requirements. The failure of the system piping or the inadvertent operation of the system does not affect the operation of the safety-related systems, as adequate drainage is provided in all buildings to prevent flooding and as all safety-related systems are designed to be protected from water spray and jet forces from the piping in the area. Flow switches provided throughout the system indicate system operation in the main control room. The layout and valving arrangement of the underground water system permit isolation of any defective section, without interruption of service to other parts of the plant. The inadvertent operation of the CO_2 systems does not affect the operation of safety-related equipment in the area. Smoke dampers in areas with gaseous fire suppression systems are remotely resettable from the main control room so that inadvertent actuation does not cause loss of ventilation to these areas.

The fire hydrants are installed at various yard locations such that the maximum distance between adjacent hydrants is not more than 300 ft, and, if possible, are within 40 ft of the plant buildings. Adequate pressure in the system lines will be available at the uppermost floors of all the buildings. Early-warning detection alarm instrumentation, smoke damper closure, CO_2 and Halon systems actuation alarms, and indication in the main control room of water fire protection system actuation provide reliable identification of the location of any fire so that corrective measures can be instituted with minimum delay. Temperature-operated (fusible-link) fire dampers in the ventilation ducts help contain the fire in the affected area. Audible fire alarms in the areas protected with CO_2 systems warn personnel of the impending actuation of the CO_2 system.

Table 9.5-2 provides a failure mode and effects analysis to demonstrate that operation of the fire protection system in areas containing safety-related equipment does not produce an unsafe condition or preclude a safe shutdown.

9.5.1.3.2 Failure of Nonseismic Fire Protection Systems

For safety-related buildings, the fire protection systems are seismic Category II/I. Therefore, the fire protection system piping will not fall and damage Category I equipment. The overall design of the fire protection system, because it is not a safety-related system, has not included design features to withstand the effects of single failures, except that the underground supply piping and fire pumps will allow for a single break or pump failure.

9.5.1.3.2.1 RHR Complex CO_2 System Failure

The CO_2 system is designed to discharge approximately 5000 lb of CO_2 into one diesel generator room. This quantity of CO_2 will flood the room and extinguish the fire by cutting off the supply of oxygen. If the CO_2 system inadvertently discharges into the diesel room, it will cause cooling that will lower the room temperature and the equipment temperature. The operating heat loads in the EDG room are less than 1,840,000 Btu/hr. The CO_2 discharge can provide approximately 20 minutes of cooling for this heat load. It is estimated that the CO_2 would not reduce the room temperature more than 100°F and at most would reduce the diesel engine generator temperature 40°F.

The inadvertent operation of the CO_2 system will not affect the operation of the EDG, since separate combustion air is provided for the engine by direct connection to the outside. Also, the CO_2 discharge horns are not directed toward any of the equipment. The horns are designed so that there is not a concentrated blast, but a diffuse stream of CO_2 vapor and solid particles. The cold gas will warm up and the solid particles will vaporize before coming into contact with the equipment. The quantity of cooling provided by the CO_2 system and the fact that it does not directly impact on the equipment will eliminate the possibility of thermal shock and will not cause a significant drop in equipment temperatures.

The rupture of a CO_2 storage tank will not cause damage to any safety-related equipment. Each CO_2 storage tank is located in its own room, and no safety-related equipment is located in that room. A rupture of the tank would confine the CO_2 to that room except for a possible small leakage under the doors. The CO_2 would extinguish any fire within that room. Leakage under the doors into the diesel generator room would not affect the operation of the diesels because they are designed to operate in a CO_2 environment.

9.5.1.3.2.2 Failure of Water Fire Protection Systems

The analysis of water fire protection line failures and the subsequent effect of water on safety-related equipment is presented in Subsection 3.6.2.3, which includes an analysis of the failure of all moderate-energy fluid systems throughout the plant, including the RHR complex.

To avoid freezing of the RHR fire protection water supply mains, a continuous flow of approximately 0.1 gpm is maintained during the winter.

9.5.1.3.2.3 Failure of Other Gaseous Systems

The gaseous systems provided other than in the control center will not cause loss of function of Class 1E equipment since the equipment can operate in a gaseous environment. The gaseous systems in the control center will also not affect Class 1E equipment. Failure (closure) of the smoke/Halon dampers for the relay room, cable spreading room or computer room will cause loss of cooling to their respective rooms. Manual actions are required to reopen these dampers to reestablish airflow. As described in Subsection 9.5.1.2.2, the smoke purge mode of the control center ventilation prevents concentration of Halon in areas outside the Halon suppression zone. The CO_2 storage tank for CO_2 systems inside the auxiliary building is located outside the plant.

9.5.1.3.3 Removal of Fire-Fighting Water

Floor drains are designed to remove the expected fire-fighting water flow from areas where fixed water fire suppression systems are installed or where fire hoses may be used. Equipment is installed on pedestals to protect it from water. Water drainage from areas which may contain radioactivity is collected in the floor drain collection tank for normal liquid radioactive waste.

9.5.1.4 Inspection and Testing Requirements

Preoperational testing of the fire pumps, hydrants, sprinklers, deluge systems, gaseous systems, standpipe, and hose systems was performed in accordance with the applicable NFPA codes. In addition, the instrumentation and control for the automatic starting of the fire pumps, flow detection and alarm, and SGTS thermal detection systems was tested for operability and limits.

Inspection, testing, and maintenance of all equipment of the fire protection system use the applicable NFPA codes as guidelines.

9.5.1.5 Personnel Qualification and Training

The fire-fighting training program, testing, and inspection are discussed in Subsection 13.2.4.

9.5.2 Communications Systems

9.5.2.1 Design Bases

A comprehensive communications system is provided to ensure reliable intraplant communications, offsite commercial telephone service, and offsite emergency communications capabilities. Effective communication between personnel during startup, operation, shutdown, refueling, and maintenance is made possible by the use of an adequate number of telephones, public address speakers, and two-way radios.

The public address speaker system and the two-way radio repeaters are powered from emergency power bus 72B. The other diverse means of communications are physically independent to preclude the loss of all systems as a result of a single failure.

An emergency alarm system is installed that provides an alarm signal to ensure personnel evacuation.

9.5.2.2 System Description

9.5.2.2.1 Two-Way Radio

Two separate communication channels of unique wave lengths for operations personnel and for maintenance personnel are provided to enable two-way radio communication between the main control room and the various plant buildings. The main control room is equipped with handheld microphones on each panel section and at the operations desk console. Portable transmitter-receivers of the hearing-protector headset and boom-mike type, operating on either or both channels, are provided for use by the operations and maintenance personnel for communication between various areas of the plant.

To improve reception from the various plant buildings, monitor receivers are provided in these buildings. The radio transmitter carrier frequencies are chosen so that no interference with the reactor building or turbine building radio-controlled crane is possible.

9.5.2.2.2 Hi-Com (Public Address) System

The Hi-Com system provides two separate and independent channels of communication, namely page and party lines. The Hi-Com loud-speakers are powered by individual amplifiers, and the system is supplied from the ac emergency system, which is powered by the EDG upon loss of normal offsite power.

The system layout permits communication between the main control room and site buildings and areas of the plant. The volume level of each Hi-Com channel is adjusted to be louder than the ambient background noise level. For high-noise areas where ear protection is required, or site emergency evacuation notification is not broadcasted, special arrangements for evacuation notification have been provided as described in Subsection 9.5.2.2.4.

The handsets permit channel switchover from paging to party line conversations between any two or more handset stations.

9.5.2.2.3 Telephone System

An independent dial telephone system is provided to facilitate simultaneous conversations between extensions which are located throughout the plant and Detroit Edison network. The main control room is provided with telephones, some of which have access to the Edison network via microwave and also have access to the local telephone company exchange via land line. Incoming calls are received automatically from either network. Microwave provides backup offsite communication in the event of loss of land line resulting from environmental conditions. A telephone is installed in each elevator.

9.5.2.2.4 Emergency Alarm System

The emergency alarm system is designed to broadcast distinct signals using the plant Hi-Com system to the plant. This alarm system is activated from the control room, and different tones have been provided. Activation of the emergency alarm system automatically adjusts the output volume level of each Hi-Com station to a preferred level of 10 dB above the calculated background noise. If the preferred level of 10 dB (above background noise) cannot be obtained, a speaker output of not less than 7 dB above the calculated background noise is acceptable. In Hi-Com broadcast areas where the 7 dB differential could not be obtained or the background noise exceeds 95 dB, visual beacons are provided for emergency notification. For high-noise areas where ear protection is required or site emergency evacuation notification is not broadcasted, special arrangements for evacuation notification are provided by damage and rescue team searches. If a plant area evacuation is required, the Emergency Director (Shift Manager - short term or Executive Director - Nuclear Production - long term) will dispatch the damage and rescue team after Security receives notification of missing personnel.

9.5.2.3 Inspection and Testing Requirements

All communication systems were inspected and tested at the completion of installation to ensure their operability. Most of the systems, except for the emergency alarm system, are used daily and hence do not need any special testing. Testing of the emergency alarm system is carried out on a routine basis.

9.5.3 Lighting Systems

9.5.3.1 Design Bases

The lighting system is designed to provide indoor and outdoor illumination during normal plant operation and during shutdown. During failure of offsite power sources, the system provides alternative emergency lighting to critical facilities.

9.5.3.2 System Description

The lighting system is composed of the normal facilities, the emergency facilities, and the special lighting for the main control room.

The normal area lighting system consists of fixtures and facilities placed in areas of the plant to meet the target light intensities identified by the Illuminating Engineering Society (IES) for nuclear power plants and industrial facilities. Light-Emitting Diode (LED) lighting is used in general areas, office areas, entry points and stairwells. Where LED lighting is not used, high intensity discharge (HID) lighting is typically used for general areas and fluorescent lighting is typically used for office areas, entry points and stairwells. Provisions for containment of mercury containing elements are made where breakage of the bulbs could potentially result in direct mercury intrusion into the reactor coolant.

Normal lighting for the plant buildings is supplied by a grounded 480/277-V and 208/120-V, three-phase, four-wire distribution system from the distribution receptacle panels located in the reactor, auxiliary, and radwaste buildings. These panels receive power from the 480-208/120-V lighting transformers that are powered by 480-V switchgears in the master distribution panels.

Lights that utilize the 480/277-V system are directly supplied from the master distribution panels. The receptacle panels are conveniently located throughout the plant to permit efficient distribution of the lighting load.

One-third of the lights in vital operating areas such as the main control room, RHR complex, reactor building, safety-related equipment areas and access routes, stairwells, and exits are powered by the ESF 480-V buses so that an offsite power failure does not produce a total blackout in these areas. In addition, emergency lighting units consisting of battery-operated sealed-beam units capable of 8 hr of continuous operation are provided in these critical areas of the plant where operator action is required within 8 hrs for safe shutdown in the event of a fire. Emergency lighting for Station Blackout (SBO) is provided by these 8-hr Appendix R Fire Protection units where they exist, or by 4-hr emergency battery lights where Appendix R lighting units are not required. These are activated automatically on loss of normal power. Adequate redundancy is provided in the emergency lighting equipment.

9.5.3.3 Safety Evaluation

Provision of normal power supply, diesel generator power, and individual batteries to the lighting system, together with physical separation and redundancy in the system, ensures dependable lighting to all critical areas at all times.

9.5.3.4 Inspection and Testing Requirements

Periodic inspection of the lighting system, including batteries and simulation tests to monitor operation for the automatic actuation of the emergency lighting, is performed to ensure a reliable lighting system.

9.5.4 Diesel Generator Fuel-Oil Storage and Transfer System

9.5.4.1 Design Bases

The diesel generator fuel-oil storage and transfer system is designed to perform its operational function automatically during emergency conditions. Each diesel generator is furnished with an individual fuel-oil storage tank.

The onsite storage capacity of each of the fuel-oil storage tanks is determined on the basis of continuous operation of the diesel generators for 7 days at continuous load. In addition, the storage capacity includes requirements for testing of the diesel generators. Full day tanks provide more than 2 hr of fuel supply to each diesel generator.

The system complies with Appendix B of ANSI Standard N195-1976, "Fuel Oil Systems for Standby Diesel Generators" and is designed to Category I requirements. The system piping and as much equipment as practicable are designed to either ASME B&PV Code Section III, Class 3 or the Diesel Engine Manufacturers Association (DEMA) standards as shown in Figures 9.5-4, 9.5-5, and 9.5-6. The diesel generator fuel-oil storage and transfer system for each diesel generator is separate and is located in separate compartments. The system is housed in the RHR complex, and, as such, is protected from flooding, tornado winds, and missiles. Adequate fire protection is provided and fire walls separate each compartment containing the individual diesel generator and its associated systems.

The ventilation system for the diesel generator room and CO_2 storage tank room is designed to maintain room temperatures between 65°F and 104°F when the diesel is not operating. The ventilation system for the fuel oil storage room is designed to maintain room temperatures between greater than 32°F and 104°F when the diesel is not operating. When the diesel is operating, the ventilation system is designed to maintain the temperature in the fuel oil storage tank room and the CO_2 storage tank room below 125°F. A separate ventilation system maintains the diesel generator room below 122°F when the diesel is running.

Provisions are made for independently testing redundant components.

9.5.4.2 System Description

Four 2850-kW diesel-engine-driven generators power the ESF buses and are located in the RHR complex. The fuel-oil storage and transfer system is shown in Figures 9.5-4, 9.5-5, and 9.5-6. Power to all of the auxiliaries for each diesel generator is fed from the respective diesel generator.

Each diesel generator set is supplied by a 42,000-gal diesel-fuel storage tank located adjacent to the associated diesel generator. The capacity of the storage tank is based on 7 days fuel supply at 210 gal/hr, plus fuel requirements for routine engine testing. The fuel-oil day tanks are of 550-gal capacity. Two redundant motor-driven fuel-oil transfer pumps deliver fuel to the day tank. Fuel flows by gravity from the day tank to the suction of the engine-driven fuel pump.

The engine driven pump is safety related and required to operate in order to mitigate a design basis accident. An electric motor driven fuel pump is also provided to purge air from the fuel line following maintenance on the fuel oil system. The electric motor driven fuel pump will receive a start signal if a low pressure condition exists on the supply side of the duplex filter. Although the electric motor driven pump is not credited to operate during a design basis accident, it is considered to be a passive safety-related pump. Both pumps supply fuel to the engine fuel injectors.

One transfer pump is started automatically when the diesel generator starts and the day tank overflow is routed to the fuel-oil storage tank. The other transfer pump is started automatically by a low-level switch on the fuel-oil day tank.

The fuel oil storage tanks are filled from tanker trucks through yard couplings and are vented above grade. Each storage tank is fitted with level sight glasses and high- and low-level alarms. Each day tank is fitted with a level sight glass and low-level alarm. Redundant motor-operated and manual valves for draining of the storage tank are provided.

Fuel quality in the storage tanks is ensured by using two strainers between the storage tank and the fill line connection and by performing delivery and periodic sampling for water and sediment. Each of the four EDGs has redundant fuel transfer pumps and separate fill lines to each day tank from each storage tank. Each transfer pump is fitted with a strainer. In addition, between the day tank and the EDG skid there is a strainer for the engine-driven fuel-oil pump line and a duplex filter before the fuel injectors.

The day tank is kept full, and, as required, one of the transfer pumps automatically operates (with the other pump in standby) to maintain the tank level. If sediment plugs the running pump's strainer and the day tank level drops, the alternate transfer pump will automatically start and the low level alarm will sound if the level continues to drop. The plugged strainer can be cleaned by blowing down within the time interval established by the fuel inventory remaining when the low level alarm sounds. Also, the strainers at the fuel transfer pumps and between the day tank and the EDG have pressure differential indicators that are to be monitored during monthly testing.

9.5.4.3 Safety Evaluation

The diesel generator fuel-oil storage and transfer system is designed to Category I requirements and also to withstand any single failure and still satisfy the design requirements. Although any single failure may result in loss of fuel to one diesel generator, the plant demand is met by the remaining three diesel generators. There are no common components of the fuel-oil system between any EDGs. The diesel generator and its associated fuel-oil storage tank, fuel-oil day tank, transfer pumps, and piping are physically separated and adequately protected against tornado missiles, flooding, and fire. The EDG fuel-oil storage tank room is designed to contain the entire volume of oil and the floor drains are sized to handle the fuel oil and sprinkler volumes. Refer to Subsection 9.3.3 for details.

Independent thermal detectors for fire detection are provided in each diesel generator compartment. Automatic fire-fighting systems such as carbon dioxide and wet-pipe sprinkler systems are also provided. In the event of a fire, fuel oil from the storage tank can be dumped to a basin in the yard by opening the dump valves from the main control room. See Subsections 9.5.1.2.3.3 and 9.5.1.2.3.5 and Appendix 9A.

No shortage of fuel supply can be reasonably anticipated, because low-level alarms are periodically inspected and an ample fuel supply is ensured, both by redundant equipment and by conservatively sized reserves. Arrangements are made for the procurement of additional supplies of oil when needed.

The diesel-fuel-oil storage tanks are fabricated from ASME-SA285, Grade C carbon steel. The piping and tanks are inside the RHR complex, and hence no corrosion problems are anticipated during the life of the plant.

9.5.4.4 Inspection and Testing Requirements

All components of the diesel-generator fuel-oil storage and transfer system are tested after installation in accordance with the applicable codes. The Preoperational Test program verifies system performance including indicating instrumentation and alarm signals. Operation of the fuel-oil system is tested by periodic operation of each generator under load.

9.5.4.5 Instrumentation Application

Each diesel-fuel-oil storage tank and fuel-oil day tank is provided with local level sight glasses. High- and low-level alarms for the storage tank and low-level alarm for the day tank are provided. Fuel transfer pump motors are provided with automatic starting circuits and standard Institute of Electrical and Electronics Engineers protection.

Remote operation of each transfer system is possible from the main control room.

9.5.5 Diesel Generator Cooling Water System

9.5.5.1 Design Basis

The diesel generator cooling water system is designed to provide adequate cooling water to remove the heat given off by the lube-oil coolers, inlet air coolers, and the engine jacket coolant heat exchangers. The engine jacket coolant system, which is a closed loop system, removes heat from the engine and transfers it to the diesel generator service water system. The diesel generator service water system is part of the RHR service water (RHRSW) system described in Subsection 9.2.5.

The jacket coolant system is designed to Category I requirements and the system piping, valves, and heat exchangers meet either the requirements of the ASME B&PV Code Section III, Class 3, the DEMA standards, or Group D (ANSI B31.1), and are seismically supported as shown in Figures 9.5-7 through 9.5-9.

9.5.5.2 System Description

The diesel generator service water system, which supplies cooling water from the RHR reservoir to the diesel generator components, is described in Subsection 9.2.5.

The diesel generator jacket coolant system shown in Figure 9.5-7 is described in this section. Each diesel generator is provided with a separate and independent jacket coolant system.

Major components of the system are an expansion tank, an engine-driven jacket coolant pump, an engine-driven air-cooler coolant pump, a standby coolant circulating pump, a heat exchanger, an air cooler, a standby heater, a three-way thermostatic bypass valve, a three-way air-operated bypass valve, high- and low-temperature alarms, low-pressure alarm, and indicators for pressure and temperature.

The jacket coolant is demineralized water with corrosion inhibitors. The engine-driven coolant pump maintains coolant circulation in the closed loop during diesel generator operation. The expansion tank accommodates the volume changes in the coolant due to temperature changes and also provides a means for venting the system. In addition, the expansion tank is to provide for minor system leaks at pump shaft seals, valve stems, and other components, and to maintain the net positive suction head (NPSH) on the system recirculating pump. System losses are made up by adding demineralized water to the expansion tank. The cooling-water expansion tank for each diesel engine has a capacity of 57 gal. The EDG manufacturer considers this tank size adequate to maintain continuous full-load operation for 7 days under normal conditions. To provide the required pump NPSH, the bottom of the expansion tank is located at an elevation of 603 ft, which is above the highest point of the engine cooling system (Elevation 601 ft).

The heat removed by the coolant from the engine is transferred to the diesel generator service water through a heat exchanger. To maintain the coolant temperature in the proper operating range, a three-way thermostatic valve controls the amount of coolant passing through or around the heat exchanger. The orifices in the bypass lines across the heat exchanger are sized based on the system piping and equipment pressure losses to provide design flows through the heat exchanger. To ensure quick starts, a motor-driven standby circulating pump maintains the jacket coolant temperature at approximately 110°F by pumping the coolant through a thermostat-controlled electric heater.

The system instrumentation consists of a low-level expansion tank alarm, a jacket coolant high- and low-temperature alarm, a jacket coolant low-pressure alarm, and system pressure and temperature indicators.

The jacket coolant also cools the scavenger air in a separate subloop of the engine jacket coolant system. This closed loop system has an engine-driven coolant pump, heat exchanger, and three-way air-operated bypass valve. This valve is automatically adjusted to maintain proper scavenger air temperature. The coolant loop is connected to the jacket water expansion tank for both filling and venting. Reliable cold fast starting requires initial EDG combustion air having a temperature of greater than 40°F. The RHR Complex Heating System, which normally maintains the EDG room temperature above 65°F, is relied upon to maintain the temperature of the initial combustion air above the 40°F design minimum required for reliable fast, cold starting of the units.

9.5.5.3 Safety Evaluation

Each diesel generator has independent jacket coolant and service water systems. The jacket coolant system meets the single- failure criterion in that if a failure in the system prevents the operation of its associated diesel generator, the remaining diesel generators will provide adequate emergency power to meet the safe-shutdown requirements of the plant.

The jacket coolant system is housed within Category I structures and the system piping, valves, and heat exchanger meet the seismic and other code requirements specified in Subsection 9.5.5.1.

9.5.5.4 Inspection and Testing Requirements

Inspection and testing of the system are performed as a part of the overall engine performance checks and routine scheduled engine testing. Instrumentation provided for expansion tank level and coolant temperature is inspected regularly. The jacket coolant chemistry is checked periodically and suitably treated to maintain desired quality.

9.5.6 Diesel Generator Starting System

9.5.6.1 Design Bases

Each diesel generator is equipped with a separate starting system to provide cranking power on demand. A compressed-air starting system is employed to provide fast starts and high reliability.

Each starting system includes separate air receivers, piping, and air start distributors and can independently start the EDG. The combined capacity of the two air receivers per system is sized to provide compressed air for starting a diesel generator five times without recharging.

One air compressor is provided for each diesel generator and automatically recharges the air receivers to normal operating pressure when required. Piping is provided to cross-connect the EDG Air Compressors so that one EDG's air compressor can charge the air receiver for both EDGs within a division.

The system piping and components, excluding the air compressors, dryers, and piping upstream of the air receiver inlet check valves, are designed to Category I requirements, and are also designed and constructed in accordance with ASME B&PV Code Section III, Class 3 where practicable. Code classifications are identified in Figures 9.5-8 through 9.5-10. The system is protected from tornado winds, external missiles, and flooding since it is housed in the RHR complex. Separation is provided between systems so that failure of one starting system disables only the associated diesel generator.

9.5.6.2 System Description

The starting system for each diesel engine consists of a motor-driven air compressor which keeps two air receivers pressurized at all times. A separate compressed-air line from the outlet of each of these air receivers serves the start distributors for the air-over-piston starting mechanism. On the inlet side of each of the air receivers, a check valve has been provided to prevent backflow to the compressor. The diesel generator starting system is shown in Figures 9.5-8 through 9.5-10.

The air receivers have low-pressure alarms, pressure indicators, and low-pressure switches to start the motor-driven air compressors and thus ensure that the air receivers are filled with air to the required pressure for EDG standby. One air compressor can be manually valved to charge the air receivers for both EDGs within a division. This operation is for temporary situations and may require manual initiation of the air compressor. The air receivers are equipped with drain valves that are manually opened to drain moisture accumulation. In addition, a refrigerated air dryer is provided between the compressors and the receivers to ensure that the air supplied is adequately dehumidified. Relief valves are provided on the air receiver and on the discharge piping from the compressor to prevent overpressurization.

There are two air start subsystems for each EDG. The two subsystems increase the reliability of an air start in the case of a failure due to fouling of an air start valve with contaminants and moisture. The use of air strainers further precludes the fouling of the air start system.

9.5.6.3 Safety Evaluation

The diesel generator starting system, excluding the air compressor, is designed to Category I requirements and is located inside the RHR complex. The starting system for each diesel generator is independent and physically separated from starting systems of other diesel generators.

Failure of a motor-driven air compressor or the piping up to the air receiver check valves does not prevent the functioning of the starting system. Similarly, manually operating an air compressor connected to all EDG air receivers within a division does not affect the function of the starting air system as an operable EDG only requires that the air receivers be charged, regardless of the source of air. A single failure of the air receiver, starting solenoid valves air distributor, or connecting piping does not prevent the starting of the EDG. Adequate redundancy is provided in the number of diesel generators to effectively perform the required safety functions.

9.5.6.4 Inspection and Testing Requirements

The system is operated and tested initially for flow path obstructions, leaks, flow capacity, and mechanical operability. The low-pressure alarms are calibrated and the low-pressure switch is checked to ensure reliability of compressor activation. Relief valves are set and checked. The diesel generator starting system was tested as part of the Preoperational Test program as discussed in Chapter 14. Subsequent testing is scheduled to meet plant Technical Specifications.

9.5.6.5 Instrumentation Application

The air receivers are provided with pressure indicators, low-pressure alarms, and low-pressure switches to activate the air compressor. Local manual starting of the air compressors is possible.

9.5.7 Diesel Generator Lubrication System

9.5.7.1 Design Bases

The diesel generator lubrication system is designed to provide adequate engine lubrication under all operating conditions, including immediate full-load operation after starting. The system maintains the lube-oil temperature in the specified range under all loading conditions and ambient temperatures.

The system is designed to Category I requirements and meets the DEMA or Quality Group D design and construction requirements except for the lube-oil cooler, which is designed and constructed in accordance with ASME B&PV Code Section III, Class 3 requirements. Specific code classifications are shown in Figures 9.5-4, 9.5-5, and 9.5-11.

9.5.7.2 System Description

The diesel generator lubrication system is shown schematically in Figure 9.5-11. This system is an integral part of the diesel generator package and is supplied by the vendor. Each diesel generator has a separate and independent lube-oil system.

Major components of the system are: a lube-oil tank, an engine-driven lube-oil pump, a lube-oil circulation pump and heaters, a full-flow lube-oil filter with an internal relief valve, a thermostat three-way bypass valve, a lube-oil cooler, a full-flow strainer, three lube-oil pressure switches, high- and low-temperature switches, a motor-driven prelube pump, and panel-mounted temperature, pressure, and crankcase vacuum gages.

The lube oil flows by gravity from the lube-oil tank to the sump located at the base of the engine. Lube-oil flow to the engine is regulated by a level control switch. The engine-driven lube-oil pump takes oil from the sump through a suction strainer and passes it through a full-flow filter. The lube-oil filters are equipped with a pressure indicator and an oil sample tap. Depending on the oil temperature, the thermostatically controlled three-way valve on the discharge side of the filter directs the lube oil through or around the lube-oil cooler. The lube oil is cooled by the diesel generator service water system, which flows through the tubes of the lube-oil cooler. Before being delivered to the engine, the lube oil passes through a three-element strainer that removes large particles that might have become entrained in the oil.

A 2-hp motor-driven prelube pump, which can be manually operated from the remote panel, is provided for prelubricating the engine prior to nonemergency starts. Prelubrication is not required on emergency starts. However, a vendor-supplied prelubrication piping modification is installed and eliminates the potential for dry starts. This piping routes the keep-warm system so that it discharges into the upstream side of the lube-oil strainer. This will provide continuous lube oil to the lower bearings and greatly reduce voids in the lube-oil system. The solid lube-oil system will provide faster lubrication of the upper bearings on the starting of the diesel and the engine-driven pump.

For purposes of lubrication on the bearings of the upper crankline, operating procedures require approximately 2 minutes of prelubrication prior to planned starts of the diesel generators. Also, operating procedures require, whenever possible, gradual loading and unloading of the diesels to ensure that the bearings are adequately lubricated before they are subjected to the stress associated with high speed and large loads.

The lube-oil headers are routed so that they will not readily drain when the engine is stopped. In addition, lube-oil booster/accumulators are provided for the more remote areas of the engine (aft lower main bearing and upper crankline). This booster system fills with oil during normal engine operation. The next time the engine is started, the lube oil in the accumulator is forced into the subject bearings by starting air pressure, thus filling the bearings with oil as the engine begins to be rotated in starting. A standby motor-driven circulation pump keeps the lube oil in the system warm (when the diesel engine is idle) by passing the oil over thermostatically controlled heater elements and returning the oil to the engine-driven pump discharge.

Three lube-oil low-pressure switches are provided. Actuation of one of the switches causes an audible alarm, and actuation of any two switches shuts down the engine. Three high-pressure switches are provided for the crankcase which actuate an audible alarm and shut down the engine in the same manner as the lube-oil low- pressure switches. The lube-oil tank is provided with high- and low-level switches and alarms and a low-level switch and alarm is provided in the engine sump. In addition, high- and low-temperature alarms, crankcase low-level alarm, pressure gauges, and temperature indicators are provided as shown in Figure 9.5-11.

9.5.7.3 Safety Evaluation

The lube-oil system, including lube-oil storage for each diesel generator, is completely independent of the lube-oil systems of the other diesel generators. Therefore, failure of one lube-oil system results in the loss of only one diesel generator in a division. The other diesel generator in the division, along with the diesel generators in the second division, is adequate to meet the safe-shutdown requirements of the plant.

The lube-oil system is designed to Category I requirements.

The diesel engines are designed to contain a crankcase explosion. The manufacturer conducted actual crankcase explosion tests (20 lb/in.^{2}) and then designed the crankcase inspection cover and fasteners to contain such explosions (100 lb/in.^{2}). These tests showed that the explosion was not harmful to the engine and posed no danger to the operators.

9.5.7.4 Inspection and Testing Requirements

The operability of the lube-oil system is tested and inspected along with the scheduled overall testing of the engine. Lube-oil samples are analyzed and diesel engine main bearing gap checks are performed in accordance with the Technical Specifications.

TABLE 9.5-2 FAILURE MODE AND EFFECTS ANALYSIS: INADVERTENT OPERATION OF SAFETY-RELATED FIRE PROTECTION SYSTEM

Fire Protection System	Safety-Related Equipment Protected	Results of Inadvertent Operation of Fire Protections System
HPCI turbine room sprinkler system	HPCI turbine	Loss of HPCI turbine. HPCI not needed for normal shutdown of reactor. Backup LOCA protection provided by automatic depressurization system and low-pressure ECCS
RCIC turbine room sprinkler system	RCIC turbine, core spray pumps	Loss of RCIC turbine. RCIC not needed for normal shutdown. If Division I reactor is isolated, backup protection provided by HPCI. Core spray pump motors are dripproof
M-G set oil coupler and oil cooler sprinkler system	Reactor building structure	Recirculation pumps lost if M-G sets lost. Recirculation pumps not needed for shutdown of reactor
EDG CO_2 system	EDG	Operation of CO_2 system will not hinder operation of an EDG
Diesel-fuel-oil storage room sprinkler system	EDG fuel-oil tanks, day tank, lube-oil tank, and fuel-oil transfer pumps	Tanks will not be affected, but transfer pumps could be lost. An EDG can run 2 hr without fuel-oil transfer pumps. At most, only one EDG can be lost. EDGs in other division provide backup to shut down reactor
SGTS CO_2 system	SGTS charcoal beds	One division of the SGTS temporarily lost until it is manually restarted. No permanent damage to the charcoal filter beds. Remaining SGTS not affected
Sprinkler system in cable tray area over torus	Cable trays, torus, and reactor building structure	Cable trays not affected by sprinklers. Motor-operated valve operators are dripproof. A sump pump is provided in torus area
Sprinkler system in railroad bay area in reactor building at Elevation 583 ft 6 in.	Division II cable trays	Cable trays not affected by sprinklers
Sprinkler system in reactor building at Elevation 613 ft 6 in.	Divisions I and II cable trays	Cable trays not affected by sprinklers
Sprinkler system in auxiliary building at Elevation 551 ft and 562 ft	Divisions I and II cable trays	Cable trays not affected by sprinklers. Control air compressors in Divisions I and II separated by 65 ft

TABLE 9.5-2 FAILURE MODE AND EFFECTS ANALYSIS: INADVERTENT OPERATION OF SAFETY-RELATED FIRE PROTECTION SYSTEM

Fire Protection System	Safety-Related Equipment Protected	Results of Inadvertent Operation of Fire Protections System
Sprinkler system in auxiliary building at Elevation 583 ft and 603 ft	Divisions I and II cable trays	Cable trays not affected by sprinklers
Halon system in relay room, control center at Elevation 613 ft	Divisions I and II relay cabinets and cable trays	Electrical equipment not affected by Halon system. Ventilation dampers remotely resettable (1)
CO_2 system in cable tunnel, auxiliary building at Elevation 613 ft	Divisions I and II cable trays	Cable trays not affected by CO_2 system
Halon system in cable spreading room, at control center Elevation 630 ft	Divisions I and II cable trays	Cable trays not affected by Halon system. Ventilation dampers remotely resettable (1)
CO_2 system in cable tray area, auxiliary building at Elevation 630 ft	Divisions I and II cable trays	Cable trays not affected by CO_2 system
CO_2 system outside switchgear room in auxiliary building at Elevation 641 ft	Divisions I and II cable trays, motor control centers	Cable trays and electrical equipment not affected by CO_2 control centers system
Halon system in main control room computer under and above floor area, Elevation 655 ft	Main control room	Computer not safety related. Control room habitability discussed in Subsection 9.5.1.2.2 (1)

Note 1): Fire Protection relay failure will cause loss of cooling to relay room, cable spreading room or computer room.

9A.1 INTRODUCTION

9A.1.1 Background and Purpose

9A.1.1.1 General

In a letter dated May 3, 1976, the NRC transmitted to Edison a copy of revised Standard Review Plan (SRP) 9.5.1, "Fire Protection," dated May 1, 1976, which included Branch Technical Position (BTP) APCSB 9.5-1. This revision of SRP 9.5.1 contained new guidelines for NRC staff evaluations of fire protection in its review of nuclear power plant construction permit applications docketed after July 1, 1976. The letter stated (1) that to the extent reasonable and practical, the revised SRP will be used by the NRC staff in evaluating fire protection provisions of operating plants, applications currently under review for construction permits and operating licenses, and future applications for operating licenses for plants then under construction; and (2) that the NRC would provide more definitive criteria or acceptable alternatives for the application of SRP 9.5.1 when available.

In a subsequent letter dated September 30, 1976, the NRC transmitted Appendix A to APCSB 9.5-1, which provides for plants docketed prior to July 1, 1976, certain acceptable alternatives to the positions given in SRP 9.5.1. This letter also directed Edison to conduct an evaluation of the fire protection provisions for Fermi 2. The evaluation must include a fire hazards analysis conducted under the technical direction of a qualified fire protection engineer and performed to the level of detail indicated by enclosure 2 to NRC's letter "Supplementary Guidance on Information Needed for Fire Protection Program Evaluation." In addition, the evaluation must provide a detailed comparison of the fire protection provisions proposed for Fermi 2 with the appropriate guidelines in Appendix A to APCSB 9.5-1, which for Fermi 2, are those designated as "plants under construction and operating plants."

As a result of the correspondence, Edison performed a fire protection evaluation of Fermi 2. The fire protection evaluation consisted of performing a fire hazards analysis, doing a point-by-point comparison to Appendix A of APCSB BTP 9.5-1, developing fire protection related drawings, and evaluating the overall Fermi 2 fire protection program.

This evaluation was conducted by Gilbert Associates, Inc., Reading, Pennsylvania, under the technical direction of W. A. Brannen, who is a qualified fire protection engineer. His qualifications include full membership in the Society of Fire Protection Engineers and registration as a Professional Engineer in fire protection in the Commonwealth of Pennsylvania.

The original evaluation report was submitted as Amendment 10 to the original FSAR in November 1977 and subsequently revised and amended in Amendments 39, August 1981; 45, November 1982; 52, December 1983; 58, July 1984; and post OL Revision 1 in March 1985. It presented the results of the fire protection evaluation (fire hazards analysis), the methodology employed, and a description of the shutdown systems of Fermi 2, as well as a point-by-point comparison to Appendix A of APCSB 9.5-1.

Subsequent Appendix R analyses have been performed and have resulted in the submittal of deviations for specific plant fire zones and the design and installation of an alternative shutdown system. The Fermi 2 safe-shutdown capability and systems are discussed in Sections 9A.3 and 7.5.

During the course of the NRC review, the NRC asked for additional information, which was transmitted in Edison letter EF2-53791, dated June 18, 1981, documenting commitments made by Edison at the fire inspection exit critique of May 15, 1981, and at a meeting in Bethesda, Maryland, on May 27, 1981. Changes to Section 9A.4 described in Edison letter EF2-53791 were incorporated in FSAR Amendment 39.

During 1984, Edison met with the NRC staff several times to resolve staff concerns about the potential consequences of a postulated fire in the Fermi 2 control room. As a result of these meetings, Edison committed to provide an alternative shutdown system that could operate independently of the control center. The basis, the design, and the analysis of this alternative shutdown approach were described in Edison letters to the NRC (EF2-72001 and EF2-71994, dated October 22, 1984, and EF2-72718, dated August 16, 1984). Appropriate information presented in these letters has been incorporated into Section 9A and Subsection 7.5.2.5.

Appendix E, "Safety Evaluation Report on the Fire Protection Program for the Fermi 2 Facility," of Supplement No. 5 to the SER issued March 1985 replaces and supersedes Appendix E of the SER dated July 1981 and SSER 2 dated January 1982. Approval of the Fermi 2 fire protection program is provided in SSER No. 5. Subsequent information and approval are provided in SSER No. 6 dated July 1985.

In the process of updating Section 9A, Generic Letter 86-10 was used as guidance in developing and incorporating Section 9A.6, Fire Protection and Alternative Shutdown System Conditions for Operations.

Since the original Fermi 2 fire hazards analysis, the NRC produced clarification on fire protection features for nuclear power facilities, for example, Generic Letters 81-12, 82-21, 84-09, 85-01, and 86-10. Generic Letter 86-10, "Implementation of Fire Protection Requirements," clarifies such subjects as documentation, deficiency notification, and removal of Fire Protection Limiting Conditions for Operation and Surveillance Requirements from the Technical Specifications. This clarification has been considered in the development of the Fermi 2 Fire Protection Program. Generic Letter 86-10 was used as guidance in developing Section 9A.6, Fire Protection and Alternative Shutdown System Conditions for Operations.

The fire protection system limiting conditions for operation and surveillance requirements have been removed from the Technical Specifications and included in Section 9A.6.

Section 9A.1 presents the results of the fire protection evaluation of Fermi 2. The methodology used and a description of the shutdown systems are presented in Sections 9A.2 and 9A.3, respectively. The fire hazards analysis is presented in Section 9A.4. The point-by-point comparison to Appendix A of APCSB 9.5-1 is provided in Section 9A.5. The fire protection and alternative shutdown system conditions for operations are provided in Section 9A.6.

9A.1.1.2 Documents

The following is a listing of pertinent correspondence with the NRC and of other fire protection program documents. The documents have been incorporated into UFSAR as appropriate.

9A.1.2 Applicable Codes

The following National Fire Protection Association (NFPA) codes were used for guidance in the development of the Fermi 2 fire protection program.

NFPA Code	Edition Used
10	1978
12	1977
12A	1977
13	1980
13A	1976
13E	1973
14	1976
15	1979
20	1970
24	1970
30	1977
72E	1974
72D	1975
198	1972

The 1978 edition was used for other NFPA codes not specifically mentioned above or in Subsection 9.5.1.1.5. Certain deviations to the above listed NFPA codes have been evaluated as being acceptable and are discussed in Subsection 9.5.1.

9A.1.3 Fire Protection Program

9A.1.3.1 Objective and Purpose

The Fermi 2 fire protection program defines the requirements and responsibilities for control of the fire protection equipment and activities and is designed to minimize the adverse effects of fires on safety-related structures, systems, and components and to ensure safe-shutdown capability in the event of a plant fire.

This program has been established to outline the fire protection systems and associated tasks and personnel necessary to perform those tasks to ensure that the fire protection program is effective in minimizing risks associated with fires. Fire protection activities associated with safety-related systems, components, or structures will be conducted in accordance with the provisions of the Operating License.

9A.1.3.2 Description

The fire protection program consists of the following components:

a. Definition of the organizational responsibilities and lines of communication, pertaining to fire protection, between the various positions/organizations

b. Qualification of personnel responsible for fire protection at Fermi 2

c. Composition, duties, and qualifications of the plant fire brigade

d. Establishment and maintenance of the fire protection training program

e. Administrative controls to minimize the amount of combustibles that safety-related areas may be exposed to and the control of potential ignition sources

f. Fire-fighting strategies for safety-related areas

g. Periodic inspection, maintenance, and testing of fire detection and protection systems

h. Training of necessary plant personnel for fire watch duty

i. Assurance that necessary actions are taken to minimize fire risk and repairs are made as soon as practical when fire equipment is taken out of service

j. Procedures that establish a method for design control, procurement, installation, and testing for fire protection in safety-related areas

k. A quality assurance (QA) program so that the requirements for design, procurement, installation, testing, and administrative controls for fire protection in safety-related areas are satisfied

l. The necessary fire protection equipment, communications equipment, and emergency lighting which has been installed in accordance with the fire hazards analysis contained in this appendix.

9A.1.3.3 Organizational Responsibilities

a. The senior onsite nuclear manager is responsible for the operation of Fermi 2 and therefore has overall responsibility for the fire protection program

b. The senior onsite nuclear manager in charge of engineering has been delegated management responsibility for the formulation and effectiveness of the fire protection program

c. Nuclear Engineering is directly responsible for:

   1. Having a qualified fire protection engineer within Nuclear Engineering. This engineer assists in the formation, maintenance, and periodic review of the fire protection program

   2. Establishing and maintaining the overall fire protection program description

   3. Developing and maintaining the fire detection/ protection design and configuration control for onsite facilities and location of the safe-shutdown equipment for fires

   4. Reviewing fire protection practices and evaluating design-related sections of insurance inspections

   5. Ensuring that the fire protection program associated with safety-related systems, components, and structures conforms to NRC requirements by:

      (a) The performance of fire hazards analyses, and evaluations as required

      (b) The review and evaluation of designs in accordance with current fire codes and standards for applicability to the plant

      (c) The evaluation of operating experience reports (i.e., License Event Reports, Safety Evaluation Reports [SERs], Inspection and Enforcement Bulletins, Circulars, and Notices) for the potential impact on plant fire safety.

d. The Executive Director – Nuclear Production has been delegated the responsibility for:

   1. Implementing and coordinating the Fermi 2 fire protection program

   2. Having a fire protection specialist

   3. Organizing and implementing the plant fire brigade. The fire brigade is composed of a minimum of five Plant personnel and shall be maintained onsite at all times.* The fire brigade shall not include the Shift Manager, the Shift Technical Advisor/Operations Shift Engineer, nor the two other members of the minimum shift crew necessary for safe shutdown of the unit nor any personnel required for other essential functions during a fire

* The fire brigade composition may be less than the minimum requirements for a period of time not to exceed 2 hr, in order to accommodate unexpected absences, provided immediate action is taken to fill the required positions.

emergency. To be a fire brigade member, personnel must first complete the required fire brigade training, rad-worker training, and respirator training, and be physically qualified

4. Managing fixed and transient combustibles; flammable and combustible liquids, cutting, welding, and grinding activities, and other ignition sources to minimize associated fire hazards

5. Housekeeping and fire inspection performance

6. Assisting Nuclear Training in development of training programs for the plant fire brigade, fire watch, and site personnel

7. Maintaining, operating, and inspecting fire protection systems, components, and equipment

8. Developing and implementing the fire "Pre-Plans"

9. Developing the maintenance, surveillance, and administrative procedures for the fire protection program.

e. Nuclear Quality Assurance is directly responsible for audits, surveillances, and inspections of the fire protection program including operations, maintenance, and modifications of fire prevention components, equipment, and systems to ensure compliance with procedural and regulatory requirements

f. Nuclear Training is responsible for maintaining the Fire Protection Training Program as follows:

1. Training both onsite and offsite fire brigade personnel.

2. Conducting and evaluating required plant fire drills.

3. Developing plant fire evacuation plans.

4. Training fire protection inspectors.

5. Training fire watch personnel.

g. Onsite Review Organization (OSRO) is responsible for review of changes to the Fire Protection Program per Section 17.2.

9A.1.3.4 <u>Drill</u>

The Frenchtown Fire Department will participate with the plant fire brigade in a drill at least once per year. This requirement may be satisfied as part of the Radiological Emergency Response Preparedness Plan program.

9A.1.3.5 <u>Audits</u>

Audits of the fire protection program shall be performed as specified in Section 17.2.

9A.2 METHODOLOGY - FIRE HAZARDS ANALYSIS

9A.2.1 Introduction

A fire hazards analysis of the Fermi 2 fire protection provisions was originally conducted in accordance with Appendix A to Branch Technical Position (BTP) APCSB 9.5-1. The original fire hazards analysis was based on the design as of April 1977. The original fire hazards analysis concentrated on buildings housing shutdown equipment. The objective of the analysis was to determine the potential effects of a fire at a given location within the plant and then to judge whether a fire at a given location would adversely affect the ability to safely shut down the plant. Specific fire hazards in other buildings and areas were evaluated to determine the effect of a fire on the 3-hr-rated walls separating these buildings and areas from the buildings containing safe-shutdown equipment. Where it was determined that a single fire might jeopardize plant safe shutdown, a design change was implemented. The final analysis and conclusions, as presented in Section 9A.4, were based on the design that incorporated these changes. Subsequent revisions have been made to keep the fire hazards analysis current. Subsequent analyses were due to the change in the rule. These analyses were performed to verify Fermi 2 compliance with the new technical requirements of 10 CFR 50, Appendix R, Sections III.G, J, and O. In this effort Edison reassessed the Fermi 2 fire protection program and performed additional safe-shutdown analyses that resulted in the design and installation of the alternative shutdown system and dedicated shutdown panel. Also, Edison requested deviations from specific conditions of Appendix R. The results of the fire protection evaluations and subsequent analyses of Fermi 2 are included in Section 9A.4.

A deviation is a condition which when analyzed/evaluated does not strictly adhere to the rule but does have conditions which provide an equivalent level of protection to that of the requirements.

The deviations of Fermi 2 from Appendix R are addressed in Reference 1. These deviations provide justification that an equivalent level of protection to that of the technical requirements of Section III.G of Appendix R exists for Fermi 2.

At Fermi 2, fire hazards analyses have been and are performed in two phases: the first is that of an information collection process; the second is the actual analysis and effects evaluation.

9A.2.2 Information Collection

Before a fire hazards analysis can be performed, Fermi 2 plant information is obtained such as plant shutdown equipment, inventory of combustibles, structural fire barriers, and existing and planned fire detection/protection equipment. This information is then reviewed and documented in the fire hazards analysis. As required, the information is then incorporated on the fire protection layout drawings, Figures 9A-1 through 9A-18.

9A.2.2.1 Plant Shutdown Equipment

Plant safe-shutdown operation starts with the reactor at normal full power and terminates with the reactor in the cold-shutdown condition with long-term cooling in operation. Plant safe- shutdown equipment is defined as mechanical, electrical, and ventilation equipment, including instrumentation, controls, and cables, required for the shutdown operation. Shutdown is from the main control room, under normal and abnormal conditions, with certain exceptions. For these exceptions, such as a fire in the control center complex (control room, relay room, and cable spreading room), the plant can be shut down from outside the control room using the alternative shutdown system. Additional information concerning the safe-shutdown sequence is presented in Section 9A.3.

9A.2.2.2 Inventory of Combustibles

The inventory of combustibles and calculation of combustible (fire) loading for all fire zones in the plant is contained in a detailed engineering design calculation. The major types of combustibles inventoried for the fire hazards analysis are petroleum products, electrical insulation, charcoal filters, Thermo-Lag material, and maintenance and operating supplies. The fire loading values (Btu/ft^2) determined in the inventory process are used to calculate the total fire loading of the zone as described in Subsection 9A.2.3.3. The resultant calculated total fire loading for each fire zone is then classified as low, moderate, or high, and this descriptive quantitative term is utilized in the Fire Hazards Analysis in Section 9A.4. These terms are being used as discussed in the Fire Protection Handbook. A low fire load is one that does not exceed an average of 100,000 Btu per square foot of net floor area; a moderate fire load exceeds an average of 100,000 Btu per square foot of net floor area but does not exceed an average of 200,000 Btu per square foot; a high fire load exceeds an average of 200,000 Btu per square foot of net floor area but does not exceed an average of 400,000 Btu per square foot. These terms were developed in British Fire Loading Studies and assume (or allow) even higher load limits in limited isolated areas for each level (low, moderate, or high) but only these average fire load limits are being used for the Fermi 2 Fire Hazards Analysis in order to add conservatism to the analysis.

Petroleum products are defined, for the purposes of the fire hazards analysis, as lubricants and fuel oil. Lubricants are tabulated for all equipment containing 1 gal, or more, of oil. Lubrication of equipment requiring smaller quantities of oil is normally accomplished through sealed bearings or oil/grease cup arrangements that require very small quantities of lubricant. These small quantities are not considered significant to the fire hazards analysis and are not included in specific area/zone fire loadings. Fuel oil for diesel-driven equipment and the auxiliary boiler is discussed in the individual zone analyses.

Transformers inside plant buildings are of dry-type construction and contain no petroleum products.

Electrical insulation consists primarily of cable insulation and jackets. Small quantities of other combustible materials are used in switchgear and control panels. The type of cable insulation used in construction was primarily ethylene propylene. Cables have overall fire-retardant jackets of Neoprene or Hypalon. For purposes of the fire hazards analysis, all cable insulation was assumed to be combustible and to have a heat content of 10,000 Btu/lb (Reference 2). Cables have been type tested in accordance with the flame test of Edison's Specification 3071-80 (Reference 3) and are certified to be of fire-retardant construction. This is equivalent to the IEEE-383 test. Metal cable trays are of either the ladder type without covers or the solid-bottom type with covers (see Subsection 9A.2.3.1.8). Control, instrument, and small power cables installed in trays are random and lie in multiple layers.

Large power cables are installed in a single layer and are spaced. Conduits contain one or more cables. Although some delay in fire propagation through conduits can be expected, no credit is taken for such delay in this evaluation.

Electric Power Research Institute (EPRI) tests have demonstrated that an electrical short will not propagate a fire in the type of cable installed at Fermi 2. Therefore, an exposure fire would be required for propagation of a cable fire. The EPRI test "NP 1881" documents that a minimum of 4 gal of flammable liquid burning for 10 minutes is necessary to cause a cable fire to slowly propagate. In the test, the cable fire self-extinguished after approximately 30 minutes. This indicates the EPR/Hypalon-jacketed cable has a high resistance to fire.

For the fire hazards analysis, cable insulation quantities were estimated using the following procedure:

a. A representative cable size was established for each tray class, based on tray classification (power, control, instrument, etc.)

b. The cable fill percentage per tray was determined from the cable routing database.

c. The insulation quantity was obtained by multiplying the tray length, weight of insulation of the cable size representative of the tray loading and actual tray fill percentage for all areas.

The total insulation weight was obtained through a summation of all trays in the fire zone. The cable tray lengths given in the cable routing database were used rather than measuring the tray length existing in each fire zone. This was a conservative simplifying assumption because the tray numbers do not automatically change where they pass through fire barriers or across fire zones boundaries. Therefore, the full length of the tray is added to the fire zones on both sides of the barrier or boundary. In most areas of the plant, cable in conduit was ignored based on the facts that it is a small percentage of the total cable and that the conservatism in the estimating procedure would offset the cable in conduit.

Insulation in motors is a small quantity in comparison to the quantity of cable insulation. Combustible materials inside instrumentation, control, and relay cabinets mainly consist of cable insulation, bakelite in relay housings, and small quantities of miscellaneous materials.

The Btu content of electrical and instrument cabinets was established based on an investigation of combustibles within several electrical panels at Fermi.

Electrical insulation in motor control centers and switchgear consists mainly of cable insulation. The Btu content was determined by a review of several MCC at Fermi.

Charcoal quantities were estimated based on the size of charcoal filters having comparable flow rates.

Maintenance and operating supplies consist of lube oil, hydraulic fluid, paper, cloth, plastic, and other items required for normal plant operations. In contrast to petroleum products, electrical insulation, and charcoal, which are permanent and are part of the plant design, these combustibles are nonpermanent, may vary with time, and can be moved. For the fire hazards analysis, it is assumed that plant housekeeping procedures will keep nonpermanent combustibles in general plant areas to limited quantities. In those areas where it is known that maintenance and operating supplies must be maintained, estimates are based on previous operational experience.

For fire hazards analyses performed subsequent to the original, the inventory of combustibles has been and is being addressed in accordance with the National Fire Protection Association (NFPA) "Fire Protection Handbook," latest edition. This document was used to determine the criteria for evaluating additions to the combustible inventory in each zone at Fermi 2.

The purpose of the inventory of combustibles (fire loading/ combustible loading descriptive level) is to provide the evaluating fire protection engineer with an approximation of the quantity of combustible hazards within the fire zone or area being evaluated or analyzed. The combustible loading is just one of several factors considered when performing a fire hazards analysis or evaluation. The fire protection engineer also considers the type of combustible, its use, its location, ignition sources, and fire detection and suppression systems within the given zone. These are more important to the evaluation than is the quantity of combustibles. Therefore, these factors are given greater consideration when performing fire hazards analyses and evaluations for Fermi 2.

When new cables, single or in conduit, are added to the plant, their fire loading values are not added to the fire zone's fire loading value because the fire loading value presented by them is insignificant compared to the existing estimates. Cables in conduit are accepted as not contributing to the fire loading of a fire zone or area.

When significant amounts of combustibles as described above or cable trays are added to a fire zone, the combustible loading is reviewed accordingly and its effects evaluated for the affected fire zones.

9A.2.2.3 Review of Structural Fire Barriers

For the original fire hazards analysis, walls, floors, and ceilings were assigned fire-resistance ratings based on their construction. Door ratings were established to conform with the fire rating of the walls in which they are installed. Each penetration in a designated fire barrier is fire stopped with the appropriately rated firestop. Cable tray penetrations through non-rated walls, floors, and ceilings are fire stopped (see Figures 9A-1 through 9A-18). See Subsection 9A.2.3.1.1 for a discussion on internal seals inside electrical conduits penetrating rated fire barriers.

Subsequent design and analysis ensures that the barriers separating safety-related zones will prevent the propagation of fires.

9A.2.2.4 Existing Fire Detection/Protection Equipment

For the original fire hazards analysis, the following information was reviewed concerning existing fire detection and protection equipment:

a. Type and location of fire detector

b. Configuration of fire protection (water) system

c. Type and location of valving

d. Type, capacity, and location of fire pump

e. Type and location of hose reel

f. Type and location of fire extinguisher

g. Location and configuration of permanently installed water sprinkler or deluge systems

h. Location and configuration of permanently installed gaseous fire suppression systems

i. Type of actuation for fire protection systems.

In addition to the above, sprinkler system densities are taken into account in performing fire hazards analyses and evaluations.

9A.2.2.5 Fire Protection Layout Drawings

Fire protection layout drawings (Figures 9A-1 through 9A-18) have been developed to present information related to the fire hazards analysis. The drawings show each safety-related building, including equipment not required for safe shutdown from a fire, fire barriers within each building, the plant shutdown equipment found within each building, and fire detection and suppression equipment. These drawings support the basis for the fire hazards analysis.

9A.2.3 Fire Hazards Analyses and Evaluations

Following information collection and drawing preparation, the original fire hazards analysis was performed.

Subsequent fire hazards analyses are performed using a similar process plus new considerations that have been learned or identified as requiring evaluation. The steps used to perform these analyses and general considerations are discussed below. The detailed analysis for each fire zone, with results, is presented in Section 9A.4.

9A.2.3.1 Identification of Fire Areas/Zones

To provide a systematic analysis that can be updated in the future, the plant is divided into fire areas in accordance with the definitions of BTP APCSB 9.5-1. The fire areas are: fire area RB, reactor building; fire area AB, auxiliary building; fire area TB, turbine building; and fire area RHR, residual heat removal complex. For analytical purposes, the fire areas have been further subdivided into fire zones. Fire zone boundaries occur at existing physical features of buildings such as floors/ ceilings and walls.

Although certain rooms are enclosed by rated fire walls, floors, and ceilings, which by definition makes them fire areas, they are considered zones or parts of a zone for this analysis.

The analysis, discussed in Section 9A.4, is presented on a building-by-building basis.

9A.2.3.1.1 Fire Barrier Penetrations

Fire barrier penetrations are provided with approved rated seals or have been evaluated via a specific fire hazards analysis.

The acceptability of the relay room stairwell seal design for cable tray crossover penetrations is based on fire tests and engineering analysis. This approach was found acceptable in SSER No. 5.

The conduit fire protection research program final report (Reference 11), submitted to the USNRC in 1987 by the Wisconsin Electric Power Company, provides the acceptance criteria to determine if an internal conduit seal is required for electrical conduits routed through rated fire barriers. This acceptance criteria which has been accepted by the USNRC (Reference 9 and Reference 10) is used at Fermi 2 to determine if and when an internal conduit seal is required for those electrical conduits routed through rated fire barriers. This criteria which evaluates each side of the fire barrier separately, is as follows:

a. Conduits that terminate in junction boxes or other noncombustible closure need no additional sealing

b. Conduits that run through an area but do not terminate in that area need not be sealed in that area

c. Conduits smaller than 2" diameter that terminate 1 foot or greater from the barrier need not be sealed

d. Open conduits of 2" diameter that terminate 3 feet or greater from the barrier need not be sealed

Consequently, electrical conduits which do not meet the criteria outlined above, and are routed through rated fire barriers, are provided with rated internal seals as required.

9A.2.3.1.2 Fire Boundaries

Fermi 2 has fire zones that are not enclosed by 3-hr-rated fire barrier boundaries. The barriers were reviewed by the NRC in 1981 and found to provide an acceptable level of protection, as stated in SSER No. 2.

As part of the 10 CFR 50, Appendix R, deviation submittal (Reference 1), additional information and analyses of these unrated boundaries were provided. SSER No. 5 reaffirms the acceptability of the zone boundaries. The unrated boundaries have unsealed openings such as pipe and duct chases, hatches, and open stairwells. Generally, the unrated boundaries are acceptable for one or more of the following reasons:

a. The Fermi 2 design separates Division I and Division II safe-shutdown cables and equipment in the reactor building

b. The lack of combustible materials in the stairwells and open penetrations

c. The large volume of the reactor building wherein heat can be dissipated

d. The installation of automatic sprinklers in areas considered to present a fire hazard and in areas to prevent fire propagation

e. The administrative control of combustible materials and ignition sources within the plant

f. Early-warning smoke detection provides assurance of prompt fire brigade response

g. Cable tray penetrations are fire stopped at boundaries, thereby eliminating cable trays as a means of fire propagation between zones.

The unrated boundaries are: All Reactor Building floors and ceilings; the walls between Reactor Building Fire Zones 01RB and 02RB, 02RB and 03RB, and 03RB and 04RB, as shown in Figures 9A-2 and 9A-3; and the walls between Auxiliary Building zones 14AB and 15AB and the floor between Auxiliary Building zones 13AB and 15AB.

9A.2.3.1.3 One-Hour Protective Envelope

The 1-hr barrier is composed of 3M fire barrier material. Initially, there were some questions whether the 3M material design and installation configuration met NRC requirements. Subsequently, this fire-retardant material was rated by the Underwriters Laboratories as a 1-hr protective envelope. In Reference 4 submittal justification was demonstrated for the 3M material and the design was found acceptable in SSER No. 5.

The 3M material is being used as a 1-hr protective envelope to protect safe-shutdown cables in specific fire zones as delineated in the fire hazards analysis. Also, it has been installed throughout the plant on cables, conduit, and supports of equipment no longer required to be protected for safe shutdown. Therefore, when it is removed for maintenance purposes, it will not be replaced.

3M material has been added to the Auxiliary Building basement to protect cable trays and supports. This protective envelope has been tested by a nationally recognized testing laboratory and qualified as a 1-hour envelope in accordance with current NRC requirements. In addition, tested fire breaks have been added to trays in the Auxiliary Building Basement to ensure that a postulated fire cannot spread through these cable trays in such a manner as to damage redundant safe shutdown components. The specific areas and cable trays protected are described in the fire hazards analysis.

