Table 9.1-3
CHEMICAL AND VOLUME CONTROL SYSTEM PERFORMANCE REQUIREMENTS[a]

Station design life	80 years[b]
Nominal pump seal-water supply flow rate (to reactor coolant pumps)	24 gpm (8 gal/pump)
Nominal pump seal-water return flow rate (from reactor coolant pumps)	9 gpm (3 gal/pump)
Normal letdown flow rate	60 to 120 gpm
Maximum design letdown flow rate	120 gpm
Normal charging pump flow rate (one pump including 60-gpm recirculation flow)	129 to 189 gpm
Normal charging line flow	45 to 105 gpm
Maximum rate of boration using 7% boric acid from the BASTs with one transfer and one charging pump, from initial reactor coolant system concentration of 0 ppm	14.1 ppm/min
Equivalent cooldown rate during the above rate of boration	4.9°F/min
Maximum rate of boron dilution with maximum design letdown flow rate at hot shutdown from initial reactor coolant system concentration of 2500 ppm	950 ppm/hr
Maximum rate of boration using 2400 ppm refueling water assuming an end of life reactor coolant system concentration of 0 ppm	5.5 ppm/min
Equivalent end of cycle cooldown rate during the maximum rate of boration	1.9°F/min
Temperature of reactor coolant entering system at full power with normal letdown and charging line flow rates	540.4°F
Temperature of reactor coolant return to reactor coolant system at full power	488°F
Normal system discharge temperature to boron recovery system	115°F
Approximate amount of 7.0% boric acid solution required to meet cold shutdown conditions	6000 gal[c]

a. Volumetric flow rates in gpm are based on 130°F and 2350 psig.

b. Original design life was 40 years. The evaluation and management of aging of components in this system demonstrate the acceptability of the design life of 80 years.

c. Range of boric acid concentration is 7.0 to 8.5%. The amount of solution is determined from the lower limit of concentration in order to obtain the more conservative figure.

Table 9.1-9
CONSEQUENCES OF FAILURES OR MALFUNCTIONS OF THE CHEMICAL AND VOLUME CONTROL SYSTEM WITHIN THE REACTOR CONTAINMENT

Component	Failure	Comments and Consequences
Letdown line	Rupture in the line inside the reactor containment	The remote air-operated valve located near the main coolant loop is closed on low pressurizer level is to prevent supplementary loss of coolant through the letdown line rupture. The containment isolation valve in the letdown line outside the reactor containment is automatically closed by the containment isolation signal initiated by the concurrent loss- of- coolant accident. The closure of that valve prevents any leakage of the reactor containment atmosphere outside the reactor containment.
Charging line	Rupture in the line inside the reactor containment	The check valve located near the main coolant loop prevents supplementary loss of coolant through the line rupture. The air operated valve located upstream of the check valve in the defective line can be remote-manually closed to isolate the reactor coolant system from the rupture. The check valve located at the boundary of the reactor containment prevents any leakage of the reactor containment atmosphere outside the reactor containment.
Seal-water return line	Rupture in the line inside the reactor containment	The motor-operated isolation valve located outside the containment is manually closed or is automatically closed by the containment isolation signal initiated by the concurrent loss of-coolant accident. The closure of that valve prevents any leakage of the reactor containment atmosphere outside the reactor containment.

9.2 BORON RECOVERY SYSTEM

The boron recovery system, shown in Figure 9.2-1 and Reference Drawings 1, 2, 3 and 4, is a common system serving both units. The system degasifies and stores borated radioactive water letdown by the chemical and volume control system (Section 9.1) to be processed as liquid waste for disposal. The boron recovery system is designed for liquid samples to be taken as appropriate for processing.

The original boron recovery system was designed to process letdown water by evaporators, filters, and demineralizers. This system was capable of producing both primary-grade water and a concentrated boric acid suitable for recycling within the chemical and volume control system. The original boron recovery evaporator and its associated filters and demineralizers are installed in the plant, but they are no longer used to process letdown water.

A review of the effects of the power uprate to a core power of 2546 MWt was conducted and the boron recovery system was found to be adequate.

9.2.1 Design Bases

The original boron recovery system capacity was sized to accommodate the coolant letdown flow produced by two cold shutdowns from full power in one unit plus one cold shutdown from full power in the second unit in a 7-day period. These shutdowns are assumed to occur at that point in core life when the operating boron concentration in the first unit is 100 ppm and the boron concentration in the second unit is 1 month out of phase. The system influent results from shutdown boration bleed, draining one reactor coolant loop for maintenance work, system expansion during heat-up, and dilution bleed to operating boron concentration on start-up. The boron recovery tanks are assumed to be 10% full at the time of a cold shutdown, and the boron evaporators 75% available at rated capacity during the period.

The original boron recovery system was sized to accommodate letdown flow due to daily load following and weekend load reductions on both units to nearly the end of core life with 75% evaporator availability with minimum use of boron recovery tank capacity. The daily load-follow cycle basis consists of 12 hours at full power, a uniform 3-hour ramp reduction to 50% power, 6 hours at 50% power, and a uniform 3-hour ramp increase to full power.

The boron recovery system was modified to allow letdown water processing for disposal at the Radwaste Facility. This provides an additional 120,000-gallon surge capacity and a process rate of 25 gpm.

The system is capable of removing gases from both units simultaneously at the maximum letdown flow rate.

The boron evaporators are capable of processing the average letdown rate of both units producing a distillate with boron content not exceeding 10 ppm boron and concentrated bottoms at 12% boric acid. Although the boron evaporators are still physically installed in the plant, they are no longer used to process letdown water.

The primary drain tank, gas stripper, gas stripper overhead condenser, primary drain tank vent chiller condenser, overhead gas compressors, and gas stripper surge tank in the boron recovery system are designed as Class I components.

Piping in the boron recovery system is type 304 stainless steel and Incoloy 825. The Incoloy 825, which is used in those parts of the system associated with the processing of liquid waste or the concentration of boric acid, is resistant to corrosive attack by the solutions concentrated in the boron recovery system. All piping joints and connections are welded except where flanged connections are required to facilitate equipment removal for maintenance.

All globe valves handling radioactive gas are packless, diaphragm valves. All valves handling primary-grade water or radioactive fluid are stainless steel or Incoloy 825.

All liquid lines, equipment, and accessories containing concentrated boric acid (6% by weight boric acid or greater) are electrically heat-traced with dual circuits to prevent crystallization of boric acid. The boron recovery tanks and primary-grade water tanks are heated by steam. The evaporator bottoms tank is maintained, when in operation, at 150°F minimum by dual electric heaters.

The design data for the boron recovery system components are given in Table 9.2-1.

9.2.2 Description

The boron recovery system is illustrated in Figure 9.2-1 and Reference Drawings 1, 2, 3, and 4. Reactor coolant letdown, with entrained hydrogen and fission gases, enters the boron recovery system via the vent and drain system (Section 9.7). This liquid is pumped under automatic level control from the primary drain tank to the gas stripper, stripped of dissolved gases, and, if necessary, passed through ion exchangers for the removal of soluble fission and corrosion products. After subsequent filtration to remove additional particulate materials, the liquid is held up in the three boron recovery tanks for processing by the liquid waste system. Noncondensable gases removed in the gas stripper are taken off the gas stripper overhead condenser and discharged into the gas stripper surge tank by the overhead gas compressors. The surge tank discharges to the gaseous waste disposal system (Section 11.2.5); however, the capability exist to discharge to the volume control tank to return the hydrogen and radioactive gases to the reactor coolant system (Chapter 4). The surge tank contains sufficient gas to provide a cover gas for the gas stripper to prevent drawing in air, which could form a combustible mixture when the stripper is shut down.

The boron recovery system is designed so that operation of the primary drain tank and gas stripper is automatic when all system control setpoints are established. If used, operation of the evaporators is automatic upon cycle initiation from the control room.

Flanged connections have been provided on the boron recovery system next to the boron recovery tanks to enable the removal of radioactive gases and fluids to external process systems without having to enter high-radiation areas. The connections are provided with isolation valves, with reach rods also provided as needed. The valves and handwheels are so located as to permit access after an accident with reduced radiation exposure to personnel.

9.2.3 Design Evaluation

The design capacity of the gas stripper is 240 gpm, which corresponds to the maximum instantaneous letdown rate of both units. The stripper is controlled automatically at any letdown rate up to its maximum, with no operator action.

The boron recovery tanks, when 10% full, have an additional capacity of approximately 340,000 gallons and the Radwaste Facility has a surge capacity of approximately 120,000 gallons. During 7 days of operation at 75% availability, the radwaste liquid waste system can process approximately 190,000 gallons. This provides a total capability of approximately 650,000 gallons of letdown that can be stored or processed during any 7-day period. This capability is in excess of the estimated 450,000 gallons produced by three cold shutdowns.

9.2.3.1 **System Reliability**

Duplicate, full-capacity pumps and compressors are provided for all equipment except the boron evaporator recirculation pumps, evaporator bottoms tank recirculation pump, waste bottoms pump and the boron evaporator bottoms coolant pump. The primary-grade water pumps, primary drain tank pumps, gas stripper pumps, and gas stripper overhead compressor are provided with automatic controls to start the standby pump if the normal pump fails. The controls of all duplicate pumps are designed to permit alternate duty to equalize operating hours.

The components of this system listed in Section 9.2.1 are designed as Seismic Category I to resist earthquakes and are protected from possible tornado missiles by concrete walls or ceilings.

9.2.3.2 **Malfunction Analysis**

A failure analysis of boron recovery system components is present in Table 9.2-2.

9.2.4 Tests And Inspections

Tests, calibrations, and checks are periodically conducted on the various instrument channels to ensure proper instrument response and operation of alarm functions.

Standby pumps are switched on a periodic basis, and continuously running equipment is inspected periodically to ensure availability. Routine inspections are performed on this system in accordance with maintenance procedures to ensure that standby equipment will perform as required.

9.2 REFERENCE DRAWINGS

The list of Station Drawings below is provided for information only. The referenced drawings are not part of the UFSAR. This is not intended to be a complete listing of all Station Drawings referenced from this section of the UFSAR. The contents of Station Drawings are controlled by station procedure.

Table 9.2-2
BORON RECOVERY SYSTEM MALFUNCTION ANALYSIS

Component	Malfunction	Comments and Consequences
Tanks and other components containing letdown liquids with dissolved gasses	Leak	Tanks and other components are protected from over-pressure by automatic controls and relief valves; therefore only minor leaks are considered possible. The total gas content of the gas stripper and associated gas holding tanks is less than the holdup tanks in the gaseous waste gas disposal system (Section 14.4.2), so even a total release via the auxiliary vent system could be accommodated (Section 9.13).
Boron recovery tanks	Leak	Only degassed liquids are normally stored in these tanks, which are protected by dikes capable of retaining the entire contents of the tank. The dikes are Class I structures.
Gas stripper and associated pumps, heater, and controls	Fail to function	Letdown due to boration of the reactor coolant system can be diverted directly to the boron recovery tanks, which are vented through the monitored gaseous waste disposal system. Dilution letdown can be delayed.
One boron recovery evaporator or auxiliaries	Fails to function	The boron recovery evaporators are no longer used to process CVCS letdown. Letdown is processed as liquid waste in the Radwaste Facility by either reverse osmosis and ion exchange or by the radwaste facility evaporators. Furthermore, the Radwaste Facility has an additional collection/surge capacity of approximately 120,000 gallons. Multiple processing options ensure that sufficient letdown processing capacity is available while repairs are being made. Sufficient capability to make boric acid solution for station requirements exists in the boric acid batch tanks, and the primary-grade water tanks can supply adequate quantities of water.
Primary-grade water pump	Fails to function	Two 100%-capacity pumps are provided to permit maintenance.

9.3 RESIDUAL HEAT REMOVAL SYSTEM

9.3.1 Design Bases

The residual heat removal system is shown in Figure 9.3-1 and Reference Drawing 1. It is designed to remove residual and sensible heat from the core and reduce the temperature of the reactor coolant system during the second phase of unit cooldown. During the first phase of cooldown, the temperature of the reactor coolant system is reduced by transferring heat from the reactor coolant system (Chapter 4) to the steam and power conversion system (Chapter 10).

The residual heat removal system is designed to be placed in operation when the reactor coolant temperature has been reduced to approximately 350°F and the reactor coolant pressure is between 400 and 450 psig. These conditions are assumed to occur approximately 4 hours after reactor shutdown. The residual heat removal system is designed to reduce the temperature of the reactor coolant from 350°F to 140°F over a period of 16 hours. With one pump in service, the residual heat removal system can reduce the temperature of the reactor coolant from 350°F to 200°F within 26 hours, and from 200°F to 140°F prior to beginning refueling operations.

The system design precludes any significant reduction in the overall design reactor shutdown margin when the system is brought into operation for residual heat removal by equalizing the boron concentration and the temperature with the reactor coolant system.

System components, whose design pressure and temperature are less than the reactor coolant system design limits, are provided with redundant isolation means and overpressure protective devices.

A residual heat removal system is provided for each unit.

Any leakage from the residual heat removal system goes either to the containment or to the component cooling system, which is a closed system. Any migration of radioactivity would be detected by the containment particulate and gas monitors (Section 11.3) if the leak was to the containment. If the leak was to the component cooling system, the component cooling water monitor would alarm in the event that the radiation level reached a preset level above the normal background.

All active system components that are relied upon to perform their function are redundant, and the system design includes provisions to enable periodic hydrostatic testing to applicable code test pressures.

9.3.1.1 **Codes and Classifications**

All piping and components of the residual heat removal system are designed to the applicable codes and standards listed in Table 9.3-1. Since the system contains reactor coolant when it is in operation, austenitic stainless steel piping is used. The residual heat removal system is a Seismic Class I system.

9.3.2 System Design and Operation

9.3.2.1 System Description

The residual heat removal system, shown in Figure 9.3-1 and Reference Drawing 1, consists of two residual heat exchangers, two residual heat removal pumps, and associated piping, valves, and instrumentation.

One pump and one residual heat exchanger are enough to perform the decay heat transfer functions for the unit. After the reactor coolant system temperature has been reduced to approximately 350°F and the reactor coolant pressure is between 400 and 450 psig, further system cooling is initiated by aligning the pumps to take suction from the reactor coolant hot leg and discharge through the heat exchangers into the reactor coolant cold leg.

During unit cooldown, reactor coolant flows from the reactor coolant system to the residual heat removal pumps, through the tube side of the residual heat exchangers, and back to the reactor coolant system. The inlet line to the residual heat removal system is located in the hot leg of reactor coolant loop A between the main loop stop valve and the reactor core. The return line connects to the B & C through the safety injection system. The heat loads are transferred by the residual heat exchangers to the component cooling water in the component cooling system (Section 9.4).

During unit cooldown, the cooldown rate of the reactor coolant is controlled by regulating the flow through the tube side of the residual heat exchangers. A single bypass line with a remotely operated control valve around both residual heat exchangers is used to maintain a constant coolant flow through the residual heat removal system while controlling coolant temperature.

To assure that adequate head is available for the RHR pumps during cold shutdown (reactor coolant level below Elevation 24 ft.) and during refueling, reactor coolant level monitoring is available. Level instrumentation to prevent loss of shutdown cooling is discussed in Section 7.11.

The entire residual heat removal system is located inside the containment, with the exception of the line penetrating the containment that connects to the refueling water storage tank.

The residual heat removal pumps are normally controlled from the control room. In the event of a control room evacuation, pumps can be operated at the switchgear in the emergency switchgear room. See Section 7.7.2 for discussion on compliance with 10 CFR 50 Appendix R.

During refueling, the water level in the reactor cavity is lowered by opening a valve at the residual heat removal pump discharge and then pumping the water into the refueling water storage tank, while maintaining as adequate flow to the RHR heat exchanger(s) to ensure the continued removal of residual heat from the core.

The RHR system air operated valves are equipped with quick-disconnect instrument air fittings to provide a method to locally operate the valves with a portable air source. The operation of these valves is required for decay heat removal during plant cooldown following a postulated fire in accordance with the requirements of Appendix R to 10 CFR 50.

The residual heat removal system is not an engineered safeguards system.

9.3.2.2 **Components**

Residual heat removal system component design data are listed in Table 9.3-2.

9.3.2.2.1 Residual Heat Exchangers

The residual heat exchangers are of the shell and U-tube type, with the tubes welded to the tube sheet. Reactor coolant circulates through the tubes while component cooling water circulates through the shell side. The tubes and other surfaces in contact with reactor coolant are austenitic stainless steel, and the shell is carbon steel.

9.3.2.2.2 Residual Heat Removal Pumps

The two residual heat removal pumps are in-line vertical centrifugal units with mechanical seals to prevent reactor coolant leakage. All pump parts in contact with reactor coolant are austenitic stainless steel or adequate corrosion-resistant material.

9.3.2.2.3 Residual Heat Removal System Valves

The valves used in the residual heat removal system are constructed of austenitic stainless steel or other adequate corrosion-resistant materials, such as Haynes alloy 25 and 17-4 PH stainless steel.

Manual stop valves are provided to isolate the pumps or the heat exchangers for maintenance. Butterfly valves are provided for control of residual heat exchanger tube-side flow. Check valves prevent reverse flow through the residual heat removal pumps.

Isolation of the residual heat removal system is achieved with two remotely operated stop valves in series in the pipe from a reactor hot leg to the suction side of the residual heat removal pump, and by a check valve (located in the safety injection system) in series with a remotely operated stop valve in each line from the residual heat removal system. System pressure is relieved through a relief valve to the pressurizer relief tank in the reactor coolant system.

Several motor operated valves in the RH System have been modified to prevent valve pressure locking. The valves have been modified to relive pressure that can be trapped between the gate valve disks. The following MOVs have been modified by drilling a hole in the downstream disk: 1-RH-MOV-1720A,B.

Valves that perform a modulating function are equipped with two sets of packing and an intermediate leakoff connection that discharges to the vent and drain system (Section 9.7).

Manually operated valves have backseats to facilitate repacking and to limit stem leakage when the valves are open. Leakoff connections are provided where required by valve size and fluid conditions.

9.3.2.2.4 Residual Heat Removal System Piping

All residual heat removal system piping is austenitic stainless steel. Piping is welded, except at the flanged connections of the flow control valves.

Portions of the residual heat removal system potentially contain stagnant oxygenated borated water during plant operation (References 1 & 2). System integrity is maintained by means of periodic sampling and inservice inspection requirements. Residual heat removal system chemistry guidelines are given in Table 9.3-3.

9.3.3 System Design Evaluation

9.3.3.1 **Availability and Reliability**

For reactor coolant system cooldown, the residual heat removal system is provided with two pumps and two residual heat exchangers. If one of the two pumps and/or one of the two heat exchangers is not operative, safe operation of the unit is not affected.

A radiant energy shield is installed between the residual heat removal pump motors to satisfy 10 CFR 50, Appendix R, requirements.

9.3.3.2 **Incident Control**

The suction side of the residual heat removal system is connected to the reactor coolant hot leg of A loop and the discharge side to the cold legs of the B & C loops through the safety injection system. On the suction side, the connection is through two electric motor-operated gate valves in series. Both valves are interlocked with reactor coolant system pressure so that, if the reactor coolant system pressure exceeds a set pressure, the valves do not open. On the discharge side of the residual heat removal system, each connection is made through an electric motor-operated valve in series with a check valve. The motor-operated valves are closed whenever the reactor coolant system pressure and temperature exceed approximately 450 psig and 350°F, respectively.

The fluid operating pressure is higher at all times on the tube side of the residual heat exchanger than on the shell side, varying over an approximate range of 450 to 100 psig, so that in case of leakage, reactor coolant leaks into the component cooling water in the shell side. Abnormally high radiation levels in the component cooling water would be indicated in the control room, at which time the control valve in the vent line from the component cooling surge tank to the process vent would be closed by manual operation of a control switch in the control room, if it had not previously closed automatically due to high-radiation signals from transmitters installed in the component cooling water piping. Inleakage to the component cooling water, if not stopped, results in high level in the component cooling surge tank, and eventually fills the tank.

Excess water from the tank is disposed of by a relief valve discharging to the auxiliary building sump. After the leakage condition is corrected, radioactivity in the component cooling water is reduced by bleed and feed or as discussed in Section 9.4.4.7.

The residual heat removal pumps are driven by drip-proof-type motors with Class B epoxy-type insulation capable of operation in high-humidity conditions. They are equipped with splash barriers to protect the motors in the event of a pipeline break in the area, which could possibly spray and wet the motors.

The inlet line from the reactor coolant system to the residual heat removal system is between the reactor core and the outlet loop isolation valve. Thus, if the outlet or inlet loop isolation valve is closed, the inlet from the reactor coolant system to the residual heat removal system is not blocked.

9.3.3.3 **Malfunction Analysis**

A failure analysis of residual heat removal pumps, heat exchangers, and valves is presented in Table 9.3-4.

9.3.4 Tests and Inspections

The residual heat removal pump flow instrument channels are calibrated during each refueling operation.

The active components of the residual heat removal system are tested in accordance with ASME Code requirements. Periodic visual inspections and preventative maintenance are conducted, following normal industrial practice.

a. Sampling is performed when the system is in operation.

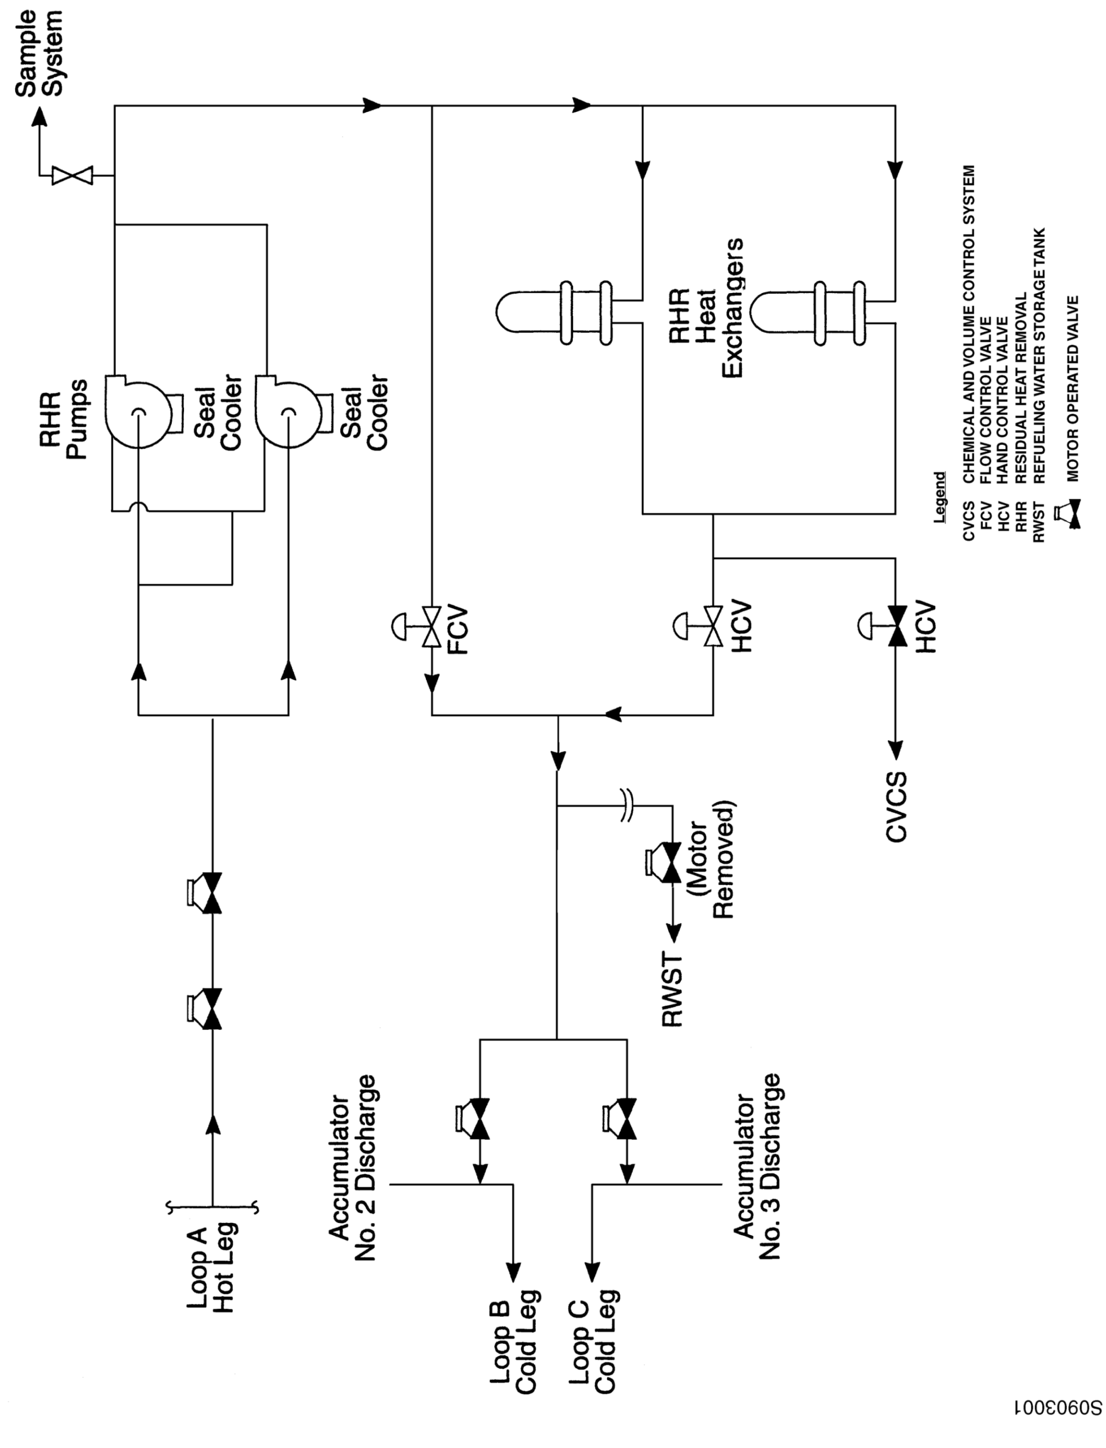
b. Expected value. Determined by the concentration of boric acid and alkali present.

c. Limit not applicable with $T_{avg} \leq 250°F$.

Table 9.3-4
RESIDUAL HEAT REMOVAL LOOP MALFUNCTION ANALYSIS

Component	Malfunction	Comments and Consequences
Residual heat removal pump	Rupture of casing	The casing and shell are designed for 600 psig and 400°F. The pump is protected from overpressurization by a relief valve in the piping discharging to the pressurizer relief tank. The pump can be inspected, and is located in the containment structure with protection against missiles. Rupture is not considered credible.
Residual heat removal pump	Pump fails to start	One operating pump furnishes enough flow to meet the required cooldown rate.
Residual heat removal pump	Manual valve on pump suction is closed	This is prevented by administrative controls during pre-startup and operational check.
Residual heat removal pump	Stop valve in discharge line closed or check valve sticks closed	Pre-startup and operational checks confirm position of valves.
Remote operated valve inside containment in pump suction line	Valve fails to open	Valve position indication light indicates that the valve has not opened. Valve is opened manually or unit is slowly cooled by feed and bleed procedures.
Motor-operated valve inside containment in system discharge line	Valve fails to open	Two valves in parallel. If one fails to open, flow passes through other valve.
Residual heat exchanger	Tube or shell rupture	Rupture is considered very unlikely because of low operating pressure as compared to design pressure. In any event, the faulty heat exchanger can be isolated and the remaining heat exchanger used for cooldown.
Valve in bypass line around residual heat exchangers	Valve sticks open	Part of flow does not pass through residual heat exchangers increases the time for unit cooldown.

Figure 9.3-1
RESIDUAL HEAT REMOVAL SYSTEM



9.4 COMPONENT COOLING SYSTEMS

The component cooling systems consist of the following:

1. Component cooling water system.
2. Chilled component cooling water system.
3. Chilled water system.
4. Neutron shield tank cooling water system.
5. Charging pump cooling water system.

These systems are used separately or in combination to supply cooling water for heat removal from various station components. The component cooling systems are shown on Figures 9.4-1 through 9.4-5 and Reference Drawings 1 through 9. A review of the effects of the power uprate to a core power of 2589.3 MWt was conducted and the component cooling system was found to be adequate.

9.4.1 Design Bases

9.4.1.1 Component Cooling Water System

A common supply of component cooling water serves both units to:

1. Provide cooling water to remove residual and sensible heat from the reactor coolant system during unit shutdown and cooldown.
2. Cool spent-fuel pool water.
3. Cool reactor coolant pump motor coolers.
4. Cool letdown flow in the chemical and volume control system during power operation.
5. Cool reactor coolant pump seal-water return flow.
6. Supply makeup water to the neutron shield tank cooling water system.
7. Supply makeup water to the charging pump cooling water system.
8. Provide the cooling water supply to the neutron shield tank coolers and the containment recirculation air coolers (Section 5.3.1.3.1).
9. Provide cooling water to dissipate waste heat from other reactor and station components.

The component cooling water system is an intermediate cooling system that transfers heat from heat exchangers containing reactor coolant or other radioactive liquids to the service water system (Section 9.9). The maximum heat load occurs during the initial stages of residual heat removal during a reactor unit cooldown. The component cooling water system is designed to reduce the temperature of the reactor coolant to 140°F based on a river water temperature of 100°F.

During normal full-power operation, one component cooling pump and one component cooling heat exchanger can accommodate the heat removal loads for each reactor unit. Operation of two pumps and two heat exchangers is the standard procedure during the removal of residual and sensible heat during unit cooldown, although one pump and one exchanger may be safely used under these conditions.

Operation of the component cooling water (CCW) system is required in the event of a hurricane for the removal of decay heat to attain and maintain long-term safe shutdown. The operation of the CCW system during a design basis hurricane is discussed in Section 2.3.1.2.2. and 9.9.1.3.

Each of the four component cooling heat exchangers is designed to remove the entire heat load from one unit plus half of the heat load common to both units during normal operation. Each heat exchanger is also capable of removing half of the heat load occurring four hours after a shutdown of one unit under conditions representing the maximum allowable cooldown rate.

The Vacuum Priming System ties into each component cooling heat exchanger at the top of the inlet and outlet channel heads, which are the high points of the portion of the service water that supplies the heat exchangers. The Vacuum Priming System is utilized to initiate the siphon action when placing the heat exchangers in service. The design of the component cooling heat exchanger service water piping system does not require that the Vacuum Priming System remain in service for the heat exchanger to be operable. To protect against a break in the vacuum priming lines and subsequent loss of service water flow, design changes were implemented to add a check valve in the vacuum priming line and provide separate float valves for the inlet and outlet channel heads. The portion of the vacuum priming line between the check valve and the channel heads of each heat exchanger is safety-related.

The presence of excess radioactivity in the component cooling water system is detected by two gamma scintillation radiation monitors. High-radiation signals from either of these detectors cause the surge tank vent isolation valve to shut and initiate an alarm in the control room. One detector monitors the supply to Unit 1 and is mounted on the 18-inch combined-discharge line from component cooling heat exchangers 1-CC-E-1A and 1B. The second detector monitors the supply to Unit 2, and is mounted on the 18-inch combined-discharge line from component cooling heat exchangers 1-CC-E-1C and 1D. Both detectors are located in the Unit 1 turbine building to prevent possible interference from background radiation levels in the auxiliary building. Operation of these detectors is described in Section 11.3.3.

Component design data for the component cooling water system are given in Table 9.4-1. A more detailed system description is given in Section 9.4.3.1.

Portions of the component cooling water system are designed as Class I (Section 15.2.1).

9.4.1.2 **Chilled Component Cooling Water System**

The chilled component cooling water system circulates chilled component cooling water to selected components for cooling when normal temperature limits cannot be maintained by the component cooling system. A more detailed system description is given in Section 9.4.3.2.

The chilled component cooling water system can be used to supply water to the following components:

1. Containment recirculation air coolers.
2. Neutron shield tank coolers.
3. Primary drain tank vent chiller condenser (Unit 1 chilled component cooling water system only).
4. Recombiner aftercooler (Unit 1 chilled component cooling water system only).
5. Steam generator recirculation coolers.

Three chilled component coolers and three chilled component cooling pumps are provided for the chilled component cooling water subsystem that serves both units. A pump and cooler serves each unit and one pump and cooler is provided for use as a spare. The piping is arranged so that the spare cooler and pump can be used together for either unit or individually to replace a component normally used for either unit.

Chilled component cooling water system component design data are given in Table 9.4-10.

9.4.1.3 **Chilled Water System**

Chilled water is provided separately for each unit. Each 400-ton capacity chilled water system is designed to supply 1260 gpm of 40°F chilled water.

The chilled water system provides cooling to the chilled component cooling heat exchangers.

Chilled water is also used directly to cool the water in the refueling water storage tank to nominal 45°F after a refueling operation.

Chilled water system component design data are given in Table 9.4-2. Additional system data are given in Tables 9.4-3 through 9.4-5. A more detailed system description is given in Section 9.4.3.3.

9.4.1.4 **Neutron Shield Tank Cooling Water System**

The neutron shield tank cooling water system is designed to circulate and cool the water in the neutron shield tank, which is heated by neutron and gamma radiation.

Two neutron shield tank coolers, a neutron shield surge tank, a corrosion control tank, and all necessary piping and valves comprise the system serving each reactor unit. Each neutron shield tank cooler has 100% capacity. The second cooler is a spare that can be placed in operation remotely by means of motor-operated valves.

Neutron shield tank cooling system component design data are given in Table 9.4-6. A more detailed system description is given in Section 9.4.3.4.

9.4.1.5 **Charging Pump Cooling Water System**

The charging pump cooling water system consists of two separate subsystems: a component cooling water subsystem and a service water subsystem. The charging pump service water system is described in Section 9.9.2.1.

A separate charging pump cooling water system is provided for each reactor unit.

The charging pump component cooling water system is designed to transfer heat from the charging pump mechanical seal coolers to the intermediate seal coolers.

Charging pump component cooling water system component design data are given in Table 9.4-7. A more detailed system description is given in Section 9.4.3.5.

The charging pump component cooling water system is designed as Class I (Section 15.2.1).

9.4.2 Piping and Valves (Check Valves and Manually Operated Gate, Butterfly, and Globe Valves)

Carbon steel pipe is used throughout the system. Joints are welded, except where flanges are used at connections to equipment and to butterfly and check valves in sizes 10-inch and larger. All valves are of steel material except certain butterfly valves, which are cast iron. Selected piping, valves, and supports are designed as Class 2. Expansion joints are provided at the suction and discharge of the component cooling water pumps. The piping system conforms to the requirements of the USA Code for Pressure Piping B-31.1.

Small thermal relief valves are constructed with stainless steel body and trim and carbon steel bonnet and cap. Larger relief valves have carbon steel bodies with stainless steel trim.

9.4.3 System Descriptions

9.4.3.1 **Component Cooling Water System Description**

During operation, component cooling water is pumped through the shell side of the component cooling water heat exchangers, where it is cooled by service (river) water (Section 9.9), and then through parallel circuits that can cool the following components:

1. Reactor coolant pump thermal barriers, bearing oil coolers, and motor stators.

2. Excess letdown heat exchangers (intermittent heat load).
3. Nonregenerative heat exchangers.
4. Various primary and steam generator blowdown sample coolers (intermittent heat load).
5. Seal-water heat exchangers.
6. Residual heat removal pumps seal coolers (during the second phase of unit cooldown, Section 9.3.1).
7. Residual heat removal exchangers (during the second phase of unit cooldown, Section 9.3.1).
8. Boron recovery system equipment (intermittent heat load).
9. Containment penetration cooling coils.
10. Fuel pool coolers.
11. Reactor shroud cooling coils.
12. Primary shield penetration cooling coils.
13. Primary shield water wall coolers.
14. Primary drain coolers.
15. Liquid waste disposal system equipment (abandoned in place, with the exception of the contaminated drain tank pump cooler).
16. Gaseous waste disposal system equipment.
17. Neutron shield tank coolers.
18. Reactor containment recirculation air coolers.
19. Containment instrument air compressor heat exchangers.

The component cooling water system is designed as a closed system, with a surge tank at the pump suctions. The tank is the high point of the system and provides the required net positive suction head for proper operation of the pumps. The heat exchangers are located in the turbine building for Unit 1. Pumps, tanks, and some of the equipment cooled by the system are installed in the auxiliary building; the fuel pool coolers are in the fuel building, the containment instrument air compressors are in safeguards, and the steam generator blowdown sample coolers are in the turbine building; the remainder of the equipment served is located in the reactor containments. Two 18-inch main supply and two 18-inch main return lines are used for each reactor unit. These mains, in full size, are connected directly to the residual heat removal exchangers, located in the reactor containments at the extremities of the two piping loops. Reduced size branches connected to the mains form cross-circuits that serve the remainder of the apparatus being cooled. The majority of equipment common to both reactor units is located in the auxiliary building; the fuel pool coolers are in the fuel building. Associated cross-circuits are double connected to the mains for both reactor units. High-point vents and low-point drains are provided as required by the piping configuration.

Each cooling water outlet line from a piece of equipment contains a valve for controlling flow; the valve is either a manually operated globe type or an automatic air-operated type positioned by pressure or temperature control signals originating in cooled systems.

The system is provided with trip valves for isolating the containment structures in accordance with the requirements of the containment isolation system (Section 5.2).

The RHR heat exchanger component cooling water trip valves are equipped with quick-disconnect instrument air fittings to provide a method to locally operate the valves with a portable air source. The operation of these valves is required for decay heat removal during plant cooldown, following a postulated fire in accordance with the requirements of Appendix R to 10 CFR 50.

The system is monitored from the control room by indicators that display the following data (data of a common nature are displayed on both control boards):

1. Component cooling pump discharge pressure.
2. Radioactivity, temperature, and flow in the supply mains immediately downstream from the component cooling water heat exchangers.
3. Temperature and flow in the residual heat removal heat exchanger return mains at the exits from the reactor containments.
4. Temperature in the return mains at the component cooling pump suctions.
5. Level in the component cooling surge tank.

Pressure switches for automatic starting of standby pumps are installed in the component cooling pump discharge mains. Local indicators for pressure, temperature, level, and flow are provided on a general basis. Selected temperatures are sensed and output signals are fed into the computer monitoring system (Section 7.8), thus providing full- time scanning and alarming. These temperatures can be read out during periods of abnormal values. Other important temperatures, pressures, levels, and flows are alarmed in the control room when abnormal values are reached.

The component cooling water pumps are normally controlled from the control room. In the event of a control room evacuation, pumps can be operated at the switchgear in the emergency switchgear room. See Section 7.7.2 for discussion on compliance with 10 CFR 50 Appendix R.

Thermal relief valves are installed around equipment with a significant potential for overpressurization by a combination of closed component cooling water inlet and outlet valves and heat input from the isolated equipment. The overhead gas compressor, boron evaporator distillate pump, primary drain tank pump, waste gas compressor, residual heat removal pump seal cooler, and containment penetration coolers (inner and outer), are examples of equipment not requiring thermal relief protection, since their overpressurization potential is insignificant. A relief valve and a vacuum breaker valve are provided for the component cooling surge tank. Also, a relief valve is installed on the line supplying makeup to the component cooling surge tank.

The surge tank level is maintained at a level sufficient to accommodate minor system surges and thermal swell due to cooldown operation without overflowing through the relief valve. The makeup line is double connected to both main condensate systems and a tie-in from the bearing cooling makeup pump; this provides redundancy, since it is unlikely that both turbine generators and bearing cooling makeup would be out of service during cooldown of a reactor unit. High level in the tank is lowered by manual operation of system low-point drains. The tank is equipped with a full-length gauge glass.

A 120-gallon-capacity chemical addition tank is connected to the component cooling pump suction and discharge piping. When utilized, the tank is charged with chemicals after being isolated and having its level lowered by manual valves. After closure of the charging and manual level valves and opening of the isolation valves, discharge pressure forces water into the tank and injects the mixture into the system at the pump suctions. Chemicals can also be added using a portable chemical addition pump.

The desired water chemistry is obtained by the addition of potassium chromate for corrosion inhibition with potassium hydroxide and potassium dichromate being added for pH control as needed. The design objective of the chemical treatment is to initially treat the system with a maximum of 500 ppm of chromate with control being maintained between 150-500 ppm of chromate at a pH of 8.0 to 9.5. Control within these parameters may be adjusted according to industry good practices. The 500 ppm maximum chromate limit applies only to subsystems that contain carbon-based mechanical seals. Sampling is performed at the central station in the auxiliary building. Several local sample points are also provided.

9.4.3.2 **Chilled Component Cooling Water System Description**

The chilled component cooling water system can be used to supply water to the following components when the component cooling water system cannot be maintained within normal limits:

1. Containment recirculation air coolers.
2. Neutron shield tank coolers.
3. Primary drain tank vent chiller condenser (Unit 1 chilled component cooling water system only).
4. Recombiner aftercooler (Unit 1 chilled component cooling water system only).
5. Steam generator recirculation coolers.

Typically, the chilled component cooling system is placed in service when the component cooling system supply temperature can no longer be maintained within normal limits. This condition is usually encountered during summer months when river water temperature is high. The heat from the various system loads is transferred to the chilled water system.