9A.2.3.1.4 TSI Three-Hour Barrier

Thermo-Lag 330-1 material is not used on site as a fire rated material; rather it is used in the following locations as a nonrated continuous smoke and gas barrier as defined in NFPA 101:

a. As a barrier between the Relay room (Fire Zone 03AB) and the control center northeast stairwell on elevation 613’-6” (also Fire Zone 03AB)

b. As a HVAC chase floor on elevation 613”-6” at column H-11 above the cable tray area (Fire Zone 02AB) on 603’-6”

c. As a HVAC chase floor on elevation 630’-6” in the southwest corner of the cable spreading room above the relay room (Fire Zone 05AB)

9A.2.3.1.5 Fire Doors

Doors in rated barriers are either listed or labeled by a nationally recognized laboratory; or have been evaluated via a specific fire hazards analysis. Fire doors R3-13, R3-27, R1-11, and R1-8 have approved deviations as listed in Section 9A.4 and SSERs No. 5 and No. 6.

In this appendix, as related to fire doors, "A" means the door has a 3-hr fire-resistance rating; "B" means the door has a 1-1/2-hr fire-resistance rating; and "C" means the door has a 3/4 hour fire resistance rating.

9A.2.3.1.6 Fire Dampers

Fire dampers installed in fire barrier boundaries at Fermi 2 are 3-hr rated or have been evaluated via a specific fire hazards analysis. In some instances, there are single 1-1/2-hr dampers, two 1-1/2-hr dampers installed in series, and ganged dampers. These conditions and installations have been evaluated and documented (Reference 7 and SSER No. 5).

The fire dampers have been justified based on manufacturer's tests of similar installations, the negligible fire loading on each side of the barrier of concern, and the installation of early-warning fire detection on each side of the barrier of concern.

For more information on fire dampers installed at Fermi 2, see Subsection 9.5.1.2.

9A.2.3.1.7 12-In. Concrete Block Walls

In certain areas of the auxiliary building, 12-in. concrete block walls have been erected to provide separation from other parts of the building. These walls are removable to facilitate equipment changeout and repairs. Edison has evaluated these walls and considers them equal to a 3-hr barrier. Although a specific rating test does not exist for this design, the 12-in. block wall will prevent any postulated fire from spreading and therefore provides protection equivalent to a 3-hr-rated barrier. (See Reference 3.)

9A.2.3.1.8 Solid-Metal Trays With Covers

Solid-metal trays with solid-metal covers are installed throughout the plant. Generally, these trays contain small instrumentation cables, and the trays are usually sparsely filled. Under such conditions, Edison has taken credit for the solid-metal tray with cover as a mechanism that restricts or eliminates the propagation of a fire. The NRC has accepted this as equivalent to a fire break in cable trays. (See SSER No. 5.)

9A.2.3.2 Review of Shutdown Equipment Within Fire Areas/Zones

A shutdown analysis was originally performed as part of the overall fire protection evaluation. With the issuance of 10 CFR 50, Appendix R, Edison performed other shutdown analyses to assess compliance to the requirements of Appendix R. The original shutdown analysis was used as a starting point. The new analyses determined the circuits that needed protection due to required fire protection separation requirements for redundant and associated circuits and for the prevention of spurious operation. A summary is provided in Section 9A.3.

An important aspect of reviewing shutdown equipment is the consideration of its function and the location of redundant or other equipment capable of performing the same function. In some cases, two or more sets of redundant equipment are located in the same fire zone. When this occurs, it is necessary to evaluate actual separation, barriers, combustibles in the immediate vicinity of the equipment, ignition sources, and fire detection and suppression equipment in the fire zone. In cases where other equipment capable of performing the same function is located in a different fire zone, it is necessary to perform an analysis to demonstrate that the equipment in the fire zone under consideration could be destroyed by a fire without adversely affecting plant shutdown capability.

9A.2.3.3 Calculation of Fire Loading

For the original fire hazards analysis and subsequent analyses, combustible materials located within each fire zone have been listed and the fire loading, in Btu/ft^2, has been calculated, and the current loadings are documented in a detailed engineering design calculation.

This loading, along with the type of combustibles and the anticipated rate of burn, is used to verify the adequacy of existing fire barriers. For fire-barrier ratings as related to heat load (Btu/ft^2), see Table 9A.2-1.

9A.2.3.4 Review of Ventilation Systems

Ventilation equipment required to cool rooms containing plant shutdown equipment is considered safe-shutdown equipment. Ventilation systems have been designed and installed as described in Section 9.4.

9A.2.3.5 Examination of Fire Detection and Suppression

The examination of fire detection and suppression consists of determining how a fire within a fire zone will be detected and extinguished. It is assumed that permanently installed fire-detection, fire-suppression, and fire-fighting equipment will function as designed.

The types of combustibles and their fire loadings are reviewed to determine the type of suppression and detection equipment required to provide early warning and contain or extinguish a fire within the zone. The effect of water on electrical components and safe-shutdown equipment is a consideration in the selection of the design and type of suppression system that was or will be installed at Fermi 2.

9A.2.3.5.1 Fire Detection Systems

Fermi 2 fire detection systems consist of the detectors, associated electrical power supplies, and the annunciator panels. The types of detectors used are: ionization, thermal, infrared, and photoelectric. The fire detection systems provide local and remote audible and visual alarms. The remote alarms are in the main control room. The fire detection systems are installed in areas having safety-related equipment and/or safety-related cables.

The fire detection systems are installed in accordance with NFPA 72D except that a permanent recording device is not installed as required. A deviation was granted in SSER No. 5 based on the fact that the operators continually man the control room and log each fire alarm received in the control room. Also, control room alarms can only be reset manually at the local fire alarm panel.

Fire detection systems that are used to actuate suppression systems in the reactor/auxiliary building are Class A systems as defined in NFPA 72D. All other redundant safety-related division areas have a cross-zoned Class B detection system.

Edison performed an evaluation of the fire detection system to verify installation with NFPA 72E. The evaluation included assessing detector spacing, location, ceiling types and construction, interferences by heating, ventilation, and air conditioning (HVAC) airflow patterns, and accessibility for testing and maintenance. As a result, some detectors were added in specific areas as described in Reference 7 and a deviation was requested for spacing of the detectors in the torus area. The deviation was approved in SSER No. 5.

Note: Fire detection in the Security Diesel Generator enclosures utilize both infrared and thermal detectors which actuate a FM-200 clean agent system and sends a signal to the security Central Alarm Station which is continually manned.

For more details on the Fermi 2 fire detection systems, see Subsection 9.5.1.2.

9A.2.3.5.2 Fire Protection Systems

Fermi 2 fire protection systems consist of automatic suppression systems including water sprinkler, CO_2, Clean Agent, and Halon systems, the water supply system, yard hydrants, fire pumps, standpipes, and hose stations. For details on these systems, see Subsection 9.5.1.2.

FM-200 Clean Agent extinguishing systems are used in certain areas of Fermi 2. These systems are activated by a NFPA-72 and NFPA-70 compliant fire detection system. These clean agent systems were designed, installed, and tested in accordance with NFPA-2001 requirements.

Halon 1301 total flooding systems are used in certain areas of Fermi 2. These systems are activated by ionization detectors of a Class A fire alarm circuit or photoelectric detectors. These systems were designed and installed using NFPA 12A as guidance.

Hose stations are located throughout the plant. The hose stations were installed using NFPA 14 as guidance. They are equipped with 1-1/2-in. approved lined hose and adjustable pattern fog nozzles. Pressure reducing devices are not installed as required by NFPA-14 at all hose station outlets where the pressure exceeds 100 psig, to reduce the pressure with required flow at the outlet to 100 psig. This is acceptable because the hose stations and fire hose are only used by trained fire brigade members, and adjustable pattern fog nozzles are provided at all hose stations, except for the fifth (refueling) floor of the reactor building where solid stream nozzles are provided. Pressure reducing devices that significantly reduce pressure are provided for hose station outlets on the fifth floor of the reactor building and on floors below the grade floor of 583 ft 6 in., due to excessively high pressure at those hose stations. The reason for utilizing a higher pressure at hose stations is to be able to more effectively fight fires at the ceiling height where cable trays are located. These reducers maintain pressure at the hose at approximately 130 psi. The higher pressure is needed for the hose stream's reach. A fire at ceiling height, 20 to 30 ft, would otherwise be difficult to extinguish. To compensate for the higher pressures, the fire brigade is trained in handling hose streams with higher pressures and signs have been placed on the hose cabinets in safety-related buildings restricting their use to the fire brigade. General employee training covers the use of and restrictions on the fire hose stations (Reference 8).

9A.2.3.6 Evaluation/Conclusions

An evaluation is performed to determine whether the plant is adequately protected in the event of a design-basis fire within a fire zone. This evaluation is based on all the previously noted information. The primary objective is to determine if a fire will jeopardize plant safe shutdown.

Questions addressed in the fire hazards analysis or evaluation of the safe shutdown fire area/zones are typically the following:

a. Is there safe-shutdown equipment within the fire zone?

b. Can the function be fulfilled by redundant equipment in other fire zones?

c. Is this a single item of equipment or are both divisions of redundant equipment involved in this fire zone?

d. Does the ventilation system contribute to the spread of the fire and/or products of combustion to other fire zones that would be otherwise unaffected?

e. How will a fire in the fire zone be detected?

f. What is the response time of the detection devices or scheme? Is this adequate?

g. How will a fire in the fire area/zone be extinguished?

h. How quickly can the suppression equipment be placed into service and what is its effectiveness? Is this adequate?

i. Can the plant be shut down despite the design-basis fire and fire hazards identified within the fire zone?

If the answer to question i. is YES after all the other questions are addressed, it is concluded that the individual fire zone is adequately protected against fire from the standpoint of plant safe shutdown.

If the answer to question i. based on the preceding analyses is NO, design changes are implemented to ensure that adequate protection is available to allow plant safe shutdown.

9A.2.3.7 Containment of Radioactivity

The reactor, radwaste, and turbine buildings house equipment that normally contains significant concentrations of radioactivity. The methods of containing radioactive leakage and releases within these buildings are as follows:

a. Gaseous activity

   Gaseous release or leakage inside the buildings will be retained and controlled within the buildings by their respective ventilation systems. These systems are described in Section 9.4. Radiation monitors are located in the exhaust points. On detection of high radioactivity in the effluents, these monitors actuate an alarm in the main control room and simultaneously trip the ventilation fans and close the isolation dampers. The consequences of a fire in an area capable of releasing radioactive gases are less severe than the most significant gaseous release from the failure of the offgas system, described in Subsection 15.11.4

b. Liquid activity

Liquid spillage or leakage from equipment within these buildings drains into the respective building floor drain sump. Subsection 9.3.3 provides a description of the floor drain systems in the various buildings. From these sumps, it is pumped to the radioactive waste floor drain collection tank for normal liquid waste processing. Section 11.2 details the handling and containment of liquid radioactive waste. The consequences of a fire in an area capable of releasing radioactive liquids are less severe than the most significant release resulting from failure of the liquid radwaste system described in Subsection 11.2.3.1.

Radioactive liquids and gases are normally contained within piping and process equipment, such as tanks, pumps, demineralizers, filters, and evaporator packages. The major source of radioactivity is process equipment that is located in shielded cubicles having very low fire loadings.

A possible problem resulting from a fire is that water used to fight the fire may become radioactively contaminated. However, such contamination does not result in uncontrolled releases. The fire-fighting water will be contained and controlled in the same manner as spillage or leakage described above.

9A.3 PLANT SAFE SHUTDOWN

The primary objective of the fire hazards analysis is to evaluate plant design and modifications to ensure the ability to achieve and maintain safe shutdown in the event of a fire in accordance with the fire protection license condition. The safe-shutdown analysis starts with the reactor at normal full power and ends with the reactor in a cold-shutdown condition with long-term cooling in progress, using the residual heat removal (RHR) system.

Safe-shutdown analyses are maintained in controlled engineering documents performed for Fermi 2 to evaluate compliance to 10 CFR 50, Appendix R, Section III.G. These analyses included safe-shutdown capability evaluations and associated circuits of concern, for example, common power supply, common enclosure, spurious operation, and high/low-pressure interfaces. For fires in most of the fire zones, safe shutdown is accomplished from the main control room using one of the divisions of safe shutdown equipment in accordance with the technical requirements of Section III.G.2 of Appendix R. For fires occurring in one of the dedicated shutdown areas of concern (Fire Zones 03AB, 07AB, 08AB, 09AB, 11AB or 13AB), safe shutdown is accomplished from outside the main control room using the alternative shutdown system (including the dedicated shutdown panel) as described in Section 7.5.2.5 in accordance with the technical requirements of Sections III.G.3 and III.L of Appendix R.

Subsection 9A.3.1 outlines the shutdown sequence on which the fire hazards analyses were based. Subsection 9A.3.2 lists the systems required to accomplish plant shutdown. Subsection 9A.3.3 discusses the method of safe-shutdown analysis.

9A.3.1 Shutdown Sequence

9A.3.1.1 Shutdown from the Main Control Room Using One of the Safe Shutdown Divisions

For the fire hazards analysis, the shutdown sequence starts with the detection of a fire of a magnitude such that plant shutdown is required. Depending on the location and magnitude of the fire, the plant may be quickly brought to hot shutdown or tripped by the plant operator. For the fire hazards analysis, it is assumed that plant shutdown is initiated with an automatic or manual scram of the reactor from the main control room. Once a scram is initiated, no further control rod motion is required.

It was also determined that, although fire damage might cause the plant to trip, no fire could negate the ability to manually trip the reactor.

There are two normal offsite ac power sources available as well as two redundant Class 1E power sources. However, for the purpose of the fire hazards analysis, a loss of offsite power is assumed to occur. The emergency diesel generators (EDGs) for the division credited for shutdown are assumed to start and restore the required portions of the emergency onsite electrical system.

It was assumed, for analytical purposes, that control of reactor pressure by the main turbine pressure regulators through the bypass valves to the condenser was lost. Therefore, the reactor was isolated from the normal heat sink and feedwater flow was stopped at the pressure associated with normal full power. In this condition, reactor pressure is relieved through the safety/ relief valves (SRVs) to the suppression pool.

Additional information pertaining to the safe shutdown systems for main control room shutdowns using one of the normal post-fire shutdown divisions, as well as information related to the safe shutdown analysis are provided in Sections 9A.3.2 and 9A.3.3. Analysis results for applicable fire zones are provided in Section 9A.4.

Manual activation of SRVs and the reactor core isolation cooling (RCIC), the HPCI, or manual activation of SRVs and low pressure coolant injection (RHR or Core Spray) system, brings the reactor to a hot-shutdown condition. During this phase of shutdown, the suppression pool is cooled by operating the RHR system in the suppression pool cooling mode. Reactor pressure is controlled and core decay and sensible heat are rejected to the suppression pool by the HPCI or RCIC turbines or by manually relieving steam pressure through the relief valves. Reactor water inventory is maintained by the high-pressure RCIC or HPCI systems or by the Core Spray or RHR system in conjunction with manual operation of two or more SRVs.

The depressurization, caused by operation of the HPCI or RCIC turbines or manual operation of the relief valves, cools the reactor and reduces its pressure at a controlled rate until the reactor pressure becomes so low that the RCIC or HPCI system discontinues operation. This condition is reached at 50 to 100 psig reactor pressure. The RHR system is then operated in a shutdown cooling mode wherein the RHR system heat exchanger is used to bring the reactor to a cold, low-pressure condition. The cooldown process is ended when long-term decay heat removal operation is established.

For fires in the control center complex and other selected zones, the reactor is tripped in the control room and safe shutdown is completed using the alternative shutdown system described in Subsection 7.5.2.5.

The alternative shutdown system has been designed and installed to meet the technical requirements of 10 CFR 50, Appendix R, Sections III.G.3 and L. This system provides safe-shutdown capability separate and remote from the control center complex and other plant fire zones. The system is used when a fire within the complex or other dedicated shutdown areas of concern is determined to have significantly damaged the safe-shutdown equipment/cabling within these zones. The alternative shutdown system consists of a dedicated shutdown panel (past correspondence with the NRC referred to this panel as the 3L panel) and selected systems that were already installed at Fermi 2. For details on alternative shutdown system capability, including the dedicated shutdown panel, system parameter monitoring, and transfer switches, see Subsection 7.5.2.5.

9A.3.1.2 Shutdown from the Dedicated Shutdown Panel Using the Alternative Shutdown System

As with the control room shutdown described in the previous subsection, the reactor is scrammed from the control room before it is abandoned and a concurrent loss of offsite power is assumed for the limiting analysis. However, the emergency diesels, HPCI, RCIC and multiple SRVs for rapid depressurization may not be available due to fire damage. The Standby Feedwater System, powered by CTG 11-1, or an alternate CTG using the standby diesel generator that provides high pressure RPV makeup and controls for a single SRV are available on the dedicated shutdown panel to provide RPV pressure control for hot shutdown conditions.

Additional information pertaining to the systems used to support the alternative shutdown system utilizing the dedicated shutdown panel and the related safe shutdown analysis are provided in Sections 9A.3.2, 9A.3.3 and applicable fire zones in Section 9A.4.

9A.3.2 Shutdown Systems

The following table is a summary of the Fermi 2 plant systems required to achieve and maintain safe shutdown following a fire. The entries in the table differentiate whether the given system is used for hot shutdown, cold shutdown, or both. It should be noted that for a specific fire zone, not all of the systems listed in the table are required. For example, the hot shutdown RPV makeup function can be performed by HPCI, RCIC, SBFW, or RHR in conjunction with SRVs. In addition, separate columns are provided for shutdown from the control room using one of the normal post-fire shutdown divisions and for shutdown from outside the control room using the alternative shutdown capability including the dedicated shutdown panel. The list of systems includes both systems that directly provide a post-fire shutdown function such as RPV makeup, as well as systems that are required to support these "front-line" systems. For example, RHR Service Water is required to support the RHR when it is aligned for shutdown cooling during the cold shutdown phase. The Appendix R safe shutdown system, component, cable list, and the basis for inclusion in the safe shutdown analysis are maintained in a controlled design calculation.

ID	System Name	Divisional Shutdown from the Control Room	Dedicated Shutdown from Outside the Control Room
B21	MSIVs (manual closure)	Hot/Cold	Hot/Cold
B21	SRVs	Hot/Cold	Hot/Cold
B21	RPV pressure & level instrumentation	Hot/Cold	Hot/Cold
B31	Recirculation (valve lineup for shutdown cooling)	Cold	Cold
C11	CRD hydraulic control units	Hot/Cold	Hot/Cold
C36	Dedicated Shutdown Panel Controls	NA	Hot/Cold
C36	Dedicated Shutdown Panel Instrumentation	Hot/Cold	Hot/Cold
C36	Dedicated Shutdown Support Systems & Components	NA	Hot/Cold
E11	RHR - suppression pool cooling	Hot	Hot
E11	RHR - low pressure RPV makeup	Hot	Hot

ID	System Name	Divisional Shutdown from the Control Room	Dedicated Shutdown from Outside the Control Room
E11	RHR - shutdown cooling	Cold	Cold
E11-51	RHR Service Water (RHRSW)	Hot/Cold	Hot/Cold
E11-56	RHRSW Cooling Towers	Hot/Cold	Hot/Cold
E21	Core Spray	Hot	NA

P45	Emergency Equipment Service Water (EESW)	Hot/Cold	Hot/Cold
P50-02	Control Air for Control Center HVAC air path (dampers)	Hot/Cold	NA
R30/R14/R16	ESF ac distribution for shutdown equipment	Hot/Cold	Hot/Cold
R30-01	Emergency Diesel Generators (EDGs) & auxiliaries	Hot/Cold	NA
R32	ESF dc system	Hot/Cold	Hot/Cold
T41	Control Center HVAC	Hot/Cold	NA
T41	ESF fan coil units	Hot/Cold	Hot/Cold
T47	Drywell Cooler Fans	NA	Hot/Cold
T49	Drywell Pneumatics	Hot/Cold	NA
X41-03	EDG & EDG Switchgear Room HVAC	Hot/Cold	NA

Systems, components and cables that are vulnerable to causing adverse consequences from hot shorts caused by cable damage have been associated with specific scenarios of concern such as loss of RPV inventory, loss of suppression pool inventory, SRV actuation, etc. Such cables and components that are not associated with the safe shutdown systems listed above are analyzed separately in the safe shutdown analysis as described in Section 9A.3.3.

9A.3.3 Method of Safe-Shutdown Analysis

To maintain a safe-shutdown capability, Fermi 2 was designed and built with the concept of keeping Division I cables and equipment separate from those of Division II. The dividing line is column line 12 for the reactor building. Division I cables and equipment are normally routed and located on the north side while those of Division II are normally on the south side of the line. The auxiliary building was designed differently. Therefore, analyses were performed and protection provided as required. In some instances where Division I and II cables cross over into the opposite division's side of the building and the cables/equipment are within 20 ft of their redundant cables, they are provided with a 1-hr-fire-rated protective envelope, to achieve or maintain 20 ft of separation with no intervening combustibles, or an analysis is performed to show that a loss of the interacting redundant divisional circuit(s) will not affect plant safe-shutdown capability.

An important requirement relevant to the fire hazards analysis is that regarding separation of cables and cable trays. Since most of the safety-related cables are also required for plant shutdown, separation of redundant safety-related cables in cable trays has been evaluated within each fire zone.

Each plant area is systematically evaluated for the ability to achieve and maintain safe shutdown, assuming that all of the equipment and cables within it are subject to fire damage. One of three shutdown strategies, Division 1 shutdown from the control room, Division 2 shutdown from the control room, or dedicated shutdown from outside the control room, is assigned to each. The dedicated shutdown strategy in accordance with the technical requirements of Appendix R Section III.G.3 and III.L is used only when divisional shutdown from the control room is not feasible. In general, these strategies were developed as part of the original plant licensing basis, and provide the framework for the NRC-approved deviations documented in docketed NRC correspondence, the plant SER, and its supplements. The inventory of safe shutdown equipment and cables, including associated circuit cables and equipment, is established, and conflicts between the shutdown strategy and the affected equipment are identified. The resolution of each of these shutdown conflicts is documented in a controlled engineering analysis. Examples of acceptable resolutions include protecting shutdown division cables with fire barriers, evaluating the electrical schematics to show that the electrical fault of concern is not applicable for the fire location being evaluated, use of NRC-approved deviations, or removal of certain fuses during power operation.

For spurious operation due to hot shorts, cables and equipment that can adversely affect safe shutdown systems (e.g., flow diversion paths from cooling systems) are evaluated, as are those that can adversely affect the safe shutdown functions or performance requirements independent of the safe shutdown systems (e.g., loss of RPV isolation or spurious SRV opening). In addition to evaluating single hot shorts between two conductors, the analysis includes any number of conductor-to-conductor shorts with a single cable and cable-to-cable shorts for any two cables within the area, in accordance with the NRC Regulatory Issue Summary RIS 2004-03 (Reference 1). For the RHR shutdown cooling letdown path high-low pressure interface, the division 2 outboard containment isolation valve is closed and de-energized.

9A.4 FIRE HAZARDS ANALYSIS

9A.4.1 Reactor Building

9A.4.1.1 General Description

The reactor building is a multilevel structure, separated from all other buildings by 3-hr-rated fire barriers. For purposes of this fire hazards analysis, the reactor building has been designated as fire area RB. It is bounded on the north, south, and west by outside walls and on the east by the auxiliary building.

The outage building is located four (4) inches south of the south wall of the reactor and auxiliary building. The outage building is of completely noncombustible construction; additionally no safe shutdown systems or equipment are located in this building. The outage building is structurally separated from plant structures, however, nonstructural flashing is attached to both the reactor and auxiliary building to seal and protect the four-inch gap between it and the outage building.

The north, south, and west exterior walls (below the metal siding on elevation 684′−6″) are constructed of at least 18 inches of reinforced concrete which will prevent an exposure fire in the yard area from propagating into the Reactor Building. Except as detailed below, these three walls are 3-hr-rated fire barriers.

The walls of the personnel airlock (on the south side of the reactor building) are constructed of 18 inches of reinforced concrete. The airlock itself, is separated from the yard area by two 1½-hr rated fire doors (R1-6 and R1-7) which together provide a level of protection at least equivalent to a 3-hr-rated fire door. In addition, as demonstrated above, the airlock walls are 3-hr-rated barriers.

The railroad bay pressure resistant door (also on the south side of the reactor building) is not a rated fire door; however, it is constructed of heavy steel channels covered with metal sheeting on both sides. This door is of much more substantial construction than the typical 3-hr-rated fire doors because of its pressure resistance rating. In addition, heat detectors and an automatic sprinkler system are provided in the railroad bay to further ensure that a fire originating outside the plant will not propagate into the reactor building via the railroad bay. These features and combustible loading in the vicinity of both the inside and outside door have been evaluated and found to provide adequate assurance that a fire will not propagate from outside the building or inside the railroad bay airlock into the southwest corner first floor of the reactor building.

The south and west walls of the reactor building contain six (6) removable plug sleeves which are 1-hr-rated penetration seals. These sleeves are either sealed with solid steel plates or contain steel plates with capped pipes and conduits passing through the penetrations from the interior of the reactor building. The sleeve openings on the exterior of the reactor building are closed with steel blind flanges. In addition, the space between these plates is totally devoid of combustible materials. Therefore, although they are not tested and approved seal configurations they are of substantial steel construction and will prevent flame propagation into the reactor building.

The fifth floor of the reactor building (elevation 684′-6″) is not being provided with fire rated exterior walls because its three exterior walls are constructed of insulated metal siding which is not a tested and rated construction. However, the siding will protect the fifth floor from the heat and smoke which would be generated from a fire in the yard. The base of the metal-sided walls is 100 feet above the yard grade level - well above any postulated exposure fire in the yard areas adjacent to the reactor building. Therefore, the as-built construction of these walls is sufficient to protect the fifth floor of the reactor building from a fire in the yard area.

The reactor building houses the reactor, reactor drywell and suppression pool, fuel handling equipment and storage pool, and other reactor auxiliary equipment.

With the exception of the drywell, ventilation of the reactor building is provided by the reactor/auxiliary building ventilation system. The drywell cooling system is provided for the drywell. These ventilation systems are discussed briefly in the individual zone descriptions. Additional details for these ventilation systems are presented in Subsections 9.4.2 and 9.4.5.

For purposes of this fire hazards analysis, the reactor building has been divided into 10 Fire Zones as follows:

a. Torus room, Fire Zone 01RB, Elevation 540 ft 0 in.

b. Northeast, northwest, southeast, and southwest basement corner rooms, Fire Zone 02RB, Elevations 540 ft 0 in. and 562 ft 0 in.

c. High pressure coolant injection (HPCI) pump and turbine and control rod drive (CRD) pump rooms, Fire Zone 03RB, Elevations 540 ft 0 in. and 562 ft 0 in.

d. Corridor area, Fire Zone 04RB, Elevations 562 ft 0 in and 564 ft 0 in.

e. First Floor, Fire Zone 05RB, Elevation 583 ft 6 in.

f. Second Floor, Fire Zone 06RB, Elevation 613 ft 6 in.

g. Third Floor, Fire Zone 07RB, Elevation 641 ft 6 in.

h. Fourth Floor, Fire Zone 08RB, Elevation 659 ft 6 in.

i. Fifth Floor, Fire Zone 09RB, Elevation 684 ft 6 in. (including the Auxiliary Building stairwell enclosure and duct space)

j. Drywell, Fire Zone 10RB, Elevation 562 ft 0 in. to 684 ft 6 in.

As discussed in Subsection 9A.3.3, the reactor building Division I cables and equipment are normally routed and located on the north side of the building (north of column line 12) and Division II cables and equipment are normally routed and located on the south side of the building (south of column line 12).

Division I is used to achieve plant safe shutdown when a fire occurs south of column line 12. Division II is used to achieve plant safe shutdown when a fire occurs north of column line 12.

9A.4.1.2 Torus Room, Fire Zone 01RB, El. 540 Ft 0 In.

9A.4.1.2.1 Description

The torus room, shown in Figures 9A-2 and 9A-3, is an octagonally shaped room which extends from the reactor building mat at Elevation 540 ft 0 in. up to Elevation 583 ft 6 in. It is bounded on the north by an outside wall; on the northeast by Fire Zone 02RB; on the east by a below-grade wall up to Elevation 551 ft 0 in. and Fire Zone 04RB thereafter; on the southeast by Fire Zone 02RB; on the south by an outside wall; on the southwest by Fire Zone 02RB; on the west by an outside wall; on the northwest by Fire Zone 02RB; and in the center by the drywell (Fire Zone 10RB), which it surrounds.

This zone houses the suppression pool (torus) and piping and cabling.

The walls (36 in.) and floor of this zone are constructed of reinforced concrete. The ceiling is constructed of 24-in.- reinforced concrete over steel beams. All penetrations through that portion of the ceiling separating this zone from the steam tunnel portion of the turbine building fire area are sealed with non-tested fire seals in the fire rated separation barrier. These seals have been evaluated and provide an adequate assurance that a fire in the Reactor Building Fire Zone 01RB will not propagate through these penetrations into the steam tunnel, or from the steam tunnel to the reactor building. Electrical penetrations through the remainder of the ceiling have fire stops. Division I cables, located in the south portion of the room, are enclosed with a 1-hr-rated fire barrier, as are Division II cables, in the north portion of the room. The doors to the corner rooms are 8-in.-thick steel watertight doors and will stop the propagation of any fire foreseen in the torus room.

Ventilation for this zone is provided by air from the four basement corner rooms (Fire Zone 02RB) abutting the northeast, southeast, southwest, and northwest walls of this zone. Air is drawn through 20 in. x 20 in. wall openings into the torus room and is directly exhausted through ductwork to the main exhaust system.

Divisions I and II redundant cables enter the torus room on the east side and traverse the room toward the west and above the center line of the torus. Division I cables are to the north and Division II cables are to the south.

Balance-of-plant (BOP) cable trays enter and traverse parallel to Divisions I and II cable trays around the torus. On the west side, the BOP trays continue around the torus, encircling the drywell above the torus and linking Divisions I and II with intervening combustibles.

Shutdown equipment located within this zone consists of the following:

a. Suppression pool (torus)

b. Divisions I and II cables

c. Divisions I and II, residual heat removal (RHR), core spray, HPCI, suppression pool instrumentation and reactor core isolation cooling (RCIC) valves, racks or equipment.

Fire detection in the torus area consists of eight ionization smoke detectors that are located adjacent to the exhaust duct grills. These detectors do not conform to the spacing requirements of NFPA 72E (beam pocket criteria). See Subsection 9A.4.1.2.4. The torus area has an automatic sprinkler system that protects the entire area. This system will protect any exposed structural steel from thermal degradation during any fire condition. The water flow alarm for the sprinkler system transmits signals to the main control room upon actuation. Fire extinguishers and manual water hose stations are located in adjacent Fire Zones.

9A.4.1.2.2 Analysis

Shutdown is achieved from the main control room. Division I is used to achieve plant safe shutdown when a fire occurs south of column line 12. Division II is used to achieve plant safe shutdown when a fire occurs north of column line 12.

There are no protective envelopes required for cables/equipment in this zone.

Redundant valves that are not backed up by functionally redundant equipment in another Fire Zone are spatially separated by more than 20 ft. The other valves, required for shutdown and located within this zone, are backed up by functionally redundant equipment in other Fire Zones.

Cable trays, which present intervening combustibles between redundant cables, have a fire break installed in them or are solid-metal trays with covers to prevent the propagation of fire within them.

Three 12-in. BOP cable trays interconnecting Divisions I and II on the west side are considered intervening combustibles. The trays are OP-016, OC-790 and OK-097. Two, OP-016 and OC-790, have fire breaks installed at about column line 12±3 ft. Cable tray OK-097 is an instrumentation cable tray and is an enclosed solid-metal tray with cover.

The automatic sprinkler system will protect the exposed steel from being adversely affected by a fire in this zone.

Inadvertent operation of the automatic fire suppression equipment will have no adverse effect on shutdown capability. Combustibles within this zone consist primarily of electrical insulation. Total fire loading for this zone is low.

9A.4.1.2.3 Conclusion

The objective for this zone is to prevent a fire from damaging redundant shutdown valves and cable and from spreading to other zones. This objective is achieved through barriers, the provision of fire detection equipment, an automatic sprinkler system, fire breaks in cable trays, and separation of redundant equipment. In addition, fire extinguishers and manual water hose stations are provided in adjacent zones.

9A.4.1.2.4 Deviations

Deviations have been approved for the following:

a. Intervening combustibles, cable trays OP-016, OC-790, and OK-097 based on area-wide sprinklers and fire stops in cable trays OP-016 and OC-790 at about column line 12 and solid-metal tray and cover for OK-097 (Reference 1, SSER No. 5 VI [1])

b. Early-warning fire detectors are not installed in accordance with NFPA 72E based on area with automatic sprinklers, alarms to the main control room, and response by the fire brigade (Reference 1, Reference 2, SSER No. 5, II.D).

9A.4.1.3 Basement Corner Rooms, Fire Zone 02RB, El. 540 Ft 0 In. and 562 Ft 0 In.

9A.4.1.3.1 Description

The basement corner rooms, shown in Figures 9A-2 and 9A-3, consist of four unconnected, triangular-shaped rooms, one of which is located in each corner of the reactor building. Each room is composed of two floors, one at Elevation 540 ft 0 in., the other at Elevation 562 ft 0 in. An open stairwell in each room connects each floor.

The zone houses the RHR pumps (Division I pumps in the northwest corner room, Division II pumps in the southwest corner room), the RCIC pump and turbine, and Division I core spray pumps (northeast corner room), and the Division II core spray pumps (southeast corner room).

Walls surrounding each room of the zone are constructed of 36-in. reinforced concrete. The doors to the torus room are 8-in.-thick steel watertight doors that will stop the propagation of fire.

The floor of the lower elevation is a reinforced-concrete mat. The floor at Elevation 562 ft 0 in. is constructed of reinforced concrete and contains unsealed penetrations and unprotected openings for stairwells and hatches. The ceilings at both elevations are 24-in. reinforced concrete and contain unsealed penetrations and other unprotected openings. Electrical penetrations through the floor and ceiling are provided with fire stops.

Ventilation air enters each room through stairwells from Elevation 583 ft 6 in. (Fire Zone 05RB). Ventilation air leaves each room through wall openings in the walls abutting the torus room (Fire Zone 01RB) on Elevation 540 ft 0 in. Each corner room has a local air-handling unit (emergency equipment room cooler) for cooling the room ambient air.

Shutdown equipment located in this zone consists of the following:

a. RHR pumps and associated valves (Divisions I and II)

b. RHR instrument racks (Divisions I and II)

c. Emergency equipment room coolers (Divisions I and II)

d. RCIC pump and turbine and associated valves (Division I)

e. Instrument racks (Division I and II)

f. Core spray pumps and associated valves (Divisions I and II)

g. Core spray instrument racks (Divisions I and II).

h. 120 V ac distribution panel (Divisions I and II)

Fire detection equipment in this zone consists of an ionization detection system in each room at each elevation. Fire suppression equipment in this zone consists of an automatic sprinkler system in the northeast room on Elevation 540 ft 0 in. and manual hose and portable fire extinguishers as shown in Figures 9A-2 and 9A-3.

9A.4.1.3.2 Analysis

Shutdown is achieved from the main control room. There is no functionally redundant equipment located in any one room within this zone. Divisions I and II RHR pumps, instrument racks, and associated valves and room coolers are located in separate rooms. Division I RHR equipment is located on Elevation 540 ft 0 in. of the room located in the northwest corner of the building. Division II pumps are located on Elevation 540 ft 0 in. of the room located in the southwest corner of the building. Division II core spray equipment is located on Elevation 540 ft 0 in. of the room located in the southeast corner of the building. Division I core spray equipment is located on Elevation 540 ft 0 in. of the room located in the northeast corner of the building. Functional redundancy for the RCIC pump located in this zone is provided by the HPCI pump located in Zone 3 of this fire area.

Division I will be used to achieve safe shutdown for fires in the southeast and southwest corner rooms and Division II will be used to achieve safe shutdown for fires in the northeast and northwest corner rooms of the zone.

Inadvertent operation of the automatic sprinkler system in the room containing the RCIC pump and turbine will have no adverse effect on shutdown capability.

The oil contained in the RCIC turbine represents a specific fire hazard in this zone due to high operating temperatures of the turbine and related piping.

Combustibles within this zone consist primarily of the following:

a. Electrical insulation

b. Lubricating oil

Total zone fire loading is low, and the fire loading in any one room is low.

9A.4.1.3.3 Conclusion

The objective for this zone is to prevent the spread of a fire in this zone to another zone containing redundant shutdown equipment and/or from damaging redundant shutdown equipment within this zone. Redundant shutdown equipment located within this zone is located in separate rooms, each located in a corner of the building. The ventilation openings to the torus room do not represent a significant potential path for fire spread due to the low fire loading within the rooms. The objective is achieved through barriers, the adequate spatial separation of redundant equipment, and the provision of early-warning detection equipment in each room, and an automatic sprinkler system on the specific fire hazard (RCIC turbine). In addition, manual water hose stations and portable fire extinguishers are provided.

9A.4.1.3.4 Deviations

Deviations have been approved for the following:

a. Installation of partial suppression in the northeast corner room, Elevations 540 ft 0 in. and 562 ft 0 in., based on cables required to achieve a safe shutdown being provided with a 1-hr fire barrier in this zone, fire detection, and low combustible loading (Reference 1, SSER No. 5, VI [13])

b. Lack of suppression in the southeast corner room, Elevations 540 ft 0 in. and 562 ft 0 in., based on low combustible loading and 1-hr fire barriers for cables required to achieve safe shutdown (Reference 1, SSER No. 5, VI [14]).

9A.4.1.4 High Pressure Coolant Injection Pump and Turbine and Control Rod Drive Pump Room, Fire Zone 03RB, El. 540 Ft 0 In. and 562 Ft 0 In.

9A.4.1.4.1 Description

This zone, shown in Figures 9A-2 and 9A-3, consists of two rooms, the HPCI pump and turbine room at Elevation 540 ft 0 in. and the CRD pump room at Elevation 562 ft 0 in. This zone is bounded on the north by a below-grade wall up to Elevation 551 ft and Fire Zone 04RB thereafter; on the east and south by a below-grade wall up to Elevation 551 ft and the auxiliary building above Elevation 551 ft; and on the west by the room containing the Division II core spray pumps (Fire Zone 02RB).

The zone houses the HPCI turbine, pump, and related valves and controls, and an emergency equipment room cooler on Elevation 540 ft 0 in., and the CRD pumps on Elevation 562 ft 0 in.

The walls and ceiling separating this zone from the auxiliary building are constructed of reinforced concrete having a fire-resistance rating of 3 hr. The door to the Division II CS pump room is watertight. The door separating this zone from the auxiliary building is a Class A fire door. Penetrations through the rated walls and the fire-rated portion of the ceiling of the 562 ft 0 in. elevation are sealed to provide a 3-hr fire-resistance rating. The floor at Elevation 540 ft 0 in. is a reinforced-concrete mat. The floor at Elevation 562 ft 0 in. is constructed of reinforced concrete with an unprotected equipment hatch. Electrical cable tray penetrations through the floor between the two elevations are provided with fire stops. Floor drains are provided on both floors.

Ventilation for this zone is provided by the reactor/auxiliary building ventilation system. Air is ducted directly to the CRD pump room and exhausted through ducts from the HPCI pump and turbine room directly to the auxiliary building main exhaust system. The HPCI pump and turbine room has an emergency equipment room cooler for cooling the room ambient air.

Shutdown equipment located in this zone consists of the following:

a. HPCI turbine, pump, and associated valves and instrument rack (Division II)

b. Emergency equipment room cooler (Division II).

No protective envelopes are required for safe-shutdown components in this zone. Fire detection equipment in this zone consists of an ionization detection system at each elevation.

Fire suppression equipment for this zone consists of a partial area automatic sprinkler system for the HPCI turbine and pump room. The hatch and stairwell opening between the two elevations of fire zone 03RB are not protected by automatic sprinklers. Manual hose stations and portable fire extinguishers are provided as shown in Figures 9A-2 and 9A-3.

9A.4.1.4.2 Analysis

Shutdown is achieved from the main control room. All of the equipment and cables in fire zone 03RB are assumed damaged due to a fire. Division I equipment outside this fire zone will be used to achieve safe shutdown for fires in this zone. The RCIC turbine and pump, and the core spray and RHR pumps located in other zones, are functionally redundant to the HPCI turbine, pump, and associated equipment in this zone. A partial area suppression system is provided in the area between the divisions in 04RB.

The lubricating oil in the HPCI turbine represents a specific fire hazard in this zone. This equipment is surrounded by curbing of sufficient height to contain any oil spills. A partial area sprinkler system has been provided for the HPCI turbine and pump room. The sprinkler system is not required for compliance with Appendix R when determining if safe shutdown can be achieved in the event of a fire in 03RB.

Inadvertent operation of the automatic sprinkler system will have no adverse effect on shutdown capability.

Combustibles within this zone consist primarily of the following:

a. Electrical insulation

b. Lubricating oil

Total zone fire loading is low.

9A.4.1.4.3 Conclusion

The objective for this zone is to prevent a fire in this zone from damaging functionally redundant equipment such as RCIC equipment and/or Division I cable located in an adjacent zone. This objective is achieved through the adequate spatial separation of redundant equipment and provision of early-warning detection equipment for the entire zone, a partial area suppression system provided in the area between the divisions in 04RB, and an approved deviation for the intervening combustibles crossing between the divisions in 04RB. In addition, manual hose stations and portable fire extinguishers are provided.

9A.4.1.5 Corridor Area, Fire Zone 04RB, El. 562 Ft 0 In. and 564 Ft 0 In.

9A.4.1.5.1 Description

This zone, shown in Figure 9A-3, consists of a north-south corridor at the Elevation 562 ft 0 in. and an east-west corridor leading to the turbine building at the Elevation 564 ft 0 in. The zone is bounded on the north by the auxiliary building; on the east by the auxiliary and turbine buildings; on the south by the auxiliary building and CRD pump room (Fire Zone 03RB); and on the west by the torus room (Fire Zone 01RB).

The zone houses electrical cables. Divisions I and II cables are all located in the north-south corridor.

The walls, floors, and ceiling separating this zone from the auxiliary and turbine buildings are constructed of reinforced concrete having a fire-resistance rating of 3 hr. The door to the turbine building is a Class A fire door. Penetrations through the rated walls, floors, and ceiling are sealed to provide a 3-hr fire-resistance rating. At the north end of the north-south corridor is a metal pressure-relieving hatch in the ceiling. The hatch is designed for steam venting of a pipe break outside the containment. Because of the light fire loading on each side of the hatch, the partial automatic sprinkler system in this zone, and the availability of manual suppression equipment, the metal hatch provides the necessary fire resistance for the zone.

Ventilation air for this zone is from the reactor/auxiliary building ventilation system. Air is duct exhausted from the zone.

Shutdown equipment located in this zone consists of Divisions I and II cables and a RCIC valve.

No protective envelopes are required for safe-shutdown components in this zone.

Fire detection equipment consists of a photoelectric and ionization detection system. Fire suppression equipment consists of an automatic sprinkler system in the 562-ft corridor, portable fire extinguishers, and manual hose.

9A.4.1.5.2 Analysis

By plant design, the reactor building Division I cables and equipment are normally routed and located on the north side of the building (north of column line 12) and Division II cables and equipment are normally routed and located on the south side of the building (south of column line 12). The RCIC valve is located on the south side of this zone.

Shutdown is achieved from the main control room. Division I will be used to achieve plant safe shutdown for fires on the south side and Division II will be used to achieve plant safe shutdown for fires on the north side of the zone.

Automatic sprinklers are installed in the north-south corridor, (562 ft) in the area of the cable trays (combustible loading for the room is concentrated in this area). There is no automatic sprinkler system in the east-west corridor (combustible loading is insignificant in this area). There are no shutdown cables in the area where automatic sprinkler protection has not been provided.

Cable trays, which present intervening combustibles between redundant cables, have fire breaks installed in them or are solid-metal trays with covers to prevent the propagation of fire. The intervening combustibles in this zone consist of two 12-in. non-Appendix R (non-R) trays (OP-020 and OC-785). Additionally, a 12-in. non-R instrument tray (OK-034) is located approximately 10 ft south of the two 12-in. non-R trays. Since the instrument tray is an enclosed solid-metal tray with cover, it is not considered an intervening combustible. An approximate 10-ft clear space exists between Division II R tray 2K-007 and of the 2 non-R trays. Also, tray 2K-007 is an enclosed solid-metal tray with cover.

All trays run horizontally, which causes a slow-burning fire with smaller heat releases.

These non-R trays represent the only in-situ intervening combustible path between Divisions I and II cables. For a single fire to affect both Divisions I and II cables, a cable tray fire must burn more than 20 ft and must traverse a clear space of approximately 10 ft.

Trays (2) OP-020 and OC-785 have a fire break installed at approximately column line 12 ±5 ft north.

Additional sprinkler heads have been installed below the pipe obstructions to improve sprinkler coverage of the area.

Combustibles located in this zone consist primarily of electrical insulation. The total zone fire loading is low.

9A.4.1.5.3 Conclusion

The objective for this zone is to prevent a fire from affecting both Divisions I and II cables located within this Fire Zone and to prevent a fire from crossing the boundaries of the zone. This is achieved through the provision of an automatic sprinkler system, barriers, fire detection system, portable fire extinguishers, and manual hose.

9A.4.1.5.4 Deviations

Deviations have been approved for the following:

a. Intervening combustibles between redundant trains based on fire stops in trays OP-020 and OC-785 (Reference 1, SSER No. 5, VI[2])

b. Partial automatic sprinklers based on the provisions of additional automatic sprinkler coverage (Reference 1, SSER No. 5, VI[2]).

9A.4.1.6 First Floor, Fire Zone 05RB, El. 583 Ft 6 In.

9A.4.1.6.1 Description

This zone, shown in Figure 9A-4, consists of the large open floor area surrounding the drywell (Fire Zone 10RB), the RHR heat exchanger rooms, railroad bay, drywell access air-lock area, and a partial height equipment room adjacent to and west of the drywell. It is bounded on the north, south, and west by outside walls; and on the east by the auxiliary building and the steam tunnel.

This zone houses the CRD hydraulic controls, RHR heat exchangers, railroad bay, neutron monitoring system (NMS) cabinets, and other auxiliary equipment. The RHR heat exchanger rooms extend up to Elevation 641 ft 6 in.

The walls and ceiling separating this zone from the auxiliary building and the steam tunnel are constructed of reinforced concrete having a 3-hr fire-resistance rating. The door opening between this zone and the steam tunnel is protected by a heavy pressure-resistant metal door. The pressure-resistant door, in combination with the labyrinth access passage, will prevent the spread of a fire from the steam tunnel area to this zone. Penetrations through rated walls and ceiling are sealed to provide 3-hr fire-resistance ratings except for the pressure equalizing line between the steam tunnel and this Fire Zone. The ability of the fire barrier to perform its function has been evaluated and determined to provide an adequate assurance that a fire in this Fire Zone will not propagate to the steam tunnel. The partial height equipment room is accessible from the south portion of the zone, and is separated from the remainder of the zone by a shield wall and ceiling. The portion of the room boundary north of column 12 has been evaluated to provide adequate separation from the north portion of the Fire Zone. The floor and unrated portion of ceiling of this zone are constructed of reinforced concrete and steel beams, and contain open stairwells, unprotected hatches, pipe chases, and unsealed penetrations. Cable tray penetrations through the floor and unrated portion of ceiling, and unrated walls are provided with fire stops.

Ventilation air for this zone is ducted directly from the reactor/auxiliary building ventilation system and is relieved to the neutron monitoring equipment room and to an area outside the personnel air lock. Air also enters the zone through the stairwells from the floor above and from the RHR heat exchanger rooms through pressure relief dampers.

Shutdown equipment located in this zone consists of the following:

a. RHR heat exchangers (Divisions I and II) and associated valves

b. CRD hydraulic control units (HCUs)

c. Instrument racks and motor control centers (Division I and II)

d. The following valves:

   1. RHR to recirculation inboard isolation valve, E1150F015A (Division I) and B (Division II)

   2. Reactor recirculation extraction to outboard isolation valve, E1150F008

   3. EECW system isolation valves, P4400F601A, P4400F603A (Division I) and P4400F601B, P4400F603B (Division II).

e. 120 V ac distribution panel

f. Standby feedwater and CTG 11-1 supervisory cables

Fire detection equipment in this zone consists of an ionization detection system. Fire suppression equipment consists of an automatic sprinkler system in the railroad bay and manual water hose stations and portable fire extinguishers as shown in Figure 9A-4.

NFPA 13 noncompliances with this sprinkler system include sprinkler protection areas exceeding the limit for ordinary hazard occupancy and sidewall sprinklers around the open equipment hoistway not installed in a staggered arrangement (in addition to those discussed and evaluated in 9.5.1.2.3.3). These noncompliances would not adversely affect the required function of this system because the large safety margin in the water supply hydraulic design calculations would adequately compensate for these and provide the required sprinkler performance. In addition, the exceptionally deep beams would result in partially obstructed discharge patterns for some sprinklers, but the sprinkler system would still prevent any fire or fire effects from traveling any significant distance north or south from the point of origin.

9A.4.1.6.2 Analysis

By plant design, the reactor building Division I cables and equipment are normally routed and located on the north side of the building (north of column line 12) and Division II cables and equipment are normally routed and located on the south side of the building (south of column line 12).

One-hour rated protective envelopes are provided for Division I cables when routed south of Column line 12.

Shutdown is achieved from the main control room. Division I will be used to achieve plant safe shutdown for fires on the south side and Division II will be used to achieve plant safe shutdown for fires on the north side of the zone.

Because of a potential high/low-pressure interface (associated circuits), E1150F008 shutdown cooling valve is required to be electrically disabled. The two sets of CRD HCUs, both of which are required for shutdown, are located on opposite sides of the drywell structure. The RHR heat exchangers and related valves are located in separate rooms located on opposite sides of the building. The redundant EECW isolation valves and Division I and II cables located within the zone are separated either by the drywell or steam tunnel structure or are separated spatially by a minimum of 40 ft.

The steel beams installed above the railroad bay area (also known as the truck bay) are evaluated based on the worst case fire in the railroad bay area. This analysis demonstrates that a fire in the truck bay area will not damage the steel beams supporting the Division 1 EECW Heat Exchanger. As a result, fire coating the steel beams in the truck bay area is not required to ensure safe shutdown of the plant during all Appendix R scenarios.

During refueling the railroad bay could represent a possible fire hazard; however, this area is protected by an automatic sprinkler system and a continuous firewatch when a refueling vehicle containing a combustible fuel is parked in the bay.

The automatic sprinkler system is installed in the railroad bay (column A-B, 9-13).

A heat detection system is installed in the railroad bay (column lines A-B, 9-13).

There is a greater than 20 ft separation with no intervening combustibles between Divisions I and II shutdown circuits in the railroad bay within the zone between column lines A-B, 11-13. The drywell and steam tunnel walls provide fire barriers at least equivalent to 3-hr-rated barriers.

Combustibles located within this zone consist primarily of electrical insulation.

The total zone fire loading is low.

9A.4.1.6.3 Conclusion

The objective for this zone is to prevent a fire from affecting both sets of redundant equipment located within this zone, and from spreading to other zones. This objective is achieved through barriers, spatial separation, the location of redundant equipment in separate rooms, the provision of early-warning detection equipment throughout the zone and a partial automatic sprinkler system over the railroad bay, a continuous firewatch when a refueling vehicle containing a combustible fuel is parked in the bay, and low fire loading.

Due to the low fire loading in the areas of both CRD HCUs and the presence of the early-warning detection equipment, it is considered unlikely that the function of the CRD HCUs (i.e., to scram the reactor) would be affected by a fire.

In addition, manual hose and portable fire extinguishers are provided.

9A.4.1.6.4 Deviations

Deviations have been approved for the following:

a. Partial suppression system based on 20-ft combustible free zone on west side of the reactor building at column line 12, high ceilings, and low combustibles (Reference 1, SSER No. 5, VI[3])

b. Lack of 3-hr fire-rated barriers separating redundant equipment based on 20-ft combustible free zone on the west side of the reactor building at column line 12, high ceilings, and low combustibles (Reference 1, SSER No. 5, VI[3]).

c. Non rated doors R1-8 and R1-11 on the first floor reactor building are special-purpose doors constructed of heavy weight, reinforced steel plates and are either blast-resistant (R1-11) or water-tight (R1-8) in addition to providing fire protection. (Reference 1, Reference 3, SSER No. 6, III.B)

9A.4.1.7 Second Floor, Fire Zone 06RB, El. 613 Ft 6 In.

9A.4.1.7.1 Description

This zone, shown in Figure 9A-6, consists of the floor area outside the drywell (Fire Zone 10RB), excluding the RHR heat exchanger rooms, at Elevation 613 ft 6 in.

It is bounded on the north, south, and west by outside walls and on the east by the auxiliary building and the steam tunnel. The west wall of the RHR Heat Exchanger Room on the Reactor Building 2nd Floor provides a three-hour fire barrier between the Division II RHR heat exchanger and the Division I EECW heat exchanger P4400B001A.

This zone houses the reactor water cleanup (RWCU) heat exchangers, phase separators, and pumps; the EECW pumps, heat exchangers, area coolers, makeup tanks and makeup pumps; instrument racks; motor control centers (MCCs); and the H_2-O_2 Division I analyzer and associated test gas cylinders.

The walls separating this zone from the auxiliary building and the steam tunnel are constructed of reinforced concrete having a fire-resistance rating of 3 hr. The door opening leading to the auxiliary building is protected by a Class A fire door. Penetrations through the rated wall are sealed to provide a 3-hr fire-resistance rating. The floor and ceiling are constructed of reinforced concrete and contain open stairwells, unprotected hatches, and unsealed penetrations. Cable tray penetrations through the floor and ceiling are provided with fire stops. Division I shutdown cables within 20 ft of Division II shutdown cables near F-11 are enclosed by a 1-hr-rated fire barrier.

Ventilation air for this zone is provided directly from the reactor/auxiliary building ventilation system supply to the general floor area. Air flows to the RWCU pump rooms, RHR heat exchanger rooms, water sample station, water sludge discharge pump room, holding area, and RWCU heat exchanger room from the general floor area. Air to or from these areas is controlled by backdraft dampers in the walls. Air in these areas is exhausted to the reactor/auxiliary building ventilation system exhaust. The EECW pump areas have local air-handling units (pump room cooling units) to cool the area ambient air.

Shutdown equipment located in this zone consists of the following:

a. Divisions I and II cables

b. Divisions I and II reactor vessel level and pressure instrument racks

c. Divisions I and II EECW pumps, heat exchangers, pump area cooling units, makeup tanks and makeup pumps, nitrogen tanks (Division I only), EESW to EECW makeup lines, and associated valves and MCCs

d. Divisions I and II drywell monitoring instrument racks

e. Divisions I and II MCCs

f. Divisions I and II core spray and RHR valves

g. Standby feedwater and CTG 11-1 supervisory control cables

h. 120 V ac distribution panel (Division I)

i. Emergency Equipment Room Coolers (Division I and II)

j. Swing bus MCC

k. Drywell pneumatic racks (Division II)

One-hour protective envelopes are required for certain cable trays in this zone.

Fire detection equipment in this zone consists of an ionization detection system. Fire suppression equipment consists of automatic sprinklers over cable trays along the east wall between columns 10 and 12 and on the west side between column lines A and C, at column line 12 and in the area near P4400B001A between columns lines A and B and 9 and 10. In addition, manual water hose stations and portable fire extinguishers are provided as shown in Figure 9A-6.

NFPA 13 noncompliances with the west side sprinklers include some sprinkler locations exceeding the maximum allowable distance below the ceiling, lack of baffles between sprinklers that are less than 6 ft apart, and some sprinklers partially obstructed by supports. These noncompliances do not prevent these west side sprinklers from providing the required fire protection for this area.

9A.4.1.7.2 <u>Analysis</u>

By plant design, the reactor building Division I cables and equipment are normally routed and located on the north side of the building (north of column line 12) and Division II cables and equipment are normally routed and located on the south side of the building (south of column line 12).

Shutdown is achieved from the main control room. Division I will be used to achieve plant safe shutdown for fires on the south side and Division II will be used to achieve plant safe shutdown for fires on the north side of the zone.

No protective envelopes are required for cable routed on the north side of the zone. One-hour protective envelopes are provided for cable trays 1C-033, 1P-038, 1P-040, and 1P-051 when routed on the south side of the zone.

Divisions I and II EECW equipment located within this zone is separated spatially by a minimum distance of approximately 50 ft. In addition, the drywell structure functions as a radiant-energy barrier between the redundant pumps.

The Division I EECW Heat Exchanger P4400B001A is located south of Column 12, above the railroad bay hatch at Column 9 between Columns A and B. The backup Division 1 EECW Heat Exchanger P4400B001C is located slightly north of column line 12 between columns A and B. Fire suppression is provided in these areas. In addition, all Division II conduit located within 20 feet of the Division I heat exchanger P4400B001A is protected with a one-hour protective envelope. The Division II RHR heat exchanger is separated from the Division I EECW heat exchanger P4400B001A by a three-hour fire barrier (RHR Heat Exchanger Room West wall between Columns 9 and 10 at Column B).

The abandoned tubing left within the three hour fire resistant penetration to the auxiliary building is evaluated to show that the seal is adequate for fires in the zone.

Reactor vessel level and pressure instrument racks are separated by the drywell structure.

Drywell monitoring instrument racks are located on opposite sides of the heat exchanger vault.

The RWCU equipment located in this zone contains significant amounts of concentrated radioactivity. This equipment is located in separate shielded cubicles with negligible fire loadings.

There are three non-safe-shutdown trays (OP-037, OC-060, and OK-066), which are routed north-south along column line B. Three cable trays (OP-047, OC-793, and OK-069) traverse the Fire Zone along the east wall near column line F. These trays represent the only intervening combustibles that could propogate a fire between Divisions I and II shutdown circuits on the east and west side respectively.

For a single fire to affect both divisions, a cable tray fire would have to burn a minimum of 35 ft.

On the east side of the reactor building, fire breaks have been installed in cable trays OP-047 and OC-793 approximately 3 ft south of column line 12.

On the west side of the reactor building, fire breaks have been installed in cable trays OP-037 and OC-060 approximately 12 ft south of column line 12.

The two instrument trays, OK-069 and OK-066, are solid-metal trays with covers.

Combustibles located within this zone consist primarily of electrical insulation.

The total zone fire loading is low.

9A.4.1.7.3 Conclusion

The objective for this zone is to prevent a fire from affecting redundant equipment, cable, and instrumentation and from spreading to other zones. This objective is achieved through barriers, early-warning detection equipment, spatial separation between redundant equipment, and low fire loading. Automatic sprinklers are provided in the area with concentrated fire loading of Divisions I and II cable trays and in the areas with the Division I EECW Heat Exchangers. In addition, manual water hose stations and portable fire extinguishers are provided.

9A.4.1.7.4 Deviations

Deviations have been approved for the following:

a. Partial suppression at column line 12 based on intervening open cable trays having fire stops and separation of Divisions I and II cables (north and south) within the zone (Reference 1, SSER No. 5, VI[4])

b. Intervening combustibles in cable trays OP-047, OC-793, OP-037, and OC-060 which are provided with fire stops (Reference 1, SSER No. 5, VI[4]).

9A.4.1.8 Third Floor, Fire Zone 07RB, El. 641 Ft 6 In.

9A.4.1.8.1 Description

This zone, shown in Figure 9A-8, consists of the floor area at Elevation 641 ft 6 in., with the exception of the drywell and fuel storage pool.

It is bounded on the north, south, and west by outside walls and on the east by the auxiliary building.

This zone houses the hydrogen recombiners, contaminated equipment storage area, CRD decontamination and repair area, the fuel storage pool heat exchangers and pumps, and the H_2-O_2 Division II analyzer and test gas cylinders.

Safe shutdown equipment located in this zone consists of the following:

a. Division I and II cables

b. Standby Feedwater cables

The wall separating this zone from the auxiliary building is constructed of reinforced concrete having a fire-resistance rating of 3 hr. Penetrations through rated walls are sealed to provide a 3-hr fire-resistance rating. The floor and ceiling are constructed of 12-in. reinforced concrete and contain open stairwells, unprotected hatches, and unsealed penetrations. Floor penetrations are sealed to provide a 3-hr fire barrier for that portion of the floor in the southeast corner which separates this zone from Zone 8 of the auxiliary building. Cable tray penetrations through the floor and ceiling are provided with fire stops.

Ventilation air for this zone is provided directly from the reactor/auxiliary building ventilation system supply to the general floor area and the area north of the fuel storage pool. Air flows to the contaminated equipment storage area, CRD decontamination and repair area, and the fuel storage pool heat exchanger and pump room from the general floor area. Air enters these areas through backdraft dampers located in the room walls and is exhausted through ducts to the reactor/auxiliary building ventilation system exhaust. Air exhausted from the contaminated equipment storage and CRD decontamination and repair areas passes through high-efficiency particulate air (HEPA) filters.

Fire detection equipment located in this zone consists of an ionization detection system. Fire suppression equipment consists of manual water hose stations and portable fire extinguishers as shown in Figure 9A-8.

9A.4.1.8.2 Analysis

By plant design, the reactor building Division I cables and equipment are normally routed and located on the north side of the building (north of column line 12) and Division II cables and equipment are normally routed and located on the south side of the building (south of column line 12).

Shutdown is achieved from the main control room. Division I will be used to achieve plant safe shutdown for fires on the south side and Division II will be used to achieve plant safe shutdown for fires on the north side of the zone.

There are no Division I shutdown cables on the west side of the reactor building. Any large openings that communicate with second floor, Division I shutdown cables, are located approximately 50 ft away. Any fire in this area will affect only Division II equipment. Therefore, protection is not necessary.

No protective envelope is required for safe-shutdown components in this zone.

The fuel storage pool heat exchangers and pumps contain significant amounts of concentrated radioactivity. This equipment is located in a separate shielded cubicle with a negligible fire loading.

Vertical cable tray risers are solid-metal trays with covers. These are located at approximately column lines F-13 (trays OP-123, OC-071, and OP-049).

Combustibles located within this zone consist primarily of electrical insulation. The total zone fire loading is low.

9A.4.1.8.3 Conclusion

The objective for this zone is to prevent the spread of a fire in this zone to another Fire Zone. This objective is achieved through barriers, low zone fire loading, and provision of early-warning detection equipment, manual water hose stations, and portable fire extinguishers.

9A.4.1.8.4 Deviations

Lack of a 3-hr barrier separating the next floor based on metal covers on vertical cable trays near column line F-13, no intervening combustibles, and the low combustible loading of the zone (Reference 1, SSER No. 5, VI[5]) .

9A.4.1.9 Fourth Floor, Fire Zone 08RB, El. 659 Ft 6 In.

9A.4.1.9.1 Description

This zone, shown in Figure 9A-9, consists of two floor areas at Elevation 659 ft 6 in. These floor areas are separated by the drywell, the dryer/separator storage pool and the fuel storage pool.

The western portion of the zone is bounded on the north, south, and west by outside walls and on the east by the drywell, dryer/ separator storage pool, and the fuel storage pool. The eastern portion of the zone is bounded on the north and south by outside walls; on the east by the auxiliary building; and on the west by the drywell, dryer/separator storage pool, and the fuel storage pool.

The western portion of the zone houses motor-generator (M-G) sets and oil cooler, dress-out facilities, and RWCU equipment. The eastern portion of the zone houses the standby liquid control system (SLCS).

The walls separating this zone from the auxiliary building are constructed of reinforced concrete having a fire-resistance rating of 3 hr. Penetrations through rated walls are sealed to provide a 3-hr fire-resistance rating. The floor is constructed of reinforced concrete and contains open stairwells, unprotected hatches, and unsealed penetrations. Floor drains are provided and trapped at the collection sumps. The ceiling is also constructed of reinforced concrete and contains unprotected hatches and unsealed penetrations. Cable tray penetrations through the floor and ceiling are provided with fire stops.

Ventilation air is supplied directly to the area around the M-G sets and the storage areas north and east of the fuel storage pool. Air then flows from these areas to the clean area, the RWCU pump room, and the RWCU south and north demineralizer rooms. Air also flows from the clean area to the personnel change area. Supply air to the RWCU holding pump room and demineralizers is controlled by backdraft dampers. With the exception of air exhausted from the area around the M-G sets, exhaust air is ducted to the reactor/ auxiliary building ventilation system exhaust. The M-G set area is locally cooled by air ducted directly to the M-G sets from three recirculating fancoil units.

Safe shutdown equipment located in this zone consists of the following:

a. Division II cables

b. Standby Feedwater cables

c. Division II 480 V ac distribution panel

Fire detection equipment located in this zone consists of an ionization detection system and heat detectors. Fire suppression equipment consists of an automatic sprinkler system in the area of the M-G sets and oil coolers, manual hose, and portable fire extinguishers as shown in Figure 9A-9.

9A.4.1.9.2 Analysis

Reactor water cleanup equipment located in this zone contains significant amounts of concentrated radioactivity. This equipment is located in separate shielded cubicles with negligible fire loadings.

Shutdown is achieved from the main control room. Division I will be used to achieve safe shutdown for fires in the south side and Division II will be used to achieve safe shutdown for fires in the north side of the zone.

Except for Standby Feedwater flow indication cables located in the south side of the zone, there are no Division I or II Appendix R cables or equipment in the zone.

Lubricating oil in the couplings and cooling units of the two M-G sets located in this zone represents a specific fire hazard. This equipment is surrounded by curbing of sufficient height to contain any oil spills.

Combustibles located within this zone consist of the following:

a. Lubricating oil

b. Electrical insulation

c. Ordinary combustibles

The total fire loading for this zone is low.

9A.4.1.9.3 Conclusion

The objective for this zone is to prevent a fire from spreading to another zone. This objective is achieved through barriers, low fire loading in the area of the SLCS, the provision of early-warning detection systems for the entire zone, curbing and an automatic sprinkler system for the M-G sets and oil coolers, and manual hose and portable fire extinguishers.

9A.4.1.10 Fifth Floor, Fire Zone 09RB, El. 684 Ft 6 In.

9A.4.1.10.1 Description

This zone, shown in Figure 9A-10, consists of the floor area at Elevation 684 ft 6 in., including the fuel storage pool, dryer/ separator pool, and decontamination area, along with the Auxiliary Building stairwell enclosure.

The zone is bounded on the north, south, and west by outside walls and on the east by the auxiliary building.

This zone houses the fuel storage pool and associated equipment, dryer/separator pool, and the decontamination area.

The east wall abutting the auxiliary building is constructed of reinforced concrete up to Elevation 701 ft 0 in. and provides a 3-hr-rated fire barrier. Penetrations in rated walls are sealed to provide a 3-hr fire rating. The east wall above Elevation 701 ft 0 in. and the north, south, and west walls are constructed of steel frame and siding. The stairwell leading to the auxiliary building is enclosed by a 3-hr-rated fire barrier to provide separation between the auxiliary building and the reactor building. The floor is constructed of reinforced concrete and contains unprotected hatches and unsealed penetrations. Cable tray penetrations through the floor are fire stopped. The roof is constructed of steel frame and deck with insulation and builtup roofing that conforms to Factory Mutual Class I requirements.

Ventilation air is supplied directly through ducts to the floor area. Air then flows from the floor area to the dryer/separator pool, reactor well, and fuel storage pool. Air is exhausted from these areas through ducts to the reactor/auxiliary building ventilation system exhaust. The elevator machine room is cooled by an air conditioning unit which rejects waste heat to the refueling area.

Equipment located in this Fire Zone is not required for shutdown.

Safe shutdown equipment located in this zone consists of the following:

a. Division I and II cables

Fire detection equipment located in this zone consists of an infrared detection system. Fire suppression equipment in this zone consists of manual hose with solid stream nozzles and portable fire extinguishers as shown in Figure 9A-10.

The combustible loading in the Auxiliary Building stairwell enclosure is extremely low. In addition future storage of combustibles in this area is not considered for the purpose of this analysis because the storage of combustibles in stairwells is controlled. Based on the extremely low combustible loading in this area, fire detection instrumentation is not installed since it would not be expected to alarm due to the small amounts of smoke/heat that could be produced by a fire in this area. The stairwell contains two (2) Division II cables routed in the same conduit above the 677′-6″ elevation which are required for safe shutdown.

9A.4.1.10.2 Analysis

Shutdown is achieved from the main control room. Division I will be used to achieve safe shutdown for fires on the south side because there are no Appendix R Division I cables located on the south side of this zone. On the north side of this zone, Division II will be used to achieve safe shutdown. There are no Appendix R Division II cables (nor are there Appendix R Division I cables) located on the north side of this zone. Combustibles located in this zone consist primarily of the reactor building and fuel-handling crane and gear box lubricating oil. The total zone fire loading is low.

9A.4.1.10.3 Conclusion

The objective for this Fire Zone is to prevent the spread of a fire in this zone to another Fire Zone. This objective is achieved through low zone fire loading, and the provision of an early-warning detection system and manual hose and portable fire extinguishers.

9A.4.1.11 Drywell, Fire Zone 10RB, El. 562 Ft 0 In. to 684 Ft 6 In.

9A.4.1.11.1 Description

This zone, shown in Figures 9A-3, 9A-4, 9A-6, 9A-8 through 9A-10, consists of a containment vessel in the shape of an inverted light bulb.

The zone is surrounded by reactor building Fire Zones 01RB through 09RB.

This zone houses the reactor pressure vessel (RPV), reactor recirculation pumps, and associated equipment.

The drywell consists of a steel pressure vessel surrounded by reinforced concrete for shielding. External to the drywell vessel but in the Fire Zone above elevation 572 ft. 1 in., the drywell is separated from the concrete biological shield by a gap of approximately 2 inches. The gap is filled with polyurethane foam material. The bottom portion of the shell is totally embedded in concrete, and the transition zone is backed by compacted sand. Access to the drywell is through an air lock located in Zone 4 at Elevation 583 ft 6 in.

Cooling of air within the drywell is provided by 14 fan-coil units located at various elevations within the drywell. These units recirculate and cool the drywell ambient air. Cooling water for these units is normally supplied from the reactor building closed cooling water system (RBCCWS). Under other than normal conditions, cooling water is supplied from the EECW system. Thermocouples located in various drywell areas actuate control room alarms on detection of high temperature.

Shutdown equipment located in this zone consists of the following:

a. Nuclear pressure relief system (NPRS) safety/relief valves (SRVs) B21-F013A, B, C, D, E, F, G, H, J, K, L, M, N, P, and R and instruments

b. Reactor recirculation shutdown cooling to RHR inboard isolation valves E11-F009 and E11-F608

c. Reactor recirculation discharge valves B31-F031A, B31-F031B, B3105F023A and B3105F023B.

d. Division 1 and 2 cables, located in drywell penetrations passing through the drywell gap area.

e. SRV accumulators (Division I and II)

f. Valves (Division I and II)

g. T50 instrumentation (Division I and II)

For maintenance operations, fire suppression equipment, consisting of manual hoses and portable fire extinguishers, is located at the drywell access air lock in Zone 4 at Elevation 583 ft 6 in. The drywell gap area is not provided with either fire detection or automatic suppression. Fire suppression consists of manual hoses located on the first and second floor level.

9A.4.1.11.2 Analysis

The drywell atmosphere is inerted with nitrogen. The concentration of nitrogen is maintained at 97 percent. Oxygen and hydrogen content is monitored. For a more detailed description, refer to Subsection 9.3.6. Fire damage is not assumed to occur under Appendix R Section III.G.2.

Combustibles within this zone consist primarily of the following:

a. Electrical insulation

b. Lubricating oil

c. Polyurethane foam in the drywell gap area

d. Silicone rubber impregnated fiberglass fabric covering permanently installed lead blankets

Because the polyurethane foam is located in the drywell gap outside the steel drywell vessel, the foam does not contribute to the total zone Btu content of the drywell.

Total zone fire loading is low.

If a fire occurs in the drywell gap area, hot shutdown can be maintained using HPCI; cold shutdown can be attained by manual operation of valves in the drywell to achieve shutdown cooling lineup.

9A.4.1.11.3 Conclusion

The objective of this zone is to prevent a fire from occurring. During reactor operation, this is achieved through the maintenance of a nitrogen atmosphere. During maintenance operation, fire suppression equipment is used. Although Division 1 and 2 cables are present in the drywell gap, redundant hot shutdown equipment is not affected by a fire in the gap area. Hot and cold shutdown can be achieved following the assumptions of 10 CFR 50, Appendix R.

9A.4.2 Auxiliary Building

9A.4.2.1 General Description

The auxiliary building is a multilevel structure. For purposes of this fire hazards analysis, the auxiliary building has been designated as fire area AB. It is bounded on the north and south by outside walls; on the east by the turbine building; and on the west by the reactor building.

The outage building is located four (4) inches south of the south wall of the reactor and auxiliary building. The outage building is of completely noncombustible construction; additionally no safe shutdown systems or equipment are located in this building. The outage building is structurally separated from plant structures, however, nonstructural flashing is attached to both the reactor and auxiliary building to seal and protect the four-inch gap between it and the outage building.

The north and south exterior walls are constructed of 24 inches of reinforced concrete which will prevent an exposure fire in the yard area from propagating into the auxiliary building. Except as noted below, these walls are 3-hr-rated fire barriers.

The auxiliary building south wall also contains five (5) non-rated removable plugs filled with at least twelve (12) inches of grout and are acceptable for use as penetration seals in a 3-hr-rated fire barrier based on their construction.

The auxiliary building also contains a sixth removable plug seal. This sleeve has six (6) 1-inch thick steel plates held into the penetration with a locked steel bar such that they are flush with the exterior plane surface of the fire barrier. A seventh 1-inch thick steel plate is bolted into the exterior wall of the auxiliary building. In addition, the eighteen (18) inches between these sets of plates is totally devoid of combustible materials. Therefore, although they are not tested and approved seal configurations they are of substantial steel construction and prevent flame propagation into the auxiliary building.

The metal-sided control center air conditioning intake is located on the south side of the auxiliary building. The base of the air intake is at elevation 643′-6″ while the actual opening into the auxiliary building is a 6′ x 20′ opening at elevation 681′-6″. Since this opening itself is 98′ above grade elevation (583′-6″), an exposure fire threat to the opening itself is not postulated based on the types, amounts, and locations of the combustible materials that could be in close proximity of the air intake either during normal operation or outages. Should the control room operators detect smoke coming into the control center because of a fire in the yard, or receive notification of a fire in the yard, the operators can switch from the air intake on the south side of the auxiliary building to the air intake on the north side of the building. This is done by placing the air conditioning system in the recirculation mode.

The auxiliary building houses reactor auxiliary systems and equipment.

With the exception of the control room, relay room, cable spreading room, standby gas treatment system (SGTS) room, and control center air conditioning equipment rooms, ventilation of the auxiliary building is provided by the reactor/auxiliary building ventilation system. Ventilation for the control room, relay room, cable spreading room, and control center air conditioning equipment room is provided by the control center heating, ventilation, and air conditioning (HVAC) system. These ventilation systems are discussed briefly in the individual Fire Zone descriptions. Additional details for these ventilation systems are presented in Subsections 9.4.1 and 9.4.2.

For the purpose of this fire hazards analysis, the auxiliary building has been divided into the following Fire Zones:

a. Basement, Fire Zone 01AB, Elevations 551 ft 0 in. and 562 ft 0 in.

b. Mezzanine and cable tray area, Fire Zone 02AB, Elevations 583 ft 6 in. and 603 ft 6 in.

c. Relay room, Fire Zone 03AB, Elevation 613 ft 6 in.

d. Switchgear room, Fire Zone 04AB, Elevation 613 ft 8 1/2 in.

e. Cable tunnel, Fire Zone 05AB, Elevation 613 ft 6 in.

f. Second floor, miscellaneous rooms, Fire Zone 06AB, Elevation 613 ft 6 in.

g. Cable spreading room, Fire Zone 07AB, Elevation 630 ft 6 in.

h. Cable tray area, Fire Zone 08AB, Elevation 631 ft 0 in.

i. Control room, Fire Zone 09AB, Elevations 643 ft 6 in. and 655 ft 6 in.

j. Divisions I and II battery rooms, Fire Zone 10AB, Elevation 643 ft 6 in.

k. Miscellaneous rooms, Fire Zone 11AB, Elevation 643 ft 6 in.

l. Switchgear room, Fire Zone 12AB, Elevation 643 ft 6 in.

m. Ventilation equipment area, Fire Zone 13AB, Elevation 650 ft 6 in.

n. Control center ventilation equipment rooms and standby gas treatment rooms, Fire Zone 14AB, Elevation 677 ft 6 in.

o. Ventilation equipment area, Fire Zone 15AB, Elevation 677 ft 6 in.

9A.4.2.2 Basement, Fire Zone 01AB, El. 551 Ft 0 In. and 562 Ft 0 In.

9A.4.2.2.1 Description

The basement, shown in Figure 9A-3, encompasses the entire floor area at Elevation 551 ft 0 in. and the floor area bounding CRD pump room on the east and south at Elevation 562 ft 0 in. The zone is bounded on the north and south by outside walls; on the east by the turbine building; and on the west by the reactor building.

This zone houses Divisions I and II control air equipment and cables. Walls and ceiling separating this zone from the reactor building, turbine building, and other zones of the auxiliary building are constructed of reinforced concrete having a fire-resistance rating of 3 hr. Door openings are protected by Class A fire doors. Penetrations through rated walls and ceilings are sealed to provide 3-hr fire-resistance ratings. Division I and II shutdown cables within 20 ft of the opposite Division's shutdown cables are enclosed with a 1-hr-rated fire barrier or an analysis has been performed to show that loss or misactivation of any interacting redundant divisional circuits does not affect plant safe shutdown. Fire breaks have been installed in trays which contain intervening combustibles in order to ensure that a postulated fire cannot spread through these cable trays in such a manner as to damage redundant safe shutdown components.

Ventilation supply air from the reactor/auxiliary building ventilation system is ducted to both control air equipment areas and to the cable tray space. Exhaust from these spaces is by direct duct connection to an exhaust main passing through these spaces. Both control air equipment areas have local air-handling units for cooling the room ambient air.

Shutdown equipment located in this zone consists of the following:

a. Divisions I and II control air equipment, fan coil units, and associated isolation valves

b. Divisions I and II cable.

For Fire Zone 01AB, Division II is primarily utilized for safe shutdown except for certain Division I areas. Division I is utilized for shutdown between 10-12, and in the southwest corner near G-9.

Fire detection equipment in this zone consists of an ionization detection system. Fire suppression equipment consists of an automatic sprinkler system for floor Elevations 551 ft 0 in. and 562 ft 0 in. and manual water hose stations and portable fire extinguishers as shown in Figure 9A-3.

9A.4.2.2.2 Analysis

Shutdown is achieved from the main control room. Division II cable trays required for shutdown (2C-027, 2C-030, 2C-036, 2P-019, and DC2P-019) are provided with a 1-hr protective envelope when they are within 20 ft of Division I circuits. Division II cable trays 2C-035, 2P-026, and DC2P-026 are partially protected along column line 11. These trays no longer require protection as the Division 1 circuits are protected in this area. Division 1 trays 1P-069, DC1P-069, 1P-024, and 1C-005 are protected between column lines H10 and H13.

The cable tray supports, along the west side, between column lines H12 and H13 are wrapped for their full height. The cable tray supports, along the west side, between column lines H11 and H12 are wrapped to approximately elevation 566'. The cable tray supports, along the west side, between column lines H10 and H11 do not require fire wrap. The cable tray support wrap was evaluated and determined to be required to protect the tray supports from direct flame impingement in the event of a transient combustible fire occurring beneath these trays.

Division II trays 2K-011 and 2K-020 are not protected, between column lines 11 and 12, because these trays are not required since they are in an area where Division I will be used to achieve shutdown.

In areas where Division I is not protected, Division II is used for shutdown.

Intervening combustibles exist between the two shutdown divisions. Between column lines 12 and 13, trays 0C-018, 0C-017, 0C-027, and 0C-028 are provided with fire breaks, and trays 1K-022, 2K-020 and 0K-001 are solid metal bottom trays with covers. Between column lines 10 and 11 trays 0P-005, 0C-018, 0C-017, 0C-027, 0C-028, and 0P-002 constitute intervening combustibles with fire breaks, and tray 1K-022 is a solid metal bottom tray with covers. The empty tray 0P-006 is not an intervening combustible. These fire breaks provide a minimum of 20 feet free of intervening combustibles and therefore meet the requirements for 20 foot separation with no intervening combustibles and with detection and suppression.

At the south end, mezzanine area 562 ft 0 in., of the zone (column line G-H, 9-11) intervening combustibles in the form of cable trays exist within the 20-ft separation zone between the divisions. Cable tray fire breaks have been installed in trays OP-005, OC-017, and OC-018. Cable tray 2K-015 is enclosed within the fire barrier in the vicinity of these breaks and thus is not an intervening combustible.

Specific fire hazards exist in the southeast and northeast portions of the zone where both Divisions I and II cables are concentrated.

The amount of lubricating oil in the control air equipment is not sufficient to allow propagation of a fire between Division I and II equipment through the floor drain system in the zone.

Combustibles located within this zone consist primarily of electrical insulation.

The total zone fire loading is low.

9A.4.2.2.3 Conclusion

The safe-shutdown analysis performed verified that either Division I or II will be available for plant safe shutdown in the event of a fire in this zone. The Division I or II power and control circuits are provided with a 1-hr-rated protective envelope, as listed above, or are separated from the redundant division's unprotected cables by at least 20 ft. Cable tray fire breaks are provided in various Balance of Plant cable trays to provide 20 ft. zones free of intervening combustibles.

9A.4.2.2.4 Deviations

Deviations have been approved for the following: intervening combustibles--based on fire stops in cable trays OP-005, OC-017, and OC-018 at column lines 9 and 11 (Reference 1, SSER No. 5, VI [15]).

9A.4.2.3 Mezzanine and Cable Tray Area, Fire Zone 02AB, El. 583 Ft 6 In. and 603 Ft 6 In.

9A.4.2.3.1 Description

This zone, shown in Figures 9A-4 and 9A-5, is divided into three sections and encompasses two floor elevations, with a common ceiling under Elevation 613 ft 6 in. The first floor elevation is at 583 ft 6 in. and is divided into two sections, a north section and a south section, separated by an extension of the turbine building. The southern section of the zone consists of a cable entry room, which extends partially along the outside of the south wall, and a cable tray area. The northern section of the zone consists of a cable tray area. The mezzanine area, the third section of the zone, is at Elevation 603 ft 6 in. above the turbine building extension. The zone is bounded on the south by an outside wall, except at the cable entry area, where a portion of the zone bounds the reactor building; on the east by the turbine building; on the north by an outside wall; on the west by the reactor building, steam tunnel, and an outside wall at the cable entry area; and is divided by an extension of the turbine building from the 583 ft 6 in. elevation up to the floor of the 603 ft 6 in. elevation.

This zone serves primarily as a cable routing area.

The walls, floor, and ceiling bounding this zone are constructed of reinforced concrete having a fire-resistance rating of 3-hr. Penetrations are sealed to provide 3-hr fire-resistance ratings except for 16 cable tray penetrations in the mezzanine area at the 603 ft 6 in. elevation east wall. These penetrations are open to the enclosed 4-inch gap area between the auxiliary and turbine buildings. Door openings leading to the turbine building extension and between the Divisions I and II cable entry rooms are protected by Class A fire doors. Division II shutdown cables within 20 ft of Division I shutdown cables in the north end of the area are enclosed with a 1-hr-rated fire barrier, as are Division I shutdown cables within 20 ft of Division II shutdown cables in the south end of the area. The equipment hatch in the southern section of the zone is provided with a reinforced-concrete cover.

The HVAC/pipe chase along column H between 10 and 11 extends from the floor opening at elevation 613’-6” to the ventilation equipment area on elevation 677’-6” (Fire Zone 15AB) and is completely devoid of combustibles for is entire 64-foot height. Additionally, the walls of this chase are constructed and sealed as 3-hour rated barriers. Finally, Thermo-Lag material was used to construct the floor of this chase. Given, that as detailed below, automatic sprinkler coverage is provided for the area around the base of this opening and that the combustible loading on the 677’-6” elevation open top of this chase is negligible (reference Section 9A.4.2.16.2), flame propagation via this combustible material free vertical chase is not a credible event. Therefore, the chase itself provides the required separation between auxiliary building Fire Zones 2 and 15. Additionally, the Thermo-Lag material used to seal the chase at elevation 613’-6” is a nonfire rated smoke and gas barrier. For identification purposes, the chase is considered as being part of Fire Zone 02AB.

Ventilation for this zone is provided by the reactor/auxiliary building ventilation system. Supply air is ducted to each section of the zone. Exhaust air returns unducted from the northern section of the zone to the mezzanine area where air is exhausted through ducts to the auxiliary building main exhaust system. Exhaust air from the southern section of the zone is ducted to the auxiliary building main exhaust system.

Shutdown equipment contained in this zone consists of the following:

a. Divisions I and II cables

b. Offsite power cables affecting CTG 11-1 feed to standby feedwater

Division II cable will be used to achieve plant safe shutdown for fires in the north half of the zone. For fires in the south half of the zone, Division I will be used to achieve plant safe shutdown.

Fire breaks have been installed in cable trays within this zone.

Fire detection equipment in this zone consists of an ionization detection system. Fire suppression equipment consists of an area-wide automatic sprinkler system and selected cable tray protection, manual water hose stations, and portable fire extinguishers as shown in Figures 9A-4 and 9A-5.

NFPA 13 noncompliances with this sprinkler system include sprinkler protection areas exceeding the limit for extra hazard occupancy, spacing between branch lines exceeding the 12 ft limit, sprinklers farther from the wall than the 6 ft limit, sprinkler spray patterns partially obstructed, and discrepancies with cable tray sprinklers (in addition to those discussed and evaluated in 9.5.1.2.3.3). These noncompliances would not adversely affect the required function of this system because the extremely conservative extra hazard occupancy water application density would adequately compensate for these and provide the required sprinkler system performance.

9A.4.2.3.2 Analysis

Shutdown is achieved from the main control room. For this zone, Division I and II cables are routed and located on the north side of the building (north of column line 12) and Division I and II cables are routed and located on the south side of the building (south of column line 12). Where redundant shutdown trains are not separated by more than 20 ft, a 1-hour fire wrap is applied to one division.

The sixteen cable tray penetrations in the east auxiliary building wall Fire Rated Separation Barrier have been analyzed. Credit is taken for the sealed turbine building wall penetrations adjacent to the auxiliary building wall, the metallic cover plates over the seismic gap opening between the buildings and the lack of signifi-cant combustibles or ignition sources in the gap as sufficient barriers to prevent the propagation of fire through the unsealed openings in the auxiliary building wall Fire Rated Separation Barrier.

Cable trays 1K-014, 1K-029, 1K-034, 2C-012 and 2C-030, and conduit JA001-1K (north end) and 1C-006, 1P-045, 1P-041, and DC1P-044 (south end) have been provided with a 1-hr protective envelope.

Because of the intervening combustibles in the form of cable trays, fire breaks have been installed in cable trays OC-617, OC-618, OC-611, OC-614, OC-582, OC-585, OC-640, OC-636, OC-916, OC-570, OC-645, OC-592, OC-671, and OC-672 which are located on the north end, Elevation 603 ft 0 in.

Combustibles located within this zone consist primarily of electrical insulation.

The total zone fire loading is moderate.

9A.4.2.3.3 Conclusion

The safe-shutdown analysis performed verified that, for a fire in this zone, plant safe shutdown will be performed using Division II equipment for fires in the north half. For fire in the south half, Division I equipment will be used to achieve plant safe shutdown. The objective for this zone to minimize the potential for the occurrence of a fire and to minimize the spread and damage, should a fire occur, has been achieved through spatial separation of control and instrument components, rated barriers, and the provision of early-warning detection, manual water hose stations, and portable fire extinguishers.

Safe-shutdown capability is protected via the above and provisions of fire breaks and 1-hr protective envelopes as required in the zone.

9A.4.2.3.4 Deviations

Deviations have been approved for the following: intervening combustibles based on area-wide sprinklers, cable tray sprinklers, and fire stops (Reference 1, and SSER No. 5, VI[6]).

9A.4.2.4 Relay Room, Fire Zone 03AB, El. 613 Ft 6 In., 630 Ft 6 In. and 643 Ft 6 In.

9A.4.2.4.1 Description

This zone, shown in Figure 9A-6, consists of the relay room and the control center northeast stairwell located in the northern portion of the building. The zone is bounded on the north by an outside wall; on the east by the turbine building; on the south by Fire Zone 05AB, an extension of the turbine building, and the steam tunnel; and on the west by the reactor building. The relay room is a part of the control center complex.

The zone houses relay cabinets, instrument racks, and cables.

Unless noted below, the walls, floor, and ceiling surrounding this zone are constructed of reinforced concrete having a fire-resistance rating of 3 hr. Penetrations are sealed to provide a 3-hr fire-resistance rating. Door openings are protected by Class A fire doors. The stairwell is enclosed by 3-hr fire-rated walls with a Class A fire door. In the control center stairwell, a 3-hr-rated fire barrier is provided for cables of one division. The access stairway to the cable tray area on Elevation 603’-6” is protected by 3-hr fire walls and a Class A fire door. The barrier wall between the relay room itself and the northeast stairwell is a nonfire rated continuous smoke and gas barrier constructed of Thermo-Lag material. This barrier is used to provide containment as a boundary for the halon suppression system in the relay room.

An HVAC chase is located in the southwest corner of the relay room ceiling which extends up to elevation 654’-0” which is above the control room suspended ceiling (Fire Zone 09AB). There are no combustible materials in this 23-foot vertical chase. The HVAC ducts entering this chase from the relay room are provided with fire and smoke and gas dampers. The 23-foot high walls and the ceiling (at elevation 654’-0”) between the existing metal HVAC ducts of this chase are constructed and sealed as 3-hour rated barriers. However, Thermo-Lag material was used in two (2) places to seal around the HVAC ducts in the floor of this chase at elevation 630’-6” as a nonfire rated smoke and gas seal to prevent the escape of discharged halon. Given, as detailed below, that automatic halon suppression is provided for the relay room and that the combustible loading in the control room ceiling is negligible, flame propagation via this combustible material-free vertical chase and out through the metal HVAC ductwork is not a credible event. At this time, it should be noted that NFPA 90 considers metal HVAC ductwork in walls as equivalent to one-hour rated fire barriers. Therefore, this chase provides the required separation between auxiliary building Fire Zones 03AB and 09AB. Additionally, the Thermo-Lag material used to seal the chase at elevation 630’-6” is a nonfire rated smoke and gas barrier. For identification purposes, the chase is considered as being part of auxiliary building Fire Zone 03AB.

Ventilation for this zone is provided by the control center HVAC system. Conditioned air is ducted directly to the relay room. Air is exhausted by ducts from the relay room.

Shutdown equipment located in this zone consists of the following:

a. Division I and II relay panels and termination cabinets

b. Division I and II cables

c. Standby feedwater and CTG 11-1 related cables

Fire detection equipment located in this zone consists of a Class A cross-zoned ionization smoke detection system and a smoke detector in the stairwell. Fire suppression equipment for this zone consists of an automatic Halon system, manual water hose stations, portable fire extinguishers, and a CO_2 hose reel station located outside the room at the south door, as shown in Figure 9A-6.

9A.4.2.4.2 Analysis

Shutdown is achieved from outside the main control room. An alternative shutdown system, independent of the control center complex, has been designed and installed to achieve plant safe shutdown for a fire in this zone.

Cable tray 1K-034 is provided with a 3-hr barrier in the northeast stairwell area.

Inadvertent operation of the automatic Halon system would have no adverse effect on safe-shutdown equipment located in this zone.

Combustibles located in this zone consist primarily of electrical insulation.

Total zone fire loading is moderate.

9A.4.2.4.3 Conclusion

For a fire in this zone, plant safe shutdown will be achieved using the alternative shutdown system.

The objective for this zone is to prevent a fire within the zone from affecting both Divisions I and II equipment and to prevent a fire from crossing the zone's barriers. This objective is achieved through spatial separation, barriers, the provision of an early-warning detection system, an automatic Halon system, manual hose, portable fire extinguishers, and a CO_2 hose reel station.

9A.4.2.4.4 Deviations

There are no deviations for this zone.

9A.4.2.5 Switchgear Room, Fire Zone 04AB, El. 613 Ft 8-1/2 In.

9A.4.2.5.1 Description

This zone, shown in Figure 9A-6, consists of one room located in the southern portion of the building. The zone is bounded on the north by Fire Zone 06AB of this fire area; on the east by the turbine building; on the south by an outside wall; and on the west by the reactor building. Within this zone, a room is constructed to enclose the Division II cables.

The zone houses Division I switchgear and the Division I remote shutdown panel.

The walls, floor, and ceiling of this zone are constructed of reinforced concrete having a fire-resistance rating of 3 hr. Penetrations are sealed to provide 3-hr fire-resistance ratings. The door opening leading to Fire Zone 06AB is protected by Class A fire doors. The stairwell is enclosed by 2-hr-rated fire walls with a Class B fire door. The room containing the Division II cables is enclosed by a 3-hr-rated fire barrier with a Class A fire door.

Ventilation for this zone is provided by the reactor/auxiliary building ventilation system. Air is ducted directly to the switchgear room and exhausted through ducts to the auxiliary building main exhaust system. In addition, the switchgear room contains two local, recirculating-type cooling units.

This zone contains the following shutdown equipment:

a. Division I switchgear
b. Division I and II cable
c. Offsite power cables affecting CTG 11-1 feed to standby feedwater
d. Switchgear room cooling units (Division I)
e. 120 V ac modular power units (Division I and BOP)
f. 130 V dc distribution panel (Division I)

Fire detection equipment located within this zone (including the Division II cable enclosure) consists of an area ionization detection system. Fire suppression equipment consists of a manual hose and portable fire extinguishers as shown in Figure 9A-6. The manual hose station and CO_2 hose reel are located in Fire Zone 06AB.

9A.4.2.5.2 Analysis

Division II cables and equipment will be used to achieve plant safe shutdown for fires in this zone except for the enclosed room near column line G-9. In this room, Division I equipment and cables are used for safe shutdown.

The abandoned tubing left within the three hour fire resistant penetration to the reactor building is evaluated to show that the seal is adequate for fires in the zone.

Combustibles located within this zone consist primarily of electrical insulation. Total zone fire loading is moderate.

9A.4.2.5.3 Conclusion

The objective for this zone is to prevent a fire in this zone from spreading to other zones and to Division II cable. This objective is achieved through fire barriers between other zones and redundant equipment, an early-warning detection system, a manual hose, portable fire extinguishers, and a CO_2 hose reel.

9A.4.2.6 Cable Tunnel, Fire Zone 05AB, El. 613 Ft 6 In.

9A.4.2.6.1 Description

This zone, shown in Figure 9A-6, consists of one room located in the central portion of this elevation adjacent to the steam tunnel. It is bounded on the north by the relay room (Fire Zone 03AB); on the east and south by Fire Zone 06AB and on the west by the steam tunnel.

This zone serves as a cable routing area for Divisions I, Division II, and BOP cable. The Division I cables are located along the east side of the tunnel while the Division II cables are located along the west wall.

The walls, floor, and ceiling separating this zone from the relay room (Fire Zone 03AB) and the turbine building extension are constructed of reinforced concrete having a fire-resistance rating of 3 hr. Penetrations through rated walls, floor, and ceiling are sealed to provide a 3-hr fire-resistance rating. The door openings leading from the cable tunnel are protected by Class A fire doors. The tunnel is divided by a 3-hr fire-rated gypsum wall that separates Divisions I and II cables.

Ventilation for this zone is provided by the reactor/auxiliary building ventilation system. Air is ducted directly to the cable tunnel and exhausted through ducts to the auxiliary building main exhaust system. Relief air flows unducted from the cable tunnel to the corridor leading to the turbine building. Airflow entering the corridor is controlled by a backdraft damper.

Shutdown equipment located in this zone consists of the following:

a. Division I and II cables

b. Standby feedwater power supply control cables

Fire detection equipment located in this zone consists of an area ionization detection system. Fire suppression equipment located in this zone consists of a manual CO_2 system. Manual water hose stations and portable fire extinguishers are available in adjacent zones, as shown in Figure 9A-6.

9A.4.2.6.2 Analysis

Shutdown is achieved from the main control room. Only Division I and standby feedwater control cables are present in the east cable tunnel. Therefore, Division II will be available for plant safe shutdown in the event of a fire in the east tunnel. Division II circuits are present in the west tunnel. The Division I systems will be used to achieve plant safe shutdown in the event of fire in the west tunnel.

The total quantity of combustibles on both sides of the wall consists primarily of electrical insulation. The resultant fire loading for the west side of the tunnel is high. The east side fire loading is also high.

The inadvertent operation of the CO_2 suppression system will have no adverse effect on the cables.

9A.4.2.6.3 Conclusion

The objective for this zone is to prevent a fire from affecting Divisions I and II cables within the zone and from spreading to another zone. The objective is achieved through the provision of a 3-hr-rated fire barrier, early-warning detection, manual CO_2 suppression equipment, and manual hose and portable fire extinguishers.

9A.4.2.6.4 Deviations

Deviations have been approved for the following: to maintain a 3-hr-rated barrier between redundant divisions and provide a manually actuated CO_2 system. (Reference 1, SSER No. 5, VI [910]).

9A.4.2.7 Second Floor, Miscellaneous Rooms, Fire Zone 06AB, El. 613 Ft 6 In.

9A.4.2.7.1 Description

This zone, shown in Figure 9A-6, consists of the personnel air lock, dress-out area, and corridor space. Generally, it is bounded on the north by the steam tunnel, cable tunnel, and the turbine building extension; on the east by the turbine building extension; on the south by the switchgear room; and on the west by the reactor building and the cable tunnel.

The zone houses instrumentation and control calibration equipment and welding equipment.

The walls, floor, and ceiling separating this zone are constructed of reinforced concrete having a fire-resistance rating of 3 hr. Door openings between this zone and the switchgear room, the turbine building extension, and the reactor building are protected by Class A fire doors. Penetrations through the rated walls, floor, and ceiling are sealed to provide 3-hr fire-resistance ratings.

Ventilation for this zone is provided by the reactor/auxiliary building ventilation system. Air is ducted directly to the personnel change room and the welding equipment area. Exhaust from the personnel change room is ducted directly to the auxiliary building main exhaust system. Relief air flows unducted from the welding equipment area to the personnel change room.

Fire detection equipment located within this zone consists of an ionization detection system. Fire suppression equipment in this zone consists of a manual hose station, a CO_2 hose reel, and portable fire extinguishers as shown in Figure 9A-6.

9A.4.2.7.2 Analysis

Only Division I and BOP instrumentation power supply cables are routed through this zone.

Combustibles located within this zone consist primarily of electrical insulation and protective clothing. The total zone loading is low.

9A.4.2.7.3 Conclusion

Division II will be used to achieve plant safe shutdown for a fire in this zone.

The objective for this Fire Zone is to prevent a fire in this zone from spreading to another Fire Zone. This is accomplished through barriers and provision of an early-warning detection system, and manual hose and portable fire extinguishers.

9A.4.2.8 Cable Spreading Room, Fire Zone 07AB, El. 630 Ft 6 In.

9A.4.2.8.1 Description

This zone, shown in Figure 9A-7, consists of one room. It is bounded on the north by an outside wall; on the east by the turbine building; on the south by the steam tunnel; and on the west by the reactor building. The cable spreading room is a part of the control center complex.

The zone serves as a cable routing area for both Divisions I and II and standby feedwater cables.

Unless otherwise noted below, the walls, floor, and ceiling of this zone are constructed of reinforced concrete with a fire-resistance rating of 3 hr. Penetrations through rated walls, floor, and ceiling are sealed to provide a 3-hr fire-resistance rating. The stairwells are enclosed by 3-hr-rated fire walls with Class A fire doors.

Ventilation for this zone is provided by the control center HVAC system. Conditioned air is ducted to and from the zone.

Shutdown equipment located in this zone consists of both Divisions I and II cables.

Fire detection equipment in this zone consists of two ionization detection systems. One of the detection systems is strictly early warning, with the other a Class A cross-zoned ionization detection system providing automatic actuation of the Halon system. Fire suppression equipment consists of an automatic Halon system, manual fusible link sprinkler system, manual water hose station, and portable fire extinguishers, as shown in Figure 9A-7.

9A.4.2.8.2 Analysis

Shutdown is achieved from outside the control room. The alternative shutdown system, independent of the control center complex, has been designed and installed to achieve plant safe shutdown for a fire in this zone.

No protective envelopes are required in this zone.

Inadvertent operation of the automatic Halon fire suppression system will have no adverse effect on the cables in this zone.

Combustibles within this zone consist primarily of cable insulation. Total zone loading is high.

9A.4.2.8.3 Conclusion

The objective for this zone is to prevent a fire within the zone from affecting both Divisions I and II cables and to prevent a fire from crossing the boundaries of this zone. This objective is achieved through spatial separation, barriers, and the provision of an early-warning detection system, an automatic Halon fire suppression system, manual fusible link sprinkler system, manual water hose station, and portable fire extinguishers.

9A.4.2.9 Cable Tray Area, Fire Zone 08AB, El. 631 Ft 0 In.

9A.4.2.9.1 Description

This zone, shown in Figure 9A-7, consists of one room. It is bounded on the north by the steam tunnel; on the east by the turbine building; on the south by an outside wall; and on the west by the reactor building. The zone serves primarily as a cable routing area for Division II cable. A small amount of Division I cable is routed through this zone.

The walls, floors, and ceiling of this zone are constructed of reinforced concrete having a fire-resistance rating of 3 hr. Penetrations through the walls, floor, and ceiling are sealed to provide 3-hr fire-resistance ratings or have been evaluated to contain an acceptable penetration seal. Penetrations that are not installed in a configuration that provides 3-hr protection are evaluated to be acceptable if the installed detail provides adequate protection to prevent spread of fire across the barrier. The stairwell is enclosed by a 2-hr-rated fire barrier with a Class B fire door.

Ventilation air is provided by the reactor/auxiliary building ventilation system. Supply air is ducted directly to this zone. Exhaust air is ducted to the auxiliary building main exhaust system.

The alternative shutdown system is used to achieve plant safe shutdown for a fire in this zone.

Shutdown equipment located in this zone consists of Divisions I and II and standby feedwater cables.

Fire detection equipment in this zone consists of an ionization detection system. Fire suppression equipment located in this zone consists of an automatic CO_2 system, manual water hose stations, and portable fire extinguishers, as shown in Figure 9A-7.

9A.4.2.9.2 Analysis

Shutdown is achieved from outside the main control room. For a fire in this zone, the alternative shutdown system will be used to bring the plant to a safe-shutdown condition. Conduit RI 005-2P/wireway RI-069 contains circuits required for the alternative shutdown system. When the conduit is routed in the zone, a 1-hr protective envelope has been provided on the circuit/wireway.

Inadvertent operation of the automatic CO_2 fire suppression system will have no adverse effect on the cables.

Combustibles located within this zone consist primarily of cable insulation. Total zone fire loading is low.

9A.4.2.9.3 Conclusion

For a fire in this zone, the alternative shutdown system will be used to achieve plant safe shutdown. The objective for this zone is to prevent a fire within the zone from spreading to another Fire Zone. This objective is achieved through spatial separation, barriers, and the provision of early-warning detection, automatic CO_2 fire suppression, manual water hose stations, and portable fire extinguishers.

9A.4.2.9.4 Deviations

There are no deviations for this zone.

9A.4.2.10 Control Room, Fire Zone 09AB, El. 643 Ft 6 In., 655 Ft 6 In, and 677 Ft 6 In.

9A.4.2.10.1 Description

This zone, shown in Figures 9A-8, 9A-9, and 9A-10 consists of the main control room, office, conference room, kitchen, and lavatory on Elevation 643 ft 6 in.; the computer equipment area on Elevation 655 ft 6 in.; and the small air conditioning room located between columns H-13 to 15 on Elevation 677 ft 6 in. The zone is bounded on the north by an outside wall; on the east by the turbine building; on the south by the turbine building corridor and battery rooms; and on the west by the reactor building.

This zone houses the main control panel, computer, and associated auxiliary equipment.

The outside walls, floor, and ceiling of this zone are constructed of reinforced concrete having a fire-resistance rating of 3 hr. The computer room is cut off from the main control room by a barrier that will prevent the propagation of fire. The remainder of the peripheral rooms to the control room, except for the Shift Supervisor's room, have walls and doors that will prevent a fire from spreading out of the room. Electrical and piping penetrations are sealed to provide the same rating as the fire barrier. Supply and return ducts for control room ventilation are provided with fire dampers at the 3-hr fire barriers. See Fire Zone 13AB and

14AB for a discussion of fire dampers F099, F0100, F0101, and F0102, which interface between the Division II control center HVAC and control rooms. Supply and return ducts for the cable spreading and relay rooms that pass through the control room are not provided with dampers at the floor or ceiling. Door openings leading into the turbine building are protected by 1.5-hr fire doors. The northeast stairwell is enclosed by a 3-hr fire barrier with a Class A fire door. A portion of the ceiling of the northeast stairwell is the underside of the stairwell leading up to the computer equipment area (elevation 655’-6”) which has been provided with a 3- hour protective barrier on the underside only. Refer to Subsection 9A.4.2.4.2 for additional details.

Refer to Subsection 9A.4.2.4.1 for a discussion of the HVAC chase between the southwest corner of the relay room on elevation 613’-6” (Fire Zone 03AB) and the area above the control room ceiling. The chase is located at column F-13.

The surface burning characteristics of the glazed block walls, duct insulation, central workstation counters, and ceiling panels in the control room area are rated 25 or less in accordance with the ASTM E-84 test method. The smoke and fuel contribution of the walls, duct insulation, central workstation counters and ceiling panels is also rated 50 or less in accordance with the ASTM E-84 test method. Both the carpeting and counter top meet the criterion requirements for critical radiant heat flux rating and smoke density rating for Class I materials as defined by NFPA standards.

Ventilation for this zone is provided by the control center HVAC system. Conditioned air is ducted directly to and from the control room and associated offices and facilities.

Shutdown equipment located in this zone consists of Division I and II main control board panels, Division I and II cables and standby feedwater cables. The shutdown circuits in the control room are contained within three pairs of cabinets. The control cabinets are mounted on a 4-in.-high concrete pad. The redundant division is contained in the adjacent cabinet. Each set of cabinets is separated from the other sets by several feet. Redundant components in adjacent cabinets are separated from each other by steel panels that have no unsealed penetrations. On the front of the cabinet, the portion below the operating panel is louvered; however, a panel of 1-in.-thick marinite has been fastened on the inside of the panel to close these openings. The annunciator windows are glass for the panels required for shutdown. The heat load and cooling requirements of the panels are satisfied by natural radiative cooling.

Fire detection for the control room is provided by ionization and photoelectric detectors above the drop ceiling and photoelectric detectors in the computer room under-floor area, ionization and/or heat detectors in the peripheral rooms, ionization detectors behind the control room panels below the drop ceiling, ionization detectors within the control boards and continuous manning of the control room (SSER No. 6). Ionization detectors are also located within the central operators consoles, which also provide detection coverage within the adjacent raised floor area. Fire suppression equipment located in this zone consists of an automatic Halon suppression system for the computer room and underfloor area and portable fire extinguishers, as shown in Figures 9A-8 and 9A-9.

The combustible loading in the air conditioning room on elevation 677′-6″ (columns H-13 to 15) is extremely low. In addition future storage of combustibles in this area is not considered for the purpose of this analysis because the area is heavily congested with non-combustible duct work with little floor space. Based on the extremely low combustible loading in this area, fire detection instrumentation is not installed since it would not be expected to alarm due to the small amounts of smoke/heat that could be produced by a postulated fire in this room.

9A.4.2.10.2 Analysis

Shutdown is achieved from outside the main control room. An alternative shutdown system and dedicated shutdown panel independent of the control center complex has been designed and installed to achieve plant safe shutdown for a fire in this zone.

Inadvertent operation of the automatic Halon suppression system in the computer room would have no adverse effect on equipment located in this zone.

Smoke removal from the control room can be accomplished using the control center HVAC system as described in Subsection 9.5.1.2.2. Total fire loading for this zone is low. Total fire loading for this zone is low. Combustibles located in this zone consist of the following:

a. Permanently installed combustibles in the computer room consist primarily of computer wiring insulation and components. In the control room, permanently installed combustibles consist primarily of wiring insulation and components, fire-retardant carpet, counter tops and paper. Paper in this category includes paper in file cabinets and shelves, and chart, recorder, terminal, and plotter paper in use at their respective machines.

b. Anticipated transient combustibles in the computer room consist primarily of paper. The remaining peripheral rooms contain primarily paper, wood, and plastic. The transient combustibles in the main control room are low. Paper not in use will be stored in enclosed metal cabinets.

9A.4.2.10.3 Conclusion

For a fire in the control room, plant safe shutdown will be achieved using the alternative shutdown system and dedicated shutdown panel. The objective for this zone is to minimize the potential for the occurrence of a fire in this zone and, should a fire occur in the zone, minimize the extent of the fire and also to prevent a fire from another zone from spreading into this zone. This objective is achieved through spatial separation of control and instrument components, barriers, and the provision of early-warning detection, automatic Halon suppression in the computer room and computer underfloor area, manual water hose stations, and portable fire extinguishers.

9A.4.2.10.4 Deviations

Deviations have been approved for the following:

a. Installing 1-1/2-hr versus 3-hr-rated fire doors for doors numbered R3-27 and R3-13 based on early-warning detection in the turbine building extension, the Turbine Building low combustible loading in the vicinity of the doors, and the construction of the doors themselves (Reference 3, Reference 2, Appendix E SSER No. 6 III.B)

b. Lack of a fixed suppression system in the control room based on continuous manning of the control room (Reference 1, SSER No. 5-VI [12] and VII).

9A.4.2.11 Divisions I and II Battery Rooms, Fire Zone 10AB, El. 643 Ft 6 In.

9A.4.2.11.1.1 Description

This zone, shown in Figure 9A-8, consists of two rooms. It is bounded on the north by the main control room; on the east and south by Fire Zone 11AB of this fire area; and on the west by the reactor building.

This zone houses the Divisions I and II engineered safety features (ESF) batteries fuse cabinets and cables.

The walls, floor, and ceiling of this zone are constructed of reinforced concrete having a minimum fire-resistance rating of 3 hr. Penetrations are sealed to provide 3-hr-rated fire barriers. The door openings in the south wall are protected by Class A fire doors.

Ventilation for this zone is provided by the reactor/auxiliary building ventilation system. Supply and exhaust are ducted separately to and from each room. Each room is provided with redundant exhaust fans.

The Division I or II batteries contained in these rooms are required for shutdown.

Fire detection equipment located in this zone consists of an area ionization detection system. Fire suppression equipment consists of portable fire extinguishers and manual water hose stations, as shown in Figure 9A-8.

9A.4.2.11.2 Analysis

Shutdown is achieved from the main control room. Divisions I and II batteries located in this zone are separated by a 3-hr fire barrier.

Combustibles in this zone consist primarily of battery cases, electrical insulation, and shock absorbers between batteries. Total zone fire loading is low.

9A.4.2.11.3 Conclusion

The objective for this zone is to prevent a fire in one battery room from spreading to the other battery room and to prevent a fire outside the zone from spreading into the zone. This objective is achieved through barriers, low fire loading, and the provision of early-warning detection, manual water hose stations, and portable fire extinguishers.

9A.4.2.12 Miscellaneous Rooms, Fire Zone 11AB, El. 643 Ft 6 In.

9A.4.2.12.1 Description

This zone, shown in Figure 9A-8, is bounded on the north by the turbine building corridor; on the east by the turbine building; on the south by the Division II switchgear room; and on the west by the battery rooms and reactor building.

This zone houses the reactor protection system (RPS) M-G sets, battery chargers, dc MCCs, and distribution cabinets. The walls, floor, and ceiling of this zone are constructed of reinforced concrete and are rated as 3-hr fire barriers. Penetrations are sealed to provide a fire-resistance rating equivalent to that of the walls, floor, or ceiling in which they are found or have been evaluated to contain an acceptable penetration seal. Penetrations that are not installed in a configuration that provides 3-hr protection are evaluated to be acceptable if the installed detail provides adequate protection to prevent spread of fire across the barrier. The ceiling has a metal hatch cover. The subject steel hatch cover has been evaluated as adequate, as a part of the fire barrier between fire zones 11ABE and 13AB, to prevent the propagation of fire based on the physical configuration of the subject hatch cover in the ceiling/floor, the very low combustible loadings, the fire detection provided in both fire zones, the automatic suppression system provided in Fire Zone 11ABE and the control of transient combustibles in procedures. Door openings are protected by Class B fire doors except in the walls abutting the turbine building corridor and the Division II switchgear room, which have Class A fire doors. Divisions I and II battery chargers are located outside their respective battery rooms on the south side in Fire Zone 11AB. The battery chargers are separated by a 4-in. concrete brick wall with a Class A door installed in it. The wall provides a minimum fire rating of 1-1/2-hr.

Ventilation for this zone is provided by the reactor/auxiliary building ventilation system. Supply air is ducted directly to the battery room air-conditioning unit and circulated through the area or exhausted to the ventilation system.

Shutdown equipment consists of the Divisions I and II battery chargers, dc MCCs, dc distribution cabinets and cables, SRV control cabinets and fan coil units.

Fire detection equipment in this zone consists of two area ionization detection systems. Fire suppression equipment consists of an automatic CO_2 suppression system in the dc MCC room, manual water hose stations, portable fire extinguishers, and a CO_2 hose reel, as shown in Figure 9A-8.

9A.4.2.12.2 Analysis

The Divisions I and II battery chargers and dc distribution cabinets are located in separate rooms.

Division I will be used to achieve plant safe shutdown from the main control room for fires in the west battery charger room.

The alternative shutdown system will be used to achieve plant safe shutdown from outside the control room for a fire in the east side of the zone.

Inadvertent operation of the automatic CO_2 suppression system would have no adverse effect on equipment located in this zone.

Combustibles within this zone consist primarily of electrical insulation. Total zone fire loading is low.

9A.4.2.12.3 Conclusion

The alternative shutdown system is used to achieve plant safe shutdown for a fire in this zone except for the west battery charger room where Division I will be available for shutdown.

The objective for this zone is to prevent a fire within this zone from spreading to another zone. This objective is achieved through barriers and the provision of early-warning detection, an automatic CO_2 suppression system, manual water hose stations, and portable fire extinguishers.

9A.4.2.12.4 Deviations

Deviations have been approved for the following: lack of a 3-hr-rated barrier separating redundant equipment based on a 4-in. solid concrete brick wall with a 3-hr rated door, smoke detection, CO_2 for Division I side, and low combustible loading (less than six cable trays) (Reference 1, SSER No. 5, VI [11]).

9A.4.2.13 Switchgear Room, Fire Zone 12AB, El. 643 Ft 6 In.

9A.4.2.13.1 Description

This zone, shown in Figure 9A-8, consists of one room. It is bounded on the north by Fire Zone 11AB of this fire area; on the east by the turbine building; on the south by an outside wall; and on the west by the reactor building.

The zone houses the Division II switchgear.

The walls, floor, and ceiling are constructed of reinforced concrete having a fire-resistance rating of 3 hr. The door openings in the north wall are protected by Class A fire doors. The door opening at the stairwell is protected by a Class B fire door. Penetrations in the walls, floor, and ceiling are sealed to provide 3-hr-rated fire barriers.

Ventilation for this zone is provided by the reactor/auxiliary building ventilation system. Air is ducted directly to the switchgear room and exhausted through ducts to the auxiliary building main exhaust system. In addition, the switchgear room contains two recirculating-type cooling units.

Shutdown equipment located in this zone consists of the following:

a. Division II switchgear

b. Division I, Division II and standby feedwater cable

c. Switchgear room cooling units (Division II)

d. 120 V ac modular power unit (Division II)

e. 130 V dc distribution panels (Division II)

Fire detection equipment located in this zone consists of an area ionization detection system. Fire suppression equipment consists of manual water hose stations, portable fire extinguishers, and a CO_2 hose reel, as shown in Figure 9A-8.

9A.4.2.13.2 Analysis

Shutdown is achieved from the main control room. Functional redundancy for the Division II switchgear located in this zone is provided by Division I equipment located in another Fire Zone.

Combustibles located within this zone consist primarily of electrical insulation. Total zone fire loading is low.

9A.4.2.13.3 Conclusion

The objective for this zone is to prevent a fire within the zone from spreading to other zones. This objective is achieved through barriers and the provision of an early-warning detection system, manual water hose stations, and portable fire extinguishers.

Division I will be used to achieve plant safe shutdown for a fire in this zone.

No protective envelope is required in this zone.

9A.4.2.14 Ventilation Equipment Area, Fire Zone 13AB, El. 659 Ft 6 In.

9A.4.2.14.1 Description

This zone, shown in Figure 9A-9, consists of one room. It is bounded on the north by the control room Fire Zone 09AB; on the east by the turbine building; on the south by an outside wall; and on the west by the reactor building.

This zone houses the reactor/auxiliary building ventilation system exhaust unit.

The walls surrounding this zone and the floor of this zone are constructed of reinforced concrete having a fire-resistance rating of 3 hr. Penetrations through rated walls and floors are sealed to provide 3-hr fire-resistance ratings. Dampers FO-85 and FO-90 are 1.5-hr-rated dampers while FO-81A and B, FO-82A and B, FO-83A and B, and FO-84A and B are two 1.5-hr-rated dampers in series. These dampers are located in the zone's west and north 3-hr boundary walls but are acceptable because of low fire loading and the presence of fire detection. Fire damper FO-90 is located in a wall separating Fire Zone 13AB from a pipe/HVAC duct chase in the southwest corner. Fire damper FO-85 is located in the wall separating the control room (Fire Zone 09AB) from Fire Zone 13AB. The floor also has a metal hatch cover which will prevent the propagation of fire. The subject steel hatch cover has been evaluated as adequate, as a part of the fire barrier between Fire Zones 11ABE and 13AB, to prevent the propagation of fire based on the physical configuration of the subject hatch cover in the ceiling/floor, the very low combustible loadings, the fire detection provided in both Fire Zones, the automatic suppression system provided in Fire Zone 11ABE and the control of transient combustibles in procedures. The ceiling is constructed of reinforced concrete and contains unprotected hatches and unsealed penetrations, except that all electrical and piping penetrations are sealed to provide a 3-hr fire barrier for that portion of the ceiling separating this zone from Fire Zone 14AB at Elevation 677’-6” and the reactor building southeast access stairs at Elevation 677’-6”. Cable tray penetrations are provided with fire stops. A radiant energy shield of 1-hr fire-rating construction has been installed from floor to ceiling on the west side of the room, the southwest corner wall of the northwest stairwell, south to approximately 3 ft beyond the south end of the Division II testability cabinets.

The pipe chase is a 12-in. concrete block wall (3-hr equivalent). The wall separating the main control room from the fourth floor auxiliary building is reinforced concrete and has a 3-hr fire rating.

The stairwell in the northwest quadrant of the zone is enclosed by a 3-hr-rated barrier with a Class A door that opens to the reactor building's Fire Zone 09AB.

Ventilation for this building area is provided by the reactor/ auxiliary building ventilation system. Supply and exhaust air is ducted to and from this area.

Shutdown equipment in this zone consists of Divisions I and II cables, and Divisions I and II instrument racks.

Fire detection equipment located in this zone consists of an ionization detection system. Fire suppression equipment consists of manual water hose stations and portable fire extinguishers, as shown in Figure 9A-9.

9A.4.2.14.2 Analysis

Shutdown is achieved from outside the main control room. Safe-shutdown capability for the zone is achieved by use of the alternative shutdown system.

Combustibles located within this zone consist primarily of electrical insulation. Total zone fire loading is low.

A radiant energy shield from floor to ceiling has been installed to separate the Divisions I and II equipment from a common heat source.

9A.4.2.14.3 Conclusion

For fires in this zone, the alternative shutdown system will be used to achieve plant safe shutdown.

The objective for this zone is to prevent a fire from spreading to another Fire Zone. This objective is achieved through adequate spatial separation, low fire loading, rated barriers, and the provision of early-warning detection, manual water hose stations(s), and portable fire extinguishers.

9A.4.2.14.4 Deviations

Deviations have been approved for the following:

a. Lack of automatic suppression based on a 1-hr radiant energy shield being installed in front of the cabinet (Reference 1, SSER No. 5 VI [16]).

b. Installation of 1-1/2-hr fire-rated dampers in 3-hr fire-rated barriers based on negligible fuel load and early-warning detection on each side of the barrier (Reference 1, SSER No. 5 III.B).

9A.4.2.15 Control Room Ventilation Equipment Room and Standby Gas Treatment Rooms, Fire Zone 14AB, El. 677 Ft 6 In.

9A.4.2.15.1 Description

This zone, shown in Figure 9A-10, consists of five rooms located in the northern half of Elevation 677 ft 6 in. of the auxiliary building. It is bounded on the north by an outside wall; on the east by the turbine building; on the south by the ventilation equipment room; and on the west by the reactor building.

This zone houses the SGTS charcoal filter units and the control center ventilation equipment.

The walls surrounding this zone are constructed of reinforced concrete. The east and west boundary walls are rated as 3-hr fire barriers. A 1-hr-rated fire barrier with Class A fire doors separates Division I and II air conditioning equipment. A 1-hr-rated fire barrier separates Divisions I and II cables. Penetrations through rated walls are sealed to provide a fire resistance equivalent to the walls in which they are located. The floor is constructed of reinforced concrete and provides a 3-hr fire-rated barrier. Electrical and piping penetrations in the floor are sealed. Ducts are encased by 3-hr-rated fire barriers. Dampers FO-99, FO-100, FO-101, and FO-102 are 1-1/2-hr rated fire dampers. These dampers separate the control room from this zone. The dampers are acceptable because of low fire loading and the presence of fire detection (see SSER No. 5). The ceiling is constructed of reinforced concrete over unprotected steel.