The major components associated with the system are three pumps and three heat exchangers. Makeup water and a surge volume for the system are provided by the component cooling system.

The three chilled component cooling pumps are single-stage, centrifugal pumps. They provide the motive force to circulate chilled component cooling water through the system. When this system is in operation, normally two chilled component cooling pumps are running (one for each unit) and the third pump is used as a spare. The spare pump can be used to supply either Unit 1 or 2. The chilled component cooling pumps are controlled from the main control room.

Three chilled component coolers (heat exchangers) are used to transfer the heat from the chilled component cooling system to the chilled water system. Each cooler consists of a horizontally mounted shell, which encloses tubes, and tubesheets. One heat exchanger is provided for each reactor unit, and one is maintained as a spare but can serve either unit. The discharge of the chilled component cooling pump is directed through the shell of the heat exchanger, where heat is rejected to chilled water flowing through the heat exchanger tubes.

9.4.3.3 **Chilled Water System Description**

Each unit has an independent, closed-loop chilled water system. A third full-size spare chiller unit is provided with cross-tie chilled water piping to permit use by either unit. Manual valves are provided for component isolation and for cross-connections.

Each of the closed-loop systems consists of:

1. Full-sized chilled water circulation pumps (three for Unit 1, two for Unit 2).
2. A packaged centrifugal liquid chiller using refrigerant R22 for the vapor compression cycle, with a rotary compressor and motor, oil coolers, purge unit, pre-wired internal controls, indication, and a condenser section.
3. A surge tank with automatic level control and makeup from alternate condensate system sources.
4. Isolation and control valves.
5. Fluid systems and electrical component protection.
6. Necessary instrumentation and controls for local control.

The Unit 1 chiller and swing chiller are located on a platform at Elevation 35 feet in the northeast sector of the Unit 1 turbine building. Piping and valves are provided so that one chilled water pump is normally aligned with each chiller unit, with the third pump serving as backup to either loop. Two surge tanks are provided on the north wall of the Unit 1 operating floor.

The Unit 2 chiller and two full-sized chilled water pumps are located on Elevation 9 ft. 6 in. in the northeast sector of the Unit 2 turbine building. A surge tank for the system is located on the north wall of the Unit 2 turbine building operating floor.

Each chiller uses a rotary compressor, driven by a 468 hp, 4000V, drip-proof motor. Cooling is supplied to the chilled component cooling heat exchangers (Section 9.4.3.2).

For the normal operation of the system, a chilled water pump is started to establish the flow, and the pump minimum flow path is established to a surge tank that maintains constant pressure at the pump suction and provides an area for chemical addition.

Local flow indication as well as low-flow cutoff of the chiller, is provided for chilled water and bearing cooling (BC) water flow. Capacity control is achieved by use of a slide valve which provides fully modulating capacity control from 100% to 10% of full-load. The minimum inlet cooling water temperature to the chiller condensers is 63°F. The supply BC water is normally maintained in a range of 65°F to 95°F by throttling the service water flow to the BC heat exchangers. The BC temperature is monitored and controlled by a station procedure.

Table 9.4-2 lists design conditions for the chilled water units.

Three 100%-capacity, horizontal centrifugal chilled water circulation pumps are provided in Unit 1:

1. One for the Unit 1 chiller.
2. One for the swing chiller.
3. One spare pump as backup to supply either chiller.

Two 100%-capacity, horizontal centrifugal chilled water pumps are provided in Unit 2.

A chilled water circulation pump is manually aligned and started to recirculate water through the chiller and service components.

See Table 9.4-3 for a more detailed description of the chilled water circulation pumps.

The design conditions of the surge tanks are provided in Table 9.4-4.

The chilled water system comprises 150-lb rated carbon steel pipe and valves to meet the existing chilled water system requirements (see Table 9.4-5 for a listing of piping and valve data).

Control of the chilled water system is maintained from local control panels. Important parameters are monitored on the panels, with alarms provided in the control room.

The Chilled Component Cooling Water System has the capability to monitor the following:

1. Flow and temperature measurements at the inlet to the reactor containment air recirculation coolers.
2. Temperature measurement at the outlet of the reactor containment air recirculation coolers.

9.4.3.4 Neutron Shield Tank Cooling Water System Description

A neutron shield tank cooling system is provided for each reactor unit to cool the water in the neutron shield tank, which is heated by neutron and gamma radiation from the reactor. The heated water in the neutron shield tank rises by natural convection to the top of the tank and into the pipe connected to the neutron shield tank cooler. The cool water from the component cooling water system or the chilled water system is circulated through the neutron shield tank cooler, cooling the heated neutron shield tank water. Only one neutron shield tank cooler is required to perform the required cooling; the other cooler is a spare and is isolated from the system by motor-operated valves. A surge tank accommodates thermal expansion of the neutron shield water. A level sensor on the surge tank sends a signal to the control room to indicate low system level. A solenoid-operated valve is actuated from the control room to replenish the system from the component cooling water system. The corrosion control tank is used for the manual addition of a corrosion inhibitor when the reactor is not operating.

9.4.3.5 Charging Pump Component Cooling Water System Description

A charging pump cooling water system for each reactor unit provides component cooling water for the charging pump mechanical seal heat exchangers, which cool the water circulating in the charging pump mechanical seal cooling loops.

Either of two 100%-capacity cooling water pumps circulates the component cooling water in the system. A surge tank accommodates thermal expansion of the component cooling water. A level sensor in the charging pump seal cooling surge tank automatically actuates a makeup valve to replenish the subsystem from the component cooling water system. The pH of the charging pump component cooling system is maintained between 8.0 and 10.5. To ensure that component cooling water is continually available to the mechanical seal coolers, one pump is in operation and the other pump is in standby. The standby pump is automatically actuated on low pump discharge pressure to supply cooling water in the event of failure of the operating pump. Two 100%-capacity charging pump intermediate seal coolers are provided to cool the component cooling water that is circulated to the mechanical seal coolers.

The installation of two full-capacity charging pump component cooling water pumps and two full-capacity charging pump intermediate seal coolers provides 100% redundancy for this component cooling water system. All components of the charging pump component cooling water system, including pumps, heat exchangers, and tanks are designed to Seismic Class I criteria.

The charging pump component cooling water pumps are connected to the emergency electrical bus to ensure that they will operate in the event of a loss of station power.

Regulatory Guide 1.97 requirements for post-accident monitoring of component cooling water system status are satisfied by flow and temperature measurement at the discharge of each charging pump component cooling water pump. Flow and temperature transmitters are environmentally and seismically qualified in accordance with IEEE 323-1974 and IEEE 344-1975 respectively. Control room display is provided through the NUREG 0696 multiplexing system.

9.4.4 Design Evaluation

9.4.4.1 **Component Cooling Water System Availability and Reliability**

The component cooling water system uses machinery and equipment of conventional and proven design. All components are specified to provide maximum economy, safety, and reliability.

The installation of four pumps and four heat exchangers for two reactor units provides 100% backup during normal operation of the two units. During cooldown of one reactor unit, there is 100% backup for it if the other unit is out of service, and 50% backup if the other unit is in normal operation. If only one pump is available for cooldown of a reactor unit, the cooldown time is extended without equipment damage or hazard to the public or operating personnel. Seismic Class I spray barriers protect the component cooling pump motors from water due to operation of fire protection equipment or other causes.

Most of the piping, valves, and instrumentation in the reactor containment are located outside the reactor primary shield wall and above the post-accident water level in the bottom of the containment. The exceptions are the lines for the neutron shield tank coolers and the primary shield penetration and water wall cooling coils; these lines can be secured by valves located outside of the primary shield wall. The equipment in the containment is protected against credible missiles and flooding during post-accident operations. Also, shielding is provided to allow limited maintenance and inspection during power operation.

Equipment not located in the containment may be inspected and maintained during power operation.

Portions of the system are of Class I design and designed to the codes stated in Section 9.4.1. The main piping loops and the loop for the fuel pool coolers are analyzed and designed to meet associated thermal stress requirements.

The following components are located inside the containment: the excess letdown heat exchanger, reactor coolant pump thermal barrier, oil coolers and motor stators, primary shield penetration and water wall coolers, neutron shield tank coolers, reactor shroud cooling coils, primary drain coolers, residual heat removal heat exchangers, containment air recirculation coolers, residual heat removal pump seal coolers, and pipe penetration cooling coils. Isolation of flow from the component cooling water system to the containment is described in Section 5.2.

The component cooling surge tank, which normally operates at atmospheric pressure, is equipped with a vent line connected into the process vent system. The tank vent line contains an automatic shutoff valve; this valve, normally open, closes automatically upon receiving a high-radiation signal from either of the two radiation monitors located on the discharge piping from the component cooling water heat exchangers, and can be manually closed from the control room. The high-radiation condition that caused the valve closure is indicated by an alarm.

An air-operated trip valve is installed in the outlet cooling water header from the reactor coolant pump thermal barriers, in the outlet cooling water line from the excess letdown heat exchanger, and in the outlet cooling water line from the primary drain cooler. A check valve is installed in the inlet cooling water header to the bearing oil coolers, stator coolers, and in the inlet cooling water line to the excess letdown heat exchanger. Two check valves are installed in the inlet cooling water line to the thermal barriers. In the event that a leak occurs in the thermal barrier cooling coil, an alarm annunciates in the control room and the high-pressure reactor coolant is safely contained by closing the appropriate stop valve. A high cooling water outlet flow signal from either the thermal barrier cooling header or the excess letdown heat exchanger automatically closes the associated isolation valves. The air-operated stop valves in the outlet cooling water header from the thermal barriers and in the reactor containment recirculation air cooler outlet lines leaving the reactor containment close on a high-high containment pressure signal. The main cooling water lines from the residual heat removal heat exchangers leaving the reactor containment close on a safety injection signal.

9.4.4.2 **Component Cooling Water System Leakage Provisions**

The component cooling water heat exchangers are located in the turbine building. Provisions are made to preclude the possible spread of radioactive contamination. These precautions include isolation of each heat exchanger by manual shutoff of the inlet and outlet component cooling water valves, treatment of any leakage and water samples from these heat exchangers as radioactive, and installation of the heat exchangers within a curbed area to preclude radioactive contamination of the turbine building floor. Any leakage is then returned to the liquid waste disposal system (Section 11.2.3) via the sump pump which services the curbed area. The component cooling heat exchanger curbed area consists of a trough covered by grating surrounding the heat exchangers to direct any leakage to the sump pump. Welded construction is used almost exclusively throughout the system to minimize possibility of leakage from pipes, valves, and fittings.

Small leakage inside the containment is not considered to be objectionable. Contamination could result from the following: side-to-side leakage in a heat exchanger in the chemical and volume control, residual heat removal, or sampling systems, or a leak in the thermal barrier of a reactor coolant pump. Leakage from the system is primarily detected by falling surge tank level. Temperature, level, and flow indicators in the control room may be used to detect leakage at certain points. Elsewhere, leaks can be located by inspection or isolation.

9.4.4.3 **Incident Control**

The piping mains have the following valves at the containment walls: shutoff valves outside containment and check valves inside containment in supply lines; trip and shutoff valves outside containment in return lines. The trip valves close upon receiving the containment isolation signal from safety injection. Piping for the reactor coolant pumps, reactor shroud cooling coils, and containment recirculation air coolers is valved in an identical manner; however, the valves close on a high-high containment pressure signal (Section 5.2.2).

A backup air bottle supply is provided to ensure the RHR component cooling outside containment isolation trip valves will fail closed in the event of a loss of primary air supply. The RCP thermal barrier component cooling inside and outside containment isolation trip valves have an air lockup valve which will maintain air pressure to hold the trip valve open on a loss of normal air supply, but will not prevent the trip valve from closing on a loss of air to the actuator or on any valid close signal.

During periods of warmer river water, chilled component cooling water supplies the cooling water to the reactor containment recirculation air coolers. The transfer, or supply and return between the two systems, is accomplished by the use of air-operated flow-diverting valves. These valves are operated remote manually by means of a switch mounted on the ventilation panel in the control room. In warmer weather, the containment air coolers remain on chilled component cooling water supply unless a minor incident occurs.

9.4.4.4 **Component Cooling Makeup Water**

Makeup for the component cooling water system is provided from the discharge of the main condensate pumps, which draw on the condenser hotwell. Operation of engineered safety features will not be affected by loss of makeup water to the component cooling water system if offsite power is lost, since the component cooling water system is not required for operation of engineered safety features.

During normal prolonged outages of both units (with station power available), a separate makeup pump supplies makeup water to the closed-loop component cooling and bearing cooling systems.

To maintain component cooling water to the fuel pool cooling system (Section 9.5), a component cooling water pump can also be operated from the emergency electrical bus during a complete loss of offsite power. The component cooling water system is closed, and leakage from this system will be at a very slow rate. In addition, the component cooling water surge tank is a source of reserve water, which must be exhausted before makeup to the component cooling water system is required. If the component cooling water system requires makeup before offsite power is restored, a portable pump can be connected to supply makeup.

9.4.4.5 Cooling Water Support for Other Systems

In the event of a single failure in the component cooling water system (e.g., at the discharge header), cooling water for the reactor coolant pumps, the excess letdown heat exchanger, the residual heat removal system, and the nonregenerative heat exchanger would be lost. The charging pumps would not be affected because they have been provided with a separate system.

In the unlikely event of a total loss of component cooling water, the operator would bring the reactor to a safe shutdown, or hot standby condition, with all reactor coolant pumps tripped and letdown flow discontinued, but with charging pumps operating to supply seal-water injection flow to the reactor coolant pump seals. This condition can be maintained until the pressurizer has been filled by the injected seal-water, thereby providing time for restoration of component cooling water.

Boron adjustments may be made, if required, by shifting the charging pumps' suction to the refueling water storage tank. Additional adjustments can be made by aligning the boric acid storage tanks directly to the suction of the charging pumps, thereby introducing concentrated boric acid to the reactor coolant system through the seal-water injection flow to the reactor coolant pump seals.

The charging pump component cooling water system cannot be totally disabled by a single passive failure. The system has been designed with cross-connect piping and sufficient valves so that any single passive failure can be isolated, which will allow the system to continue to operate and provide cooling water to at least two charging pumps (Reference Drawing 9).

The isolation of a single passive failure and arrangement of the operable portion of the system to continue to provide the cooling water must be performed manually by the plant operators. In addition, the standby charging pump may have to be placed in operation, since the isolation of the single passive failure might prevent cooling water from reaching the operating charging pumps. The complete system is expected to be accessible during an accident; however, if the course of an accident were to result in gross fuel failure, the local area radiological dose rates may substantially restrict auxiliary building access. For this situation, the continued operation of the charging pump component cooling water system is not essential for the proper operation of the charging pumps.

9.4.4.6 Component Cooling Water System Malfunction Analysis

A failure analysis of equipment, components, and system interconnections is presented in Tables 9.4-8 and 9.4-9.

9.4.4.7 Component Cooling Cleanup

In the event the Component Cooling Water System becomes contaminated through leakage at interface points with radioactive systems, a means for removing the contaminants and reducing radiation levels is provided. Cleanup is provided from the Chilled Component Cooling Water

Subsystem which recycles a portion of the chilled water flow through one or both of the Boron Cleanup Ion Exchangers (1-BR-I-2A & B). Once through the ion exchanger(s), the processed component cooling water is returned to the Chilled Component Cooling Water pumps' suction header. Flow through the cleanup piping is monitored and maintained by local flow indication and a manual throttling valve. All piping and valves conform to Section 9.4.2.

9.4.5 Tests and Inspections

The component cooling system is subject to the applicable inservice inspection and inservice testing requirements of the ASME Code, as required by 10 CFR 50 (Code of Federal Regulations, Title 10, Part 50). Following installation of spare parts or piping modifications, visual inspections are conducted to confirm normal operation of the system. Routine pre-startup inspections are performed, along with periodic observation during operation.

9.4.6 Minimum Operating Conditions

Minimum operating conditions for the cooling water systems, if any, are given in the Technical Specifications.

CONSEQUENCES OF COMPONENT COOLING WATER SYSTEM MALFUNCTIONS

Components	Malfunction	Comments and Consequences
1. Component cooling water pumps	Pump casing ruptures	The casing is designed for 180°F temperature; design pressure is 130 psig and maximum test pressure is 200 psig. These conditions exceed those that could occur during any operating conditions. The casings are made from cast iron (ASTM A48); this metal has corrosion-erosion resistance and produces sound casings. Corrugated metal expansion joints are installed close to the pump suctions and discharges. These joints isolate the pumps from forces and moments originating in the connected piping; in addition, the pumps are designed as Class I. Pumps are missile-protected and may be inspected at any time. Rupture by missiles is not considered credible. A relief valve is installed on the line supplying makeup to the system, so that makeup source pressure cannot be applied to the casings. All units can be isolated by valves, and the standby pump can carry full load.
2. Component cooling water pumps	Original pump fails to start	Standby pump for that reactor unit can be used.
3. Component cooling water pumps	Standby pump fails to start	Standby pump for other reactor unit can be started manually in control room, after manually repositioning valves at the pumps.
4. Component cooling water pumps	Manual butterfly valve at a pump suction closed	Prevented by pre-startup and operational checks. During normal operation, each pump is checked periodically, together with its valves.
5. Component cooling water pumps	Check valve at a pump discharge sticks closed	Valve is checked periodically during normal operation.
6. Check valves in supply mains at inlet penetrations	Sticks closed	One main is flowing at all times. The valves have split disks loaded by light springs, and sticking closed is not considered credible.
7. Component cooling water heat exchangers	Tube or shell ruptures	Because of the low system operating pressure and temperature, and Class I design, rupture is considered unlikely. Each unit can be isolated and can carry full load. The standby unit intended for one reactor unit may be used for the other unit by repositioning valves. The exchangers are protected from missiles.

Table 9.4-8 (CONTINUED)
CONSEQUENCES OF COMPONENT COOLING WATER SYSTEM MALFUNCTIONS

Components	Malfunction	Comments and Consequences
8. Component cooling water heat exchanger vent or drain valve	Left open	Prevented by pre-startup and operational checks. On a unit in service, this condition would be noted by operating personnel during routine observation. On activation of a standby unit, the condition would be observed by personnel engaged in manually positioning valves at the exchanger.

Table 9.4-9
COMPONENT COOLING WATER RELIANCE ON INTERCONNECTED SYSTEMS

Interconnected System	Purpose of Interconnection	Consequences If Interconnection Is Lost
Main condensate (in turbine room)	Makeup for surge tank	The makeup line is double-connected to both main turbine generator units. A tie-in from the bearing cooling makeup pump also exists. Since it is unlikely that both units will be out of service simultaneously along with bearing cooling make-up, the source has a high degree of redundancy. If a loss of offsite power has occurred and makeup is required, a portable pump can be connected to fulfill this function.
Boron recovery	Signals to automatic control valves in component cooling water system piping	None; use of equipment is intermittent.
Sampling	Conduct sample to central sampling station	None; samples at all important points may be collected at local sampling connections in the piping.
Vent and drain	Disposal of equipment vents and piping drains	Since lines are open, without valves or other devices, loss of the interconnections is not considered credible.
Containment isolation	Signals to trip valves for isolation purposes, under accident conditions	Valves fail safe (to closed position) upon loss of signal.

9.5 FUEL POOL COOLING SYSTEM

The fuel pool cooling system shown in Figure 9.5-1 and Reference Drawing 1 pumps borated water from the spent-fuel pool through heat exchangers and back to the pool to maintain fuel pool water temperature. Additional pumps are provided for purification through an ion exchanger and filter and for surface clarification. A review of the effects of the power uprate to a core power of 2589.3 MWt was conducted and the fuel pool cooling system was found to be adequate.

9.5.1 Design Bases

The Fuel Pool Cooling System has the capability to:

1. Maintain the temperature of the fuel pool water below 140°F during a normal core offload condition commencing 100 hours after shutdown. A normal core offload condition is a planned offload of up to a full core. The most limiting condition for normal core offload is a full core offload following refueling of the other unit.
2. Maintain the temperature of the fuel pool water below 170°F during an abnormal core offload condition commencing 100 hours after shutdown. An abnormal core offload is an unplanned offload of up to a full core. The most limiting condition for an abnormal core offload is an unplanned full core offload following back-to-back refuelings of both units.

The fuel pool cooling system is designed as a Seismic Class I system and consists of two complete cooling loops, each of which has a design water flow rate of 4200 gpm. Each loop can remove about 34×10^6 Btu/hr while maintaining the fuel pool outlet water temperature at 170°F, assuming that the component cooling water system, which is the heat sink, is at a temperature of 105°F.

The fuel pool water temperature is continuously indicated in the control room, and an alarm in the control room alerts the operator prior to this temperature reaching 140°F. There are also indicators in the control room to inform the operator when either or both of the fuel pool cooling pumps are operating.

The fuel pool cooling system is also designed to maintain the clarity of the refueling water to permit observation of fuel element placement during refueling operations. The system also maintains a minimum pool water level of 41 ft. 2 in., which will provide a minimum water shield of 20 feet in depth (Section 11.3).

In addition, wide range level instrumentation provides indication of spent fuel pit level in the cable spreading room. The instrumentation measures spent fuel pit water level from 7 inches above the top of the fuel racks to 10 inches above normal water level.

The design data for the fuel pool cooling system components are given in Table 9.5-1.

9.5.2 System Description

The fuel pool cooling system has two shell and tube coolers, two circulating pumps (4200 gpm), and two full-size purification pumps (150 gpm), all located in the fuel building. The coolers and pumps are arranged for cross-connected operation. The coolers are cooled with component cooling water.

The purification pumps take suction at the outlet of the fuel pool coolers and pump water to a 45-ft^3 ion exchanger and filter located in the auxiliary building. The ion exchanger or the filter can be bypassed if not required. The water returns to the fuel pool at the far end opposite the suction point to ensure mixing. The surface of the water is kept clear of floating matter by two skimmers connected to two skimmer pumps (10 gpm). The pumps discharge to the skimmer filters, after which the water returns to the far end of the pool.

The purification system is operated independently of the cooling system, and remains in operation essentially continuously to maintain a clean, clear pool. The maximum allowable differential pressure across the purification filter is 25 psid. The maximum allowable differential pressure across the demineralizer (ion exchanger) is 25 psid. If the delta P exceeds the allowable value, the filter is replaced or the demineralizer resin is replenished.

The lowest level of pipe penetration through the fuel pool structure is 20 feet above the top of stored fuel elements.

9.5.2.1 **Components**

All piping, valves, and components of the fuel pool cooling system that come in contact with the fuel pool water are austenitic stainless steel.

9.5.3 Design Evaluation

9.5.3.1 **Availability and Reliability**

Two circulating pumps and two fuel pool coolers are provided to ensure system availability for meeting cooling requirements using the appropriate alignments of required pumps and coolers. For most normal conditions, the system capacity is sufficient to maintain pool temperatures below 140°F with one pump and one cooler. During refueling operations, flexibility exists to add the other cooler or the other cooling loop, as required to meet the existing heat load while maintaining the pool temperatures consistent with fuel handling operations. The design condition presenting the most limiting capacity for the system is the back-to-back refueling case. In this case, one pump and two coolers maintain the pool below 140°F, with restrictions on allowable Component Cooling water temperature (Section 9.5.3.4), leaving the standby pump to be placed in operation if the operating pump should malfunction. Sufficient cooling water is available to increase the system heat rejection capacity and maintain the pool below 170°F at the abnormal heat load with one pump and one cooler, if required. Redundant piping is provided from the fuel pool through the pumps and coolers to the main return header located above the pool water level.

9.5.3.2 **Purification of Water**

The 150-gpm filtering rate of the purification system results in a refueling water cleanup half-life of 2 days, and maintains suspended solids at a low concentration for optical clarity. The skimmer filter removes particles that fall and float on the water surface. This reduces the amount of impurities that enter the water and also reduces surface refraction.

The fuel pool purification system removes both radioactive and nonradioactive particulates from the pool water. The purity of water is normally maintained between 0.0 to 0.3 ppm, with a maximum particulate concentration of about 0.4 ppm. This purity level provides sufficient optical clarity for refueling operations. Based on samples taken since station start-up, the major isotopes that have been detected in the pool water, with approximate concentrations, are listed in Table 9.5-2.

Crud buildup along the sides of the fuel pool has not significantly affected the radiation levels at the edge of the pool. Crud buildup on the sides of the pool is removed with hydrogen peroxide (H_2O_2).

9.5.3.3 **Fuel Pool Water Leakage Control**

Slow leakage of water from any point in the piping or components of the cooling or purification systems can be stopped by valves mounted close to the pool penetrations. An alarm is provided on the pool to sound at a level loss of approximately 0.5 foot; this provides ample time to isolate the leaking equipment. Further, a large piping system leak can reduce the water level in the pool to only 4 feet below normal, since at this elevation the water level is below the pipe penetrations in the pool wall. This minimum water level ensures at least 20 feet of water over stored fuel and provides ample shielding and cooling.

9.5.3.4 **Heat Load**

At Surry a single spent fuel pool provides storage of irradiated fuel assemblies for both units. For normal refueling operations, a full core offload of one unit following a refueling of the other unit represents the most limiting spent fuel pool heat load. For this back-to-back refueling condition the assumption is made that as soon as one unit has completed refueling, the second unit begins its refueling outage. This results in the most recently discharged batch of fuel prior to the current refueling having a decay time of 28 days.

The offload of the core for the current refueling is assumed to begin at 100 hours after shutdown and finish at 130 hours after shutdown. The 30 hours assumed for off-loading of the core is conservative with respect to actual practice.

The heat load from the irradiated fuel in the pool prior to these refuelings is accounted for through a cumulative decay heat load determined from successive refueling discharges decayed for 1.5 to 10.5 years. At this time the pool would be full except for a full core discharge capability (157 storage cells).

The back-to-back refueling scenario results in a heat load on the spent fuel pool cooling system of 37.5×10^6 Btu/hr. At this heat load the spent fuel pool cooling system can maintain the pool temperature below 140°F with one pump and two coolers in operation and the component cooling water supply temperature at a maximum of 97°F.

The most limiting spent fuel pool heat load for abnormal core offload is determined by assuming an unscheduled shutdown of the first unit which requires a full core offload after the second unit has gone back on-line following back-to-back refuelings. The heat load is conservatively determined assuming the most recently discharged fuel batch has a decay time of 28 days, the next most recently discharged batch has a decay time of 56 days, and the core being off-loaded to have operated for a sufficient length of time to produce maximum decay heat prior to being transferred to the pool by 130 hours after shutdown of the unit. The heat load from the irradiated fuel in the pool prior to the refuelings is accounted for through a cumulative decay heat load determined from successive refueling discharges decayed for 1.5 to 10.5 years. The abnormal condition also assumes that the unscheduled full core offload completely fills the pool. This results in a heat load of 40.8×10^6 Btu/hr placed on the spent fuel pool cooling system. The capability of the spent fuel pool cooling system is more than sufficient to maintain the pool temperature below 170°F with the component cooling water supply temperature at 105°F through the use of one pump and two coolers.

The design flow rate of the component cooling water through the shell side of each fuel pool heat exchanger is 1322 gpm. The actual flow rate is controlled based on cooling water temperature and the fuel pool water temperature. The component cooling water system is discussed in Section 9.4.

9.5.3.5 **Malfunction Analysis**

The consequences of the malfunction of various fuel pool cooling system components are described by Table 9.5-3.

9.5.4 Tests and Inspection

The fuel pool level and temperature instrumentation are calibrated on a periodic basis. Periodic visual inspections and preventive maintenance are conducted on all system components. Periodic sampling of fuel pool water is conducted.

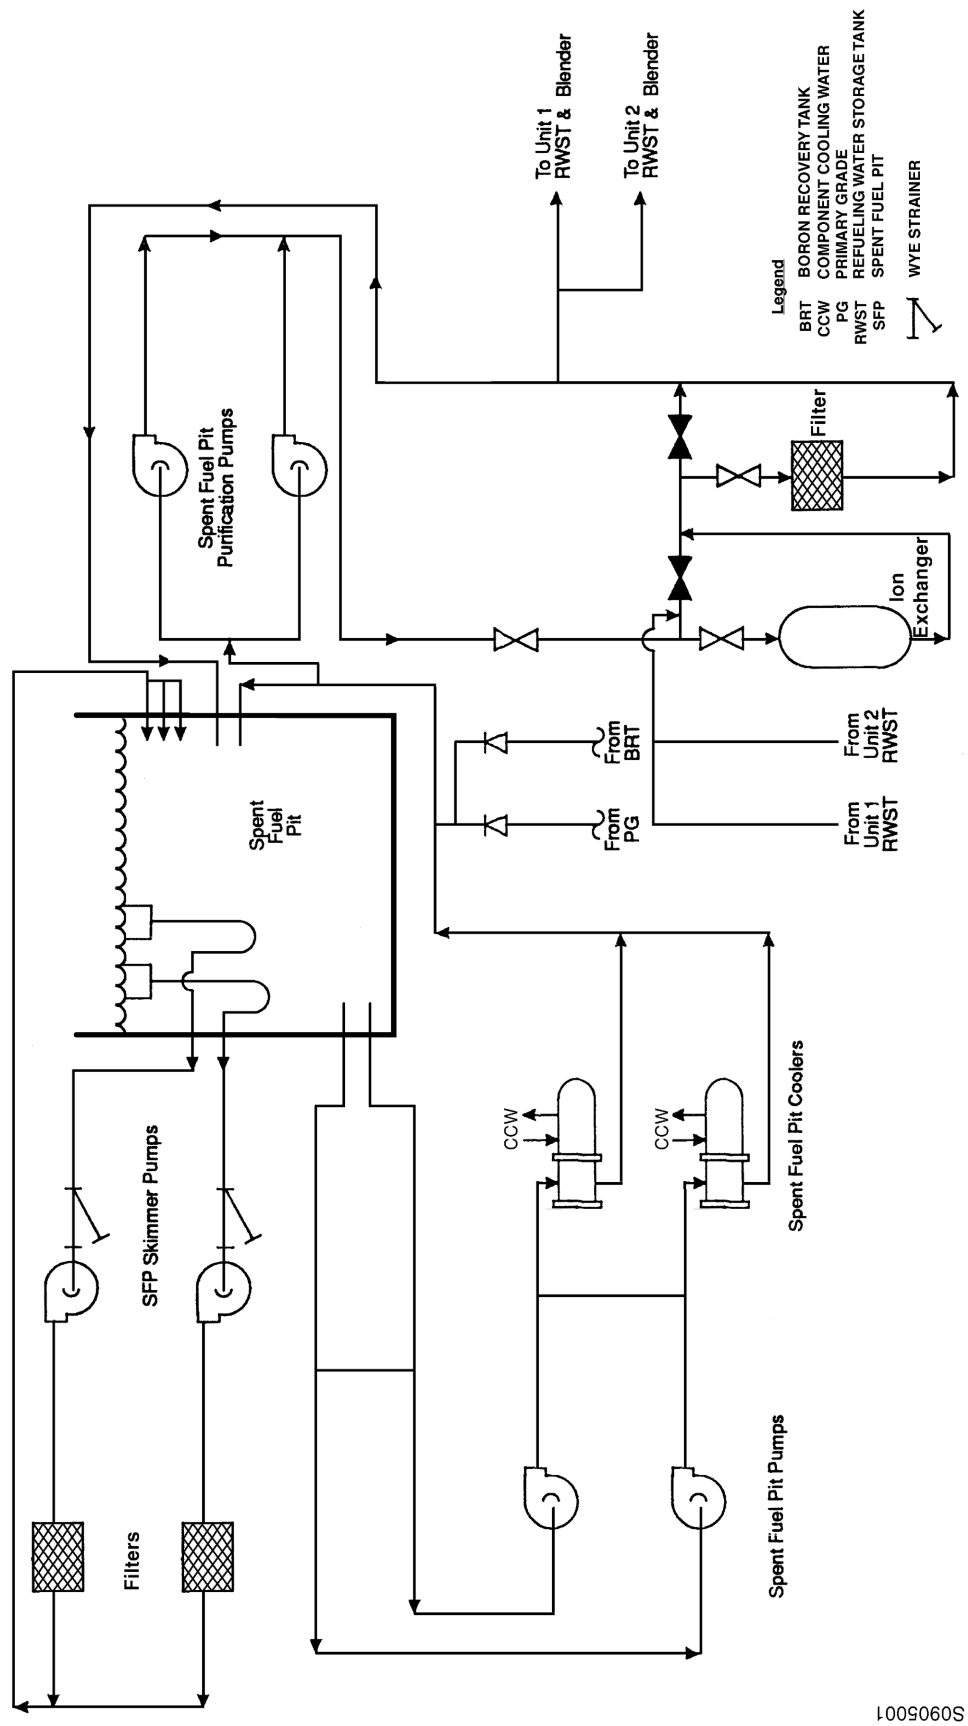
Table 9.5-3
MALFUNCTION ANALYSIS

Component	Malfunction	Comments and Consequences
Spent-fuel pool pumps	Pump fails to start, or fails during operation	The redundant cooling loop would remain operational. The operator in the control room would be alerted of the failure by pump status light and/or temperature alarm and the redundant pump would be manually started and placed in service. In the event the operating pump stops, over 1 hour is available before the pool water heats up 10°F; therefore, a number of hours would be available to start the spare pump. The failed pump would be repaired and returned to service. Furthermore, normal power to both pumps is supplied from station emergency buses, alternate power is supplied from the B bus and back-up power is supplied from the opposite emergency bus.
Fuel pool coolers	Loss of function	Although a passive failure of this type would not cause a loss of function, e.g., leaks might occur, the redundant cooler could be placed in service while the failed cooler is repaired. As with the pump, sufficient time is available to manually realign the coolers.
Pumps, coolers, piping, valves, and other components	Leaks of any size	A slow leak (less than 100 gpm) will permit over 2 hours to isolate the leak before loss of 1 foot of water. A large leak can only reduce water to the lowest pool penetration, which is at a level to ensure adequate shielding.

Figure 9.5-1
FUEL POOL COOLING SYSTEM



9.6 SAMPLING SYSTEM

The station sampling systems provide for obtaining samples from primary and secondary plant systems, as well as for obtaining post-accident samples should they be required. Chemistry sampling of various process fluids and gases ensures that (1) fuel element failures are promptly detected, (2) plant systems are functioning properly, (3) corrosion is being adequately controlled, and (4) samples are available for determining certain post-accident system conditions, if required. The primary and secondary plants are sampled routinely. Data from the sample systems throughout the plant are relied upon for daily operations, as well as to provide assessment information in the event of a fuel element failure of a design basis accident.

9.6.1 Design Bases

9.6.1.1 Sampling System—Routine Operation

Process fluids and gases are representatively sampled for testing to obtain data from which performance of the station, equipment, and systems may be determined.

Routine samples of process fluids and gases associated with both the primary and secondary systems are either taken periodically or are continuously monitored. Two general types of samples are obtained by the sampling system: high-temperature samples (greater than 150°F) such as the reactor coolant system samples, and low-temperature samples (less than or equal to 150°F) such as the high-level waste drain tank samples. Various samples taken are listed in Table 9.6-1.

Primary samples are analyzed to determine the amount of radioactivity in the reactor coolant. If the radioactivity level is high, a reactor coolant sample is analyzed for iodine and other isotopes and counted as an indication of defects in fuel cladding. The frequency of sampling for radiochemical analysis of the reactor coolant is given in the Technical Specifications.

9.6.1.2 High Radiation Sampling System—Post-Accident Operation

The High Radiation Sampling System (HRSS) is no longer required for post accident sampling and has been removed from the Surry Power Station Technical Specifications but is maintained to provide contingency measures in accordance with Reference 1. Surry Power Station contingency measures are being provided by maintaining portions of the HRSS to facilitate acquiring diluted and non-diluted samples of the RCS, containment sump, and containment atmosphere. These samples can then be analyzed on site or sent off site for analysis. Station procedures control the sampling and analysis evolutions. The in-line analysis capability of the HRSS is no longer required for timely analysis of post-accident samples and will not be maintained. The system is designed to obtain and analyze representative samples of reactor coolant, the containment atmosphere, and the containment sump after an accident. Sampling and analysis of reactor coolant and containment atmosphere samples can provide information needed to assess and control the course of recovery from an accident. The system provides the ability to obtain grab samples from each reactor coolant hot leg, each reactor coolant cold leg, the residual heat removal system, the chemical and volume control system mixed-bed demineralizer effluent, containment sump, and the containment atmosphere. The system has the capability to cool and depressurize samples at high temperature and high pressure to allow grab sampling and in-line chemical analysis; however, in-line chemical analysis is no longer performed.

The system also provides the means to remotely dilute reactor coolant and containment sump samples by a factor of 1000 to reduce the personnel exposure levels that would otherwise be associated with post-accident sampling. This initial dilution also reduces the exposure that would be associated with subsequent manual dilutions, if required.

The diluted and undiluted liquid grab samples and the containment air samples are put into specially designed transfer carts with integral shielding. Placement of the samples inside the shields can be accomplished with minimal operator exposure because the cart is integrally designed to nest within the sample panel. The transfer carts facilitate movement to designated areas for isotopic or chemical analysis with low operator exposure.

The sampling system has the ability to strip reactor coolant of dissolved gases for grab sampling and analysis.

An in-line chemical analysis panel is no longer used but was designed to facilitate remote measurement of important chemical parameters with a minimum of manual action or exposure to the operator. This chemical analysis panel has the capability to measure primary coolant pH, boron, oxygen concentration, and hydrogen concentration, as well as containment hydrogen concentration. The capability for in-line chloride measurement utilizing a portable ion chromatograph is also provided. Each parameter (except chloride) is either indicated or recorded on a remote-control panel located in the cable spreading room.

The high radiation sampling system panels are located within existing space in the auxiliary building. The reactor coolant is drawn from sample system lines outside of containment, upstream of the normal sample system coolers.

Controls are provided to prevent post-accident samples from being inadvertently introduced to the normal sample room.

Sample liquid resulting from recirculation, purging, and drainage can be routed to the high radiation sampling system waste tank, from which the fluid can be pumped or displaced with nitrogen back to the containment sump. Connections are provided to recirculate, purge, and drain non-accident liquid samples via normal sample system flow paths for purposes of operator training and periodic equipment testing.

The containment atmosphere sample panel has the capability to take suction from within the hydrogen monitor system. Motive force for the containment atmosphere sample panel is provided by an integral nitrogen eductor. The discharge of the containment atmosphere panel is routed back to the containment via the high radiation sampling system waste tank and evacuating compressor.

9.6.2 Description

9.6.2.1 Sampling System—Routine Operation

The sample lines coming from within the containment contain high-temperature samples, with the exception of the pressurizer relief tank sample. Where two or more samples join into a common header (i.e., the primary coolant cold-leg samples), each individual sampling line has a solenoid-operated valve in the line that can be remotely operated from a control board in the auxiliary building sampling room. The primary coolant hot-leg and cold-leg samples flow through delay coils before penetrating the containment. These delay coils permit sufficient decay of nitrogen-16 so that these samples can be handled in the sampling room.

Sample lines penetrating the containment have two automatically operated valves in the line, one just inside and one just outside the containment. These trip valves close on receipt of a safety injection signal. Samples may also be obtained from interfacing systems (e.g., gaseous waste) which have containment isolation valves that may be operated under administrative control in accordance with Technical Specifications. The high-temperature samples pass through sample coolers located in the auxiliary building sampling room. These coolers cool the high-temperature samples to a temperature low enough for safe handling. Sample flows leaving the cooler are manually throttled and can be directed to a purge line or to the sampling sink. The pressurizer vapor space samples, in addition, pass through capillary tubes that limit the flow of steam.

The sampling lines from sampling points outside the containment but inside the auxiliary building also discharge to the auxiliary building sampling sink. Sample lines from sampling points in the turbine building discharge to one of the turbine building sample sinks. The high-temperature samples also pass through sample coolers and are manually throttled. In general, samples can either be directed to a purge line or to the sampling sink. The main steam samples also pass through capillary tubes.

The purge flows of the various samples are discharged to the volume control tank, the vent and drain system, or elsewhere, as appropriate. The radioactive samples in the auxiliary building sampling room discharge into hooded sampling sinks.

The on-line chemistry monitoring system (OLCMS) provides continuous monitoring from four main sample locations in the secondary system (feedwater, steam generator blowdown, main steam and condensate) and from two supplemental sample locations (condensate make-up and moisture separator reheater/heater drains). Samples are cooled by primary coolers which use bearing cooling water. Samples flow to their respective conditioning and monitoring panels which are located in the Units 1 and 2 turbine building basements. Output signals from the sample panel monitors and analyzers go to an I/O data controller for input to an onsite computer. Selected signals go to recorders in the control room.

Radiation monitors in the steam generator blowdown sample line detect primary-to-secondary leaks in the steam generators. Monitoring of the condensate pump discharge is used to detect tube leaks in the condensers.

9.6.2.2 **High Radiation Sampling System—Post-Accident Operation**

Representative post-accident liquid and gas samples from either reactor unit can be routed to one common high radiation sample system. Samples can be received from the sources listed in Table 9.6-2. The tie-in locations for all reactor coolant samples are outside the containment, upstream of the sample system coolers. Since the reactor coolant sample lines are combined into common headers inside containment, one common hot-leg sample and one common cold-leg sample for each unit is routed to the high radiation sampling system liquid sample panel.

The motive force for all reactor coolant samples is primary system pressure. A containment sump pump, appropriate for its service duty, is provided to obtain containment sump samples. The motive force for a containment atmosphere sample is provided by a nitrogen eductor contained within the containment air sample panel.

The high radiation sampling system is designed so that incoming liquid sample lines can be purged to ensure that the grab samples are representative. The line volumes will be purged several times during this operation. During post-accident conditions, primary system liquid samples are purged directly to the high radiation sampling system waste tank. The associated waste pumps can then transfer the accumulated liquid waste to the appropriate containment sump. For system test and operator training, liquid samples can be recirculated via the normal sample pathways to the appropriate volume control tank or high-level drain tank purge headers.

The high radiation sampling system is comprised of five subsystems.

These are:

1. Liquid sample panel and coolers.
2. Containment atmosphere sample panel.
3. Chemical analysis panel (use of this subsystem has been discontinued).
4. Waste tank and pump.
5. Process control panel.

9.6.2.2.1 Liquid Sample Panel and Coolers

The liquid sample panel and coolers perform multiple functions:

1. Sample cooling to about 135°F during the recirculation mode and about 120°F during the grab sample mode.
2. Sample depressurization.

3. Liquid degassing to obtain a representative dissolved gas sample.
4. Liquid degassing to the extent necessary to allow in-line chemical analysis downstream in the chemical analysis panel (use of this subsystem has been discontinued).
5. Provide undiluted liquid grab sample inside a shielded transfer cask.
6. Provide diluted (1000 to 1) liquid grab sample inside a shielded transfer cask.
7. Provide diluted dissolved gas grab sample inside a shielded syringe.
8. Provide integral shielding to minimize operator exposure while working in front of the panel.
9. Provide a ventilated cabinet, held below atmospheric pressure, to contain potential subsystem leakage. Cabinet ventilation is connected to the auxiliary building HVAC system.

The liquid sample subsystem is divided into three modules, based upon the pressure of the incoming liquid. A reactor coolant module handles hot-leg, cold-leg, and residual heat removal system samples. A demineralizer module handles the chemical volume and control system mixed-bed demineralizer effluent samples. A radwaste module handles the containment sump samples.

The liquid sample subsystem contains provisions for flushing with station primary-grade water. The flush water is routed to the high radiation sampling system waste tank.

9.6.2.2.2 Containment Air Sample Panel

The containment air sample panel performs the following functions:

1. Provides the motive force to obtain a representative grab sample of containment atmosphere. A nitrogen eductor is provided that is capable of operation when the containment pressure is either slightly negative or at the maximum post-accident pressure.
2. Provides three shielded sample bombs and a gas partitioner device to obtain containment atmosphere samples on a preprogrammed timer sequence. The gas partitioner device is independently controlled and separates the containment air sample for particulate, iodine, and noble gas determination.
3. Provides a motive force by a nitrogen eductor to deliver containment air sample flow to the chemical analysis panel for atmospheric analysis to determine the hydrogen concentration.
4. Provides a means to purge and backflush containment air sample lines back to the affected containment.
5. Provides an integrally shielded panel front to minimize post-accident operator dose rates.
6. Provides a ventilated cabinet held below atmospheric pressure to contain potential subsystem leakage. Cabinet ventilation is connected to the auxiliary building HVAC system.

9.6.2.2.3 Chemical Analysis Panel

The in-line chemical analysis panel is no longer required for post accident sampling. The chemical analysis panel is no longer used but was designed to perform the following functions:

1. Accept a preconditioned, cooled, depressurized and degassed, liquid sample from the liquid sample subsystem for post-accident chemical analysis for boron, pH, dissolved hydrogen and dissolved oxygen, and hydrogen concentration in post-accident containment atmosphere samples.
2. Provide remote readout of chemical analysis panel parameters on the remote process control panel of the high radiation sampling system.
3. Provide an integrally shielded panel front to minimize post-accident operator dose rates.
4. Provide a ventilated cabinet held below atmospheric pressure to contain potential subsystem leakage. Cabinet ventilation is connected to the auxiliary building HVAC system.
5. Provide the necessary connections to connect a portable ion chromatograph for in-line chloride analysis of the reactor coolant.

Table 9.6-3 lists the types of instrumentation to be used for determination of post-accident chemical parameters; however, in-line chemical analysis is no longer performed. Instrumentation has been selected based upon the following criteria:

1. The ability to measure accurately the full anticipated range of parameters.
2. The ability to withstand high radiation fields.
3. The ability to reproduce results after calibration.
4. The ability to measure chemical parameters with small sample volumes.

The chemical analysis panel is designed with built-in instrument calibration equipment. Instrument calibration will be performed by station personnel on a periodic basis to maintain a ready condition and to minimize instrument drift.

9.6.2.2.4 Waste Tank, Pumps, and Evacuating Compressor

The waste tank and pumps have the ability to collect and return system purge and flush liquids to either containment or to the plant high level waste drain tank. The liquid sample purge return lines to the containment are routed to the containment sump. The waste tank is sized to hold the volume of liquid residue generated by the acquisition of two post-accident samples.

Two 100%-capacity waste tank pumps are provided to pump the tank contents back to the containment. A nitrogen purge connection is provided to force the contents of the tank back to the containment in the event of pump failure, and also to maintain a nitrogen blanket in the waste tank to preclude accumulation of hydrogen.

During post-accident conditions, the waste tank can be held under a slight vacuum by an evacuating compressor, and can be nitrogen-blanketed. An evacuating compressor is provided to maintain the tank under negative pressure. The evacuating compressor also discharges containment air samples which enters the waste tank from the containment air sample panel. A bleed and feed system will control the evacuating compressor and nitrogen purge flow. The evacuating compressor discharge can be directed to either containment.

Tables 9.6-4, 9.6-5, and 9.6-6 provide design data for the waste tank, the waste tank pumps, and the evacuating compressor, respectively.

9.6.2.2.5 Process Control Panel

The process control panel performs the following functions:

1. Provides remote location in the service building in a low dose rate area for operation of the high radiation sampling system remotely operated valves, with the exception of the routine sample system containment isolation valves, which are operated from the control room.
2. Provides space for chemical analysis panel instrument indicators and recorders.

The process control panel contains a complete system graphic display for the other four subsystems. A communication system is provided between the sample panel area in the auxiliary building, the process control panel in the service building, and the control room.

9.6.2.2.6 Instrumentation Application

The chemical analysis panel measured parameters are no longer used but were designed to indicate and record on the remote process control panel. Parameters measured were boron concentration, pH, dissolved oxygen, chloride, dissolved hydrogen, and containment air hydrogen concentration; however, in-line chemical analysis is no longer performed. Local flow and pressure indication are on the face of the liquid sample, containment atmosphere, and chemical analysis panels to enable the operator to manually align and adjust system flows.

The process control panel permits remote operation of the high radiation sampling system automatic valves, including those routine containment sample system valves, which are normally operated from a panel in the routine sample room.

The maximum postulated activity concentration of post-accident samples is far in excess of the capabilities of normal counting equipment and geometries. Thus, sample dilution will be required prior to analysis. The liquid sample subsystem provides a 1000 to 1 dilution of reactor coolant samples. However, depending upon the accident condition, additional final dilution can be accomplished in a shielded fume hood. The diluted sample can then be analyzed by existing laboratory counting equipment.

The liquid sample subsystem can provide a shielded syringe sample of diluted reactor coolant gases that can also be further diluted, if necessary, in the adjacent shielded fume hood. These samples can then be analyzed in existing laboratory counting equipment.

The containment atmosphere samples are collected in 5 cc shielded sample casks in the containment atmosphere sample panel. Samples of 1 ml will be isotopically analyzed by a Ge detector, which measures through a 0.25-inch aperture in the sample vessel lead shield. The shield apertures are designed to allow measurement in several orientations. Halides and noble gases can be analyzed together. Successive analyses of containment air samples collected on a known time sequence enable the operator to determine the extent of the accident and the effectiveness of the containment spray system.

A particulate, iodine, and gas sample is connected to and operates in conjunction with the containment air sample panel. This device separates the containment air into components for analysis in the laboratory.

Design conditions of the various sampling panels are given by Table 9.6-7.

9.6.3 Design Evaluation

9.6.3.1 **Sampling System—Routine Operation**

If a critical sampling line becomes nonfunctional due to some malfunction, there is at least one alternate path that can be used to obtain a similar periodic sample, or for continuous monitoring. If one of the steam generator blowdown radiation monitors malfunctions, a second similar radiation monitor in each unit can be used. If one of the steam generator blowdown sampling lines becomes inoperative, the condenser air ejector radiation monitor provides indication of a steam generator primary-to-secondary-side leak.

9.6.3.2 **High Radiation Sampling System—Post-Accident Operation**

The high radiation sampling system equipment is designated Quality Group D, non-seismic, as defined in Regulatory Guide 1.26. Seismic failure will not damage station safety-related equipment or the building structures. Electrical power supply is from the station service buses. In the event of a loss of normal power, a manual selector switch is used to provide power from the opposite unit.

The air-operated trip valves in the residual heat removal sample lines and the reactor coolant system hot-leg and cold-leg sample lines have been replaced with direct-acting solenoid valves. This ensures that the valves can be reopened to draw the sample, under the single-failure criterion after an accident. The air-operated valves that are required to operate in order to obtain the reactor coolant sample are furnished with dedicated instrument air accumulators so that the ability to open the valves remotely will be available in the event that the station instrument air system is temporarily nonfunctional. System interlocks are provided throughout to perform the following basic functions:

1. To ensure that samples obtained after an accident can only be returned to the affected containment. A similar philosophy is applied to system purge and flush fluids.
2. To ensure that post-accident sample fluid cannot inadvertently enter the routine sample system.

Permanent system connections to the station nitrogen system are provided, along with a nitrogen bottle backup system.

Redundant waste tank pumps are provided to pump post-accident samples back to the affected containment. Nitrogen can be used to empty the waste tank in the event of dual pump failure or loss of electric power.

System flush water is obtained from the station's primary grade water system. Primary-grade water connections to the system are quick-disconnect type. After each use of flush water, the system will be disconnected to minimize the possibility of primary-grade water contamination by post-accident samples. Each sample acquisition will be followed by a flush to keep background radiation levels to a minimum, in accordance with the ALARA concept.

A shielding analysis has been performed to ensure that operator exposure while obtaining and analyzing a post-accident sample will be less than 5 rem whole-body and 75 rem to the extremities. Operator exposure will be accumulated while entering and exiting the sample panel area, operating sample panel manual valves, positioning the grab sample into the shielded transfer carts, and performing additional manual sample dilutions, if required, for isotopic analysis. The major sources of operator exposure are from:

1. General auxiliary building background from components not associated with the high radiation sampling system. Operator exposure is limited by the stay time associated with sample panel manual operations, and by selecting entrance and exit routes to the sample room via the lowest dose rate paths.
2. Direct radiation from sample lines that are routed behind the shielded sample and analysis panels. Operator exposure is limited by the integral shielding located in the front of each of the system sample analysis panels. This shielding consists of up to 6 inches of lead shot poured into panel front sections.
3. Backscatter from the walls and roof behind and above the shielded sample and analysis panels. Operator exposure is limited by positioning the panel in an orientation such that the distance from the back of the panel to the nearest wall is maximized to the greatest extent practicable. A shadow shield is provided above the normal operator area.

9.6.4 Tests and Inspections

9.6.4.1 **Sampling System—Routine Operation**

Most components are used regularly during power operation, cooldown, and/or shutdown, thus providing assurance of the availability and performance of the system. The continuous monitors are periodically tested, calibrated, and checked to ensure proper instrument response and operation of alarm functions.

9.6.4.2 **High Radiation Sampling System—Post-Accident Operation**

The high radiation sampling system is no longer required for post accident sampling and the system has been removed from Surry Power Station Technical Specifications. However, the system remains in place and available, and portions of the system will be maintained to provide contingency sampling measures. Station personnel are trained on the system to ensure familiarity with and to test the functions and operations of the system that are required for use as contingency sampling measures. The chemical analysis instrumentation is no longer used, therefore calibration and testing of this portion of the system is no longer required.

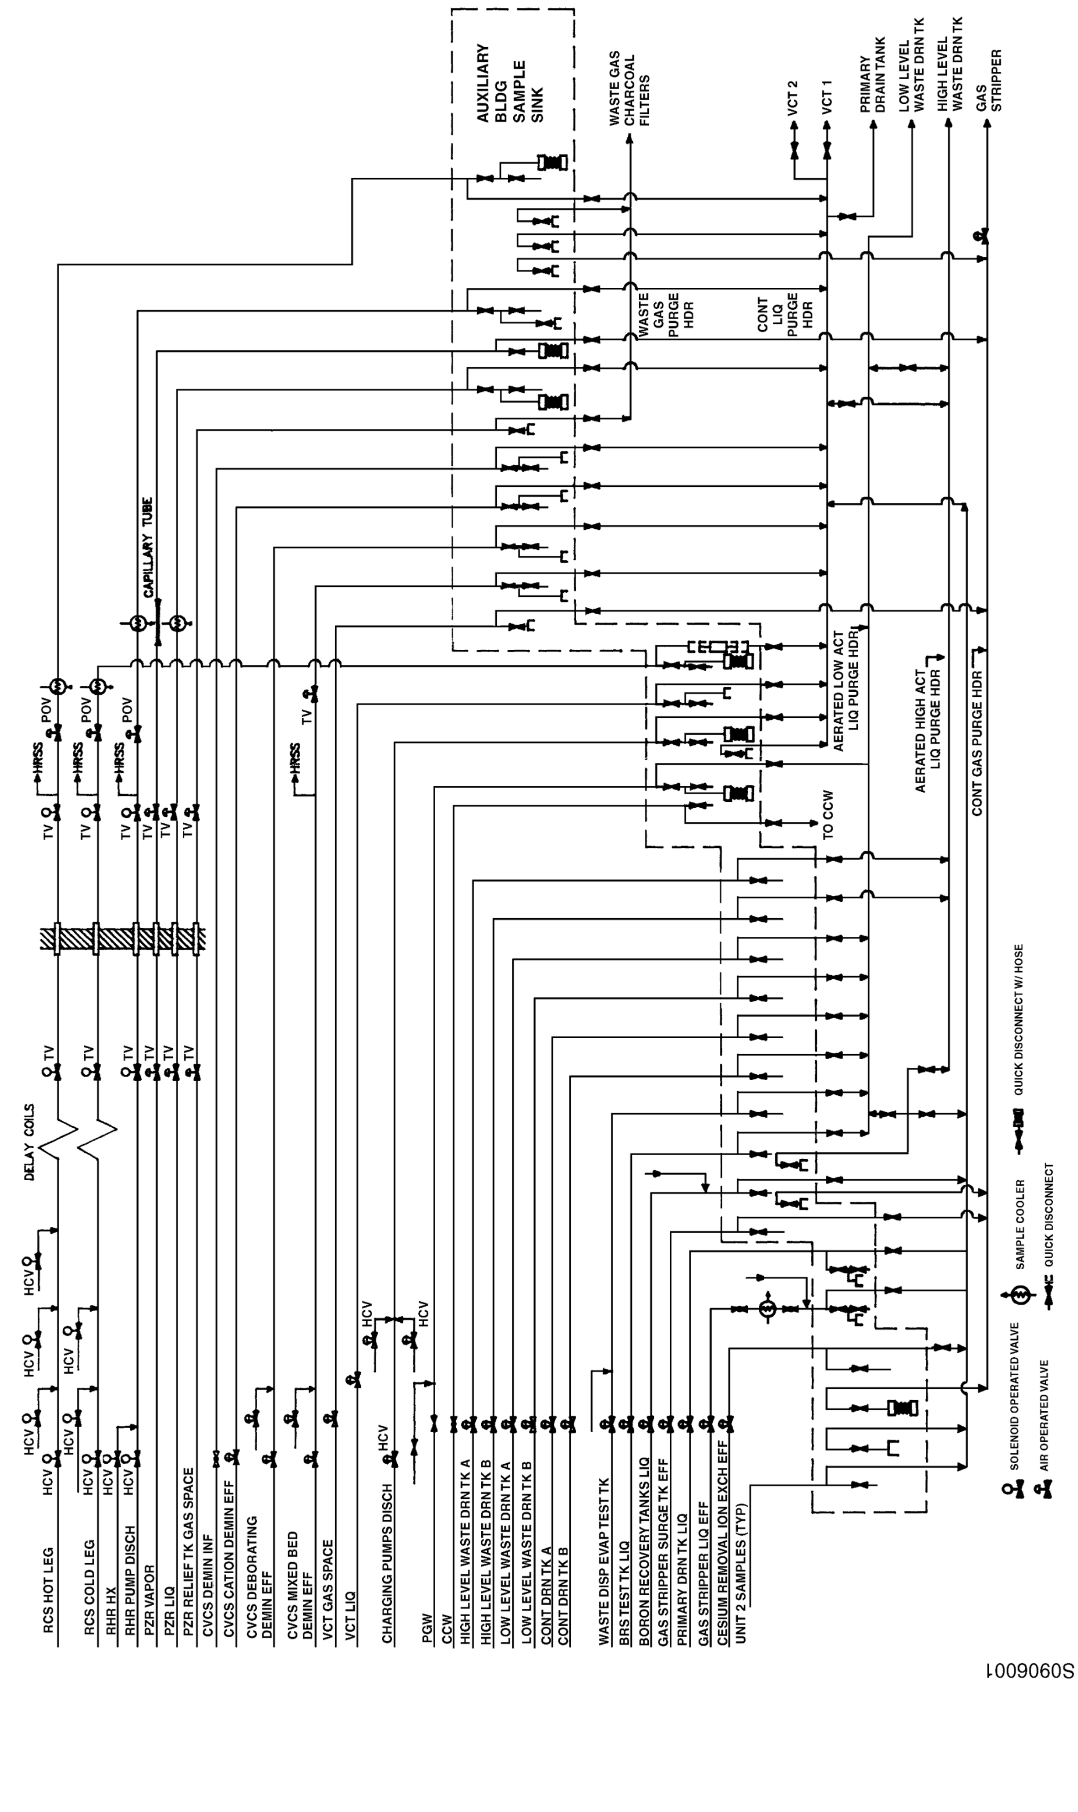
PRIMARY SAMPLING SYSTEM



9.7 VENT AND DRAIN SYSTEM

The vent and drain system collects potentially radioactive fluids and gases from various systems and discharges them either to the waste disposal system (Section 11.2) or to the boron recovery system (Section 9.2).

9.7.1 Design Bases

The vent and drain system is shown in Figure 9.7-1 and Reference Drawings 1 and 2. The drains are separated into those carrying waste fluids to the waste drain tanks for processing and disposal, and those carrying reactor coolant fluids to the primary drain transfer tank and primary drain tank for processing and recovery. The vents are separated into vents in which air is the predominant gas (filtered and discharged to the atmosphere), and vents in which hydrogen and radioactive gases are the predominant gases (discharged to the gaseous waste disposal system).

Redundancy has been provided for all active system components to ensure system operation.

The primary drain transfer tanks, primary drain coolers, relief valves, and the piping, valves, and supports of the vent and drain system conform to Seismic Class I criteria.

The design data for the vent and drain system components are given in Table 9.7-1.

9.7.2 Description

Radioactive liquids, other than letdown from the reactor coolant system (Chapter 4), are gathered and transferred to the high-level or low-level waste drain tanks in the liquid waste disposal system (Section 11.2.3) by either the high-level or low-level waste drain headers.

Both containment structures, the Auxiliary Building, the Fuel Building, both safeguards areas, the component cooling water heat exchanger area in the Turbine Building, and both incore instrumentation areas have been provided with sumps for collecting drainage. The drainage is transferred by gravity or sump pumps to either the high-level or low-level waste drain tank. Segregation of the various waste streams is based on operational and health physics discretion.

The containment sump collects all liquid waste in the containment. The auxiliary building sump collects floor drains, equipment drains, ion exchanger drains, and filter drains. The fuel building sump, safeguards area sumps, and component cooling heat exchanger pit sump collect floor drains in the respective areas.

Drain liquids originating from each reactor coolant system are discharged to a primary drain transfer tank through a high-pressure drain header. The high-pressure drain header permits high-pressure or low-pressure gravity draining of individual reactor coolant loops, the pressurizer relief tank, or the complete reactor coolant system, except for the reactor vessel. An alternate use of the high-pressure drain header is to provide a path for draining the loops during hot shutdown.

Low-pressure radioactive drains, pressurizer relief tank drains, and leakoff liquids from valve stems and reactor coolant pumps drain by gravity to the high-pressure drain header through the primary drain cooler to the primary drain transfer tank. From there, they are pumped to the primary drain tank in the boron recovery system (Section 9.2) by the primary drain transfer pumps. The primary drain cooler is provided to cool all liquid entering the primary drain transfer tank. A high-temperature alarm is provided in the primary side of the cooler outlet to warn the operator of excessive hot liquid flowing into the primary drain transfer tank.

The sample header drains flow directly to the primary drain tank. In the event of high level in the volume control tank of the chemical and volume control system (Section 9.1), the demineralized letdown flow is diverted directly to the primary drain tank through the primary drain transfer pump discharge header.

An air vent header is provided in each reactor containment and may be used to vent the reactor coolant system and components during filling operations. A vent pot located at the end of this header separates any entrained liquid for drainage by gravity to the containment sump. Air leaving the vent pot is discharged to the gaseous waste disposal system (Section 11.2.5). Vents from the ion exchangers and demineralizers, the component cooling surge tank, and waste drain tanks are handled in the same manner.

Radioactive gases are vented to the gaseous waste disposal system. Included in this category are vents from the pressurizer relief tanks, volume control tanks, reactor coolant pumps standpipe vent, bypass vents, and the sampling system gas sample purge line. The gases can also be vented to external process systems following an accident. Flanged connections with isolation valves and reach rods are provided for this purpose. In order to reduce exposure, the connections are located in an area that permits access after an accident.

Piping for the vent and drain systems is designed in accordance with the ANSI B31.1 Code for Pressure Piping. Isolation valves are provided in all vent and drain lines from the containment structures (Section 5.2).

The Teflon seats and packing in the trip valves of the primary drain transfer tank vent lines have been replaced with ethylene propylene seats and graphite packing material. In addition, the ball valves in the primary drain transfer pump discharge line have been replaced with diaphragm valves containing ethylene propylene rubber diaphragms. The ethylene propylene is qualified to 1.0×10^7 rads which is above the calculated total integrated doses of 7.4×10^6 rads and 5.0×10^6 rads, respectively, for the valves. The Teflon was only qualified to 1.0×10^4 rads. These changes ensure that the valves will function as designed in the calculated radiation fields.

9.7.3 Design Evaluation

The vent and drain system is sized to handle the maximum amounts of liquids and gases expected during station operation. Sizing the equipment for these maximum values results in design parameters shown in Table 9.7-1.

Austenitic stainless steel piping is used to transfer liquids and radioactive gaseous waste; carbon steel piping is used for nonradioactive gases.

The fuel building sump pumps are a duplex pump arrangement. The pumps, which are full-size, are controlled by float switches that cycle the pumps on and off. An alternator is provided to obtain equal wear on the pumps. Two additional float switches are provided; the first one starts the standby pump if the operating pump fails, and the second one sounds an alarm on high sump level.

The auxiliary building sump pumps are a duplex pump arrangement. The pumps, which are full-sized, are controlled by a level detector that cycles the pumps on and off, and provides an alternator to obtain equal wear on the pumps. The level detector also starts the standby pump if the operating pump fails, and sounds an alarm on high sump level.

The containment sump pumps are a duplex pump arrangement. Each pump is full-size and independently controlled. One pump is in automatic service, the other in standby. When the water level in the sump reaches a specified height, an alarm sounds and the pump starts. The pump stops automatically upon emptying the sump. Containment isolation valves are provided in the discharge piping. The isolation valves are normally open but close upon a safety injection signal loss of power or air to the valves, or operation of the test switch. When initiated, the containment isolation signal closes the valves or overrides the pump start signal to keep the isolation valves closed.

The primary drain transfer pumps are full-size and independently controlled. Two pumps are provided for each unit. One pump is in automatic service, the other on standby. When the water level in the tank reaches a specified height, an alarm sounds and the pump starts. The pump stops automatically upon emptying the primary drain transfer tank. Containment isolation valves are provided in the discharge piping and are interlocked with the pump controllers. The isolation valves open and close on pump start and stop. When initiated, the containment isolation signal closes the valves or overrides the pump start signal to keep the isolation valves closed.

The primary drain coolers and primary drain transfer tanks and interconnecting piping, valves, and supports are designed as Seismic Category I components. They are also protected from the design tornado by being located inside the containment structures.

9.7.4 Tests and Inspections

Formal testing of this system is unnecessary, since it is in normal day-to-day operation. Inspection is performed in accordance with normal plant maintenance procedures.

9.8 COMPRESSED AIR SYSTEM

The compressed air system includes a service air subsystem, an instrument air subsystem, and a containment instrument air subsystem for each unit. Air service to certain common station areas may be provided from either unit.

9.8.1 Design Bases

The compressed air system is shown in Figure 9.8-1 and Reference Drawings 1 and 2. The design objective of the compressed air system is to ensure availability of sufficient quantities of compressed air of suitable quality and at the pressures required for station operation.

Design pressures are dictated by the expected uses of instrument or service air. Design temperatures are those resulting from extreme ambient conditions and are based on 105°F for the air cooled service air and instrument air compressors. The dew point of the instrument air is reduced by air driers. In the turbine building and low level subsystems, the air driers incorporate desiccants that reduce the pressure dew point to approximately -40°F or lower. This air is also provided to the Auxiliary Building and Condensate Polishing Building Subsystems. The containment building and subsystem incorporate refrigerant driers that reduce the pressure dew point to approximately +50°F. The lowest indoor temperature expected at the point of instrument air use is about +50°F everywhere other than containment. Inside of containment, the lowest expected temperature is higher.

Design data for components of the compressed air system are given in Table 9.8-1.

The compressed air system, compressors, air receivers, driers, piping, valves, and supports to critical instrument and controls are designed to provide reliable sources of compressed air. Portions of the subsystems (critical system components and designated containment isolation features) are designed to Seismic I Criteria (Table 15.2-1). Instrument air compressors function as backup sources of compressed air to the instrument air system and the containment instrument air subsystem and are connected to the emergency power system for greater availability of compressed air in the event off-site power is lost.

While the piping, compressors, and related equipment associated with the compressed air system are not required to operate during or following a design bases accident, air operated devices, both safety related and non-safety related, are designed to fail to a safe position on a loss of air to the device. The safety related air operated devices required to function after an accident are provided with backup air or nitrogen bottles to operate the devices for the complete loss of normal instrument air supply. The plant systems that have critical components which require safety related-dedicated air tanks are as follows: component cooling (Section 9.4.4.3), main steam/feedwater (Section 10.3.5.2), reactor coolant (Section 4.3.4.2), and ventilation vent systems (Section 5.3.1.3.4).

9.8.2 Description

The service air subsystem is equipped with three 100% capacity electric motor driven air compressors, operating at approximately 110 psig. The service air compressors are the primary source of compressed air to both the service air and instrument air subsystems including the condensate polishing building air system during normal station operation. These compressors are located outside on the south side of the turbine building. The service air subsystem also provides service air at hose connections in each unit for operating equipment and tools during normal operation and refueling.

The instrument air subsystem is used to provide air as required for instruments and controls associated with each unit outside containment, and are also available as a backup source of air for the containment instrument air subsystem. The instrument air subsystem is equipped with two (one per unit) 100% capacity electric motor driven air compressors, which operate at approximately 110 psig. The instrument air compressors are used to provide compressed air to the instrument air subsystem during loss of power events and to provide backup instrument air during normal station operation. These compressors are located in the turbine building in an area protected from tornadoes, missiles, and earthquakes.

The three service air compressors are connected to a common discharge header. This header simultaneously supplies compressed air to each of the two unit specific and the shared service air receivers. In addition, this header branches off and provides the source of compressed air to the Condensate Polishing Building. The shared diesel powered service air compressor is so connected as to supply compressed air to all three service air receivers.

The service air compressors are connected to a control system that provides for one of the three compressors to function in a “lead” capacity. In such a configuration, should the air header pressure fall below a predetermined value, the second or “lag” compressor will automatically start and restore header pressure. Should the “lead” and “lag” compressor be unable to restore header pressure the “lag-lag” compressor will start automatically to restore header pressure. The shared diesel powered service air compressor is manually started when needed.

Each instrument air receiver is directly connected to its unit specific service air receiver. In this manner the service air subsystem becomes the primary air source for the instrument air subsystem. Each instrument air receiver is isolated from its associated service air receiver by means of a check valve.

Each unit specific instrument air compressor is connected to its associated instrument air receiver. Each instrument air compressor is capable of automatically starting should its associated receiver pressure fall below a predetermined value. In this manner, the instrument air compressors provide a backup source of compressed air to the instrument air subsystem.

The compressors in both the service air and instrument air subsystems are classified as non-lubricated or oil free. The shared diesel powered service air compressor is of oil flooded screw design. This compressor has charcoal filters installed between the compressor and the service air subsystem piping. These filters prevent oil contamination of the compressed air piping systems.

The compressed air in both the service air and instrument air subsystems is filtered and dried. The compressed air in both the service air and instrument air subsystems is suitable for human consumption (breathing air).

The instrument air compressors and their driers are connected to the emergency power system (Section 8.5) so that continuous instrument air supply is ensured after a loss-of-power accident. The three electric motor driven service air compressors, one shared diesel engine driven service air compressor, and two instrument air compressors are air cooled.

Station instrument air and service air lines penetrating the containment structures are provided with normally closed manual shutoff valves located outside the containment to seal the containment internal atmosphere from the outside atmosphere during an accident. Instrument and service air line penetrations are isolated in accordance with Class V piping, as described in Section 5.2.

The containment instrument air normal supply line from the compressors and air dryers located outside containment, has a containment isolation trip valve outside containment and a check valve located inside containment. The suction line from the containment to the compressors has both an inside and outside containment isolation trip valve. The containment trip valve piping configuration is Class I, as described in Section 5.2 for containment isolation.

The equipment includes the conventional accessories, such as cylinder cooling systems, storage receivers, aftercoolers, and safety valves.

The containment instrument air subsystem consists of two water-sealed, rotary compressors and associated refrigerant air driers installed at the 11 ft. 6 in. elevation of the safeguards area buildings for Units 1 and 2. The compressors take a suction from the containment via a 3-inch penetration. Containment trip valves are provided on both sides of the penetration. Each compressor can provide a minimum of 19.6 scfm at 90 psig minimum. A shell and tube heat exchanger is provided on each compressor to cool the seal water. Cooling water for these heat exchangers comes from the component cooling water system. A connection to primary grade water is also provided for sealwater makeup. One compressor will be in continuous service and will automatically load or unload to meet system demand. The other compressor will be on standby and will start automatically if system pressure decreases to 90 psig.

Each compressor discharges to its own moisture separator and filter. Water removed from the air by the moisture separators and air driers is directed to a sump, where a small sump pump transfers the water to the liquid waste system. Each air compressor discharges to its own refrigerant air drier. The piping allows the air compressors to be cross-connected with the air driers as well as allowing them to bypass the driers completely. Air exiting the driers will have a dewpoint of about +50°F. The air will enter the containment through a containment trip valve tied into the turbine building control air cross-connect piping, using containment penetration 47.

Since the compressors process potentially contaminated air, an enclosure is provided around the air compressors, driers, and associated equipment. During normal operation, the enclosure air is ducted to and monitored for radioactivity prior to entering the ventilation vent number 2. During abnormal conditions, the enclosure exhaust ventilation dampers are closed on a safety injection signal, and the safeguards exhaust fans are subsequently tripped. In addition, during a DBA the containment instrument air subsystem is isolated by the containment isolation trip valves. The enclosure consists of sheet metal walls and roof. The floor of the enclosure is a poured concrete pad with integral sump and slopes toward the sump.

The compressors are powered from normal buses, since they are not required to operate during or following an accident.

Associated piping is designed in accordance with ANSI B31.1-1967. Design conditions are 150 psig and 150°F.

9.8.3 Design Evaluation

The following devices are provided to preserve an adequate instrument air supply under abnormal conditions, and to ensure system reliability:

1. High capacity service air compressors supply both service air and instrument air subsystems. If instrument air pressure falls, additional compressors may be automatically or manually started. Service air loads can be isolated from the main control room via solenoid operated valves. A bypass line is also provided from the outlet of each unit specific service air receiver to the inlet of its associated instrument air drier. In the event of failure of an instrument air receiver, compressed air may be directly supplied by the service air receiver. In addition, the instrument air compressors are supplied by the emergency bus for loss of off-site power events.

2. Alternate standby air sources are available. If the service air header pressure falls, the second or “lag” service air compressor will automatically start and restore header pressure. In the event that the “lead” and “lag” service air compressors are unable to restore service air header pressure, the “lag-lag” service air compressor will automatically start and restore header pressure. If the instrument air header pressure falls, the instrument air compressors automatically start and restore the instrument air subsystem pressure. Also, the shared, diesel-powered service air compressor can be manually started when needed.

3. Instrument air backup between the two units. This is provided by means of cross-connecting lines between the two units at the main headers.

4. Instrument air backup to containment instrument air subsystem. In the event of the loss of both containment instrument air compressors and receivers, containment instrument air can

be supplied from the instrument air system by opening the manually operated valves in the cross-connect line provided.

5. Compressed air backup system to each instrument air line leading to a Spent Fuel Pool (SFP) canal door seal (2 doors). In the event of loss of instrument air pressure to a SFP canal door seal, the compressed air system provides backup pressure to ensure that the seal remains inflated to prevent leakage from the SFP into the fuel transfer canal.

The containment instrument air system is non-safety-related because the components requiring containment instrument air are not necessary for safe shutdown. The majority of loads on this system are spring-diaphragm-type air-operated valves, which use spring force to maintain the valves in a fail-safe condition. The remaining loads are the personnel airlock inner-door locking device and the reactor head inflatable seal in the head storage area. The compressors, accessories, and piping upstream from the first containment isolation valve and associated pipe support outside containment are not seismically qualified.

9.8.4 Tests and Inspections

Testing of the compressed air subsystems consists of air quality tests and compressor tests. Air quality is monitored through surveillance procedures that ensure air hydrocarbon content, particulate content, and dew point meet acceptable standards. Generally, compressor tests are conducted at refueling, with the exception of a more frequent test of the instrument air compressor. Preventive maintenance and inspection of the systems is performed in accordance with normal station maintenance procedures.

9.8 REFERENCE DRAWINGS

The list of Station Drawings below is provided for information only. The referenced drawings are not part of the UFSAR. This is not intended to be a complete listing of all Station Drawings referenced from this section of the UFSAR. The contents of Station Drawings are controlled by station procedure.

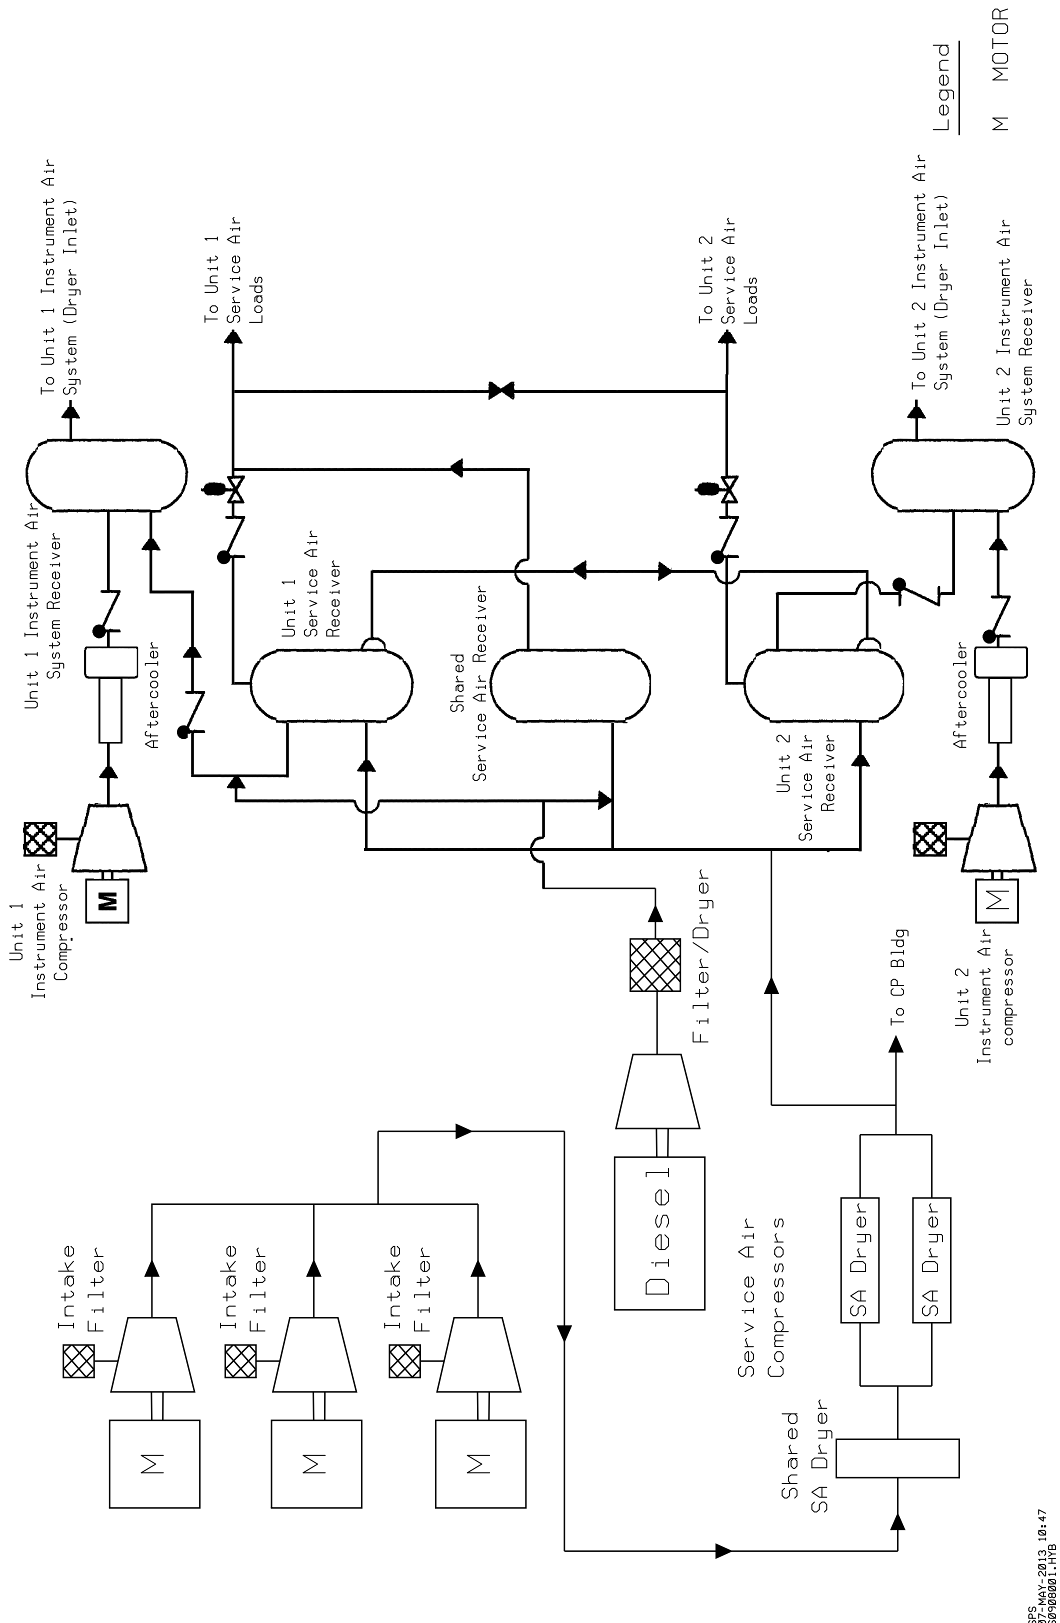
a. Since the containment operates under a vacuum, an exception is permitted to the ISA dewpoint standard by NRC's review correspondence of March 25, 1993 by which a dewpoint temperature of 50°F is acceptable.

Figure 9.8-1
COMPRESSED AIR SYSTEM



9.9 SERVICE WATER SYSTEM

River water is the source of service water for the Surry Power Station. Since this water is brackish, it is not directly used for cooling critical equipment. Service water is used as cooling water for heat exchangers that remove heat from the component cooling water system (Section 9.4), the bearing cooling water system (Section 10.3.9), the recirculation spray system (Section 6.3.1), charging pump service water subsystem (Section 9.9.2.1), and other station applications such as air conditioning and chilled water. A review of the effects of the power uprate to a core power of 2589.3 MWt was conducted and the service water system was found to be adequate.

The service water system is shown in Figure 9.9-1 and Reference Drawings 1 through 4.