Ventilation for this zone is provided by the control center air conditioning system (CCACS). Conditioned air is supplied through ducts to the control room air conditioning equipment room and by an extension of the duct to the north standby gas treatment room. Exhaust air from the control room air conditioning equipment room is drawn through a return duct opening to the control center air-conditioning units located in the room. Additionally, local cooling and recirculation units in the control room air conditioning equipment room maintain suitable room ambient temperature when the CCACS is operating in the emergency recirculation mode. During operation in the emergency recirculation mode, flows of supply and return air to and from the control center air conditioning equipment room are stopped. There are 1.2 air changes per hour.

A fire in either ventilation equipment room may result in closure of fire damper T4100F903. This damper is located in common ductwork on the discharge of the Division I and Division II CCACS return air fans and is part of the 3-hour fire barrier between the ventilation equipment room and the Control Room. Closure of this damper will result in loss of CCACS return air flow for both divisions and will result in a reduction of cooling air flow to the various ventilation zones served by the CCACS. Once the fire is extinguished, plant procedures have been established to detect closure of fire damper T4100F903 and to manually open it to reestablish the return air flow path. There is sufficient time to open the damper and to start the CCACS Division that did not experience the fire prior to exceeding maximum temperature limits in the zones served by the CCACS.

This zone contains the following shutdown equipment:

a. Division I and II control center air conditioning equipment

b. Divisions I and II control and power cables for control center HVAC fan coil units and drywell pneumatics.

Cable trays 1P-070 and 1C-037 are provided with a 1-hr rated fire barrier within the Division II control center ventilation equipment room when they are within 20 ft of their redundant cables.

Fire detection equipment located within this zone consists of an area ionization detection system. Fire suppression equipment located in this zone consists of an automatic low-pressure CO_2 system for the SGTS charcoal filters, manual water hose stations, and portable fire extinguishers, as shown in Figure 9A-10.

9A.4.2.15.2 Analysis

Shutdown is achieved from the main control room.

Combustibles located within this zone consist primarily of the following:

a. Lubricating oil

b. Charcoal filter material

c. Electrical insulation

Area fire loading is low.

9A.4.2.15.3 Conclusion

Division I will be used to achieve plant safe shutdown for fires in the Division II control center ventilation equipment room and standby gas treatment rooms.

Division I cable trays required for safe shutdown are protected with a 1-hr rated fire barrier when in the Division II control center ventilation equipment room.

Division II will be used to achieve plant safe shutdown for fires in the Division I control center ventilation equipment room.

The objective for this zone is to prevent a fire in the zone from spreading to another Fire Zone and from affecting both Divisions I and II equipment located within the zone. The objective is achieved through fire barriers, low fire loading, and provision of an early-warning detection system, automatic CO_2 fire suppression equipment, manual water hose stations, and portable fire extinguishers.

9A.4.2.15.4 Deviations

Deviations have been approved for the lack of automatic suppression based on 1-hr wrap being provided and low combustible loading (Reference 1, SSER No. 5 VI [9]).

9A.4.2.16 Ventilation Equipment Area, Fire Zone 15AB, El. 677 Ft 6 In.

9A.4.2.16.1 Description

This zone, shown in Figure 9A-10, consists of one room comprising the southern half of Elevation 677 ft 6 in. of the auxiliary building. It is bounded on the north by Fire Zone 14AB; on the east by the turbine building; on the south by an outside wall; and on the west by the reactor building.

The walls surrounding this zone are constructed of reinforced concrete. The east and west bounding walls are rated as 3-hr fire barriers. Penetrations through these walls are sealed to provide 3-hr-rated fire barriers. The door opening leading to the reactor building is protected by a Class A fire door. The floor is constructed of reinforced concrete with unprotected openings. Cable tray penetrations are provided with fire stops. The ceiling is constructed of reinforced concrete over unprotected steel. Ventilation for this zone is provided by the reactor/auxiliary building ventilation system. Supply air is ducted directly to the zone. Exhaust air is ducted to the auxiliary building main exhaust system.

Refer to Subsection 9A.4.2.3.1 for a discussion of the open chase from the mezzanine and cable tray area on the 603’-6” elevation (Fire Zone 02AB) and this area. The opening is located along column H between 10 and 11.

Shutdown equipment located in this zone consists of Divisions I and II HVAC equipment and cables.

Fire detection equipment located in this zone consists of an ionization detection system. Fire suppression equipment located in this zone consists of a manually actuated water flooding system for the charcoal filters, manual water hose stations, and portable fire extinguishers as shown in Figure 9A-10.

9A.4.2.16.2 Analysis

Shutdown is achieved from the main control room. For a fire in this zone, Division II safe shutdown capability is maintained/protected by the installation of isolation devices (fuses) for Division II associated circuits within the zone.

Combustibles located in this zone consist primarily of charcoal filter material and electrical insulation. Total zone fire loading is low.

9A.4.2.16.3 Conclusion

The objective for this zone is to prevent the spread of a fire within this zone to another zone and from affecting both Divisions I and II equipment located within this zone. This objective is achieved through low fire loading and provision of early-warning detection, a manual water flooding system, manual water hose stations, and portable fire extinguishers and isolation devices.

9A.4.2.16.4 Deviations

Deviations have been approved for the lack of automatic suppression based on a 1-hr rated fire barrier, low combustible loading, and charcoal filters having a suppression system(s) (Reference 1, SSER No. 5 VI [7]).

9A.4.3 Residual Heat Removal Complex

9A.4.3.1 General Description

The RHR complex, shown in Figures 9A-13 through 9A-17 inclusive, is a separate reinforced-concrete structure located 230 ft west of the reactor building. The complex is divided at its east-west centerline by a reinforced-concrete wall that has a minimum fire-resistance rating of 3 hr. Each half of the complex contains essentially the same equipment with Division I equipment in the southern portion and Division II equipment in the northern portion of the complex.

Each half of the complex houses a reservoir, cooling tower and service water pump and equipment rooms which comprise the plant's ultimate heat sink. Each half of the complex also houses one set of emergency diesel generators (EDGs), diesel-fuel-oil storage tanks, and switchgear, which are utilized to provide ac power to the plant during a loss of offsite power.

Rated walls, floors, and ceilings are constructed of reinforced concrete having a fire-resistance rating of 3 hr. Doors in rated walls are Class A fire doors. Penetrations in rated walls, floors, and ceilings are sealed.

Floor drains in rooms containing oil are connected to a common manway which is connected by an overflow line to the liquid waste holding pond. Floor drains in other rooms are connected to a different manway which is connected by an overflow line to the circulating water reservoir.

Ventilation for the north diesel generator rooms is provided by outside air drawn by two fans through a louver in the west wall above the 617 ft 0 in. elevation and from there through a motorized outside air damper in the west wall of the fan room at the same elevation. Each diesel room is then supplied by two fans located above the 617 ft 0 in. elevation. Air is relieved through grating in the diesel room ceiling and then through a motorized damper back to the fan room.

Ventilation for the north service water pump room is provided by outside air drawn through a filter plenum by two fans and distributed to the pump room by ductwork along the room's west wall. Room air is relieved through the roof in the northeast and southeast corners of the room. The filter plenums are located at grade along the northeast and southeast corners of the complex.

Ventilation supply air for the north diesel-fuel-oil storage room is drawn by room exhaust fans through an opening in the north CO_2 storage room wall. Exhaust air from the north diesel-fuel-oil storage room is fan exhausted through ducts.

Ventilation for the north CO_2 storage room is provided by continuous exhaust through the space. Exhaust air from the EDG room enters through dampers in the east wall. Exhaust air leaves the room through a damper located in the west wall of the room.

The north switchgear room and ventilation equipment rooms are cooled by outside air. The switchgear room ventilation air is drawn through a filter plenum by two fans and is distributed to the switchgear room by ductwork located along the west wall. This air also supplies the switchgear ventilation equipment room through an outlet in the supply duct main. Air is relieved from the switchgear room through two separate relief openings in the west wall of the room. One of these openings relieves to the switchgear ventilation equipment room. The second of these openings relieves to an air relief room and the EDG room. Air is relieved from the air relief room through dampers to the outside or to the diesel equipment room for recirculation.

The north ventilation equipment room is ventilated by ducted exhaust air from the diesel-fuel-oil storage tank room.

The north diesel generator air intake filter area is ventilated by outside air drawn through fixed louvers located in the west wall by the switchgear and diesel room ventilation fans. Air flows from the louvers, along the west wall housing the diesel intake filters, to the west wall of the switchgear and diesel room ventilation equipment rooms.

Ducts or openings penetrating rated walls are provided with fire dampers.

Ventilation of the south portion of the RHR complex is the same as that for the north portion of the complex. There are no interconnections between north and south ventilation systems.

Shutdown equipment located in the RHR complex consists of the following Divisions I and II equipment:

a. EDGs and auxiliary equipment

b. EDG fuel-oil storage tanks, day tanks, and transfer pumps

c. RHR service water pumps

d. EESW pumps

e. EDG service water pumps

f. RHR complex ventilation equipment

g. RHR cooling towers

h. Switchgear and MCCs.

Fire detection equipment provided in each half of the RHR complex consists of ionization detection systems for the service water pump rooms, switchgear rooms, and ventilation equipment rooms. Fire suppression equipment consists of an automatic, low-pressure CO_2 system in the EDG rooms, automatic sprinkler systems in the fuel-oil storage tank rooms, and portable fire extinguishers and manual water hoses throughout the complex, as shown in Figures 9A-13 through 9A-15.

NFPA 13 noncompliances with these sprinkler systems include location of sprinklers in excess of the maximum allowable distance below the ceiling and distance between some sprinklers under tanks in excess of the maximum allowable distance for extra hazard occupancies (in addition to those discussed and evaluated in 9.5.1.2.3.3). These noncompliances would not prevent the sprinkler systems from fulfilling their required function of controlling a fire and confining it to the room of origin.

9A.4.3.2 Analysis

Shutdown is achieved from the main control room, using Division I systems for a fire in the north half of the RHR Complex and Division II systems for a fire in the south half of the RHR Complex. Divisions I and II equipment is separated by a 3-hr-rated fire barrier.

Fuel-oil storage within the complex represents a specific fire hazard. Tanks are surrounded by rated walls to contain oil in the event of a tank rupture. In addition, tanks can be remote manually drained. Further details are discussed in Subsection 9.5.4. Fuel oil accounts for the major portion of combustible materials. Other combustibles consist primarily of electrical insulation and lubricating oil. The total fire loading for each half of the complex is greater than the high classification.

Because diesel fuel oil is delivered to the valve station near the northwest corner of the RHR complex at regular intervals, the unlikely possibility exists for a catastrophic failure of one of these delivery trucks resulting in an oil spill fire in close proximity to the RHR complex itself. It should be noted plant personnel escort the truck at all times when it is being driven within the protected area and will provide prompt notification of an oil spill/fire.

The actual exposure fire threat to the RHR complex from an oil spill fire such as described above is very low. The exterior walls are constructed of reinforced concrete with an equivalent fire resistance rating of at least three hours. All openings in the exterior walls above elevation 590′-0″ (which is six feet above grade level and the possible oil spill/fire) are protected by heavy steel plates/doors or are within the reinforced concrete RHR cable vaults. All safety related equipment and cables in the RHR complex are located on or above elevation 590′-0″. Four overflow pipe penetrations are provided below elevation 590′-0″. These openings are not provided with any type of covering. However, there are no combustibles in the RHR complex below the 590′-0″ elevation; thus flame propagation through these openings is not postulated. Finally, any heat postulated to enter the complex via the air intakes or non fire rated penetration assemblies will be quickly dissipated by the HVAC system.

The north side of RHR complex, near a postulated fire at the valve station only contains Division II equipment therefore, no credible exposure to both divisions exists and, Division I equipment would be available for safe shutdown.

Because no other combustible materials are stored or located adjacent to the RHR complex, a diesel fuel oil fire is considered the worst case transient combustible exposure fire that the RHR complex could be postulated to receive therefore, the plant's ability to achieve and/or maintain safe shutdown would not be adversely affected by an exposure fire to the RHR complex.

9A.4.3.3 Conclusion

The objective for the RHR complex is to prevent a fire in one half of the complex from spreading to the other half of the complex. This is accomplished by the rated fire barrier between halves of the complex, existing fire detection and suppression equipment, and the ability to drain fuel oil from the storage tanks to a remote area.

9A.4.4 Radwaste Building

9A.4.4.1 General Description

The radwaste building is structurally part of the turbine building and has, for purposes of this fire hazards analysis, been designated as a single, separate fire area. The building is bounded on the north by an outside wall, on the south and west by the turbine building and office and service building, and on the east by the onsite storage building.

The radwaste building houses the liquid and solid waste processing equipment.

The walls, floor, and ceiling are constructed of reinforced concrete and concrete block. Door openings to the turbine building are equipped with Class A, B, and C fire doors. Penetrations through walls of the turbine building and office service building are sealed to provide a 3-hr barrier. Cable trays passing through floors are fire stopped.

The alternative/dedicated shutdown system panels are located on the second floor of this building.

Shutdown equipment contained in this zone consists of the following:

a. Offsite power cables affecting CTG 11-1 feed to standby feedwater

b. RHR Instrumentation equipment and cable

c. Standby feedwater and CTG 11-1 equipment and cable

Fire detection equipment consists of thermal, photoelectric, and ionization type fire detection instruments throughout the building for early warning. Fire suppression equipment for the radwaste building consists of an automatic sprinkler system for the chemical stores room, the two oil-coalescer rooms, the extruder-evaporator room, the drum-turntable room, the drum-capper room, the drum-transfer-conveyor room (all on the first floor), and the main corridor, the drum-conveyor room, the main corridor west of the drum decontamination room and storage room (both on the third floor); an automatic deluge system for the roof-mounted voltage regulator; Clean Agent extinguishing systems for various administrative areas; and a manual hose and portable fire extinguishers. The radwaste building ventilation system is completely separate from other plant areas or buildings.

9A.4.4.2 Analysis

Shutdown is achieved from the main control room using either Division I or Division II systems. The building is separated from the turbine and the office service buildings by 3-hr-rated fire barriers, except for the opening placed in the south wall of the radwaste building which has wet pipe sprinkler protection installed to separate the office and service building fire zone from the new storage area. The fire barrier separating the Radwaste and Turbine Buildings contains class A, B, and C fire doors. The class B fire doors were constructed without windows and in the exact same manner as class A doors; and are therefore considered equivalent to class A doors. The three (3) class C (3/4 hour fire rated) doors are located along column line K at elevation 583’-6” and form part of the separation between the Radwaste Building control room and office area and the Turbine Building. Because the office and control room area is provided with automatic fire detection and the combustible loading on both sides of these doors is low, these doors do not prevent the fire barrier separating the Turbine and Radwaste Buildings from performing its intended design function. Therefore, fire in this building will not affect plant safe-shutdown capability because of the separation and isolation of plant equipment. This arrangement meets the system interface requirements of BTP-CMEB 9.5-1.

Inadvertent operation of automatic fire suppression systems provided for this fire area will have no adverse effect on the ability to shut down the plant. The floor drain system is contained within the building; therefore, combustible liquid spills cannot travel outside the radwaste building.

Combustibles within the radwaste building have been protected by automatic suppression systems as noted in Subsection 9A.4.4.1.

The Conveyor system area of the radwaste building is converted to a storage are. It is isolated from the radwaste building with 3-hr rated fire walls. A cutout in the south wall connects this room to the office and service building. A sprinkler curtain was installed on both sides of the cutout. Effectively, this room is part of the office and service building. Therefore, the radwaste building compliance with Branch Technical Position APCSB 9.5-1 is not impacted by this change.

9A.4.4.3 Conclusion

A fire in the radwaste building will not adversely affect plant shutdown. The 3-hr fire-resistance rating of the walls separating the turbine and the office and service buildings from the radwaste building is adequate, based on the fire hazards and the protection provided for the specific fire hazards in the radwaste building.

9A.4.5 Turbine Building

9A.4.5.1 General Description

The turbine building, which for purposes of this fire hazards analysis includes the steam tunnel and a portion of the auxiliary building at Elevation 583 ft 6 in., comprises one fire area. This fire area is bounded on the north by the radwaste building; on the east by the office and service buildings; on the south by an outside wall; and on the west by the auxiliary building, reactor building, and transformer area.

The west wall of the turbine building is a 3-hr-rated barrier below elevation 679′-6″. This rated barrier serves to protect the turbine building from an exposure fire originating in one of the adjacent oil-filled transformers. In addition, fixed automatic water spray systems are provided for these transformers to reduce their exposure fire hazard. Therefore, the turbine building is adequately protected from a transformer oil exposure fire.

The turbine building houses the turbine generator and related auxiliary equipment. Also located in the turbine building is equipment for the condenser offgas system.

Walls separating the turbine building from other buildings are constructed of reinforced concrete and concrete block. These walls have a 3-hr fire-resistance rating. Doorways in boundary walls separating the turbine building from the auxiliary and reactor buildings are equipped with Class A fire doors. As detailed in Section 9A.4.4.2, doorways in boundary walls separating the turbine building from the radwaste building contain class A, B, and C fire doors. All other penetrations in these boundary walls are sealed to provide 3-hr-rated fire barriers except for the pressure equalizing line between the first floor of the reactor building and this Fire Zone. The ability of the fire barrier to perform its function has been evaluated and determined to provide an adequate assurance that a fire in this Fire Zone will not propagate to the reactor building first floor. Two penetrations in the west wall at approximately 603 ft elevation that contain the Calvert Cable Buses are not sealed with a tested configuration design. However, the lack of combustibles in the area adjacent to and below these openings, the configuration of the Calvert Cable Buses and the rated seals on the auxiliary building wall have been evaluated and provide adequate assurance that a fire in the turbine building will not propagate through these penetrations into the auxiliary building. The floor penetrations in the steam tunnel are provided with a non-tested configuration in the fire rated separation barrier. These seals have been evaluated and provide an adequate assurance that a fire in the Reactor Building Fire Zone 01RB will not propagate through these penetrations into the steam tunnel, or from the steam tunnel to the reactor building.

Safe shutdown equipment consists of the following:

a. Offsite power cables affecting CTG 11-1 feed to standby feedwater

b. Standby feedwater and CTG 11-1 equipment and cables

c. HPCI and RCIC cables, Division I and Division II

d. RHR instrumentation cables

e. HPCI and RCIC equipment and cables, Division I and Division II, in the TB Steam Tunnel

Fire suppression equipment is provided as follows:

a. Automatic water sprinkler systems for the reactor feed pump turbines and turbine-oil reservoir, main lube-oil reservoir, oil storage and turbine-oil tank rooms, the second floor pipe space, and the equipment hatch area and decontamination room on the first floor

b. Automatic water deluge systems for the hydrogen seal oil unit.

In addition to the above automatic systems, manual fire hoses and portable fire extinguishers are provided.

9A.4.5.2 Analysis

Shutdown is achieved from the main control room. Division II is used to achieve shutdown in the turbine building, except for the steam tunnel. In the turbine building steam tunnel, Division I is used to achieve safe shutdown.

Combustibles within the turbine building are typical for a turbine generator complex. The major fire hazard in this fire area is the large quantity of oil required for turbine bearing lubrication and the oil required for the generator hydrogen seals. This hazard is protected against by the fixed suppression systems noted in Subsection 9A.4.5.1.

Inadvertent operation of automatic fire suppression systems provided for this fire area will have no adverse effect on the ability to shut down the plant.

There are no combustibles in the steam tunnel. The major source of fire in the turbine building is remotely located from the valves in the steam tunnel. This distance, coupled with the fixed fire suppression systems provided, protects against a fire hazard to equipment in the steam tunnel. In addition, both shutdown valves (RCIC and HPCI pump discharge isolation valves) are backed up by the automatic depressurization, LPCI, and core spray systems.

The HWC System introduces hydrogen into the turbine building through supply piping at the north end. This piping is routed along the inner east and north walls of the turbine building, bordering the radwaste building. A barrier installed between the northeast stairwell and the hydrogen skid assembly will provide protection for personnel using the stairs in the event of a fire. The elevator shaft is enclosed by a 12-inch thick hollow concrete block wall, which will provide protection and prevent the spread of a fire into the shaft. The quantity of hydrogen which could be released into the turbine building in the event of a pipe break will be limited to that amount contained in the 1.5-inch hydrogen piping (between the upstream automatic isolation valve module and the downstream automatic isolation valves on the injection skid; these will all close on detection of high hydrogen levels). These valves are located inside the turbine building, and will isolate the piping in the building from the hydrogen supply facility. Because of the highly flammable nature of the gas, local area monitors are installed above each heater feed pump injection point, at the hydrogen skid assembly, and at the isolation module at the turbine building entrance. The detection of small amounts of hydrogen (about 1% concentration in air) will result in a local alarm at the HWC control panel, and the detection of levels above 2% in air will result in a system trip and isolation. Since the flammability limit is 4% hydrogen in air, the leak detection system should provide isolation before a flammable mixture can result.

9A.4.5.3 Conclusion

A fire emergency in the turbine building would not adversely affect the ability to shut down the plant. The 3-hr fire- resistance rating of the walls separating the auxiliary, reactor, and radwaste buildings from the turbine building is adequate, based on the fire hazards and the protection provided against specific fire hazards in the turbine building.

9A.4.5.4 Deviations

Deviations for the steam tunnel have been approved for the following:

a. Lack of automatic suppression based on negligible fuel load, heat monitoring instrumentation in place of detectors, and 7 ft separation of redundant valves (Reference 1, SSER No. 5 VI[8]).

b. Lack of 20 ft separation (Reference 1, SSER No. 5 VI).

9A.4.6 Office and Service Building

9A.4.6.1 General Description

The office and service building is primarily a single story structure; however, the office portion of this building consists of two stories. For purposes of this fire hazards analysis, the office and service building has been designated as a single fire area. This building is bounded on the north by a portion of the radwaste building and an outside wall; on the east and south by outside walls; and on the west by the turbine building.

Housed within the office and service building are office spaces, locker rooms, kitchen and dining areas, shops, and warehouse space.

The walls separating this building from adjoining buildings are constructed of reinforced concrete. Penetrations in these walls are sealed to provide a fire stop. Doorways to adjoining buildings are equipped with metal doors, except for the opening placed in the south wall of the radwaste building which has wet pipe sprinkler protection installed to separate the office and service building fire zone from the new storage area.

Shutdown cables contained in this area include cables associated with diversion of inventory from the Condensate Storage Tank, which is the source of water for the SBFW pumps.

Fire suppression equipment for this fire area consists of an automatic water pre-action sprinkler system for the warehouse loading dock, an automatic water sprinkler system in the office storage and fill areas, tool crib and warehouse, and manual hose and portable fire extinguishers.

9A.4.6.2 Analysis

Safe shutdown is achieved from the main control room using Division I or Division II systems. Shutdown cables lost are associated with SBFW. The SBFW system is not required for a fire in the Office and Service Building. The building is separated from adjacent buildings by fire barriers. Along the northern boundary of the OSB on elevation 589’-6”, row line 13A between column lines S and V, there is an unrated opening to the Radwaste building. This opening has an automatic water curtain sprinkler system installed around it to prevent the passage of fire from one zone into the other. This along with the Radwaste and Office and Service Buildings automatic sprinkler systems, early warning fire detection, and low combustible loading in the vicinity of the opening justify that the unrated boundary is acceptable. Additionally, the adjacent buildings house no shutdown equipment nor is there shutdown equipment nearby.

Inadvertent operation of automatic fire suppression systems provided for this fire area will have no adverse effect on ability to shut down the plant.

Combustibles within the office and service buildings have not been quantified since they consist primarily of transient materials typical of office and service buildings.

9A.4.6.3 Conclusion

The objective for this fire area is to prevent fire in this building from jeopardizing the ability to shut down the plant. This objective is achieved by adequate separation from shutdown equipment by barriers, use of automatic, partial coverage fire suppression systems, and manual hose and portable fire extinguishers.

9A.4.7 Yard Area

9A.4.7.1 General Description

The yard area, shown in Figure 9A-1, includes the open areas of the plant site not occupied by buildings. Equipment located in this area includes, but is not limited to, the following:

a. Condensate storage tanks

b. Auxiliary boiler fuel-oil storage tank

c. Auxiliary boiler house

d. Transformers

e. Storage facility for hydrogen

f. Underground safety related cable ducts

g. HWC gas supply facility

h. CTG 11-1 and auxiliaries and 120 kV Mat Equipment located at Fermi 1

i. Offsite power cables affecting CTG 11-1 feed to SBFW

j. Egress area between Reactor Building and RHR complex

See the following subsections for individual analyses of each of the above.

9A.4.7.2 Condensate Storage Tanks

9A.4.7.2.1 Description

The condensate storage tanks are located approximately 100 ft east of the services building and approximately 112 ft south of the auxiliary boiler house.

The tanks are located inside a lined diked area which is designed to collect the contents of a tank spill/overflow. The dike around the tanks is a three foot high concrete wall.

These tanks are used as the supply of water for SBFW, HPCI and RCIC. HPCI and RCIC pumps can be supplied from the suppression pool as another source of water. Fire suppression equipment in this portion of the yard area consists of a fire hydrant, supplied from the fire service water system, and manual hose.

9A.4.7.2.2 Analysis

Shutdown is achieved from the main control room using either Division I or Division II systems. One of the two condensate storage tanks and associated level instrumentation are used for shutdown operations using HPCI or RCIC. However, should the tanks be damaged as a result of fire, the suppression pool can be used as an alternative water source. SBFW does not have another water source. Safe shutdown for the fires in the yard where these tanks could be damaged does not rely on SBFW.

The three foot high concrete wall surrounding the condensate storage tank (to contain the tank contents) will prevent an exposure fire or the heat from an exposure fire in the yard area adjacent to the storage tanks from affecting the tanks themselves. This includes a postulated oil spill/fire due to a catastrophic failure of an oil truck enroute to the RHR complex. In the case of the oil truck, the concrete walls will prevent the burning oil from getting within 25 feet of the storage tanks. In addition, the oil truck is escorted by plant personnel (while the truck is being driven within the protected area) who will promptly notify the Control Room in the event of an oil spill/fire.

9A.4.7.2.3 Conclusion

The objective for this portion of the yard area is to prevent damage to the condensate storage tanks as a result of fire in nearby equipment or buildings. The minimum spatial separation (approximately 100 ft) between these tanks and nearby buildings is adequate. The objective is achieved by this spatial separation and provision of manual fire protection equipment. Additionally, an alternative source of water is provided through connections between the suppression pool and the RCIC, HPCI, low pressure coolant injection (LPCI), and core spray systems.

9A.4.7.3 Auxiliary Boiler Fuel-Oil Storage Tank

9A.4.7.3.1 Description

The auxiliary boiler fuel-oil storage tank is located approximately 200 ft from the service building and approximately 100 ft north of the auxiliary boiler house.

This tank is above ground and surrounded by a dike; therefore, should leakage occur, it would be contained in the diked area.

This tank is not shutdown equipment.

Fire suppression equipment in this portion of the yard area consists of a fire hydrant, supplied by the fire service water system, and manual hose.

9A.4.7.3.2 Analysis

Since this tank is not required for shutdown operation, functional redundancy is not a consideration. Separation by more than 200 ft between this tank and the condensate storage tanks is adequate.

9A.4.7.3.3 Conclusion

The objective for this portion of the yard is to prevent fire in this area from spreading to buildings housing shutdown equipment. This objective is achieved by a dike surrounding the tank, the remote location of the tank, and the fire hydrant in the vicinity.

9A.4.7.4 Auxiliary Boiler House

9A.4.7.4.1 Description

The auxiliary boiler house is located approximately 90 ft east of the service building and approximately 110 ft north of the condensate storage tanks.

This structure houses the auxiliary boiler. The auxiliary boiler is not required for shutdown.

Fire suppression equipment in this portion of the yard area consists of a fire hydrant, supplied from the fire service water system, and manual hose.

9A.4.7.4.2 Analysis

Shutdown is achieved from the main control room using either Division I or Division II systems. Since the auxiliary boiler is not required for safe shutdown, functional redundancy is not a consideration. Separation of this building from other buildings is adequate.

9A.4.7.4.3 Conclusion

The objective of this portion of the yard area is to prevent a fire in the auxiliary boiler house from spreading to other buildings or adversely affecting the condensate storage tanks. This objective is achieved by spatial separation and the fire hydrant in the vicinity.

9A.4.7.5 Transformers

9A.4.7.5.1 Description

Transformers are located in a portion of the yard area adjacent to the west wall of the turbine building and south of the auxiliary building. The main and auxiliary transformers are located in this area, which is surrounded on the north, south, and west sides by a curb to contain any oil leakage from the transformers. Fire barriers are provided between the transformers.

Except for SS #64, none of these transformers are necessary for shutdown operation since required electrical power can be supplied by the EDGs. SS #64 is utilized as part of the SBFW power supply from CTG 11-1 to the SBFW pumps.

Fire suppression equipment for this portion of the yard area consists of automatic deluge systems for the transformers. Fire hydrants, supplied from the fire service water system, and manual hose are also provided.

9A.4.7.5.2 Analysis

Shutdown is achieved from the main control room utilizing either Division I or Division II. SS #64 can affect the ability to power SBFW pumps from the CTG, but SBFW is not necessary for shutdown in the yard area. Since the transformers located in this portion of the yard area are not required for shutdown, functional redundancy is not a consideration. Separation is adequate in light of the fire suppression systems provided.

9A.4.7.5.3 Conclusion

The objective for this portion of the yard area is to prevent a fire spreading from this area to other buildings or yard areas containing shutdown equipment. This objective is achieved by automatic deluge systems, fire hydrants, and a curb around three sides of the area (the turbine building west wall encloses the fourth side).

9A.4.7.6 Hydrogen Storage Facility

9A.4.7.6.1 Description

The hydrogen storage area is located approximately 80 ft south of the turbine building.

Hydrogen is not required for shutdown.

Fire suppression equipment for this area consists of fire hydrants, supplied from the fire service water system, and manual hoses.

9A.4.7.6.2 Analysis

Shutdown is achieved from the main control room using either Division I or Division II systems. Spatial separation of this area from buildings containing shutdown equipment is adequate. Additionally, gas storage cylinders in this storage area are oriented to minimize the probability of striking a safety-related building should an explosion occur.

9A.4.7.6.3 Conclusion

The objective is to prevent fire in the hydrogen storage area from causing damage to shutdown equipment in other buildings. This objective is achieved by the remote location of the hydrogen storage area, the orientation of gas storage cylinders away from safety-related buildings, and fire hydrants in the vicinity.

9A.4.7.7 Underground Safety Related Cable Ducts

9A.4.7.7.1 Description

There are two sets of Category I 4160-V ductbanks between the RHR complex and the Reactor/Auxiliary building, with a Division I and Division II ductbank in each set.

The first set of ductbanks was installed during plant construction. These two underground safety related cable ducts run parallel to each other and carry safe shutdown cables between the RHR complex and the Auxiliary Building cable vault. The most northerly duct carries Division II safe shutdown cables while the other carries Division I safe shutdown cables. The cables in each of these ducts are routed in approximately 30 fiber pipes. The spaces between and around these pipes are filled with approximately 3″ of concrete and the entire structure is reinforced with steel.

Each of the ducts is provided with a manhole structure which is also of reinforced concrete construction and an integral part of the duct. The opening which is approximately 30″ in diameter, is covered by a tight fitting malleable iron cover with cast iron ring. These underground ducts are separated by at least 10′ of soil and are covered by at least 2 feet of soil. The top of the manhole structures are approximately one foot below grade and the manhole covers are covered with soil and gravel.

Immediately adjacent to each manhole is a handhole structure, which is physically independent of the manhole structure but it does become part of the underground duct as it ties into it on both sides of the manhole structure. These handholes provide access to communication cables which are separated by concrete from fiber pipes carrying safety related cables.

The second set of ductbanks and associated manholes is installed above the maximum ground water elevation of 576.0 ft with ducts sloped to the manholes, such that circuits contained are not subject to continuous wetting. These are cast-in-place, rectangular reinforced concrete ductbanks, located with the ductbank top approximately six inches below the surface and manhole covers at grade level. The spaces around the ducts are filled with a minimum of five inches of reinforced concrete. The portion of the ductbanks located below the ISFSI Transfer Pad is covered by the two foot thick reinforced concrete roadway and are separated by a minimum of 7'-8" of soil and reinforced concrete. In the balance of the ductbanks, the ducts are covered with a minimum of 12 ½" of reinforced concrete above the ducts and 18" of reinforced concrete along the sides of the outside ducts.

Three manholes are provided in each of the two ductbank runs. The manholes are 8'-0" long x 6'-0" wide (inside dimension) with 18" thick reinforced concrete walls and 16" thick bottom slab/mat. The top of the manholes is at the finished grade elevation. The manhole covers consist of a 12 ½" thick reinforced concrete removable top slab with two equal 4'-6" x 7'-0" overlapping sections. The manhole cover interface surfaces are provided with joint sealant at the vertical surface and an additional gasket at the horizontal surfaces to avoid the entry of water or other fluids.

The ductbanks rise above grade for a length of approximately six feet in an area of thickened reinforced concrete at the entrance to the RHR cable vaults and for a length of approximately thirteen feet at the entrance to the Reactor/Auxiliary building cable vault. At the Reactor/Auxiliary building entrance, the ducts are covered with eight inches of reinforced concrete and a 1" thick steel plate.

Category I ductbanks from manholes 16946C and 16947C to the RHR complex terminate in RHR cable vaults with 18" thick reinforced concrete walls and 12 ½" thick reinforced concrete roofs. The cable vaults have access openings measuring 2'-6" x 2'-6" and covered with 1 ½" thick steel plate in the north and south walls. The RHR cable vaults are separated by 80 feet. The walls extend 6" below grade, which has a cover of approximately six inches of bituminous pavement. The cable vault floors are gravel to allow drainage.

9A.4.7.7.2 Analysis

Shutdown is achieved from the main control room using either Division I or Division II systems. The underground ducts are separated from each other by distance, construction and soil and gravel. A fire involving solid combustibles stored outside the posted area does not pose a threat to the safe shutdown cables within the manholes because of the insulating properties of the soil and gravel or concrete and the fact that most of the heat will be dissipated into the atmosphere. A combustible liquid fire is not a viable threat to cables inside the manholes because the burning liquid will be extinguished due to the absence of oxygen, as it soaks into the soil and gravel over the manhole. The manholes with reinforced concrete slab covers are equipped with barriers on both the vertical and horizontal surfaces to minimize the possibility of liquid entry.

In addition, the top of the manhole structure is a reinforced concrete slab approximately 12″ thick and the manhole opening is covered by either a tight fitting iron plate that lays inside of a cast iron ring or a 12 ½" thick reinforced concrete slab in two overlapping sections, provided with sealant and gaskets.

The RHR cable vaults for Division I and Division II cables are separated by 80 feet and are constructed of reinforced concrete, with steel covers for the access openings.

9A.4.7.7.3 Conclusion

The objective is to prevent a fire in the yard area from impacting the safe shutdown cables in manholes 16946 and 16947, manholes 16946A, B, and C and 16947A, B, and C, or the RHR cable vaults, and to prevent a fire in either divisional manhole or cable vault from spreading to a manhole or cable vault of the other division.. These objectives are achieved by the insulating capabilities of soil, gravel, and concrete and by physical separation (location).

9A.4.7.8 HWC Gas Supply Facility

9A.4.7.8.1 Description

The HWC gas supply facility is located approximately 1100 feet northwest of the nearest safety-related structure (RHR Complex).

Neither the HWC system nor the gases at the supply facility are required for safe shutdown.

Fire suppression equipment in the area includes yard area fire hydrants supplied from the fire service water system and manual hoses. The hydrogen supply system contains fire control valves which will isolate the hydrogen supply in the event of a fire.

9A.4.7.8.2 Analysis

Shutdown is achieved from the main control room using either Division I or Division II systems. The HWC gas supply facility is located far enough away to prevent fires or explosions from affecting safety-related structures and to prevent the formation of combustible mixtures at safety-related intakes in the event of a release of tank contents without fire or explosion. Therefore, the spatial separation of the gas supply facility from buildings containing safe shutdown equipment is adequate.

9A.4.7.8.3 Conclusion

The objective is to prevent fire in the HWC gas supply facility area from causing damage to shutdown equipment in other buildings. The objective is achieved by the remote location of the gas supply facility and yard area fire hydrants.

9A.4.7.9 CTG 11-1 and Auxiliaries, 120 kV Mat Breakers at Fermi 1

9A.4.7.9.1 Description

At the 120 kV mat area of Fermi 1 and the Fermi 1 building, the CTG 11-1 and auxiliaries and certain breakers are used to provide power to SBFW if offsite power is lost to Fermi 2.

Safe shutdown equipment contained in the 120 kV mat and Fermi 1 zones are as follows:

a. CTG 11-1 and CTG 11-1 starting diesel engine
b. Peaker fuel oil storage tank and delivery system to the CTGs

c. 120 kV offsite breakers, 13.8 kV and 13.2 kV breakers

d. Battery power supplies for the CTG, breakers and supervisory control equipment

Fire suppression equipment for this portion of the yard area consists of automatic CO_2 suppression on the CTG units, fire hydrants and manual hose.

9A.4.7.9.2 Analysis

Shutdown is achieved from the Fermi 2 main control room using either Division I or Division II equipment. Damage to the equipment identified above can affect the power supply to the SBFW pumps, but will not cause loss of power to other divisional shutdown equipment. Use of SBFW is not required for a fire in the yard zone involving the CTG 11-1 or Fermi 1.

9A.4.7.10 Offsite Power Cables

9A.4.7.10.1 Description

The power cables from the 120 kV mat breakers to SS Transformer #64 are run in underground cable ducts. The power cables from SS Transform #64 run in an underground cable duct into the cable entry vault outside the auxiliary building Fire Zone 02AB, and then in an enclosed cable bus along the outside of the auxiliary building until it enters the Division 1 Switchgear Room (Fire Zone 04AB). This power train of cables provides power from CTG 11-1 to the SBFW pumps if offsite power is lost.

The power cables from SS Transformer #65 run in an enclosed cable bus along the outside of the turbine building and the auxiliary building until it enters the Division 2 Switchgear Room (Fire Zone 12AB). The offsite power feed from the 345 kV Mat and SS Transformer #65 are not credited for required or system shutdown.

9A.4.7.10.2 Analysis

Shutdown is achieved from the main control room using either Division I or Division II. SBFW is not required for shutdown for fires in the yard that damage either SS Transformer #64 or the enclosed cable bus outside the buildings.

9A.4.7.11 Egress Area between Reactor Building and RHR Complex

9A.4.7.11.1 Description

In the process of shutting down the plant due to a fire using the alternative dedicated shutdown system, the operators cross the yard area to the RHR complex.

9A.4.7.11.2 Analysis

Shutdown is achieved from the main control room using either Division I or Division II systems. The yard area is lighted for safeguard purposes but is not battery-backed.

However, backup power is available from the combustion turbine generator (CTG 11-1 or an alternate CTG using the standby diesel generator) which supplies power for alternative shutdown. An analysis showed that the CTG can provide power for the yard lights required for shutdown without adversely affecting plant safe-shutdown capability.

9A.4.7.11.3 Deviations

Justification for a deviation from the technical requirements of Section III.J of Appendix R has been documented in a deviation approval request letter dated February 20, 1986, for yard lighting from CTGs versus 8-hr battery packs (Reference 4).

9A.4.8 General Service Water Pump House

9A.4.8.1 General Description

The general service water (GSW) pump house consists of a metal-clad steel building founded on a reinforced-concrete intake structure. This structure is located on the west shore of Lake Erie, south of the main group of plant buildings.

This structure houses the circulating water makeup pumps, GSW pumps, and associated mechanical and electrical equipment. Also housed in this structure are the two fire service pumps. One fire service pump is diesel-engine driven; the other, electric-motor driven.

The diesel-engine driven fire service pump is located in a cubicle surrounded by a 3-hr-rated barrier. The doorways between the diesel-engine-driven pump cubicle and the remaining floor area of this building are equipped with Class A fire doors. The roof of this building satisfies Factory Mutual Class I requirements.

No shutdown equipment is located within the GSW pump house.

Fire suppression equipment for the GSW pump house consists of an automatic water sprinkler system for the diesel-engine-driven fire service pump cubicle, manual hose, and portable fire extinguishers.

9A.4.8.2 Analysis

Shutdown is achieved from the main control room using either Division I or Division II systems. The electric-motor-driven and diesel-engine-driven fire service pumps are redundant. Separation of these pumps is accomplished by enclosure of the diesel-engine-driven fire service pump within a 3-hr-rated fire barrier. The electric-motor-driven fire service pump is separated from other equipment by a minimum distance of approximately 15 ft.

The diesel-driven fire service pump fuel-oil tank represents the only significant concentration of combustible material. This tank is located outside, at grade, adjacent to the north wall of the building housing the fire service pumps.

9A.4.8.3 Conclusion

The objective for the GSW pump house is to prevent fire from damaging both fire service pumps. The objective is achieved through location of the diesel-engine-driven fire service pump within a 3-hr-rated fire barrier, the provision of an automatic sprinkler system for protection of this pump, and the outdoor location of the fuel-oil tank.

9A.4.9 Office Building Annex and Technical Support Center

9A.4.9.1 General Description

The technical support center (TSC) is described in Subsection 7.8.1. The remainder of the building is a two-story steel frame office service building. This portion of the building houses office space and a computer room.

No shutdown equipment is located within the office building.

Fire detection equipment consists of an ionization detection system.

Fire suppression for the office building annex consists of an automatic Halon extinguishing system for the computer room and portable extinguishers.

In addition to the suppression systems listed above, an automatic sprinkler system is installed in the TSC's records room.

9A.4.9.2 Analysis

Shutdown is achieved from the main control room using Division I or Division II systems. No shutdown equipment is jeopardized by a fire in the annex portion of the office building. Inadvertent operation of the automatic fire suppression system will have no adverse effect on ability to shut down the plant.

Combustibles within the office portion have not been qualified since they consist primarily of transient materials typical of an office building.

9A.4.9.3 Conclusion

The objective for this area is to prevent fire in this building from jeopardizing the ability to shut down the plant. This objective is achieved by spatial separation from necessary safety systems.

9A.4.10 Onsite Storage Building

This building is described in Section 11.7.

9A.4.11 Outage Building

9A.4.11.1 General Description

The outage building is primarily a two story structure; however, a one story breezeway connects the turbine building with the outage building. For the purpose of fire hazard analysis, the outage building is designated as a single fire area. The outage building is a free standing structure located four inches south of the reactor and auxiliary buildings.

The outage building contains a radiation protection control point area and access into the Plant Radiologically Controlled Area (RCA), as well as lunch room and rest room facilities.

The building is of completely noncombustible construction. The walls separating this building from the safety-related areas of the plant are constructed of reinforced concrete and contain fire rated doors.

No shutdown equipment is located within the outage building. The drywell pneumatic valves and connection lines are located in the yard between the reactor building and the one-story breezeway connecting the turbine building and the outage building.

Fire suppression equipment for this structure consists of a fire hydrant, supplied by the fire service water system, and manual hose. Fire detection is also provided in the outage building.

9A.4.11.2 Analysis

Shutdown is achieved from the main control room using Division I or Division II systems. No shutdown equipment is jeopardized by a fire in the outage building. The building is separated by reinforced concrete walls and fire rated doors from the safety-related areas of the plant.

Combustibles within the outage building have not been quantified since they consist primarily of transient materials consistent with lunchrooms, offices, and protective clothing storage areas.

9A.4.11.3 Conclusion

The object for this zone is to prevent fire from spreading to buildings housing shutdown equipment. This objective is achieved by the reinforced concrete walls and fire rated doors between the outage building and the safety-related areas of the plant.

9A.4.12 ISFSI Equipment Storage Building

9A.4.12.1 General Description

The Independent Spent Fuel Storage Installation (ISFSI) equipment storage building is located just north of the 345 KV switchyard, approximately 158 feet west of the RHR Complex.

This structure houses the equipment (e.g. – the Vertical Cask Transporter) required for ISFSI cask loading campaigns when not in use and also provides part-time office space and functions as an ISFSI crew briefing/turnover meeting area. This structure is not required for shutdown.

Fire suppression equipment in this structure consists of a wet pipe sprinkler system, supplied from the fire service water system and portable fire extinguishers.

9A.4.12.2 Analysis

Shutdown is achieved from the main control room using either Division I or Division II systems. Since the ISFSI equipment is not required for safe shutdown, functional redundancy is not a consideration. Separation for this building from other buildings is adequate.

9A.4.12.3 Conclusion

The objective is to prevent a fire in the ISFSI equipment storage building from spreading to other buildings and jeopardizing the ability to shut down the plant. This objective is achieved by spatial separation from necessary safety systems.

9A.4.13 FLEX Storage Facility #1 and #2

9A.4.13.1 General Description

There are two FLEX Storage Facilities (FSF) installed at Fermi. FSF#1 is located inside the protected area approximately 150 feet north of the Reactor Building and approximately 240 feet N-E of the RHR complex. FSF#2 is located outside the protected area in the owner controlled area approximately 200 feet west of the Circulating Water Pump House and approximately 210 feet S-E of the south Cooling Tower.

These structures provide storage for equipment that is designated to mitigate the consequences of a Beyond Design Basis External Event. The buildings are made of reinforced concrete and designed to withstand events including Seismic, External Floods, High Winds, Snow/Ice and High/Low Temperatures. Buildings are heated as required to prevent freezing of wetted components.

Fire suppression equipment consists of a dry pipe sprinkler system.

9A.4.13.2 Analysis

Shutdown is achieved from the main control room using either Division I or Division II systems. The equipment stored in FSF#1 and FSF#2 is not safety related and not required for safe shutdown. Separation between the two FLEX Storage Facilities and other plant buildings is adequate.

9A.4.13.3 Conclusion

The objective is to prevent a fire in either of the two FLEX Storage Facilities from spreading to adjacent buildings/SSC’s jeopardizing the ability of these buildings/SSC’s to bring the plant to safe shutdown. FSF#1 and #2 are sufficiently separated from systems credited with safe shutdown.

9A.5 POINT-BY-POINT COMPARISON

This section contains a point-by-point comparison with Appendix A to NRC Branch Technical Position APCSB 9.5-1, dated August 23, 1976.

Position For Plants Under Construction and Operating Plants	EF-2 Response
Positions	
a. Overall Requirements of Nuclear Plant Fire Protection Program	
1. Personnel	
Responsibility for the overall fire protection program should be assigned to a designated person in the upper level of management. This person should retain ultimate responsibility even though formulation and assurance of program implementation is delegated. Such delegation of authority should be to staff personnel prepared by training and experience in fire protection and nuclear plant safety to provide a balanced approach in directing the fire protection programs for nuclear power plants. The qualification requirements for the fire protection engineer or consultant, who will assist in the design and selection of equipment, inspect and test the completed physical aspects of the system, develop the fire protection program, and assist in the fire-fighting training for the operating plant should be stated. Subsequently, the FSAR should discuss the training and the updating provisions such as fire drills provided for maintaining the competence of the station firefighting and operating crew, including personnel responsible for maintaining and inspecting the fire protection equipment. The fire protection staff should be responsible for: (a) Coordination of building layout and systems design with fire area requirements, including consideration of potential hazards associated with postulated design basis fires, (b) Design and maintenance of fire detection, suppression, and extinguishing systems, (c) Fire prevention activities, (d) Training and manual fire-fighting activities of plant personnel and the fire brigade. (NOTE: NFPA 6 - Recommendations for Organization of Industrial Fire Loss Prevention, contains useful guidance for organization and operation of the entire fire loss prevention program.)	Fermi 2 has agreed to implement the fire protection program contained in the staff supplemental guidance, "Nuclear Plant Fire Protection Functional Responsibilities, Administrative Controls and Quality Assurance," dated August 29, 1977, including (1) fire protection organizations (2) fire brigade training (3) control of combustibles (4) control of ignition sources (5) fire-fighting procedures.

Position For Plants Under Construction and Operating Plants	EF-2 Response
2. Design Bases	
The overall fire protection program should be based upon evaluation of potential fire hazards throughout the plant and the effect of postulated design basis fires relative to maintaining ability to perform safety shutdown functions and minimize radioactive releases to the environment.	Section 9A.4 (Fire Hazards Analysis) provides this comparison. Likewise, plant emergency procedures are based on maintaining the plant in a safe condition.
3. Backup	
Total reliance should not be placed on a single automatic fire suppression system. Appropriate backup fire suppression capability should be provided.	In areas where automatic suppression systems are provided, adequate manual suppression equipment, including fire-hose stations and/or portable fire extinguishers, is available.
4. Single-Failure Criterion	
A single failure in the fire suppression system should not impair both the primary and backup fire suppression capability. For example, redundant fire water pumps with independent power supplier and controls should be provided. Postulated fires or fire protection system failures need not be considered concurrent with other plant accidents or the most severe natural phenomena. The effects of lightning strikes should be included in the overall plant fire protection program.	The fire suppression systems satisfy this requirement and are described in Position E.
5. Fire Suppression Systems	
Failure or inadvertent operation of the fire suppression system should not incapacitate safety related systems or components. Fire suppression systems that are pressurized during normal plant operation should meet the guidelines specified in APCSB Branch Technical Position 3-1, "Protection Against Postulated Piping Failures in Fluid Systems Outside Containment."	Failure or inadvertent operation of any fire suppression system will not incapacitate more than one division of safety-related systems or components. Analysis of fire protection piping failures was included in the moderate energy piping break evaluation, UFSAR Subsection 3.6.2.3.
6. Fuel Storage Areas	
Schedule for implementation of modifications, if any, will be established on a case-by-case basis.	The fire protection system as described in the FSAR in the fuel storage areas is operational
7. Fuel Loading	
Schedule for implementation of modifications, if any, will be established on a case-by-case basis.	The Fermi 2 Fire Protection System as described in UFSAR Subsection 9.5.1 and in this appendix in safety-related areas is operational.
8. Multiple-Reactor Sites	
On multiple-reactor sites where there are operating	N/A

Position For Plants Under Construction and Operating Plants	EF-2 Response
reactors and construction of remaining units is being completed, the fire protection program should provide continuing evaluation and include additional fire barriers, fire protection capability, and administrative controls necessary to protect the operating units from construction fire hazards. The superintendent of the operating plant should have the lead responsibility for site fire protection.	
9. Simultaneous Fires	
Simultaneous fires in more than one reactor need not be postulated, where separation requirements are met. A fire involving more than one reactor unit need not be postulated except for facilities shared between units.	N/A
b. Administrative Procedures, Controls and Fire Brigade	
1. Administrative procedures consistent with the need for maintaining the performance of the fire protection system and personnel in nuclear power plants should be provided. Guidance is contained in the following publications: NFPA 4 - Organization for Fire Services NFPA 4A - Organization for Fire Department NFPA 6 - Industrial Fire Loss Prevention NFPA 7 - Management of Fire Emergencies NFPA 8 - Management Responsibility for Effects of Fire on Operations	Fermi 2 has agreed to implement the fire protection program contained in the staff supplemental guidance, "Nuclear Plant Fire Protection Functional Responsibilities, Administrative Controls and Quality Assurance," dated August 29, 1977, including: (1) fire protection organizations (2) fire brigade training (3) control of combustibles (4) control of ignition sources (5) fire-fighting procedures.
NFPA 27 Private Fire Brigades	NFPA codes containing information on the above topics were used for guidance.
2. Effective administrative measures should be implemented to prohibit bulk storage of combustible materials inside or adjacent to safety related buildings or systems during operation or maintenance periods. Regulatory Guide 1.39, "Housekeeping Requirements for Water-Cooled Nuclear Power Plants," provides guidance on housekeeping, including the disposal of combustible materials.	
3. Normal and abnormal conditions or other anticipated operations such as modifications (e.g., breaking fire stops, impairment of fire detection and suppression systems) and refueling activities should be reviewed by appropriate levels of management and appropriate special actions and procedures such as fire watches or temporary fire barriers implemented to assure adequate fire protection and reactor safety. In particular:	

Position For Plants Under Construction and Operating Plants	EF-2 Response
(a) Work involving ignition sources such as welding and flame cutting should be done under closely controlled conditions. Procedures governing such work should be reviewed and approved by persons trained and experienced in fire protection. Persons performing and directly assisting in such work should be trained and equipped to prevent and combat fires. If this is not possible, a person qualified in fire protection should directly monitor the work and function as a fire watch.	
(b) Leak testing, and similar procedures such as air flow determination, should use one of the commercially available aerosol techniques. Open flames or combustion generated smoke should not be permitted.	
(c) Use of combustible material, e.g., HEPA and charcoal filters, dry ion exchange resins or other combustible supplies, in safety related areas should be controlled. Use of wood inside buildings containing safety related systems or equipment should be permitted only when suitable noncombustible substitutes are not available. If wood must be used, only fire retardant treated wood (scaffolding, lay down blocks) should be permitted. Such materials should be allowed into safety related areas only when they are to be used immediately. Their possible and probable use should be considered in the fire hazard analysis to determine the adequacy of the installed fire protection systems.	
4. Nuclear power plants are frequently located in remote areas, at some distance from public fire departments. Also, first response fire departments are often volunteer. Public fire department response should be considered in the overall fire protection program. However, the plant should be designed to be self-sufficient with respect to fire fighting activities and rely on the public response only for supplemental or backup capability.	
5. The need for good organization, training and equipping of fire brigades at nuclear power plant sites requires effective measures be implemented to assure proper discharge of these functions. The guidance in Regulatory Guide 1.101, "Emergency Planning for Nuclear Power Plants," should be followed as applicable.	

Position For Plants Under Construction and Operating Plants	EF-2 Response
(a) Successful fire fighting requires testing and maintenance of the fire protection equipment, emergency lighting and communication, as well as practice as brigades for the people who must utilize the equipment. A test plan that lists the individuals and their responsibilities in connection with routine tests and inspections of the fire detection and protection systems should be developed. The test plan should contain the types, frequency and detailed procedures for testing. Procedures should also contain instructions on maintaining fire protection during those periods when the fire protection system is impaired or during periods of plant maintenance, e.g., fire watches or temporary hose connections to water systems.	
(b) Basic training is a necessary element in effective fire fighting operation. In order for a fire brigade to operate effectively, it must operate as a team. All members must know what their individual duties are. They must be familiar with the layout of the plant and equipment location and operation in order to permit effective fire fighting operations during times when a particular area is filled with smoke or is insufficiently lighted. Such training can only be accomplished by conducting drills several times a year (at least quarterly) so that all members of the fire brigade have had the opportunity to train as a team, testing itself in the major areas of the plant. The drills should include the simulated use of equipment in each area and should be preplanned and post-critiqued to establish the training objective of the drills and determine how well these objectives have been met. These drills should periodically (at least annually) include local fire department participation where possible. Such drills also permit supervising personnel to evaluate the effectiveness of communications within the fire brigade and with the on scene fire team leader, the reactor operator in the control room, and the off-site command post.	
(c) To have proper coverage during all phases of operation, members of each shift crew should be trained in fire protection. Training of the plant fire brigade should be coordinated with the local fire department so that responsibilities and duties are delineated in	

Position For Plants Under Construction and Operating Plants	EF-2 Response
advance. This coordination should be part of the training course and implemented into the training of the local fire department staff. Local fire departments should be educated in the operational precautions when fighting fires on nuclear power plant sites. Local fire departments should be made aware of the need for radioactive protection of personnel and the special hazards associated with a nuclear power plant site.	
(d) NFPA 27, “Private Fire Brigade” should be followed in organization, training, and fire drills. This standard also is applicable to the inspection and maintenance of firefighting equipment. Among the standards referenced in this document, the following should be utilized: NFPA 194, "Standard for Screw Threads and Gaskets for Fire Hose Couplings," NFPA 196, "Standard for Fire Hose," NFPA 197, "Training Standard on Initial Fire Attacks," NFPA 601, "Recommended Manual of Instructions and Duties for the Plant Watchman on Guard." NFPA booklets and pamphlets listed on page 27-11 of Volume 8, 1971-72 are also applicable for good training references. In addition, courses in fire protection and fire suppression which are recognized and/or sponsored by the fire protection industry should be utilized.	

Position For Plants Under Construction and Operating Plants	EF-2 Response
c. Quality Assurance Program	
Quality assurance (QA) programs of applicants and contractors should be developed and implemented to assure that the requirements for design, procurement, installation, and testing and administrative controls for the fire protection program for safety-related areas as defined in this Branch Position are satisfied. The program should be under the management control of the QA organization. The QA program criteria that apply to the fire protection program should include the following:	The Quality Assurance Program for Plant Operation governs all activities which may affect safety-related structures, systems, and components at the plant. This program is described in Section 17.2 (QAPD) In view of the fact that safety-related structures, systems, and components are protected by the fire protection systems, portions of the Quality Assurance Program for Plant Operation are designed to ensure that fire protection in safety-related areas is maintained through requirements on design, procurement, installation, testing, and administrative controls. The QA program is under the management control of the Nuclear Quality Assurance (NQA) Department. The NQA Department verifies that the fire protection program incorporates suitable requirements and is acceptable to the senior onsite nuclear manager and also verifies its effectiveness through review, surveillance, and audits. All portions of the fire protection program that impact safety-related areas of the plant are programmatically defined in the Fermi Conduct Manuals and meet the guidtance as addressed in Appendix A of NRC Branch Technical Position APCSB 9.5-1 with the following stipulation. The fire protection system was not originally designed to be safety related.
1. Design Control and Procurement Document Control	
Measures should be established to assure that all design-related guidelines of the Branch Technical Position are included in design and procurement documents and that deviations there from are controlled.	These measures are part of the QA Program.
2. Instructions, Procedures and Drawings	
Inspections, tests, administrative controls, fire drills and training that govern the fire protection program should be prescribed by documented instructions, procedures or drawings and should be accomplished in accordance with these documents.	These items have been developed in accordance with the Fermi Conduct Manuals.

Position For Plants Under Construction and Operating Plants	EF-2 Response
3. Control of Purchased Material, Equipment and Services	
Measures should be established to assure that purchased material, equipment and services conform to the procurement documents.	This item is included in the QA Program.
4. Inspection	
A program for independent inspection of activities affecting fire protection should be established and executed by, or for, the organization performing the activity to verify conformance with documented installation drawings and test procedures for accomplishing the activities.	This item is included in the QA Program.
5. Test and Test Control	
A test program should be established and implemented to assure that testing is performed and verified by inspection and audit to demonstrate conformance with design and system readiness requirements. The tests should be performed in accordance with written test procedures; test results should be properly evaluated and acted on.	The test program is developed according to the requirements of the QA Program. The test results are reviewed by NQA through inspections, surveillances, or audits.
6. Inspection, Test and Operating Status	
Measures should be established to provide for the identification of items that have satisfactorily passed required tests and inspections.	These measures are part of Edison's tagging system and are part of the QA Program.
7. Non-Conforming Items	
Measures should be established to control items that do not conform to specified requirements to prevent inadvertent use or installation.	These measures are part of Edison's tagging system and are part of the QA Program.
8. Corrective Action	
Measures should be established to assure that conditions adverse to fire protection, such as failures, malfunctions, deficiencies, deviations, defective components, uncontrolled combustible material, and nonconformances are promptly identified, reported and corrected	This item is included in the QA Program.

Position For Plants Under Construction and Operating Plants	EF-2 Response
9. Records	
Records should be prepared and maintained to furnish evidence that the criteria enumerated above are being met for activities affecting the fire protection program.	Fire protection records are being maintained for this purpose according to the requirements of the QA Program.
10. Audits	
Audits should be conducted and documented to verify compliance with the fire protection program including design and procurement documents; instructions; procedures and drawings; and inspection and test activities.	Audits conducted by the NQA Department include the fire protection program.
d. General Guidelines for Plant Protection	
1. Building Design	
(a) Plant layouts should be arranged to:	The fire hazards analysis (Section 9A.4) identifies the fire areas and the safe-shutdown equipment within each area.
(1) Isolate safety related systems and	
(2) Separate redundant safety related systems from each other so that both are not subject to damage from a single fire hazard. Alternatives:	
(a) Redundant safety related systems that are subject to damage from a single fire hazard should be protected by a combination of fire retardant coatings and fire detection and suppression systems, or (b) a separate system to perform the safety function should be provided.	Locations where redundant systems are exposed to a single fire hazard are identified in the fire hazards analysis (Section 9A.4). Adequate fire protection is provided for these areas.
(b) In order to accomplish 1(a) above, safety related systems and fire hazards should be identified throughout the plant. Therefore, a detailed fire hazard analysis should be made. The fire hazards analysis should be reviewed and updated as necessary. Additional fire hazards analysis should be done after any plant modification.	See the fire hazards analysis, Section 9A.4.
(c) Alternative guidance for constructed plants is shown in Section E.3, "Cable Spreading Room."	