9.9.1 Design Bases

The service water system is designed for the removal of heat resulting from the simultaneous operation of various systems and components of two units based on a maximum river water temperature of 100°F. Component capacities with a SW inlet temperature of 95°F shown in Table 9.4-1 for Component Cooling Heat Exchanger, Table 9.4-2 for Chilled Water System and Table 9.9-3 for Charging Pump reflect the design rating of the equipment. A Service Water temperature of 95°F was assumed for equipment specifications. This equipment will function acceptably with a slightly reduced capacity at a maximum river water temperature of 100°F. This temperature is 7°F warmer than river model tests indicate for the river water temperature on record (Reference 1). The service water system is designed as a Class I system (Section 15.2.4).

The charging pump cooling water system consists of two separate subsystems: a component cooling water subsystem and a service water subsystem. The charging pump component cooling water system is described in Section 9.4.3.5.

A separate charging pump service water system is provided for each reactor unit. The charging pump service water system is designed to provide cooling water from the service water system to the charging pump intermediate seal coolers and to the charging pump lubricating oil coolers. Charging pump service water system component design data is given in Table 9.9-3. A more detailed system description is given in Section 9.9.2.1. The charging pump service water system is designed as Class I (Section 15.2.1).

9.9.1.1 **Accident Design Bases**

During a LOCA without a loss of station power, the supply and discharge isolation valves to the recirculation spray heat exchangers open in the affected unit. All valves in the service water supply to the other heat exchangers will remain open. During this type of accident, the service water requirements will increase above those listed under Section 9.9.2 and include the flow to the recirculation heat exchangers, which is given in Table 9.9-2.

If a total loss of station power occurs simultaneously with a LOCA in either unit, the recirculation spray heat exchanger supply and discharge isolation valves open and all other isolation valves in the service water system of the LOCA affected unit are closed. Under these conditions the service water flow to the recirculation spray heat exchangers will be at least 12,280 gpm and vary as a function of the intake canal level.

In the event of a total loss of station power only, the recirculation spray heat exchanger supply and discharge isolation valves remain closed and all other service water isolation valves remain open.

The operation of condenser and service water valves under accident conditions and various other events is described in Table 9.9-1.

9.9.1.2 **Emergency Service Water Pumps**

In the event of a loss of station power at the river intake, three diesel-driven, vertical emergency service water pumps have been provided for both units at the river intake structure to supply makeup to the high-level canal. The pumps are sized to provide the design required make-up to the intake canal with the James River at design low water level (i.e., maximum expected developed head).

The following criteria were used in sizing the emergency service water pumps:

1. In the event of a LOCA and a total loss of station power, with the requirement that the unit that did not undergo the LOCA must also be cooled down, water flow is required to the recirculation spray heat exchangers, component cooling heat exchangers, other miscellaneous loads, and make-up for various non-cooling related high level canal inventory losses. This would require two of the three pumps to be operated.
2. In the event of a design-basis accident (LOCA in either unit and a total loss of station power), water flow is required to the recirculation spray heat exchangers, component cooling heat exchangers, other miscellaneous loads, and make-up for various non-cooling related high level canal inventory losses. This condition, assuming one unit is in cold shutdown and the heat load from the shut down unit and spent fuel is less than 25 million BTU/Hr, would require one emergency service water pump in operation.
3. In the event of a loss of station power in two units, component cooling heat exchangers would be required to cool down the units. Additional flow would be required for other miscellaneous loads and make-up for various non-cooling related high level canal inventory losses. This would require two of the three pumps to be operated.

9.9.1.3 **System Operation During Design Basis Hurricane**

A Probable Maximum Hurricane (PMH), as described in Section 2.3.1.2.2, will result in reduced available service water flow due to the decreased driving head across the gravity flow service water system. The driving head will be reduced since the river level, to which the service water flow path discharges, will be higher due to storm surge. The revised design basis PMH analysis documents the adequacy of the Service Water System to maintain the units in a safe intermediate shutdown condition by removing decay heat concurrent with the loss of off site power. The design basis PMH analysis requires that operating units be brought to intermediate shutdown prior to the hurricane reaching the site and subsequently maintaining RCS temperature below 350°F. Units at cold shutdown or in refueling would be maintained at either cold or intermediate shutdown with RCS temperature below 350°F. Refueling activities would be suspended prior to the arrival of the hurricane. In accordance with design basis criteria, a design basis accident (LOCA) is not considered during the PMH (Reference 2).

Prior to arrival of the hurricane, site procedures require the start of hurricane preparations such as closing missile doors, putting flood protection barriers in place, and preparing equipment required for shutdown. Emergency service water (ESW) pump house door seal plates and louver opening covers will be procedurally installed.

With both units operating prior to the hurricane, the units are to be shut down two hours before the hurricane reaches the site. Decay heat will be removed using the circulating water/service water system until a loss of power occurs after which the auxiliary feedwater system will be used. For analysis basis, this is assumed to be 2 hours after the plant has shut down (i.e., the loss of power occurs coincident with the arrival of hurricane winds on site). This criteria is consistent with the guidelines provided in NUMARC 87-00 (Section 2.11, *Hurricane Preparations*) (Reference 3).

The water elevation in the Intake Canal will be established at 28-30 feet to ensure that sufficient driving head is available to provide heat removal capability for the Component Cooling System during the expected storm surge. Reanalysis of the wave run-up within the intake canal indicates a freeboard of 4 feet from the top of the canal (Elevation 36 ft.) is required. Therefore, a canal elevation of approximately 28-30 feet is within the requirements of the wave run-up analysis.

Due to the potential for the intake canal siphoning back through the circulating water pump discharge lines, the circulating water pumps will be shut down prior to the hurricane reaching the site. The plant has been modified to break the siphon at Elevation 23 ft., however, the hurricane analysis required an elevation of 28 feet to ensure adequate service water flows with peak river surge. Therefore, the circulating water pumps will be shut down and the siphon broken after raising the canal level to at least 28 feet.

To ensure adequate decay heat removal of the shutdown unit(s) at the peak river surge (Elevation 22.7 ft.), the CCW heat exchangers and pumps will be cross-connected to allow the flow of the CCW pumps to be equally distributed to three CCW heat exchangers. Also, to minimize the CCW heat loads, all nonessential heat loads will be isolated. The analysis is based on using CCW for decay heat removal (using the RHR heat exchangers) for the cold shutdown unit(s), and CCW for heat removal for letdown and auxiliary feedwater for decay heat removal for the intermediate shutdown unit(s).

For the case where one unit was initially operating and one unit was at cold shutdown, an additional 60,000 gallons of AFW is available for the operating unit. This additional 60,000 gallons will allow AFW operation for 39 hours after shutdown of the circulating water system. The decay heat load analysis is based on the operating unit(s) being shut down 2 hours prior to the hurricane reaching the site and loss of power occurs. However, in order to ensure that a canal level of 28 feet is established and isolation of the circulating water system occurs without siphoning the canal, the operating unit will be shut down by procedures before hurricane wind speed is reached to enable operators to verify that the active vacuum breakers on the circulating water discharge piping have opened. This operator action will be carried out at the low level intake to ensure isolation of the canal and no siphoning prior to high winds and high river elevation.

For less severe hurricane conditions characterized by storm tides at the Surry site less than or equal to 8.0 feet, adequate head for the service water system will remain available for cooling the component cooling system without performing some special actions. A storm tide of 8.0 feet is equivalent to the effective CW/SW discharge elevation with an unprimed CW discharge tunnel. Therefore, securing the CW pumps, and breaking the siphon prior to arrival of the hurricane are not necessary to ensure adequate intake canal inventory remains available. Similarly, advance re-alignment of the CCW system and isolation of non-essential loads also are not required to be performed.

9.9.2 Description

Service water is supplied from the circulating water system (Section 10.3.4) by gravity flow between the high-level intake canal and discharge canal seal pit. During normal operation, the water level in the intake canal is approximately 28 feet above the level in the seal pit at the discharge canal. This differential head supplies the service water to parallel flow paths through the bearing cooling water heat exchangers, component cooling heat exchangers, and recirculation spray heat exchangers, which are also in parallel with the main condenser. Service water is also supplied to the control room and relay room air conditioning system chiller condensers, charging pump lubricating oil coolers, and to the charging pump cooling water system intermediate seal coolers.

Remotely operated butterfly valves are installed at the four inlets and outlets of each main condenser and in the supply lines to the bearing cooling water heat exchangers and the component cooling heat exchangers. For the recirculation spray heat exchangers remotely operated butterfly valves are installed in the supply and discharge lines to each cooler in addition to the supply valves associated with each service water supply header. The operation of these valves is listed in Table 9.9-1. These motor-operated valves are positioned automatically for various accident conditions to conserve water in the intake canal for critical services. Power for these valves is from the station emergency 480V motor control centers.

To minimize the potential for macrofouling and to facilitate venting of the recirculation spray heat exchangers during the initial inrush of water, a portion of the service water supply lines to the heat exchangers is maintained in wet layup and chemically treated during normal operation. The section of pipe to be maintained in layup begins downstream of valves SW-MOV-103/203, A, B, C, and D and extends to the four 24-inch supply line tie-ins off the 36-inch service water supply header. The water maintained in these lines is chemically treated to prohibit marine growth. In addition, the service water supply to the component cooling heat exchangers is also chemically treated to reduce biofouling of the heat exchangers.

Service water is supplied to the cooling water subsystem of the control room and relay room air conditioning system chiller condensers and to the charging pump service water subsystem from three separate circulating water lines through three independent flow paths. The three flow paths provide the operating flexibility to remove a flow path from service for cleaning without entering into a Technical Specification limiting condition for operation.

A temporary service water flow path may be provided to perform maintenance on the single service water supply to the component cooling heat exchangers. Use of the temporary flow path must be in accordance with an approved temporary change to Technical Specifications and an associated license condition. The piping is routed through the turbine building basement from the circulating water inlet piping to the supply piping of two of the component cooling heat exchangers. The temporary service water supply is used only during a Unit 1 outage.

Trash racks have been installed to prevent large pieces of trash from entering the intake structure which could adversely affect the operation of the emergency service water pumps. Since each bay of the intake structure is sized for a total flow of 220,000 gpm and each emergency service water pump is assumed to deliver a minimum of approximately 14,000 gpm, sufficient water will be provided to the emergency service water pumps as long as approximately 7.5% of the flow area of the racks remains clear.

In the event of a power failure simultaneous with the accumulation of trash at the trash racks, accumulated trash can be removed from the screens of the station intake by manual raking. This procedure could be done indefinitely if necessary although it is expected that the duration of the loss of power would be relatively short, i.e., less than 1 week.

The maximum service water requirements of the system during normal operation are given in Table 9.9-2.

9.9.2.1 **Charging Pump Service Water System Description**

A charging pump service water system for each reactor unit provides water to cool the charging pump intermediate seal coolers and the charging pump lubricating oil coolers.

Either of two 100%-capacity charging pump service water pumps delivers water from the service water system to the charging pump intermediate seal coolers and the charging pump lubricating oil coolers, thereby maintaining the charging pump lubricating oil and the component cooling water used to cool the charging pump mechanical seals at the proper temperature. To ensure that service water is continually available, one pump is in operation and the other on standby. The standby pump is automatically actuated on low pump discharge pressure to supply service water in the event of failure of the operating pump.

The two redundant 100%-capacity charging pump service water pumps are separated by seismic, missile-protected, 3-hour fire rated walls, ceiling, and floor. An automatic actuating fire safe isolation ball valve is installed in the cross-connect piping between the two pump trains. The separation and cross-connect of the two redundant pump trains is designed to meet the requirements stipulated in Appendix R, Section III.L.2(e), of 10 CFR 50.

The installation of two full-capacity charging pump service water pumps provides 100% redundancy for this cooling water system. All components of the charging pump service water system, including pumps and heat exchangers are designed to Seismic Class I criteria.

The charging pump service water pumps are connected to the emergency electrical bus to ensure that they will operate in the event of a loss of station power.

Regulatory Guide 1.97 requirements for post-accident monitoring of charging pump service water system status are satisfied by flow and temperature measurement at the discharge of each charging pump service water pump. Flow and temperature transmitters are environmentally and seismically qualified in accordance with IEEE 323-1974 and IEEE 344-1975 respectively. Control room display is provided through the NUREG 0696 multiplexing system.

9.9.3 Design Evaluation

The following components of the auxiliary cooling systems are required for performance of the engineered safety features:

MOV-SW-103A, B, C, & D	Motor-operated valves that admit SW to the RS coolers SW supply header.
MOV-SW-104A, B, C, & D	Motor-operated valves that admit service water to the recirculation spray coolers.
MOV-SW-105A, B, C, & D	Motor-operated valves that discharge service water from the recirculation spray coolers.
MOV-CW-106A, B, C, & D	Motor-operated valves that stop water flow to the main condenser.
MOV-CW-100A, B, C, & D	Motor-operated valves that stop water flow from the main condenser discharge

MOV-SW-102A & B	Motor-operated valves that stop service water to component cooling water heat exchangers.
MOV-SW-101A & B	Motor-operated valves that stop service water to the bearing cooling water heat exchangers.
SW-P-10A & B	Charging pump service water pumps to supply cooling water to the charging pump cooling water system.
CC-P-2A & B	Charging pump cooling water pumps that circulate the component cooling water of the charging pump cooling water system.
1-CW-LS-102 &103	Canal level switches which provide a signal to isolate non-essential flows from the intake canal.
2-CW-LS-202 & 203	Canal level switches which provide a signal to isolate non-essential flows from the intake canal.

The associated instrumentation and power systems for the operation of these components are redundant, and have protected power and control circuits in conformance to IEEE-279 and 10 CFR 50, General Design Criteria.

The components themselves are redundant except for motor-operated valves MOV-SW-102A & B and MOV-SW-101A & B, which stop service water to the component cooling water heat exchangers and the bearing cooling water heat exchangers. Motor-operated valves MOV-SW-102A & B are in parallel pipelines, as are motor operated valves MOV-SW-101A & B. Failure of one of these valves will allow service water to escape from the service water canal through the component cooling water heat exchangers or the bearing cooling water heat exchangers. However, in the event of failure of one of these motor-operated valves, manual valves that are accessible immediately following a design-basis accident are provided to isolate the service water pipelines to the bearing cooling water heat exchangers and the component cooling heat exchangers, thereby conserving water in the intake canal for the recirculation spray coolers.

In the event of the design-basis accident, the valves in the supply lines to the component cooling heat exchangers may be reopened remote-manually from the control room, provided low canal level setpoint has not been reached, if service water to this system is considered necessary.

Automatic temperature control of the charging pump lube-oil systems is provided by the use of air-operated control valves. These valves are installed in the service water outlet of each lube-oil cooler. Capillary type thermal elements are installed in the oil lines which provide the signal to a pneumatic-indicating temperature controller with the output signal operating the control valve.

The piping and equipment movements at the recirculation spray heat exchangers have been analyzed in accordance with earthquake design criteria and have been installed to ensure that no undue forces are exerted on piping or equipment nozzles.

The gravity flow of service water from the intake canal ensures adequate cooling water to the recirculation spray heat exchangers and other essential loads in the case of the design-basis accident. This supply of cooling water is based on service water flow through recirculation spray heat exchangers, component cooling heat exchangers, and miscellaneous loads that include control room chiller condensers and charging pump coolers. Depending on the initial conditions and the single failure assumed, one or more emergency service water pumps are required to assist in maintaining the intake canal inventory within design limits.

A diesel fuel-oil storage tank provides sufficient fuel to operate three emergency service water (ESW) pumps for 24 hours and two for an additional 72 hours. Diesel operation for all three ESW pumps is locally controlled. Canal inventory calculations consider pump operation by diesel drive following a loss of offsite power.

The possibility of leakage from the reactor containment into the service water through the recirculation spray heat exchangers after a LOCA is discussed in Section 6.3.1.

9.9.3.1 **System Reliability**

A double set of normally closed parallel motor-operated butterfly valves control the service water supply to the recirculation spray service water headers. The heat exchanger inlet and outlet valves are closed during normal plant operation to prevent service water inleakage, which could cause tube fouling. These service water valves are opened in response to a Consequence Limiting Safeguards (CLS) hi-hi containment pressure signal. Each individual valve has a CLS activated relay in its opening circuit to open the valves in the event of a design basis accident. The double set of parallel butterfly valves assure that service water will always be provided to the recirculation spray service water header in the event of a malfunctioning valve. Malfunction of a single heat exchanger inlet or outlet valve will result in isolation of service water to only one heat exchanger as discussed in Section 9.9.3.2.

Three diesel-driven emergency service water pumps are furnished to provide makeup to the intake canal during a loss of offsite power. Batteries provide the power required to start and shutdown the diesels and to monitor diesel status. Battery chargers, fed from normal station power, are used to maintain the batteries in a fully charged condition. The three diesels are also each equipped with an alternator capable of carrying running loads and maintaining a float charge on the starting batteries during extended operation of the diesels. Safety-related blocking diodes are provided to isolate the safety related batteries from the non-safety related battery chargers.

9.9.3.2 **Malfunction Analysis**

Failure of the service water system is precluded as follows:

1. Malfunction of the butterfly valves in supply lines to recirculation spray service water headers is accommodated by a double set of valves in parallel to ensure that water will be available at all times.
2. Malfunction of either a recirculation spray heat exchanger inlet or outlet isolation valve upon receipt of a CLS hi-hi signal will result in isolation of service water to a single recirculation spray heat exchanger. Loss of one heat exchanger will not prevent mitigation of the design basis accident since only two recirculation spray heat exchangers are required (minimum safeguards).
3. Failure to restore power to circulating water pumps is accommodated by three diesel-engine-driven emergency service water pumps. One or more pumps are required to operate, depending on the particular event or single failure assumed, to supply water to control any of the accidents or events listed in Table 9.9-1.

The charging pump service water system cannot be disabled totally by a single passive failure. With the exception of the single discharge header common to both units, the system has been designed with cross-connect piping and sufficient valves so that any single passive failure can be isolated as necessary to allow the system to continue to operate and provide cooling water to support operation of at least two charging pumps. If a passive failure of the seismically qualified discharge header occurs, the system can still fulfill its safety-related design basis function without requiring operator action. In the redundant portions of the system, the isolation of a single passive failure and re-arrangement to continue to provide cooling water must be performed manually by the plant operators. In addition, the standby charging pump may have to be placed in operation, since isolation of the single passive failure might prevent cooling water from reaching the operating charging pumps. The complete system is expected to be accessible during an accident; however, if the course of an accident were to result in gross fuel failure, the local area radiological dose rates may substantially restrict access. For this situation, acceptable operation of the charging pump service water system can continue without isolation of credible passive failures.

9.9.4 Tests and Inspections

Periodic testing confirms that proper operation and safety signal actuation of the service water system valves in the lines supplying the recirculation spray heat exchangers is maintained.

The design head capacity characteristics of the service water system were verified by determining flows through the recirculation spray heat exchangers during initial start-up testing and subsequent special tests.

The diesel-driven emergency service water pumps are tested in accordance with the station’s Inservice Testing Program to ensure availability when needed. In addition, one diesel-driven pump is operated during tornado warning periods or at any time when it is thought that the backup operation of this pump materially contributes to the safety of the station.

The starting batteries, alternators, and blocking diodes for the diesels are periodically checked. The batteries are checked for specific gravity and voltage. Over a period of time, these tests will indicate weak or weakening trends in any cell, and replacement will be made, as necessary. In addition, the batteries are replaced per manufacturer's recommendation on a fixed maintenance schedule. The alternators are checked to ensure their ability to maintain a float charge on the starting batteries. The blocking diodes are checked to ensure current blockage and pass through capability has not been impaired.

Table 9.9-1
AUTOMATIC OPERATION OF CONDENSER AND SERVICE WATER VALVES

	Initial Valve Action	
Accident or Event	Service Water Valve	Main Condenser Valves
Loss of coolant, either unit, and total loss of offsite power (design-basis accident)	a. Open recirculation spray heat exchangers [a] to the affected unit	Close all valves on affected unit/throttle outlet valve on unaffected unit
	b. Close all others on affected unit/unaffected unit remains as-is	
Loss of coolant, either unit, without a loss of power to the affected unit [b]	a. Open recirculation spray heat exchangers [a] to the affected unit	All valves remain as-is both units
	b. All others remain as-is	
Total loss of offsite power	a. All valves remain as-is	Throttle outlet valves, both units
Loss of intake canal level	a. Recirculation spray heat exchangers [a] remain as-is	Close all valves, both units
	b. Close all others, both units	

a. Recirculation spray heat exchangers valves include SW inlet and outlet to each heat exchanger and SW supply from CW system.
b. A loss of power to the unaffected unit will cause the condenser outlet valves for that unit to throttle.

Table 9.9-2
SERVICE WATER REQUIREMENTS

	Flow gpm	Heat Transfer 10^6Btu/hr	No. of Exchangers Operating	No. of Exchangers Furnished
I. Normal Operation				
Component Cooling System[a]	18,000	100.6	2 (one for each unit)	4 (two for each unit)
Bearing Cooling System	48,000	144	4 (two for each unit)	6 (three for each unit)
Control Room Air Conditioning	501 [b]	1.94	2 (one for each unit)	5
Charging Pump:				
Lube-Oil Coolers	10 [c]	-	2 (one for each unit)	6 (three for each unit)
Intermediate Seal Coolers	20 [c]	-	4 (two for each unit)	4 (two for each unit)
II. LOCA Conditions				
Recirculation Spray System	12,280[d]	300 [e]	4 [f](four for each accident unit)	8 (four for each unit)
Component Cooling System	[g]		2 (non-accident unit)	4 (non-accident)
Control Room Air Conditioning	501 [b]	1.94	2 (one for each unit)	5
Charging Pump:				
Lube-Oil Coolers	20 [c]	-	4 [h]	6 (three for each unit)
Intermediate Seal Coolers	20 [c]	-	4 (two for each unit)	4 (two for each unit)

a. Flow and heat transfer rates are based on 2 heat exchangers operating at conditions appearing on the vendor data sheet. Typically, 4 CCHXs are aligned with throttled service water flow, as required to maintain component cooling supply temperature within design limits.

b. Peak flow required for design maximum load. Actual flow will normally be less and vary seasonally. A nominal 60 gpm service water flow rate is also supplied for backwashing the supply side strainers.

c. Flow rates are based on satisfying heat duty requirements. Actual flow rates on some coolers will be higher due to unbalanced parallel flow paths.

d. During a LOCA with a LOOP four RSHXs on the accident unit will initially operate, but only two RSHXs are required. Flow rate stated is based on 2 heat exchangers operating at an intake canal elevation of 17.2 feet. Actual flow rates will vary as a function of the intake canal level.

e. Heat transfer is based on a total of 2 heat exchangers operating (minimum ESF). Actual heat transfer rate will vary, depending on the time after accident initiation. Due to the time dependent SW flow rates through the heat exchangers, the heat transfer rate stated is not coincident with the indicated flow.

f. The maximum number of heat exchangers that can be operating at any given time is 4, which is based on the design basis event.

g. Depending on the initial conditions and the elapsed time after an accident, one or two CCHXs may be in service with throttled SW flow.

h. Three lube oil coolers are in service for the accident unit with one cooler in service for the non-accident unit.

9.10 FIRE PROTECTION

9.10.1 Design Bases

The basic regulatory criterion for fire protection is set forth in 10 CFR 50, Appendix A, General Design Criterion 3. The station's fire protection program for Surry Power Station satisfies the regulatory criteria set forth in General Design Criterion 3, in 10 CFR 50 Appendix R (Sections III.G, III.J, III.L and III.O), and in Appendix A to Branch Technical Position APCSB 9.5-1 dated August 23, 1976.

Compliance with these criteria is contained in the following documents:

1. *10 CFR 50 Appendix R Report, Surry Power Station, Units 1 and 2* includes the description of systems, equipment, and manpower required for safe shutdown (Chapters 3, 5); the fire hazards analysis (Chapters 2, 4, 8); major commitments that form the basis for the fire protection program (Chapters 1, 6); engineering evaluations and exemption requests from Appendix R (Chapter 7); and the safe shutdown circuit analysis (Chapter 9).
2. *Fire Protection Program* document and the associated Administrative Procedures describe the administrative and technical controls, the organization, and other plant features associated with fire protection.
3. NRC's *Fire Protection Safety Evaluation Report, Surry Power Station, Units 1 and 2,* dated 9/19/79.
4. NRC's Safety Evaluation Report for Sections III.G and III.L of Appendix R, dated 12/4/81, and Supplemental Safety Evaluation Report, dated 11/18/82.
5. NRC's *Safety Evaluation by the Office of Nuclear Reactor Regulation Relative to Appendix R Exemptions Requested,* Surry Power Station, Units 1 and 2, transmitted by letter dated 2/25/88.
6. NRC's *Safety Evaluation by the Office of Nuclear Reactor Regulation, Surry Power Station, Units 1 & 2, Post-Fire Safe Shutdown Evaluation, Appendix R,* July 23, 1992.

Changes to the 10 CFR 50 Appendix R Report and Administrative Procedures are evaluated in accordance with 10 CFR 50.48. Consistent with the facility operating license, changes to these documents may be made without prior approval of the Nuclear Regulatory Commission provided the change does not adversely affect the ability to achieve and maintain safe shutdown in the event of a fire. The acceptance criteria for this assessment are that (a) the level of fire protection is not being diminished, and (b) the change will not adversely affect the ability to achieve and maintain safe shutdown in the event of a fire. If this acceptance criteria is met, then the revision is made.

The Surry fire protection program is intended to satisfy the basis regulatory criterion by meeting the following objectives, given the actual plant relationship between combustibles, safety-related equipment, and fire protection features:

1. Reduce the likelihood of fires.
2. Promptly detect and extinguish fires that do occur.
3. Maintain safe-shutdown capability if a fire does occur (timely achievement of Hot Shutdown, and achievement of Cold Shutdown within 72 hours in Appendix R III.G.3 areas).
4. Prevent release of a significant amount of radioactive material if a fire does occur.

The Surry fire protection features are generally designed in accordance with the National Fire Protection Association code of record to furnish water and other extinguishing agents throughout the plant. Engineering evaluations of NFPA code compliance and other fire protection related items are provided in the 10 CFR 50 Appendix R Report. The types of fire protection features have historically been based on the recommendations of the Nuclear Energy Property Insurance Association, and provide the following:

1. Supply of water for fire fighting.
2. System for delivery of water to potential fire locations.
3. Automatic fire or smoke detection in the more critical areas.
4. Fire extinguishment by fixed equipment activated automatically or manually.
5. Manually operated portable fire-extinguishing equipment at strategic locations.
6. Fire barriers.

The following components are designed to Class I criteria (Section 15.2.1):

1. Engine-driven fire pump.
2. Diesel oil tank for engine-driven fire pump.
3. Yard hydrant piping.

Fire protection system design data are given in Table 9.10-1.

In addition to its primary function, the fire protection system also provides alternate sources of makeup water to certain other plant systems as follows:

1. Auxiliary Feedwater System. This interconnection can be used for the fire protection system to provide an emergency water supply to the suction of the Unit 1 and Unit 2 Auxiliary Feedwater Pumps.
2. Spent Fuel Pool. A normally covered outlet above the spent fuel pool is supplied from the fire protection system for emergency makeup water to the pool. Teeing into this FP makeup

line inside the Fuel Building is a line that is accessible external to the Fuel Building which can be used to enable supply by an external makeup source.

These secondary functions of the fire protection system do not prohibit the system from performing its primary function. In accordance with BTP-APCSB 9.5-1, Appendix A, Paragraph A.4, postulated fires need not be considered concurrently with other plant accidents.

As previously stated, part of the regulatory criterion is compliance with Appendix A to BTP APCSB 9.5-1. Section F to Appendix A, *Guidelines for Specific Plant Areas,* identifies the specific areas of the plant that require fire suppression systems. Section F.18, *Miscellaneous Areas,* states “Miscellaneous areas such as records storage areas, shops, warehouses, and auxiliary boiler rooms should be so located that a fire or effects of a fire, including smoke will not adversely affect any safety related systems or equipment.” Section F.18 does not require a fire suppression system but relies on building location to protect safety related systems and equipment. The following fire suppression systems are not required for compliance to regulatory criterion since the areas they protect meet Section F.18 and do not adversely affect safety-related structures, systems or components or affect safe shutdown capability in the event of a fire.

Administration Building Sprinkler System
Construction Clean Change Building Sprinkler System
Fabrication Shop Sprinkler System
Fuel Oil Storage Tank Foam System
Gravel Neck Combustion Turbine Facility Sprinkler System

Station and Chemical Warehouse Sprinkler System
Surry Nuclear Information Center (SNIC) Sprinkler System
Training Center Halon and Sprinkler System
Warehouses (1, 2, 7, and 8) Sprinkler Systems
Turbine Deck Security Office (TDSO) Sprinkler System
Beyond Design Basis (BDB) Storage Building Clean Agent System

9.10.2 Description

An arrangement drawing of the fire protection system is provided in Figure 9.10-1.

9.10.2.1 **Fire Detection and Signaling**

The fire detection and alarm systems are installed on a multiplexed system in accordance with the guidelines of National Fire Protection Association (NFPA) Standard 72D-1975. (See Section 9.10.1 for reference to code evaluations) An operator Information Management System (IMS) panel, installed in the Main Control Room, provides plant operators with the status of the system and its detectors. This operator IMS panel employs color graphics displays to indicate the current status of the system. Addressable smoke and heat detectors are utilized which allow the status of individual detectors to be available to plant operators and technicians. The detectors for each zone are connected to local multiplex panels; these multiplex panels are located throughout the plant and are connected via computer network back to the operator IMS panel. The multiplex network is a combination of Class A and B circuits as defined in NFPA 72D-1975. All detector zones on this system are supervised circuits.

Electronic programmable heat detectors combine the features of rate compensated/fixed temperature sensing and rate-of-rise temperature sensing. The rate-of-rise and rate compensated/fixed temperature features are independently configurable. Additionally, the fixed temperature setpoint is configurable. Configurable features are individually set for each detector through programming of the Fire Alarm Control Panel which monitors the detector.

Smoke detectors of the photoelectric type use a pulsed infrared LED light source and a silicon photoelectric receiver for smoke sensing. The sensitivity of the detector is user-selectable. The ability of this detector to sense smoke particles in the smoke chamber is not adversely affected by air flow. These detectors are also capable of detecting and compensating for environmental factors, such as dust and dirt.

The system provides fire detection coverage for the following areas:

1. Reactor Containment (Units 1 and 2)
    - Cable penetration area (includes thermal detectors)
    - Recirculation Air System ducts
2. Emergency Switchgear and Relay Rooms (Units 1 and 2)
    - Normal Switchgear Rooms (Units 1 and 2)
    - Cable Tray Room (Units 1 and 2)
3. Auxiliary Building
    - Charging pump cubicles general area
    - Charging pump cubicles exhaust ducts
    - Elev. 45'-10"
    - Elev. 27'-6"
    - Elev. 13'-0"
    - Elev. 2'-0" above the charging pump cooling water pumps
    - Solid Waste Drumming Room
    - S. E. and S. W. cubicle exhaust ducts
4. Containment Spray Pump House (Units 1 and 2)

- Upper Level
- Basement Level

5. Main Steam Valve House (Units 1 and 2)
6. Safeguards Building, Elev. 19’ 6” (Units 1 and 2)
7. Control Room Complex
8. Fuel Building, Elev. 6'-10"
9. Decontamination Building, vent system exhaust duct
10. Fire Pump Building
11. Mechanical Equipment Room 3
12. Battery Rooms 1A, 1B, 2A, 2B
13. Security CAS Building (includes thermal detectors)
14. Condensate Polishing Building - above MCCs
15. Boron Recovery Pump House
16. Technical Support Center
    - Main Area (includes one thermal detector)
    - HVAC Room
    - Battery Room
    - Electrical Room
17. Black Battery Building
18. Laundry Building (includes thermal detectors)
19. Cable Vault (Units 1 and 2)
    - Penetration Area
    - General Vault Area
    - MCC Room
20. Service Building Cable Tunnel (Units 1 and 2)
    - North South Cable Tunnel
    - East West Cable Tunnel
    - Service Building Cable Vault
21. Mechanical Equipment Room No. 5
22. AAC Building (includes smoke and thermal detectors)
23. Low Level Intake Structure (LLIS) Buildings

24. Mechanical Equipment Room 4 (Charging Pump Service Water Pump Room)

Two heat detectors have been installed in the charcoal filter of each unit in the gaseous waste disposal room of the auxiliary building.

The fire detection system is powered from normal station service distribution panels. On loss of power, an emergency 24V battery power unit supplies power to the detectors. The emergency power unit consists of a 24V battery, battery charger, a static inverter and an automatic switching control capability. Normal power is restored automatically following recovery from a loss of offsite power.

Upon actuation of an individual detector for a Fire Alarm Control Panel, an alarm signal is transmitted to the operator IMS panel in the control room, where the signal is visually annunciated by area and an audible alarm is initiated.

Activation of sprinkler and deluge extinguishing systems also annunciates an alarm (by area) on the operator interface panel in the control room. The CO_2 extinguishing systems also annunciate an alarm (by area) on the operator IMS panel. The Fire Alarm Control Panel and CO_2 extinguishing system at the Low Level Intake Structure alarm on the Operator IMS panel.

The fire detection and alarm system is electrically supervised. Trouble indication is initiated at the fire alarm control panels as well as the operator IMS panel in the event of loss of power, undervoltage, shorted/open circuits, or ground faults.

9.10.2.2 **Fire Control Systems**

9.10.2.2.1 Water Storage Tanks

Water for fire fighting is obtained from two 300,000-gallon water storage tanks each with 250,000 gallons reserved exclusively for the fire protection system, and 50,000 gallons in the upper portion of the tanks available for domestic water use. Each tank has a separate line to the suction header of the fire pumps located in the adjacent fire-pump house. The lines from the tanks to the suction header are equipped with isolation valves that can be closed to prevent both tanks from draining in the event of a leak. The tanks are supplied from two wells.

Backup water for fire protection can be obtained in an emergency from the two 300,000 gallon condensate storage tanks or by taking suction from the intake canal and discharging into the fire loop through a hydrant.

9.10.2.2.2 Fire Pumps

Individual 16-inch suction lines, adequately separated, are provided from each of the two water storage tanks to the fire-pump house, which is situated adjacent to the tanks. Two horizontal shaft, centrifugal fire pumps are installed in the pump house, each with a design capacity of 2500 gpm at a total dynamic head of 231 feet (minimum). One of the fire pumps is diesel-engine-driven and is supplied from a 460-gallon fuel tank that is capable of supplying the unit for over 8 hours of running time. The second fire pump is electric-motor-driven, with power supplied from the normal plant electrical system.

The firewater system is normally pressurized by a 30-gpm pressure maintenance pump and hydropneumatic tank that is automatically cycled to maintain 100 to 110 psig. The motor-driven and diesel-driven pump operate automatically and sequentially. The motor-driven pump will start automatically when the fire main pressure drops below 89 psig. A further drop of pressure in the fire water system will automatically start the diesel-driven fire pump. The diesel-driven fire pump will also start automatically upon a loss of ac control power. Both fire pumps may be manually started from the control room. The status of the fire pumps is indicated in the control room and at the fire pump control panels in the pump house. There are no safety-related cables or equipment in the fire-pump house.

The fire pumps and their ancillary equipment are adequate to deliver the required quantities and pressures of water to the fire protection systems.

The adequacy of the arrangement of the equipment within the fire-pump house is addressed in Section 9.10.4.24.

9.10.2.2.3 Firewater Piping System

The underground yard main system encircling the plant is supplied by two 12-inch lines from the fire-pump house, and is provided with isolation valves at the juncture, enabling either or both fire pumps to discharge into either line supplying the yard main loop.

All yard fire hydrants, automatic suppression systems, and interior fire-hose lines are supplied from the fire main yard loop. Post indicator sectional valves are provided on the loop to permit isolation of sections of the loop without interrupting service to the entire loop.

Fire hydrants with hose houses are provided approximately 250 feet apart around the exterior of the plant. Each hose house contains an inventory of fire-fighting equipment (hose, nozzles, adapters, wrenches, portable lights, etc.), and the doors generally are secured by breakable locks. Hose houses are set on concrete pads to prevent water accumulation and are clear of obstructions to opening properly. The area around the houses is maintained clear of objects that could block access or inhibit the extension of hose during fire-fighting evolutions.

Frostproof hydrants with 6-inch barrels with at least two 2.5-inch hose outlets are connected to the yard loop with 6-inch lead-ins from the yard main loop. A block valve is provided in the line to the hydrant that branches from the auxiliary building fire main feeder. This will allow servicing this hydrant without closing down part of the yard loop. This is the only hydrant for which closing down a portion of the yard loop would interrupt suppression capability to safety-related areas or areas posing a potential hazard to safety-related areas.

Threads on each of the hydrant outlets are compatible with the local fire department hose threads, and the guard posts provide acceptable protection to the hydrants against vehicular traffic.

9.10.2.2.4 Interior Fire Hose Stations

Manual hose stations are located throughout the plant.

Most areas of the plant containing safety-related equipment can be reached by hose stations. Hose stations in the turbine building have sufficient hose to cover all areas of the switchgear rooms and are equipped with nozzles suitable for extinguishing electrical fires. All locations on the 29 ft. 6 in. elevation of the turbine building can be reached by a maximum of 100 feet of 1.5-inch hose from an interior hose station.

The auxiliary building is protected by interior hose stations. To increase reliability, the auxiliary building fire hose system was modified so that the fire hose stations could be supplied from either Unit 1 or Unit 2 turbine building fire suppression headers, in addition to its normal supply from the yard fire main loop. The turbine building hose station at the entrance to the cable tray rooms has sufficient hose to reach all areas of both cable tray rooms and both mechanical equipment rooms. The hose rack outside the cable tray rooms is equipped with a fog-type nozzle suitable for electrical fires. The auxiliary building hose system can also supply, at a reduced flow, the auxiliary building general area exhaust filters should the normal supply from the Unit 1 and 2 turbine building fire protection loop fail.

The reactor containment of each unit is protected with normally dry interior hose stations. The fire hose standpipe system may be filled by opening manual valves in the auxiliary building piping penetration areas.

9.10.2.2.5 Water Suppression Systems

Automatic sprinkler systems are installed at the following areas:

1. Turbine Building, Ground Floor and Mezzanine Levels
2. Turbine Oil Storage Room
3. Auxiliary Boiler Room
4. Portions of the Service Building (Renovated Personnel Areas, Maintenance Services Offices, etc.)
5. Condensate Polishing Building
6. Machine Shop Building
7. Laundry Building
8. Station Warehouse
9. Construction Clean Change Building

10. New Training Center Building
11. Southeast extension of Simulator Building
12. On-line Chemistry Monitoring Computer Room (Pre-action system with smoke detectors)
13. AAC Building (includes smoke and heat detectors)
14. Turbine Deck Security Office (TDSO)

A manually activated sprinkler system is installed in each unit's Service Building Cable Vault and Tunnel. This system has open heads for protection of cable trays in the high ceiling upper level of the Vault, and closed heads for floor coverage in the lower area of the Vault. Manually initiated deluge systems are provided at the lube-oil reservoir coolers, hydrogen seal oil units, and the turbine lube-oil conditioners. Automatic heat-actuated deluge systems are provided at the main and service transformers and at the auxiliary building charcoal filter 1-VS-FL-14. Heat collector plates are installed per NFPA requirements over sprinkler heads under grating walkways in the turbine building.

The design and installation of these systems conform to the provisions of the National Fire Protection Association Standards 13 and 15. (See Section 9.10.1 for reference to code evaluations) In general, sprinkler and deluge systems have been provided at major concentrations of hazardous combustibles.

Electrical supervision of all automatic fire suppression systems is provided. In the event that any isolation valve in a sprinkler or deluge system is less than fully open, a control room annunciator and a local indicator are actuated. No electrical supervision is provided for normally closed valves in the fire water system.

9.10.2.2.6 Foam Extinguishing Systems

The aboveground steel fuel-oil tank in the yard is provided with a foam fire suppression system capable of applying foam to the surface of the liquid within the tank. Equipment consists of a foam-making eductor, piping to the tank, and supplies of AFFF-type foam concentrate. Adequate supplies of foam are kept on hand.

9.10.2.2.7 Carbon Dioxide Gas Suppression Systems

Low-pressure fixed carbon dioxide suppression systems utilizing a central storage tank capable of two applications are provided at the following areas:

1. Switchgear room, Unit 1.
2. Switchgear room, Unit 2.
3. Service building cable vault, Unit 1.
4. Service building cable vault, Unit 2.
5. Containment cable vault, Unit 1.

6. Containment cable vault, Unit 2.
7. Cable tray rooms, Unit 1.
8. Cable tray rooms, Unit 2.
9. Charcoal filter assembly A.
10. Charcoal filter assembly B.
11. High-pressure turbine bearing enclosure, Unit 1.
12. High-pressure turbine bearing enclosure, Unit 2.
13. Low-pressure turbine bearing enclosure, Unit 1.
14. Low-pressure turbine bearing enclosure, Unit 2.
15. Generator bearing enclosure, Unit 1.
16. Generator bearing enclosure, Unit 2.
17. Emergency generator room 1.
18. Emergency generator room 2.
19. Emergency generator room 3.
20. Motor control center room, Unit 1.
21. Motor control center room, Unit 2.

There are also three separate high-pressure carbon dioxide extinguishing systems utilizing agents stored in cylinders located adjacent to the point of application. These systems protect the fuel-oil pump houses A and B, the emergency service water pump house at the low-level intake structure, and the Technical Support Center (TSC) charcoal filter. The system that protects the charcoal filter in the TSC area is not required for safe shutdown.

The low pressure and high pressure CO_2 systems are provided with heat detectors and with remote manual pull stations. CO_2 systems for Charcoal Filter Assemblies 1-VS-FL-3A and B for Emergency Generator Rooms 1, 2, and 3 are manual systems only, so heat detectors for these two areas provide an alarm only. The CO_2 systems in other areas are actuated by heat detectors. Hand valves on the discharge heads of the high-pressure cylinders or manual activation switch provide manual release of the carbon dioxide gas.

For the high pressure systems, emergency electric power is provided by rechargeable batteries. The battery charger transfer module maintains the batteries at full charge and provides the means of automatically supplying 24V dc emergency power to the system during main power outages.

Areas protected by automatic discharge systems are equipped with predischarge alarms to alert personnel that carbon dioxide flooding is imminent. Carbon dioxide lockout control for personnel protection is installed for the switchgear rooms, cable tray rooms, and service and containment cable tunnels, intake structure and fuel oil pumphouse. Actuation of a system lockout switch will initiate an alarm on the main control board and at the carbon dioxide system control panel.

All ventilation system fans in the Low Pressure CO_2 Fire Protection System protected areas are stopped and the area open doors are closed upon initiation of the CO_2 discharge. All ventilation and fire dampers that are required for CO_2 retention are closed upon initiation of the CO_2 discharge in the affected area.

9.10.2.2.8 Portable Fire Extinguishers

Fire extinguishers are installed and are maintained in accordance with NFPA 10 and 10A. (See Section 9.10.1 for reference to code evaluations)

9.10.2.2.9 Halon 1301 Systems

Total flooding, Halon 1301 (bromotrifluoromethane) systems are provided for the following areas:

1. Emergency Switchgear and Relay Room, Unit 1 (manual)
2. Emergency Switchgear and Relay Room, Unit 2 (manual)
3. Training Center Building
   a. Computer Room of the Simulator Control Room
   b. Simulator Area
   c. Computer Room in Southeast extension of Simulator Building
4. Under-floor area of the main Security Building

The Emergency Switchgear and Relay Rooms contain equipment required for safe shutdown. The Halon systems for these rooms are described in detail below.

The Halon 1301 System for the Unit 1 and 2 emergency switchgear rooms is a total flooding system (will fill entire enclosure for Unit 1 or Unit 2). Each unit's Emergency Switchgear Room is considered a separate hazard area. The systems are manually operated.

The main bank of Halon storage bottles for each Unit's Emergency Switchgear Room Halon system is located outside the hazard area. The reserve cylinders may be manually connected once the main bank is exhausted if required. The system has been designed in accordance with the requirements of NFPA 12A. (See Section 9.10.1 for reference to code evaluations)

The initial discharge will be completed within seconds and will attain the design concentration level in the protected space. A subsequent discharge will occur to make up for the reduction in Halon concentration due to leakage or dilution by ventilation. The concentration of Halon in air will be maintained for a minimum of 10 minutes. Factors such as uncloseable openings, time required for dampers to close, and general tightness of enclosure have been taken into consideration.

Nozzles have been placed to provide a uniform level of concentration throughout the rooms.

The manual discharge switches are provided outside each protected area. The Unit 2 switch is located near the main entrance to the Unit 2 Emergency Switchgear Room, and the Unit 1 switch is located in Unit 2 Emergency Switchgear Room near the entrance to Unit 1. One push button for each system is also provided in the Control Room Halon Control Panel. Operation of the manual discharge switches causes immediate activation of horns, warning lights, shutdown devices (such as fire dampers) and the pre-discharge timer, which delays system activation for 60 seconds to allow for the exiting of personnel from the ESR before discharging Halon into the room.

In the event of loss of normal power, the control panel will provide battery backup to operate the panel under normal load for 24 hours and then be capable of operating the system for five minutes continuously during an alarm condition.

Both the supply air and exhaust air ducts leading from the Emergency Switchgear Rooms are isolated from the rest of the plant by automatic closing of the fire dampers located in these ducts where they penetrate the ESR enclosure. The recirculating HVAC system will remain in operation to help provide for continual mixing of Halon within the enclosure. Air movement patterns, ceiling configuration and equipment configuration have all been taken into consideration in locating the discharge nozzles.

The Halon 1301 Fire Suppression System is not required to operate during or after a seismic event but portions of the system are seismically supported to prevent possible damage to surrounding safety-related equipment.

The existing structures which interface with the Halon System have been reviewed to ensure that the addition of the Halon System does not have any adverse impact on the seismic qualification of the existing structures, systems, or other components important to safety.

The Emergency Switchgear Rooms (ESRs) are required to meet the requirements of Section III.G.3 of Appendix R. Section III.G.3 requires fire detection and a fixed fire suppression system be installed in the area under consideration. Manually actuated Halon fire suppression systems were installed in the ESRs as part of the modification made to comply with Appendix R. The system design was based on NFPA 12A (Reference 1), and in accordance with paragraph 1-8.1.1, the system can be manually actuated if acceptable to the authority having jurisdiction.

Based on discussion in Generic Letter (GL) 83-33 (Reference 2), the Halon system installed in the ESRs meets the requirements of a fixed fire protection system as required by III.G.3, in contrast to Section III.G.2 which requires an automatic fire suppression system. The installation of a manual Halon system is in accordance with NFPA 12A, 1980 edition. The Halon system meets the definition of a fixed fire suppression system as described by GL 83-33 and the Halon system is expected to extinguish a fire in the ESRs as concluded in NUREG/CR-3656 (Reference 3). In addition, the NRC's Inspection Report (IR) (Reference 4) addressed implementation of 10 CFR 50 Appendix R Sections III.G, III.J, III.L, and III.O at Surry. The IR acknowledged the fixed manual Halon system in the ESRs and concluded the fire area barriers and the fixed detection and suppression systems provided for these areas appear adequate. The ESRs are located beneath the control room thereby providing for prompt response from operations in the event of an alarm allowing the Halon system to be activated with minimal delay.

The Individual Plant Examination for External Events (IPEEE) submittal addressing fire (Reference 5) established an acceptable CDF without taking any credit for detection and suppression of fires in the ESRs. Since the ESRs comply with Section III.G.3, the units can be safely shutdown even in the event of a complete loss of the area. From an IPEEE perspective, the existence of detection and a fixed suppression system in the ESRs provides additional protection, which if modeled in the IPEEE, would result in an even more acceptable CDF.

9.10.2.3 **Ventilation Systems**

9.10.2.3.1 Smoke Removal

No special smoke-exhausting systems are provided at the plant. The normal ventilation systems can be used for smoke removal for some types of fires, even though they are not specifically designed for this purpose.

When normal ventilation systems cannot be used, the fire brigade will use portable ventilation units with flexible ducting for smoke removal.

9.10.2.3.2 Filters

Charcoal filters are used in the auxiliary building ventilation system filters, the Technical Support Center (TSC) ventilation system, the containment iodine charcoal filter units, the gaseous waste disposal system, and the control room emergency ventilation system. The auxiliary building ventilation system contains redundant safety related trains of charcoal filters housed in separate metal cabinets enclosed in separate concrete cubicles. The inlet and outlet dampers on these filter units can be shut to prevent radiation release from a damaged unit and the redundant unit can continue to operate. These units are currently protected by a manually actuated carbon dioxide suppression system. The auxiliary building ventilation system also contains a third, nonsafety-related charcoal filter housed in a separate enclosure. The third charcoal filter unit is protected by an automatic water spray system. The TSC charcoal filter unit is located in the service building in a concrete vault. It is protected by a heat detector system and a carbon dioxide system which may be either automatically or manually operated. The containment iodine charcoal filter units are enclosed in separate structures with 18-inch-thick concrete walls and roof. A fire in the containment iodine or TSC charcoal filter units would have no direct effect on safety-related equipment or cables because of the intervening distance and barriers. The gaseous waste disposal system charcoal filters are housed in a metal enclosure away from safety-related equipment and cables. These filters have heat detectors and can be isolated and air-cooled if subjected to excessive decay heating. The control room emergency ventilation system charcoal filters are located in the turbine building in a metal enclosure. These filters are isolable from the control room by a normally shut motor-operated damper in the supply pipe to the control room. The only safety-related cable located near the control room emergency ventilation charcoal filter is the power feed to the respective fan motor; therefore, a fire would not affect safe shutdown of the plant.

9.10.2.3.3 Breathing Equipment

There are at least 25 self-contained air-breathing apparatuses (SCBAs) dedicated at all times to fire brigade use. There are in excess of 50 spare air cylinders, rated at 30-minute capacity, available in the plant. Self-contained units are distributed at various locations throughout the plant, with five sets kept at the control room. The use of SCBAs for fire fighting is discussed in Section 11.1.

Air recharging for the fire brigade cylinders is from a twenty-cylinder cascade system that is recharged by an air compressor designed for that purpose. Recharging is carried out in the loss prevention storage room in the service building.

9.10.2.4 **Floor Drains**

In general, measures have been taken to prevent the spread of combustible liquids in the event of leakage from reservoirs and piping. The lube-oil reservoir, lube-oil cooler, and high-pressure control fluid reservoir for each unit are located in a diked area. The only floor drain is isolated by a locked-closed valve. The hydrogen seal oil unit is surrounded by a spillage trench to prevent the spread of lube oil. The two lube-oil storage tanks are located together in a diked area without drains. The fuel tank for the diesel-driven emergency service water pumps is located in a separate diked room, without floor drains. The lube oil conditioning unit and transfer pump for each unit are located in a diked area without floor drains. The wall tank portions of the emergency diesel generator day tanks are each located in a diked area without floor drains. Drains in the diesel generator rooms outside the dikes are plugged and dikes are provided at the doorway to each room. The diesel driven fire pump is located in a diked room and the floor drain is plugged.

Dikes have been provided at all doorways into the emergency switchgear rooms to prevent equipment damage due to water or combustible liquid flooding from adjacent areas. (See Section 9C.1.1.) A 3-inch dike has been provided between Units 1 and 2 emergency switchgear rooms to prevent possible fire protection water in one unit from flooding the adjacent unit. A deflector shield has been placed by the overhead fire main near the entrance to the emergency switchgear room in the turbine building to cause possible leakage flow to be diverted outside the dike (Section 9C.1.2).

Two foot high dikes are erected at the entrances to the charging pump cubicles to prevent pump damage from a transient combustible liquid spill or from possible fire protection leakage (Section 9C.1.2). These measures are adequate to contain leakage to the area of origin.

9.10.2.5 **Lighting Systems**

In addition to the normal plant lighting system, fixed emergency lighting is provided in the control room and at points of access and egress in the containment, auxiliary building, turbine building, and service building.

A fire could damage both normal and emergency lighting for any area of the plant. To deal with such a situation, emergency lanterns are provided. In addition, several portable emergency lanterns are provided for the exclusive use of the fire brigade.

A post-fire emergency lighting system has been provided for illumination of all areas needed for operation and/or monitoring of safe shutdown equipment, and to assure access/egress routes thereto, after a postulated fire in any area in accordance with the requirements of 10 CFR 50 Appendix R, Section III.J. The capacity of the installed emergency lighting is 8 hours. See Section 8.4.5 for further discussion of lighting systems.

9.10.2.6 **Communications System**

Reliance is placed primarily on the in-plant telephone system and a loudspeaker page and answer system for normal communications. In addition, a voice-powered telephone system is provided that uses voice-powered headsets and phone jacks installed throughout the plant. Due to loud background noise and the potential for fire damage such fixed systems are not always effective for fire-fighting operations. To overcome these problems, several fixed handsets or portable two-way radios are provided in the control room, the security building, and the Appendix R locker. One or more brigade members would take a two-way radio on the way to the fire scene.

To meet the requirements of 10 CFR 50 Appendix R, an emergency radio communication system is installed. The system provides total plant wide coverage.

There are two redundant radio transmission sites which simultaneously broadcast: the Primary Site in the station switchyard and the Secondary Site in the Unit 2 cable spreading room. Each radio site includes repeaters, antenna and network communication equipment and is capable of trunked radio operation.

Redundant antenna trains with amplifiers are installed throughout the Auxiliary Building and inside both containment structures to improve radio coverage. The Unit 1 communications system amplifier is located in the Auxiliary Building, and the Unit 2 amplifier is located in the Unit 2 Cable Tray Room.

The location of system equipment is such that a postulated fire in any one area would only destroy one system.

The communication system also consists of fixed handsets, and mobile and portable handheld units.

Also, additional portable mobile satellite phone equipment is available for offsite communication during a beyond design basis (BDB) event.

Dedicated system pagers are used to call out emergency personnel. Radio desksets used in the control room have telephone interconnects that allow notification of the pagers. A backup paging telephone utilizing a different telephone line is located at the Unit 1 Auxiliary Shutdown Panel.

9.10.2.7 **Electrical Cable**

The cable insulation used for power and control circuits consists primarily of cross-linked polyethylene with neoprene or hypolon jacket. Power circuits for some large components use interlocked armored cable. The flame test standard for cables, Institute of Electrical and Electronics Engineers Standard 383-1974, was not in effect at the time these cables were purchased and installed. However, 5000V and 6000V power cables were tested in accordance with IPCEA Standard 5-19-81, and 1000V control cables and 600V instrument cables were tested in accordance with ASTM D2633. In addition, control and instrumentation cables were required to pass a special flame resistance test detailed by Vepco in the purchase specifications. Based on the results of these tests, flame retardant coatings are not necessarily used on cables installed in the plant. Specifications for cables added in cable trays in recent years since the approval of IEEE 383 have required that the cable meet IEEE 383-1974, unless an evaluation is performed, documented and approved by Engineering.

9.10.2.8 **Fire-Barrier Penetration**

Fire barriers such as walls, floors, and ceilings are penetrated by ventilation ducts, electrical raceways, mechanical piping systems, and doors.

Electrical cable penetrations in fire barriers surrounding safety-related areas throughout the plant are sealed using materials and methods that have been tested by Vepco to verify their effectiveness as a fire barrier. The fire test for penetration seals, as described by Vepco in a fire hazards analysis, utilized a gas burner as a flame source. The test on each specimen was conducted for 3 hours or until flame or hot gases, hot enough to ignite cables, penetrated the top of the sealing material. The test verified that penetration seals meet NRC Branch Technical Position APCSB 9.5-1.

New penetration seals are made using silicone foam or other Engineering approved fire stop material with a 3-hour fire rating. The fire stop material may be used in conjunction with an approved permanent damming material, or in conjunction with temporary damming materials which are removed.

All doors which penetrate fire barriers required for 10 CFR 50 Appendix R are fire-rated. (See Section 9.10.1 for reference to engineering evaluations) These fire doors are labeled by

Underwriter's Laboratories or are addressed in the 10 CFR 50 Appendix R Report, Chapter 7, Exemption Requests, Engineering Evaluations, and Fire Retardant Cable Characteristics.

Most doors to areas containing significant amounts of combustible material are controlled by a magnetic key card locking device to ensure that they remain closed. Leaving one of these doors open results in an alarm in the security building control room. All members of the fire brigade are provided with magnetic key cards. In addition, keys readily available to security members of the fire brigade can be used to open doors if the magnetic latching mechanism is inoperative and the door failed in the locked position.

As in the case of electrical penetrations, ventilation duct and pipe penetrations have been sealed using methods that are considered adequate for most areas of the plant.

9.10.2.9 **Separation Criteria**

In most cases, redundant safety-related system components (e.g, pumps, diesel generators) are separated by distance or barriers. Cables of redundant safety-related divisions installed in the same area are separated using:

1. Rigid metal conduit (following separate routes where practical).
2. Trays one above the other without barriers when the trays are more than 4 feet apart.
3. Trays one above the other with barriers or tray covers when the trays are 4 feet or less apart.
4. Trays side by side with barriers.

Solid metal tray covers or equivalent have been provided on all cable trays where the separation of redundant safety-related cables does not meet the guidelines of Regulatory Guide 1.75 in the following areas: emergency switchgear rooms, cable vault and tunnels, cable tray spreading rooms, and auxiliary building. Also, solid metal tray covers or equivalent have been provided on cable trays in the reactor containment building cable penetration area. A barrier consisting of a fire resistive material has been provided between cable trays in the safeguards area where the separation does not meet the guidelines of Regulatory Guide 1.75.

Equipment and cable that is required for safe shutdown following a fire is identified in the 10 CFR 50 Appendix R Report, Chapter 3, *Safe Shutdown Systems Analysis,* and Table 9-2 of Chapter 9, *Electrical Associated Circuits & Separation Analyses,* respectively. Physical and electrical separation is provided between redundant or alternate shutdown components as described in 10 CFR 50 Appendix R Report, Chapter 4, Chapter 7, and Chapter 9.

9.10.2.10 **Fire Barriers**

Most of the Appendix R fire barriers in the plant are concrete or block with 3-hour fire resistance, or have evaluations that demonstrate equivalence to a 3-hour rating.

9.10.2.11 **Access and Egress**

All safety-related areas except the safeguards areas, service building cable vaults, fuel-oil pump houses, reactor containment buildings, and intake structure are reasonably accessible for manual fire fighting. Components within the safeguards area are adequately separated such that an increased response time from the fire brigade will not delay safe shutdown of the plant. A manual sprinkler system has been added in the service building cable vault such that the need for manual fire fighting is minimized. The fuel-oil pump houses are adequately protected by fixed suppression systems. During normal operation the containment is sealed, and special procedures are followed to gain access through a personnel air-lock. Since the intake structure is located 1.25 miles from the plant buildings, fire-fighting personnel and equipment must be transported to the intake structure. See Section 8.4.5 for discussion of features of the post-fire emergency lighting system which assures access and egress in accordance with the requirements of 10 CFR 50 Appendix R.

9.10.2.12 **Toxic and Corrosive Combustion Products**

The products of combustion of many polymers are toxic to humans and corrosive to metals. Prompt fire detection and extinguishment are relied on to minimize the quantity of such products. Additionally, means for smoke removal are provided as discussed in Section 9.10.2.3.1. The fire brigade is also provided with and trained in the use of emergency breathing apparatus for manually fighting fires involving such materials.

9.10.3 Evaluation of Plant Features

There are several combinations of safe-shutdown systems available in either unit that are capable of shutting down the reactor and cooling the core of either unit during and subsequent to a fire. The combinations available in a fire shutdown will depend upon the location of the fire and the effects of the fire on such systems, their power supplies, and their control stations. To ensure the safe shutdown of the reactor plants, those systems and components which insert negative reactivity into the reactor core, control cooldown of the primary reactor coolant system, and maintain reactor coolant inventory should be protected in the event of a fire, and measures should be taken to ensure their availability.

The general functional requirement for safe shutdown, and the system auxiliaries, major components, and instrumentation required to fulfill these requirements are described below.

9.10.3.1 **Reactivity Control**

The rod control system is of a fail-safe design. Faulting in the system circuits trips the reactor. Following the reactor trip, soluble poisons are added to the primary coolant system to ensure subcriticality. This is accomplished by using a charging pump to inject borated water from the boric acid system, if available, or from the refueling water storage tank into the reactor coolant system. There are three charging pumps per unit, one of which is required for reactivity control. In addition, a charging system cross-connect is installed to allow the use of the opposite unit's charging pumps for cooldown following an accident (Section 9.1.3.1).

In providing reactivity control, the boric acid solution is transferred from the boric acid tanks by the boric acid transfer pumps to the suction of the charging pumps. Alternatively, borated water can be supplied directly to the suction of the charging pump from the refueling water storage tank of either unit. Normally, operation of the charging pump requires operation of the charging pump cooling water and service water systems. The charging pump cooling water system provides a source of cooling for the charging pump mechanical seals. This system is cooled in turn through a heat exchanger by the charging pump service water system. The charging pump service water system also provides cooling directly to the charging pump lube-oil cooler. In the event of a fire, the charging pump cooling water system is not required for safe shutdown (since the charging pump suction would be from the cold water in the RWST), but the charging pump service water system is required for hot and cold shutdown as explained in the 10 CFR 50 Appendix R Report, Chapter 10, Engineering Evaluations.

9.10.3.2 **Reactor Coolant System Inventory Control**

Following a reactor shutdown or trip, the reactor coolant system water inventory is maintained by operation of the charging pumps. Reactor primary-grade water is added with boric acid solution to provide makeup for normal primary system leakage and shrinkage. The primary-grade water is transferred from the primary-grade water tanks by the primary-grade water supply pumps to the blender, located on the discharge of the boric acid transfer pumps. The primary-grade water supply pumps are not safety-related, and in the event of a loss of offsite power that would disable these pumps, the refueling water storage tanks would be used as the source of makeup water. Primary coolant letdown may be isolated, and the charging pump can be operated to maintain pressurizer level, which would otherwise decrease due to coolant contraction during cooldown. Operation of the reactor coolant letdown systems is not required to maintain pressurizer level, however an alternate means of reactor coolant letdown can be used as noted in Section 9.10.3.3. During normal operation, the charging pumps will provide reactor coolant makeup through the normal charging path and through reactor coolant pump seal injection. As part of establishing stable RCS flowpaths during certain fire scenarios, the reactor coolant pump seal injection is isolated on the fire affected unit, and charging flow is established through the normal charging flowpath, the High Head SI to Cold Legs flowpath, or the Alternate High Head SI to Cold Legs flowpath.

During normal operation, seal injection flow from the chemical and volume control system is provided to cool the reactor coolant pump seals, and the component cooling water system provides flow to the thermal barrier heat exchanger to limit the heat transfer from the reactor coolant to the reactor coolant pump internals. In the event of loss-of-offsite power, the reactor coolant pump motor is de-energized and both of these cooling supplies are terminated; however, the diesel generators are automatically started and seal injection flow is automatically restored within seconds. Component cooling water to the thermal barrier heat exchanger, however, must be manually reinitiated. Either of these cooling supplies is adequate to provide seal cooling and prevent seal failure due to loss-of-seal cooling during a loss-of-off-site power for at least 2 hours.

Appendix R requires the plant with fire damage to reach hot shutdown immediately and cold shutdown within 72 hours in Appendix R III.G.3 areas. Documentation was provided by the seal vendor (Flowserve) that shows that no additional seal leakage (other than Controlled Bleed-Off flow) would occur over the 72 hour Appendix R scenario duration.

9.10.3.3 **Decay Heat Removal**

Following a normal plant shutdown, the condenser steam dump system bypasses steam to the condenser to provide cooldown. If the condenser steam dump is not available, power operated relief valves on the main steam lines will provide cooldown by relieving main steam to the atmosphere. These power operated relief valves are backed up by code safety valves on each steam generator. For decay heat removal following a reactor trip, it is necessary only to maintain control of one steam generator. For the continued use of the steam generator for decay heat removal, it is necessary to provide a source of water and means of delivering that water. The auxiliary feedwater pumps (two motor-driven pumps and one turbine-driven pump per unit) are provided to deliver the water. The power and control cables for these pumps are located in the same fire zone at a number of points (i.e., containment spray, auxiliary feedwater, and main steam valve area, and the emergency switchgear and relay rooms). A fire in one of these areas could disable all three auxiliary feedwater pumps of a given unit; however, in the event of such a fire, there exists the alternative of providing auxiliary feedwater from the opposite unit. Since these cross-connect valves are not located in an area that would be affected by a fire that could damage the auxiliary feedwater pumps or cables for one unit, the auxiliary feedwater pumps of the opposite unit would be available to supply water to the steam generator being used for decay heat removal. A fire in one of these areas could disable remote operation of all three power operated relief valves on the main steam lines of a given unit. However, in the event of such a fire, there exists the alternative of locally operating the power operated relief valves using a portable air source and quick-connect instrument fittings provided at the valves.

For cooldown of the reactor coolant to a temperature of less than 200°F, the residual heat removal system is used. The residual heat removal system consists of redundant heat exchangers, pumps, and associated piping, valves, and instruments. A QA Category II, Seismic Class 1 radiant energy shield is installed between the residual heat removal pump motors to protect one of the two motors in the event of a motor fire. This shield ensures that at least one residual heat removal pump is available for the safe shutdown of the unit. A post-fire repair will be used to restore power to the RHR pump motors in the event a fire disables both pump’s cables or power supplies.

Adequate subcooling can be maintained by cooling the reactor coolant system faster than the pressurizer is being cooled and depressurized by ambient heat without the use of pressurizer heaters. Loss of pressurizer heaters would only accelerate plant cooldown. The resultant cooldown rate would be within Technical Specification limits.

To insure compliance with 10 CFR 50 Appendix R for providing plant cooldown capability following a postulated fire, certain valves in the chemical and volume control system, the residual heat removal, and the component cooling water system are required to be functional in order to provide an alternate means of reactor coolant letdown, pressurizer pressure control, and decay heat removal. These valves, which are identified in Section 9.1.2.1, 9.3.2.1, and 9.4.3.1, are equipped with quick-disconnect instrument air fittings so that they may be operated locally with a portable air source.

9.10.3.4 Auxiliaries

Auxiliaries required for safe shutdown include the component cooling system, the service water system, the circulating water system, certain ventilation systems, and appropriate instrumentation and power supplies. Multiple outside sources of power are available to the plant for both normal operation and shutdown functions. Normal operations may utilize either offsite or unit-generated power. The power supplies to redundant safe shutdown equipment are electrically separated. Emergency diesel generators supply power for shutdown operations when offsite or unit-generated power is not available.

The fuses supplying 125V dc control power to the safety-related 4160V and 480V circuit breaker close and trip circuits are sized to provide electrical coordination between the fuses and the feeder and load breakers. The original fuses were replaced by smaller fuses to eliminate the possibility of causing the loss of the 4160V or 480V switch gear control circuitry. This modification assures availability of power sources to safe shutdown equipment in accordance with 10 CFR 50 Appendix R.

The component cooling water pumps may be cross connected to serve either unit. Component cooling water system operation is not required for hot shutdown.

The circulating water and service water systems are required for cold shutdown in order to supply cooling to certain safe shutdown components such as the component cooling water heat exchangers, and the air conditioning and chilled water condensers.

Ventilation is required for several areas of the plant during safe shutdown operations in order to protect electrical equipment from heat damage and allow access for operator actions (such as in the control room, emergency switchgear room, and auxiliary building).

9.10.3.5 Instrumentation and Control

An auxiliary shutdown panel located in each emergency switchgear room has control switches for the following functions:

1. Emergency boration valve.
2. Auxiliary feedwater pumps and associated discharge valves.
3. Charging pump.
4. Pressurizer heaters.

Complete electrical isolation from the Control Room is provided for those circuits on the auxiliary shutdown panels which are required for safe shutdown. Appendix R isolation panel

(AS-2) is located in MER-5. In the event the control room becomes uninhabitable, chillers 1-VS-E-4D and 4E control power can be locally controlled.

The Remote Monitoring Panels, located in the Unit 1 Cable Spreading Room, have vital process instrumentation for both Units 1 and 2. Cabling for this instrumentation is independent of the cabling for similar instrumentation in the Control Room. (See Section 7.7.2.)

Emergency Condensate Storage Tank Level can be monitored via indication on the tank. Refueling Water Storage Tank Level is not required to be monitored during safe shutdown following a fire (see NRC’s Safety Evaluation dated 2/25/88 regarding exemption requested).

9.10.3.6 **Effects of Fire Suppression Systems on Safety Systems**

The following effects have been reviewed: (1) breaks in fire protection piping that may result in water flooding damage to safety-related equipment; (2) cracks in fire protection piping that may result in water spray damage to safety-related equipment, or that may impair suppression capability of both primary and backup means of suppression; and (3) inadvertent fire protection system actuation that may result in damage to safety-related equipment.

In most areas, curbs, drains, and the mounting of equipment above the floor level minimizes the potential for flooding damage. In other areas, water will drain out doors or via stairways or through grating to lower elevations, so that the standing water would not affect safety-related equipment. In addition, valves have been provided to isolate sections of piping inside buildings to preclude the buildup of water and thus prevent equipment from being incapacitated due to flooding.

Water flows from automatic fire suppression systems are annunciated on the fire panel in the control room. Flow from manual hose stations is not annunciated but will cause the fire pump to start, thereby transmitting a “fire pump running” signal to the control room. A flow from the fire protection water system can thus be inferred.

There is some safety-related equipment in various areas of the plant that would be vulnerable to the effects of water spray. There are, however, no fixed water suppression systems in these areas.

9.10.4 Evaluation of Specific Plant Areas

9.10.4.1 **Control Room Complex**

The control room complex is an area approximately 52 feet by 104 feet located at grade level adjacent to the turbine building, between the turbine building and the auxiliary building. The complex consists of the control room, the control room annex, office area and toilet, the Unit 1 and Unit 2 control room air-conditioning equipment rooms, and the Unit 1 and Unit 2 computer rooms.

The only spaces within the control room complex that contain safety-related equipment are the separate Unit 1 and Unit 2 control room air-conditioning rooms, and the single control room that serves both units. Each air-conditioning room contains two 100%-capacity air-handling units for the control room complex. The control room is a continuously manned station that contains all of the instrumentation and control equipment necessary to operate the plant under both normal and abnormal conditions. This equipment includes the redundant control cables, indicating instruments, and control switches used to trip the reactor and to maintain it in a safe-shutdown condition.

An auxiliary shutdown panel located in each emergency switchgear room contains control switches to facilitate shutdown in the event of damage to control room equipment or a forced evacuation of the control room. A remote monitoring panel located in the Unit 1 Cable Tray Room contains process instrumentation to facilitate safe shutdown, and emergency diesel generators No. 1 and No. 2 are provided with local control panels which are electrically isolated from the Control Room. These and other features provide an alternative safe shutdown capability in the event of a fire in the Control Room in accordance with 10 CFR 50 Appendix R. The residual heat removal pumps and the component cooling water pumps are normally controlled from the control room. In the event of a control room evacuation the pumps for both systems can be operated at the switchgear in the emergency switchgear room. See Section 7.7.2 for discussion on compliance with 10 CFR 50 Appendix R. Other modifications made as a result of 10 CFR 50 Appendix R requirements provide the operator with the capability of manually closing the main steam line trip valves from either the control room or the emergency switchgear room. The steam generator power operated relief valves can be closed using key-operated switches located in the unit's cable vault or the valve positioner controller located in the MCR. These redundant controls allow valve closure in the event that one of the control methods has sustained damage due to a fire or the area where the control is located must be evacuated. See Section 10.3.1.2 for additional discussion of this modification which is in accordance with 10 CFR 50 Appendix R requirements.

The combustible material in the control area consists of a moderate amount of electrical cable insulation, parts of electrical components in panels and consoles, desktops on the SRO console and Plant Computer System consoles, parts of computer terminals, carpeting, anti-fatigue flooring, and a moderate amount of Class A combustibles such as log books, drawings, operating procedures, and computer printouts.

The control room complex is bounded on all sides by concrete, which provides a 3-hour-rated fire barrier. Ventilation ducts that penetrate the boundaries are provided with fire dampers. The south wall of the complex, adjacent to the turbine building, contains emergency ventilation ducts constructed of heavy-gauge pipe which may be sealed by motor-operated dampers controlled from the control room. Closure of these dampers will provide adequate protection for the control of smoke and hot gases. Individual spaces within the complex are separated by 8-inch concrete block walls and metal doors with no specified fire rating. The control room is penetrated by ventilation ducts from the control room annex, computer room No. 1, and the control room ventilation rooms, which are provided with manual smoke dampers. Access to the control room is via fire-rated doors. The fire rated doors are from the turbine building walkway to the control room, from the back stairway to the Unit 1 control room air conditioning room, from the back stairway to the rear control room corridor, from the control room annex to the turbine building, and from the control room annex to the tagging room.

Access to the control room annex is via two Class A fire rated doors which are; (1) from the turbine building walkway, and (2) from the operations personnel support room.

The doors; (1) from the turbine building walkway to the control room annex, (2) from the turbine building walkway to the control room, and (3) from the operations personnel support room to the control room annex are backed up by missile protection doors.

The door between the control room and the control room annex is a bullet-proof door locked closed with a card reader. Louver covers, which are mounted on the doors, can be manually slid down in place to prevent smoke from entering the control room through the door louvers.

Manual actions by plant personnel are relied upon to suppress a fire. The area is relatively uncongested, with adequate space for manual fire fighting. Portable dry-chemical and carbon dioxide extinguishers are located throughout the control room complex. A hose station is located in the turbine building just outside the entrance to the control room. Self-contained breathing units are located in the control room.

9.10.4.2 **Emergency Switchgear Rooms**

Separate areas located below the control room and the Technical Support Center are provided for each unit's emergency switchgear and control relays. Each area is composed of two emergency switchgear rooms, one for each division, and a single relay room. Each room has approximately 2500 ft^2 of floor space. The rooms within each area adjoin each other in an L-shaped configuration, with open passageways between them. There is also an open passageway with a 3-hour fire-rated sliding door between the Unit 1 and Unit 2 areas. The sliding fire door is normally open and will automatically close upon actuation of either the Unit 1 or Unit 2 Halon system or a smoke detector associated with the door.

The emergency switchgear and relay room contain safety-related switchgear and control relays, including redundant equipment required for safe shutdown, and the remote shutdown control panels for each unit. Large quantities of safety-related power and control cables are routed above the switchgear cubicles and relay boards throughout the area and in the open passageways between rooms. The emergency 125V dc batteries are also located in the area in separate rooms within their associated division switchgear rooms. Alternative safe shutdown capability in the event of a fire in this area is provided in accordance with 10 CFR 50 Appendix R. See Section 9.10.4.1 for discussion on the post-fire capability of manually closing the main steam line trip valves and/or the steam generator power operated relief valves. These features provide compliance to the requirements of 10 CFR 50 Appendix R.

The combustible materials in the area consist of a large amount of electrical cable insulation and parts of electrical components in the switchgear cubicles and relay boards. There is also a potential for a small amount of transient lubricating oil to be transported via the Unit 2 switchgear rooms to mechanical equipment room No. 3.

The emergency switchgear and relay room areas for each unit are bounded on all sides by concrete, which provides a 3-hour fire barrier. The individual rooms within each area are also separated by concrete or concrete block walls. As noted above, these walls are penetrated by open passageways. Where cable trays penetrate the walls separating individual rooms within each unit, intermediate fire stops are installed in the trays.

Manual actions by plant personnel are relied upon to suppress a fire. Access to the Unit 1 area is through the normally open fire-rated door from the Unit 2 area and through two fire-rated doors from the Unit 1 cable vault. The Unit 2 area is accessed through (1) a fire-rated set of double doors from the turbine building; (2) a 3-hour fire-rated door to a stairwell from the control room above; and (3) a fire-rated door from the Unit 2 cable vault.

Both the Unit 1 and Unit 2 area floor space is sufficiently clear to permit access by fire fighters, and smoke can be exhausted through the turbine building roof fans or into the cable vault and tunnel area to the motor control center rooms and outside.

Portable carbon dioxide extinguishers are located in both areas, and a 150-lb wheeled, carbon dioxide extinguisher is located in the Unit 2 area. Also, a 1.5-inch hose station is located in the turbine building just outside the entrance to the Unit 2 area.

The emergency switchgear and relay room area for each unit is protected by its own Halon fire suppression system. Each system is capable of flooding an emergency switchgear and relay room area with an adequate concentration of Halon for 10 minutes. The bottles supplying this system are located outside the emergency switchgear rooms in the turbine building.

9.10.4.3 **Containment Penetration Vaults, Cable Tunnels, and Service Building Cable Vaults**

Each unit’s containment penetration vaults (outside containment), cable tunnels, and service building cable vaults are adjoining spaces used as cable spreading and routing areas. The penetration vaults and service building cable vaults are connected by the cable tunnels. These three spaces constitute a single fire area. Separate areas are provided for each unit on either side of the auxiliary building between the service building and the unit containment building. Alternative safe shutdown capability in the event of a fire in this area is provided in accordance with 10 CFR 50 Appendix R. Modifications made as a result of 10 CFR 50 Appendix R requirements provide the operator with the capability of manually closing the steam generator power operated relief valves from either the control room or the units’ cable vault and tunnel area. See Section 10.3.1.2 for additional discussion of this modification.

All of the spaces within these cable spreading and routing areas contain a large number of safety-related cables, including control and power cables for equipment required for safe shutdown. The outside containment penetration vaults also contain the redundant hydrogen recombiner power supplies and emergency motor control centers.

The only combustible material in significant quantity is the insulation for the large number of electrical cables in the areas.

The separate cable spreading and routing area provided for each unit is bounded on all sides by concrete or concrete blocks, which provide a fire barrier surrounding the three adjoining spaces within a unit. Each area is provided with a total flooding automatic carbon dioxide suppression system and a separate fire detection system that alarms in the control room. The automatic carbon dioxide system is backed up by manual suppression capability using manually actuated water sprinkler system in the Service Building Cable Vault, portable extinguishers located in the area, and water hoses from cable vault standpipe, yard hydrants and the hose stations in the turbine building. The areas can be accessed at one end from the outside yard via the motor control center rooms and a spiral staircase down to the outside containment penetration vaults, and at the other end from the turbine building via one of the emergency switchgear rooms. Smoke and heat can be exhausted up the spiral staircases and through the doors of the motor control center rooms to the outside. Adequate floor space is available to permit access by fire fighters to all locations within the areas.

9.10.4.4 **Battery Rooms**

There are four 125V dc station battery rooms. A separate battery is provided for each division of each unit’s safety-related equipment. Each battery is housed in a separate battery room approximately 9 feet by 14 feet, located within or adjacent to the associated division’s emergency switchgear room.

The combustible material in the rooms consists of the plastic battery cases and the battery power cable insulation.

An unmitigated fire in a battery room could disable one of the station batteries. Such a fire would not prevent safe shutdown, however, since redundant equipment controlled from the other train’s battery would still be available, and since the dc load on the other train’s battery would still be fed from the battery chargers.

Each battery room is bounded on all sides by concrete or concrete block, which provides an adequate fire barrier. Ventilation ducts that penetrate the barrier are provided with fire dampers and the doors to the rooms are 3-hour fire-rated. Manual actions by plant personnel are relied upon to suppress a fire. The battery rooms themselves and the areas used for access to the battery rooms are relatively uncongested, with adequate space for manual fire fighting. Portable Class C extinguishers are located nearby in the emergency switchgear rooms, and a wheeled Class C extinguisher is located in the Unit 2 division J emergency switchgear room. Also, 1.5-inch hose stations are located in the turbine building within reach of all the battery rooms.

During normal system operation the fire potential in a battery enclosure is virtually negligible because battery hydrogen generation is negligible. Even though battery hydrogen generation is negligible, air flow detectors have been installed in the battery room ventilation exhaust ducts with annunciation in the control room if there is no air flow. If the smallest battery room was sealed at equalize charge at an elevated temperature of 87°F, the lead calcium batteries would require greater than 40 hours to attain the burnable threshold concentration of four percent hydrogen. In the event of the worst case two-hour design basis battery discharge at an elevated temperature of 110°F, it would require more than two hours following charger power restoration for the hydrogen concentration to reach four percent. In addition, special features in the battery room supply air provide for ventilation under conditions where the normal battery room exhaust flow path is sealed. The special features provide a means for manual operator action that will occur within one hour of the beginning of the battery charging process to supplement ventilation to the applicable battery rooms under these conditions as necessary.

9.10.4.5 **Cable Tray Rooms**

The two cable tray rooms are large, open spaces directly above the control room. Each room is used as a cable-spreading area primarily for non-safety-related cables of its respective unit. The two Cable Tray Rooms contain one train of redundant safe shutdown equipment (Unit 1 Charging Pump Service Water Pump cables) for use during an Appendix R fire scenario outside the cable tray rooms. Adequate separation exists between the two trains. There are, however, a small number of non-safety-related cables that are important to plant operation, and a concrete cubicle containing the reactor protection system trip breakers and switchgear, located in each of the rooms. The non-safety-related cables are those associated with the interlocks between the reactor coolant pumps and the rod control system, and the interlocks between the main feedwater pumps and the motor-driven auxiliary feedwater pumps. The feed pump interlocks are part of a system that may be used for safe shutdown, since they function to provide the automatic start capability by the motor-driven auxiliary feedwater pumps. These pumps, however, may be started manually at the control board.

Two remote monitoring panels (RMP) are installed in the cable tray area of Unit 1. The RMP designated ASC RMP-1 monitors steam generator and pressurizer wide-range levels, Reactor Coolant System (RCS) wide-range pressures and RCS loop hot-leg temperatures. The RMP designated PNL-REM, monitors steam generator pressures, RCS cold-leg temperatures and source and wide-range neutron flux. Both units share each RMP; and the instrumentation from each unit is powered by the emergency power system of the opposite unit. This design feature is intended to assure that indications of these parameters from both units will be available even if a fire disables the emergency power system of either unit. See Section 7.7.2 for further information on the remote monitoring panels. These features and capabilities are part of the requirements of 10 CFR 50 Appendix R.