Position For Plants Under Construction and Operating Plants	EF-2 Response
(d) Interior wall and structural components, thermal insulation materials and radiation shielding materials and sound-proofing should be noncombustible or listed by a nationally recognized testing laboratory, such as Factory Mutual or Underwriters Laboratory, Inc. for flame spread, smoke and fuel contribution of 25 or less in its use configuration (ASTM E-84 Test, "Surface Burning Characteristics of Building Materials").	Plant structural components satisfy thie criterion or have approved deviations.
(e) Metal deck roof construction should be noncombustible (see the building materials directory of the Underwriters Laboratory, Inc.) or listed as Class I by Factory Mutual System Approval Guide. Where combustible material is used in metal deck roofing design, acceptable alternatives are (i) replace combustibles with non-combustible materials, (ii) provide an automatic sprinkler system, or (iii) provide ability to cover roof exterior and interior with adequate water volume and pressure.	All metal deck roof construction is noncombustible and is listed as Class I by the Factory Mutual System Approval Guide.
(f) Suspended ceilings and their supports should be of noncombustible construction. Concealed spaces should be devoid of combustibles. Adequate fire detection and suppression systems should be provided where full implementation is not practicable.	Plant areas satisfy these criteria.
(g) High voltage - high amperage transformers installed inside buildings containing safety related systems should be of the dry type or insulated and cooled with non-combustible liquid. Safety related systems that are exposed to flammable oil filled transformers should be protected from the effects of a fire by: (i) replacing with dry transformers or transformers that are insulated and cooled with noncombustible liquid; or (ii) enclosing the transformer with a three-hour fire barrier and installing automatic water spray protection.	Inside transformers are dry type.

Position For Plants Under Construction and Operating Plants	EF-2 Response
(h) Buildings containing safety related systems, having openings in exterior walls closer than 50 feet to flammable oil filled transformers should be protected from the effects of a fire by: (i) closing of the opening to have fire resistance equal to three hours (ii) constructing a three-hour fire barrier between the transformers and the wall openings; or (iii) closing the opening and providing the capability to maintain a water curtain in case of a fire.	Outdoor oil-filled transformers are within 50 ft of openings in the turbine building wall. Transformers are adequately protected by fixed automatic water spray systems. A solid metal door is provided for the turbine building west wall
(i) Floor drains, sized to remove expected fire fighting water flow should be provided in those areas where fixed water fire suppression systems are installed. Drains should also be provided in other areas where hand hose lines may be used if such fire-fighting water could cause unacceptable damage to equipment in the area. Equipment should be installed on pedestals, or curbs should be provided as required to contain water and direct it to floor drains. (See NFPA 92M, "Waterproofing and Draining of Floors.") Drains in areas containing combustible liquids should have provisions for preventing the spread of fire throughout the drain system. Water drainage from areas which may contain radioactivity should be sampled and analyzed before discharge to the environment. In operating plants or plants under construction, if accumulation of water from the operation of new fire suppression systems does not create unacceptable consequences, drains need not be installed.	Floor drains are designed to remove the expected fire-fighting water flow from areas where fixed fire suppression systems are installed or where fire hose may be used. Equipment is installed on pedestals. Drains in areas containing combustible liquids are designed to prevent the spread of fire throughout the drain system. Water drainage from areas that may contain radioactivity is collected in the floor drain collection tank for normal liquid waste. Subsection 9.3.3 of the UFSAR describes the floor drain system in all the buildings. Section 11.2 of the UFSAR describes the handling and processing of liquid radioactive waste.

Position For Plants Under Construction and Operating Plants	EF-2 Response
(j) Floors, walls and ceilings enclosing separate fire areas should have minimum fire rating of three hours. Penetrations in these fire barriers, including conduits and piping, should be sealed or closed to provide a fire resistance rating at least equal to that of the fire barrier itself. Door openings should be protected with equivalent rated doors, frames and hardware that have been tested and are approved by a nationally recognized laboratory. Such doors should be normally closed and locked or alarmed with alarm and annunciation in the control room. Penetrations for ventilation system should be protected by a standard "fire door damper" where recognized. (Refer to NFPA 80, "Fire Doors and Windows.") The fire hazard in each area should be evaluated to determine barrier requirements. If barrier fire resistance cannot be made adequate, fire detection and suppression should be provided, such as: (i) water curtain in case of fire, (ii) flame retardant coatings, (iii) additional fire barriers.	The fire hazards analysis identifies the fire barriers and determines the requirements for maintaining their integrity. As detailed in Section 9A.4, door openings are protected with equivalent rated doors, frames, and hardware that have been tested and approved by a nationally recognized laboratory. Such doors are normally closed and alarmed with alarm and annunciation in the control room (a continuously manned location), or checked daily, or alarmed with annunciation to Security (a continuously manned location), or locked and checked weekly, all of which are acceptable monitoring methods described in Branch Technical Position CMEB 9.5-1, Revision 2. Penetrations for ventilation systems are protected by fire dampers where deemed necessary as a result of the fire hazards analysis. Electrical conduits penetrating rated fire barriers are provided with internal seals unless they meet the criteria of 9A.2.3.1.1 for not requiring internal seals for fire.
2. Control of Combustibles	
(a) Safety related systems should be isolated or separated from combustible materials. When this is not possible because of the nature of the safety system or the combustible material, special protection should be provided to prevent a fire from defeating the safety system function. Such protection may involve a combination of automatic fire suppression, and construction capable of withstanding and containing a fire that consumes all combustibles present. Examples of such combustible materials that may not be separable from the remainder of its system are: (1) Emergency diesel generator fuel oil day tanks (2) Turbine-generator oil and hydraulic control fluid systems (3) Reactor coolant pump lube oil system	The fire hazards analysis identifies these hazards and the protection afforded.

Position For Plants Under Construction and Operating Plants	EF-2 Response
(b) Bulk gas storage (either compressed or cryogenic), should not be permitted inside structures housing safety-related equipment. Storage of flammable gas such as hydrogen, should be located outdoors or in separate detached buildings so that a fire or explosion will not adversely affect any safety related systems or equipment. (Refer to NFPA 50A, "Gaseous Hydrogen Systems.")	Bulk gas is stored in outside areas. A fire or explosion will not adversely affect any safety-related systems or equipment.
Care should be taken to locate high pressure gas storage containers with the long axis parallel to building walls. This will minimize the possibility of wall penetration in the event of a container failure. Use of compressed gases (especially flammable and fuel gases) inside buildings should be controlled. (Refer to NFPA 6, "Industrial Fire Loss Prevention.")	High-pressure gas storage containers will be located with the long axis parallel to the adjacent safety-related building wall.
(c) The use of plastic materials should be minimized. In particular, halogenated plastics such as polyvinyl chloride (PVC) and neoprene should be used only when substitute non-combustible materials are not available. All plasticmaterials, including flame and fire retardant materials, will burn with an intensity and BTU production in a range similar to that of ordinary hydrocarbons. When burning, they produce heavy smoke that obscures visibility and can plug air filters, especially charcoal and HEPA. The halogenated plastics also release free chlorine and hydrogen chloride when burning which are toxic to humans and corrosive to equipment.	Plastic materials throughout the plant are negligible.
(d) Storage of flammable liquids should, as a minimum, comply with the requirements of NFPA 30, "Flammable and Combustible Liquids Code."	NFPA 30 was used as a guideline for storage of flammable liquids.
3. Electric Cable Construction, Cable Trays and Cable Penetrations	
(a) Only non-combustible materials should be used for cable tray construction.	Cable trays are of non-combustible metal construction.
(b) See Section F.3 for fire protection guidelines for cable spreading rooms.	

	Position For Plants Under Construction and Operating Plants	EF-2 Response
(c)	Automatic water sprinkler systems should be provided for cable trays outside the cable spreading room. Cables should be designed to allow wetting down with deluge water without electrical faulting. Manual hose stations and portable hand extinguishers should be provided as backup. Safety related equipment in the vicinity of such cable trays, that does not itself require water fire protection, but is subject to unacceptable damage from sprinkler water discharge, should be protected from sprinkler system operation or malfunction. When safety related cables do not satisfy the provisions of Regulatory Guide 1.75, all exposed cables should be covered with an approved fire retardant coating and a fixed automatic water fire suppression system should be provided.	Automatic water sprinkler systems will be provided in areas of concentrated cable loading of redundant channels in accordance with the fire hazards analysis. Manual hose stations and portable hand extinguishers are provided as backup. Potential water damage will be considered where water sprays are used. Safety-related and balance-of-plant (BOP) cables are in compliance with IEEE 383/1974 for flame-retardant cable. This standard is referenced in Regulatory Guide 1.75. As addressed in UFSAR Subsection A.1.75, the noncompliance with Regulatory Guide 1.75 is in the identification of associated circuits only. (NOTE: For Exceptions, See Section 8.3.1.4.2)
(d)	Cable and cable tray penetration of fire barriers (vertical and horizontal) should be sealed to give protection at least equivalent to that fire barrier. The design of fire barriers for horizontal and vertical cable trays should, as a minimum, meet the requirements of ASTM E-119, "Fire Test of the Building Construction and Materials, "including the hose stream test, Where installed penetration seals are deficient with respect to fire resistance, these seals may be protected by covering both sides with an approved fire retardant material. The adequacy of using such material should be demonstrated by suitable testing.	Cable penetrations in fire barriers are sealed with silicone foam consistent with fire barrier fire resistance requirements.
(e)	Fire breaks should be provided as deemed necessary by the fire hazards analysis. Flame or flame retardant coatings may be used as a fire break for grouped electrical cables to limit spread of fire in cable ventings. (Possible cable derating owing to use of such coating materials must be considered during design.)	Fire breaks are provided where electrical cables penetrate walls and floors. Also, fire breaks are installed in cable trays of intervening combustibles. Instrument cable trays are enclosed solid-metal trays with covers which serve as radiant energy barriers.

	Position For Plants Under Construction and Operating Plants	EF-2 Response
(f)	Electric cable constructions should as a minimum pass the current IEEE No. 383flame test. (This does not imply that cables passing this test will not require additional fire protection.) For cable and plants under construction that do not meet the IEEE No. 383 flame test requirements, all cables must be covered with an approved flame-retardant coating and properly derated.	Safety-related and BOP cable* satisfies Edison Specification 3071-80 flame test requirements. This specification required a flame test setup on both ladder and solid bottom trays at a horizontal/vertical joint. The test used a 120,000 Btu, 14-in. wheel-type propane burner with a contact flame at 1500°F. Trays were loaded with a single layer of cable spread 1/2 diameter apart. On the ladder tray, the fire could not be self-propagating nor could the cable fail electrically after 5 minutes. On the solid bottom tray, the fire could not be self-propagating after 10 minutes of burner operation. In December 1988, Detroit Edison Specification 3071-080 was revised to require flame tests in accordance with IEEE 383-1974.
(g)	To the extent practical cable construction that does not give off gases while burning should be used. Applicable to new cable installations.	New cables will satisfy Edison Specification 3071-80 test requirements. (NOTE: For Exceptions, See Section 8.3.1.4.2)
(h)	Cable trays, raceways, conduit, trenches, or culverts should be used only for cables. Miscellaneous storage should not be permitted, nor should piping for flammable or combustible liquids or gases be installed in these areas. Installed equipment in cable tunnels or culverts, need not be removed if they present no hazard to the cable runs as determined by the fire hazards analysis.	This criterion is satisfied.
(i)	The design of cable tunnels, culverts and spreading rooms should provide for automatic or manual smoke venting as required to facilitate manual fire fighting capability.	The cable spreading areas are not provided with automatic or manual smoke venting. A low-pressure carbon dioxide system or Halon system is installed to provide extinguishment prior to generation of any appreciable amount of smoke. Portable fans would be used to exhaust smoke from affected areas.
(j)	Cables in the control room should be kept to the minimum necessary for operation of the control room. All cables entering the control room should terminate there. Cables should not be installed in floor trenches or culverts in the control room. Existing cabling installed in concealed floor and ceiling spaces should be protected with an automatic total flooding halon system.	Cables in the control room come from the cable spreading area and terminate in control panels, consoles, or equipment. However, some cabling is installed in the concealed floor of the computer area. An automatic Halon suppression system is provided for the protection of the concealed floor and the computer room.

Position For Plants Under Construction and Operating Plants	EF-2 Response
4. Ventilation	
(a) The products of combustion that need to be removed from a specific fire area should be evaluated to determine how they will be controlled. Smoke and corrosive gases should generally be automatically discharged directly outside to a safe location. Smoke and gases containing radioactive materials should be monitored in the fire area to determine if release to the environment is within the permissible limits of the plant Technical Specifications. The products of combustion which need to be removed from a specific fire area should be evaluated to determine how they will be controlled.	Ventilation for critical areas is evaluated in Sections 9A.2 and 9A.4 of this report. Areas having potential for release of radioactive material are also outlined. Monitoring of radioactive contamination is discussed in UFSAR Subsection 12.2.4.
(b) Any ventilation system designed to exhaust smoke or corrosive gases should be evaluated to ensure that inadvertent operation or single failures will not violate the controlled areas of the plant design. This requirement includes containment functions for protection of the public and maintaining habitability for operations personnel.	No systems are designed solely for smoke removal. Existing ventilation systems that would be used for smoke removal satisfy these criteria.
(c) The power supply and controls for mechanical ventilation systems should be run outside the fire area served by the system.	The power supply and controls for the mechanical ventilation systems used to cool redundant safe-shutdown equipment have been run in the same area as the applicable equipment. These controls satisfy the separation requirements
(d) Fire suppression systems should be installed to protect charcoal filters in accordance with Regulatory Guide 1.52, "Design Testing and Maintenance Criteria for Atmospheric Cleanup Air Filtration."	Charcoal filters are protected with manual deluge or carbon dioxide suppression systems.
(e) The fresh air supply intakes to areas containing safety related equipment or systems should be located remote from the exhaust air outlets and smoke vents of other fire areas to minimize the possibility of contaminating the intake air with the products of combustion.	Fresh air supply intakes are remotely located with respect to exhaust air outlets. Thus the possibility of contaminating the intake air with the products of combustion is minimized.

	Position For Plants Under Construction and Operating Plants	EF-2 Response
(f)	Stairwells should be designed to minimize smoke infiltration during a fire. Staircases should serve as escape routes and access routes for fire fighting. Fire exit routes should be clearly marked. Stairwells, elevators and chutes should be enclosed in masonry towers with minimum fire rating of three hours and automatic fire doors at least equal to the enclosure construction, at each opening into the building. Elevators should not be used during fire emergencies. Where stairwells or elevators cannot be enclosed in three hours fire rated barrier with equivalent fire doors, escape and access routes should be established by a pre-fire plan and practiced in drills by operating and fire brigade personnel.	Some of the stairwells are enclosed. (See the fire protection layout drawings attached to this report.) Stairwells serve as escape routes and access routes for fire fighting. Escape and access routes will be established by pre-fire plan and will be practiced in drills by operating and fire brigade personnel.
(g)	Smoke and heat vents may be useful in specific areas such as cable spreading rooms and diesel fuel oil storage areas and switchgear rooms. When natural-convection ventilation is used, a minimum ratio of 1 sq. foot of venting area per 200 sq feet of floor area should be provided. If forced-convection ventilation is used, 300 CFM should be provided for every 200 sq feet of floor area. See NFPA No. 204 for additional guidance on smoke control.	Natural convection heat venting of 1 ft^2 per 200 ft^2 is used in the turbine room floor area. Forced convection ventilation is provided in all other areas with a minimum design of one air change per hour. The control center smoke purge mode provides 250 cfm per 200 ft^2 floor area for the cable spreading room.

	Position For Plants Under Construction and Operating Plants	EF-2 Response
(h)	Self-contained breathing apparatus, using full face positive pressure masks, approved by NIOSH (National Institute for Occupational Safety and Health - approval formerly given by the U.S. Bureau of Mines) should be provided for fire brigade, damage control and control room personnel. Control room personnel may be furnished breathing air by a manifold system piped from a storage reservoir if practical. Service or operating life should be a minimum of one-half hour for the self-contained units. At least two extra air bottles should be located onsite for each self-contained breathing unit. In addition, an onsite 6-hour supply of reserve air should be provided and arranged to permit quick and complete replenishment of exhausted supply air bottles as they are returned. If compressors are used as a source of breathing air, only units approved for breathing air should be used. Special care must be taken to locate the compressor in areas free of dust and contaminants.	The plant will use full-face positive-pressure breathing masks, approved by NIOSH. Masks will be available for the fire brigade, damage control, or other control room personnel. The plant breathing air system provides a manifold on the south wall of the control room which will supply breathing air to five connection points. Each self-contained breathing unit will have at least two extra fully charged bottles onsite at all times. The plant will have an onsite air compressor for charging the breathing air bottles.
(i)	Where total flooding gas extinguishing systems are used, area intake and exhaust ventilation dampers should close upon initiation of gas flow to maintain necessary gas concentration. (See NFPA 12, "Carbon Dioxide Systems," and 12A, "Halon 1301 Systems.")	Where required, ventilation dampers close on actuation of gaseous extinguishing systems to maintain the necessary gas concentration.

5. Lighting and Communication

Lighting and two way voice communication are vital to safe shutdown and emergency response in the event of fire. Suitable fixed and portable emergency lighting and communication devices should be provided to satisfy the following requirements:

	Position	EF-2 Response
(a)	Fixed emergency lighting should consist of sealed beam units with individual 8-hour minimum battery power supplies.	Fixed emergency lighting with 8-hr battery power supplies is provided for the control room, safety-related equipment areas, and means of egress except in the yard area route to the residual heat removal (RHR) complex where yard security lights are used to provide a lighted pathway.
(b)	Suitable sealed beam battery powered portable hand lights should be provided for emergency use.	Automatically operated, sealed-beam battery-powered lights and sealed-beam battery-powered portable hand lights will be provided for emergency use.

Position For Plants Under Construction and Operating Plants	EF-2 Response
(c) Fixed emergency communication should use voice powered head sets at preselected stations.	Emergency communications capability is provided by telephones, public address systems, and radio communications equipment powered from redundant power sources.
(d) Fixed repeaters installed to permit use of portable radio communication units should be protected from exposure to fire damage.	Repeater stations are installed to improve the quality of radio communication. Loss of a particular repeater will not result in a loss of communication capability in the area adjacent to the repeater.
e. Fire Detection and Suppression	
1. Fire Detection	
(a) Fire detection systems should as a minimum comply with NFPA 72D, "Standard for the Installation Maintenance and Use of Proprietary Protective Signaling Systems." Deviations from the requirements of NFPA 72D should be identified and justified.	Fire detection systems were installed using NFPA 72D as guidance. No recorder is provided in the main control room. This deviation has been approved because adequate records are kept.
(b) Fire detection system should give audible and visual alarm and annunciation in the control room. Local audible alarms should also sound at the location of the fire.	Plant fire detectors will alarm in the control room on the fire protection control panel that will designate general fire location (detector subpanels). Local alarms will sound at the sub-panels that will pinpoint individual room and/or detector location.
c) Fire alarms should be distinctive and unique. They should not be capable of being confused with any other plant system alarms.	Fire alarms will be distinctive and unique and should not be confused with any other plant system alarms.
(d) Fire detection and actuation systems should be connected to the plant emergency power supply.	Fire detection and actuation systems are connected to the plant emergency power supply.
2. Fire Protection Water Supply Systems	
(a) An underground yard fire main loop should be installed to furnish anticipated fire water requirements. NFPA 24 - Standard for Outside Protection - gives necessary guidance for such installation. It references other design codes and standards developed by such organizations as the American National Standards Institute (ANSI) and the American Water Works Association (AWWA). Lined steel or cast iron pipe should be used to reduce internal tuberculation. Such tuberculation deposits in an unlined pipe over a period of years can significantly reduce water flow through the	The underground yard fire main loop was installed using NFPA 24 for guidance. Subsection 9.5.1.2.1 of the UFSAR gives a detailed description of the system. Underground carbon steel pipe is coated, wrapped and provided with cathodic protection. Above-ground pipe is carbon steel. Flushing is accomplished using Fire hydrants. No means for treatment is available. Sectional control valves (post indicator valves) are provided to isolate portions of the fire main for maintenance or repair without shutting down the entire system. Position indicators are provided with the sectional control valves. Branch lines outside the protected area

	Position For Plants Under Construction and Operating Plants	EF-2 Response
	combination of increased friction and reduced pipe diameter. Means for treating and flushing the systems should be provided. Approved visually indicating sectional control valves, such as Post Indicator Valves, should be provided to isolate portions of the main for maintenance or repair without shutting off the entire system. Visible location marking signs for underground valves is acceptable. Alternative valve position indicators should also be provided.	include coated, wrapped and cathodically protected carbon steel, cement lined ductile iron, asbestos-cement and poly vinyl chloride pipe.
	The fire main system piping should be separate from service or sanitary water system piping. For operating plants, fire main system piping that can be isolated from service or sanitary water system piping is acceptable.	The fire main system piping is connected to the general service water system. Isolation valves are provided.
(b)	A common yard fire main loop may serve multi-unit nuclear power plant sites, if cross-connected between units. Sectional control valves should permit maintaining independence of the individual loop around each unit. For such installations, common water supplies may also be utilized. The water supply should be sized for the largest single expected flow. For multiple reactor sites with widely separated plants (approaching 1 mile or more), separate yard fire main loops should be used. Sectionalized systems are acceptable.	N/A
(c)	If pumps are required to meet system pressure or flow requirements, a sufficient number of pumps should be provided so that 100% capacity will be available with one pump inactive (e.g., three 50% pumps, two 100% pumps). The connection to the yard fire main loop from each fire pump should be widely separated, preferably located on opposite sides of the plant. Each pump should have its own driver with independent power supplies and control. At least one pump (if not powered from the emergency diesels) should be driven by non-electrical means, preferably diesel engine. Pumps and drivers should be located in rooms separated from the remaining pumps and equipment by a minimum three-hour fire wall. Alarms indicating pump running, driver availability, or failure to start should be provided in the control room.	Two fire pumps (2500 gpm at 150 psig; one diesel driven and one electric motor driven) are provided for the plant. Connections to the yard fire main loop are 2.68 ft apart. The diesel-driven fire pump is separated from the electric-motor-driven fire pump by a 3-hr-rated fire barrier in the general service water pump house. Alarms indicating pump running, driver availability, and failure to start are provided in the control room.

	Position For Plants Under Construction and Operating Plants	EF-2 Response
	Details of the fire pump installation should as a minimum conform to NFPA 20, "Standard for the Installation of Centrifugal Fire Pumps."	The fire pump installation conforms to the intent of NFPA 20, except for certain deviations, with supporting justifications, identified in section 9.5.1.2.3.2.
(d)	Two separate reliable water supplies should be provided. If tanks are used, two 100% (minimum of 300,000 gallons each) system capacity tanks should be installed. They should be so interconnected that pumps can take suction from either or both. However, a leak in one tank or its piping should not cause both tanks to drain.	Water supply is from Lake Erie.
	The main plant fire water supply capacity should be capable of refilling either tank in a minimum of eight hours. Common tanks are permitted for fire and sanitary or service water storage. When this is done, however, minimum fire water storage requirements should be dedicated by means of a vertical standpipe for other water services.	N/A
(e)	The fire water supply (total capacity and flow rate) should be calculated on the basis of the largest expected flow rate for a period of two hours, but not less than 300,000 gallons. This flow rate should be based (conservatively) on 1,000 gpm for manual hose streams plus the greater of: (1) all sprinkler heads opened and flowing in the largest designed fire area; or (2) the largest open head deluge system(s) operating.	The maximum flow demand is estimated to be less than 1500 gpm to the most remote deluge system, plus 500 gpm for manual hose streams. A single pump is designed to operate at 150 percent of rated capacity and provide 3750 gpm. The capabilities of the Diesel Fire Pump and diesel engine driver are described in section 9.5.1.2.3.2.
(f)	Lakes or fresh water ponds of sufficient size may qualify as sole source of water for fire protection, but require at least two intakes to the pump supply. When a common water supply is permitted for fire protection and the ultimate heat sink, the following conditions should also be satisfied:	Lake Erie is the source of fire service water.
	(1) The additional fire protection water requirements are designed into the total storage capacity; and	N/A
	(2) Failure of the fire protection system should not degrade the function of the ultimate heat sink.	N/A
(g)	Outside manual hose installation should be sufficient to reach any location with an effective hose stream. To accomplish this	Fire hydrants are located not more than 300 ft apart around the perimeter of the plant. The lateral to each fire hydrant is provided with a

Position For Plants Under Construction and Operating Plants	EF-2 Response
hydrants should be installed approximately every 250 feet on the yard main system. The lateral to each hydrant from the yard main should be controlled by a visually indicating or key operated (curb) valve. A hose house, equipped with hose and combination nozzle, and other auxiliary equipment recommended in NFPA 24, "Outside Protection," should be provided as needed but at least every 1,000 feet.	valve. The system is designed so that the sectional control valves (post-indicator valves) can isolate one, two, or three fire hydrants. Selected fire hydrants are provided with hose houses which contain 250 ft of 2-1/2 in. hose, 200 ft of 1-1/2 in. hose, combination fog nozzle, and auxiliary equipment, as deemed necessary.
Threads compatible with those used by local fire departments should be provided on all hydrants, hose couplings and standpipe risers.	The thread size used on hydrants, hose couplings, and standpipe risers is compatible with the Frenchtown Township Fire Department.
3. Water Sprinklers and Hose Standpipe Systems	
(a) Each automatic sprinkler system and manual hose station standpipe should have an independent connection to the plant underground water main. Headers fed from each end are permitted inside buildings to supply multiple sprinkler and standpipe systems. When provided, such headers are considered an extension of the yard main system. The header arrangement should be such that no single failure can impair both the primary and backup fire protection systems.	Underground connections are provided to various buildings to supply standpipe and sprinkler systems as shown on Figure 9A-1. Headers fed from both ends are not provided in the buildings. In the reactor/auxiliary building, two connections (feeds) are provided from the plant underground water main. All standpipes are fed from one connection; all sprinkler systems are fed from the other connection. Isolation valves are provided to separate the primary (automatic) sprinkler systems from the secondary (standpipe) systems.
Each sprinkler and standpipe system should be equipped with OS&Y (outside screw and yoke) gate valve, or other approved shut off valve, and water flow alarm. Safety related equipment that does not itself require sprinkler water fire protection, but is subject to unacceptable damage if wetted by sprinkler water discharge should be protected by water shields or baffles.	Each sprinkler and standpipe system is equipped with an OS&Y gate valve. Each sprinkler system is equipped with a water flow alarm. Standpipe systems are equipped with a water flow alarm. Safety-related equipment has been protected from water damage.
(b) All valves in the fire water systems should be electrically supervised. The electrical supervision signal should indicate in the control room and other appropriate command locations in the plant. (See NFPA 26, "Supervision of Valves.") When electrical supervision of fire protection valves is not practicable, an adequate management supervision program should be provided. Such a program should include locking valves open with strict key control; tamper proof seals; and periodic, visual check of all valves.	Shutoff valves controlling sprinkler and deluge systems are electrically supervised and actuate alarms in the control room or other normally manned security area. Sectional and divisional valves of the underground fire main and major valves inside the building will be locked open. Routine fire inspection by the plant operations engineer delegate will check valve positions, status, and seals.

	Position For Plants Under Construction and Operating Plants	EF-2 Response
(c)	Automatic sprinkler systems should as a minimum conform to requirements of appropriate standards such as NFPA 13, "Standard for the Installation of Sprinkler Systems," and NFPA 15, "Standard for Water Spray Fixed Systems."	Sprinkler systems throughout the plant were installed using NFPA 13 and/or NFPA 15 for guidance. Certain noncompliances to NFPA 13 have been evaluated in accordance with Generic Letter 86-10 and are referenced in section 9.5.1.1.2.
(d)	Interior manual hose installation should be able to reach any location with at least one effective hose stream. To accomplish this, standpipes with hose connections equipped with a maximum of 75 feet of 1-1/2 inch woven jacket lined fire hose and suitable nozzles should be provided in all buildings, including containment, on all floors and should be spaced at not more than 100-foot intervals. Individual standpipes should be at least 4-inch diameter for multiple hose connections and 2-1/2-inch diameter for single hose connections. These systems should follow the requirements of NFPA No. 14 for sizing, spacing and pipe support requirements (NELPIA).	Hose reels are provided throughout the plant as indicated on the fire protection layout drawings. Fire hose is approved 1-1/2 in. lined hose. Individual standpipes are 4-in.-diameter for multiple hose connections and 2-1/2-in.-diameter for single hose connections. NFPA 14 was used for guidance for sizing, spacing, and pipe supports.
	Hose stations should be located outside entrances to normally unoccupied areas and inside normally occupied areas. Standpipes serving hose stations in areas housing safety-related equipment should have shutoff valves and pressure-reducing devices (if applicable) outside the area.	Hose stations are mainly located outside entrances to normally unoccupied areas. Shutoff valves are provided at each hose station where required. Pressure-reducing devices are provided on the 5th floor of the reactor building and below grade, 583 ft 6 in., due to excessive system pressure. Since fog nozzles, which act as effective pressure-reducing devices, are used throughout the remainder of the plant and since fire brigade members who use the hose stations are trained to use the higher outlet pressures in excess of 100 psi, pressure-reducing devices are not provided elsewhere.
(e)	The proper type of hose nozzles to be supplied to each area should be based on the fire hazard analysis. The usual combination spray/straight-stream nozzle may cause unacceptable mechanical damage (for example, the delicate electronic equipment in the control room) and be unsuitable. Electrically safe nozzles should be provided at locations where electrical equipment or cabling is located.	All areas are provided with adjustable pattern fog nozzles, except for the refueling floor, which has solid stream nozzles. Personnel are adequately trained to make proper use of hose stations.
(f)	Certain fires such as those involving flammable liquids respond well to foam suppression. Consideration should be given to use of any of the available foams for such	There are no major flammable liquid hazards in the plant. Areas involving combustible liquids are adequately protected with a sprinkler or deluge system.

Position For Plants Under Construction and Operating Plants	EF-2 Response
specialized protection application. These include the more common chemical and mechanical low expansion foams, high expansion foam and the relatively new aqueous film forming foam (AFFF).	
4. Halon Suppression Systems	
The use of Halon fire extinguishing agents should as a minimum comply with the requirements of NFPA 12A and 12B, "Halogenated Fire Extinguishing Agent Systems-Halon 1301 and Halon 1211." Only UL or FM approved agents should be used.	NFPA 12A was used for guidance for the Installation of Halon systems.
In addition to the guidelines of NFPA 12A and 12B, preventative maintenance and testing of the systems, including check weighing of the Halon cylinders should be done at least quarterly. Particular consideration should also be given to:	Liquid level measurement of the cylinders and testing of the system will conform to the fire protection conditions for operation, Section 9A.6.
(a) minimum required Halon concentration and soak time (b) toxicity of Halon (c) toxicity and corrosive characteristics of thermal decomposition products of Halon.	Consideration will be given to items (a), (b), and (c).
5. Carbon Dioxide Suppression Systems	
The use of carbon dioxide extinguishing systems should as a minimum comply with the requirements of NFPA 12, "Carbon Dioxide Extinguishing Systems."	Carbon dioxide systems are provided for protection of certain cable tray areas outside the control center complex, the EDG rooms, and SGTS charcoal filters. The carbon dioxide systems are designed using NFPA Standard 12 for guidance.
Particular consideration should also be given to: (a) minimum required CO_2 concentration and soak time; (b) toxicity of CO_2; (c) possibility of secondary thermal shock (cooling) damage; (d) offsetting requirements for venting during CO_2 injection to prevent over-pressurization versus sealing to prevent loss of agent; (e) design requirements from over-pressurization; and (f) possibility and probability of CO_2 systems being out-of-service because of personnel safety consideration. CO_2 systems are disarmed whenever people are present in an area so protected. Areas entered frequently (even though duration time for any visit is short) have often been found with CO_2 systems shut off.	Consideration has been given to items (a) through (f).

Position For Plants Under Construction and Operating Plants	EF-2 Response
6. Portable Extinguishers	
Fire extinguishers should be provided in accordance with guide lines of NFPA 10 and 10A, "Portable Fire Extinguishers, Installation, Maintenance and Use." Dry chemical extinguishers should be installed with due consideration given to cleanup problems after use and possible adverse effects on equipment installed in the area.	Portable fire extinguishers are provided using NFPA 10 as guidance.
F. Guidelines for Specific Plant Areas	
1. Primary and Secondary Containment	
(a) Normal Operation	
Fire protection requirements for the primary and secondary containment areas should be provided on the basis of specific identified hazards. For example: a. Lubricating oil or hydraulic fluid system for the primary coolant pumps b. Cable tray arrangements and cable penetrations c. Charcoal filters	
Fire suppression systems should be provided based on the fire hazards analysis. Fixed fire suppression capability should be provided for hazards that could jeopardize safe plant shutdown. Automatic sprinklers are preferred. An acceptable alternate is automatic gas (Halon or CO_2) for hazards identified as requiring fixed suppression protection. An enclosure may be required to confine the agent if a gas system is used. Such enclosure should not adversely affect safe shutdown, or other operating equipment in containment. Automatic fire suppression capability need not be provided in the primary containment atmospheres that are inerted during normal operation. However, special fire protection requirements during refueling and maintenance operations should be satisfied as provided below.	The fire hazards analysis outlines the protection for containment areas.

Position For Plants Under Construction and Operating Plants	EF-2 Response
(b) Refueling and Maintenance	
Refueling and maintenance operations in containment may introduce additional hazards such as contamination control materials, decontamination supplies, wood planking, temporary wiring, welding and flame cutting (with portable compressed fuel gas supply). Possible fires would not necessarily be in the vicinity of fixed detection and suppression systems. Management procedures and controls necessary to assure adequate fire protection are discussed in Section 3a. In addition, manual fire fighting capability should be permanently installed in containment. Standpipes with hose stations, and portable fire extinguishers, should be installed at strategic locations throughout containment for any required manual fire fighting operations. Equivalent protection from portable systems should be provided if it is impractical to install standpipes with hose stations. Adequate self-contained breathing apparatus should be provided near the containment entrances for fire fighting and damage control personnel. These units should be independent of any breathing apparatus or air supply systems provided for general plant activities	It is impractical to provide a standpipe system inside the plant Mark I containment. During refueling, portable extinguishers and self-contained breathing apparatus will be located outside primary containment and portable extinguishers will be located inside containment at various work locations. Hose stations with hose reels are located nearby in the reactor building.
2. Control Room	
The control room is essential to safe reactor operation. It must be protected against disabling fire damage and should be separated from other areas of the plant by floors, walls and roofs having minimum fire resistance ratings of three hours.	The control room is separated from other areas of the plant by fire rated floor, walls, and ceiling. Section 9A.4 discusses fire-resistance ratings of these barriers and outlines the protection for the control room.
Control room cabinets and consoles are subject to damage from two distinct fire hazards: (a) Fire originating within a cabinet or console; and (b) Exposure fire involving combustibles in the general room area	
Hose stations adjacent to the control room with portable extinguishers in the control room are acceptable.	A hose station is provided adjacent to the control room. Fire extinguishers are provided adjacent to or in the control room.
Nozzles that are compatible with the hazards and equipment in the control room should be provided for the manual hose station. The nozzles chosen should satisfy actual fire fighting needs, satisfy electrical safety and minimize physical damage to electrical equipment from hose stream impingement.	Adjustable pattern fog nozzles are provided. Personnel are trained in their safe use.

Position For Plants Under Construction and Operating Plants	EF-2 Response
Fire detection in the control room cabinets, and consoles should be provided by smoke and heat detectors in each fire area. Alarm and annunciation should be provided in the control room. Fire alarms in other parts of the plant should also be alarmed and annunciated in the control room.	Ionization detectors are provided in the ceiling of the room as well as in the control room cabinets and consoles. Additional protection is outlined in the fire hazards analysis. Fire alarms in other plant locations are annunciated and actuate alarms in the control room.
Breathing apparatus for control room operators should be readily available. Control room floors, ceilings, supporting structures, and walls, including penetrations and doors, should be designed to a minimum fire rating of three hours. All penetration seals should be air tight.	Breathing apparatus for the control room operators will be readily available in the control room. Control room floors, ceiling, supporting structures, and walls, including penetrations and doors, are fire rated as discussed in Section 9A.4. All penetration seals will be airtight.
Manually operated ventilation systems are acceptable.	The ventilation system will automatically be placed in the smoke purge mode by confirmed activation of the Halon system in the cable spreading room or relay room. The smoke purge mode can also be manually initiated.
Cables should not be located in concealed floor and ceiling spaces. If such concealed spaces are used, however, they should have fixed automatic total flooding halon protection. All cables that enter the control room should terminate in the control room. That is, no cabling should be simply routed through the control room from one area to another.	The concealed space beneath the computer room subfloor will be provided with a Halon system.
3. Cable Spreading Room	
(a) The preferred acceptable methods are:	
(1) Automatic water system such as closed head sprinklers, open head deluge, or open directional spray nozzles.	The cable spreading room is protected by an automatic Halon system.
Deluge and open spray systems should have provisions for manual operation at a remote station; however, there should also be provisions to preclude inadvertent operation. Location of sprinkler heads or spray nozzles should consider cable tray sizing and Arrangements to assure adequate water coverage. Cable should be designed to allow wetting down with deluge water without electrical faulting. Open head deluge and open directional spray systems should be zoned so that a single failure will not deprive the entire area of automatic fire suppression capability. The use of foam is acceptable, provided it is of a type capable of being delivered by a sprinkler or deluge system, such as an Aqueous Film Forming Foam (AFFF).	In addition, a manually actuated automatic sprinkler system is installed for backup capability.

Position For Plants Under Construction and Operating Plants	EF-2 Response
(2) Manual hoses and portable extinguishers should be provided as backup.	Manual hose and portable fire extinguishers are provided.
(3) Each cable spreading room of each unit should have divisional cable separation, and be separated from the other and the rest of the plant by a minimum three-hour rated fire wall (refer to NFPA 251 or ASTM E-119 for fire test resistance rating).	Section 9A.4 discusses the fire rating of barriers
(4) At least two remote and separate entrances are provided to the room for access by fire brigade personnel; and	Two remote entrances are provided to the room. (See Figure 9A-7.)
(5) Aisle separation provided between tray stacks should be at least three feet wide and eight feet high.	Aisles 3 ft wide and 8 ft high are not provided.
(b) For cable spreading rooms that do not provide divisional cable separation of a(3), in addition to meeting a(1), (2), (4), and (5) above, the following should also be provided:	Cable separation has been provided adequately to permit safe plant shutdown in case of a fire in the cable spreading room. See Subsection 9A.4.2.8.
(1) Divisional cable separation should meet the guidelines of Regulatory Guide 1.75, "Physical Independence of Electric Systems."	
(2) All cabling should be covered with a suitable fire retardant coating.	
(3) As an alternate to a(1) above, automatically initiated gas systems (Halon or CO_2) may be used for primary fire suppression, provided a fixed water system is used as a backup.	
(4) Plants that cannot meet the guidelines of Regulatory Guide 1.75, in addition to meeting a(1), (2), (4), and (5) above, an auxiliary shutdown system with all cabling independent of the cable spreading room should be provided.	
4. Plant Computer Room	
Safety related computers should be separated from other areas of the plant by barriers having a minimum three-hour fire resistant rating. Automatic fire detection should be provided to alarm and annunciate in the control room and alarm locally. Manual hose stations and portable water and halon fire extinguishers should be provided.	Plant computers are not safety related.

Position For Plants Under Construction and Operating Plants	EF-2 Response
5. Switchgear Rooms	
Switchgear rooms should be separated from the remainder of the plant by minimum three-hour rated fire barriers to the extent practicable. Automatic fire detection should alarm and annunciate in the control room and alarm locally. Fire hose stations and portable extinguishers should be readily available.	Safety-related switchgear rooms are separated from the remainder of the plant by walls, floors, and ceilings which have fire-resistant barriers. (See Section 9A.4, which discusses the fire rating of the barriers.) Automatic fire detection devices, which actuate alarms and annunciate in the control room, are provided. Fire hose and portable fire extinguishers are readily available.
Acceptable protection for cables that pass through the switchgear room is automatic water or gas agent suppression. Such automatic suppression must consider preventing unacceptable damage to electrical equipment and possible necessary containment of agent following discharge.	
6. Remote Safety Related Panels	
The general area housing remote safety related panels should be provided with automatic fire detectors that alarm locally and alarm and annunciate in the control room. Combustible materials should be controlled and limited to those required for operation. Portable extinguishers and manual hose stations should be provided.	Areas housing remote safety-related panels are provided with automatic fire detectors that alarm in the control room. Combustible materials are controlled in these areas. Manual fire suppression equipment is provided for these areas. The fire hazards analysis details these areas.
7. Station Battery Rooms	
Battery rooms should be protected against fire explosions. Battery rooms should be separated from each other and other areas of the plant by barriers having a minimum fire rating of three hours inclusive of all penetrations and openings. (See NFPA 69, "Standard on Explosion Prevention Systems.") Ventilation systems in the battery rooms should be capable of maintaining the hydrogen concentration well below 2 vol. % hydrogen concentration. Standpipe and hose and portable extinguishers should be provided.	The battery rooms are separated from other areas by at least 1-1/2 hr fire-resistance-rated walls, floors, and ceiling. The fire hazards analysis outlines the protection provided for these areas. The ventilation system will maintain the hydrogen concentration well below 2 percent by volume. Portable fire extinguishers and a hose reel are provided.
Alternatives:	
(a) Provide a total fire rated barrier enclosure of the battery room complex that exceeds the fire load contained in the room.	
(b) Reduce the fire load to be within the fire barrier capability of 1-1/2 hours.	
OR	
(c) Provide a remote manual actuated sprinkler	

Position For Plants Under Construction and Operating Plants	EF-2 Response
system in each room and provide the 1-1/2 hour fire barrier separation.	
8. Turbine Lubrication and Control Oil Storage and Use Areas	
A blank fire wall having a minimum resis-tance rating of three hours should separate all areas containing safety related systems and equipment from the turbine oil system. When a blank wall is not present, open head deluge protection should be provided for the turbine oil hazards and automatic open head water curtain protection should be provided for wall openings.	N/A
9. Diesel Generator Areas	
Diesel generators should be separated from each other and other areas of the plant by fire barriers having a minimum fire resistance rating of three hours.	Emergency diesel generators of opposite divisions are separated by a 3-hr fire barrier.
When day tanks cannot be separated from the diesel-generator one of the following should be provided for the diesel generator area:	Day tanks are separated from the diesel generator by 3-hr fire barrier walls. The day tanks are also protected by a wet pipe sprinkler system.
(a) Automatic open head deluge or open head spray nozzle system(s)	
(b) Automatic closed head sprinklers	
(c) Automatic AFFF that is delivered by a sprinkler deluge or spray system	
(d) Automatic gas system (Halon or CO_2) may be used in lieu of foam or sprinklers to combat diesel generator and/or lubricating oil fires.	
10. Diesel Fuel Oil Storage Areas	
Diesel fuel oil tanks with a capacity greater than 1100 gallons should not be located inside the buildings containing safety related equipment. They should be located at least 50 feet from any building containing safety related equipment, or if located within 50 feet, they should be housed in a separate building with construction having a minimum fire resistance rating of three hours. Buried tanks are considered as meeting the three hour fire resistance requirements. See NFPA 30, "Flammable and Combustible Liquids Code," for additional guidance.	Diesel fuel-oil tanks are separated from the EDG by construction having a 3-hr fire-resistance rating. The fire hazards analysis (Section 9A.4) discusses the diesel fuel storage room fire protection.

Position For Plants Under Construction and Operating Plants	EF-2 Response
When located in a separate building, the tank should be protected by an automatic fire suppression system such as AFFF or sprinklers.	
In operating plants where tanks are located directly above or below the diesel generators and cannot reasonably be moved, separating floors and main structural members should, as a minimum, have fire resistance rating of three hours. Floors should be liquid tight to prevent leaking of possible oil spills from one level to another. Drains should be provided to remove possible oil spills and fire fighting water to a safe location.	
One of the following acceptable methods of fire protection should also be provided: (a) Automatic open head deluge or open head spray nozzle system(s) (b) Automatic closed head sprinklers; or (c) Automatic AFFF that is delivered by a sprinkler system or spray system	
11. Safety Related Pumps	
Pump houses and rooms housing safety related pumps should be protected by automatic sprinkler protection unless a fire hazards analysis can demonstrate that a fire will not endanger other safety related equipment required for safe plant shutdown. Early warning fire detection should be installed with alarm and annunciation locally and in the control room. Local hose stations and portable extinguishers should also be provided.	The fire hazards analysis outlines fire protection for safety-related pumps.
Equipment pedestals or curbs and drains should be provided to remove and direct water away from safety related equipment.	Equipment is installed on concrete pads. Adequate water drainage is provided.
Provisions should be made for manual control of the ventilation system to facilitate smoke removal if required for manual fire fighting operation.	Smoke removal will be provided by portable fans, if required.
12. New Fuel Area	
Hand portable extinguishers should be located within this area. Also, local hose stations should be located outside but within hose reach of this area. Automatic fire detection should alarm and annunciate in the control room and alarm locally. Combustibles should be limited to a minimum in the new fuel area. The storage area should be provided with a drainage system to preclude accumulation of water.	Manual suppression equipment, such as hose stations and portable fire extinguishers, is provided. Automatic fire detection is provided.
The storage configuration of new fuel should always be so maintained as to preclude criticality for any	

Position For Plants Under Construction and Operating Plants	EF-2 Response
water density that might occur during fire water application.	
13. Spent Fuel Pool Area	
Protection for the spent fuel pool area should be provided by local hose stations and portable extinguishers. Automatic fire detection should be provided to alarm and annunciate in the control room and to alarm locally.	Manual suppression equipment, such as hose stations and portable fire extinguishers, is provided. Automatic detection is provided.
14. Radwaste Building	
The radwaste building should be separated from other areas of the plant by fire barriers having at least three-hour ratings. Automatic sprinklers should be used in all areas where combustible materials are located. Automatic fire detection should be provided to annunciate and alarm in the control room and alarm locally. During a fire, the ventilation systems in these areas should be capable of being isolated. Water should drain to liquid radwaste building sumps. Acceptable alternative fire protection is automatic fire detection to alarm and annunciate in the control room, in addition to manual hose stations and portable extinguishers consisting of hand held and large wheeled units.	Except as noted in section 9A.4.4.2, the radwaste building is separated from the turbine building by fire barriers having a 3-hr fire-resistance rating. For a discussion of the onsite storage building, see Section 11.7 of the UFSAR. Automatic sprinklers are provided as discussed in Subsection 9A.4.4. Automatic fire detection annunciates and alarms in the control room. The ventilation system can be isolated during a fire. The building water drains are discussed in Section 9A.4.4.2
15. Decontamination Areas	
The decontamination areas should be protected by automatic sprinklers if flammable liquids are stored. Automatic fire detection should be provided to annunciate and alarm in the control room and alarm locally. The ventilation system should be capable of being isolated. Local hose stations and hand portable extinguishers should be provided as backup to the sprinkler system.	No significant quantity of flammable liquids is stored in the decontamination areas. Automatic fire detection alarms and annunciates in the control room. Hose stations and portable extinguishers are provided.
16. Safety Related Water Tanks	
Storage tanks that supply water for safe shutdown should be protected from the effects of fire. Local hose stations and portable extinguishers should be provided. Portable extinguishers should be located in nearby hose houses. Combustible materials should not be stored next to outdoor tanks. A minimum of 50 feet of separation should be provided between outdoor tanks and combustible materials where feasible.	Subsection 9A.4.7 of the fire hazards analysis outlines the protection for this area.

Position For Plants Under Construction and Operating Plants	EF-2 Response
17. Cooling Towers	
Cooling towers should be of noncombustible construction or so located that a fire will not adversely affect any safety related systems or equipment. Cooling towers should be of non-combustible construction when the basins are used for the ultimate heat sink or for the fire protection water supply. Cooling towers of combustible construction, so located that a fire in them could adversely affect safety related systems or equipment should be protected with an open head deluge system installation with hydrants and hose houses strategically located.	Residual heat removal cooling towers are of noncombustible construction. Circulating water cooling towers are located such that a fire will not affect safety related equipment.
18. Miscellaneous Areas	
Miscellaneous areas such as records storage areas, shops, warehouses, and auxiliary boiler rooms should be so located that a fire or effects of a fire, including smoke, will not adversely affect any safety related systems or equipment. Fuel oil tanks for auxiliary boilers should be buried or provided with dikes to contain the entire tank contents.	The record storage areas, shops, outage building and warehouse are separated from safety-related systems or equipment by fire barriers. Therefore, fire or smoke would not affect safety-related systems or equipment. The fuel-oil tank for the auxiliary boiler is provided with a dike.
G. Special Protection Guidelines	
1. Welding and Cutting, Acetylene-Oxygen Fuel Gas Systems	
This equipment is used in various areas throughout the plant. Storage locations should be chosen to permit fire protection by automatic sprinkler systems. Local hose stations and portable equipment should be provided as backup. The requirements of NFPA 51 and 51B are applicable to these hazards. A permit system should be required to utilize this equipment. (Also refer to 2f herein.)	Storage of welding and cutting acetylene-oxygen gas bottles will be in the warehouse areas protected by automatic sprinklers. A permit system is used to control open flames in the plant as explained previously in Section B.3(a).
2. Storage Areas for Dry Ion ExchangeResins	
Dry ion exchange resins should not be stored near essential safety related systems. Dry unused resins should be protected by automatic wet pipe sprinkler installations. Detection by smoke and heat detectors should alarm and annunciate in the control room and alarm locally. Local hose stations and portable extinguishers should provide backup for these areas. Storage areas of dry resin should have curbs and drains. (Refer to NFPA 92M, "Waterproofing and Draining of Floors.")	Dry ion exchange resins will be stored in the warehouse which is removed from safety-related areas and protected by an automatic wet pipe sprinkler system. The warehouse area is also provided with a fire detector system that provides local and control room alarms. Local hose stations and portable extinguishers are provided in the warehouse as backup to the sprinkler system. A curb and drain system is not necessary in the warehouse as the entire area is sprinkled.

Position For Plants Under Construction and Operating Plants	EF-2 Response
3. Hazardous Chemicals	
Hazardous chemicals should be stored and protected in accordance with the recommendations of NFPA 49, "Hazardous Chemicals Data." Chemicals storage areas should be well ventilated and protected against flooding conditions since some chemicals may react with water to produce ignition.	Minor amounts of hazardous chemicals may be stored in the laboratory or shop areas. NFPA 49, "Hazardous Chemicals Data," is used as a guideline for storage. Portable extinguishers and hose stations are provided in these areas.
4. Materials Containing Radioactivity	
Materials that collect and contain radioactivity such as spent ion exchange resins, charcoal filters, and HEPA filters should be stored in closed metal tanks or containers that are located in areas free from ignition sources or combustibles. These Materials should be protected from exposure to fires in adjacent areas as well. Consideration should be given to requirements for removal of isotopic decay heat from entrained radioactive materials.	Materials that collect and contain radioactivity are stored in the radwaste area until processed. Spent resins are stored (wet) in the phase separator tanks until processed. Spent charcoal filter material and HEPA filters will be stored in metal containers in the radwaste bailed waste storage room. This room removes the material from other areas of the radwaste building. This area is provided with fire detectors.

CHAPTER 10: STEAM AND POWER CONVERSION SYSTEM

10.1 SUMMARY DESCRIPTION

The steam and power conversion system for Fermi 2 includes a tandem-compound, single-stage reheat, six-flow exhaust, 1800-rpm turbine with nominal 43-in. (8th stage) last-stage buckets (blades). The turbine nominal rating at the generator terminals is 1235 MWe at 1.5 in. Hg abs, 100 percent reactor flow, and zero percent makeup. The design rating of the generator coupled to the turbine is 1,350,000 kVA at 22,000 V, 60-Hz frequency, and 0.90 power factor. Steam at 981.0 psia, 544°F, and 0.46 percent moisture is provided by the nuclear steam supply system (NSSS) at the turbine throttle to drive the main turbine generator.

Moisture separation with one stage of reheat is provided between the high-pressure and the low-pressure turbines for all steam entering the low-pressure turbines. Steam from the low-pressure turbines is condensed in a single-pressure condenser of divided water-box design. Condensate is collected in the condenser hot-wells and pumped through the condensate/feedwater cycle to the NSSS. Heater drains are cascaded into the condenser, except for the heater drains from heaters 5 and 6. The condensate/feedwater from these is pumped forward into the reactor feed pump (RFP) suction.

The condensate and feedwater system supplies feedwater to the NSSS through a condensate cleanup system and then through six stages of extraction feedwater heating.

Circulating water from a circulating water reservoir is pumped through the main condenser and returned to the cooling towers. There, the heat rejected from the steam conversion system is dissipated into the atmosphere. Makeup water for the circulating water system is taken from Lake Erie.

The heat balance at design rating is shown in Figure 10.1-1. Key cycle characteristics are shown in Table 10.1-1.

Normally, the turbine and auxiliary equipment use all the steam being generated by the NSSS; however, an automatic pressure-controlled 23.5 percent-capacity turbine bypass system discharges excess steam directly into the condenser. The capacity of this system is 23.5 percent of the rated reactor flow.

The steam and power conversion system is designed to use the energy available from the NSSS. It has the capability of accepting at least rated reactor flow and reactor pressure for safe, continuous operation. The necessary biological shielding for the main turbines, RFP turbines, moisture separators and reheaters, and condenser is provided for personnel protection.

The individual components of the steam and power conversion system are based on a proven conventional design acceptable for use in large central-station power plants. All auxiliary equipment has been sized on the basis of the design flow rating and pressure rating with turbine valves providing adequate margin for pressure control in accordance with the heat balance shown in Figure 10.1-1. Design margins have been included to ensure adequate capacity under all operating circumstances.

The steam turbine is provided with an electro-hydraulic control (EHC) system having three electrical speed inputs. Speed logic is redundantly processed in both electronic and hydraulic channels. Turbine steam supply valves are provided in serial pairs; a stop valve is actuated by either of two redundant overspeed trip systems followed by a controlling valve modulated by the speed governing system. The latter valve is tripped by either of the two overspeed trip systems. Failure of a single component in the speed control system does not lead to excessive overspeed.

Logic circuits are provided for turbine protection and operation. Additionally, testing circuits for the turbine steam valves are provided. Emergency trip devices include a manual trip, a mechanical overspeed trip, an electrical overspeed trip, and an electrical vacuum trip.

None of the components of the power conversion systems are required to operate to ensure a safe reactor shutdown. This is because reactor safety systems are provided that are designed to protect the reactor under all conditions, including complete isolation from the power conversion systems. Therefore, reliability of these power conversion systems, except where concerned with control of radioactivity, is primarily a function of system operating requirements.

Redundant equipment is provided, wherever feasible, to prevent excessive loss of plant output or excessive frequency of reactor scram.

The safety-related aspects of several postulated failures that might occur within the power conversion system have been considered. The following specific situations have been analyzed:

a. Breaks in the feedwater system that allow discharge of contaminated feedwater into the turbine building

b. Failure of the air-ejection line resulting in discharge of activity directly into the turbine building

c. Missiles generated by a postulated turbine failure

d. Introduction of contaminants into the reactor vessel via the condensate/feedwater system.

Feedwater system breaks and failure of the air-ejection line are both discussed in Chapter 15. These analyses indicate that the amount of radiation released into the environment following any one of these studied incidents is within acceptable limits.

The effects of turbine missiles are analyzed in Subsections 10.2.3 and 3.5.1.2.2. The conclusion is that postulated turbine missiles are not a plausible event.

Regulatory Guide 1.56, Maintenance of Water Purity in Boiling Water Reactors, will be met to ensure that contaminants from the feedwater entering the reactor vessel are kept at acceptably low levels.

TABLE 10.1-1 SUMMARY OF IMPORTANT NOMINAL AND PERFORMANCE CHARACTERISTICS OF THE POWER CONVERSION SYSTEM

Turbine Data	
Manufacturer	General Electric Company Turbine Generator, LTD.[a] GE for HP and LP Steam Path replacement components
Type / LSB length, in.	43 (8th stage)
Number of cylinders	One higher pressure, three low pressure
Gross electrical output at the generator terminals (MWe)	1235
Condenser pressure, in. Hg abs	1.5
Final feedwater temperature, °F	426.5 (nominal)
Steam conditions at throttle valves inlet	
Flow, lb/hr	13,722.820
Pressure, psia	981.0
Temperature, °F	544
Enthalpy, Btu/lbm	1190.6
Moisture content, percent	0.46
Turbine cycle arrangement	
Number of steam reheat stages	One
Number of feedwater heating stages	Six
Heater drain system	Heaters 5 and 6 pumped forward
Feedwater heaters in condenser neck	Numbers 1 and 2
Type of condensate demineralizer	Mixed-powdered-resin type
Main steam bypass capacity, percent of rated reactor flow	23.5

UPDATED FINAL SAFETY ANALYSIS REPORT

FIGURE 10.1-1

HEAT BALANCE AT 100 PERCENT
REACTOR FLOW

10.2 TURBINE GENERATOR

10.2.1 Design Bases

The turbine generator is designed to meet the following conditions:

a. Gross electrical output at the generator terminals at 100 percent reactor flow is 1235 Mwe.

b. Steam conditions at the turbine throttle valves inlet

1.	Flow, lb/hr	13,722,820
2.	Pressure, psia	981.0
3.	Temperature, °F	544
4.	Enthalpy, Btu/lbm	1190.6
5.	Moisture content, percent	0.46

c. Exhaust pressure, in. Hg abs 1.5

d. Final feedwater temperature, °F 426.5

e. Stages of feedwater heating Six

f. Stages of steam reheating One

These figures represent the 100 percent reactor flow heat balance conditions shown in Figure 10.1-1.

The unit is to be operated initially in a base-loaded manner but has the provision to be operated in a load-following manner when this becomes beneficial from the standpoint of system reliability and economics.

The nuclear steam supply system (NSSS) and turbine have the ability to provide continuous load-following capability over a range of approximately 31.5 percent of rated power. This power change via recirculation flow can be accomplished at the rate of 1.5 percent/sec for both load increases and decreases. Step-change electrical load reductions that do not exceed 23.5 percent of rated power are handled by operation of the main steam bypass system without requiring an associated change in reactor power.

10.2.2 Description

10.2.2.1 Turbine Generator

The General Electric Company Turbine Generator, Ltd. (formerly English Electric Co.) turbine is a four-casing, tandem-compound, six-flow, 1800-rpm unit that has been modified. During RF05, the LP Turbine Steam Path consisting of rotors, buckets (blades), diaphragms and steam flow guides was replaced with GE designed components. The HP Turbine Steam Path was replaced during RF07 with GE designed components. The major components replaced were the rotor, diaphragms, associated seals, and coupling spacers. An inlet snout was added to provide the steam flow path into the first stage nozzles. An ac generator is connected to the turbine shaft. The excitation system consists of an automatic voltage regulator and excitation transformer.

The turbine consists of one double-flow high-pressure element in tandem with three double-flow low-pressure elements.

Turbine-generator bearings are lubricated by a conventional pressurized oil system. Two 100 percent electric (ac) motor-driven pumps supply bearing oil to the turbine generator under normal operation. Normally one ac pump is running and one is a spare. One electric (dc) motor-driven backup pump is provided in the event both ac pumps fail as a result of a loss of ac power.

Steam from the NSSS enters the high-pressure turbine through four 24-in. stop valves and governing control valves. One stop valve and one control valve form a single assembly. After expanding through the high-pressure turbine, the steam flows through the moisture separators and reheaters to the six intermediate stop valves and six intercept valves into steam lines leading to the three low-pressure turbines. Steam from each low-pressure turbine is then exhausted into the main condenser.

Moisture separation and reheating of the steam are provided between the high-pressure and low-pressure elements in two parallel shells, each of which contains combined moisture-separator-reheater assemblies. A separator-reheater assembly is located on each side of the turbine parallel to the turbine shaft.

The turbine generator is protected from excessive overspeed by two emergency overspeed trip protection systems, the mechanical overspeed trip system and the electrical overspeed trip system. The mechanical overspeed trip system consists of two redundant systems using two separate spring-loaded throwout plungers mounted on the turbine shaft. Should the turbine accelerate to its over-speed trip set point, each plunger strikes its respective position limit switch mounted adjacent to each of the plungers, energizing a system of protective relays that will trip the turbine.

The electrical overspeed system uses four separate and redundant channels of speed measurement. The four channels are fed through a network of comparative logic gates. This comparative logic system monitors the speed input signals and alerts the operator with an alarm if any one of the four inputs fails to match the others. The system ac power supply is redundant with automatic throwover to the backup ac supply. The power supplies, main, backup, and test, are monitored for loss of potential and alarmed for operator corrective action. Figure 10.2-1 is the block diagram of the electrical overspeed system.