The Unit 2 communications system amplifier and associated cabling are located in the Unit 2 Cable Tray Room.

The combustible material in the rooms consists of a moderate amount of cable insulation.

An unmitigated fire in one of the cable tray rooms could damage the automatic start function of the motor-driven auxiliary feedwater pumps of one unit. However, the function could be performed manually at the control board in the control room. In addition, the turbine-driven auxiliary feedwater pump and the auxiliary feedwater pumps of the other unit would be available.

A fire in one of the concrete cubicles containing the reactor system trip breakers would not prevent a reactor scram because redundant components and circuits are located in separate enclosed panels and raceways. Due to the fail-safe nature of the reactor protection system design, a fire would not prevent a reactor scram.

Each cable tray room is bounded on all sides by concrete or concrete block, which provides an adequate fire barrier. The doors in this area are 3-hour-rated. All cable penetrations are sealed. Ventilation ducts that pass between the rooms and other plant areas are provided with fire dampers.

A smoke detection system is installed in each room along with an automatic heat-actuated total flooding CO_2 system. Portable extinguishers and manual hose stations are located in the turbine building to provide manual backup to the automatic suppression system. The rooms are relatively uncongested with adequate space for manual fire fighting.

The walls, ceiling and floor of the reactor trip switchgear cubicles are of concrete construction. The entrance to each cubicle is of a labyrinth design.

9.10.4.6 **Switchgear Rooms**

The switchgear rooms are large, open spaces located adjacent to the turbine building at the 58-feet elevation directly above the cable tray rooms. These rooms contain 480V and 4160V switchgear and other miscellaneous electrical equipment and associated cables. None of this equipment is considered safety-related. The Normal Switchgear Rooms are not considered safe shutdown areas by the Appendix R Report, but these areas do contain a limited number of alternate cables and equipment that support safe shutdown to address fires in other fire areas. Redundant trains of safe shutdown equipment are not affected by a fire in the Normal Switchgear Rooms.

The only combustible material in significant quantity in the switchgear rooms is the insulation on the moderate number of electrical cables present.

Due to the fire barriers separating the rooms and the absence of safety-related equipment, no adverse effects on plant safety are likely, even from an unmitigated fire.

The floors and walls of the switchgear rooms are constructed of concrete or concrete block, which provides an adequate fire barrier. The ceilings are also the roof of the building, an insulated metal deck. All penetrations in the floor to the cable tray rooms below are sealed.

9.10.4.7 Motor Control Center Rooms

The motor control center rooms for each unit are located above their respective outside containment penetration vaults. Each room contains 480V motor control centers, and the ventilation units for the cable vault and the motor control centers. None of this equipment is considered safety-related.

The combustible material consists of a small amount of cable insulation.

The only safety-related equipment in the motor control center rooms is the pressurizer heater panels. An unsuppressed fire in the rooms due to the combustion of the small quantity of cable insulation would not affect plant safety. Such a fire could disable the pressurizer heaters; however, the heaters are not credited for safe shutdown.

The floors, ceilings, and walls of the motor control center rooms are constructed of concrete or concrete block. The rooms each contain two non-fire-rated doors, one of which leads to the yard, and an open stairwell leading to the outside containment penetration vault located below.

A smoke detection system is installed in each room that alarms in the control room. Nozzles for a total-flooding CO_2 system are installed in each room. Heat detectors, located in the cable vault below the MCC room, actuate the automatic release of CO_2 into both rooms. Ventilation ducts leading to each room do not have fire dampers installed. However, the ventilation fan is shutdown in the event of actuation of the gas suppression system. Manual hose stations are located in the yard area and portable extinguishers are located near one entrance to each room. The room is relatively uncongested, with adequate space for manual fire fighting.

9.10.4.8 Auxiliary Building - Elevation 2 Ft.

This elevation of the auxiliary building is composed of large, open floor areas and separate equipment cubicles. There are separate concrete compartments for the safety-related seal-water heat exchanger, nonregenerative heat exchanger, and the demineralizers, and for the non-safety-related boron recovery system equipment and liquid waste system equipment. The six charging pumps (three per unit) are located in separate cubicles with concrete walls in the center of the floor area. The charging pump cubicles are completely enclosed on this elevation; access to the pump cubicles is on Elevation 13 ft. One charging pump is required for safe shutdown of both units.

Ventilation of the charging pump cubicles is provided during normal operation and after a LOCA. References 6 and 7 show that forced ventilation of the charging pump cubicles is not required after an Appendix R fire event.

Equipment in the open floor areas includes the four component cooling water pumps, classified as NSQ and pipes and valves for the Chemical and Volume Control System, classified as Safety Related. The component cooling water pumps are cross connected to serve either unit; one pump per unit is required for safe cold shutdown capability. The equipment cooled by the component cooling water system includes reactor coolant pump thermal barriers, residual heat removal pump seal coolers, reactor containment recirculation air coolers, spent-fuel pit coolers, and the excess letdown, nonregenerative, seal-water and residual heat removal heat exchangers.

The CCW pumps and the reactor containment piping penetration areas are ventilated by two fans which have their cables routed together through common fire areas. In this case the requirements of 10 CFR 50 Appendix R can be satisfied by the installation of temporary fans and ducting, since adequate time exists (i.e., several hours). No permanent modifications therefore are required to assure ventilation for these areas in the event of a postulated fire which disables normal ventilation. Appropriate procedures are in place to support this provision.

Cables for redundant divisions of safety-related and safe-shutdown equipment are routed through many areas of this elevation. Alternative safe shutdown capability in the event of a fire in this area is provided in accordance with 10 CFR 50 Appendix R.

The major combustible material on this elevation is cable insulation. Trash containers are used on this elevation. There is a lube-oil system associated with each charging pump, and minor amounts of lubricants in the other pumps.

A fire on this elevation could not damage redundant charging pumps because of the barriers between the individual pumps and between the pumps and other areas on this elevation. (See Exemption Request #1, 10 CFR 50 Appendix R Report.)

The component cooling water (CCW) pumps are mounted on pedestals and are separated by 15 feet. It is not expected that a postulated fire could damage more than one of these pumps because of the separation between pumps and the open hatch above the pumps, which would prevent local heat buildup. Nevertheless, a repair procedure has been developed in accordance with 10 CFR 50 Appendix R for repair of a CCW pump motor and cable.

Fire hose stations are provided on this elevation for manual fire fighting. Floor drains are available for removal of fire suppression water. Water spray shields have been provided on the CCW pump motors to minimize the possibility of water-induced damage.

9.10.4.9 **Auxiliary Building - Elevation 13 Ft.**

The six charging pumps are located on the 2-foot elevation in separate concrete cubicles accessible from the 13-foot elevation. The front walls of the cubicles are open on this elevation; the back walls of the three pumps for one unit face the back walls of three pumps for the other unit.

Three boric acid tanks and four boric acid transfer pumps are located in the open floor area. These tanks and pumps provide a source of boric acid for safe shutdown of both units. An alternative source of borated water is the refueling water storage tank, which is located outside the building.

Cables for redundant divisions of safety-related and safe-shutdown systems are located on this elevation. Alternative safe shutdown capability in the event of a fire in this area is provided in accordance with 10 CFR 50 Appendix R. The separation provided between safe shutdown components in this area is described in 10 CFR 50 Appendix R Report, Chapter 7, Exemption Requests. A repair procedure and replacement cable is available for replacing the component cooling water pump power cables in this area in the event of fire-induced damage.

The major combustible material on this elevation is cable insulation. A hydrogen line is routed in the overhead of this elevation to the volume control tanks on Elevation 27 ft. 6 in.

Although the front walls of the charging pump cubicles are open, it is not expected that a fire in one cubicle would affect adjacent charging pumps because of the floor-to-ceiling concrete barriers between pumps on this elevation. Also, because of the grating floor at Elevation 13 ft., charging pump lube-oil leakage would collect at Elevation 2 ft., where the cubicles are completely enclosed.

The four boric acid transfer pumps are 8 feet apart, and redundant pumps could be damaged by a transient combustible liquid spill; only minor amounts of lubricants are associated with the pumps themselves. Loss of redundant pumps would not prevent safe shutdown because of the alternate boration capability provided by direct supply of borated water from the refueling water storage tanks.

Fire hose stations are provided on this elevation for manual fire fighting. Floor drains are available for removal of fire suppression water. Portable fire extinguishers are provided on this elevation.

9.10.4.10 **Auxiliary Building - Elevation 27 Ft. 6 In.**

The safety-related equipment on this elevation includes the component cooling water surge tank, volume control tanks, and boric acid storage tanks. This equipment is not required for safe shutdown. The component cooling water surge tank and the volume control tanks are in separate concrete cubicles; the other safety-related equipment is located in the open floor area.

The nonsafety-related gaseous waste disposal equipment, solid waste disposal equipment, and some sampling system equipment are also located in separate cubicles on this elevation.

Cables for safety-related equipment are routed through many of the open floor areas on this elevation in conduit and in cable trays with corrugated metal top covers.

Combustible cable insulation and protective clothing in open drums are located in the open floor areas. A charcoal filter is located in the gaseous waste disposal room. A hydrogen pipeline enters the auxiliary building at the 2-foot level in vicinity of the SI lines supplying the high head SI pumps from which it is routed to the volume control tank area.

Fire hose stations and portable extinguishers are provided on this elevation for manual fire fighting. In addition, this elevation is accessible to yard hose facilities via two exterior doors in the general area and an exterior door from the drumming room. Floor drains are provided for removal of fire suppression water. The gaseous waste system charcoal filter can be air cooled if a temperature rise due to decay heat is detected by operators, or by heat detectors.

9.10.4.11 **Auxiliary Building - Elevation 45 Ft. 10 In.**

Components of the safety-related auxiliary building ventilation system (see Section 9.10.4.8), including redundant charcoal filter trains, are located on this elevation. Fuel building, decontamination building, and safeguards area ventilation equipment is also located on this elevation, along with the containment purge supply and exhaust fans. Safety-related cables in conduit and cable trays are routed through the area.

The combustible materials on this elevation include cable insulation, protective clothing in drums, and three charcoal filter units. Each of the two safety-related trains of the auxiliary building ventilation system filters contains about 2640 lb of charcoal.

Each of the safety-related charcoal filter units is in a separate metal enclosure and completely enclosed in separate concrete cubicles with metal closures for the ceilings and doorways. An unsuppressed fire in one filter would not propagate to the redundant unit, nor would it damage other safety-related equipment or cables. The inlet and outlet dampers can be shut to prevent radiation release, and the redundant unit can continue to operate. The non safety-related charcoal filter unit in the auxiliary building ventilation system is housed in a separate enclosure, independent of the other filter units and independent of safety-related equipment.

Fire hose stations and portable extinguishers are provided on this elevation for manual fire fighting. Floor drains are available for removal of fire suppression water.

The auxiliary building ventilation system safety-related charcoal filters are protected by separate total-flooding carbon dioxide suppression systems. These suppression systems are manually actuated, and are provided with heat detectors that will alarm in the control room at a filter temperature of 225°F. The non-safety-related charcoal filter unit is protected by an automatic water deluge system.

9.10.4.12 **Reactor Containment Buildings**

The reactor containment buildings for each unit are essentially identical structures. The containment building is divided by the polar crane wall into an outer annulus section and a central section. The central section is further subdivided into equipment cubicles that are connected to each other and to the outer annulus by open archways, grating floors, and unsealed penetrations. The entire containment can be considered a single fire area.

Safety-related equipment located inside containment includes the regenerative and excess letdown heat exchangers, steam generators, redundant residual heat removal pumps and heat exchangers, containment recirculation spray pumps and heat exchangers, safety injection accumulators, pressurizer, reactor vessel, and rod drive mechanism. Non-safety-related iodine charcoal filters and filtration fans are also located inside containment.

Power, control, and instrument cables for safety-related and non-safety-related equipment are located in the central compartments and are routed around the perimeter of the containment in the outer annulus. In some areas of the annulus, there are cables in open ladder trays with approximately 10 inches of separation between the trays in a stack. The trays are fitted with sheet metal covers that are raised approximately 1 inch above the top of the tray. Various safe-shutdown functions are served by the cables in containment. Radiant energy shields have been installed between primary and alternate safe shutdown instrumentation, and firestops have been installed in cable trays which are intervening combustibles between primary and alternate safe shutdown components. See NRC's Safety Evaluation dated 2/25/88 regarding exemption requested. A radiant energy shield is installed between the residual heat removal pump motors to satisfy 10 CFR 50, Appendix R requirements.

There are 200 gallons of lube-oil associated with each of the three reactor coolant pump motors. There are 175 gallons in the upper bearing reservoir and 25 gallons in the lower bearing reservoir. Combustible cable insulation is located in the containment annulus and in most of the central compartments. The fire loading due to cable insulation is particularly high in containment annulus penetration area. Each of the two iodine charcoal filter units contains about 170 lb of charcoal.

The combustible materials in containment, with the exception of the reactor coolant pump lube-oil, do not constitute a severe enough fire hazard to damage safety-related fluid system components such as heat exchangers, safety injection accumulators, the reactor vessel, and the pressurizer.

The iodine charcoal filters are enclosed in separate structures with 18-inch-thick concrete walls and roofs. An unmitigated filter fire would have no direct effect on safety-related equipment or cables.

Temperature sensors are provided on each reactor coolant pump to detect pump overheating. Portable fire extinguishers are provided outside the personnel hatch of the containment for manual fire fighting. A dry-type fire hose standpipe system has been installed in the containments for manual fire suppression capability. Heat and smoke detectors have been installed in the annulus cable penetration area for detection of a fire within the penetration area.

A reactor coolant pump motor oil collection system has been installed to ensure that oil leakage will not contact hot equipment and to reduce the possibility of a fire. Oil leakage from the reactor coolant pump motor lube-oil system is diverted by enclosures and open dams to a drain tank. This drain tank is sized to contain the total oil inventory of the motor.

The enclosures surround the following oil-bearing components that may leak and are fitted with covers to contain oil from leaks in pressurized lines and to keep foreign matter out of the drain. The oil-bearing components that require oil collection enclosures are:

1. Oil lift pumps (pressurized lines)

2. Oil cooler (pressurized lines and housing)
3. Oil level indicators
4. Oil fill and drain points
5. Flanged connections for the lower oil reservoir
6. Sight glasses
7. All flanged oil-bearing connections

In addition, open dams will drain any potential leakage from the gasketed joint between the upper oil pot housing and the support plate for the upper bearing.

The collection system is designed to withstand an SSE (Safe Shutdown Earthquake) and to collect lube oil from all potential pressurized and unpressurized leakage sites in the reactor coolant pump lube oil systems. Leakage is collected and drained to a vented closed container that can hold the entire lube oil system inventory for one RCP. A flame arrester is installed to minimize the hazard of fire flashback. The drain line is large enough to accommodate the largest potential oil leak.

9.10.4.13 **Containment Spray Pump and Auxiliary Feedwater Pump Buildings**

The containment spray pump and auxiliary feedwater pump buildings for each unit are essentially identical structures, each located adjacent to its unit's reactor containment building. The two containment spray pumps are located at ground level in one compartment. The two electric-motor-driven auxiliary feedwater pumps and the steam-turbine-driven auxiliary feedwater pump are located in an adjacent compartment. A grating is located above the auxiliary feedwater pumps. This floor grating provides access to the steam generator power operated relief valves, the main steam nonreturn valves, the main steam safety valves, and the main steam trip valves. A basement area under the pump compartments contains auxiliary feedwater booster pumps, service water pipes, and safety-related and non-safety-related cables. The cables are for the equipment in the building plus cables for the low-head safety injection pumps and recirculation spray pumps, and associated valves, located in the adjacent safeguards equipment building. The auxiliary feedwater pumps are required for safe shutdown in the event of a fire. The other equipment and cables are required to mitigate the consequences of a LOCA.

Small amounts of grease and oil are associated with each of the pumps. Some combustible cable insulation is located in the pump and valve areas. The basement contains a considerable quantity of cable insulation.

Alternative safe shutdown capability in the event of a fire in this area is provided in accordance with 10 CFR 50 Appendix R.

Loss of the steam generator power operated relief valves would not prevent safe shutdown, because the main steam safety valves would relieve steam pressure.

Loss of the auxiliary feedwater pumps for one unit would not prevent shutdown of that unit, because the auxiliary feedwater discharge lines for the two units are cross connected, and feedwater could be provided from the undamaged unit. The cross-connect valves are not located in the affected auxiliary feed water pump area and would not be incapacitated by a fire in that area.

Damage to redundant systems with components and cables in this building would not prevent safe shutdown, since a LOCA is not postulated simultaneously with a fire.

Portable extinguishers are provided for manual fire fighting. The fire hose at a yard hose cabinet could be used to fight a fire in parts of this building.

9.10.4.14 **Fuel Building**

The fuel building is bounded by the auxiliary building, decontamination building, and the two reactor containment buildings. The top surfaces of the spent-fuel pool and the new-fuel storage pit are located at Elevation 47 ft. 4 in. The spent-fuel pool cooling pumps and purification pumps are located below the new-fuel storage pit at Elevation 6 ft. 10 in. The motor control centers for the pumps are located on a stairway landing at Elevation 16 ft. 10 in. None of the equipment in the building is required for safe shutdown.

The combustible materials in the fuel building consist of small amounts of cables.

Because of the separation between combustibles and equipment, and the low fire loading, a fire in most areas of the building would cause minor damage. An unmitigated fire in the pump area could damage redundant spent-fuel pool cooling pumps. A cable fire could incapacitate redundant pumps. In the event of the loss of both pumps, the spent fuel could be cooled by makeup water supplied from the primary-grade water system, firewater system, or external supply source.

Fire hose stations and portable fire extinguishing equipment are provided inside the fuel building. For flood protection, a normally closed trip valve placed outside the building isolates the water to the building during normal operation. Existing hose racks are equipped with a remote control station to provide pressurization of the fire lines when demanded. Access for manual fire fighting is from the auxiliary building, decontamination building, and the yard area.

9.10.4.15 **Safeguards Equipment Buildings**

The safeguards equipment buildings for each unit are essentially identical structures, each located adjacent to its unit’s reactor containment building.

Access to the building is from the yard at Elevation 28 ft. 6 in. Ladders lead from this elevation down to the redundant containment recirculation spray pumps and the redundant low-head safety injection pumps. Each of these pumps is located in a separate pit. Valve operators and the cables for these pumps are located in a separate compartment on Elevation 19 ft. 6 in., accessible by ladder from Elevation 28 ft. 6 in. None of the equipment or cables in this building is required to achieve safe shutdown.

The combustible materials in this building are the cables in the valve operator area and grease in the pumps and valves.

The pumps are in separate cubicles with walls of 12-inch reinforced concrete; a fire in one pump cubicle would not affect other pumps. For a fire in this area, cables for both divisions could be lost. Safe shutdown would be accomplished using alternate equipment from the "opposite unit." Appendix R Safe Shutdown Analysis takes no credit for survival of the normal system equipment and cables in this area.

Portable fire extinguishing equipment is provided at Elevation 28 ft. 6 in. Fire hose would be available from the yard hose houses.

9.10.4.16 **Intake Structure**

The intake structure is located approximately 1.25 miles from the main plant buildings. Two separate compartments are located on top of the intake structure. One compartment contains non-safety-related cables, 4-kV switchgear, and motor control centers. The other compartment contains the three safety-related emergency service water pumps, and a fuel-oil tank cubicle. The fuel-oil tank supplies the diesel engines that drive the emergency service water pumps. The emergency service water pumps provide cooling water for plant shutdown in the event of a loss of offsite power. The three pumps are shared by both units.

The combustible material in the non-safety-related electrical equipment compartment is primarily cable insulation. There are 15 gallons of lube-oil associated with each emergency service water pump. The fuel-oil cubicle in the pump compartment contains a 4800-gallon fuel-oil tank.

A fire resulting in damage to all the cables in the electrical equipment compartment would have no effect on the ability to achieve safe shutdown in accordance with 10 CFR 50 Appendix R, since equipment and cables necessary to perform the shutdown function would be available outside of the fire area. An unmitigated fire in the electrical equipment compartment would not spread to the emergency service water pump compartment.

The walls between the fuel-oil day tank and the emergency service water pumps are 3-hour barriers.

Smoke detectors that alarm in the control room are provided in the electrical equipment compartment and in the emergency service water pump compartment. The fuel-oil tank cubicle is protected by a total-flooding carbon dioxide suppression system supplied by a bank of carbon dioxide cylinders in the pump room. The carbon dioxide system is automatically actuated by heat detectors or can be manually actuated. Actuation of the carbon dioxide system sounds a pre-discharge alarm and pneumatically closes vent dampers and releases doors when discharge occurs. Discharge is alarmed in the control room. After initial discharge, additional carbon dioxide may be released by manual operation of the system.

Portable and wheeled fire extinguishers are provided at the intake structure. The fire truck has a built in tank and also can draft water from nearby to supply fire suppression water. The fire truck and fire hose would be brought to the intake structure in response to a detector alarm or in response to a call from a plant operator, who inspects the area once per shift.

9.10.4.17 **Mechanical Equipment Room No. 3**

Mechanical equipment room No. 3 is located adjacent to the Unit 2 relay room and the train "2H" emergency switchgear room. Three safety-related air-conditioning chillers and chiller circulating pumps are located in this room. If all three air conditioning chillers are simultaneously disabled in mechanical equipment room No. 3, there are two chillers in mechanical room No. 5 that are available to maintain cooling in the main control room and emergency switchgear and relay rooms.

Mechanical equipment room No. 3 also contains two charging pump service water pumps. One pump is required to support operation of two charging pumps to achieve and maintain safe hot shutdown and safe cold shutdown for both units. In the event of a fire in this area, service water to the charging pumps would be provided by one of the charging pump service water (CPSW) pumps located in Mechanical Equipment Room No. 4 in the turbine building basement, which is independent of this area. Cables for the equipment are located in conduits and cable trays in this room.

One wall of this room is shared with the turbine building and with the charging pump service water pump room; however, a fire in the turbine building cannot affect safe shutdown equipment in mechanical equipment room No. 3 because 3-hour-rated fire barriers are used to separate MER-3 from the turbine building.

Combustible material in the room includes the approximately 10 gallons of lube-oil associated with each of the three chiller units and a moderate amount of combustible cable insulation.

Portable fire extinguishers are provided in the room and nearby for manual fire suppression. A fire hose station is located nearby in the turbine building, but the hose may not reach the mechanical equipment room. A floor drain is provided in the room for removal of fire suppression water. The door to the emergency switchgear room is curbed to prevent the spread of a lube-oil fire to the switchgear room.

9.10.4.18 **Mechanical Equipment Room No. 4**

MER-4 is a separate pump room located on the safety-related, Seismic Category I, service building foundation slab, which abuts the adjacent turbine building foundation slab. The doorway to MER-4 is accessed from the 9 ft.-6 in. elevation of the Unit 2 turbine building. MER-4 provides tornado missile protection to safety-related equipment housed within. MER-4 houses two charging pump service water pumps 1-SW-P-10A and 2-SW-P-10A. One pump 1-SW-P-10A is required to support operation of two charging pumps to achieve and maintain safe hot shutdown and safe cold shutdown for both units. Smoke detectors are installed within MER-4 in accordance with National Fire Protection Association (NFPA) Standard 72.

The north wall, shared with MER-3, has a 3-hour fire rating. The remaining walls, which are 3-hour fire rated, separate MER-4 from the turbine building.

The amount of combustible material in the room is low and consists of fiberglass piping and grease. A fire hose station is provided outside the room and in the nearby area for manual fire suppression.

9.10.4.19 **Turbine Building**

The turbine building is a steel-framed structure with the lower portions of the exterior walls constructed of masonry and the upper portions of uninsulated metal siding. The roof is metal decking covered with insulation and membrane roofing. The building is divided into two identical sections, except for the operating floor, each measuring approximately 330 feet long by 150 feet wide, housing the turbines and generators for Units 1 and 2. Each section has three levels, situated at Elevations 9 ft. 6 in., 29 ft. 6 in., and 58 ft. 6 in. The operating floor is reinforced concrete, supported on steel framing. The mezzanine level and platforms are steel-framed, with metal floor grating. Stairways between floors are constructed of metal grating.

The turbine building is bounded on the west side by the office building and on the south side by exposed exterior walls. The north side shares a common wall with a portion of the service building that contains the safety-related diesel-generator rooms, emergency switchgear rooms, control room, and battery room 2B. Other non-safety-related areas of the service building opening off the turbine building include the shop area, labs, locker, and wash rooms. The turbine building is bounded on the east side by the condensate polishing building.

Safety-related equipment located within the turbine building includes control room and switchgear area emergency ventilating units, component cooling water heat exchangers, service water valves, circulating water valves, and charging pump service water subsystem valves. Most of this equipment is located at Elevation 9 ft. 6 in. Circulating water valves isolate the main condensers from the intake canal to conserve water in the canal for shutdown. Components required for safe shutdown are separated in accordance with the requirements of 10 CFR 50 Appendix R.

Cable trays are located at all elevations of the turbine building, although most are located at Elevations 29 ft. 6 in. and 9 ft. 6 in.

Normal combustibles in the turbine building include the lubricating oil and hydrogen gas contained within the turbine generator. Combustibles at the 29 feet 6 inches elevation include the 21,000-gallon turbine oil reservoir and coolers, heavy concentrations of cabling, hydrogen piping, and several 55-gallon drums of flammable materials, including used oil and grease. The combustibles at Elevation 9 ft. 6 in. include two 22,000-gallon turbine lube-oil storage tanks enclosed within a separate room. Other combustibles at this elevation include the turbine oil conditioner unit, containing about 330 gallons of oil, the hydrogen seal oil unit, containing about 70 gallons of oil, redundant trains of safety-related cabling, and various transient combustible materials including lubricants, welding gas, lumber, and polyethylene plastic film used to isolate and protect equipment during maintenance procedures.

The operating floor of the turbine building is an open area containing both the Unit 1 and 2 steam turbines and generators. A 12-inch block wall is provided to separate Units 1 and 2 below the operating floor. The turbine building is separated from the safety-related portions of the service building by reinforced-concrete walls. Other areas of the service building are separated from the turbine building by 12-inch-thick masonry walls.

The 21,000-gallon turbine oil reservoirs and coolers at Elevation 29 ft. 6 in. are provided with 3.5-foot-high concrete curbs, which are capable of containing the entire contents of the reservoirs. The turbine lube-oil tanks, containing 44,000 gallons, are located at Elevation 9 ft. 6 in. within the turbine lube-oil rooms, and are arranged with diking adequate to contain the entire contents of the tanks. The room is penetrated by a 3-hour sliding steel fire door on the north wall and an unrated door in the east wall. The hydrogen seal-oil units are located at Elevation 9 ft. 6 in. and contain approximately 70 gallons of oil. These units are not provided with curbing, although a drainage trench surrounds the units. The turbine lube-oil conditioners, which contain 330 gallons of oil, are located at Elevation 9 ft. 6 in. The units are provided with dikes adequate to contain the entire amount of oil contained within the equipment.

The hydrogen seal-oil units, the turbine oil reservoir and coolers, and the turbine lube oil conditioners are protected by deluge systems actuated manually at the control room or locally. These areas are also provided with thermal fire detectors with annunciation in the control room. The turbine lube-oil rooms are protected by an automatic sprinkler system with alarm indication in the control room.

The turbine generators contain lube oil and hydrogen at the bearing enclosures. These areas are provided with fixed, low-pressure carbon dioxide suppression systems automatically initiated by temperature detectors when the enclosure temperatures exceed 450°F. The systems may also be manually initiated locally.

Sprinkler protection is provided at all levels of the turbine building except for the operating deck. The sprinklers inside the turbine deck security office (TDSO) are the only sprinklers above the turbine operating deck.

Backup fire-fighting capability is provided by manual hose stations located in various areas of the building and from the hydrant/hose houses in the yard, as well as portable extinguishers.

9.10.4.20 **Diesel-Generator Rooms**

There are three adjacent identical diesel-generator rooms, each measuring approximately 28 feet wide by 58 feet long by 16 feet high. The rooms are located in the service building in a one-story, reinforced-concrete structure.

Each room contains a diesel-driven generator, day tank, starting air compressor, air storage tank, batteries, and a control panel.

The combustibles in each room consist of approximately 1100 gallons of diesel fuel oil and about 500 gallons of lubricating oil. Other minor quantities of combustible materials consist of the battery cases and cabling. The day tanks are supplied from the yard by transfer pumps started by level switches in the day tanks.

An unmitigated fire in one of the emergency diesel-generator rooms would result in the loss of function of one emergency diesel generator.

The diesel-generator rooms are enclosed with 2-foot-thick reinforced-concrete walls and ceilings with an equivalent fire rating in excess of 3 hours. The 3-hour walls separating the diesel-generator rooms are not penetrated by doors or ducts. The rooms are accessed through fire rated doors from the turbine building.

A fixed, manually actuated, total-flooding carbon dioxide suppression system is provided in the emergency diesel-generator rooms. Two thermostats located near the ceiling initiate an alarm in the control room when the temperature exceeds 190°F. The carbon dioxide suppression system can be actuated from a push-button station in the control room or from manual break-glass stations at the entrances to each room. Initiation of the carbon dioxide suppression system is arranged to automatically close doors to the area and trip the room exhaust fan, but does not shut the overhead air intake louvers. Prior to manually actuating the suppression system, the ventilation system must be manually shut down.

Backup fire-fighting capability is provided by a dry-chemical and a carbon dioxide portable extinguisher in each diesel-generator room. Manual hose stations serving this area are provided in the turbine building.

Venting of smoke from these rooms, as well as disposal of large quantities of fire-fighting water, can be made through the exterior doors.

Because the three redundant diesel-generator rooms are completely separated from each other, with no open penetrations through the walls separating the units, the potential for an unmitigated fire in one unit spreading to the other units is small.

9.10.4.21 **Compressed-Gas Storage Areas**

There is no safety-related equipment in these areas.

Compressed gases stored in the yard area include hydrogen in cylinders stored under a protective roof, with concrete walls on three sides and the fourth side open. Main generator hydrogen storage is in tanks set on a concrete pad. Welding gas, including oxygen and acetylene cylinders, is also stored on a concrete pad. Compressed-gas cylinders are also stored in the yard adjacent to the auxiliary building.

A fire in any of these areas would result in the loss of all the stored compressed gas in that area but would not affect safety-related areas.

Fire protection provisions for the combustible gas main storage area include adequate separation distance from safety-related equipment, and manual fire fighting utilizing the hydrants and equipment in the hose houses.

The separation distances and manual suppression capability are adequate to prevent a fire in compressed-gas storage areas from affecting safety-related equipment.

9.10.4.22 **Transformer Area**

There is no safety-related equipment in this area.

There is a large amount of oil in the transformer units, which include the main and station service transformers for Units 1 and 2.

A fire in one of the transformers would cause the loss of function of at least one transformer, but would not have any effect on the ability to safely shut down the plant.

Each of the transformers is protected by an automatic water spray suppression system actuated by heat detectors. Hose lines from nearby hose houses are available for manual suppression.

The transformers are separated from each other by 12-inch-thick concrete fire walls 19 feet tall. The transformers are located 35 feet away from the turbine building. The units sit on a bed of crushed stone with a 6-inch-high dike surrounding each transformer. The crushed stone pits are sized to the full volume of oil released from a transformer, preventing the oil from spreading.

The fire detection and suppression equipment are adequate to control a fire in the transformer area.

9.10.4.23 **Fuel-Oil Pump Houses and Storage Tanks**

The fuel-oil pump houses and tanks are located at the northeast corner of the yard. The system consists of one 210,000-gallons aboveground storage tank, two 20,000-gallon underground tanks, and two identical pump houses. The pump houses are located below grade and are separated from each other by an 8-inch-thick concrete wall. The interiors of the pump houses are reached from grade via steel ladders in a hatchway. Each pump house measures approximately 17 feet by 17 feet in area, with a 16-foot-high ceiling. Each pump house contains three fuel-oil transfer pumps and a 275-gallon drain tank. Each pump house contains one of the redundant safety-related pumps that supplies the diesel-generator day tanks.

The combustibles in each of the pump houses consist of approximately 300 gallons of fuel-oil contained in the drain tank, pumps, and piping. The maximum combustible loading of the aboveground fuel-oil storage tank is 210,000 gallons.

An unmitigated fire in one of the fuel-oil pump houses could damage or destroy all the equipment within the enclosure. A fire in one of these pump houses, however, would not affect the adjacent pump house containing redundant equipment. A leak in the aboveground oil storage tank would be contained within the diked area and would not affect other areas of the plant. The two underground 20,000-gallon fuel-oil tanks are not subject to a fire.

The two fuel-oil pump houses are located below grade adjacent to each other, and are separated by a 8-inch-thick reinforced-concrete wall with 3-hour equivalent fire rating. Ventilation to these areas is provided by fans and concrete ducts.

Fire suppression for the fuel-oil pump houses is provided by a fixed high-pressure carbon dioxide extinguishing system. The carbon dioxide system is automatically actuated by heat detectors or can be manually actuated. Initiation of the system shuts off the ventilation fans and sounds a predischarge alarm. Following a 30-second delay, carbon dioxide is discharged into the room and the discharge is alarmed and annunciated in the control room. After the initial discharge, additional release of carbon dioxide must be manually actuated. The system has a lockout valve for personnel safety which alarms in the control room when the system is locked out. Backup manual fire suppression is provided by a nearby hydrant and hose house with provisions for foam application.

The 210,000-gallon aboveground steel fuel-oil storage tank is encircled with an 8.5-foot-high impoundment wall constructed of 12-inch-thick reinforced concrete and sized to the entire 210,000-gallon capacity of the fuel-oil storage tank. The fuel tank is also provided with a fixed pipe foam application system arranged to deliver foam/water solution to the topside of the tank, utilizing a foam eductor and foam concentrate stored in an enclosure located near the tank. Manual application of foam is possible by use of a foam hose line and nozzle provided on the fire engine.

The two 20,000-gallon underground fuel-oil storage tanks are not provided with any fire protection systems. The fire protection features for the two underground fuel-oil pump houses are adequate.

The impoundment diked area and the foam application suppression system protecting the 210,000-gallon aboveground fuel-oil storage tank is adequate. Provisions for manual fire fighting using hydrants and hose lines are also adequate.

9.10.4.24 **Fire-Pump House**

The fire-pump house is a free-standing, reinforced-concrete building approximately 35 feet wide by 53 feet long, situated in the southwest portion of the yard. The building is separated by a wall with a metal door, forming two separate rooms. One room contains the electric-motor-driven fire pump, motor control center, surge tank, and two small water booster pumps. The other room contains the diesel-engine-driven fire pump, fuel tank, pump controller, batteries, air compressor, and water tanks.

None of the equipment at this location is safety-related.

The major combustibles in this building consist of approximately 460 gallons of diesel fuel in the day tank, a minor quantity of lube-oil in the diesel engine pump, and small quantities of cabling.

The reinforced-concrete exterior walls and the wall separating the two rooms have an equivalent fire rating in excess of 3 hours. The door in this wall is fire rated. Floor drains are provided at each of the two fire-pump rooms, which are connected to a common drain line, but the drains in the diesel fire pump room have been plugged.

An outside hydrant and hose house is located approximately 35 feet from the building and is the primary provision for fighting a fire in this building. Three Class C extinguishers are provided in the electric-motor-driven fire-pump room at the doorway between the two rooms.

Ventilation in the two fire-pump rooms is provided by large air intake screens for the diesel engine and double doors to the outside from the electric-driven fire-pump room.

9.10.4.25 **Auxiliary Boiler Room**

The auxiliary boiler room measures approximately 45 feet wide by 60 feet long and contains the two oil-fired auxiliary boilers with associated equipment. The room is located at the northeast corner of the turbine building, and contains no safety-related equipment.

The combustibles in this room consist of fuel-oil in the burner supply lines and minor quantities of cabling and waste materials.

The floor drainage system in the auxiliary boiler room does not communicate with other areas of the plant; therefore, fuel oil leakage in the room cannot spread to other plant areas via the floor drainage system.

An unmitigated fire in this area would not affect safe shutdown. Because of the corrugated metal wall panels at each side of the room, an explosion would be safely vented outside, and safe-shutdown capability would not be affected.

Primary fire protection for this area is provided by automatic sprinklers. Secondary fire-fighting capability is provided by a manual hose station and two 20-lb dry-chemical extinguishers located within the room. An outside hydrant is located approximately 80 feet away.

The existing fire protection systems are adequate for the hazards presented in this area.

9.10.4.26 Main Switchyard, Surry Nuclear Information Center (SNIC) and Gravel Neck Combustion Turbines

A fire main and accompanying hydrants and hose houses have been installed in the storage area, main switchyard area, SNIC, and Gravel Neck combustion turbine area to provide a greater level of fire protection. The fire main is suppled with water from the existing fire main, which runs alongside the main warehouse.

Hose houses in the area of the Gravel Neck combustion turbine Units 1 and 2 (original gas turbines) are equipped with a foam unit consisting of tanks of foam solution, fire hose, foam proportioner, and nozzles.

The 10-inch fire main routed to the Gravel Neck combustion turbine Units 3, 4, 5, and 6 supplies fire hydrants and a 1500 gpm booster pump with fire water. The booster pump supplies fire hydrants, a foam house for foam discharge into the fuel tanks, foam-type fire hose suppression systems, deluge systems for transformers, and a sprinkler system. Blanked flange and tee provisions will permit future facility expansion.

The underground fire main in this area is classified as a Category III structure and the design is consistent with the non-seismic classification. The system was designed to the requirements of NFPA 24.

9.10.4.27 Mechanical Equipment Room No. 5

Mechanical equipment room No. 5 (MER-5) is located at the 9 ft.-6 in. elevation of the Unit 2 turbine building. MER-5 houses two chillers, associated chiller auxiliaries, and electrical equipment. Smoke detectors are installed within MER-5 and are spaced in accordance with National Fire Protection Association (NFPA) Standard 72E.

Appendix R isolation panel AS-2 is located in the electrical area of MER-5. In the event that the Control Room becomes uninhabitable, chillers 1-VS-E-4D and 4E control power can be transferred, and the chillers and their associated equipment can be locally controlled.

One wall of this room is shared with the turbine building. A fire in the turbine building cannot affect safety-related equipment in MER-5 because the walls are constructed of 2-foot thick concrete, and the doors are 3-hour fire-rated. Two 3-hour fire-rated fire dampers are used to seal the duct openings in the roof.

The major combustible material in the room is the lube oil associated with each of the two chiller units. There is also a moderate amount of combustible cable insulation in the room. Portable fire extinguishers are provided in the room and in the nearby area for manual fire suppression.

Equipment in MER-5 is protected from turbine building flooding by the presence of flood dikes at the doors which provide access to the room. The electrical equipment is protected by a

2-foot high wall separating the electrical equipment from the mechanical room and turbine building sump. Backflow from the turbine building drains is prevented by means of backflow preventers installed downstream of the mechanical room drains.

9.10.4.28 **Condensate Polishing Building and Maintenance Building**

The Condensate Polishing Building and Maintenance Building are located east of the Turbine Building and contain various pieces of equipment for processing secondary water and maintenance activities. These areas contain no safe shutdown equipment.

The combustibles in this room consist of lube oil associated with pumps and motors, cables, and other various combustibles associated with maintenance.

An unmitigated fire in this area would not affect safe shutdown. This area is separate from safe shutdown components located in the Turbine Building and other plant areas.

Primary fire protection for this area is provided by automatic sprinklers. Secondary fire-fighting capability is provided by manual hose stations and fire extinguishers located within the rooms. The Condensate Polishing Building is also equipped with smoke detection.

9.10.5 Tests and Inspections

Tests and inspections of fire protection systems are performed in accordance with the Technical Requirements Manual.

9.10.6 Administrative Controls

The fire protection program, previously known as the Fire Protection Plan, includes sections which discuss Fire Brigade organization, structure, training, and records.

Ignition sources used in both safety-related and non-safety-related areas of the station require written authorization from the Supervisor - Nuclear Site Safety except for exempted areas, such as workshops, as delineated in the program. Ignition sources shall be removed from safety-related areas at the end of each workday.

Location of transient combustibles in safety-related areas requires written authorization from the Supervisor - Nuclear Site Safety.

FIRE PROTECTION SYSTEM ARRANGEMENT

9.11 WATER SUPPLY AND TREATMENT SYSTEMS

9.11.1 Well-Water Supply System

The well-water supply system provides makeup water to the fire protection and domestic water storage tanks. Water from the fire protection and domestic water storage tanks is then used to supply the hydropneumatic tank in the potable water system and the fire protection system. The well-water supply system is shown on Figure 9.11-1.

There are three cased water wells located south of the site, wells B, C, and E as shown on Figure 15.1-1. Each well has a 200-gpm submersible pump discharging to a wellwater storage tank. Each well pump has a separate underground discharge line that is interconnected at the storage tank. Centrifugal-type well-water transfer pumps deliver water from the storage tank to consuming systems as required.

The well-water supply system is designed to be automatically or manually controlled.

9.11.2 Domestic Water Supply System

A 4000-gallon hydropneumatic tank, located in the fire-pump house, is provided for the domestic water supply system. Pressure in the hydropneumatic tank is maintained at 40 to 60 psig by a pressure system, consisting of a pressure-level regulator, air compressor, and related controls and accessories. Hypochlorinator equipment provides a means of chlorinating the domestic water supply. Piping from the hydropneumatic tank supplies cold water to safety showers, drinking water coolers, hot-water storage tanks, and domestic cold water throughout the station.

Domestic water supply component design data are given in Table 9.11-1.

9.11.3 Make-Up Water System

The make-up water system is shown on Figure 9.11-2 and Reference Drawings 1, 2, 3, 4, and 6. The system consists of equipment for the production of high-purity water by demineralizing well water for makeup to the various station systems. The flash evaporation system (Reference Drawing 1) is no longer used to treat water, however, the equipment remains installed in the plant.

Well water is stored in the Fire Protection and Domestic Storage Tank. The Condensate Polishing System is available to provide supplementary chemical treatment of condensate for feedwater conditioning. High-purity water is pumped to the primary-water storage tanks (Section 9.1) for reactor plant makeup, and to the condensate storage tank for secondary plant makeup.

The fire protection system is discussed in Section 9.10.

9.11 REFERENCE DRAWINGS

The list of Station Drawings below is provided for information only. The referenced drawings are not part of the UFSAR. This is not intended to be a complete listing of all Station Drawings referenced from this section of the UFSAR. The contents of Station Drawings are controlled by station procedure.

9.12 FUEL HANDLING SYSTEM

The fuel handling system provides a safe, effective means of transporting and handling fuel from the time it reaches the station in an unirradiated condition until it leaves the station after postirradiation cooling.

The system is designed to minimize the possibility of mishandling that could cause fuel damage and potential fission product release.

The fuel handling system consists basically of:

1. The reactor cavities, one in each unit’s containment structure, which are flooded only during unit shutdown for refueling, and a manipulator crane for each unit.
2. The spent fuel storage pool, which is maintained full of borated water and is always accessible to operating personnel, and a movable platform with hoists. It is shared by both units.
3. The fuel transfer system for each unit, which consists of an underwater conveyor that carries the fuel from the reactor cavity, through the containment wall, and into the spent fuel storage pit.

9.12.1 Design Bases

The fuel handling system and areas comply with appropriate criteria, as discussed in Section 1.4. The applicable criteria are:

Criterion 4—Sharing of Systems

Criterion 18—Monitoring Fuel and Waste Storage

Criterion 66—Prevention of Fuel Storage Criticality

Criterion 67—Fuel and Waste Storage Decay Heat

Criterion 68—Fuel and Waste Storage Radiation Shielding

9.12.2 System Design and Operation

Each reactor is refueled with equipment designed to handle the spent fuel under water from the time it leaves the reactor until it is placed in a cask for shipment and/or storage on site. Boric acid is present as required in the water to ensure subcritical conditions during all phases of the refueling process.

In each reactor cavity, in each unit’s containment, fuel is removed from the reactor vessel, transferred through the water, and then placed in the fuel transfer system by a manipulator crane. There is a separate fuel transfer system with each unit. It is then transferred through the fuel transfer tube to the spent fuel pool. Fuel is removed from the fuel transfer system and placed in storage racks with a long manual tool suspended from an overhead electric monorail hoist on a bridge structure mounted on a movable platform that runs over the new fuel and spent fuel storage areas, which are common to the two units. After a sufficient decay period, the fuel may be removed from storage and loaded into a cask for removal to the onsite Independent Spent Fuel Storage Installation pad or to offsite facilities.

New fuel assemblies are received and stored in racks in the new fuel storage area. The new fuel storage area does not contain any water. New fuel is delivered to the reactor by transferring it from the new fuel storage area to the spent fuel storage pool and taking it through the transfer system. The new fuel storage area is sized for storing two-thirds of a core plus 20%, as detailed in Table 9.12-1. A portion of the fuel for the initial core loading was temporarily stored in the spent fuel pool.

The reactor cavity and spent fuel pool are reinforced-concrete structures with butt-welded stainless steel plate liners. These concrete structures are designed as Seismic Class I to withstand the anticipated earthquake loadings.

All liner butt welds conform strictly to the requirements of Section IX of the ASME Code, and are provided with test chambers to check for leaktightness.

Fuel-handling data are given in Table 9.12-1.

9.12.3 Fuel-Handling Structures

9.12.3.1 Refueling Cavities

Each reactor cavity is a reinforced-concrete structure forming a pool above the reactor when filled with borated water for refueling. The cavity is filled to a depth that limits the radiation at the surface of the water to 50 mR/hr during those brief periods when a fuel assembly is transferred to the upender and is at the closest approach to the surface of the water.

The reactor vessel flange is sealed to the bottom of the refueling cavity by a segmented seal ring that prevents leakage of refueling water from the cavity. This seal is fastened and closed after reactor cooldown, but before flooding the cavity for refueling operations. The segmented seal uses a passive sealing design which will preclude failure and leakage. During reactor operation, the seal is removed and normally stored outside the containment structure.

The cavity is large enough to provide storage space for the reactor upper internals, the control rod assembly drive shafts, miscellaneous refueling tools, and the lower internals.

The walls and floor of the refueling cavity are lined with 0.25-inch type 304 stainless steel.

9.12.3.2 Fuel Transfer Canals and Transfer Tubes

In each unit, a fuel transfer canal extends along one wall of the refueling cavity to the inside surface of the reactor containment. The canal is formed by two concrete shielding walls, which extend upward to the same elevation as the refueling cavity. The floor of the canal is at a lower elevation than the refueling cavity, to provide the greater depth required for the fuel transfer system upending device and the control rod assembly change fixture.

9.12.3.3 **Spent Fuel Pool**

The spent fuel pool is designed for the underwater storage of spent fuel assemblies and control rod assemblies after their removal from the reactor. It is designed to accommodate a total of approximately 1044 fuel assemblies. The nominal size of a full core is 157 assemblies.

The spent fuel pool is constructed of reinforced concrete. The entire interior of the pool is lined with 0.25-inch type 304 stainless steel.

High-density storage racks erected on the pool floor are provided to hold the spent fuel assemblies. Fuel assemblies are placed in vertical cells, grouped in parallel rows with a minimum center-to-center spacing of 14 inches. The racks ensure the necessary spacing between assemblies to prevent criticality even if the pool were inadvertently filled with unborated water. Control rod assemblies and other non-fuel inserts/components may be stored in the fuel assemblies. Storage rack design details are given in Appendix 9A.

Failed fuel rods removed when reconstituting fuel assemblies will be stored in a fuel rod canister which will be stored in one cell of the spent fuel storage racks. Each fuel rod canister is manufactured to the same exterior dimensions as a fuel assembly with a top nozzle similar to the fuel assembly. This will permit handling of the canister using normal fuel handling equipment and storage in the rack. Each canister contains tubes for the storage of individual fuel rods. The accidental dropping of a fully loaded fuel rod canister in the spent fuel pool is conservatively bounded by the Fuel Handling Accident in the Spent Fuel Pool described in Section 14.4.1.3, since that accident assumes all 204 rods of the highest power assembly are failed. The fuel rod canisters hold less than 204 rods.

Radiation monitors for the spent fuel pool area are provided as described in Section 11.3.4.

9.12.3.4 **New-Fuel Storage**

New fuel assemblies and control rod assemblies are stored in a separate area of the fuel building, where they are unloaded from trucks. This storage area is designed to hold 126 new fuel assemblies in vertical racks, and is used primarily for the storage of the one-third replacement core plus 10% for each of the two units. The new fuel assemblies are stored in racks in parallel rows having a minimum center-to-center distance of 21 inches.

Radiation monitoring for the new fuel storage area is discussed in Section 11.3.4.

9.12.4 Refueling Equipment

9.12.4.1 **Reactor Vessel Stud Tensioners**

Stud tensioners are used to make up the reactor vessel head closure joint. During this process all studs are stressed sufficiently to hold the closure heads seated and maintain leaktightness during operation.

The stud tensioner is a hydraulically operated device provided to permit preloading and unloading of the reactor vessel closure studs at cold shutdown conditions. Stud tensioners minimize the time required for the tensioning or unloading operations, minimize thread damage, and permit precision stud tensioning. Three tensioners are provided for each unit, and they are applied simultaneously to three studs 120 degrees apart. One hydraulic pumping unit operates the tensioners, which are hydraulically connected in parallel. The studs are tensioned to their operational load in two steps to prevent high stresses in the flange region and unequal loadings in the studs. Relief valves are provided on each tensioner to prevent overtensioning of the studs due to excessive pressure. In addition, micrometers are provided to measure the elongation of the studs after tensioning.

9.12.4.2 **Reactor Vessel Head Lifting Device**

The reactor vessel head lifting device consists of a welded and bolted structural steel frame with suitable rigging to enable the reactor containment crane operator to lift the bead and store it during refueling operations.

9.12.4.3 **Reactor Internals Lifting Device**

The reactor internals lifting device is a structural frame suspended from the reactor containment polar crane. One lifting device is provided for each unit. The frame is lowered onto the guide tube support plate of the internals and manually bolted to the support plate by three bolts, with long torque tubes extending up to an operating platform on the lifting device. Bushings on the frame engage guide studs in the vessel flange to provide close guidance during removal and replacement of the internals package.

9.12.4.4 **Manipulator Crane**

The manipulator crane is a rectilinear bridge and trolley crane with a vertical mast extending down into the reactor cavity water. A manipulator crane is provided for each unit. The bridge spans the reactor cavity and runs on rails set into the floor along the edge of the reactor cavity. The bridge and trolley motions are used to position the vertical mast over a fuel assembly in the core.

A long tube with a pneumatic gripper on the end is lowered down from the mast to grip the fuel assembly. The gripper tube is a telescopic device that is long enough that the upper end is still contained in the mast when the gripper end contacts the fuel. A winch mounted on the trolley raises the gripper tube and fuel assembly up into the mast tube. The fuel, while inside the mast tube, is transported to its new position.

All controls for the manipulator crane are mounted on a console located on the bridge. The bridge is positioned on a coordinate system laid out on one rail. The camera assembly monitors the bridge target and transmits that position to the closed circuit television screen. The operator visually observes the bridge scale assembly to line up the bridge to the appropriate location. The scale is read directly by the operator at the console. The drives for the bridge, trolley, and winch are variable speed, and include a separate inching control for each drive. Electrical interlocks and limit switches on the bridge and trolley drives protect the equipment. The bridge, trolley, and winch can also be operated manually using handwheels on the motor shafts.

The suspended weight on the gripper tool is monitored by an electrical load cell indicator mounted on the control console. A load in excess of approximately 2700 lb stops the winch drive from moving in the up direction. The gripper is interlocked through a weight-sensing device, and also a mechanical spring lock, so that it cannot be opened when supporting a fuel assembly.

In addition to the travel limit switches on the bridge and trolley drives, the following safety features are incorporated in the system:

1. Bridge, trolley, and winch drives are mutually interlocked to prevent simultaneous operation of any two drives.
2. Bridge and trolley main motor drive operation is prevented, except when the GRIPPER TUBE UP or GRIPPER UP DISENGAGED position switch is actuated.
3. A solenoid valve in the air line to the gripper is de-energized, except when less than or equal to 600 lb suspended weight is indicated by a force gauge. As backup protection for this interlock, the mechanical weigh-actuated lock in the gripper prevents operation of the gripper under load, even if air pressure is applied to the operating cylinder.
4. Hoist drive circuit in the up direction is opened when the “overload” switch is actuated.
5. Hoist drive circuit in the up direction is operable only when either the GRIPPER ENGAGED or GRIPPER DISENGAGED indicating switch on the gripper is actuated.
6. The limit switch in the electrical load cell indicator parallels the gripper-engaged switch. To complete the “hoist-up” circuit, either the gripper must be engaged or the load cell indicator must read less than 1200 lb. This will prevent inadvertently raising a disengaged fuel assembly that is for some reason hung up on the gripper.
7. Bridge and trolley drives are interlocked in the direction of the transfer system so that the bridge is prevented from traveling beyond the core area unless the trolley is aligned with the refueling canal centerline. The trolley drive is locked out when the bridge is moved beyond the edge of the core. The trolley drive is not locked out; it is enabled in the refueling canal area.

Suitable restraints are provided between the bridge and trolley structures and their respective rails to prevent derailing due to the design-basis earthquake. The manipulator crane is designed to prevent disengagement of a fuel assembly from the gripper under the design-basis earthquake. The manipulator crane is parked to one side of the reactor and secured when not in use. The manipulator crane is designed as a Class I component (Section 15.2.1).

9.12.4.5 **Motor-Driven Platform and Hoist**

The movable platform with hoists in the fuel building is a wheel-mounted, motor-driven platform with overhead trusses supporting electric monorail hoists for lifting new fuel assemblies, spent fuel assemblies, and fuel assembly inserts. The platform spans the spent fuel pool and may be maneuvered over any part of the fuel building area necessary for fuel handling operations. The hoist travel and the length of the long fuel-handling tool are designed to limit the maximum lift of a spent fuel assembly to ensure an adequate water shield above the fuel. The movable platform is designed as a Class I component (Section 15.2.1), and is parked to one side of the spent fuel racks and secured when not in use. Suitable restraints are provided between the bridge and the rails to prevent derailing during the design-basis earthquake.

9.12.4.6 **Fuel Handling Tools**

A variety of fuel assembly and component handling tools are used during the core alteration process in the containment and the fuel building, during the loading or unloading of storage casks, or during the loading of shipping casks.

In the containment, movement will be between core locations and the fuel upender. Use of the rod cluster control change fixture is prohibited by procedure because of concerns related to potential loss of refueling cavity level. Fuel assembly movements in the containment are done with the manipulator crane and gripper tube. The locations of these components are shown on Reference Drawings 1 and 2.

In the fuel building, movement during refuelings will be between the fuel upender and/or fuel storage locations and/or the fuel elevator. Fuel assembly movements for spent fuel casks will be between fuel storage locations and the cask. Fuel and component movements in the fuel building are done with the following tools:

1. Spent fuel assembly handling tool
2. Thimble plug handling tool
3. Hand-operated burnable poison rod assembly handling tool
4. Rod cluster control assembly handling tool

9.12.4.7 **Reactor Irradiation Sample and Sample Handling Tool**

As part of the reactor vessel irradiation surveillance program, reactor irradiation sample assemblies are removed from the vessel at approximately 10-year intervals for examination and testing. The sample assemblies are approximately 10 feet long, 1.25 inches in cross-section, and weigh approximately 25 lb. To remove the sample, a sample basket is transferred from the fuel building to the containment using the fuel transfer system. The sample assembly is removed from the vessel using the sample handling tool, and placed in the sample basket. The sample basket is then returned to the fuel building for storage in the spent fuel racks. The sample is shipped off-site for analysis within a short period of time.

9.12.4.8 **Core Mapping Equipment**

Following core alterations, the proper location of fuel assemblies is verified. An underwater television camera and videotape equipment may be used. The camera is suspended above the fuel assemblies during the mapping process.

9.12.4.9 **Fuel Transfer System**

The fuel transfer system for each unit, shown in Reference Drawing 2, is an underwater conveyor car and track system that extends from the refueling canal through the transfer tube and into the spent fuel pool. The conveyor car receives a fuel assembly in the vertical position from the manipulator crane, after which the fuel assembly is tilted to a horizontal position and passed through the transfer tube to the spent fuel pool. Inside the spent fuel pool, it is tilted to a vertical position in preparation for placement in the storage racks. Cranes over the spent fuel pool are used for moving new fuel assemblies, spent fuel assemblies, and fuel assembly inserts (Reference Drawing 3).

During reactor power operation, the conveyor car is stored in the containment and the transfer tube cover is in place on the transfer tube to seal the reactor containment penetration.

9.12.4.10 **Fuel Elevator**

The fuel elevator lowers new fuel assemblies from the top to the bottom of the spent fuel pool so that the new fuel-handling tool and the hook and cable of the traveling platform hoist do not become contaminated by immersion in the pool water. Removal of the fuel assembly from the elevator at the bottom of the pool is accomplished with the long fuel-handling tool, which also is used for transferring spent fuel. To ensure that the spent fuel is not raised above the water level in the spent fuel pool, a key lock switch has been placed in series with the elevator up-button. The fuel elevator is a Class I component.

9.12.4.11 **Control Rod Assembly Changing Fixture**

A fixture is mounted on a wall of each reactor cavity for removing control rod assemblies from spent fuel assemblies and inserting them into other fuel assemblies. The fixture consists of two main components: a guide tube mounted to the wall for containing and guiding the control rod assembly, and a wheel-mounted carriage for holding the fuel assemblies and positioning fuel assemblies under the guide tube. The guide tube contains a pneumatic gripper on a winch that grips the control rod assembly and lifts it out of the fuel assembly. By positioning the carriage, a new fuel assembly is brought under the guide tube and the gripper lowers the control rod assembly into place. The manipulator crane loads and removes the fuel assemblies into and out of the carriage. The above noted equipment is available. However, it is not used at this time. The removal and reinsertion of the control rods into the fuel assemblies are performed in the spent fuel pool. A portable change tool is utilized to relocate the control rods in the spent fuel pool.

9.12.4.12 **Refueling Water Storage Tank**

The refueling water storage tank of each unit (Section 6.2.2.1) provides the water for filling the reactor cavity and for certain safeguards systems.

9.12.4.13 **Fuel Cask Trolley**

The crane for handling the spent fuel cask is a trolley of 125-ton capacity running on fixed rails. The rails span the east end of the fuel pool in an area where no spent fuel storage racks are installed. The rails pass over the decontamination building and then over the roadway. The fuel cask trolley is designed as a Seismic Category I component.

Restraints are provided to prevent displacement of the trolley from the rails.

A 10-ton auxiliary hoist is installed on the South side of the crane. A 1-ton electric chain hoist is installed on the South side and top of the crane to permit fuel-handling tools to be removed from the spent fuel pool for the purposes of inspection or maintenance.

The spent fuel cask and other heavy objects cannot be moved over stored fuel. The 125-ton fuel building crane is a trolley that moves only in a north-south direction over an area at one end of the fuel pool. Spent fuelracks are excluded from this area.

Originally there was a built-up pad of energy-absorbing material over the floor of the fuel pool in the cask loading area. This has been replaced with a pad requiring no maintenance. The new cask pad utilizes large pipes that will plastically deform under a heavy-impact load and thus prevent pool damage. The pipes are open-ended to allow for free movement of water. All materials are stainless steel for corrosion resistance. The cask pad is designed to prevent significant damage to the spent fuel pool from a dropped shipping cask and is designed to protect the pool against spent fuel casks of various sizes. The cask pad also provides a support platform for the shipping cask during loading of spent fuel.

The new cask pad has been installed in the recessed area provided in the spent fuel pool and located in the northeast corner of the pool. A smaller pad has been installed on the pool floor just south of the cask loading area. The smaller pad extends the length of the protected area to prevent unacceptable damage to the fuel pool bottom from the postulated accident of the cask tipping after hitting the bottom. The design of the smaller pad is similar to the larger cask pad.

An analysis has been performed for dropping of a spent fuel shipping cask into the spent fuel pool. The analysis addressed the consequences of a cask drop to adjacent spent fuel and to the pool structure. See Section 9B.1.5.

If the stainless steel fuel pool liner plate is damaged by a cask-drop accident, water could leak into the liner test channels. The test channels are connected to a 0.5-inch pipe, which is buried under the fuel pool and leads to the fuel building sump. This pipe is plugged at the entrance to the sump to prevent any water from escaping from the fuel pool. Should the plug fail or be inadvertently left off, and if the impact damaged the liner at a test channel, water would leak out of the fuel pool at a rate not exceeding 5 gpm.

The normal makeup capability from the primary-grade water system is 200 gpm. An emergency source of makeup is available from the fire main at a rate of up to 2000 gpm.

9.12.4.14 **Polar Crane**

The overhead crane in the containment is of the polar configuration and is supported on the circular crane wall. The crane has two main hooks with a capacity of 140 tons each, with a maximum hook elevation of approximately 52 feet above the operating floor. The polar crane has access to the entire area within the crane wall. The crane is designed as a Class I component. No parts of the crane can be dislodged during an earthquake.

Restraints are provided between the trolley and bridge and between the bridge and rails to prevent derailing during a design-basis earthquake.

9.12.5 Refueling Procedure

9.12.5.1 **Design Bases**

The refueling operation follows a detailed operating procedure that is established to provide a safe, efficient refueling operation. The movement of heavy loads near spent fuel is discussed in Appendix 9B. The following significant points are ensured by the refueling procedure:

1. The refueling water contains approximately 2500 ppm boron. The boron concentration, together with the control rods, is sufficient to keep the core approximately 5% delta k/k subcritical during the refueling operations. The boron concentration is sufficient to maintain the core shutdown if all of the control rods were removed from the core.
2. The water level in the reactor cavity is high enough to keep the radiation levels within acceptable limits when the fuel assemblies are being removed from the core. This water also provides adequate cooling for the fuel assemblies during transfer operations.
3. Fuel-handling operations and equipment are designed so that the possibility of fuel mishandling or damage is minimized.

9.12.5.2 **Preparation Sequence**

1. For Unit 1, the reactor is shut down and cooled to ambient conditions.
2. For Unit 1, the control rod assembly drive mechanism missile shield is removed and stored in the containment.

For Unit 2, CRDM cables, RPI cables, instrument leads, and RV head vent valve cables are disconnected and the CRDM cable bridge and RPI cable bridge are raised.

3. For Unit 1, control rod drive assembly mechanism cables and cooling air ducts are disconnected from the mechanisms and stored in the containment.

   For Unit 2, the RV head lift tripod is installed on the Head Assembly Upgrade Package and cooling air ducts are disconnected from the plenum and stored in the containment.

4. Reactor vessel head insulation and instrument leads are removed.

5. The reactor vessel cavity seal ring is placed in position and installed.

6. The fuel transfer tube cover is removed.

7. The reactor vessel head nuts are loosened with the hydraulic tensioners.

8. The reactor vessel head studs are removed for testing and storage.

9. Checkout of the fuel transfer device and manipulator crane is completed.

10. Guide studs are installed in three holes, and the remainder of the stud holes are plugged.

11. Final preparation of underwater lights and tools is made.

12. The reactor vessel water-level is raised to the level of the vessel flange. The water is transferred from the refueling water storage tank through the reactor vessel.

13. The reactor vessel head is unseated and raised with the reactor containment polar crane and held for inspections of the head lift rig.

14. The source range instrumentation is monitored to verify that the RCC's are not being removed with the closure head.

15. When the reactor vessel head is lifted between 8 and 10 feet, the head lift is stopped and a visual inspection is made to verify that the RCC element drive shafts are free from mechanism housing and were not raised with the closure head.

16. The reactor vessel head is removed to its storage pedestal on the bottom floor of the reactor containment.

17. As the vessel head is being stored, the cavity is immediately being filled to minimize radiation exposure. The refueling cavity is filled 1 ft. 6 in. to check cavity seal integrity. Then the cavity is filled to approximately 16 feet.

18. Before removing the reactor vessel upper internals, all the control rod assembly drive shafts are unlatched and verified.

19. The reactor vessel internals lifting rig is lowered into position by the containment crane and latched to the support plate.

20. The cavity is filled to between the 26 and 27 feet level in coordination with lifting the internals.

21. The reactor vessel upper internals package is lifted out of the vessel and placed in the underwater storage stand on the floor of the refueling cavity.

22. Removal, insertion, and shifting of fuel assemblies proceed in accordance with the refueling sequence (Section 9.12.5.3).

9.12.5.3 **Refueling Sequence**

The refueling sequence is started with the manipulator crane. The sequence for fuel assemblies is as follows:

1. Spent fuel is removed from the core and placed into the fuel transfer system for removal to the spent fuel pool.

2. New fuel and partially spent fuel assemblies are brought in from the spent fuel pool through the fuel transfer system and loaded in the core.

3. The subcriticality of the reactor will be determined after a minimum of 8 fuel assemblies have been added to the reactor core. Thereafter, whenever a fuel assembly is added to the reactor core, either the source range counts is to be monitored for a doubling, or a reciprocal curve of source neutron multiplication is to be plotted to verify the subcriticality of the core at periodic intervals.

9.12.5.4 **Reassembly Sequence**

1. The fuel transfer system conveyor car is parked and the fuel transfer tube isolation valve closed.

2. The reactor vessel internals package is picked up by the reactor containment polar crane and replaced in the reactor vessel. As the upper internals are lowered into the reactor vessel, the refueling cavity water level is lowered to an intermediate level. The reactor vessel internals' lifting rig is removed to storage.

3. The control rod assembly drive shafts are relatched to the control rods.

4. The refueling cavity water-level is lowered, and water is pumped from the refueling cavity into the refueling water storage tank.

5. When the water in the refueling cavity is slightly below the vessel flange level, the pump down is secured.

6. The reactor vessel head is picked up by the reactor containment polar crane and positioned over the reactor vessel.

7. The reactor vessel head is slowly lowered to engage the guide studs. Lowering the head is stopped when the guide studs penetrate the bolt holes.

8. Lower inspectors into the cavity and visually inspect for drive shaft to thermal sleeve alignment. Slowly lower the reactor vessel head until all drive shafts are in their thermal sleeve guide funnels.
9. The reactor vessel head is seated.
10. The guide studs are removed to their storage rack. The stud hole plugs are removed.
11. The fuel transfer tube cover is replaced.
12. The reactor vessel cavity seal may be removed anytime following replacement of the transfer tube cover.
13. The head studs are replaced and retensioned.
14. Vessel head insulation is replaced.
15. For Unit 1, electrical leads and cooling air ducts are reconnected to the control rod assembly drive mechanisms.

    For Unit 2, the CRDM cable bridge and RPI cable bridge are lowered into place and electrical leads and air cooling ducts are reconnected. The head lifting rig tripod is removed.
16. For Unit 1, the control rod assembly drive mechanism missile shield is picked up with the reactor containment crane and replaced.
17. - An inservice leak test is performed on the reactor coolant system.
    - Control rod assembly drive operation is checked.
    - Preoperational start-up tests are performed.

NOTE: The activities listed under item #17 are not necessarily performed in that order.

9.12.6 Fuel Handling System Design Evaluation

Underwater transfer of spent fuel provides essential simplicity and safety in handling operations. Water is an effective, economic, and transparent radiation shield, and a reliable cooling medium for removal of decay heat.

Basic provisions to ensure the safety of refueling operations include the following:

1. Gamma radiation levels in the containment and fuel storage areas are continuously monitored. These monitors provide an audible alarm at the initiating detector and in the control room, indicating an unsafe condition. Continuous monitoring of reactor neutron flux provides immediate indication and alarm in the control room of an abnormal core flux level.
2. Violation of containment integrity is not permitted when the reactor vessel head is removed unless the shutdown margin is maintained greater than 5% delta k/k.
3. After a minimum of 8 fuel assemblies have been added to the reactor core, the reciprocal curve of source neutron multiplication is monitored to verify the subcriticality of the core.

4. The operation is adequately supervised and planned.
5. During REFUELING OPERATIONS, the personnel airlock, the equipment hatch, and other containment penetrations must be capable of being closed. ‘Capable of being closed’ means the openings are able to be closed; they do not have to be sealed or meet the leakage criteria of TS 4.4.

9.12.6.1 **Incident Control**

Direct communication between the control room and the reactor cavity manipulator crane will be established whenever changes in core geometry or conditions are taking place. This provision allows the control room operator to inform the manipulator crane operator of any impending unsafe condition detected by control room indicators during fuel movement.

During refueling operations personnel will be assigned tasks to ensure that open containment penetrations are closed following a fuel handling accident in containment. There should be an individual, who, in addition to their normal duties, is also responsible for making sure one of the personnel airlock doors is closed when the last person is out of containment. The individual should not be outside the protected area but neither does the person have to remain near the airlock. Closure of the equipment access hatch is the duty of a team trained for that task and controlled in accordance with station procedures. Equipment hatch closure will be accomplished as allowed by containment dose rates, which may require containment entry after the personnel airlock has been closed. A part of the closure responsibilities is the removal of objects that penetrate the equipment access hatch and the personnel airlock and would hinder closure. These objects include, but are not limited to guards over the door seals to protect the seals from being damaged, tracks that allow movement of heavy equipment into and out of containment, temporary power lines, etc. These objects are not considered blocking closure as long as they are removable in a reasonable time.

9.12.6.2 **Malfunction Analysis**

An analysis of the consequences of a fuel-handling incident is presented in Section 14.4.1.

9.12.7 Minimum Operating Conditions

Minimum operating conditions for the fuel handling system are contained in the Technical Specifications.

9.12.8 Tests and Inspections

Prior to initial fueling, preoperational checkouts of the fuel handling equipment were performed to ensure proper performance of the fuel handling equipment, and to familiarize operating personnel with operation of the equipment. A dummy fuel assembly was used.

Electrical lighting receptacles are mounted around the spent fuel pool. These receptacles provide additional lighting during fuel pool inspections. All of the receptacles have weather-proof covers.

Upon completion of initial core loading and installation of the reactor vessel head, certain mechanical and electrical tests were performed prior to initial criticality. The electrical wiring for the control rod assembly drive circuits, the control rod assembly position indicators, the reactor trip circuits, the incore thermocouples, and the reactor vessel head water temperature thermocouples were tested at the time of installation. The tests were repeated on these electrical items before initial operation.

Prior to subsequent refueling operations, the equipment is inspected for operating condition, and certain components, such as the fuel transfer car and manipulator crane, are operated to ensure reliable performance before moving irradiated fuel. Pre-refueling checks are part of a continuing program.

9.12.9 Spent Fuel Storage at the Independent Spent Fuel Storage Installation (ISFSI)

As described in Section 9.12.3.3 and Appendix 9A, spent fuel assemblies are stored in the Surry spent fuel pool to allow post-irradiation cooling of the spent fuel. With construction of the Surry ISFSI, dry storage provides additional capacity for on-site interim storage of spent fuel. The Surry ISFSI is licensed for dry storage systems under 10 CFR 72 (License No. SNM-2501). Surry has also selected the NUHOMS-HD spent fuel storage system under the 10 CFR 72 general license issued to Transnuclear, Inc. (Certificate of Compliance #1030)

Pads 1 and 2 at the ISFSI are designed for vertical, metal dry storage systems, and the NRC, as part of the site license, has approved five storage systems. The design and operation of the ISFSI and the approved storage systems are described in the ISFSI Safety Analysis Report (SAR) (Reference 1) and the storage system Topical Safety Analysis Reports (TSARs) referenced in the SAR. Pad 3 at the ISFSI is designed for storage using the NUHOMS-HD system. The design and operation of this system are described in the NUHOMS FSAR (Reference 2). Pad 4 at the ISFSI is designed for storage using the NUHOMS EOS system. The design and operation of this system are described in the NUHOMS EOS UFSAR (Reference 3).

Handling of dry storage systems in the Surry Station for loading or unloading must meet the requirements of Appendix 9B.

9.12 REFERENCE DRAWINGS

The list of Station Drawings below is provided for information only. The referenced drawings are not part of the UFSAR. This is not intended to be a complete listing of all Station Drawings referenced from this section of the UFSAR. The contents of Station Drawings are controlled by station procedure.

	Drawing Number	Description
1.	11448-FM-1B	Machine Location: Reactor Containment, Elevation 18'- 4"
2.	11448-FM-1E	Machine Location: Reactor Containment; Sections “A-A”, “E-E”, & “Z-Z”
3.	11448-FM-9B	Arrangement: Fuel Building, Sheet 2, Unit 1

Table 9.12-1
FUEL-HANDLING DATA

New fuel storage area (common to both units)	
Core storage capacity	2/3 +20%
Equivalent fuel assemblies	126
Center-to-center spacing of assemblies	21 in.
Maximum k_{eff} possible with unborated water	0.98
Spent fuel storage pool (common to both units)	
Core storage capacity	6-1/3 +30%
Equivalent fuel assemblies	1044
Number of space accommodations for spent fuel casks	1
Center-to-center spacing of assemblies	14 in.
Maximum k_{eff} possible with unborated water	0.95
Miscellaneous details	
Width of refueling canal	3 ft
Wall thickness for spent fuel storage pool	3 to 6 ft
Weight of fuel assembly with control rod assembly (dry)	≈1635 lb
Capacity of each refueling water storage tank	375,000 gal
Minimum contents of each refueling water storage tank for safety injection and spray system operability	350,000 gal
Quantity of water required for refueling	220,000 gal

9.13 AUXILIARY VENTILATION SYSTEMS

9.13.1 General Description

The auxiliary ventilation system diagrams are shown on Reference Drawing 5. These include the ventilation and heating systems for the auxiliary building, fuel building, decontamination building, and safeguards areas adjacent to the reactor containments. The cable vault cooling is shown on Reference Drawings 1 and 3. The control and relay room area cooling is shown on Reference Drawing 3. The auxiliary building, fuel building, decontamination building, control room, and ventilation vents are shared by the two units. Individual cable vaults and safeguards areas, and relay rooms, are provided for each unit. The control room and relay rooms for both units are in the service building.

The auxiliary building is a four-level compartmented structure containing the auxiliary nuclear equipment for both units. Equipment handling radioactive fluids is located on the lower three levels, isolated and shielded as required. The upper level is a ventilation equipment room.

Waste gases with a relatively high potential for radioactivity are discharged through filters or the gaseous waste disposal system to the process vent (Section 11.2.5.1). The ventilation exhausts from some primary plant areas are subject to comparatively slight radioactive contamination from such limited sources as pump gland or pipe weepage. The following features are incorporated in these exhaust systems to protect the environment from this relatively remote contamination possibility:

1. For all areas except the auxiliary building central area, two exhaust fans, which provide 100% of the required capacity, are installed in parallel, with an automatic back-flow damper on each fan. One fan will provide approximately 60%-capacity exhaust in the event the other fan fails, or a step flow reduction capacity is desired in the event of radioactive contamination. The auxiliary building central area has two parallel 100%-capacity exhaust fans, also equipped with automatic back-flow dampers.
2. Three iodine filter assemblies, two safety-related and one non-safety-related, are provided. Each filter bank consists of roughing, high efficiency particulate air (HEPA), and charcoal filters. Perforated plate air distribution and straightening sub-plenums are installed in the inlet and outlet plenums of the two safety-related filter housings to provide uniform air flow through the filter housings. The parallel arrangement provides an effective standby filter if one assembly becomes saturated.
3. Two safety-related, high-head fans, sized to draw 36,000 cfm each primarily from emergency core cooling system (ECCS) equipment areas through the safety-related filters, are provided. One non-safety-related, high-head fan, sized to draw the design flow rate of the auxiliary building general area exhaust system through the non-safety-related filter system, is also provided. The capacity of each safety-related high-head fan is 100%. When operating individually, the capacity of each safety-related fan is automatically controlled by electrohydraulically operated inlet valves to draw the design flow rates. When both are

operating, the system configuration limits the flow through each fan to less than 32,400 cfm, even though both inlet valves are full open. In this alignment, the total system flow is greater than the 36,000 cfm required for cooling purposes. The 36,000-cfm ±10% capacity of each filter train equals the maximum design exhaust flow rate from ECCS equipment areas. Each fan has redundant 480V power supplies.

4. Exhaust bypass arrangements allow for selective filtration of any exhaust system. Parallel dampers for each of the safeguards and charging pump exhaust systems provide redundant flow paths to the filters following a loss-of-coolant accident (LOCA). Other exhaust systems have dampers in series to provide redundant closure following a LOCA. All bypass and filter dampers are remote manually operated from the control room as required. In addition, the affected safeguards area and the charging pump ventilation exhaust systems are automatically aligned upon a safety injection signal to ensure flow is diverted to safety related charcoal filters such that airborne radioactivity from the safeguards area and from the exhaust stream from the charging pump cubicles will be removed. The automatic realignment feature for the ventilation system may be defeated as discussed in Section 9.13.4.1. This condition is not expected however, since defeating the automatic realignment is no longer credited in the fuel handling accident analysis, and procedural controls have been established to eliminate operating with automatic alignment defeated. During refueling, the fuel building exhaust may be passed through charcoal filters to ensure radioactivity removal in case of airborne contamination from any source. However, there is no requirement to filter the exhaust since filtration is not credited in the fuel handling accident analysis.

5. Exhaust to the atmosphere is through a common, continuously monitored ventilation vent (ventilation vent no. 2) located on the roof of the auxiliary building. The vent discharges upward with a velocity in excess of 4000 fpm. For details of monitoring equipment and diversion of ventilation control, see Section 11.3.3. A second ventilation vent (ventilation vent no. 1) is located on top of the service building. The gases originating from labs and counting facilities may contain radioactive gases and are monitored just prior to entering this vent stack. The other potentially contaminated inputs entering this vent are the condenser air ejector exhausts. These vent streams are separately monitored.

HVAC systems which are designed primarily to be used only for post accident are in the Technical Support Center (TSC). Filtration is provided in the post accident modes consistent with the anticipated hazards.

The normal HVAC systems which have neither airborne contamination control functions or post accident mitigation functions are not considered available following a loss of offsite power. The system designs range from once through to full recirculation depending on equipment and personnel needs. The design bases are similar to the post accident or airborne contamination systems described in Section 9.13.2.

9.13.2 Design Bases

Outside ambient conditions used for design purposes are 93°F summer dry bulb, 78°F summer wet bulb, 73°F summer dewpoint, 10°F winter dry bulb, 58°F all-year ground temperature, and 15-mph all-year wind velocity.

Normal, full power ventilation is based on limiting the temperature in various locations as follows:

Building	Temperature
Fuel building (with a fuel pool water temperature of 140°F)	105°F maximum, 75°F minimum and 79°F dewpoint
Decontamination building	120°F maximum, 50°F minimum for storage and tank spaces
	105°F maximum, 65°F minimum for work spaces
Safeguards building	120°F maximum in pump cubicles, 50°F minimum
Auxiliary building	120°F maximum, 50°F minimum in nuclear auxiliary equipment cubicles
	105°F maximum, 50°F minimum for the balance of the building and ventilation equipment room
Reactor containment	60°F minimum with purging system in operation
Laundry facility	78°F maximum to 68°F minimum
	80% RH to 10% RH

The use of the high-head fans when the exhaust systems are diverted through the filters ensure that the design space temperatures and purging rates are maintained.

Ventilation for nuclear auxiliary systems is designed on a once-through basis. Supply air is introduced to areas least likely to be contaminated, and then exhausted directly from those with the greatest contamination potential.

The safety-related auxiliary ventilation exhaust filter system is designed to mitigate the release of iodine following a Chapter 14 design basis accident to ensure that both the offsite doses and, in conjunction with the Control Room Air Filtration System, the Control Room doses are maintained within the limits of 10 CFR 50.67. The design of the system provides for (1) uniform air distribution across the prefilter bank within 20% of average velocity, (2) a HEPA filter with 99.5% particulate removal efficiency, (3) charcoal adsorber banks which have less than 1% halogen leakage when tested, and (4) charcoal adsorbers which have a methyl iodide removal efficiency of ≥ 86% when tested in accordance with Technical Specification Surveillance Requirement 4.12.B.7.

The TSC charcoal filter meets the qualifications for a safety-related filter and is tested on the safety-related frequencies.

The non-safety-related filter used to filter frequently contaminated auxiliary building exhaust air has a 99% particulate removal efficiency and a 1% halogen leakage. The air is uniformly distributed within ±20% of the average flow across the face of the filter.

The control room air conditioning is designed to maintain 75±10°F dry bulb during either normal or emergency conditions for personnel comfort except during a turbine building high energy line break (HELB). The emergency switchgear and relay rooms are designed for 80°F dry bulb during normal conditions, and 87°F dry bulb during emergency operations except during a turbine building HELB. Refer to Section 7.7 for equipment qualification information.

The control and relay room area exhaust and replenishment supply ventilation is provided by external systems for normal operations. In an emergency, the control and relay room area is sealed with weather-stripped doors and tight external duct closures. The air conditioning systems will continue to operate normally. Emergency supply fans can be manually aligned to take suction from the turbine building through roughing, particulate, and iodine filters to supply filtered breathing air to the control room indefinitely.

Air-conditioning and associated auxiliary equipment required to operate during emergency conditions are powered from emergency buses.

The ventilation exhaust from the safeguards areas to ventilation vent no. 2, and ventilation vent no. 2, meet Class I design criteria (Section 15.2). This includes the entire ECCS collection and filtration system and the Units 1 and 2 purge exhaust ducts between the containment purge exhaust isolation valves and the safety-related filters. Air-conditioning and emergency ventilation equipment for the control and relay room area also meet Class I design criteria.

Ventilation system arrangements are shown on Reference Drawings 1 through 4.

9.13.3 System Descriptions

9.13.3.1 Auxiliary Building Ventilation

The auxiliary building is supplied with air by two 31,000-cfm air-handling units. The systems have automatic roll filters for continuous cleaning, and steam coils for winter heating. Under normal operating conditions, three exhaust fans are used: one fan for the central spaces, and two fans for the general area which includes the remainder of the potentially contaminated spaces in the auxiliary building. Airflow from the central spaces is nominally 24,000 cfm and is based on two charging pumps operating. Airflow from the general area is approximately 48,000 cfm. The exhausts with radioactive contamination potential always discharge through ventilation vent no. 2. These exhausts can be diverted remotely through the common filter subsystems from the control room, as described in Section 9.13.1. Particulate filters are installed in the exhaust branches from the auxiliary building sample cooler spaces for continuous filtration.