The generator is sized to accept the gross rated output of the turbine at rated reactor pressure and reactor flow at the throttle. The generator is a direct-coupled, 60-Hz, three-phase, 22,000-V unit designed at 1,350,000 kVA at 0.90 power factor, and has a short-circuit ratio of 0.58, at a maximum hydrogen pressure of 75 psig. The generator shaft seals are oil-sealed to prevent hydrogen leakage. The static excitation system has been sized for a rated field current of 5,189 A at a rated field nominal voltage of 575 VDC.

Excitation power for the generator rotor is supplied from the excitation transformer through thyristor bridges in a configuration to allow continuous operation with a minimum of two bridges in service at full power, with the excitation being controlled by the excitation control cubicle.

10.2.2.2 Cycle Description

Steam is fed from the reactor, through four lines and associated isolation valves, into a 52-in. common manifold. From the manifold, steam is supplied to the high-pressure turbine through four 24-in. lines. Each line contains a turbine stop valve and a turbine control valve. The control valves adjust the quantity of steam admitted to the turbine and thus control the reactor steam pressure and the electrical power output.

If operation with one control valve out of service is necessary, steam is supplied to the high-pressure turbine through three 24-in. lines. An evaluation of the limiting transients and issues associated with one turbine stop or control valve out of service for Fermi 2 has been documented in Reference 2. The evaluation is qualitative and independent of fuel type through GE14. The conclusions are generic and can be applied to both current and future cycles of Fermi 2. Reference 3 confirms that the Reference 2 evaluation is applicable to GNF3 fuel with the power and steam flow capacity updates for 1 Turbine Control Valve Out of Service (TCVOOS) at 3486 MW. The assessment with one turbine stop or control valve out-of-service in Reference 2 along with Reference 3 covers the adequacy of the current power and flow dependent MCPR and MAPLHGR limits and the impact on ECCS/LOCA and ATWS. The assumptions for the assessments and conclusions are that operation with one steam feed to the main turbine isolated by a TCV or TSV is acceptable if:

a. Core thermal power will be at or below 91.5 percent

b. Operating dome pressure is maintained at or above normal off-rated operating dome pressure but below the LCO maximum dome pressure

c. The turbine bypass system is operable

d. The moisture separator reheaters are operable

e. Operating with normal feedwater heating

f. Reactor Flow Limiter Setpoint is at 115 percent or higher.

g. Maximum Steam Flow Available is 109.4% rated steam flow.

During an electrical load reduction, steam may be bypassed directly to the condenser to maintain constant reactor pressure. The capacity of the bypass system is 23.5 percent of rated reactor flow.

After passing through the high-pressure turbine, steam is exhausted to the moisture separators and reheaters, where it is reheated by steam taken from the main steam lines ahead of the turbine stop valves. The reheated steam then passes into the low-pressure turbines. There, the steam is equally divided among the three low-pressure turbines and is eventually exhausted into the condenser. The condensed heating steam is drained to the No. 6 feedwater heaters.

Steam is extracted from six points on the turbine for feedwater heating. There is one extraction point from the high-pressure turbine, one from the high-pressure turbine exhaust, and four from the low-pressure turbines, as shown in Figure 10.2-2.

Steam is supplied to the reactor feed pump (RFP) turbines from two sources: (1) the main steam manifold during startup and low-load operation and (2) the hot reheat line during normal operation.

10.2.2.3 Instrumentation Application

The turbine generator uses an electro-hydraulic control (EHC) system that controls the speed, load, pressure, and flow for startup and planned operation, and trips the unit when required. The EHC system operates the high-pressure stop valves, bypass valves, control valves, low-pressure stop and intercept valves, and other protective devices. Turbine-generator supervisory instrumentation is provided for operational analysis as well as for pre- and postmalfunction diagnosis.

The automatic control functions of the turbine generator are correlated with the reactor pressure control and recirculation control. For details, see Subsection 7.7.1.

The turbine EHC system uses solid-state electronics and high-pressure hydraulics to control the nuclear steam flow from the reactor.

Four major functions are performed by the turbine EHC system, as follows:

a. Speed control

b. Pressure control

c. Valve position control

d. Supervisory control.

Speed control is accomplished by comparing a turbine shaft speed signal to a speed reference to produce a speed error signal. In addition, a digital technique is used to produce a turbine acceleration signal from the turbine shaft speed pickup pulses. This acceleration signal is compared to a reference to produce an acceleration error signal that is summed with the speed error signal to produce a speed/acceleration error. The speed/ acceleration error is modified by an adjustable proportional constant to produce a valve position demand. The speed governing system has been designed using three redundant systems.

Pressure control is accomplished by comparing turbine inlet steam pressure to a pressure reference and thereby producing a pressure error signal. This pressure error is modified by an adjustable electronic regulator to obtain a valve position demand.

Unitized actuators at each turbine steam valve accept the electrical signals from the pressure control, speed control, or the supervisory control and position the valve in the required manner. Each valve is provided with an individual valve actuator, which eliminates the need for extensive high-pressure control oil piping. The unitized actuator is a self-contained, electro-hydraulic valve positioner that converts the electrical control signals to valve position. Each unitized actuator is designed to perform a specific valving function.

Supervisory control is provided to maintain the turbine in a safe controlled state or to initiate a rapid shutdown in case of an emergency.

Rapid shutdown is achieved by initiating the fast closure mode of valve control. Under this mode of control, the maximum closure rate is obtained. Fast-closure full-stroke travel time of the turbine stop valves is 0.20 to 0.22 sec. The fast-closure full-stroke travel time of the turbine control valves is 0.20 to 0.22 sec. Low-pressure stop and intercept valves close in approximately 1.0 sec when operating in the fast closure mode.

10.2.2.4 Emergency Control Operations

Loss of electrical load with respect to subsequent interactions should be considered under three conditions (a., b., and c. below). For these three conditions, the turbine-generator emergency overspeed will not exceed 120 percent of rated speed (1800 rpm).

a. Generator breakers (two) trip

   The generator has a system of protective devices that protect the generator from damage. This protection is achieved by tripping open the generator breakers. The generator breakers have position switches that will initiate a direct turbine trip when both breakers are tripped open.

b. System disturbances resulting in sustained loss of electrical load

   If the turbine generator has been running at maximum load and the load on the generator is suddenly lost (not the result of generator breaker trips), the following events will occur in controlled rapid succession:

   1. The turbine will accelerate at a rate proportional to loss in electrical load until the turbine control system starts to close the control valves
   2. The turbine control will initiate the fast closure mode of the turbine control valves (TCV) when the turbine acceleration exceeds a prescribed trip setpoint
   3. The operation of the HP stop valve and the associated RPS turbine stop valve closure limit switch initiates fast closure mode which will initiate a direct reactor scram
   4. The control valves will close at the maximum closure rate by means of the fast-acting solenoid valves
   5. The entrained steam between the valves and the turbine, in the turbine steam casing, and in the extraction lines will expand. Some of the accumulated water will flash into steam, supplying energy to the turbine at a relatively moderate rate
   6. The turbine speed will cease to increase when the entrained steam has stopped expanding. The turbine will trip on reverse power when its speed is less than synchronous
   7. Generator breaker and turbine trips will be initiated on reverse power to the generator if the loss of electrical load has not already isolated the generator from the system
   8. The turbine will coast down until turning gear speed is established. The turning gear will maintain slow rotation of the turbine to allow even cooling during the desoaking period.

c. Partial loss of electrical load

   On a small loss of load, the turbine will accelerate slowly. Assuming that the fast closure mode is not initiated, the bypass valves will divert the nuclear steam supply to the condenser until the steam supply can be decreased.

The emergency trip system closes all valves (turbine stop valves, control valves, intercept valves, and reheat stop valves), shutting down the turbine on the following signals:

NOTE: Setpoints are approximate and are for illustration only.

a. Turbine speed approximately 7 to 10 percent above rated speed by
   1. Magnetic speed pickups - four provided (106 to 108 percent speed)
   2. Overspeed trip plungers - two provided (107 to 110 percent speed).
b. Vacuum less than a preselected value (7.5 in. Hg abs)
c. Excessive thrust-bearing wear (±0.050 in.)
d. Low flow of generator stator water coolant (600 gpm or less after a time delay of 60 seconds)
e. High stator-coolant outlet temperature (195°F)
f. Generator protection, including reverse-power sustained and both generator breakers tripped
g. Low lube-oil pressure - below 10 psig after a 20-sec time delay
h. Loss of two speed-sensing signals (failure of two of three computing channels)
i. Loss of both main and emergency power supplies to the EHC cubicle
j. High pressure in separator-reheaters - 256 psia
k. High reactor water level
l. Manual trip from control room panel
m. Deleted
n. High shaft or pedestal vibration after a 7.5 second (maximum) time delay with
   1. "Hi Hi" (12 mils shaft or 10 mils pedestal) on any bearing and
   2. "Hi" (<10 mils) on an adjacent bearing
o. Hydrogen-seal oil-pressure differential low - 10 psig after a 20-sec time delay
p. Hydrogen gas temperature high - 185°F
q. Both main lube-oil reservoir emergency valves open.

10.2.2.5 Turbine-Generator Supervisory Instruments

The turbine supervisory instrumentation is located in the main control room and is sufficient to detect malfunctions.

The turbine-generator supervisory instrumentation includes monitors for the following:

a. Electrical load
b. Shaft speed
c. Control valve position
d. Vibration and eccentricity
e. Thrust-bearing wear
f. Exhaust hood temperature and spray pressure
g. Oil system pressures, levels, and temperatures
h. Bearing metal and oil drain temperatures
i. Shell temperatures
j. Valve positions
k. Shell and rotor differential expansion
l. Hydrogen temperature, pressure, and purity
m. Stator-coolant temperature and conductivity
n. Stator winding temperature
o. Excitation equipment area temperature
p. Steam seal pressure
q. Gland steam condenser vacuum
r. Steam chest pressure
s. Hydrogen-seal oil pressure.

10.2.2.6 Testing Provisions

Provisions are made for testing each of the following devices while the turbine generator is operating:

a. Main stop and control valves
b. Intermediate stop and intercept valves
c. Overspeed governor
d. Turbine extraction nonreturn valves (excluding small valves)
e. Vacuum trip
f. Lubricating oil system backup pumps.

The following testing and inspection activities are performed in accordance with the manufacturer's recommendations and operational experience or constraints:

a. The mechanical and electrical overspeed trip systems are operated and checked

b. The main steam stop valves, main steam control valves, low pressure stop valves, and intercept valves are dismantled and inspected

c. The main steam stop valves, main steam control valves, low pressure stop valves, and intercept valves are exercised.

10.2.3 Turbine Missiles

Fermi 2 was designed with barriers to resist potential turbine missiles. These barriers were designed to protect the safety related plant components from a design basis turbine missile which, prior to the replacement of the LP turbines during RF05, was a 120° segment of the largest main low-pressure turbine wheel. That missile weighed 8650 lbs. and had an initial velocity of 383 mph.

During the fifth refueling outage, the three built-up low pressure rotors, including blades and diaphragms, for Fermi 2 LP turbines were replaced. The maximum attainable speed of the new rotors will be approximately 218-222% of rated speed. At this point, the steam flow through the rotating steam path is well away from design conditions with some stages being driven by the steam while the remainder absorb energy. This scenario assumes that all the buckets remain intact on the rotor, the generator does not loosen retaining rings, wedges or field bars, and that the unit does not experience severe rubbing, all of which would keep the rotor at lower speeds.

Considering the minimum rotor material specification strength values, and assuming all buckets remain attached, the minimum overspeed capability of the rotors is about 219-225%. Using typical strength values, the overspeed capability of the rotors is considerably higher than the shrunk-on designs and exceeds the maximum overspeed the rotors can attain. However, the turbine overspeed control system is designed to limit maximum turbine overspeed of 120% of the turbine rated speed.

A complete failure of the control system and safety-related items is required to reach the event described. The probability of this occurring is well below 10 to the -8 power. In conclusion, the rotor stress levels are quite low; the probability of missiles being generated by the low pressure rotors is not present.

During the seventh refueling outage, the high pressure rotor, including blades and diaphragms for Fermi 2 HP turbine, was replaced. Although the HP rotor was replaced after the LP rotors, the LP rotor document regarding nuclear turbine missile analysis still governs. This concluded that blades will not penetrate outer casings. The minimum speed at which the HP blades fail is bounded by the LP turbine analysis performed for RF05.

The generator is not being replaced. The existing calculations indicate that missiles emanating from the generator rotor will be stopped before they can completely breach their respective outer casings. Concluding, with the low-pressure rotor replacement, there will no longer be a design basis turbine missile at Fermi 2, however the originally designed missile barriers remain intact.

The probability of a failure of a rotor or bucket (blade) is further minimized by the selection of materials, manufacturing process, preservice inspections and established inservice inspection programs.

The LP rotors are a GE proven monoblock design, whereby a rotor is machined from a single forging that accounts for bucket (blade) attachment points, as well as the coupling configuration; thus, eliminating the need for shrunk on discs and couplings. The new rotors are forged out of a GE proprietary NiCrMoV material that is similar to ASTM A470 Class 6 which meets the requirements specified in the purchase specification. The monoblock forging material chemistry is optimally balanced to have high hardenability, to achieve good fracture toughness at the required tensile strength, low tramp elements to minimize temper embrittlement and low sulfur to minimize harmful segregation. The rotors have the bucket (blade) wheel dovetails machined directly into the rotor forgings. The first six stages utilize tangential entry “pinetree” dovetails to attach the buckets, the last two stages utilize radial entry finger dovetails with pins.

The buckets (rotor blades) are either fabricated from bar stock or forged. The material is a GE proprietary material that consists of nominal 12% Cr. and is similar to ASTM A479, except with more stringent quality requirements. To protect against moisture erosion of the blade tips, GE uses flame hardening in lieu of stellite shields to provide an equivalent resistance to erosion, and to minimize the addition of cobalt into the primary system. The last four bucket stages (5, 6, 7 and 8) will be flame hardened. In addition to flame hardening, stages 5, 6 and 7 have moisture removal grooves that help direct water to drainage paths through the diaphragms. This design helps prevent water build-up, and that will reduce bucket’s loading during turbine operation.

The first six bucket stages have standard GE shot peened pinetree dovetails for attachment to the rotor wheels. The last two stages have finger dovetails with shot peened pins for attachment to the rotor wheels. Shot peening reduces concentrated stresses, therefore significantly improving the material resistance to stress corrosion cracking and improving the dovetail reliability.

The last stage bucket is what GE refers to as a 43C design. The bucket length is only 43 inches as compared to the original last stage blade which was approximately 45 inches. The 43C bucket is based on GE proven designs and latest technology utilizing, at its outer periphery, a two-piece over-under continuous cover connecting each bucket (blade) in its row together. This helps maintain the space at the bucket tips where the steam flows through and helps resist blade twisting, thus allowing for a more efficient bucket design.

The turbine supervisory instrumentation is used as a continuous inservice monitoring process of the turbine and associated equipment performance.

Edison performed the inspection of the low-pressure turbine disks during the second refueling outage in accordance with the Technical Specifications. This inspection consisted of volumetric examination of the disk bore area using ultrasonic techniques. Future inspection requirements will be per the turbine manufacturer’s recommendation.

10.2.4 Evaluation

The primary source of activity in the steam and power conversion system is radiation from ^{16}N, formed by activation in the reactor. Nitrogen-16 has a half-life of approximately 7 sec. The activated nitrogen is carried with the steam to the turbine. Fission-product noble gases and other activation gases, such as ^{19}O, ^{17}N, and ^{13}N, are also carried with the steam to the turbine. Some nongaseous fission and activation products are present in the turbine as a result of moisture carryover in the steam from the NSSS.

The activity entering the low-pressure turbine is reduced because of the presence of moisture separation and transit time between the high-pressure and low-pressure turbines, which permits the ^{16}N to decay.

Most of the noncondensible gases in the condenser are removed by the steam-jet air ejectors to the offgas system, which is described in Section 11.3. The activity remaining in the condensate is reduced significantly by the nominal 4-minute holdup time in the condenser hotwell.

Shielding requirements are discussed in Section 12.1. The turbine generator is in an administratively controlled access area.

EXTRACTION STEAM SYSTEM

10.3 MAIN STEAM SUPPLY SYSTEM

10.3.1 Design Bases

10.3.1.1 Safety Design Bases

To satisfy the safety design bases, the main steam lines from the reactor up to the second isolation valves are designed according to the following piping classification, which is in accordance with the ASME Boiler and Pressure Vessel Code:

a. From the reactor to the drywell wall - ANSI B31.7, Class A, Category I

b. From the drywell wall to the outer main steam isolation valve - Section III, Class 1, Category I

c. The outer isolation valve to the third isolation valve is seismically qualified and designed to ANSI B31.1.0, Group D, Category II/I.

10.3.1.2 Power Generation Design Bases

The main steam supply system is designed to fulfill the following functions:

a. To deliver steam from the nuclear steam supply system (NSSS) up to the turbine generator

b. To provide steam for the reheater and the steam-jet air ejectors

c. To provide steam for the reactor feed pump (RFP) turbines during startup and low-load operations

d. To provide steam for the turbine seal system and flange warming during startup

e. To deliver excess steam produced in the NSSS to the condenser during startup and transients whenever the steam used by the turbine is less than that produced by the NSSS.

10.3.2 Description

The main steam supply system is shown in Figure 10.3-1.

The main steam piping consists of four 24-in. lines from the outboard (second) main steam isolation valves (MSIVs) to the 52-in. manifold (including the motor-operated [third] MSIVs), and then to the locations described in Subsection 10.3.1.2. The turbine stop valves and MSIVs may be tested independently during plant operation.

The main steam line pressure relief system, main steam line flow restrictors, and MSIVs are described in Subsections 5.2.2, 5.5.4, and 5.5.5, respectively.

The design pressure-temperature rating of the main steam piping is 1250 psig/575°F, the same as the design pressure-temperature of the NSSS. The Category I design requirements are placed (1) on the main steam piping from the reactor up to the second isolation valve and (2) on all branch lines up to and including the first valve, which is either normally closed or capable of automatic closure during all modes of normal NSSS operation. The main steam line is also analyzed for the dynamic loadings caused by fast closure of the turbine stop valves. For further information on the design of the main steam piping and valves, see Subsection 6.2.6.6.

A 52-in. manifold is installed ahead of the turbine stop valves. This provides a common point for the four steam lines from the reactor, the four steam lines to the turbine, the two bypass steam lines, the steam line to the RFP turbines, and plant auxiliaries.

A drain line is connected to the low points of each main steam line, both inside the drywell and outside the containment. Both sets of drains are headered and connected by valving to permit steam line isolation and drainage to the main condenser hotwell. To permit draining the lines for maintenance, an additional drain is provided from the low points of the drains to the radwaste system.

The drains inside and outside the containment are capable of equalizing pressure across the MSIVs prior to restart following steam line isolation. Assuming all MSIVs are closed, and the steam lines outside the drywell have been depressurized, the isolation valves outside the drywell are opened first. Then the drain lines are used to warm up and pressurize the outside steam lines. Finally, the MSIVs inside the drywell are opened.

10.3.3 Evaluation

The seismic and quality group requirements of all main steam lines and components are defined in Section 3.2. This design ensures conformance with the intent of Regulatory Guide 1.26.

Per Subsection 6.2.6, a re-analysis of the Loss-of-Coolant Accident (LOCA) using an Alternative Source Term (AST) methodology made it no longer necessary to credit the Main Steam Isolation Valve Leakage Control System (MSIVLCS) for post-LOCA activity leakage mitigation. Conformance with Regulatory Guide 1.96 was superseded by License Amendment 160, which approved the use of the AST methodology and the deletion of the MSIVLCS (Ref. Subsection A.1.96). The main steam lines from the RPV to the third MSIVs are seismically qualified as indicated in License Amendment 160.

10.3.4 Inspection and Testing Requirements

Inspection and testing are carried out in accordance with the requirements of Regulatory Guide 1.68 and ANSI N18.7. The mainsteam line is hydrostatically tested to confirm leaktightness. All welding in the above steam line is 100 percent volumetrically inspected.

UPDATED FINAL SAFETY ANALYSIS REPORT

FIGURE 10.3-1

MAIN STEAM SYSTEM

10.4 OTHER FEATURES OF THE STEAM AND POWER CONVERSION SYSTEM

10.4.1 Main Condenser

10.4.1.1 Design Bases

10.4.1.1.1 Performance Requirements

The main condenser provides the heat sink for the turbine exhaust steam, turbine bypass steam, and other turbine cycle flows, and receives and collects flows for return to the nuclear steam supply system (NSSS).

The main condenser accommodates or provides for the following at rated (nominal) full load (see Figure 10.1-1):

a.	Total turbine exhaust steam	8.10×10^6 lb/hr
b.	Total condensate outflow	10.88×10^6 lb/hr
c.	Total condenser heat duty	7.81×10^9 Btu/hr
d.	Number of condenser shells	One
e.	Condenser pressure	1.5 in. Hg abs
f.	Exhaust pressure limit	5.0 in. Hg abs
g.	Circulating water	
	1. Flow(Nominal)	836,700 gpm
	2. Number of passes	One
	3. Temperature to limit condenser pressure to 4.5 in. Hg abs	100°F
	4. Condenser temperature rise	18°F

10.4.1.1.2 Turbine Bypass Steam

The main condenser is designed to accept up to 23.5 percent rated reactor steam flow from the turbine bypass system, as described in Subsection 10.4.4 (also see Figure 10.3-1). This condition is accommodated without increasing the condenser backpressure to the turbine trip setpoint or exceeding the allowable turbine exhaust temperature.

10.4.1.1.3 Condensate Deaeration

One purpose of the main condenser is to deaerate the condensate. More specifically, it is designed to reduce the dissolved oxygen level in the condenser hotwell effluent to 7 ppb or less under normal full-load operation. This level is undesirable from a carbon steel corrosion standpoint. However, experience has shown that the normal dissolved oxygen level will be 10 to 50 ppb. If the main condenser deaerates the condensate values consistently less than 10 ppb dissolved oxygen, actions must be promulgated to restore oxygen levels and/or evaluate the consequences consistent with Owners' Group guidelines and site programs. An Oxygen Injection System has been provided to inject oxygen gas into the condensate system to restore oxygen to normal levels. (See UFSAR Figure 10.4-8(1)).

10.4.1.1.4 Air Leakage

The main condenser is designed to minimize air inleakage. Welded construction is used for the condenser shell and for condenser shell connections and penetrations. Equipment and piping connected to the condenser shell are also designed to minimize air inleakage to the main condenser. The design of the evacuation system is described in Subsection 10.4.2.

10.4.1.1.5 Condensate Detention

The condenser hotwell is designed to store a sufficient volume of condensate to provide a nominal of 4 minutes' effective detention of the condensate to allow for radioactive decay.

10.4.1.1.6 Design Codes

Condenser construction is in accordance with the requirements of Heat Exchange Institute (HEI) standards for steam surface condensers.

10.4.1.2 System Description

During plant operation, steam from the last stage of the low-pressure turbine is exhausted directly downward into the condenser shell through exhaust openings in the bottom of each of the three turbine casings and is condensed. The condenser consists of one shell serving three double-flow, low-pressure turbines. The condenser also serves as a heat sink for several other flows: the two reactor feed pump (RFP) turbine exhausts, cascading heater drains, steam line drains, pump vents and recirculation lines, heater vents, and condensate system makeup.

During transient conditions, the condenser is designed to receive bypass steam, feedwater heater drainage, and moisture-separator drainage. The condenser is also designed to receive relief valve discharges from the feedwater heater shells, steam seal regulator, and the various steam supply lines. The moisture-separator relief valves discharge to the turbine room. These valves are backed up by rupture disks.

The condenser is cooled by the circulating water system, which removes the heat rejected to the condenser as described in Subsection 10.4.5.

The condensate is pumped from the condenser hotwell by the condenser pumps, described in Subsection 10.4.7, and is returned to the feedwater and steam cycle.

The main condenser is a single-pressure, single-shell, single-pass, deaerating-type condenser with divided water boxes. The condenser tubes are 1 in. in diameter, 50 ft in length, and are made of titanium.

The condenser shell is solidly supported on the turbine foundation mat. It has expansion joints provided between each turbine exhaust opening and the steam inlet connections of the condenser shells.

The condenser hotwell has horizontal and vertical baffles. They improve deaeration and ensure a nominal detention of 4 minutes for all condensate from the time it enters the hotwell until it is removed by the condenser pumps.

Valves in the circulating water system permit one-half of the condenser to be removed from service. This might be required in case of a condenser tube leak.

The air leakage and noncondensible gases include hydrogen and oxygen gases contained in the turbine exhaust steam as a result of dissociation of water in the NSSS. These gases are collected in the condenser and passed through the air-cooling section of the condenser, where they are removed by the main condenser evacuation system, described in Subsection 10.4.2.

10.4.1.3 Safety Evaluation

During operation, radioactive steam, gases, and condensate are present in the shell of the main condenser. The anticipated inventory of radioactive contaminants during operation is discussed in Sections 11.1 and 11.3. Shielding for the main condenser is provided as discussed in Section 12.1.

Condensate is retained in the main condenser for a nominal of 4 minutes to permit radioactive decay before the condensate enters the condensate system.

Hydrogen buildup during operation is not a problem because of the provisions for continuous evacuation of noncondensibles from the main condenser. During shutdown, significant hydrogen buildup in the main condenser does not occur because the main condenser is then isolated from the NSSS.

The main condenser is not required to cause or support the safe shutdown of the NSSS or to perform in the operation of NSSS safety features.

Exhaust hood overheating protection is provided by the low-pressure exhaust hood spray systems located just downstream from the last-stage blades of the turbine.

The loss of main condenser vacuum causes the turbine to be tripped. This transient and its effect on the reactor are discussed in Chapter 15.

Four rupture diaphragms on each turbine exhaust hood open at a few pounds per square inch, gage, to protect the condenser and turbine exhaust hoods (15 psig design) against overpressure. Failure of a rupture diaphragm results in radionuclides being admitted directly to the turbine building rather than passing to the offgas system. This specific failure is not analyzed but the results of a more significant event, i.e., failure of the air ejector line, are analyzed in Chapter 15.

Any leakage of circulating water into the condensate is detected by continuous monitoring of conductivity. Leakage of condensate out to the circulating water is detected by radioactivity monitoring in the circulating water reservoir decant line.

10.4.1.4 Tests and Inspections

The condenser shell received a field hydrostatic test prior to initial operation. This test consisted of filling the condenser shell with water and, while at the resulting static head, inspecting all tube joints, accessible welds, and surfaces for visible leakage and/or excessive deflection.

Each condenser water box received a field hydrostatic test and a visual inspection of all joints and external surfaces.

10.4.1.5 Instrumentation Application

The condenser shell is provided with local and remote indications of hotwell level and pressure, including alarms in the main control room.

Condensate temperature is measured in the suction lines to the condenser pumps.

Water-box pressure and temperature are measured.

Conductivity instruments detect leakage of circulating water into the condenser steam space.

Air leakage is monitored at the offgas system.

The condensate level in the condenser hotwell is maintained within proper limits by automatic controls. The controls provide for transfer of condensate to and from the condensate storage tank as needed to satisfy the requirements of the thermal cycle.

The condenser hotwell has heating coils in each of the four hotwell sections, however they are not used at Fermi 2.

Turbine exhaust temperature is monitored and controlled with water sprays to protect the turbine blading and exhaust hood from overheating.

A high condenser backpressure alarm is provided at a nominal 4.5 in. Hg abs.

Turbine trip is activated on loss of main condenser vacuum, when condenser backpressure reaches or exceeds a setpoint of a nominal 7.5 in. Hg abs.

10.4.2 Main Condenser Evacuation System

10.4.2.1 Design Bases

The main condenser evacuation system during normal operation removes the noncondensible gases from the condenser, including air inleakage and dissociation products originating in the NSSS, and exhausts them to the offgas system (see Section 11.3).

10.4.2.2 System Description

The main condenser evacuation system consists of four 25 percent-capacity, two-stage steam-jet air ejector units, complete with intercondensers for normal plant operation and mechanical vacuum pumps for use during startup. Typically, only two of the four steam-jet air ejector units are required for normal operation.

The mechanical vacuum pumps are used to remove the air and offgases from the main condenser. The discharge from the vacuum pumps is routed to the reactor building vent stack via the 2-minute holdup pipe. The offgases from the vacuum pump are discharged directly to the environment. This is acceptable because the vacuum pump is in service when little or no radioactive gases are present. However, the gas is monitored for radioactivity and pumps will be shut down if Technical Specifications limits are exceeded. In addition, the mechanical vacuum pumps are tripped automatically on main steam line high radiation.

When suitable steam is available, the steam-jet air ejectors are put into service to remove the gases from the main condenser after 6 in. Hg abs vacuum has been established in the main condenser by the mechanical vacuum pumps. Main steam, reduced in pressure to a nominal value of 200 psig by an automatic steam-pressure-reducing station, is supplied as the driving medium to the two-stage air ejectors. The first stages take suction from the main condenser and exhaust the gas vapor mixture to the intercondensers. The second stages exhaust the suction gas vapor mixture from the intercondensers to the offgas system. The steam-jet inter-condensers are drained back to the main condenser.

10.4.2.3 Safety Evaluation

The treatment of radionuclide releases from the main condenser via the offgas system is discussed in Section 11.3. Prolonged shutdown of the offgas system can cause significant hydrogen buildup in the condenser and require shutdown of the unit within 5 to 10 minutes, if condenser backpressure warrants.

Failure of the air ejector line leading to the release of radionuclides directly to the turbine building is discussed in Chapter 15.

Automatic trip of the mechanical vacuum pumps on main steam line high radiation mitigates the potential release of radionuclides through this pathway during a control rod drop accident as described in Chapter 15.

10.4.2.4 Tests and Inspections

All tests and inspections of the equipment that is part of the main condenser evacuation system are performed in accordance with ANSI N18.7.6 and the applicable section of Regulatory Guide 1.68.

10.4.2.5 Instrumentation Application

Process instrumentation applying to the evacuation system is described in Section 11.4. High radiation at the main steam line radiation monitors will trip and isolate the vacuum pumps. High radiation at the 2-minute holdup pipe or from the offgas system causes an alarm signaling the operator to take corrective action.

10.4.3 Main Turbine Gland Sealing System

10.4.3.1 Design Bases

The main turbine gland sealing system prevents air leakage into, or radioactive steam leakage out of, the main turbine.

The main turbine gland sealing system is designed to seal the main and RFP turbine shaft glands and valve stems (high-pressure stop, control, low-pressure stop, intercept, and bypass valves).

10.4.3.2 System Description

The turbine gland sealing system (Figure 10.4-1) consists of a startup steam supply from the 52-in. manifold or from the auxiliary boiler, steam seal pressure regulators, steam seal header, one full-capacity gland steam condenser, two full-capacity exhauster blowers, and the associated piping, valves, and instrumentation.

Sealing steam for turbine shaft packing glands and valve stem packing glands is supplied from the steam seal header, which is maintained at a positive pressure of approximately 2 psig. During startup and low load, the header is supplied with live steam from the 52-in. manifold or from the auxiliary boiler. At normal load, the turbine becomes self-sealing as the seal header is then supplied with steam from the high-pressure turbine center gland.

The outer pockets of all glands are routed through the gland steam condenser, which is maintained at a slight vacuum of approximately 20 in. H_2O by the exhauster blowers. This positively prevents escape of steam from the glands into the turbine room. Instead, air is drawn into the outer glands at these points, and the steam/air mixture is routed to the gland steam condenser. The gland steam condenser, which is cooled by the main condensate flow, condenses the gland steam and returns this to the main condenser, while allowing saturated air and noncondensible gases to be drawn out by the exhauster.

The gland steam exhauster discharges to the reactor building vent by way of the 2-minute holdup pipe. This flow is throttled by valve VR3-2578 to keep the discharge as low as possible but still maintain proper vacuum. The exhausters are tripped automatically on main steam line high radiation.

10.4.3.3 Safety Evaluation

The turbine gland sealing system provides a continuous supply of steam to the turbine shaft glands and the valve stems.

The high-pressure turbine shaft packing can accommodate a range of turbine shell pressures from zero to full-load pressure. The low-pressure turbine shaft packing seals against vacuum at all times. The sealing steam enters the high- and low-pressure turbine shaft packings and the valve stem packings through the inner annulus pocket. Steam is positively prevented from leaking into the turbine room by maintaining a vacuum at each gland outer pocket at all times. This vacuum is provided by the gland steam exhauster. A standby exhauster is provided.

If exhauster vacuum falls below approximately 10 in. H_2O, caused for example by loss of ac power, a vacuum switch initiates the closing of the live steam supply to the gland steam header.

An analysis of possible failure modes of the turbine gland sealing system is presented in Chapter 15.

Automatic trip of the gland seal exhausters on main steam line high radiation mitigates the potential release of radionuclides through this pathway during a control rod drop accident as described in Chapter 15. This trip is only required at the low power levels analyzed in the control rod drop accident and is therefore bypassed above the low power setpoint associated with the rod worth minimizer (see Subsection 7.7.1.3.3.5) to minimize the potential for spurious exhauster trips that could result in a malfunction of the turbine glad sealing system.

10.4.3.4 Tests and Inspections

Normal manufacturers' tests are performed on all equipment. The following tests are required for the gland steam condenser: leak test for tube-to-tube-sheet joints, hydrostatic test, and eddy current tube tests.

10.4.3.5 Instrumentation Application

The liquid level in the gland steam condenser is maintained by a control valve connected to the main condenser. Local pressure-control valves are provided to maintain the gland steam header pressure constant at approximately 2 psig, by either supplying or dumping steam as required. If pressure rises above 5 psig, excess steam is discharged to the condenser by a relief valve.

Temperature and pressure gages are installed in a local panel. Test flow orifices are provided to monitor operation of the system.

10.4.4 Turbine Bypass System

10.4.4.1 Introduction

The Fermi 2 bypass system is a composite of passive and active components that provides a steam path following a turbine- generator trip.

The Fermi bypass system has two key features: the live steam supply to the turbine reheaters, which has a nominal flow of 8 percent of nuclear boiler rating, and the electro-hydraulic control (EHC) redundant bypass valves, which are each designed to bypass a nominal 11.75 percent (23.5 percent total) rated reactor flow to the condenser.

Immediately following a turbine or generator trip from rated power, the bypass system will have a nominal capacity of 31.5 percent of nuclear boiler rating (reheater steam supply plus bypass valves). Following a typical trip, the live steam supply is eventually isolated and the pressure control system maintains the setpoint pressure by modulating the bypass valves.

10.4.4.2 Summary

The Fermi bypass system is designed in such a manner that the loss of the bypass system would require multiple random failures in the system. However, as identified in Table 10.4-1, loss of the BOP dc feeding the system causes both bypass valves to close. Because this is very unlikely, the turbine trip without bypass transient was analyzed as the turbine trip with a single bypass valve failure prior to initial fuel load. This event was not the limiting transient with respect to minimum critical power ratio (MCPR) limits.

Edison maintained that the design of the Fermi 2 bypass system obviates the need to consider the turbine trip without bypass to be part of the design basis. Currently, Fermi performs the turbine trip event and the load reject event assuming that all bypass valves fail to open during the transient. The analysis was based on input parameters specified in Table 15.0-1 and used the TRACG computer code. The results are summarized in Subsection 15.2.3. The technical specification for MCPR is frequently based on these results.

The analysis of reheater steam flow, which is important in the turbine trip analysis, is described further in Subsection 10.4.4.3.

10.4.4.3 Passive Bypass (Live Steam to Reheaters)

10.4.4.3.1 Design Bases

The primary purpose of piping the live steam to the reheater is to improve cycle efficiency by drying and superheating the high-pressure turbine exhaust before it enters the low-pressure turbines. In addition, piping live steam to the reheater minimizes the mechanical damage to turbine blades due to erosion by water droplets and the tearing of sealing surfaces due to leakage of wet steam. The reheat steam quality and flow at rated load are illustrated in the heat balance shown in Figure 10.1-1. As a secondary result of live-steam-reheat flow, a passive bypass system exists and continues to operate following a turbine stop and/or throttle valve closure. The length of time this passive system operates is a function of the time required to close the motor-operated isolation valve in the supply line. The rate of decay of flow following the turbine trip is controlled primarily by the thermodynamic response of the reheater's heat-exchange process until the isolation valve closes.

10.4.4.3.2 System Description

Each moisture separator reheater (MSR) is a cylindrical vessel located on either side of the main turbine generator on the turbine floor. The pressure vessel (shell) is approximately 12 ft in diameter and 111 ft long. Each MSR is equipped with a heating bundle at each end of the MSR vessel. The heating bundle consists of 1195 U-tubes configured in two sets of vertically arranged U-tubes, one located on top of the other to provide a "four pass" heating geometry. Each U-tube is 3/4 in. in outer diameter (nominal) with finned surface to promote more efficient heat transfer. Heating/live steam from the reactor enters the bottom bundle of the U-tubes, completes the first two passes, exits to the top bundle and completes the third and fourth passes. The drains from second pass are routed to the Reheater Seal Tank. Whereas the drains from the fourth pass are routed to the shell of the MSR. Cold reheat steam from the high-pressure turbine exhaust enters the bottom of the separator reheater through four inlet connections. The steam is directed upward through the moisture separators, and passes the reheater tube bundles. The reheated steam then leaves the reheater and passes through the low-pressure turbine-stop and intercept valves and into the low-pressure turbines.

Live steam is supplied as shown in Figure 10.3-1. The steam source is the 52-in.-diameter pressure-equalizing manifold which supplies steam to the four turbine inlet connections through the high-pressure turbine-stop valves. The EHC-controlled bypass valves are also connected to this manifold. The live steam passes through two parallel motor-operated isolation valves (N3018F607) and bypass valve (N3018F609) and then through the parallel combination of two pressure-control valves (N30F006 and N30F007) and a full-flow valve (N3018F608). During normal operation at rated load, the isolation valve and the full-flow valve are fully open. On a turbine or generator trip, valve N3018F607 is closed automatically at a nominal 12-inch-per-minute rate. The bypass valve (N3018F609) is used for warmup purposes only. The two automatic pressure control valves are used during initial startup to maintain a controlled heatup rate. These valves are held completely open during normal operation to prevent the lines from forming/collecting condensate. The live steam then flows through the tube bundles inside each reheater where the heat is transferred to reheat the cold steam from the high-pressure turbine.

In addition to reheating the high pressure turbine exhaust steam, the MSRs provide the passive bypass capability to the reactor steam supply system following a main turbine/generator trip. UFSAR section 10.4.4.3.4 discusses the evaluation of the MSR passive bypass flow adequacy during a postulated turbine trip.

10.4.4.3.3 Single-Failure Analysis

Because the amount of live steam flow following a turbine or generator trip, for the time period of interest, does not depend on the action or inaction of an active component, none of the single failures identified can terminate this flow.

10.4.4.3.4 Transient Analysis

During Fermi 2 initial licensing process, the assumed passive bypass flow capability through the Moisture Separator Reheaters (MSRs), following a turbine trip was documented in Detroit Edison Letter to the NRC dated April 27, 1982 (Reference 1). The NRC acceptance of Fermi 2 analysis was based on reviewing the results generated using the NRC approved version of the RETRAN computer code. The NRC Safety Evaluation Report, NUREG-0798, (Reference 2), Supplement 1, September 1981 Section 15. 1, p. 15-1 and NUREG-0798, Supplement 3, January, 1983, Section 15.1, p 15-1(Reference 2) documented the NRC review and acceptance of Fermi 2 methodology. The model included the following physical entities:

a. Main steam and reheat steam lines, isolation valves, and MSR drains

b. High pressure turbine-stop and throttle valves

c. High-pressure turbine

d. Extraction flows to heaters 5 and 6

e. Shell side of reheater

f. Reheater heat transfer

g. Low pressure turbine intercept valves

h. Low-pressure turbines

i. Reheater seal tanks

j. Heaters 5 and 6.

Significant physical entities that affect the passive bypass flow during a turbine trip transient are as follows:

a. The configuration of the reheat steam supply piping

b. The physical characteristics of the MSRs

c. The configuration of the reheater drain piping upstream of the reheater seal tanks

The analysis showed that the passive bypass flow through the MSRs was in excess of the assumed 8% of the nuclear boiler rating (NBR) flow during the first two seconds following a turbine trip.

The original MSRs were replaced during the 2006 Refueling Outage (RF11). The above transient analysis to demonstrate the passive bypass capability was repeated for the replacement MSRs using the NRC approved version of the RETRAN computer code, as documented in "RETRAN02 Analysis for a Moisture Separator Reheater Flow Distribution", Dated October 18, 2005 (Reference 3). The new transient analysis models the steam cycle including the physical entities a through j listed above in order to establish initial steady state conditions. For conservatism, the above RETRAN02 Analysis (Reference 3) did not include the third and fourth passes of either of the two new MSRs. This RETRAN02 analysis (Reference 3) showed that the passive bypass flow through the replacement MSRs remains in excess of the assumed 8% of the nuclear boiler rating (NBR) flow during the first two seconds following a turbine trip.

Additional sensitivity analyses were performed to determine the parameters that may affect the assumed passive bypass flow through the MSRs following a hypothetical turbine trip event, as documented in "RETRAN02 Analysis for a Moisture Separator Reheater Flow Distribution", Dated October 18, 2005 (Reference 3). These sensitivity analyses show that the required passive bypass flow capability through the MSRs can be maintained when: (1)180 tubes are plugged in each of the MSR's first and second passes even after excluding the third and fourth passes in each MSR; and (2) when the volumes of the nearest and the next to the nearest nodes upstream and down stream of the MSRs are varied by plus or minus 10 percent. Therefore, future tube plugging and changes in nodal volumes that are within the bounds of the above sensitivity analysis (Reference 3) can be performed without further analysis.

A bounding (conservative) flow characteristic, documented in "RETRAN02 Analysis for a Moisture Separator Reheater Flow Distribution", (Reference 3) is used as an input to Subsection 15.1.2, Feedwater Controller Failure transient analysis, Subsection 15.2.2 Generator Load Rejection transient analysis and Subsection 15.2.3 Turbine Generator Trip transient analysis, as shown in Figure 15.0-2.

The RETRAN02 Analysis was repeated for operation at 3486 MWt. The revised RETRAN02 Analysis (Reference 8) showed that the passive bypass flow through the MSRs remains in excess of the assumed 8% of the NBR flow during the first two seconds of a trip.

10.4.4.4 Active Bypass (EHC-Controlled Bypass System)

10.4.4.4.1 Design Bases

The EHC-controlled (electro-hydraulic control) bypass system is designed to control reactor pressure whenever the turbine throttle valves are not able to maintain control. This includes startup and shutdown operations. The bypass system possesses an emergency open mode of operation in which the bypass valves are opened at a full-stroke rate equal to the full-stroke, trip- closure rate of the high-pressure turbine-stop and throttle valves.

The bypass system control logic is designed with triple redundant channels to be compatible with the English Electric (EE) philosophy used on the turbine-governor portion of the system. Each of the two bypass valves operates independently and each has its own self-contained hydraulic (unitized actuator) system. Each valve is sized to pass a nominal 11.75 percent rated reactor flow in the full-open position for a controlled total bypass of 23.5 percent rated reactor flow. The system is designed so that any postulated failure will not cause both valves to fail to open in the fast-opening mode of operation coincident with the closure of the turbine-stop or throttle valves. The controlled bypass failure analysis is discussed in Subsection 10.4.4.4.3 and the failure mode and effects analysis is presented on a systems basis in Table 10.4-1.

10.4.4.4.2 System Description

The pressure control system used on Fermi 2 is a solid-state electronic system, designed by English Electric Company Elliot Automation. The system is a three-channel design operating with a two-out-of-three logic. A simplified sketch of the pressure control system is shown in Figure 10.4-3. The positioning of each bypass valve is achieved by using an individual, unitized actuator for each valve. Each module of each channel has its own power supply, which is connected to two independent ac sources. Each module power supply can use either source to supply its requirements. Consequently, a fault in one module cannot affect the other module power supplies.

The total power requirement for the governor/pressure control system (approximately 2.5 kVA) is supplied entirely by twenty- nine ±15-V dc and three ±5-V dc power supplies. Each of these supplies provides operating potential for one module/control function such as a bypass valve control module. These precision-regulated power supplies are not interconnected with the other module supplies and are fed from redundant and independent 110-V ac power feeds.

The sources for these two independent power feeds are the reactor pressure system buses A and B, which would supply ac power to the system following a loss of offsite power for a period of at least 2 sec. Isolation within a power supply is accomplished using diodes, and each redundant portion of an individual supply is sized to carry the entire module power requirement. A loss of either ac power feed to an individual power supply is alarmed in the control room.

A 480-V ac supply is provided for each valve actuator oil pump. These feeds are common from one power supply. The oil pumps operate in an on-off fashion to replenish the hydraulic accumulators in the actuators as demand dictates.

The 130-V dc power supply that energizes the valve actuator solenoid valves is supplied from the plant battery system. All the turbine valves and the bypass valve solenoids are supplied by BOP battery.

Referring to Figure 10.4-3, in each pressure module the pressure signal from the associated pressure transmitter is compared with the pressure-regulator setpoint. The resulting difference is the pressure error signal. The pressure error signal is operated on by the control algorithm of the pressure regulator and steam line resonance filter to produce a pressure demand signal.

The pressure demand from each pressure regulator is auctioneered against the other demands in three independent, high-value gates. This results in the selection of the pressure demand that will produce the largest bypass valve flow demand. The output of each of the three gates is modified by the flow limiter, which is adjustable and consists of a three-gang potentiometer. The resulting signal is the pressure-steam signal, which is transmitted to the three computing channel modules. At this point, each signal is compared on a per-channel basis in a low-value gate with the other signals controlling the turbine-stop, throttle, and intercept valves.

The low-value gates send the lowest signal back to the pressure control modules. A turbine and/or generator trip sets the low- value gates to a minimum, which results in the generation of a large, opening-demand signal at the input to each of the bypass valve control modules. This error signal is sent from each pressure module and the pressure control module to the input- averaging amplifier of each bypass valve control module. The input amplifier in the bypass valve module averages the three signals and detects and removes any signal that deviates from the average.

The average-demand signal is compared to the actual bypass valve position as measured by redundant valve position transducers (LVDTs) to generate a control signal to drive the bypass servovalve through a power amplifier. The spool valve of the servovalve is mechanically biased to open the bypass valve if the control current through the servovalve is zero. A position-error detection circuit is provided to activate the fast-opening mode of operation when the bypass valve position error (in the open direction) exceeds approximately 8 percent. A contact from the comparator output relay energizes the fast-opening solenoid valve (c) shown in Figure 10.4-4. The solenoid valve allows high-pressure oil from the accumulators to operate the fast- opening valve. The fast-opening valve admits high-pressure oil directly into the bypass valve servocylinder to achieve an opening time of 0.2 sec for full stroke.

An independent one-out-of-two-times-two condenser pressure logic also interfaces with the close solenoid of each actuator to trip the valves closed on low condenser vacuum. When the fast-opening solenoid and the close solenoid are operated at the same time, the close solenoid will override the fast-opening solenoid, and the bypass valve will close. The station battery powers the control solenoids on the bypass valve unitized actuators. Alarms are provided on loss-of-actuator pressure, pressure-module failure, pressure-control-module failure, computing-channel failure, excessive valve-position error, power-supply failure, low fluid level, LVDT failure, or a single condenser switch failure.

10.4.4.4.3 Controlled Bypass Failure Analysis

Due to the redundancy of the control logic and the hydraulic actuator hardware, no identified hardware failure can result in the fast closure of the turbine stop and/or throttle valves and prevent the fast opening of both the bypass valves. In addition, external failures such as loss of condenser vacuum have been considered. A protection logic using separate and redundant condenser-pressure trip strings for both turbine-trip and bypass-trip functions has been provided. The trip setpoint for closure of the turbine control valve and stop valve occurs at a much lower condenser pressure than the bypass valve condenser pressure trip. This allows ample time for the fast opening of the bypass valves to mitigate the effects of the fast stop and/or control valve closure during a condenser vacuum loss.

The control power for the stop and control valve unitized actuators is separate from the bypass valve control power, thereby preventing a single battery failure from closing all the valves through the loss of power to the trip solenoids.

In the unlikely event that all offsite power is lost, the turbine stop and throttle valves will close in the fast closure mode. The bypass system will function in the fast opening mode as intended in this situation. Each unitized actuator has two accumulators that store enough hydraulic energy to stroke each valve approximately three times. Battery control power is provided for the critical control solenoid valves and a supply of ac power to the pressure control module is provided for the duration of the transient. Refer to Table 10.4-1 for a summary of EHC- controlled bypass failure mode and effects analyses.

10.4.4.4.4 Transient Analysis

To exhibit an additional degree of conservatism for the turbine- trip transient analysis, it is assumed that one of the redundant bypass valves fails to open in the fast mode and therefore credit has been taken for only one-half of the controlled bypass capability. The one bypass valve is analyzed with an opening delay of 0.1 sec and a full-stroke time of 0.2 sec. The capacity of one valve at full-open is a nominal 12-1/2 percent rated steam flow.

10.4.5 Circulating Water System

10.4.5.1 Design Bases

The circulating water for cycle heat rejection from the main condenser is provided by a closed cycle circulating water system using two parallel natural draft cooling towers. The cooling towers remove the design heat load from the circulating water for all weather conditions.

10.4.5.2 System Description

The circulating water system supplies the main condenser with the necessary cooling water at temperatures ranging from nominal 55°F to 94°F. In the winter, the water temperature may be as low as 35°F; however, if that is the case, the cooling towers are bypassed. The system consists of the main condenser, cooling towers, circulating water reservoir, and circulating water pumps, as shown in Figure 10.4-5. Data on specific components are given in Table 10.4-2.

The circulating water reservoir is sized to support limited operation of Fermi 2 following loss of makeup water, which might occur with simultaneous conditions of sustained strong westerly winds and low Lake Erie water level, or damage to or blockage of the intake structure. The reservoir base area is nominally 5.5 acres. Approximately 23 x 10^6 gal are available at sufficient head for the circulating water pumps and are sufficient for the evaporative losses expected during a limited period of operation and plant shutdown. Following this, if makeup water is still not available, approximately 7.9 x 10^6 gallons would still remain in the reservoir to supply general service water (GSW) following shutdown of the circulating water pumps.

Five 20 percent (180,000 gpm each), motor-driven, vertical, wet- pit circulating water pumps are located in the circulating water pump house. These pumps take suction from the circulating water reservoir and discharge the circulating water via two 12-ft- diameter pipes to the main condenser where the water temperature is raised 18°F (nominal). The heated water is discharged from the two outlet water boxes into two circulating water pipes, which are 12 ft in diameter and are interconnected so that a cooling tower may be removed from service during operation.

The natural draft cooling towers are designed for a wet-bulb temperature of 74°F. The design range and the design approach are both 18°F. The design range and design approach may vary slightly due to the installation of wind vanes and replacement fill which improve performance under wind conditions. ("Range" is the amount the water is cooled. "Approach" is the difference between cooled water temperature and air wet-bulb temperature.) Each tower is approximately 450 ft in diameter at the base; the maximum elevation is 400 ft above the grade elevation.

After passing through the cooling tower fill, the circulating water flows into the circulating water reservoir and then to the circulating water pump house located at the south end of the reservoir.

A decanting blowdown system is provided on the circulating water system. This is required to maintain water quality because the evaporative process in the cooling tower tends to increase the dissolved solids content in the circulating water. Blowdown (approximately 10,000 to 30,000 gpm) is taken from the circulating water reservoir by one, two, or three decanting pumps, monitored, and discharged to Lake Erie through the 36-in.-diameter decanting line.

A makeup water system replaces the circulating water losses caused by evaporation and blowdown. Makeup water is fed into the circulating water system from the GSW system discharge or from the circulating water makeup pumps (normal and standby). Approximately 22,000 to 28,000 gpm of makeup water are required, depending upon the season of the year.

A biocide can be added to the circulating water to prevent growth of algae and slime on the inner surfaces of the condenser tubes. Regular monitoring of residual halogens at the decanting line is done to comply with environmental regulations. The biocide injection system and dehalogenation system are shown in Figure 10.4-6. A chemical scale inhibitor that has been evaluated to be compatible with materials in the Circulating Water System is added to minimize formation of scale on internal system surfaces. Sulfuric acid is added as needed to adjust the system pH.

The circulating water system is designed with cross-connected discharge piping from the circulating water pumps. The pumps are equipped with separate butterfly valves that permit any circulating water pump or pumps to be isolated while the remaining pumps continue to operate.

Appropriate valving allows the plant to operate on one train of condenser water boxes (one longitudinal half of the condenser can be taken out of service). The system piping is designed in accordance with ANSI B31.1.0.

Cooling water pumps are tripped on high pressure to prevent over-pressurization of the 12-ft lines. Relief valves are provided at the cooling towers to prevent overpressurization by the GSW system.

10.4.5.3 Safety Evaluation

The closest cooling towers are located at least one tower height away from the NSSS containment and auxiliary and turbine buildings complex. It is extremely unlikely that the towers will collapse because they were designed for a wind velocity of 90 mph. If a cooling tower were to collapse, however, it would fall inward, because its base is wider than its top. Therefore, the potential for the debris to damage any plant structure is minimal.

Circulating water is not required for safe shutdown of the plant.

The potential for water hammer in the circulating water piping and the associated rupture of expansion joints has been minimized by using motor-operated valves in place of fast-acting hydraulic or pneumatic positioners. A postulated rupture of the expansion joint in the system may flood the basement of the turbine building; however, even this would not result in any risk to the health and safety of the public because there is no engineered safety feature equipment located in the turbine building.

The reactor/auxiliary building houses safety-related components and is designed against site flooding to Elevation 588 ft, as described in Subsection 2.4.2.2.2. It would therefore withstand turbine building flooding to first floor and grade Elevation 583 ft, at which point the water would run out of the building.

Even though flooding of the turbine building does not pose a safety threat, the following additional information has been provided to describe some aspects of such an event.

First, if the failure were to occur in a circulating water line because of a pressure surge, that same surge would probably trip off the circulating water pumps by means of the pressure switches that protect the system. Flooding would thus not occur.

Second, if the joint should completely fail in either the 9- or 12-ft-diameter circulating water lines, and the pumps did not trip, water would be forced out the resulting 3.5-in. gap at an estimated rate of about 200,000 gpm and would take about 45 minutes to fill the turbine building to grade level. However, the operator would be made aware of the problem due to variations in process parameters and would trip the circulating water pumps long before flooding to grade level would occur.

10.4.5.4 Tests and Inspections

All active components of the system (except the main condenser) are accessible for inspection during station operation. Cooling tower tests, if deemed necessary, are in accordance with the ASME power test code for atmospheric water cooling equipment, PTC-23.

The circulating water pump house (CWPH) will be sampled every spring and fall for the presence of Mollusks. The Fermi 2 Mollusk Monitoring Implementation and Treatment Plan requires that the inlet and outlet water boxes to the main condenser be inspected during the next scheduled outage following the detection of Mollusks in the CWPH. Also, the inlet and outlet water boxes of the main condenser will be inspected if performance decreases significantly.

10.4.5.5 Instrumentation Application

The condenser shell water boxes are equipped with isolation valves that enable either half of the condenser to be isolated. All isolation valves are operated by remote switches in the main control room. Temperature and pressure are measured at the condenser. Circulating water flow and reservoir level are monitored. Also, analysis of the circulating water for pH, biocide residual, and radioactivity is performed.

10.4.6 Condensate Polishing Demineralizer System

Condensate polishing is performed by a full flow polishing demineralizer of the mixed-powdered-resin type.

10.4.6.1 Design Bases

10.4.6.1.1 Fraction of Condensate Flow Treated

The condensate polishing demineralizer system processes all of the condensate from the condenser hotwell (approximately 10.5 x 10^6 lb/hr at full load). The heater drains are pumped forward from the No. 5 heaters to the feedwater stream and are not demineralized (approximately 4.3 x 10^6 lb/hr at full load). These drains, however, are continuously recycled and deaerated to less than 70 ppb dissolved oxygen prior to forward pumping. They are also continuously monitored for oxygen and conductivity to provide additional assurance of no adverse impact to final feedwater quality. Turbidity is monitored on an as-needed basis by local grab during periods when corrosion product concentrations are expected to be higher than normal.

10.4.6.1.2 Effluent Impurity Levels To Be Maintained

Operating procedures ensure that the effluent from the condensate polishing demineralizer system results in reactor impurity levels that meet the requirements of Regulatory Guide 1.56 (see Subsection A.1.56). Further limits on condensate composition and electrical conductivity are established in GE Specification 22A2707, BWR Plant Requirements, Part 7, Water Quality.

The condensate polishing demineralizer maintains the required purity of feedwater flowing to the reactor. During normal operation, the system removes dissolved and suspended solids from the feedwater and maintains a high effluent quality based on the following design values:

a. Specific conductivity (μmho/cm) at 25°C ≤ 0.1

b.	pH at 25°C	6.5 to 7.5
c.	Metallic impurities, as the metal (ppb)	≤ 10 (of which copper shall not exceed 2 ppb)
d.	Silica, as SiO_2 (ppb)	≤ 5
e.	Chloride (ppb)	≤ 2

The limit of metallic impurities in the feedwater measured at the outboard isolation valve is 15 ppb, including a maximum of 2 ppb of copper. During initial plant testing and startup, the normal limit of metallic impurities may be exceeded for the first 500 hr of effective full-power operation. During such a period, the average concentration of metallic impurities shall not exceed 50 ppb at greater than 50 percent power, nor shall it exceed 100 ppb at less than or equal to 50 percent power.

During restarts or periods of operational disturbance, the normal limit of 15 ppb may be exceeded for up to 14 days in any 12-month period. However, the average concentration during this period shall not exceed 50 ppb.

10.4.6.1.3 Design Codes

The condensate cleanup system pressure vessels are constructed in accordance with the ASME Boiler and Pressure Vessel (B&PV) Code Section VIII, Division I. All piping is in accordance with the ANSI B31.1.0 Code for Pressure Piping.

10.4.6.2 System Description

The condensate polishing-demineralizer system is shown in Figure 10.4-7. It consists of eight parallel-operating demineralizers. Normally, all eight demineralizers are in operation except when one is in backwash/precoat or down for maintenance. The number of demineralizers in service may be varied to accommodate the varying differential flow and pressure requirements of the system. The system includes the associated piping, effluent strainers, backwash, precoat system (with backwash tank and pumps), as well as the necessary valves, instrumentation, and controls required to provide proper operation and protection against malfunction.

The body feed system (with body feed tank pumps) has been abandoned in place and no longer in service.

Instrumentation includes an automatic flow-balancing control that can be used to maintain equal flow (approximately 3000 gpm) through each onstream unit. The valves, pumps and flow can also be controlled manually from local panels.

In the event that a high pressure differential occurs across the condensate cleanup system, an automatic bypass valve opens to prevent damage to the demineralizer. It is highly unlikely that the bypass valve will open during normal operation. However, if this were to occur, appropriate steps would be taken to minimize the introduction of untreated water to the reactor.

10.4.6.3 Safety Evaluation

The condensate demineralizers provide high purity water to the reactor pressure vessel (RPV). Any loss of performance of the demineralizers would be immediately detected by process instrumentation. Buildup of impurities in the RPV is restrained by Technical Specifications limits such that the reactor is shut down well before unacceptable limits are reached. Additionally, more conservative limits and corrective actions are maintained and administered by the plant chemistry section. Subsequent safe shutdown of the reactor does not require the condensate demineralizers.

Resins are not regenerated at Fermi 2. However, they are replaced before the differential pressure of an individual demineralizer or the conductivity of a demineralizer effluent reaches detrimental levels. The alarm setpoint for the influent conductivity meter is 0.2 μS/cm. At this point, the plant chemistry section is notified to acquire samples of influent to check the possibility of a condenser leak. If analysis indicates that a leak exists, corrective action is taken before the 0.5 μS/cm high-high alarm is reached. The alarm setpoints for the effluent conductivity meter are 0.1 and 0.09 μS/cm for the individual and the combined demineralizer outlet, respectively. Corrective action is initiated at 0.1 μS/cm but before 0.2 μS/cm for all individual demineralizer effluents.

The conductivity meter in the condensate cleanup system will be calibrated by comparing it with an in-line laboratory cell once a week. The flow rate through each demineralizer is measured at the outlet from the pressure drop across an orifice plate.

The initial total capacity of condensate polishing and reactor water cleanup demineralizer resins will be measured at least once per year before demineralizer vessel loading. Capacity determinations will be performed by one of the following:

a. Plant Chemistry Section, Fermi 2

b. Engineering Services Organization, Edison

c. Resin vendor/supplier.

The chemistry performed to determine the total resin ionic capacity is outlined by ASTM D-2187. If the type or the supplier of cation and anion resins is changed, a measurement of initial total capacity will be performed before vessel loading. Excess capacity exists in the condensate treatment system to provide for the orderly shutdown of the reactor in the event of a postulated condenser leak of 50 gpm.

The condensate quality guidelines of condensate influent, effluent, final feedwater, and reactor water are summarized in Table 10.4-3.

10.4.6.4 Tests and Inspections

The condensate polishing demineralizer system is tested and inspected in accordance with ANSI N18.7.6 and applicable sections of Regulatory Guide 1.68. All pressure vessels and piping are hydrostatically tested at a pressure 1.5 times the design pressure. Additionally, before the equipment was put into service, a performance test was run to ascertain that the equipment is performing according to the specifications.

10.4.6.5 Instrumentation Application

The performance of the condensate polishing demineralizer system is monitored by conductivity instrumentation at the inlet and outlet and downstream of each demineralizer. Small condenser leaks as low as 6 gpm will be detected. Other instrumentation on the feedwater and reactor water checks for dissolved oxygen, pH, and conductivity. Differential pressure measurements are made to detect solids buildup on the filtering elements. Both local alarms and main control room alarms alert the plant operators whenever undesirable limits are reached. The alarm setpoint at the inlet of the demineralizers in the condensate system is 0.2 μS/cm, and the setpoints for the individual and overall demineralizer outlet are 0.1 and 0.09 μS/cm, respectively.

10.4.7 Condensate and Feedwater System

10.4.7.1 Design Bases

The condensate and feedwater system provides a dependable supply of feedwater to the NSSS, provides feedwater heating, and maintains high feedwater quality. The system provides the required flow at the required pressure to the NSSS and allows sufficient margin to provide continued flow under anticipated transient conditions.

10.4.7.1.1 Performance Requirements

The system provides feedwater at a nominal pressure of 1173 psia from the two RFPs. It has sufficient capacity with appropriate margin to provide feedwater flow for the unit design-basis rating. The feedwater heaters provide feedwater at the required temperature to the NSSS with six stages of closed feedwater heating. The final feedwater temperature is 426.5°F at 100 percent reactor flow.

10.4.7.1.2 Feedwater Quality

Feedwater quality limits are established to prevent adverse effects to fuel, material integrity, and equipment performance. Corrosion product generation/transport and chemical intrusions are controlled and minimized so that a suitable environment is provided for high reliability of plant components.

During startup, condensate is recirculated to the main condenser hotwell until water quality specifications are met. The recirculation line is located downstream of the high-pressure feedwater heaters, and thus full-cycle recirculation is accomplished prior to introduction to the reactor. Guidelines for feedwater quality are listed in Tables 10.4-3 and 10.4-4.

Operating practices limit the conductivity of purified condensate during power operation to the reactor vessel to 0.07 μmho/cm. The control program for dissolved and suspended solids, including sampling frequency and chemical analysis, is described below.

Suspended and dissolved-solids samples are part of an integrated on-line sample collection, which consists of collecting both filterable and dissolved species in one filter housing that contains a membrane filter and ion exchange filter. The on-line filters are checked routinely for flow rate. Integrated on-line samples for feedwater are collected continuously during operation. There are three sample collection intervals weekly.

Filters collected are analyzed for certain metals necessary to conform to fuel warranty specifications. Metal species of interest are typically iron (Fe), copper (Cu), nickel (Ni), chromium (Cr), and zinc (Zn).

Suspended-solids samples are acquired by grab sampling for qualitative analysis by filter color comparison during periods when corrosion product concentrations are expected to be higher than normal.

Control program limits are imposed within the limitations of fuel warranty specifications. Total metals are limited during power operation to <15 ppb with no more than 2 ppb copper.

The basis for these limits is to minimize deposit buildup on fuel heat transfer surfaces and the transport of corrosion products from the core surfaces. Consequently, high heat transfer is maintained, and out-of-core radiation levels are at a minimum.

Zinc is added to the feedwater to control radiation buildup in out-of-core primary coolant piping. The zinc will compete with the cobalt for deposition sites. This will have the end effect of reducing out-of-core radiation dose rates. The additional zinc will add to the dissolved metals and total metals in the feedwater. The amount of zinc to be added to the feedwater is much less than 1 ppb. The zinc will provide the beneficial outcome of controlling radiation build-up on out-of-core surfaces; however, overall metals concentration will still be maintained within the fuel warranty limits to ensure no impact on fuel performance.

Forward-pumped heater drains are untreated and account for approximately 30 percent of total feedwater flow. These drains are monitored for dissolved oxygen and conductivity prior to and during introduction to the feedwater. Turbidity is monitored on an as-needed basis by local grab during periods when corrosion product concentrations are expected to be higher than normal.

10.4.7.1.3 Design Codes

All components of the condensate and feedwater system, except the main condenser and the feedwater piping from the second valve outside the containment to the reactor, are designed and constructed in accordance with the applicable requirements of the following codes:

a. ANSI Code for Pressure Piping, B31.1.0 - Power Piping

b. ASME B&PV Code Section VIII, Division I - Unfired Pressure Vessels.

10.4.7.2 System Description

The condensate and feedwater system consists of the piping, valves, pumps, heat exchangers, controls, instrumentation, and the associated equipment and subsystems that supply the NSSS with heated feedwater in a closed steam cycle using regenerative feedwater heating. The system described in this section extends from the main condenser to the second valve outside the primary containment. The remainder of the system, extending to the reactor, is described in Subsection 5.5.9.

The main portion of the feedwater flow (approximately 70 percent) is condensate pumped from the main condenser. The remaining portion, which comes from the moisture-separator drains, steam reheater drains, and drains from the fifth- and sixth-stage feedwater heaters, is pumped forward from the fifth stage of feedwater heating into the feedwater stream. Turbine extraction steam provides six stages of closed feedwater heating, with the drains from the first four stages of feedwater heating being cascaded through successively lower pressure feedwater heaters to the main condenser.

The condenser pumps take the deaerated condensate from the main condenser hotwell and deliver it through the steam-jet air ejector condensers, the gland steam condenser, and offgas condenser to the condensate polishing demineralizers (see Figure 10.4-8). Demineralizer effluent then passes to the heater feed pumps, which discharge through the first-, second-, third-, fourth-, and fifth-stage low-pressure feedwater heaters to the RFPs.

Additional drain flow comes to the RFPs from the fifth-stage drains, and then is pumped forward and injected into the feedwater stream at the RFP suction header. These drains originate as shown in Figure 10.4-9. The shell drains from the sixth-stage high-pressure feedwater heaters are directed to the shells of the fifth-stage low-pressure feedwater heaters. The shell drainage from the fifth-stage feedwater heaters is collected in the heater drain flash tanks, and then is pumped into the feedwater system by the heater drain pumps.

The RFPs discharge the total feedwater flow through the sixth-stage high-pressure feedwater heaters to the NSSS, as shown in Figure 10.4-10.

10.4.7.2.1 Condenser Pumps

Three condenser pumps operate in parallel (see Figure 10.4-8). Each is a motor-driven, vertical, multistage, centrifugal pump installed at an elevation that allows operation at low condensate level in the main condenser hotwell. The condenser pumps are sized to provide the necessary suction head at the heater feed pumps, even with one condenser pump out of service.

Isolation valves allow each condenser pump to be removed from service individually while maintaining full system capability with the remaining two condenser pumps; however, maintenance must be performed on the pumps during shutdown, with the condenser drained. Condenser pump capacities are given in Table 10.4-5.

10.4.7.2.2 Heater Feed Pumps

Three heater feed pumps operate in parallel (see Figures 10.4-8 and 10.4-9), taking suction from the polishing demineralizer outlet piping and discharging through the low-pressure feedwater heaters. Each is a motor-driven, horizontal, single-stage, centrifugal pump. The heater feed pumps are sized to provide the necessary suction head to the RFPs even with one heater feed pump out of service.

Isolation valves allow each heater feed pump to be removed from service individually while maintaining full system capability with the remaining heater feed pumps. Capacities are given in Table 10.4-6.

Controlled condensate recirculation to the main condenser hotwell is provided downstream of the condensate polishing demineralizer. This ensures that the minimum safe flow through the condenser pumps, steam-jet air ejectors, gland steam condenser, and offgas condenser, is maintained during operation. This recirculation path also provides cleanup during startup since flow is through the demineralizer. Separate minimum flow bypass lines are provided for the heater feed pumps. A Heater Feed Pump (HFP) running signal is taken from the auxiliary contact off of the switchgear breaker feeding each HFP. The use of auxiliary contacts prevents HWC System operation from impacting HFP operation.

10.4.7.2.3 Feedwater Heaters

The first- and second-stage low-pressure feedwater heaters are identically arranged in three parallel streams. The third, fourth, fifth, and sixth stages of feedwater heating are arranged in two parallel streams. The first- and second-stage feedwater heaters are located in the necks of the three steam inlets of the main condenser.

Integral drain-cooling sections are included in the second-, third-, fourth-, and sixth-stage feedwater heaters. External drain coolers are provided for the first-stage heaters and are located on the first floor of the Turbine Building.

Each feedwater heater and drain cooler is of the horizontal, closed type, installed at an elevation that allows proper shell drainage at all loads. Each feedwater heater uses U-tube construction. All feedwater heater and drain cooler tubes are made of stainless steel.

Isolation valves and bypasses allow the feedwater heaters and the drain coolers to be removed from service in groups. System operability is maintained with the remaining feedwater heaters, drain coolers, and bypasses.

The startup and operating vents from the steam side of the feedwater heaters are piped directly to the main condenser. Discharges from shell relief valves on the steam side of the feedwater heaters are piped directly to the main condenser.

10.4.7.2.4 Heater Drain Flash Tank

A heater drain flash tank receives deaerated drainage from the shells of the fifth-stage feedwater heaters. The drain tank provides reservoir capacity for the heater drain pumps suction. The heater drain flash tank is installed at an elevation beneath the fifth-stage feedwater heaters that allows the heaters to drain freely by gravity flow. Remote indicator light is provided to annunciate low tank level switch actuation. When necessary, the fifth-stage heater drains may be diverted to the main condenser instead of the drain tank.

10.4.7.2.5 Heater Drain Pumps

Two one-half capacity heater drain pumps operate in parallel, each taking suction from the heater drain flash tank and discharging to the feedwater stream before the RFPs. A third one-half capacity pump is provided as a spare. Each is a motor-driven, vertical, multistage, centrifugal-type pump located below the heater drain flash tank and designed for the available suction conditions. Nominal sizes, capacities, and other information are given in Table 10.4-7.

The piping arrangement allows a heater drain pump to be removed from service individually while maintaining system operability.

Controlled drain recirculation is provided from the discharge side of each heater drain pump to the heater drain flash tank. This ensures that the minimum required flow through each heater drain pump is maintained during operation at low throughput.

10.4.7.2.6 Reactor Feed Pumps

Two one-half capacity RFPs operating in parallel (see Figure 10.4-10), act in series with the condenser pumps and heater feed pumps and heater drain pumps. The RFPs take suction from the fifth-stage low-pressure feedwater heaters and discharge through the sixth-stage high-pressure feedwater heaters to provide the pressure head required at the NSSS. Each pump is a turbine-driven, horizontal, single-stage, centrifugal unit. Isolation valves allow either RFP to be removed from service individually while maintaining system operability with the remaining RFP. Data for these pumps are given in Table 10.4-8.

Controlled feedwater recirculation is provided from the discharge side of each RFP to the main condenser hotwell. This ensures that the minimum required flow through each RFP is maintained during operation at low throughput.

10.4.7.2.7 Reactor Feed Pump Turbine Drives

Each of the two one-half capacity RFPs is driven by an individual steam turbine. The turbine drives are the dual-admission type, each equipped with two sets of main stop and control valves. One set of valves regulates the low-pressure steam flow extracted from the main turbine hot reheat piping. The other set regulates the high-pressure steam flow from the main steam supply. During normal operation, the turbine drives run on the low-pressure reheat steam. Main steam is used during plant-startup, low-load, or transient conditions when reheat steam either is not available or is of insufficient pressure. The turbine drives exhaust to the main condenser.

Isolation valves allow either turbine drive to be removed from service individually while maintaining system operability with the remaining turbine-driven RFP.

Total turbine output is 14,200 bhp at 4355 rpm with a low-pressure steam pressure of 225 psia and back-pressures of 1.5 in. Hg abs. Further data are given in Table 10.4-9.

10.4.7.3 Safety Evaluation

During operation, radioactive steam and condensate are present in the feedwater heating portion of the system, which includes the extraction steam piping, feedwater heater shells, heater drain piping, and heater vent piping. Shielding and restricted access are provided as necessary (Section 12.1). The condensate and feedwater system is designed to minimize leakage with welded construction being predominantly used. Relief discharges and operating vents from heater shells are treated through closed systems and piped to the condenser. System components are designed for pump shutoff pressures.

The condensate and feedwater system is not required to cause or support the safe shutdown of the NSSS or to perform in the operation of NSSS safety features.

If it is necessary to remove a component such as a feedwater heater, pump, or control valve from service, continued operation of the system is possible by use of the multistream arrangement and the provisions for isolating and bypassing equipment and sections of the system. The isolation capability of the system limits the magnitude of radioactive releases from failed components.

An analysis is presented in Chapter 15 for a feedwater system piping break, which results in the massive leakage of contaminated feedwater directly to the turbine building.

10.4.7.4 Tests and Inspections

During manufacture, shop performance tests on all pumps were carried out. Each feedwater heater, drain cooler, heater drain tank, and pump received a shop hydrostatic test performed in accordance with applicable codes. All tube joints of feedwater heaters and drain coolers were individually shop leak tested. Prior to initial operation, the complete condensate and feedwater system received a field hydrostatic test and inspection in accordance with ANSI N18.7.6 and applicable sections of Regulatory Guide 1.68. Periodic tests and inspections of the system will be performed in conjunction with scheduled maintenance outages.

10.4.7.5 Instrumentation Application

Feedwater flow-control instrumentation measures the feedwater flow rate from the condensate and feedwater system. This measurement is used by the feedwater control system that regulates the feedwater flow to the NSSS to meet system demands. The feedwater control system is described in Sections 7.1 and 7.7.

Instrumentation and controls are provided for regulating pump recirculation flow rate for the condenser pumps, heater feed pumps, and RFPs.

Measurements of pump suction and discharge pressures are provided for all pumps in the system.

Sampling means are provided for monitoring the quality of the final feedwater, as described in Table 9.3-1.

In the feedwater heating portion of the system, temperature measurements are provided for each stage of heating. Steam pressure measurements are provided at each feedwater heater.

Instrumentation and controls are provided for regulating the heater drain flow rate in order to maintain the proper condensate level in each feedwater heater shell or heater drain tank. High-level alarm and automatic emergency drain action on high level are also provided.

A feedwater flowrate signal is taken from the Feedwater Flow Loop and isolated to prevent HWC equipment from affecting the loop. The circuit is similar to the Integrated Plant Computer System (IPCS) input circuit, which is already used in this loop.

10.4.8 Standby Feedwater System

10.4.8.1 Design Basis

The standby feedwater (SBFW) system provides condensate from the condensate storage tank to the feedwater system downstream of the No. 6 feedwater heater. It is a manually initiated system to provide additional assurance of the capability to maintain reactor core cooling and to prevent the uncovering of the core. No credit for the SBFW system has been assumed in the accident analyses in Chapters 6 or 15. The system may be initiated by the control room operator in response to an operational transient, e.g., loss of normal feedwater. This minimizes demands on other high-pressure core cooling systems. The system is not safety related and is nonseismic.

10.4.8.2 System Description

The SBFW system consists of piping, valves, pumps, motors, controls, instrumentation, and associated equipment that supply the feed- water system with condensate from the condensate storage tank. There are two SBFW pumps with a nominal capacity of 1300 gpm and 1247 psig. Each pump is driven by a 700-hp motor; the motors are independently fed from the SS64 and SS65 transformers. The pumps discharge to two parallel motor-operated (dc) modulating flow control valves. The larger valve (6 in.) is used when reactor pressure is near 1120 psi; the other (4-in.) valve is used when reactor pressure is low. There is a motor-operated (dc) isolation valve before tying into the feedwater system. This valve will automatically open when either pump is started and will close at RPV Level 8. The system diagram is shown in Figure 10.4-11.

10.4.8.3 Safety Evaluation

The SBFW system is not required to support the safe shutdown of the reactor except for its use in the alternate shutdown system to meet 10 CFR 50, Appendix R, Section III.L. See Subsection 7.5.2.5. (Inadvertent initiation of the system is bounded by the inadvertent high-pressure-coolant-injection (HPCI) transient, discussed in Subsection 15.5.1, since HPCI flow is approximately five times SBFW flow.)

10.4.8.4 Tests and Inspections

Normal manufacturer's tests were performed on the SBFW pumps and motors. Prior to initial operation, the system received a field hydrostatic test and inspection in accordance with ANSI N18.7.6.

10.4.8.5 Instrumentation Application

Controls are located in the main control room. Measurement of pump discharge flow is provided in the main control room. Pump, motor bearing, and winding temperatures are displayed and alarmed in the main control room.

10.4.9 Zinc Injection System

10.4.9.1 Design Basis

The zinc injection system is designed to allow Fermi 2 to continuously inject a dilute solution of zinc oxide into the reactor feedwater system. Zinc has been shown to reduce radiation fields coming from various primary coolant pipes (primarily in the drywell) by competing for the sites that ^{60}Co would occupy. The system utilizes the differential pressure developed across the reactor feed pumps to provide motive force for the system and is completely manual. It is designed with a low flow bypass line in order to prevent thermal shock.

The zinc injection system is nonsafety related, QA level Non-Q, seismic category none. The system and associated piping and valves meet ANSI B31.1 requirements. The piping and components connected to the reactor feed pump discharges are designed for 1750 psig and 450ºF. The piping and components connected to the reactor feed pump suctions are designed for 950 psig and 430ºF. The dissolution column is designed to hold enough sintered zinc oxide pellets to last a fuel cycle.

10.4.9.2 System Description

The zinc injection system consists of piping, valves controls, instrumentation, and associated equipment that dissolves a dilute solution of zinc oxide into the reactor feedwater system. The system is provided water from the discharge of one of the reactor feed pumps through connections on the pumps minimum flow lines. It enters the skid and passes through a flow straightening vane to ensure a fully developed flow. The flow is measured by a local flow element and then passes through the dissolution column. Dissolution column vessel temperature is measured locally by a thermometer attached to the dissolution vessel. Temperature is measured so that the vessel is not opened for maintenance until it has cooled sufficiently. Flow passes through an outlet strainer which prevents large particles of sintered zinc oxide from entering the feedwater stream. The differential pressure across the column and strainer is measured by a local ΔP indicator. The solution then exits the skid through a manual flow control valve and is returned to the suction of the reactor feedwater pumps. The system flow is manually controlled between zero and 100 gallons per minute. It is based on reactor water zinc concentrations. Zinc dissolution rate is controlled by flow through the vessel, by feedwater temperature, and by the amount of zinc pellets in the column.

To prevent thermal shock of mechanical components and the zinc oxide pellets, a low flow, heat up, bypass loop is provided around the main flow control valve. This bypass loop has a filter that will prevent small zinc oxide pellet fragments or other particles from lodging in the bypass flow control valve. The skid is provided with vents, drains, and test connections for maintenance purposes. Skid isolation valves are also provided. No pumps are installed in the system. All valves are manual and all instruments are local indication only. Therefore, the new system is passive and has no active components. The skid is bolted to the floor on the southeast corner of the TB-1 steam tunnel near column N-3. The system diagram is on drawing M-2012.

10.4.9.3 Safety Evaluation

The zinc injection system is not required for safe shutdown or operation of the reactor. The zinc injection system is not required for plant operation. The addition of this new system does not change the operation or function of the condensate or feedwater systems.

10.4.9.4 Tests and Inspections

The manufacturer performed testing to verify that the equipment operated prior to shipment. They also perform a hydrostatic test of the skid equipment. Prior to initial operation, the system received a pressure test, instrumentation calibration check, and system flow testing.

10.4.9.5 Instrumentation Application

All indications are local. There is local flow indication on the zinc skid for better control of zinc injection rate. Differential pressure indication for the dissolution vessel and outlet strainer is provided to indicate when strainer cleaning or dissolution vessel basket maintenance is required. The dissolution column vessel has local temperature indication provided such that the vessel is not opened for maintenance before the water has cooled to less than 212°F. All system control is local. There are no indications or controls in the control room.

10.4.10 Hydrogen Water Chemistry (HWC) System

10.4.10.1 Design Basis

The purpose of the Hydrogen Water Chemistry (HWC) system is to inject hydrogen into the feedwater system at rates sufficient to allow the noble metal applied to stainless steel reactor vessel internals surfaces to control intergranular stress corrosion cracking (IGSCC) of the vessel internals. IGSCC control is accomplished by the addition of H_2 gas to the final feedwater in an effort to reduce the dissolved O_2 concentration due to the radiolytic decomposition of water in the reactor core. By reducing the O_2 concentration in the reactor water, the corrosion potential of the water is reduced.

With a few exceptions, the HWC system has been designed in accordance with the BWR Owners Group “Guidelines for Permanent BWR Hydrogen Water Chemistry Installation - 1987 Revision” (Reference 4). The HWC system is designed to meet the following design bases:

1. To supply hydrogen for feedwater injection at rates up to approx. 7-15 scfm, which corresponds to feedwater concentration of approx. 0.14 – 0.31 ppm.
2. To supply oxygen to the Off-Gas system at a rate equal to 50% of the hydrogen injection rate to ensure a stoichiometric mixture for recombination of hydrogen and oxygen.
3. To supply oxygen into the Condensate system to keep the oxygen levels in the condensate and feedwater systems high enough to minimize general corrosion.
4. To automatically isolate hydrogen and oxygen injection in the event of system or component failures.

The HWC System injects sufficient hydrogen into the feedwater system to allow the noble metal applied to stainless steel reactor internal surfaces via the On Line NobleChem (OLNC) System to catalytically recombine oxygen and hydrogen peroxide in the reactor coolant. OLNC is a technology developed by General Electric (GE) for applying noble metal to stainless steel reactor internals. This technology has successfully reduced the electrochemical corrosion potential (ECP) of internals below -230mV$_{SHE}$ (Standard Hydrogen Electrode). It has been shown that at this ECP and below, IGSCC is successfully mitigated in a BWR.

In addition to the EPRI Guidelines (Reference 4), the HWC system was designed to meet the following codes and standards:

OSHA 29 CFR 1910.103	Hydrogen
OSHA 29 CFR 1910.104	Oxygen
OSHA 29 CFR 1990.119	Process Safety Management of Highly Hazardous Chemicals
NFPA 50, 1990	Bulk Oxygen Systems at Consumer Sites
NFPA 50A, 1994	Gaseous Hydrogen Systems at Consumer Sites
NFPA 50B, 1994	Liquefied Hydrogen Systems at consumer Sites
CGA G-4	Oxygen
CGA-4.1, 1985	Cleaning Equipment for Oxygen Service
CGA G-4.3	Commodity Specification for Oxygen
CGA G-4.4, 1993	Industrial Practices for Gaseous Oxygen Transmission and Distribution Piping
CGA G-5	Hydrogen
CGA G-5.3	Commodity Specification for Hydrogen
CGA G-5.4, 1992	Hydrogen Piping Systems at Consumer Locations

The piping at the Gas Supply Facility is designed to ASME B31.3, Chemical Plant and Petroleum Refinery Piping. The underground yard piping and the piping inside the Turbine Building is designed to the requirements of ANSI/ASME B31.1, Power Piping.

All liquid and gas storage vessels are designed, fabricated and stamped as ASME Boiler and Pressure Vessel Code, Section VIII, Division I, Unfired Pressure Vessels.

System wiring, grounding and cathodic protection is designed in accordance with NFPA 70, the National Electric Code. In addition, lightning protection for the GSF has been designed per NFPA 780-92, “Lightning Protection Code.”

10.4.10.2 System Description

The HWC system continuously injects hydrogen gas into the heater feed pump suction to reduce the dissolved oxygen concentration in the Reactor. Oxygen gas is continuously injected into the Off-Gas system at the common 18” manifold to recombine with hydrogen to maintain the stoichiometric balance for recombination. Oxygen gas is also added to the

Condensate system at the condensate pump suction to make up for the reduced oxygen concentration in the condenser. The operating modes of the HWC system are startup, operation, and shutdown. For overall system piping configuration, see drawing 6M721-2013.

Liquid hydrogen is stored in a cryogenic tank at the gas supply facility. The hydrogen is stored under its own vapor pressure until withdrawn by the compressor system. Two 100% capacity parallel compressor trains are provided for system reliability. One compressor operates while the other acts as a backup. The operating compressor withdraws a combination of cold gas from the tank head space and liquid from the tank bottom and compresses it to a pressure several hundred psig above the required pressure. This allows the supply system to preferentially withdraw gaseous hydrogen from the tank head space, reducing system losses. After compression, the hydrogen is sent through ambient air vaporizers which evaporate it to within 20°F of ambient temperature. Each compressor train has two, 100% capacity vaporizers with automatic switching to allow de-icing. Gaseous hydrogen flows to a pressure control manifold which reduces the supply pressure to the operating pressure.

Hydrogen gas then flows via underground piping to the Turbine Building and through piping in the Turbine Building to the injection skid. The injection skid contains a flow element and three injection legs, each equipped with a flow control valve and isolation valve. Each injection leg from the skid is piped to the suction of one of the heater feed pumps. The isolation valve in each injection leg closes on a system shutdown signal, or individually, if the respective pump is tripped. There is a check valve at each heater feed pump suction connection to prevent backflow of water into the hydrogen piping. Each pump suction connection also contains a manual isolation valve and purge connection.

Liquid oxygen is stored in a cryogenic tank at the gas supply facility. The oxygen is stored under its own vapor pressure. Upon demand, oxygen is withdrawn from the tank and passed through an ambient air vaporizer. An economizer circuit preferentially withdraws oxygen vapor from the tank head space, reducing system losses. There are two 100% capacity vaporizers piped in parallel with automatic switching to allow de-icing. Gaseous oxygen flows to a pressure control manifold which reduces the supply pressure to the operating pressure.

Oxygen gas then flows via underground piping to the Turbine Building and through piping in the Turbine Building to the injection skid. The injection skid contains a flow element and two parallel flow control valves. The skid outlet is piped to the common 18” manifold in the Off-Gas system. There is a check valve in the oxygen piping, upstream of the Off-Gas connection, to prevent backflow from the Off-Gas into the oxygen piping. (For system configuration details, see drawing 6M721-2013.)

Oxygen gas is also injected into the Condensate pumps suction common header to make up for the reduced oxygen concentration in the condenser. Injection can be accomplished through the supply piping routed from the gas supply facility, or through an alternate bottled gas station.

Liquid nitrogen is stored at the gas supply facility for use in purging, instrumentation, and valve actuation as required in the design of the gas supply facility. Prior to use, the liquid nitrogen is converted to gas by an ambient vaporizer.

10.4.10.3 Safety Evaluation

The HWC system is non-safety related, QA level non-Q, seismic category none. The electrical components are not Class 1E or environmentally qualified. The HWC system is not required to mitigate the consequences of any accident or malfunction, nor to achieve safe shutdown of the reactor or safe plant operation.

The HWC system has been designed and sited in accordance with the requirements of Reference 1. Where full compliance could not be achieved, technical justification was provided. The liquid hydrogen storage tank is located at a distance greater than 800 feet from the nearest safety related structure (RHR Complex). This separation distance assures that a worst case hypothetical detonation of the liquid hydrogen storage tank will not endanger safety-related structures and equipment. An explosion of the liquid hydrogen tank may cause damage to the roof and siding of the Reactor Building above the elevation of the Refuel Floor, and the roof and siding of the Turbine Building above the elevation of the Operating Deck. However, due to the large separation distance, the force on these structures would be less than those generated by design-basis tornadoes or earthquakes. Therefore, the effects of a hydrogen tank explosion on the upper floors of the Turbine and Reactor Buildings is bounded by the analysis for the design basis tornado.

All hydrogen and oxygen storage vessels have sufficient separation from safety-related intakes in the event of vessel failure without fire or explosion. The liquid hydrogen storage tank and piping over 0.4-inch diameter are seismically designed to prevent failure during a safe shutdown earthquake. The liquid hydrogen and oxygen tanks and the gaseous hydrogen tube banks are designed to remain in place during a design basis tornado, earthquake, or flood so that any releases would originate from that source location. The storage vessels are also designed to be adequately protected from lightning and transportation accidents.

Excess flow protection devices at the gas supply facility and Turbine Building entrance will provide rapid isolation in the event of a line break. Area hydrogen detectors are installed in the Turbine Building near HWC equipment to detect hydrogen leakage and initiate system isolation. Once hydrogen injection is isolated by the system trip signals identified in the section below (Instrumentation and Controls), oxygen injection isolation will lag the hydrogen injection isolation by a pre-set time to ensure the maximum recombination of hydrogen in the Off-Gas system.

10.4.10.4 Instrumentation and Controls

The hydrogen injection rate is initiated with a low flow that is sufficient for establishing IGSCC mitigation during heatup. This rate is maintained until reactor power reaches approximately 25% at which point the injection rate increases proportionally with reactor power level. The oxygen flow is approximately half the hydrogen flow rate. The flow control valve in each injection leg is controlled from a single flow control signal. The flow element on the skid provides feedback to the flow control loop. Once activated, injection will be isolated under any of the following actions/conditions:

a. Manual Shutdown

b. Reactor Protection System Trip

c. Hi-Hi Hydrogen (From Area H_2 Monitor)

d. High Hydrogen Flow

e. Off-Gas Flow Restriction (Valves not Fully Open)

f. Deleted

g. Low Percent Oxygen in Off-Gas

h. High Hydrogen Supply Pressure

i. Deleted

j. Supply Facility Trip

Local instruments are provided at the gas supply facility and at the HWC control panels in the Turbine Building. System shutdown and trouble annunciators are provided in the Control Room. In addition, hydrogen injection enable/trip control is provided in the Control Room.

All signals from safety related circuits are isolated to prevent the HWC system from adversely affecting the operation of safety related systems.

10.4.11 On-Line Noble Chemistry Injection System

10.4.11.1 Design Basis

The On-Line Noble Chemistry (OLNC) Injection System is designed to allow Fermi 2 to inject a dilute solution of platinum or other noble metals into the reactor feedwater system. The injection results in a fine layer of noble metal being deposited onto the wetted surfaces of the reactor and associated piping.

As documented in Reference 6, surfaces with noble metal compound in a low hydrogen coolant environment have been shown to reduce the potential of intergrannular stress corrosion cracking (IGSCC) and mitigate existing IGSCC in the reactor vessel by reducing the electrochemical corrosion potential (ECP). Based on laboratory data, when the ECP is below 230 mV_{SHE}, (SHE = Standard Hydrogen Electrode) IGSCC crack initiation is mitigated and crack growth rates are lowered. Noble metal coating on the wet surfaces of the reactor coolant system piping has been shown to slow or mitigate IGSCC in the reactor vessel and attached reactor coolant system piping. The noble metal penetrates existing cracks to help slow or mitigate crack growth.

The OLNC application is performed after a sufficient time of power operation after a refueling outage to ensure oxide layer is developed on newly inserted fuel assemblies and within the vendor recommended range of power and core flow necessary to ensure adequate noble metal deposition. The online injection results in a more even distribution of metals throughout the system and deeper penetration in to the existing cracks and crevices.

References 5 and 6 evaluated the effects of injection noble metal into the reactor coolant system. The evaluation reviewed effects on the reactor fuel, reactor fuel performance, reactor coolant piping, the Reactor Recirculation System, and the Reactor Water Clean-up System.

The OLNC injection system is non-safety related, QA level Non-Q, seismic category II/I. The system and associated piping and valves meet ANSI B31.1 requirements. The piping and components connected to the reactor fed water system are designed for 1275 psig and 450°F. The system is designed to inject sufficient noble metal solution to reduce the ECP of reactor coolant surfaces below -230 mV_{SHE}, as measured at the mitigation monitoring system in the Reactor Water Clean-up System, when the injected noble metals, the zinc injection system, and the Hydrogen Water Chemistry system work concurrently.

10.4.11.2 System Description

The OLNC injection system consists of piping, valves, controls, instrumentation, and associated equipment that injects a dilute solution of noble metal into the reactor feedwater system. The system pumps solution from a temporarily staged OLNC injection skid on the north-east corner of the Reactor Building First Floor by the steam tunnel entrance. The injection skid is connected to the injection lines viaflexible hose connections. The flow and the injection pressure are indicated at the injection skid.

The injection skid is provided with vents, drains, and test connections for maintenance purposes. Skid isolation valves are also provided. All valves are manual and all instruments are local indication only. Therefore, the new system is passive and has no active components. When not in use, the injection skid will be stored on Reactor Building Third Floor. The system tie-ins to the feedwater system are indicated in Figure 10.4-10.

The Mitigation Monitoring System (MMS) is a one-pass-through system that provides a series of tubing samples to monitor and analyze the amount of noble metal remaining on the tubing interior surfaces, which is representative of the amount of noble metal remaining on the internal surfaces of the reactor vessel during and following an OLNC application. The MMS consists of a Durability Monitor Panel, a Data acquisition System Panel, and an Automatic Flow Control Module Panel. The MMS includes sensors that are installed to measure the ECP of the reactor water.

The MMS skid is provided with vents, drains, and test connections for maintenance purposes. Skid isolation valves are also provided. All valves are manual and all instruments are local indication only. Therefore, the new system is passive and has no active components. The system tie-ins to the Reactor Water Cleanup System are shown in Figures 5.5-19 and 5.5-20.

10.4.11.3 Safety Evaluation

The OLNC injection system is not required for safe shutdown or operation of the reactor. The OLNC injection system is not required for plant operation. The addition of this new system does not change the operation or function of the Reactor Water Clean-up, condensate or feedwater systems.

10.4.11.4 Tests and Inspections

The manufacturer performed testing to verify that the equipment operated prior to shipment, including a hydrostatic test of the skid equipment. Prior to initial operation, the system received a pressure test, instrumentation calibration check, and system flow testing.

10.4.11.5 Instrumentation Application

All indications are local. There is local flow indication on the OLNC injection skid for control of noble metal injection rate. Local indicators are provided on the durability monitor panel for flow and water temperature. All system control is local. There are no indications or controls in the control room.

TABLE 10.4-1 EHC-CONTROLLED BYPASS FAILURE MODE AND EFFECTS ANALYSES

SUBSYSTEM: AUXILIARY SYSTEMS

No.	Component	Failure Mode	Cause	Effect	Method of Detection	Disable Bypass Fast Opening	Initiate Fast Closure of Turbine Stop or Throttle Valves	Comments
1.	120-V ac supply to EHC cabinet	Loss of potential	Fuse failure, short, bus trip	No effect	Alarms on failure	No	No	Load pickup by backup supply feeder
2.	130-V dc battery supply	Loss of potential	Fuse failure, short	Deenergizes both closure solenoids in bypass valve actuators	Alarms, pump duty	Yes	No	Solenoid power supply for turbine valves is obtained from the other plant 130-V dc battery
3.	Actuator cooling water	Loss of flow	Line fails, trip of TBCCW system	Temperature increase in actuator	Alarms on high temperature	No	No	Temperature rise is slow, addition of heat due to pump that is not operating continuously
4.	Condenser	Loss of vacuum	Condenser failure, loss of circulating water, loss of steam-jet air ejectors	Trips bypass and turbine valves closed via actuator solenoids	Alarms on decreasing vacuum; alarms on equipment loss	Yes	Yes	Separate vacuum switch logic with redundant devices is provided for each trip (bypass valve and turbine valve vacuum trips); the setpoint for each trip is different, allowing the turbine to be tripped before the bypass valves are finally tripped as the condenser vacuum is lost
5.	Equipment cabinet environment	Loss of cooling	Loss of fan power, filters plugged, ambient temperature high	Possibly failure system, progressive failure most probable	Alarms on high temperature	Yes	Yes	System has been operated continuously in a test ambient of 40°C as part of acceptance test
6.	Actuator oil pumps	Manual trip of all actuator oil pumps	Operator error	Trip of turbine and bypass valves after 2-minute time delay	Alarms	Yes	Yes	This trip is normally used to lock valve closed during maintenance on turbine

SUBSYSTEM: UNITIZED ACTUATOR

No.	Component	Failure Mode	Cause	Effect	Method of Detection	Disable Bypass Fast Opening	Initiate Fast Closure of Turbine Stop or Throttle Valves	Comments
1.	Valve control module	Output zero	Electronic failure	Deenergizes solenoid valve	Alarms on failure of module	Yes on one bypass valve	No	None
2.	Valve control module	Position error detector	Electronic failure	Fails to energize solenoid valve	Alarms, test of valve	Yes on one valve	No	None
3.	Bypass valve position transducer (LVDT)	Output zero	Mechanical or electrical failure	Deenergizes solenoid valve	Alarms on failure	Yes on one valve	No	Redundant LVDTs provide check circuit for alarm

CHAPTER 11: RADIOACTIVE WASTE MANAGEMENT

In September 1992, the NRC issued Amendment 87 to the Fermi 2 Operating License authorizing a change in the thermal power limit from 3293 MWt to 3430 MWt (References 1 and 2). The data provided in Chapter 11 for the original power level (3293 MWt) was calculated at 3430 MWt for source terms, activity releases, and doses to the public. As a result of the power uprate, source terms, activity releases, concentrations, and doses have been adjusted linearly to correspond to 102 percent of 3430 MWt or 3499 MWt. Flow rates, masses, and volumes are also scaled linearly for the uprated conditions. Table 11.1-1 provides the scale-up factors used in Sections 11.2, 11.3, 11.5, and Appendix 11A, Compliance with Appendix I. The Appendix I evaluation showed that the radiation doses associated with power uprate operation meet the Appendix I objectives.

The values in Table 11.1-2 have not been adjusted for power level because they are derived from the standard annual average design basis release rate of 0.1 Ci/sec at t=30 minutes. However, activities, concentrations, releases, and doses based on 11.1-2 are adjusted for power level. While the inconsistency in this approach is recognized, the calculations are reasonably conservative and the methodology is consistent with the General Electric Licensing Topical Report, NEDC-31897P-1 "Generic Guidelines for General Electric Boiling Water Reactor Power Uprate," June 1991.

On February 10, 2014, the NRC issued Amendment 196 to the Fermi 2 operating license authorizing a change in the thermal power limit from 3430 MWt to 3486 MWt, a 1.64 percent increase in thermal power. This Measurement Uncertainty Recapture (MUR) power uprate was performed in accordance with 10 CFR 50, Appendix K and the analyses performed at 102% of the pre-MUR licensed thermal power (3430 MWt) remain applicable at the MUR uprated thermal power (3486 MWt) because the 2% uncertainty is effectively reduced by the improvement in feedwater flow measurement. As such, the source terms, activity releases, concentrations, and doses were not adjusted as a result of the MUR power uprate.

11.1 SOURCE TERMS

The General Electric Company (GE) has evaluated radioactive material sources (activation products and fission product release from fuel) in operating BWRs over the past decade. These source terms are reviewed and periodically revised to incorporate up-to-date information. Release of radioactive material from operating BWRs has generally resulted in doses to offsite persons that have been only a small fraction of permissible doses or of natural background dose.

The information provided in this section defines the design-basis radioactive material levels in the reactor water, steam, and offgas. The various radioisotopes listed have been grouped as coolant activation products, noncoolant activation products, and fission products. The fission product levels are based on measurements of BWR water and offgas at several stations through mid-1971. Emphasis was placed on observations made at KRB and Dresden 2. The design-basis radioactive material levels do not necessarily include all the radioisotopes observed or theoretically predicted to be present. The radioisotopes included are considered significant to one or more of the following criteria:

a. Plant equipment design

b. Shielding design

c. Understanding system operation and performance

d. Measurement practicability

e. Evaluating radioactive material releases to the environment.

For halogens, radioisotopes with half-lives of less than 3 minutes were omitted. For other fission product radioisotopes in reactor water, radioisotopes with half-lives of less than 10 minutes were not considered.

11.1.1 Fission Products

11.1.1.1 Noble Radiogas Fission Products

The noble radiogas fission product source terms observed in operating BWRs are generally complex mixtures whose sources vary from minuscule defects in cladding to tramp uranium on external cladding surfaces. The relative leakage rate of amounts of noble radiogas isotopes can be described as follows:

a. Equilibrium: $R_g \approx k_1 Y$ (11.1-1)

b. Recoil: $R_g \approx k_2 Y\lambda$ (11.1-2)

The nomenclature in Subsection 11.1.1.4 defines the terms in these and succeeding equations. The constants k_1 and k_2 describe the fractions of the whole fission product that are involved in each of the releases.

The equilibrium and recoil mixtures are the two extremes of the mixture spectrum that are physically possible. The equilibrium mixture results when a sufficient time delay occurs, between the fission event and the time of release of the radiogases from the fuel to the coolant, for the radiogases to approach equilibrium levels in the fuel. When there is no delay or impedance between the fission event and the release of the radiogases, the recoil mixture is observed.

Prior to the Vallecitos BWR and Dresden 1 experience, it was assumed that noble radiogas leakage from the fuel would be the equilibrium mixture of the noble radiogases present in the fuel.

The Vallecitos BWR and early Dresden 1 experience indicated that the actual mixture most often observed approached a distribution that was intermediate in character to the two extremes. This intermediate decay mixture was termed the diffusion mixture. It must be emphasized that this diffusion mixture is merely one possible point on the mixture spectrum, ranging from the equilibrium to the recoil mixture, and does not have the absolute mathematical and mechanistic basis for the calculational methods possible for equilibrium and recoil mixtures. However, the diffusion distribution pattern that has been described is as follows (Reference 3):

Diffusion: $R_g \approx k_3 Y\lambda^{0.5}$ (11.1-3)

The constant k_3 describes the fraction of total fissions involved in the release. As can be seen, the value of the exponent of the decay constant λ is midway between that of equilibrium (0) and recoil (1). The diffusion pattern value of 0.5 was originally derived from diffusion theory, but the assumptions have become discredited.

Although the previously described diffusion mixture was used by GE as a basis for design since 1963, the design-basis release magnitude used has varied from 0.5 Ci/sec to 0.1 Ci/sec as measured after 30-minute decay (t = 30 minutes).*

Since about 1967, the design-basis release magnitude used, including the 1971 source terms, has been established at an annual average of 0.1 Ci/sec at t = 30 minutes. This design basis is considered as an annual average, with some time above and some time below this value.

This design value was selected on the basis of operating experience rather than predictive assumptions. Several judgment factors-including the significance of environmental release, reactor water radioisotope concentrations, liquid waste handling and effluent disposal criteria, building air contamination, shielding design, and turbine and other component contamination affecting maintenance-have been considered in establishing this level.

Experience in the operation of open-cycle BWRs has indicated that in-plant contamination and other operating restrictions may limit plant operation at levels well below emission rates that would correspond to the 10 CFR 20 dose limit of 500 mrem/yr to any offsite person.

Although noble radiogas source terms from fuel above 0.1 Ci/sec at t = 30 minutes can be tolerated for reasonable periods of time, long-term operation at such levels may be undesirable. Continual assessment of this value is made on the basis of actual operating experience in BWRs. There is no experimental or operational basis for changing this design-basis value because of increased reactor size or fuel power density, since limiting conditions are largely independent of these parameters.

While the noble radiogas source-term magnitude was established at 0.1 Ci/sec at t = 30 minutes, it was recognized that there may be a more statistically applicable distribution for the noble radiogas mixture. Sufficient data were available from KRB operations from 1967 to mid-1971 along with Dresden 2 data from operation in 1970 and several months in 1971 to more accurately characterize the noble radiogas mixture pattern for an operating BWR.

The basic equation for each radioisotope used to analyze the collected data is

$$R_g = K_g Y \lambda^m (1 - e^{-\lambda T}) (e^{-\lambda \tau}) \qquad (11.1\text{-}4)$$

With the exception of ^{85}Kr with a half-life of 10.74 years, the noble radiogas fission products in the fuel are essentially at an equilibrium condition after an irradiation period of several months (rate of formation is equal to rate of decay). Therefore, for practical purposes the term $(1 - e^{-\lambda T})$ approaches unity and can be neglected when the reactor has been operating at a steady state for long periods of time. The term $(e^{-\lambda t})$ is used to adjust the releases from the fuel at t = 0 to the decay time for which values are needed. Historically, t = 30 minutes has been used. When discussing long steady-state operation and leakage from the fuel, the

* The noble radiogas source-term rate after 30-minute decay has been used as a conventional measure of the design-basis fuel leakage rate, since it is conveniently measurable and was consistent with the nominal design-basis 30-minute offgas holdup system used on a number of plants.

following simplified form of Equation 11.1-4 can be used to describe the leakage of each noble radiogas isotope:

$$R_g = K_g Y \lambda^m \qquad (11.1\text{-}5)$$

The constant K_g describes the magnitude of leakage. The rate of noble radiogas leakage with respect to each other (composition) is expressed in terms of m, the exponent of the decay constant term λ.

Dividing both sides of Equation 11.1-5 by y and taking the logarithm of both sides results in the following equation:

$$\log(R_g/Y) = m \log(\lambda) + \log(K_g) \qquad (11.1\text{-}6)$$

Equation 11.1-6 represents a straight line when $\log(R_g/y)$ is plotted versus $\log(\lambda)$; m is the slope of the line. This straight line is obtained by plotting R_g/y versus λ on logarithmic graph paper. By fitting actual data from KRB and Dresden 2, using least squares techniques, to the equation, the slope m can be obtained. This can be estimated on the plotted graph. With radiogas leakage at KRB over the nearly 5-year period varying from 0.001 to 0.056 Ci/sec at t = 30 minutes, and with radiogas leakage at Dresden 2 varying from 0.001 to 0.169 Ci/sec at t = 30 minutes, the average value of m was determined. The value form is 0.4 with a standard deviation of ±0.07. This is illustrated in Figure 11.1-1 as a frequency histogram. As can be seen from this figure, variations in m were observed in the range m = 0.1 to m = 0.6.

After establishing the value of $\bar{m} = 0.4$, the value of K_g can be calculated by selecting a value for R_g or, as has been done historically, by setting the total design-basis source-term magnitude at t = 30 minutes. With ΣR_g at 30 minutes equal to 100,000 µCi/sec, K_g can be calculated as being 2.6×10^7. Equation 11.1-4 then becomes

$$R_g = 2.6 \times 10^7 Y \lambda^{0.4} (1 - e^{-\lambda t}) (e^{\lambda t}) \qquad (11.1\text{-}7)$$

This updated noble radiogas source-term mixture has been termed the 1971 mixture to differentiate it from the diffusion mixture. The noble gas source term for each radioisotope can be calculated from Equation 11.1-7. The resultant source terms are presented in Table 11.1-2 as leakage from fuel at t = 0, at t = 7 sec, and at t = 30 minutes. While ^{85}Kr can be calculated using Equation 11.1-7, the number of confirming experimental observations was limited by the difficulty of measuring the very low release rates of this isotope. Therefore, the table provides an estimated range for ^{85}Kr based on a few actual measurements.

11.1.1.2 Radiohalogen Fission Products

Historically, the radiohalogen design-basis source term was established by the same equation as that used for noble radiogases. In a fashion similar to that used with gases, a simplified equation can be shown to describe the release of each halogen radioisotopes:

$$R_h = K_h Y \lambda^n \qquad (11.1\text{-}8)$$

The constant K_h describes the magnitude of leakage from fuel. The rate of halogen radioisotope leakage with respect to each other (composition) is expressed in terms of n, the exponent of the decay constant λ. As was done with the noble radiogases, the average value was determined for n. The value for $\bar{n}$ is 0.5 with a standard deviation of ±0.19. This is illustrated in Figure 11.1-2 as a frequency histogram. As can be seen from this figure, variations in n were observed in the range of n = 0.1 to n = 0.9.

As mentioned above, it appeared that the use of the previous method of calculating radiohalogen leakage from fuel was overly conservative. Figure 11.1-3 relates KRB and Dresden 2 noble radiogas and ^{131}I leakage. It can be seen from Dresden 2 data, during the period August 1970 to January 1971, that there is a relationship between noble radiogas and ^{131}I leakage under one fuel condition. However, there was no simple relationship for all fuel conditions experienced. Also, it can be seen that during this period, high radiogas leakages were not accompanied by high radioiodine leakage from the fuel. Except for one KRB datum point, all steady-state ^{131}I leakages observed at KRB or Dresden 2 were equal to or less than 505 μCi/sec. Even at Dresden 1 in March 1965, when severe defects were experienced in stainless-steel-clad fuel, ^{131}I leakages greater than 500 μCi/sec were not experienced. Figure 11.1-3 shows that these higher radioiodine leakages from the fuel were related to noble radiogas source terms of less than the design-basis value of 0.1 Ci/sec at t = 30 minutes. This may be partially explained by inherent limitations due to internal plant operational problems that caused plant derating.

In general, one would not anticipate continued operation at full power for any significant time period with fuel-cladding defects. These defects would be indicated by ^{131}I leakage from the fuel in excess of 700 μCi/sec. When high radiohalogen leakages are observed, other fission products will be present in greater amounts. This may increase potential radiation exposure to operating and maintenance personnel during plant outages following such operation.

Using these judgment factors and experience to date, the design-basis radiohalogen source terms from fuel were established based on an ^{131}I leakage of 700 μCi/sec. This value, as seen in Figure 11.1-3, accommodates the experience data and the design-basis noble radiogas source term of 0.1 Ci/sec at t = 30 minutes. With the ^{131}I design-basis source term established, K_h can be calculated as being 2.4 x 10^7, and halogen radioisotope release can be expressed by the following equation:

$$R_h = 2.4 \times 10^7\, Y\lambda^{0.5}\,(1 - e^{-\lambda T})\,(e^{-\lambda t}) \qquad (11.1\text{-}9)$$

Concentrations of radiohalogens in reactor water can be calculated using the following equation:

$$C_h = \frac{R_h}{(\lambda + \beta + y)M} \qquad (11.1\text{-}10)$$

Although carryover of most soluble radioisotopes from reactor water to steam is observed to be <0.1 percent (<0.001 fraction), the observed carryover for radiohalogens has varied from 0.1 percent to about 2 percent in newer plants. The average of observed radiohalogen carryover measurements has been 1.2 percent by weight of reactor water in steam with a standard deviation of ±0.9. In our present source-term definition, we have used a radiohalogen carryover of 2 percent (0.02 fraction).

The halogen release rate from the fuel can be calculated from Equation 11.1-9. Concentrations in reactor water can be calculated from Equation 11.1-10. The resultant concentrations are presented in Table 11.1-3.

11.1.1.3 Other Fission Products

The observations of other fission products and transuranic nuclides, including ^{239}Np, in operating BWRs are not adequately correlated by simple equations. For these radioisotopes, design-basis concentrations in reactor water have been estimated conservatively from experience data and are presented in Table 11.1-4. Carryover of these radioisotopes from the reactor water to the steam is estimated to be <0.1 percent (<0.001 fraction). In addition to carryover, however, decay of noble radiogases in the steam leaving the reactor results in production of noble gas daughter radioisotopes in the steam and condensate systems.

Some daughter radioisotopes, such as yttrium and lanthanum, were not listed as being in reactor water. Their independent leakage to the coolant is negligible. However, these radioisotopes may be observed in some samples in equilibrium or approaching equilibrium with the parent radioisotope.

Except for ^{239}Np, trace concentrations of transuranic isotopes have been observed in only a few samples where extensive and complex analyses were carried out. The predominant alpha emitter present in reactor water is ^{242}Cm at an estimated concentration of 10^{-6} μCi/g or less, which is below the maximum permissible concentration in potable water applicable to continuous use by the general public. The concentration of alpha-emitting plutonium radioisotopes is more than one order of magnitude lower than that of ^{242}Cm. Plutonium-241, a beta emitter, may also be present in concentrations comparable to the ^{242}Cm level.

11.1.1.4 Nomenclature

The following nomenclature defines the terms used in equations for source-term calculations:

R_g = Leakage rate of noble gas radioisotope, μCi/sec

R_h = Leakage rate of halogen radioisotope, μCi/sec

y = Fission yield of radioisotope, atoms/fission

λ = Decay constant of radioisotope, per sec

T = Fuel irradiation time, sec

t = Decay time following leakage from fuel, sec

m = Noble radiogas decay constant exponent, dimensionless

n = Radiohalogen decay constant exponent, dimensionless

K_g = Constant establishing level of noble radiogas leakage from fuel

k_h = Constant establishing level of radiohalogen leakage from fuel

C_h = Concentration of halogen radioisotope in reactor water, μCi/g

M = Mass of water in operating reactor, g

β = Reactor water cleanup system removal constant, per sec

$$\beta = \frac{\text{Reactor water cleanup system flow rate, g/sec}}{\text{M,g}} \qquad (11.1\text{-}11)$$

$\gamma =$ Halogen steam carryover removal constant, per sec

$$\gamma = \frac{\left[\frac{\text{con.of halogen radiosotope in steam,}\mu\text{Ci/g}}{C_h}\right][\text{steam flow,g/sec}]}{M} \quad (11.1\text{-}12)$$

11.1.2 Activation Products

11.1.2.1 Coolant Activation Products

The coolant activation products are not adequately correlated by simple equations. Design-basis concentrations in reactor water and steam have been estimated conservatively from experience data. The resultant concentrations are presented in Table 11.1-5. For plant operation with Hydrogen Water Chemistry, in-plant tests have shown that the N-16 steam activity values will increase by a maximum factor of six.

11.1.2.2 Noncoolant Activation Products

The activation products formed by activation of impurities in the coolant or by corrosion of irradiated system materials are not adequately correlated by simple equations. The design-basis source terms of noncoolant activation products have been estimated conservatively from experience data. The resultant concentrations are presented in Table 11.1-6. Carryover of these isotopes from the reactor water to the steam is estimated to be <0.1 percent (<0.001 fraction).

11.1.3 Tritium

The estimated amount of tritium released from Fermi 2 is calculated using the GALE code contained in NUREG-0016, Rev. 1. Actual amounts released are determined by sampling and included in the Annual Radioactive Effluent Release Report. The portions of this section discussing specific amounts of tritium released have been left in for historical reference.

In a BWR, tritium is produced by three principal methods:

a. Activation of naturally occurring deuterium in the primary coolant

b. Nuclear fission of UO_2 fuel

c. Neutron reactions with boron used in reactivity control rods.

With regard to tritium, which may be released from a BWR in liquid or gaseous effluents, the tritium formed in control rods which is released is believed to be negligible. A prime source of tritium available for release from a BWR is that produced from activation of deuterium in the primary coolant. Some fission product tritium may also transfer from fuel to primary coolant. This discussion is limited to the uncertainties associated with estimating the amounts of tritium generated in a BWR which are available for release.

All of the tritium produced by activation of deuterium in the primary coolant is available for release in liquid or gaseous effluents. The tritium formed in a BWR can be calculated using the equation

$$R_{act} = \frac{\Sigma\phi V\lambda}{3.7 \times 10^4 P} \quad (11.1\text{-}13)$$

where

R_{act}	=	tritium formation rate by deuterium activation, μCi/sec/MWt
Σ	=	macroscopic thermal neutron cross section, cm^{-1}, for deuterium
ϕ	=	thermal neutron flux, neutrons/cm^2/sec
V	=	coolant volume in core, cm^3
λ	=	tritium radioactive decay constant, 1.78 x 10^{-9} sec^{-1}
P	=	reactor power level, MWt

For recent BWR designs, R_{act} is calculated to be 1.3 ± 0.4 x 10^{-4} μCi/sec/MWt. The uncertainty indicated is derived from the estimated errors in selecting values for the coolant volume in the core, coolant density in the core, abundance of deuterium in light water (some additional deuterium will be present because of the H(n,γ) D reaction), thermal neutron flux, and macroscopic cross section for deuterium.

The fraction of tritium produced by fission which may transfer from fuel to the coolant, and which will then be available for release in liquid and gaseous effluents, is much more difficult to estimate. However, since zircaloy-clad fuel rods are used in BWRs, essentially all fission product tritium remains in the fuel rods unless defects are present in the cladding material (Reference 4).

The study made at Dresden 1 in 1968 by the U.S. Public Health Service (USPHS) (Reference 5) suggests that essentially all of the tritium released from the plant could be accounted for by the deuterium activation source. For purposes of estimating the leakage of tritium from defective fuel, the assumption can be made that it leaks in a manner similar to the leakage of noble radiogases. Thus, the empirical relationship described as the diffusion mixture can be used for predicting the source term of individual noble gas radioisotopes as a function of total noble gas source term. The equation that describes this relationship is

$$R_{dif} = Ky\sqrt{1} \qquad (11.1\text{-}14)$$

where

R_{dif}	=	leakage rate of radioisotope, μCi/sec
y	=	fission yield fraction
λ	=	radioactive decay constant, sec^{-1}
K	=	constant related to total leakage rate

If the total noble radiogas source term is 10^5 μCi/sec after a 30-minute decay, leakage from fuel is calculated to be about 0.24 μCi/sec of tritium. To place this value in perspective in the USPHS study, the observed rate of ^{85}Kr, which has a half-life similar to that of tritium, was 0.06 to 0.4 times that calculated using the diffusion mixture relationship. This would suggest that the actual tritium leakage rate might range from 0.015 to 0.10 μCi/sec. Since the annual average noble radiogas leakage from a BWR is expected to be less than 0.1 Ci/sec at t = 30 minutes, the annual average tritium release rate from the fission source can be conservatively estimated at 0.12 ± 0.12 μCi/sec.

For a 3293-MWt reactor, the estimated total tritium appearance rate in reactor coolant and release rate in the effluent are about 17 Ci/yr.

Tritium formed in the reactor is generally present as tritiated oxide (HTO) and to a lesser degree as tritiated gas (HT). Tritium concentration in the steam formed in the reactor is the same as that in the reactor water at any given time. This tritium concentration is also present in condensate and feedwater. Since radioactive effluents generally originate from the reactor and power cycle equipment, radioactive effluents also have this tritium concentration. Condensate storage receives treated water from the radwaste system and rejects water from the condensate system. Thus, all plant process water should have a common tritium concentration.

Offgases released from the plant contain tritium, which is present as tritiated gas (HT) resulting from reactor water radiolysis as well as tritiated water vapor (HTO). In addition, a lesser amount present in ventilation air due to process steam leaks or evaporation from sumps, tanks, and spills on floors also contains tritium. The remainder of the tritium leaves the plant in liquid effluents.

Recombination of radiolysis gases in the offgas system forms water, which is condensed and returned to the main condenser. This tends to reduce the amount of tritium leaving in gaseous effluents. Reducing the gaseous tritium release results in a slightly higher tritium concentration in the plant process water. Reducing the amount of liquid effluent discharged also results in a higher process coolant equilibrium tritium concentration.

Essentially all tritium entering the primary coolant is eventually released to the environs, either as water vapor and gas to the atmosphere or as liquid effluent to the plant discharge. Reduction due to radioactive decay is negligible due to the 12-year half-life of tritium.

The USPHS study at Dresden 1 estimated that approximately 90 percent of the tritium release was observed in liquid effluent, with the remaining 10 percent leaving as gaseous effluent. Efforts to reduce the volume of liquid effluent discharges may change this distribution so that a greater amount of tritium leaves as gaseous effluent. The fraction of tritium leaving as liquid effluent may vary between 60 percent and 90 percent, with the remainder leaving in gaseous effluent.

11.1.4 Fuel Fission Product Inventory and Fuel Experience

11.1.4.1 Fuel Fission Product Inventory

Fuel rod and fuel plenum radioisotopic inventory, along with escape rate coefficients and release fractions, is not used in establishing BWR design-basis source-term coolant activities. Fuel fission product inventory information is used in establishing fission product source terms for accident analysis and is therefore discussed in Chapter 15.

11.1.4.2 Fuel Experience

A discussion of fuel experience gained for BWR fuel, including failure experience, burnup experience, and thermal conditions under which the experience was gained, is available in two GE topical reports (References 6 and 7).

11.1.5 Process Leakage Sources

The release of radioactive material from operating BWRs has generally resulted in doses to offsite persons which have been only a small fraction of permissible doses. With greater emphasis being placed on keeping doses from radioactive material in effluents as low as reasonably achievable, Edison utilizes augmented systems for further reduction of doses to offsite persons. Release paths such as process leaks into ventilation, which were previously negligible relative to normal effluents, become prominent although still negligible with respect to doses to offsite persons when augmented systems are provided on the principal process release pathways.

General Electric had a measurement program to identify and quantify these low-level release paths. Concurrently, analytical and mathematical model studies were performed to provide a description of the transport, residence, and release of various radionuclides in and from an operating BWR. This BWR Radiochemical Mode has been supplied in NEDO-10871 (Reference 8).

Expected sources of liquid and gaseous radwaste releases are described in Sections 11.2 and 11.3, respectively.

Process leakage measurements and control methods are further discussed in Subsections 5.2.7 and 7.1.2.

11.2 LIQUID RADWASTE SYSTEM

The liquid radwaste system collects, monitors, processes, stores, and returns radioactive liquid wastes to the plant for reuse, or to the circulating-water reservoir blowdown line for controlled discharge. The collection and processing are done in a controlled, preplanned manner in compliance with established regulatory requirements. Any leakage or spillage due to equipment failure or malfunction will be contained and re-collected in the system. The system is capable of handling anticipated quantities of liquid radwaste without affecting the normal operation or availability of the plant.

11.2.1 Design Objectives

The liquid radwaste system is designed to function as follows:

a. Produce effluents that meet the limits of 10 CFR 20 and the design objectives of 10 CFR 50, Appendix I

b. Control and monitor releases of radioactive materials to the environment per the requirements of 10 CFR 50, Appendix A, General Design Criteria (GDC) 60 and 64

c. Produce treated waste of condensate quality for reuse within the plant

d. Provide the capacity to process liquid radioactive wastes produced in the plant during normal operation and during anticipated operational occurrences

e. Handle anticipated quantities of liquid radwaste without affecting the normal operation or availability of the plant

f. Segregate wastes into subsystems for more efficient processing

g. Provide alternative methods and redundancy of major items of equipment for processing radioactive liquids to ensure the flexibility of operation and maintenance

h. Use the plant drainage system to collect radioactive leakage or spillage due to equipment failure or malfunctions during normal plant operations

i. Provide for the transfer of liquid radwaste system processed waste by-products (evaporator bottoms, filter backwashes, tank sludge letdown, and spent resin) to the solid radwaste system

j. Protect plant personnel from radiation exposure and incorporate the basic as-low-as-reasonably-achievable (ALARA) objectives by the use of automated systems, shielding, and remotely operated instrumentation and controls.

Note: The following Section 11.2 description of the Liquid Radwaste System details the as-designed and as-installed design basis system. However, three of the described portions or subsystems are not presently being used, for various reasons. These subsystems remain in place and have not been isolated by any plant modifications, except as discussed in each section. They (and all components of them) have not officially been retired, or abandoned, and they could be made operational at some time in the future. Therefore, the full original design-basis description, usage, and tables for these items has been retained in Section 11.2 and all other pertinent sections of this UFSAR. These statements describing the system design are all technically correct; however, these items (and therefore their flow paths) are not considered operational at this time. These three subsystems or components are:

a. Radwaste Evaporator and supporting components

b. Two radwaste Etched-Disc Filters and supporting components

c. Two radwaste Oil Coalescers and supporting components

11.2.2 System Description

The liquid radwaste system is composed of two major subsystems--the floor drain collector (FDC) subsystem and the waste collector subsystem. The overall radwaste system's piping and instrumentation diagram is included as Figures 11.2-1 through 11.2-14, Figure 11.2-15 depicts the process flow diagram and Figure 11.2-16 (Sheets 1 through 3) depicts the sump pump diagrams.

Tables 11.2-1, 11.2-2, and 11.2-3 list the estimated design inputs to the liquid radwaste system along with the corresponding process flow diagram stream numbers (Figure 11.2-15).

At times the liquid radwaste system may produce water that may not be required for reuse in the station's water balance, in which case the system effluent could be discharged in a controlled manner to the circulating-water reservoir blowdown line. Processed liquid not meeting the criteria for either discharge or reuse is normally returned to the system for reprocessing.

The liquid and solid radwaste systems have a number of piping connections for use by portable waste-processing systems. (See Table 11.2-4 and Figure 11.2-15.) Vendor-contract services are available onsite for waste processing and solidification. These services meet applicable regulations and are more fully described in Subsections 11.2.10 and 11.5.6.

11.2.2.1 Floor Drain Collector Subsystem

The FDC subsystem will receive periodic and uncontrolled inputs from a variety of plant floor drain sources. The sources to this subsystem have been segregated from the waste collector subsystem because their water quality will probably be poor, will have high conductivity, and will normally contain higher contents of suspended and dissolved solids. The activity content will generally be lower than that of the waste collector subsystem. The estimated chemical characteristics of liquid radwaste input streams for this subsystem are listed in Table 11.2-5.

The chemical nature of the FDC subsystem inputs will also be highly variable. The effluent from the chemical waste tank will be particularly important to the overall stream process requirements because it is a source of high concentrations of dissolved solids. Periodic and variable quantities of oil and grease must also be accommodated by this subsystem. Most of this type of contaminant will be removed by the FDC oil coalescer when it is in service. Otherwise, but to a lesser extent, removal is accomplished by the precoat filters.

The FDC subsystem has an expected higher concentration of both dissolved and suspended solids, with a lower activity level and lower flow rate, than the waste collector subsystem.

Evaporators can be used to separate the FDC subsystem low-purity liquid by evaporation and condensation into a concentrated liquid that is fed to the solid radwaste system and a high-purity distillate that is fed to the FDC and waste collector demineralizers. Both the FDC and waste collector streams are normally passed through both demineralizers in series. Both subsystems offer independent etched-disk filters and oil coalescers to remove suspended solids and oil from the input liquids. In addition, precoat filters are provided for each stream but are not as volume-efficient because of the larger amount of solid radwaste they generate. The two streams are connected by a cross tie to allow the precoat filter or the etched-disk filter in the other stream to be used as a backup.

Each major input to the FDC subsystem is listed in Table 11.2-1 along with its corresponding stream number from Figure 11.2-15. Table 11.2-2 provides a summary of the design daily input to the chemical waste tank, which is in turn directed to the FDC tank for further processing.

The estimated design-basis daily volume inputs for the FDC subsystem total 15,219 gal, whereas the maximum daily volume input to this subsystem is calculated to be 42,284 gal. For the maximum volume input, it is assumed that the probability of the simultaneous occurrence of two or more volume input maximums is extremely low. Thus, the maximum is assumed to be the largest of the individual stream maximums plus the design daily inputs of the other streams. For this subsystem, the largest maximum daily volume input is estimated as 28,800 gal from the drywell floor drain sump. This amount, when added to the design daily volume inputs from the other FDC subsystem inputs, yields the maximum daily volume input value of 42,284 gal.

The normal collection point of the inputs to the FDC subsystem is the FDC tank, which has a working volume of about 20,000 gal. The design basis daily input of 15,219 gal can be accommodated for 1 day in the unlikely event of simultaneous failure of the redundant tank pumps. During the infrequent periods of anticipated maximum inputs, the waste surge tank will serve as an alternative collection point. This tank has a working volume of 65,700 gal and could contain the entire volumetric input (42,284 gal) to the FDC subsystem for 1 day during the maximum anticipated operational occurrence. Flow to the waste surge tank is accomplished by pumping from the FDC tank using the FDC pumps and the cross tie between the FDC subsystem and the waste collector subsystem.

Liquid radwaste system processing will normally be expected to be performed any time of day, 7 days a week; thus, for the design daily input case, an average FDC subsystem process rate of only 10.5 gpm would be required. For periods of maximum inputs, the FDC subsystem is capable of processing at a rate of at least 30 gpm. The processing rates account for periods of equipment unavailability during filter backwashes, resin replacement, and equipment maintenance. Generous liquid radwaste system subsystem interconnects, process equipment redundancy, and bypass capabilities provide maximum operational flexibility during periods of large input surges or unexpected equipment failures.

The FDC subsystem process equipment is discussed in Subsection 11.2.3.2.

11.2.2.2 Waste Collector Subsystem

The waste collector subsystem will receive periodic inputs from a variety of plant equipment drain sources. The equipment drain sources have been segregated from the FDC subsystem (and other sources) because the waste collector inputs will probably be of a higher purity (lower conductivity and suspended solids) than the FDC inputs. The activity concentration in the waste collector subsystem will tend to be higher than in the FDC subsystem. The estimated chemical characteristics of the liquid radwaste input streams for this subsystem are listed in Table 11.2-5.

Like the FDC subsystem, the chemical nature of the waste collector subsystem inputs will be variable, but should not be subject to the large fluctuations that may occur in the FDC subsystem. It is assumed that oil and grease will be present in the waste collector subsystem input, although this should occur much less frequently than in the FDC subsystem. Oil coalescers are included to provide for oil removal before ion exchange.

The waste collector subsystem process equipment is designed to also handle liquid input from the solid radwaste system. This consists of the discharge from the waste surge tank, whose primary function is to collect clarified liquid from the waste clarifier tank. Most of the clarified liquid is produced by the phase separator tank decant operation within the solid radwaste system. The solid radwaste system input to the waste collector subsystem enters downstream of the waste collector tank and, therefore, has no bearing on the size of the waste collector tank. Table 11.2-3 lists the design-basis daily volume input to the waste collector subsystem.

The combined result of all equipment drain inputs to the waste collector subsystem is represented by the waste collector tank effluent.

The estimated design-basis daily volume inputs for the waste collector subsystem total 28,805 gal. The maximum daily equipment drain volume input to this subsystem is calculated to be 48,846 gal. It is assumed that the probability of the simultaneous occurrence of two or more input maximums is extremely low; therefore, the maximum input is assumed to be the largest of the individual stream maximums plus the design daily volume inputs of the other streams. For this subsystem, the largest maximum daily equipment drain volume input will be 28,800 gal from the drywell equipment drain sump. This amount, when added to the design daily volume inputs from the other waste collector subsystem inputs, yields the maximum daily volume input value of 48,846 gal.

The collection point for the equipment drain volume input to the waste collector subsystem is the waste collector tank, which has a working volume of about 23,400 gal. The waste surge tank (which has a working volume of about 65,700 gal) will serve as the backup collection point for excessive equipment drain volume input to the waste collector subsystem.

The waste collector subsystem process equipment is discussed in Subsection 11.2.3.2.

11.2.2.3 Side Stream Liquid Radwaste Processing Subsystem

The Side Stream Liquid Radwaste Processing Subsystem (SSLRPS) processes primarily Chemical Waste Tank (CWT) contents prior to forwarding to the Floor Drain Collector Tank (FDCT). In addition, it processes liquids, such as: sludge from various building sumps, water collected in 55 gallon drums from the Standby Liquid Control System rinses during refueling outages and water from mopping of the building floors.

The SSLRPS includes two 45 kW evaporators, and two 20 gpm trains of Post Treatment System (PTS). Each train of PTS consists of a Granulated Active Charcoal Filter, an Ultra

Violet (UV) Total Organic Carbon (TOC) reducing System, and a Mixed Bed Filter, and associated Tanks, pumps and other system components as shown in Figure 11.2-18, Sheets 1, 2, and 3.

Each evaporator processes liquids in 55 gallons batches at a nominal rate of 0.2 gpm. The vapors from the evaporator will be condensed in a water-cooled condenser and collected in the Post Treatment Inlet Batch (PIB) Tank. The evaporator bottoms will be processed and shipped as solid radwaste. Liquids from the PIB Tank will be processed in one or both trains of the Post Treatment System, at a nominal rate of 20 gpm per train. PTS can process FDCT liquids at a nominal 40 gpm rate, when needed, using both streams of the system.

The Post Treatment System processes consist of carbon adsorption columns, photo-chemical oxidation of soluble organics using Ultraviolet (UV) light reactors and mixed bed filtration in succession. Particles above 5 microns in size and approximately, 90 percent of the Total Organic Carbon (TOC) will be removed by the Carbon filters. The effluents from the Carbon Bed Filters will flow through one or both of the UV Reactors. The UV reactors oxidize soluble organics into organic acids that can be more effectively removed by adsorption or ion exchange. The UV also kills bacteria, if present, in the liquid stream. The effluents from either of the UV reactors will flow through one or both mixed bed filters. The mixed bed filters remove the soluble organic acids generated by the UV reactors via adsorption and ion exchange.

The processed liquid will be collected in the Sample Batch Tank and returned to the FDCT via Radwaste Building basement floor drain system.

11.2.3 System Design

The liquid radwaste system is designed to ensure that system operation can be accomplished in a safe manner and to minimize the accumulated radiation exposure to system operators. Design practices that result in the achievement of the ALARA philosophy are used throughout. Where appropriate, redundant pump capacity is provided. Shielding is located to protect workers from operating equipment radiation.

The liquid radwaste system is designed to accommodate ease of maintenance in a radiation area, and, to the extent practicable, components are separated by shield walls to reduce radiation exposure to maintenance personnel. Clearance provisions are adequate for in-place maintenance activities and for the removal or replacement of components.

All normal liquid release pathways to the environment are continuously monitored to ensure that the dose to the general public will be well within the allowable limits of 10 CFR 20 and 10 CFR 50, Appendix I.

11.2.3.1 System Classifications

The following documents govern the codes, regulatory classifications, and regulatory requirements of the liquid radwaste system:

a. 10 CFR 20, Standards for Protection Against Radiation

b. 10 CFR 50, Appendix A, General Design Criteria for Nuclear Power Plants (GDC 60 and 64)

c. 10 CFR 50, Appendix I, Numerical Guides for Design Objectives and Limiting Conditions for Operation to Meet the Criterion "As Low As Is Reasonably Achievable" for Radioactive Material in Light-Water-Cooled Nuclear Power Reactor Effluents

d. Regulatory Guide 1.143, Design Guidance for Radioactive Waste Management Systems, Structures, and Components Installed in Light-Water-Cooled Nuclear Power Plants (Revision 1, October 1979)

e. Regulatory Guide 1.26, Quality Group Classifications and Standards for Water, Steam, and Radioactive Waste Components of Nuclear Power Plants

f. Regulatory Guide 8.8, Information Relevant to Ensuring That Occupational Radiation Exposure at Nuclear Power Stations Will Be As Low As Is Reasonably Achievable.

The initial design classification of the liquid radwaste system was Quality Group D per Regulatory Guide 1.26. The current design, which is based on Regulatory Guide 1.143, retains the Quality Group D classification (Table 11.2-6).

Table 11.2-6 lists both ASTM and ASME Section II materials for use in atmospheric and 0- to 15-psig storage tanks rather than ASME Section II materials only. The reasons for this are as follows:

a. API-650 and AWWA-D100 specify materials conforming to ASTM specifications

b. ASTM material specifications and ASME Section II material specifications are essentially identical.

For the Fermi 2 radwaste modification, the materials employed for the fluid-retaining boundaries of new atmospheric tanks and modifications to existing atmospheric tanks conform to ASME Section II material specifications as listed, respectively, in Tables 11.2-7 and 11.5-2. The single exception to the conformance is the material for the new, conical bottom of the spent resin tank. ASTM A36 material is used rather than ASME SA-36. However, material specifications for ASTM A36 and ASME SA-36 are essentially identical.

Table 11.2-6 lists manufacturers' standards for welder qualification and procedures as well as ASME Section IX for welding employed in the manufacture of pumps. In this respect, Table 11.2-6 conforms to Table 4-1 of ANSI/ANS-55.1 and Table 2 of ANSI/ANS-55.6. The reason for not excluding manufacturers' standards in Table 11.2-6 is that the pumps used in radwaste systems are frequently of a standard commercial design, and welding that meets the requirements of ASME Section IX is not always available.

Regulatory Guide 1.143 also requires that foundations of walls and structures housing the liquid radwaste system be designed to specified seismic criteria to a height sufficient to contain the liquid inventory expected to be in the building. Seismic calculations previously performed by Edison show that the radwaste building satisfies Category I requirements; therefore, it meets the criteria of Regulatory Guide 1.143.

Regulatory Guide 1.143 and Standard Review Plan 15.7.3 require an analysis to assess the consequences of a hypothetical uncontrolled release of radioactive liquids and the effect of the release on the health and safety of the public. The initiating event for this accident sequence would be a seismically induced total failure of the liquid radwaste system. This assumption is conservative compared with the requirements in Regulatory Guide 1.29. Subsection 15.7.3 describes the basic method and results of this analysis. The results of the analysis indicate offsite radioactivity concentrations that are well within the NRC requirements stated in Appendix B of 10 CFR 20.

11.2.3.2 Process Equipment Description

The process equipment for the liquid radwaste system is capable of processing several combinations of chemical and/or radioactive inputs.

One component of the FDC system is the evaporator subsystem (two redundant low-pressure, single-shell, submerged-tube units). The use of the evaporators is optional (at the discretion of the plant, based upon such considerations as economics, ALARA, input-stream characteristics, offsite releases and doses, etc.), and the system design has provided evaporator bypasses directly to the radwaste demineralizers. The evaporators are preceded in the FDC system by either the precoat filter or the etched-disk filter and oil coalescer train. The etched-disk filter serves several functions: (1) it removes particulates larger than 5 µm in order to minimize plugging and changeout of the oil coalescer; (2) it removes particulates that would lead to fouling and scaling of the evaporators; and (3) if the evaporators are bypassed, the etched-disk filter will remove particulates that could affect the downstream demineralizers. The oil coalescer removes emulsified oil and grease that would foul the downstream demineralizers or cause foaming and carryover from the evaporators.

If the evaporators are in use, evaporator distillate is pumped through two mixed-bed demineralizers normally aligned in series. The demineralizers serve to polish the evaporator distillate in order to achieve condensate-quality effluent. Processed water qualifies as condensate-grade water and can be reused within the plant if it meets the specifications listed in Table 11.2-8.

Because the specific conductivity of input streams to the waste collector subsystem is normally expected to be low (less than 50 µmho/cm), demineralization was selected as the primary processing method. The demineralizers are also preceded by a 5-µm etched-disk filter and an oil coalescer to remove particulates, oil, and grease that could foul the demineralizer resin. The waste collector subsystem precoat filter, located in parallel with the etched-disk filter/oil coalescer train, can otherwise be placed in service. Two mixed-bed demineralizers, normally aligned in series, remove dissolved solids. Although one demineralizer is assigned to the FDC subsystem and the other to the waste collector subsystem, they are normally used in series and process the FDC or waste collector streams.

The principal design parameters for the major liquid radwaste system components are given in Table 11.2-7.

11.2.3.2.1 Floor Drain Collector Tank

The FDC tank collects drainage containing high concentrations of dissolved and suspended solids from the drywell, reactor building, turbine building, radwaste building, and onsite storage facility. The system is designed so that liquid can be normally processed through combinations of etched-disk filters, oil coalescers, precoat filters, evaporators, and demineralizers.

The expected normal design-basis volume input is 15,219 gal, as shown in Figure 11.2-15, stream number 23. The tank working volume is about 20,000 gal. The estimated normal processing rate from this tank is about 50 gpm.

The FDC tank is provided with a slant bottom and sludge well to enhance sludge blowdown. The sludge blowdown is augmented by spray nozzles at the tank bottom to direct settled solids to the sludge well. The tank is provided with a bottom sludge connection located in the tank floor at the sludge well and also a decant connection located in the vertical tank wall about 2 ft above the sludge connection. The lines from these two connections join into a three-way diverter valve whose position can be set to allow pump suction to be taken from either connection. During the bottoms mode of operation, the tank contents will be pumped out through the bottom sludge connection. The decant connection can be used either for normal operations or when large quantities of wastes containing high concentrations of suspended solids are input to the tank. In this case, suspended solids would be allowed to settle to the tank bottom, and liquid would be drawn off the top and out the decant connection for processing through the downstream filter. The settled solids (sludge) in the tank bottom can be directed to the sludge well and then pumped out through the bottom sludge connection to the condensate phase separators. The drain to the tank is blind flanged outside the cubicle. Tank overflow is directed to the radwaste building floor drain sump. The tank is vented to the building vent system through a 4-in. connection.

11.2.3.2.2 Floor Drain Collector Pumps

The purpose of the FDC pumps is to transfer liquid waste from the FDC tank through one of the following:

a. Floor drain etched-disk filter and oil coalescer to the evaporator feed tank
b. Floor drain precoat filter to the evaporator feed surge tank
c. Waste collector precoat filter or etched-disk filter and oil coalescer to the evaporator feed tank
d. Spray nozzles in the FDC tank (recirculation line)
e. Waste surge tank.

The pumps are also used on an infrequent basis to pump the FDC tank sludge letdown to the phase separator tanks in the solid radwaste system.

The capacity of these pumps is determined from the overall processing rate requirements of the FDC subsystem. For design daily inputs, the stream should be able to process at a minimum rate of 10.5 gpm and at a rate of 29.3 gpm during peak input surges. The actual pumps used for this service are sized to deliver flow in a range of 100 to 150 gpm. Two 100 percent-capacity pumps are provided for this purpose.

11.2.3.2.3 Floor Drain and Waste Collector Etched-Disk Filters

Floor drain and waste collector etched-disk filters are designed to remove suspended solids particles down to 5 μm in size. The particulate removal serves the following three purposes:

a. To prevent premature plugging of the downstream oil coalescers

b. To prevent large particulates from entering the evaporators

c. To remove particulates that could plug the downstream demineralizers.

The floor drain and waste collector etched-disk filters are estimated to remove most of the suspended solids that enter the liquid radwaste system via the FDC and waste collector subsystems. When the FDC tank effluent (stream 23) is processed, the flow rate will normally be about 50 gpm and the average suspended solids content is estimated to be about 129 ppm. Since the floor drain etched-disk filter was designed as a backup to the waste collector etched-disk filter, it should also be capable of processing the combined flows of the waste collector subsystem for streams 24 and 40. The average suspended solids input from the waste collector subsystem is estimated at 20 ppm.

The etched-disk filters for the floor drain and the waste collector are identical. Since the normal flow rate through the floor drain etched-disk filter is less than that through the waste collector etched-disk filter, it should have a higher dirt-holding capacity before reaching the automatic differential pressure cutoff prior to backwashing. When operated at 50 gpm, the etched-disk filter is calculated to hold 2.64 lb of suspended solids before reaching 75 psid across the filter. At 140 gpm, the etched-disk filter is calculated to hold 1 lb of suspended solids before reaching 75 psid. These values are based upon the assumed water/crud characteristics (5 percent suspended solids smaller than 5 μm).

The etched-disk filter was selected for this service because it was thought to require little or no filter-aid material that would otherwise add to the ultimate volume of the solid radwaste system. The filters require primarily air for backwashing; they add minimal backwash water for processing by the liquid radwaste system.

The etched-disk filter consists of stacks of hundreds of individual disks, each of which is chemically etched on the top surface. When the disks are stacked, the top surface of one disk against the bottom surface of another forms pores around the perimeter of the stack. The etching is controlled so that the pore size is equal to the minimum particle size to be removed. These stacks of disks are placed inside a vessel, and wastewater is pumped into the vessel, where it flows perpendicular to the stacks, through the pores into the center of the stacks, and out the top of the filter vessel. Suspended solids in the wastewater are trapped in the pores and retained on the exterior of the stacks.

The backwash sequence proceeds automatically after being initiated by a high differential pressure signal across the filter as sensed by a pressure element or by manual initiation. Backwashing takes about 2 minutes.

Filter backwash for both the waste collector and floor drain etched-disk filters is directed to the condensate phase separator tank A. The total backwash volume is about 21 gal.

11.2.3.2.4 Floor Drain and Waste Collector Oil Coalescers

The oil coalescers remove mechanically emulsified oil from the floor drain and waste collector subsystems to maintain the optimal performance of the downstream process equipment. If sufficient oil is present in the wastewater, the downstream demineralizer resins will be coated with oil, degrading the demineralizing capacity and necessitating more frequent resin-bed changeout. The upstream etched-disk filters should normally be in service at all times when the oil coalescers are operating.

Although it is not possible to quantify all experience with oil in radwaste systems, oil has historically presented serious operational problems. Some plants have instituted strict administrative controls to prevent oil from entering the radwaste system.

These controls have included careful surveillance for oil leaks, immediate isolation of leaks, and the isolation of any oil-contaminated sumps. These measures require the dedication of manpower and the collection of spilled or leaked oil by makeshift means. Oil may enter the radwaste collection tanks if the source is not discovered and isolated quickly.

Oil in the radwaste system could affect the performance of demineralizers and evaporators. Any goal of maximum recycle of processed water to the condensate system requires that oil be minimized or removed.

The assumed design oil concentrations in the collector tanks are somewhat subjective and actual values will depend on administrative control procedures and general housekeeping. A survey of floor and equipment drains at Fermi 2 showed that oil sources were fairly well segregated from the equipment drains that flow to the waste collector subsystem. Therefore, the higher concentrations of oil would be in the floor drain subsystem. In design work for oil-removal systems for coal-fired generating stations, the designer had considered 100 ppm of oil in the influent stream as the design basis. Sample data available to the designer for the FDC tank at another BWR averaged approximately 66 ppm over a 6-month period and almost 9 ppm for the waste collector tank. For Fermi 2, design-basis averages of 5 ppm and 20 ppm for the waste collector and FDC subsystems, respectively, were selected.

The option to use oil coalescers was based only on the assumed use of etched-disk prefilters. Otherwise, the oil coalescers would experience rapid pressure buildup and plugging, since they have a 3-μm rating for other suspended solids.

The floor drain oil coalescers will be used as backup for the waste collector subsystem coalescers and vice versa. Hence, both oil coalescers are designed to handle maximum flows of 150 gpm.

11.2.3.2.5 Waste Oil Tank

The waste oil tank collects the oily wastes from the two liquid radwaste system oil coalescers. Since the flow of oil to the tank is small, long-term oil storage is also provided by this tank.

The tank is sized to provide a minimum of 1 year of oil storage from the oil coalescers. The maximum expected oil flow is less than 300 gal per year; therefore, a tank size of 1000 gal provides both storage and a contingency for carryover from the coalescers and unexpected oil spills.

11.2.3.2.6 Waste Oil Pump

The waste oil pump transfers the waste oil from the waste oil tank to a portable disposal container.

The pump capacity (10 gpm) is based on emptying the waste oil tank (1000-gal capacity) in about 100 minutes. The pump differential pressure will be about 150 psi when the oil temperature is near 40°F. If the oil temperature is 60°F, the differential pressure is about 75 psi.

11.2.3.2.7 Evaporator Feed Surge Tank

This tank is for collection of the water from the FDC subsystem after filtration. Because the FDC subsystem is designed for a nominal 50 gpm processing rate and the evaporator system is designed for a nominal 30 gpm rate, the evaporator feed surge tank provides surge capacity.

The input to the tank contains minimal suspended solids, and the tank is therefore not provided with either a slant bottom or a sludge-drawoff line.

The tank is designed to be at least large enough to contain 15,219 gal, the design daily input from the FDC subsystem. The evaporator feed surge tank has a capacity of 25,000 gal, which will accommodate the design inputs for 1 day assuming the failure of the redundant tank discharge (evaporator feed) pumps. Downstream processing from this tank can normally occur 24 hr per day. It can be emptied of the design daily input in about 8 hr, assuming there are no further inputs to it.

11.2.3.2.8 Evaporator Feed Pumps

The evaporator feed pumps process water from the evaporator feed tank under different operating modes, as follows:

a. From the evaporator feed tank to the evaporator

b. From the evaporator feed tank through the floor drain and waste collector demineralizers to the waste sample tank when the evaporators are bypassed

c. Recycle or recirculation back to the evaporator feed tank through an eductor

d. From the evaporator feed tank to portable demineralization equipment in the onsite storage facility.

e. From evaporator feed tank to the Side Stream Liquid Radwaste Processing System distillation inlet batch tank

The capacity of the pumps is determined from the nominal evaporator-processing capacity of 30 gpm. The pump head is based on the head requirements for the above modes of operation. Two 100 percent-capacity pumps are provided.

11.2.3.2.9 Evaporators

The two redundant evaporators can process the prefiltered FDC subsystem low-purity waste by evaporation and condensation to produce concentrated liquid bottoms and a high-purity distillate.

The dissolved solids in the wastewater, including dissolved radioactive material, are concentrated in the evaporator bottoms. The evaporators provide the function of concentration or volume reduction of radioactive and nonradioactive material in the floor drain wastewater. The evaporators are sized to process floor drain water at a 30-gpm flow rate in each unit.

The concentrates (refuse liquid) are concentrated to an assumed practical density of less than 8 percent by weight and are normally discharged at a nominal temperature of 165°F.

Two 100 percent-capacity radwaste evaporators are provided. Normally, only one is used to process floor drain wastewater.

The evaporators operate on a semibatch basis. Under this type of operation, feed and distillate production is a continuous process, but the removal of concentrates occurs only after the desired bottoms concentration is reached.

The evaporators are of the low-pressure, single-shell, submerged-tube type. The units are heated by steam supplied by the main plant auxiliary boilers (through pressure-reducing stations) to tube bundles. Each unit contains a distiller condenser cooled by general service water. The units operate under a partial vacuum (about 20-in. Hg vacuum). Vacuum is maintained by a liquid-ring type mechanical vacuum pump that removes noncondensibles from the shell. Each unit is provided with a single vacuum pump, distillate pump, and concentrates pump. Each unit is also fitted with a single distillate cooler (which is cooled by general service water) as well as the required valves and instrumentation. Internal baffles and demisters are provided for the removal of entrained water droplets from the vapor. The evaporators are skid mounted, with the vacuum pumps and the concentrates and distillate pumps located off the skids behind shield walls to minimize radiation exposure to maintenance and operations personnel. All equipment that is in contact with process fluid is constructed of stainless steel (except for the Incoloy tube bundles).

During steady-state operation, feed to the evaporator is continuous and is controlled automatically by the level in the shell. The concentrates pump operates automatically in the recirculation mode. A chemical metering pump pumps additives to continuously adjust the pH in the recirculation line of the concentrates pump so that frothing in the evaporator and scaling of heat transfer surfaces are avoided. The chemical metering pump is electrically interlocked to the concentrates pump; this permits the operation of the chemical injection system only when the concentrates pump is in operation recirculating bottoms. The vacuum pump is in continuous operation. The distillate pump also operates continuously and discharges to the distillate surge tank as long as distillate purity meets the conductivity limit (about 2 μmho/cm). Cavitation of the distillate pump is prevented by maintaining a minimum level in the pump suction pipe. Suction pipe level instrumentation ensures this level by throttling a flow control valve in the pump discharge line.

The distillate surge tank may be operated in the batch or continuous mode. In the batch mode, the tank is allowed to fill before the transfer of its contents is initiated. Once full, the evaporator distillate pump discharge is shifted to the standby evaporator's distillate surge tank by means of the distillate crossover piping. The contents of the full tank can then be sampled and, if within conductivity limits for further processing by the demineralizer train, can be pumped through the demineralizers. It is also possible to return the contents of the distillate surge tank to the evaporator feed surge tank for recycling if required. When the tank contents have been transferred and the standby evaporator's distillate surge tank has been filled, the distillate pump discharge can be shifted back to the operating evaporator's distillate surge tank. The surge tanks can continue to be alternated in this manner.

In the continuous mode of operation, the distillate may be transferred from the operating evaporator's distillate surge tank at the same rate that it is filling. The transfer rate is adjusted to match the fill rate by correctly selecting the flow setpoint of the distillate transfer flow control valve. In this mode of operation, primary reliance for distillate purity must be placed on the evaporator distillate conductivity instrumentation. Periodic grab samples may be obtained from the sample tap on the distillate transfer pump recirculation line or directly from the tank. The continuous mode of distillate transfer is also possible using the standby evaporator's distillate surge tank and distillate transfer pump in case the operating evaporator's distillate transfer pump is out of service.

System analysis indicates that about 8 days of operation would be required to reach 6 percent to 10 percent by weight dissolved solids in the concentrates. The evaporator is not required to be completely shut down if there are short time periods (within a long-term evaporator run) when the unit is not processing FDC subsystem water; rather, the evaporator can be kept in standby. In the standby mode, the evaporator concentrates are kept at the approximate operating temperature by a submersible heater in the evaporator shell. The heater is thermostatically controlled and has a low-level cutout.

Once the desired concentration of the evaporator bottoms has been reached, the bottoms are transferred to the concentrates feed tank either directly from the evaporator shell or indirectly via the evaporator drains holdup tank. From the concentrates feed tank, the bottoms are transferred to the extruder/evaporator for solidification in the solid radwaste system. The evaporator drains holdup tank and concentrates feed tank and associated piping are electrically heated to maintain the temperature of the concentrates and to prevent possible crystallization of the dissolved material.

11.2.3.2.10 Concentrates Pumps

The concentrates pumps transfer concentrates from the evaporator shell to the evaporator drains tank or the concentrates feed tank. They also circulate evaporator concentrates through the evaporator shell during normal operation to prevent solution precipitation.

These pumps are capable of emptying the full evaporator shell of concentrates (800 gal) within about 1 hr. The pumps are conservatively sized to have a capacity of about 50 gpm. One pump is provided for each evaporator subsystem.

11.2.3.2.11 Evaporator Drains Holdup Tank

This tank serves as an emergency backup tank to the concentrates feed tank (described in Subsection 11.5.3.2.16). During normal evaporator operation this tank is bypassed. The tank can be used when it is necessary to drain the evaporator and the concentrates feed tank is unavailable.

The tank is designed to hold the volume of one evaporator batch (about 800 gal) in the event that draining is necessary. During normal evaporator operation, the evaporator drains discharge directly to the concentrates feed tank.

11.2.3.2.12 Evaporator Drains Pump

The evaporator drains pump mixes and maintains a uniform temperature of the contents in the evaporator drains holdup tank.

The pump capacity is determined by the tank-mixing requirements. The evaporator drains tank has a capacity of about 1500 gal and should be completely recycled at least once per hour; thus, a pump capacity of 30 gpm is adequate.

11.2.3.2.13 Distillate Pumps

The purpose of these pumps is to deliver distillate from the evaporator to the distillate surge tank through the seal water/ distillate cooler.

The capacity of the pumps is determined from the evaporator capacity plus reflux (about 35 gpm). The head requirement for the pump is based on the system resistance for the above operating mode.

11.2.3.2.14 Distillate Surge Tanks

The two distillate surge tanks provide a surge capacity between the evaporators and the floor drain and waste collector demineralizers. Provision is made for sampling the distillate collected in these tanks. After sampling, the distillate can be pumped through the demineralizers or returned to the evaporator feed tank through a recycle line.

The evaporators are designed to operate at a nominal flow rate of 30 gpm. Each tank has a volume of 5100 gal which would provide an operating time of over 2.5 hr before the distillate has to be transferred. This is enough time to sample the distillate and to pump to either of the demineralizers for polishing or back to the evaporator feed tank for reprocessing.

11.2.3.2.15 Distillate Transfer Pumps

The distillate transfer pumps transfer liquid from the evaporator distillate surge tank to one of the following:

a. A waste sample tank through the floor drain and waste collector demineralizers

b. The waste surge tank (or waste collector or floor drain collector tanks) through the floor drain and waste collector demineralizers (recycle mode)

c. Directly to the evaporator feed tank (recycle mode).

This pump also provides recirculation to mix the evaporator distillate surge tank liquid to acquire a representative sample.

These pumps are capable of discharging the evaporator distillate surge tank contents at a rate that ensures that one surge tank can be sampled and emptied while the other surge tank is being filled. Since the nominal evaporator system capacity is 30 gpm, the pumps are conservatively sized to have a nominal capacity of 50 gpm. Two 100 percent-capacity pumps are provided. The distillate surge tanks are provided with crossover inlet connections that allow one tank to fill while the other is being sampled and discharged.

11.2.3.2.16 Floor Drain and Waste Collector Demineralizers

The demineralizers remove, by ion exchange, the dissolved solids contained in the floor drain collector subsystem and the waste collector subsystem. The goal of demineralization is to produce water of sufficient quality to be recycled to the plant via the condensate storage tank or the condensate return tank.

The nominal combined simultaneous flow rate from the waste collector subsystem and the floor drain system through the demineralizers should be about 140 gpm.

The demineralizers are designed to reduce the dissolved solids concentrations such that the conductivity is less than 1 μmho/cm. It is calculated that on the average, a resin bed will require replacement about every 8 days for the design daily inputs.

The floor drain demineralizer holds approximately 49 ft^3, and the waste demineralizer approximately 49 ft^3 of mixed cation and anion resin and activated carbon. Each vessel has type 304 stainless steel internals, including an inlet distributor and a wire-wrapped underdrain collector that prevents the escape of resins. During service, water enters the demineralizers through the inlet distributor, is distributed over and passes down through the resin bed, and discharges through the underdrain collector. When resin exhaustion is indicated by high conductivity in the effluent, the spent resins are dumped by manual initiation to the spent resin tank, and new resins are added to the demineralizers.

Under normal conditions, these two demineralizers will operate in series to process combined wastes from the FDC and waste collector subsystems. If required, the demineralizers can be used individually for either subsystem to process liquid wastes. Each demineralizer is sized to operate at a flow rate of about 140 gpm, if necessary. Using the demineralizers in series provides maximum loading of the ion exchange resins before they have to be replaced with new resins. The piping system is designed such that either demineralizer can be used as the lead or follow unit. As the liquid wastes are processed through the demineralizers, the effluent is continuously monitored. If the conductivity out of the second demineralizer is below a preset value, then the processed liquid is directed to the waste sample tanks. If the conductivity of the processed liquid exceeds the preset value, then the flow is automatically diverted and returned to a selected subsystem (normally to the waste surge tank) for reprocessing.

11.2.3.2.17 Waste Sample Tanks

The purposes of the waste sample tanks are the following:

a. To collect treated water processed by the demineralizers from the floor drain and waste collector subsystems

b. To allow analysis of the tank contents for radioactivity and conductivity after the tank contents have been mixed

c. To discharge the water to either the condensate storage tank, to the blowdown discharge, or to the waste collector or waste surge tanks for recycling, depending on the radiochemical analysis of the water.

The calculated design daily input from the FDC subsystem is 15,219 gal. The calculated design daily input from the waste collector subsystem is about 34,173 gal. The three waste sample tanks have a capacity of about 24,300, 24,300, and 21,000 gal, respectively. The treated water will be sampled before discharge to the condensate storage tank, the blowdown line, or the waste collector or waste surge tank. At any given time, one sample tank will be receiving a batch while the second one can be in the sample mode and the third can be in the discharge mode. Therefore, the three tanks together meet the design requirements. During periods of maximum operational occurrences, one of these three tanks can provide surge capacity.

11.2.3.2.18 Waste Sample Pumps

Three waste sample pumps are provided. Two are normally associated with sample tanks G1101-A004 A and B. The third is normally associated with sample tank G1101-A009. One pump is provided for each tank, but a manual valve alignment will allow pumping from the A tank with the B pump or C pump and vice versa.

These pumps transfer water from the waste sample tanks to the following:

a. Condensate storage tank

b. Waste surge tank (off-standard water quality)

c. Blowdown discharge line

d. Waste sample tank (recirculation line).

The capacity of the waste sample pumps is determined by providing a reasonable rate for the tank to empty to accommodate overall system inputs. Since the waste sample tanks can be filled at a rate of about 140 gpm via the waste collector subsystem, the waste sample pumps should be capable of discharging to the condensate storage, waste surge, or waste collector tanks at a similar rate.

Flow to the blowdown discharge line will be throttled back to a level of 5 to 50 gpm. Excess pump flow while discharging through throttling valves will be recycled to the waste sample tank.

11.2.3.2.19 Chemical Waste Tank

The chemical waste tank collects wastewater, including decontamination solutions and laboratory drains that may require pH or other suitable adjustment before processing. Provisions exist for the addition of an acid or base to the tank to adjust the pH, and the wastes are then sent to the floor drain collector tank for further processing.

The design-basis maximum daily input to this tank is from the periodic evaporator cleaning rinse operation (stream 13, Figure 11.2-15). This is assumed to produce about 3350 gal of solution twice a year.

11.2.3.2.20 Chemical Waste Pumps

The purpose of these pumps is to mix the contents of the chemical waste tank and to transfer neutralized waste to the FDC tank. These pumps also transfer the Chemical Waste Tank Contents to the Side Stream Liquid Radwaste Processing System Distillation Inlet Batch Tank. The capacity of the pumps is based on the mixing requirement of the chemical waste tank, which has a 5200-gal capacity, and the capability to empty a full tank within one shift. The selected size of 60 gpm would allow one complete turnover of the tank contents followed by tank emptying, within one 8-hr shift. Two 100 percent-capacity pumps are provided.

11.2.3.2.21 Precoat Filters

The floor drain precoat filter and the waste-collector precoat filter provide processing paths that are in parallel with the etched-disk filter/oil coalescer trains. The removal efficiency for particulate is based on the amount of filter aid used and is generally found to be 0.1 lb of crud removed for each pound of filter aid. The floor drain precoat filter is designed to handle 50 gpm with a 64-ft^2 filter area and a 210-gal filter vessel volume. The waste collector precoat filter is designed to handle 125 gpm with a 115-ft^2 filter area and a 460-gal filter vessel volume.

Precoating is accomplished by recirculating a powdered resin/ fiber mixture through the vessel where it collects and forms a layer on filter elements. A holding pump provides minimum flow through the filter to prevent the material from falling off after precoating or when the filter is taken out of service upon the completion of a batch. During service, wastes flow into the filter, suspended solids and oil are retained on the filter resin layer, and liquid passes through the layer out of the vessel. As the filter cycle continues, solids build up on the surface of the filter elements and cause the differential pressure across the filter to increase. The filter can be left in service until the differential pressure reaches about 30 psi, at which time it will automatically be taken out of service and put into a hold condition. It must then be backwashed before it can be put back into service. If the differential pressure cutoff is not reached but the filter is no longer required for service, it can be manually put into a hold condition. During service, a filter aid solution can be injected into the incoming wastes as body feed to prevent the filter cake from blinding, which would cause the filter to rapidly reach differential pressure cutoff. This body feed is particularly important with oily wastes. When differential pressure is reached or the filter is no longer required for filtration, it is removed from service and backwashed by using an air bump method. After backwashing, it is left cleaned and full of water, ready for the next precoating and service cycles.

11.2.3.2.22 Waste Precoat Tank

The waste precoat tank mixes the powdered resin/fiber into a uniform slurry before precoating the precoat filters. The tank services both the floor drain and waste collector precoat filters.

The precoat tank is designed to contain enough powdered resin/ fiber solution to allow the precoating of one filter before refilling the tank.

11.2.3.2.23 Filter Aid Tank

The filter aid tank mixes the filter aid into a slurry before feeding it to the floor drain or waste collector precoat filters along with the incoming wastes.

The filter aid tank supplies filter aid to both the floor drain and waste collector precoat filters. The tank is sized to feed sufficient filter aid to each filter for one batch run before refilling is necessary.

11.2.3.2.24 Waste Collector Tank

This tank collects waste from different sources, which include the reactor water cleanup system, drywell and reactor building equipment drain sumps, waste and floor drain demineralizer drains, distillate surge tank drain and overflow, the turbine building equipment drain sump, and the radwaste building equipment drain sump. These inputs are periodic in nature. The wastewater collected in the tank can be pumped from either the bottom-sludge well connection or from the decant nozzle (2 ft above the bottom suction). Any sludge collected over time can be let down via the bottom-sludge well connection to the phase separator tanks. The volume to overflow of the waste collector tank is approximately 23,400 gal. This capacity, combined with the processing rate through the filters, will be adequate to handle the flows to the waste collector tank. Excessive inputs during surge periods will be pumped to the waste surge tank.

The waste collector tank is modified to provide a sludge well with a slant bottom. Spray nozzles are provided at the bottom of the tank to direct solids to the sludge well. The tank is vented to the building vent system, and the tank overflow is directed to the radwaste building floor drain sump. The tank drain is blind flanged outside the cubicle.

11.2.3.2.25 Waste Collector Pumps

The purpose of these pumps is to pump water from the waste collector tank through one of the following:

a. Waste collector etched-disk filter, oil coalescer, and floor drain and waste collector demineralizers to waste sample tank

b. Waste collector precoat filter and floor drain and waste collector demineralizers to waste sample tank

c. Floor drain precoat filter or etched-disk filter and oil coalescer, and floor drain and waste collector demineralizers to waste sample tank

d. Recirculation lines back to the waste collector tank.

The pumps are also used infrequently to pump, through a system-balancing valve, the waste collector tank sludge letdown to the phase separator tanks in the solid radwaste system.

The capacity of these pumps is determined by the overall processing rate requirements for the waste collector subsystem. Waste collector tank contents should normally be processed at a minimum rate of 100 gpm in order to accommodate the design daily inputs. The actual pumps used in this service are sized to deliver a flow range of 100 to 160 gpm. Two 100 percent-capacity pumps are provided. These pumps are vertical, in-line, centrifugal pumps capable of operating under several modes of operation.

11.2.3.2.26 Waste Surge Tank Pumps

These pumps pump water from the waste surge tank through one of the following:

a. Waste collector etched-disk filter, oil coalescer, and floor drain and waste collector demineralizers to the waste sample tank

b. Waste collector precoat filter and floor drain and waste collector demineralizers to the waste sample tank

c. Floor drain precoat filter or etched-disk filter, oil coalescer, and floor drain and waste collector demineralizers to the waste sample tank

d. System-balancing valve to the condensate phase separator tanks (sludge letdown)

e. Spray nozzles to the waste surge tank (recirculating line).

The capacity of these pumps is based on the overall processing rate requirements dictated by the inputs to the waste surge tank. The waste surge tank contents should normally be processed at a minimum rate of 100 gpm in order to accommodate the design daily input.

Two 100 percent-capacity pumps are provided. The pumps are vertical, in-line, centrifugal pumps capable of operating under different operating modes. During the sludge blowdown mode, a system-balancing valve is utilized to generate the necessary pressure drop.

The waste surge tank is described in Subsection 11.5.3.2.4 as a solid radwaste system component.

11.2.3.2.27 Ultraviolet (UV) Total Organic Carbon Reduction System

Organically contaminated water produced by plant operation is drained into the liquid radwaste system for treatment. Total organic carbon (TOC) can be treated using UV radiation. Certain wavelength UV radiation has the capability to destroy TOC by breaking bonds and oxidizing the organic compounds. The process passes the waste stream past UV radiation emitting lamps. The effluent from the unit can then be demineralized to remove the products of the TOC breakdown.

To treat various liquid radwaste streams, a portable UV water treatment unit will be used as necessary to reduce organics from the liquid radwaste process waste streams.

11.2.3.3 Side Stream Liquid Radwaste Processing System Equipment Description

The Side Stream Liquid Radwaste processing System is depicted in Figure 11.2-18. Major components are briefly described below and their design capabilities are summarized in Table 11.2-7.

11.2.3.3.1 Distillation Inlet Batch (DIB) Tank

The DIB tank stores liquids forwarded from the Chemical Waste Tank and from 55 drums that collect water from building floor mopping operations. The Tank's working volume is 800 gallons. Water from the Fermi 2 Condensate System is provided to clean the tank, when needed. The tank level is monitored and controlled from the local control panel. The over flow line is routed to the Radwaste Building Floor Drain. The tank vent is hard piped to the Radwaste Building Ventilation system.

11.2.3.3.2 High and Low Radwaste Evaporators

The high and low Radwaste Evaporators are both capable of processing liquid radwaste in 55 gallon batches at a nominal rate of 0.2 gpm. The vapor from the evaporators is conveyed to the condenser using Station Air stream. Return air is discharged to the Radwaste Building Ventilation System. Solids will remain in the 55 gallon drum. When sufficient amount of solid is collected or when the radiation level reaches a predetermined level, the drum is released for offsite shipment.

11.2.3.3.3 High and Low Radwaste Condensers

Each evaporator is provided with a water cooled condenser. The station air drives the vapors across the condenser tubes carrying General Service Water. The condenser liquids are collected in the Condensate Receiver. The condensate thus collected is forwarded Post treatment Inlet Batch Tank via the condensate forwarding pump.

11.2.3.3.4 Post Treatment Inlet Batch (PIB) Tank

The PIB Tank collects the condensate from the high and low Radwaste Evaporators for processing via the Post Treatment System. The tank's working volume is about 800 gallons. The tank level is monitored and controlled from the local control panel. The over flow line is routed to the Radwaste Building Floor Drain. The tank vent is hard piped to the Radwaste Building Ventilation system.

11.2.3.3.5 PIB Tank Forwarding Pump

The contents of the PIB Tank are forwarded to the Post Treatment System using a 10 gpm pump. This pump can also be aligned for tank recirculation.

11.2.3.3.6 Granular Activated Carbon Bed Filters

Two adsorption columns each capable of holding over 20 cubic feet of Granular Activated Carbon (GAC) are designed to remove particles above 5 microns in size from the liquid streams flowing at or below 20 gpm. The tank vent is hard piped to the Radwaste Building Ventilation system.

11.2.3.3.7 Ultraviolet (UV) Light Reactors

Two 1.5 kW medium pressure UV Reactors are provided to oxidize the effluents from the Carbon Bed Filters. The UV rays also kill bacteria, if present in the effluent stream. Each UV reactor is capable of handling up to 20 gpm effluent flow.

11.2.3.3.8 Mixed Bed Filters

Two mixed bed filters each capable of holding 20 cubic feet of Cation and anion resin beads. The mixed Bed Filter removes the organic acids produced by the UV reactor by oxidizing soluble organics in the effluent stream. Each Mix Bed Filter can handle flows up to 20 gpm. The tank vent is hard piped to the Radwaste Building Ventilation system.

11.2.3.3.9 Sample Batch (SB) Tank

The effluents from the mixed bed filters are collected in the Sample Batch Tank. The tank's working volume is 1000 gallons. The tank level is monitored and controlled from the control panel. The over flow line is routed to the Radwaste Building Floor Drain. The tank vent is hard piped to the Radwaste Building Ventilation system.

11.2.3.4 Pipe Routing

To aid the routing of piping normally carrying radioactive fluids, a shielded pipe tunnel runs along the north, south, and west walls of the radwaste building at an elevation of 564 ft. Whenever possible, pipes carrying radioactive fluids are routed through this tunnel and exit at the tunnel when required to connect to a piece of process equipment. When a pipe cannot be routed via the tunnel, proper care, including the installation of shielding material, is taken to reduce the radiation levels to acceptable values.

11.2.4 Operating Procedure

The liquid radwaste system is basically a manual-start/automatic-stop processing system that does not require continuous on-line operation. The system is designed around large collecting tanks that accept inputs from a variety of sources. As tank levels increase, an operator selects the appropriate system lineup and manually initiates treatment by manipulating control panel switches. Upon completion of system lineup, the operator starts the appropriate pump to draw down the collecting tank. The pump will stop automatically on low tank level and will remain de-energized unless manually restarted.

If radioactive liquid must be discharged from the site, it is treated by the liquid radwaste system and transferred to a waste sample tank for sampling. The treated water is sampled before discharge to verify compliance with discharge criteria; if the criteria are not satisfied, the water is recycled through the liquid radwaste system. Liquid radwaste discharge monitoring is further described in Section 11.4.

11.2.5 Performance Tests

Since the liquid radwaste system is operated as required during the operation of the power plant, its ongoing operability is demonstrated without recourse to special testing. Operating logs, records, and sample results reflect the day-to-day performance of the system. Conditions such as high-volume processing, short filter or demineralizer runs, or high wastewater conductivity or activity are evaluated when they occur.

11.2.6 Estimated Releases

The liquid radwaste system is designed so that, with proper water management techniques, minimal or zero discharge of liquid waste should be needed. It is recognized that during some operating conditions, such as startup, the discharge of excess water may be desirable or even necessary.

The total design-basis liquid releases (excluding tritium) are estimated to be about 0.14 Ci per year. Tritium releases are estimated to be about 52.5 Ci per year. The radwaste system is designed to effectively capture the majority of incoming radionuclides (and ultimately process them as solid wastes) and to so reduce the radioactivity levels in the radwaste sample tanks to minimal values (for discharge). Therefore, the exact configuration of the radwaste equipment/trains utilized or in use is not so important as long as the end-point (discharge) isotopic-concentration criteria are maintained. This is illustrated by the results shown in Tables 11.2-9 and 11.2-10, where estimated design-basis releases have been calculated for two different modes of operating the radwaste equipment. It is seen that the resultant release quantities are virtually the same.

All releases to the environment from the liquid radwaste system are discharged past a radiation monitor that isolates the discharge line if high radioactive concentrations in the discharged liquid should occur. This monitor and the isolation valve are located so that, if a high radiation level is detected, the line is isolated before any liquid can be discharged. The flow is rerouted back to the system for reprocessing. The monitor and discharge lines would then be decontaminated by flushing.

11.2.7 Release Points

Any release of liquid radwaste is directed to the circulating water reservoir blowdown line. This discharge is from the Fermi 2 circulating water pump house and is directed to Lake Erie. The discharge path is shown in Figure 2.1-5.

11.2.8 Dilution Factors

If small amounts of liquid radwaste are to be released from Fermi 2, they will be released to Lake Erie via the circulating water reservoir blowdown line. The minimum dilution flow will be about 10,000 gpm. Further dilution of the blowdown is provided by the natural mixing characteristics of Lake Erie in the vicinity of the discharge. Section III of Appendix 11A provides an evaluation of dilution factors to the nearest individual receptors both northeast and south of Fermi 2 and at the Monroe and Toledo potable water intakes. These dilution factors are as follows:

a. 45 at nearest shoreline northeast of Fermi 2 (1770 m)

b. 67 at nearest shoreline south of Fermi 2 (1530 m)

c. 77 at 3200 m south of Fermi 2 (Monroe potable water intake)

d. 100 at distances greater than 3200 m.

11.2.9 Estimated Doses From Liquid Effluents

The possible pathways for radiation exposure to Man from plant effluents are presented in Figure 11.2-17. The following general pathways have been evaluated for liquid effluents:

a. Drinking water

b. Aquatic food chains

c. Direct radiation from water and shores.

These pathways can be divided into internal exposures resulting from pathways a. and b. and external exposures resulting from pathway c.

The radiation doses described in this section are predicated upon design-basis source terms, radwaste throughput values, and annual releases into Lake Erie. They were updated for power uprate conditions, and are considered to be conservative upper-limit values, and are being retained as such in the UFSAR for "historical" purposes. It is understood that the actual releases, source terms, and offsite dose values will be different than these UFSAR values, will be estimated via the Offsite Dose Calculation Manual, and will be periodically reported to the NRC.

A detailed design-basis evaluation of the potential doses from liquid effluents to an individual is presented in Appendix 11A, Section III. The maximum exposure from liquid effluents to an individual was assumed to be located, as discussed in Subsection 11.2.8 above, at 1770 m northeast of Fermi 2 and 1530 m south of Fermi 2. The resident south was assumed to drink potable water obtained from the Monroe water intake located 3200 m south of Fermi 2. The resident north was assumed to obtain his potable water from the Detroit municipal water system, which will be unaffected by Fermi 2 operation. Table III-1 of Appendix A presents conservative usage factors for liquid exposures. The activities usage factors represent 2 hr/day for boating, swimming, and shoreline use, each for a period of 90 days/yr for the teenager and child, while the adult will participate 1 hr/day in each activity. The ingestion rates are those recommended by Regulatory Guide 1.109 (Reference 2). The individual doses are summarized in Table 11.2-11 for the mode of radwaste operation with evaporators and the etched-disk filters in service.

Doses to the maximum exposed individual were calculated based on Mode One Operation (i.e., normal operation with the evaporators and etched disk filters in use). These doses are tabulated in Table 11.2-11. A comparison of Mode One annual liquid effluent releases with those corresponding to Mode Two operation (i.e., normal operation without the radwaste evaporators and with the precoat filters in use) shows that both sets of releases are almost identical. Therefore, it is reasonable to expect that doses to the maximum individual based on Mode Two operation, if they were to be calculated, would be approximately equal to those tabulated in Table 11.2-11. The total body doses tabulated in Table 11.2-11 are within the guidelines established by Appendix I and 10CFR20, and are less than the value calculated by the NRC (1.6 mrem/year total body, as reported in the Safety Evaluation Report, Table 11-5, NUREG-0798, July 1981).

The population exposures from both internal and external pathways were evaluated using the guidance provided in Regulatory Guide 1.109, Revision 1 (Reference 3). The exposures were calculated using the LADTAP II computer code (Reference 4). LADTAP II is a computer code received from the Radiation Shielding Information Center at Oak Ridge National Laboratory, which implements the models in Reference 3.

The population exposures from internal and external pathways were reviewed for the mode of operation without the evaporators and etched disk filters. As shown in Tables 11.2-9 and 11.2-10, there is no significant difference in the source terms between operation in mode one and mode two. It can be expected that the population exposure from internal and external pathways would not change significantly and that any differences would be due to changes in the assumptions in Subsections 11.2.9.1 and 11.2.9.2 used to evaluate the doses rather than from the radiological source term.

11.2.9.1 Internal Population Exposure

Internal population exposure will arise from the ingestion of potable water and from the ingestion of fish.

The locations of all municipal potable water intakes within 50 miles of Fermi 2 are presented in Table 2.1-12. The population data of each municipality were extrapolated to represent the population in the year 2000. The growth rates used for the U.S. locations were based on the assumption that the country growth rate established from 1970 to 1980 (Reference 5) would be maintained and would be applicable to the appropriate municipality. For the Canadian locations, a provincial growth rate from 1976 to 1980 (Reference 6) was assumed to be maintained until the year 2000. The dilution factors presented in Subsection 11.2.8 were assumed to be applicable. Table 11.2-12 presents the data on the municipal potable water intake locations, populations, and dilution factors.

For the expected population exposure from fish ingestion, an upper limit was estimated from the following assumptions:

a. The commercial fish catch from Lake Erie landed in Michigan is assumed to be affected by plant releases (Reference 7). The 1980 catch amounted to 280,000 kg

b. The sport fish catch described in Reference 7 is affected by plant activity releases. It was assumed to consist of 70 percent yellow perch and 30 percent walleye and amounts to 1,837,000 kg

c. The applicable dilution factor is conservatively taken to be 100 in all cases

d. The edible portion of the fish was assumed to be 60 percent

e. The population doses for fish ingestion are based on the estimated 50-mile population for the year 2000 (Reference 8).

Table 11.2-13 provides the internal population exposure by pathway and various organs.

11.2.9.2 External Population Exposure

External population exposure resulting from liquid effluents can arise from swimming, boating, and other shoreline activities.

The population of concern in the evaluation of the dose due to external exposure is residents of the nearby communities along the Lake Erie beachfront. It is estimated that 50 percent of the persons living in beachfront communities in Monroe County, Michigan, and the Toledo area use the beach for recreational purposes (Reference 5). The communities of interest, 50 percent of their year 2000 populations, their distances from the plant, and dilution factors are given in Table 11.2-14. The estimated year 2000 populations were calculated by extrapolating the 1980 population (Reference 8) to the year 2000, assuming that the country growth rates established from the year 1970 to the year 1980 will be maintained.

Other communities are either at greater distances from the plant or have beachfronts that are generally unsuitable for recreational activity. For the purpose of estimating population doses, it was assumed that a resident using the beach would spend 200 hr per year engaging in beach activities. Of this total time, it was assumed that 50 hr would be spent for swimming, 50 hr for water-surface activities (fishing, boating, waterskiing, and sailing), and 100 hr for shoreline activities such as sunbathing or walking along the shore (listed as shoreline in Table 11.2-14, which presents the external population doses from the liquid effluents by pathway and various organs).

11.2.10 Vendor-Supplied Liquid Processing System

If the permanent Fermi 2 liquid processing system is not available due to system malfunction, or if needed for any other reason, a vendor-supplied portable system can be utilized. The system normally will be operated by the vendor and will be closely monitored by Edison personnel. The types and quantities of waste to be processed are the same as for the permanent radwaste systems (as described in Subsection 11.2.2). Fermi 2 specific operating procedures or approved vendor procedures will be used for operating the portable system interfaced with the Fermi liquid radwaste system.

This vendor-supplied portable system would normally be installed in the areas immediately adjacent to the truck bay in the onsite storage facility. These areas of the onsite storage facility were specifically designed and constructed to contain and handle mobile process systems (see Subsection 11.7.2.2.11). Concrete floors and walls in this region are coated, and all drains are routed back to the liquid radwaste system. The remote-operated overhead crane is available to move the process equipment. The design of these onsite storage facility areas and the methods of operation have incorporated features to maintain personnel exposures ALARA. Permanent piping installed in the shielded onsite storage facility pipe tunnel will transport the radioactive process fluid to the vendor's equipment.

The interface connections between the mobile system and the Fermi 2 system are shown in Figure 11.2-15 and described in Table 11.2-4. A typical portable radwaste system operates by passing the contaminated water through a series of pressure vessels, as necessary, containing filtration media or ion-exchange resins. When these vessels are removed from service, the media are sluiced to a disposal container and processed further or dewatered or solidified in situ and then shipped to an approved burial site for disposal. In both cases, the resulting end products comply with all federal and state disposal regulations. The processed water is, in turn, routed to the waste sample tanks when established conductivity limits are met.

---

[a] Material manufacturer's certified test reports should be obtained whenever possible.

[b] ASME Code stamp and material traceability are not required.

[c] API-650 and AWWA D-100 apply to atmospheric tanks, whereas API-620 applies to 0- to 15-psig tanks. ASME Section III, Class 3, has rules .pertaining to both atmospheric (Subarticle ND-3800) and 0- to 15-psig (Subarticle ND-3900) tanks.

[d] Manufacturer's standard for the intended service. Hydrotesting should be 1.5 times the design pressure.