The exhaust ducts from the cubicles of the volume control tanks, containment vacuum pumps, sampling coolers and sinks, process vent blower, gaseous waste disposal system, and recombiner are connected to the general area exhaust system. These cubicle exhausts represent non-safety-related cubicle exhausts and are therefore combined with the general area exhaust system. This exhaust is normally exhausted to the atmosphere via the radiologically monitored ventilation vent no. 2, but can be routed through the non-safety-related filter.

The exhaust duct of each charging pump cubicle has a two-position damper installed to open and exhaust air when the pump is operating and to close when the pump stops. The charging pump exhaust system flow rate is nominally 22,000 cfm following a LOCA. This is the major contribution to the design flow rate capability of the safety-related filter system.

Spaces subject to radioactive contamination have exhaust intakes located as far removed from the space access as feasible. The resulting negative pressure draws the makeup air in through the access and sweeps the space with supply air so that airborne contamination from equipment leakage will be drawn inward to the exhaust.

9.13.3.2 **Fuel Building Ventilation**

The ventilation provides heating to 90°F to inhibit the buildup of condensation, high-efficiency filtration to reduce the possibility of clouding the spent-fuel pool, and an excess exhaust flow to maintain a negative pressure in the building for inward leakage. Two supply fans and dual exhaust fans are provided to permit step capacity reduction in case of airborne contamination and to reduce steam requirements for winter heating.

Two supply fans are provided, one of 29,000-cfm capacity serving the spent-fuel pit, and one of 5000-cfm capacity for the remote equipment space at Elevation 6 ft. 10 in. Both take suction from a common plenum fitted with a combination roll and high-efficiency filter (minimum 90% NBS atmospheric dust) and steam coils for space heating. Heating control, both summer and winter, is as follows:

1. 75°F minimum summer and winter inside temperature, 105°F maximum temperature.
2. Vary the temperature difference between inside and outside from 30°F delta T at 45°F outside to 15°F delta T at 75°F outside.
3. Terminate heating at 90°F inside temperature.

Dual exhaust fans of 17,500-cfm capacity each discharge through ventilation vent no. 2. The larger exhaust flow rate (compared to supply flow rate) is to ensure that only inward leakage occurs. This exhaust may be diverted through the common iodine filter bank during refueling. The exhaust duct from the waste gas compressor cubicle of the fuel building was disconnected from the decontamination building exhaust header and connected to the fuel building exhaust header. Dampers are installed in series to provide redundant closure following a LOCA.

9.13.3.3 **Decontamination Building Ventilation**

The decontamination building is ventilated at approximately 15 air changes per hour, and arranged to maintain a negative pressure for inward leakage.

The supply system incorporates a continuous roll filter, steam coils for space heating, and supply fan. During normal operation, the supply fan is only operated if both exhaust fans are operated. Following a LOCA, the supply fan may continue to operate.

Dual exhaust fans discharge through ventilation vent no. 2 with a remote manual bypass arrangement to discharge through a filter bank, if needed. Dampers are installed in series to provide redundant closure following a LOCA.

9.13.3.4 **Safeguards Area Ventilation**

The safeguards areas are outside of, and adjacent to, each reactor containment structure. They contain the recirculation spray pumps, low-head safety injection pumps, refueling water recirculation pumps, containment spray pumps, and motor control center. These areas have a contamination potential and are exhausted by 6000-cfm-capacity dual fans located in the auxiliary building, which discharge to ventilation vent no. 2. An automatic capability is provided for the recirculation spray pumps, low-head safety injection pumps, and valve operating space areas for particulate and iodine filtration on a safety injection signal. Parallel dampers are installed to provide redundant flow paths to the filters following a LOCA.

Heated supply air is provided for all spaces. The supply system is fitted with continuous roll filters and steam heating coils for cold-weather space heating. The ventilation system is operated with a larger exhaust flow rate than supply flow rate to ensure inward leakage. This is accomplished by not operating the 16,000 cfm supply fan.

The Main Steam Valve House (MSVH) is adjacent to the safeguards area and houses the auxiliary feedwater pumps. The MSVH is not considered a potentially contaminated area and, therefore, this area is exhausted directly to atmosphere. Ventilation is provided by a wall-mounted exhaust fan and by openings in the wall at ground level and in the roof. The space is not heated since the main steam lines within the structure provide sufficient heating.

9.13.3.5 **Service Building Ventilation**

The ventilation for service building spaces subject to possible radioactive contamination is described below.

The hot laboratory, count room, and Health Physics lab are exhausted by two 2325-cfm fans in parallel. The exhaust is continuously drawn through roughing and particulate filters and discharged through the monitored ventilation vent no. 1. The controlled corridors, decontamination area, and one laboratory fume hood are exhausted by a 4000 cfm fan through roughing and particulate filters. Discharge is to the monitored ventilation vent no. 1.

Ventilation exhausts for the remainder of the service, turbine, and yard buildings are discharged directly to the atmosphere.

9.13.3.6 Main Control Room and Emergency Switchgear and Relay Room Ventilation

The air-conditioning equipment for the main control room (MCR) and emergency switchgear and relay room area is located within tornado-protected and missile-protected structures to ensure cooling during both normal and accident conditions.

Each MCR and emergency switchgear and relay room area is air conditioned by one of two air-handling units installed within the space served. The eight AHUs are arranged in two separate chilled water loops (4 AHUs on each loop), and either one or both chilled water loops are operated, as necessary, to maintain space temperatures. With only one loop in operation, one chiller provides chilled water to all operating AHUs. With both loops in service, two chillers provide chilled water separately to each loop, but only two AHUs are operating on each loop. Condensing cooling water is provided by service water lines described in Section 9.9.

Three chillers are located in Mechanical Equipment Room No. 3 (MER-3), and two chillers are located in Mechanical Equipment Room No. 5 (MER-5). This arrangement prevents full loss of cooling in the event of a fire in either MER-3 or MER-5. Three of the five chillers are powered from either of two buses, enabling maximum system flexibility in aligning the chillers as required. Additional equipment includes control panels and isolation switches for affected air handling units and cables routed to provide the required separation. The additional equipment is seismically and environmentally qualified, as applicable. Control of the air conditioning system is remote manual from the control room. An Appendix R power feed is available to power one chiller in MER-5 from MCC 1A2-3 (which can be supplied from the AAC) in the event of an Appendix R fire in Unit 2 Emergency Switchgear Room.

The MCR and emergency switchgear and relay rooms supply and exhaust air is provided by other systems. These systems are balanced to provide a positive pressure within the MCR and emergency switchgear and relay rooms with the boundary doors closed. Tight, redundant, Seismic Category I isolation dampers (remote manually or automatically operated closures in the ducts) and weather-stripped doors permit isolation of the control room envelope. Emergency ventilation is provided for each space. Emergency ventilation takes suction from the turbine building through roughing particulate filters, high efficiency particulate air (HEPA) filters, and charcoal adsorbers to remove airborne radioactivity. Following a design basis accident, the emergency ventilation system is assumed to operate within 1 hour of control room envelope isolation. The emergency ventilation system will indefinitely provide a supply of filtered breathing air. Control of the emergency ventilation system is remote manual from the control room. Emergency power is supplied for emergency ventilation equipment (Section 8.5). The redundant, seismic Category I isolation dampers in the control room and emergency switchgear relay rooms' area supply and exhaust air ducts close automatically in response to a safety injection signal. On the loss of power, the dampers fail to the closed position. The dampers can also be closed by remote manual operation. To minimize MCR Pressure Envelope Inleakage, the non-safety related ventilation fans which serve adjacent spaces to the envelope are automatically stopped upon closure of the isolation dampers. Safety-related pressure differential indicators have been installed in the envelope to verify positive pressure with respect to adjacent spaces.

HEPA filters are installed before the charcoal adsorbers to prevent clogging of the charcoal adsorbers. The charcoal adsorbers are installed to reduce the potential intake of radioiodine to the control room. When performed, the in-place test results should indicate a system leak-tightness of less than 1% bypass leakage for the charcoal adsorbers and particulate removal efficiency of at least 99.5% for the HEPA filters. New charcoal adsorbent for the emergency ventilation is qualified as discussed in Section 9.13.2 for safety-related filters. The adsorbent is replaced every 720 hours of use or following painting, fire, or a chemical challenge while running. The control room dose calculations for the design basis accidents assume a 90% elemental iodine removal efficiency and a 70% organic iodine removal efficiency for the air passing through the charcoal filters. Therefore, if the efficiencies of the HEPA filters and charcoal adsorbers are demonstrated to be as specified, at flow rates, velocities, and temperatures within the design values of the system, the resulting doses will be less than the allowable levels stated in 10 CFR 50.67.

10 CFR 50 Appendix R requirements and control room fire protection provisions are discussed in Section 9.10.

9.13.3.7 **Auxiliary Ventilation Control Panel and Annunciator**

The auxiliary ventilation control panel (VNTX) and annunciator is located in the control room area. The panel consists of an instrument nest and relay section, and a control indication section.

The control and indicating section contains control switches and indicating lights. The indicating lights are arranged in a mimic display on the panel front, and monitor damper position and ventilation system status and alignment. The control switches are required for filter/unfilter system alignment and to defeat the ventilation system realignment in response to a safety injection signal. Further discussion of defeating the automatic alignment feature of the ventilation system is in Section 9.13.4.1. This condition is not expected however, since defeating the automatic realignment is no longer credited in the fuel handling accident analysis and procedural controls have been established to eliminate operating with automatic alignment defeated.

Also located on the indicating and control section is the auxiliary ventilation system filtered exhaust fan controls and instrumentation.

The instrumentation includes a vane actuator control station and discharge flow indicator for each fan. This provides the operator with exhaust filter status, capacity control, and flow indication.

9.13.3.8 **Laundry Facility Ventilation**

The laundry facility ventilation is subject to possible radioactive contamination. The combined airborne effluent from the laundry facility (i.e., dryer exhaust, hood exhaust, and HVAC exhaust) is passed through HEPA filters before it exits the facility. The exhaust flow rate is 16,000 cfm. To assure that no unmonitored releases occur, the airborne exhaust, downstream of the HEPA filters is continuously monitored.

9.13.3.9 **TSC Ventilation**

The TSC spaces expected to be occupied are maintained at a positive pressure, post event, by turbine building air drawn through roughing, HEPA, and charcoal filters at a nominal 1000 cfm. The filter automatically starts on an SI signal and the normal air supply and exhaust are double-damper isolated. A positive pressure is maintained in the TSC spaces, as indicated on installed gauges, to ensure that no inleakage occurs.

9.13.3.10 **LEOF Ventilation**

The LEOF may be pressurized with outside air drawn through roughing and HEPA filters. The LEOF is manually activated post event and habitability determined by surveys performed as part of activation. The CEOF will replace the LEOF if necessary.

9.13.4 Design Evaluation

The ventilation systems in areas of potential contamination provide contamination control by ensuring that air is not recirculated, that 10 or more air changes per hour are supplied, and that the air is supplied to the least likely areas to be contaminated for circulation to and exhaust from locations subject to the greatest contamination potential. After being monitored for gaseous and particulate activity, the systems are exhausted through a ventilation stack discharging upward at a velocity in excess of 4000 fpm. A capability is provided for all nuclear auxiliary exhaust systems subject to airborne radioactive contamination to be realigned through roughing, particulate, and activated charcoal filters.

The ventilation system limits summer space temperatures to 105°F in occupied spaces and 120°F in normally unoccupied machinery spaces. Ventilation is based on the heat-producing equipment operating, and summer space temperatures will be lower whenever such equipment is down for maintenance.

The heating system provides space temperatures sufficient for winter operations and/or the inhibition of condensation in the fuel building and spaces below grade.

The MCR and emergency switchgear and relay rooms' area is completely enclosed in a tornado-proof and missile-proof concrete structure that requires air conditioning for operation. Each of the two redundant air handling units within each area is served by one of two chillers powered from the same power source (normal and emergency).

9.13.4.1 **Incident Control**

The safeguards area and charging pump cubicle exhausts to ventilation vent no. 2 are automatically realigned through the safety related particulate and iodine filters upon a safety injection signal unless the re-alignment is defeated due to the movement of irradiated fuel in the spent fuel pool. This condition is not expected however, since defeating the automatic realignment is no longer credited in the fuel handling accident analysis and procedural controls have been established to eliminate operating with automatic alignment defeated. If re-alignment is not defeated and a safety injection signal is received, the signal produces common pneumatic safety signals that cause the running exhaust fans to trip. Various air-operated and motor operated dampers are automatically repositioned to redirect exhaust flow through the safety related filters. The high capacity, safety related fans are automatically started. Except for the decontamination building, inward leakage is ensured, as the supply fans are shutdown. In the event of leakage from the recirculation spray system, or the low-head and high-head safety injection systems during recirculation mode transfer, airborne radioactivity would be removed from the safeguards area and from the exhaust ventilation stream from the charging pump cubicles by these filters. Ventilation fans and dampers receiving a safety injection signal require operator action to return the component to its non-safety mode upon reset of the safety injection signal.

Defeating the automatic alignment feature requires that, in the event of a LOCA, manual actions are required by the operator to re-enable the automatic alignment of the ventilation system to the safety related filters to process the exhaust from the safeguards area and charging pump cubicles following actions to secure fuel handling activities (Reference 1). Following a safety injection signal, an alarm is received in the MCR after a time delay if the automatic re-alignment is defeated.

During refueling, the fuel building and containment exhaust may be diverted through the two safety-related filter trains. However, there is no requirement to filter the exhaust since filtration is not credited in the fuel handling accident analysis. This will remove airborne particulate radioactivity.

If a high-radiation alarm from the ventilation vent continuous monitor occurs, the control room operator will:

1. Trip any operating supply fans and exhaust fans for:
    a. Auxiliary building central area
    b. Auxiliary building general area
    c. Fuel building
    d. Decontamination building
    e. Unit 1 safeguards
    f. Unit 2 safeguards

2. Locate source of activity by:

    a. Aligning auxiliary building exhaust to nonsafety charcoal filter

    b. Aligning remaining areas to safety-related filter or filters while maintaining filter flows within desired range

3. When the source area is detected, this area remains on filtered exhaust. Additional areas may be filtered as needed to keep filter flow within design range.

4. Request Health Physics to:

    a. Verify area evacuated as necessary,

    b. Control area access as necessary,

    c. Survey area, and

    d. Investigate cause.

The MCR may be isolated as necessary.

There are seven flow streams connectable to the safety related filters. The fuel building and either containment purge may be individually filtered by a single filter train. The volumetric flow may be less than 32,400 cfm but will remain above the fan low flow trip setpoint. The lower flow increases the residence time in the charcoal.

Except as noted above, and in Section 9.13.1, the flow through the safety related filters is procedurally controlled in the design range between 32,400 cfm and 39,600 cfm. Up to three areas may be filtered simultaneously by a single train.

For a discussion of incident control during containment purging or refueling, see Section 5.3.1.3.4.

In the event of a LOCA, the control room and emergency switchgear and relay room's area is sealed off by closing the weather-stripped access doors and the pressure-tight external duct closures at the space boundaries and internal fire barriers. The duct closure is automatic from a safety injection signal or can be closed from the control room by hand switches. The ventilation fans which serve adjacent spaces to the MCR will automatically shutdown to minimize inleakage into the MCR. A handswitch has been provided in the MCR if manual stopping is required. The air conditioning will continue to operate normally without change. Within 1 hour of control room envelope isolation, procedures require the alignment of the control room emergency ventilation system to provide a filtered breathing air supply to the control room envelope. The emergency ventilation is filtered through a roughing filter, a HEPA filter, and iodine adsorbers. All functions can be manually controlled from the control room ventilation control board.

Incipient fires in the control and emergency switchgear and relay room's area will be extinguished with portable equipment. If a fire becomes uncontrollable, the affected space will be isolated by closing the fire doors. The air-conditioning ductwork is self-contained within each space, and the closures in the replenishment air and exhaust ducts fitted at each fire barrier will prevent smoke contamination in adjacent spaces. The motor operated normal supply dampers may be closed should smoke enter the control room from outside the control room area. If the control room becomes untenable because of fire or smoke, the reactor units can be controlled in the hot shutdown mode from their respective auxiliary control areas in the emergency switchgear rooms.

9.13.4.2 **Malfunction Analysis**

To assure that potential contaminated air flows from areas of low potential to high potential, selected supply fans are procedurally controlled to operate only when sufficient air is being exhausted. For example, the larger Fuel Building supply fan cannot be operated unless both unfiltered exhaust fans are running or the building is on filtered exhaust. Exhaust fans whose operation could potentially lead to unmonitored releases are procedurally controlled to preclude operation or abandoned in place.

The total flow is measured in ventilation vent no. 2 and displayed within the MCR. Status lights are also provided in the MCR for each fan connected to the vent. If a fan becomes inoperative, a change will be indicated in the total flow. Where applicable, procedural controls have been established to preclude operating a supply fan when one of a pair of associated exhaust fans is not operating.

Each Unit’s MCR and emergency switchgear and relay room is equipped with two 100% capacity air handling units for a total of eight AHUs. The eight AHUs are arranged in two separate chilled water loops (4 AHUs on each loop), and either one or both chilled water loops are operated, as necessary, to maintain space temperatures. With only one loop in operation, one chiller provides chilled water to all operating AHUs. With both loops in service, two chillers provide chilled water separately to each loop, but only two AHUs are operating on each loop. The air handling units’ fans are started from inside the MCR. The MCR and emergency switchgear and relay room air conditioning system includes five 100% capacity chillers.

9.13.5 Tests and Inspections

The systems are inspected, tested, and balanced upon installation, and tested periodically thereafter. Operating hours are equalized on redundant systems. Particulate and charcoal filters are individually tested by the manufacturer after fabrication and again after installation. Replacement filters are tested in the same manner. Filter banks can be tested for leakage and dioctylphthalate (DOP) smoke test efficiency while in place, and defective cells identified for removal and replacement. Equipment installed for emergency use is tested during installation and operated monthly thereafter to ensure proper functioning.

Individual filter assemblies are periodically tested in accordance with Technical Specifications. In addition, equipment has been installed to allow regular monitoring of the filters. This equipment includes filter differential pressure indication, view ports, inside lights, inside and outside shrouds, and test ports. Not all of the filters contain all of the above monitoring equipment, but most filters can be monitored directly.

The two safety-related filter trains have 18 charcoal canisters installed in parallel with the main adsorber tray banks. The canisters are filled with the same adsorbent as the main adsorber trays and are removable from the outlet plenum for laboratory analysis. Charcoal analysis is to be performed every 720 hours of safety-related filter operation.

9.14 DECONTAMINATION FACILITY

The decontamination facility (Reference Drawing 1) is a poured-concrete and concrete-block structure on the north side of the fuel building, under the fuel cask trolley rails. This location makes it accessible for transporting in and out of the building major items to be decontaminated. Roof hatches and a rolling steel door provide access for equipment.

9.14.1 Design Bases

The facility is designed to provide an area in which equipment can be decontaminated and spent fuel dry storage casks can be prepared for storage without releasing activity to the environment in an uncontrolled manner. Decontamination procedures are specified to reduce surface contamination to a level such that the components can be handled in a safe manner. Certain decontamination activities (such as deconning small tools and equipment) are performed at the Radwaste Facility.

9.14.2 Description

The decontamination building is a poured-concrete and concrete-block building abutting the east end of the fuel building's north wall. A 125-ton trolley runs through a high-bay portion of the building immediately adjacent to the fuel building, and over the roof for the remainder of the decontamination building. Three roof hatches permit casks or other objects to be lowered from the trolley into the building. A tramrail in the building permits the movement of small parts between work areas and tanks with minimum personnel exposure. A T-shaped rolling steel door encloses the high-bay area from the outside when the trolley is not in use. The fuel building and decontamination building are separated by a weathertight structural gap to permit independent motion of the buildings in the event of an earthquake.

Ventilation air is exhausted from the decontamination building through the monitored ventilation vent no. 2. On a high alarm by ventilation vent no. 2 monitors, the decontamination exhaust is remote-manually diverted through charcoal filters as described in Section 9.13. The exhaust capacity is greater than the supply capacity of this system, thus producing a slightly negative pressure in the buildings, so that all air leakage is inwards.

Liquid wastes from decontamination work are piped to the liquid waste disposal system (Section 11.2.4) for processing.

The interior surfaces of the building are covered with suitable materials to permit easy decontamination. A stainless steel pad is provided to protect the floor under heavy objects. Hose connections are provided for compressed air and primary-grade water at each work area. The various decontamination methods provide a flexibility that will give the best decontamination for a specific job, minimize personnel exposure, and limit the release of radioactive material to the environment. Technical information on the equipment provided in the facility is given in Table 9.14-1.

Spent ion exchanger resins can also be processed in the decontamination building via the spent resin catch and blend tanks and their associated transfer pumps. The operation of this equipment and component data are provided in Section 11.2.4.

Final preparations for the spent fuel storage casks takes place in the north bay of the decontamination building. These final preparations consist of decontamination of the external cask surfaces, vacuum drying of the cask interior to remove residual spent fuel pool water, backfilling the cask cavity with helium, placement of the cask secondary lid as applicable, and testing the cask seals for leak-tightness.

To facilitate these preparations, a permanent work platform is installed. The work platform is a two-level platform located in the north bay of the decontamination building. The platform is designed with swing-up sections to facilitate cask entry and to preclude any potentially hazardous openings in the flooring. The cask, which has been loaded with spent fuel assemblies in the spent fuel pool and transferred to the decontamination building via the 125-ton trolley, is lowered into the opening in the work platform.

A piping system is used to remove the Spent Fuel Pool water from the fuel storage Dry Shielded Canister (DSC) prior to vacuum drying. The system is manually operated and consists of a centrifugal DSC Drain Pump, flow indicator, valves and piping routed from the DSC to below the surface of the Spent Fuel Pool water. Additionally, if required, a DSC Reflood Pump is provided to fill the canister with Spent Fuel Pool water. This system consists of a self-priming centrifugal pump, flow indicator, valves and piping routed from below the Spent Fuel Pool water surface to the DSC.

A Vacuum Drying System (VDS) is installed near the DSC (Dry Shielded Canister) on the working level platform Elevation 37 ft. 0 in.). The VDS is a single skid mounted computer controlled unit with monitor and all the necessary valves, pumps, moisture separator tank, cooling and heating systems, flow meters, pressure and vacuum gauges and external boom connections to facilitate vacuum drying, draining, reflooding and helium back filling of the DSC. The VDS is capable of performing draining and reflooding of the DSC in addition to the installed DSC drain pump and DSC reflood pump.

The discharge from the VDS vacuum exhaust is piped to the decontamination building ventilation system. This ventilation system monitors the air discharged from the decontamination area for radioactive contamination and has the equipment available for removing radioactive contaminants from the air steam, should the need arise.

The helium system is made up of a helium bottle rack containing helium bottles, and is located in the crane enclosure. From this bottle manifold, helium is piped to the VDS. The VDS supplies helium to the DSC for helium backfilling through boom piping.

Nitrogen bottles located in the crane enclosure are piped from a manifold to the VDS. Nitrogen is utilized by the VDS for operation of its internal pneumatic valves, to purge collected moisture from the VDS vacuum pumps and piping, and for pneumatic operation of the moisture separator tank drain and vent valves.

9.14.3 Design Evaluation

The facility provides a contained area with all discharges controlled to prevent the inadvertent release of activity to the environment.

In the event of leakage from piping or equipment, areas of the building are provided with sumps to which fluids will drain. The sumps discharge to the liquid waste disposal system. Airborne particulate matter is retained within the building because of the slightly subatmospheric pressure, and is discharged in a controlled manner through the monitored ventilation vent no. 2.

9.14.4 Tests And Inspections

Periodic tests are conducted on the radiation detection equipment in the ventilation system.

Operating equipment and storage tanks are subjected to periodic visual inspections.

Appendix 9A
High-Density Spent-Fuel Storage Rack Design

Intentionally Blank

APPENDIX 9A HIGH-DENSITY SPENT-FUEL STORAGE RACK DESIGN

9A.1 DESIGN BASES

The high-density spent-fuel storage racks are designed to provide vertical storage locations for up to 1044 irradiated fuel assemblies, including insert components, in a borated water pool (with a boron concentration not less than 2300 ppm). The racks are designed to maintain the stored fuel, having maximum initial uranium enrichment of 4.3 weight percent U-235 in UO_2, in a safe, coolable, and subcritical configuration under all conditions.

The reinforced concrete structure and steel superstructure of the Fuel Building and spent fuel storage racks are designed to withstand Design Basis Earthquake loadings as Class 1 structures. The spent fuel pool has a stainless steel liner to protect against loss of water.

The spent fuel pool is divided into a two-region storage pool. Region 1 includes the first three rows of fuel racks (324 storage locations) adjacent to the Fuel Building Trolley Load Block. Region 2 contains the remainder of the fuel racks in the fuel pool. During spent fuel cask handling, Region 1 is limited to storage of spent fuel assemblies which have decayed at least 150 days after discharge and will be restricted to those assemblies in the “acceptable” domain as described in Technical Specification 5.4.

9A.2 STORAGE RACK DESCRIPTION

The spent fuel pool is a seismic Category I structure. Its primary function is to store spent fuel assemblies. The spent fuel pool is a 72 ft. 6 in. long, 29 ft. 3 in. wide and 40 ft. 6 in. deep reinforced concrete structure resting on a pile foundation. The floor and walls of the pool are nominally 6 feet thick. The pool is lined with 0.25-inch thick stainless steel liner plate. The spent fuel cask loading area (12 ft x 12 ft) is located at the northeast end of the pool. The floor of the cask loading area is 2 ft. 6 in. lower than the pool floor. The cask pad sits in this area.

Each fuel storage rack consists of a 6 x 6 array of fuel storage cells, which are square stainless steel boxes spaced nominally 14 inches on centers. The rack is shown on the general arrangement drawing, Figure 9A-1.

The fuel storage rack has two basic components: the support structure and the fuel storage cell. The support structure consists primarily of the four corner storage cells, which interface with the spent-fuel pool floor pads, and two horizontal grid members, which are supported by the four corner cells and which maintain the horizontal position and vertical alignment of the remaining 32 (inner) storage cells. The inner storage cells rest directly on the spent-fuel pool floor. Diagonal bracing is provided on the structure to accommodate the loads imposed by rack installation, by fuel handling, and by seismic events.

Horizontal seismic loads are transmitted from the rack structure to the spent-fuel pool floor through restraint devices that capture the existing spent-fuel pool floor pads and mate with the fuel rack structure corner cells. The restraint devices also permit leveling of the fuel racks, and require no modification of the existing fuel rack support pad. The vertical seismic loads are essentially transmitted directly to the pool floor by each storage cell. No bracing to the pool wall is required to support the racks during a seismic event. The racks, however, are connected to each other at the top grid to preclude potential uplift.

Each corner storage cell is nominally 9.56 inches by 9.56 inches (o.d.) by approximately 172 inches long, with 0.250-inch walls. Each of the 32 inner storage cells is nominally 9.12 inches by 9.12 inches (o.d.) by approximately 170 inches long, with 0.090-inch walls. The cells are flared at the top to aid in insertion of the fuel assembly into the cell. Attached to the bottom of each cell are four stainless steel posts that support the fuel assembly. The posts attached to the 32 inner cells rest directly on the floor of the spent-fuel pool and space the cells off the pool floor a sufficient distance to ensure adequate area for cooling flow. To accommodate any unlevelness in the pool floor liner, the rack is designed to permit the inner cells to move vertically within the rack structure (a ±1-inch motion is provided). The inner cells, however, are positively locked into the support structure so that they cannot be inadvertently lifted out of the rack.

The corner cells rest on adapter plates. The adapter plates are keyed to the existing rack stops, and the corners of the fuel storage cells are keyed to the adapter plates through 1-5/8-inch-diameter restraint pins. For installation purposes, a nominal clearance of 1/16 inch is provided all around between the restraint pin hole in the corner storage cells and the restraint pin, and between the clearance cutouts in the adapter plates and the existing rack stops. The clearance also provides sufficient allowance for thermal expansion. Horizontal seismic loads are transmitted from the rack structure to the existing rack stops at each corner of the rack through the adapter plates and pins. The racks cannot slide during any design-basis seismic event.

There is no interference between the spent-fuel storage racks and the gates and tools in storage within the pool. All of the equipment stored within the fuel pool, except the refueling canal gates, weighs less than a fuel assembly. Therefore, any possible interaction between these tools and the fuel racks would be less severe than interaction between a fuel assembly and the spent-fuel storage racks, which has been analyzed. The refueling canal gates, however, weigh approximately 3200 lb, which is more than a fuel assembly. These gates are stored so as to be captured at both the top and the bottom, making interaction between the gate and the spent-fuel storage racks very unlikely.

The rack grids maintain the horizontal position of the inner cells relative to each other and the corner cells so that impact between inner cells and/or corner cells is not possible. Each grid consists of welded 4 inches by 1.5 inches by 3/16 inch channels forming square openings in which the inner cells are placed. The grids are welded to the top and bottom ends of the heavy wall (0.25-inch thick) corner storage cells to form the basic rack structure. Diagonal bracing welded to the corner storage cells completes the rack structure and provides the lateral and torsional rigidity to accommodate seismic and installation loads.

At each grid elevation, four angle clips capture the corners of each inner cell. These clips are welded to the channel members of each grid to maintain pitch and vertical plumbness. A slight clearance is provided between the clips and the cells (1/64-inch maximum for each clip) to facilitate fabrication and to permit vertical movement of the inner cells. Such vertical movement does not introduce any stresses/deformations in the rack structure or the inner storage cells, since each inner cell can move freely past the grid retaining clips to sit directly on the pool floor. The design permits the vertical loads for each inner cell to be transmitted to the pool floor. It is necessary to limit the vertical travel of the inner storage cells to prevent (1) removal of a cell during fuel-handling operations (e.g., stuck fuel assembly load case) and (2) a cell dropping out of the rack during rack installation/removal. Mechanical stops welded to each inner cell limit the total vertical travel to about 2 inches (±1 inch). These stops will support the weight of the fuel cell plus a fuel assembly if necessary.

A fuel assembly guard structure is provided to prevent a fuel assembly from being brought up against the side of the peripheral fuel racks wherever the space between the fuel racks and the fuel pool walls is sufficient to insert an assembly. The structure is a 4 inches by 2 inches by 3/16 inch angle welded to the outside channel of the upper grid. With this structure in place it will not be possible to move a fuel assembly closer than approximately 8 inches to stored fuel, thereby maintaining a pitch in excess of 17 inches for this condition. The guard structures are required on the east and west sides of the storage rack array, and on the two racks adjacent to the Unit 2 refueling canal. The space between the fuel racks and the north or south walls is not sufficient to insert a fuel assembly.

9A.3 STORAGE RACK EVALUATION

9A.3.1 Structural and Seismic Analysis

The high-density fuel storage racks are designed to meet the requirements for Seismic Class I structures. Detailed structural and seismic analyses of the high-density storage racks have been performed to verify the adequacy of the design to withstand the loadings encountered during installation, normal operation, the severe and extreme environmental conditions of the operating-basis and safe-shutdown earthquakes, and the abnormal loading condition of an accidental fuel-assembly-drop event.

The ground acceleration values in Section 2.5 were used to generate the amplified response spectra used in the design of the spent-fuel racks. A dynamic model representing the fuel building structure and the subgrade was prepared. This model was used to calculate amplified response spectra (ARS) due to the specified earthquake. Amplified response spectra were generated for both the safe-shutdown earthquake and the operational-basis earthquake (one-half of the safe-shutdown earthquake) at the mat surface, the top of the concrete structure, and the roof of the steel superstructure. The response spectra of the design earthquakes used are consistent with the requirements set forth by NRC Regulatory Guide 1.60, and the damping levels are from NRC Regulatory Guide 1.61.

The dynamic analysis was performed for a range of subgrade properties to account for uncertainties in soil parameters. The amplified response spectra provided are the result of enveloping the response spectra obtained from these analyses. They also include the design ground response spectrum.

The various load combinations considered in the design of the high-density fuel storage racks and the allowable stress values for these load combinations are given in Tables 9A-1 and 9A-2, respectively. The yield stress value for stainless steel used in calculating the section strength for all the load combinations was taken as 30.0 ksi.

9A.3.1.1 **Applicable Codes, Standards, and Specifications**

The applicable codes, standards, and specifications used in the design, fabrication, inspection, installation, and evaluation of the high-density fuel storage racks are given below.

1. Design: A.I.S.C. Manual of Steel Construction, Seventh Edition, 1970.
2. Fabrication:
   a. ASME Code, Section VIII.
   b. ASME Code, Section IX, Welding and Brazing Qualifications.
3. Inspection: ASME Code, Section V, Nondestructive Examination.
4. Installation:
   a. ASME Code, Section VIII, Appendix 9.
   b. ASME Code, Section IX.
5. Evaluation:
   a. USNRC Regulatory Guide 1.60, *Design Response Spectra for Seismic Design of Nuclear Power Plants*, December 1973.
   b. USNRC Regulatory Guide 1.61, *Damping Values for Seismic Design of Nuclear Power Plants*, October 1973.
   c. USNRC Regulatory Guide 1.92, *Combination of Modes and Spatial Components in Seismic Response Analysis*, Revision 1, February 1976.

9A.3.1.2 **Loads and Load Combinations**

The following load cases were considered in the analysis, in accordance with the requirements of USNRC Standard Review Plan, Section 3.8.4, *Other Seismic Category 1 Structures*.

1. Dead weight of rack plus corner fuel assemblies, D + L (normal load) - Under normal operating conditions, the rack is subjected to the dead weight loading of the rack structure itself plus the loads resulting from four fuel assemblies stored in the four structural corner cells. The loads resulting from the individual storage cells and contained fuel assemblies are not considered, since these transmit their load directly to the pool floor and not through the structure.
2. Dead weight of rack and storage cells, D + I.L. (normal load) - During installation, the rack is subjected to the loading resulting from its own structural weight plus the weight of the empty storage cells.
3. Operating-basis earthquake, E (severe environmental load) - The rack, fuel assemblies, and virtual water mass react to the simultaneous loading of the horizontal and vertical components of the seismic response acceleration spectra specified for the operating-basis earthquake in the Surry 1 and 2 seismic design specifications. The seismic loading is applied to two storage conditions: a fully loaded rack, and a partially loaded rack with 21 assemblies.
4. Safe-shutdown earthquake, E' (extreme environmental load) - Same as Load Case 2, except the seismic response acceleration spectra corresponding to the safe-shutdown earthquake were used in the analysis.
5. Uplifting load, U.L. (abnormal load) - The possibility of a fuel assembly becoming jammed in a fuel storage cell during fuel handling was considered. The uplift force considered for this load case is the maximum force that can be applied by the fuel-handling bridge fuel hoist (4000 lb) less the weight of the jammed fuel assembly and the fuel storage cell (combined weight is 1650 lb). The uplift force used in the analysis (2400 lb) is very conservative, since the fuel hoist has a load-limit cell set at 2000 lb. With such a load-limit device, the net uplift force would be about 350 lb. No credit was taken for operation of the load-limit cell.
6. Assembly drop impact load, F.I. (abnormal load) - The possibility of dropping a fuel assembly on the rack from the highest possible elevation during spent-fuel handling was considered. A 2000-lb weight was postulated to drop on the rack from a height of 42 inches.

For the service load cases described above, the following load combinations were considered, using elastic working stress design methods of the AISC:

D + L	(Load Case la)
D + I.L.	(Load Case lb)
D + L + E	(Load Case 2)

For the factored load cases described above, the following load combinations are considered, using elastic working stress design methods of the AISC:

D + L + E' (Load Case 3)

D + U.L. (Load Case 4)

D + F.I. (Load Case 5)

9A.3.1.3 **Design and Analysis Methods**

9A.3.1.3.1 Static Analysis

The response of the rack structure to specified static loading conditions was evaluated by means of linear-elastic analysis using the finite element method. The rack was mathematically modeled as a three-dimensional finite element structure consisting of discrete three-dimensional elastic beams and plates. Six degrees of freedom (three translations and three rotations) were permitted at each nodal point. Appropriate boundary conditions were assumed for each load case.

9A.3.1.3.2 Dynamic Analyses

The response of the rack structure to specified seismic loading conditions was evaluated by mathematically modeling the storage rack as a lumped mass, multi-degree-of-freedom system. The fuel storage rack structure has been mathematically modeled as a three-dimensional finite element structure consisting of discrete three-dimensional elastic beam and plate elements interconnected at a finite number of nodal points. Masses were lumped so as to represent the dynamic characteristics of the storage racks. The eigenvalues and eigenvectors (frequency and mode shapes of vibration) of the lumped mass model were calculated using the Householder-QR technique.

The seismic response analyses were then performed using response spectrum modal superposition methods of dynamic analysis, using the Surry amplified response spectra and appropriate damping for welded steel structures. The damping values used in the seismic analysis of the high-density fuel storage racks are 4% for the operating-basis earthquake and 6% for the safe-shutdown earthquake. NRC Regulatory Guide 1.61 permits damping values of 2% for the operating-basis earthquake and 4% for the safe-shutdown earthquake for welded steel structures functioning in air. These damping values are increased by 2%, since the fuel storage racks are welded stainless steel structures completely submerged in water. This 2% increase in damping value for submerged structures is based on Section 6.4 of *Fundamentals of Earthquake Engineering* by N. M. Newmark and E. Rosenblueth.

The fuel storage rack (6 x 6 array of fuel storage cells) consists of upper and lower grid structures connected to each other by means of four corner cells and diagonal bracing members. The fuel storage rack thus structurally becomes equivalent to a box-shaped structure which is inherently strong in torsion. The torsional effects due to possible nonuniform mass distribution was considered by analyzing the partially loaded rack.

Individual modal responses of the system were combined in accordance with Section 1.2.1 of Regulatory Guide 1.92. The maximum responses of the system for each of the three orthogonal spatial components (two horizontal and one vertical) of an earthquake were combined on a square root of the sum of the square (SRSS) basis (Regulatory Guide 1.92).

The sloshing effects of water on the fuel racks were evaluated using the analytical methods given in the ASCEs *Structural Analysis and Design of Nuclear Plant Facilities*. The "rattling" effects of the fuel inside the cell were accounted for by increasing the seismic inertia loads produced by the impacting masses by applying an impact factor of two, and adding the resulting loading to the seismic inertial loading produced by the non-impacting masses.

The masses considered in the seismic analysis include the fuel assembly weight, the storage cell weight, structural member weight, and tributary water mass. Of these masses, only the fuel assembly will produce impact. The fuel assembly will only impact the fuel storage cell at the top of the fuel assembly, since the fuel assembly will pivot on the bottom support pads. Therefore, the impact factor of two was applied to the seismic inertial loads produced by the upper half of the fuel assembly weight, resulting in an equivalent factor of 1.4 when the seismic inertia loads due to the total cell weight were considered. The equivalent loading (1.4 times the seismic inertia loads to account for fuel assembly impact effects) was considered for local effects as well as overall effects on the structural members of the rack, the rack/floor pad connection plates, and the floor pads.

The static, seismic, and stress analyses for the fuel storage racks were performed utilizing the STARDYNE computer code.

The fuel assembly drop load case (Load Case 5) was compared to the results from the refueling canal gate drop analysis. The results are discussed in Section 9A.3.1.5.

9A.3.1.3.3 Thermal Growth

The maximum thermal growth of the fuel storage racks would be 0.11 inch for a fuel pool bulk water temperature change from 70°F to 210°F. Sufficient clearance between the fuel storage rack and the pool floor support pads (0.125 inch minimum) has been provided to eliminate any potential interference between the rack and the support pads caused by thermal expansion. The installation approach permits those clearances to be achieved during wet installation of the Surry fuel racks. Since there will not be any interferences between the rack and its support points, the stresses and reaction loads due to thermal loadings would be insignificant. Furthermore, there will not be any local stresses due to thermal gradients across the fuel storage rack structural members, since significant increases in pool water bulk temperature occur very gradually (a change from 70°F to 210°F would take approximately 20 hours).

9A.3.1.4 **Structural Acceptance Criteria**

The following allowable limits constitute the structural acceptance criteria used for load cases 1 through 4 presented in Section 9A.3.1.2:

Load Combinations	Limit
1a and 1b	S
2	S
3	1.6S
4	1.6S

where S is the required section strength based on the elastic design methods and the allowable stresses defined in Part 1 of the AISC *Specification for the Design, Fabrication and Erection of Structural Steel for Buildings*, February 12, 1969.

9A.3.1.5 **Results of Analysis**

The results of the static structural analysis for load combinations 1 and 4 show that the deflections and stresses in the various structural members of the fuel storage rack are nominal and less than the applicable acceptance criteria.

The results of the seismic structural analyses for load combinations 2 and 3 show that the maximum stresses and deflections in the rack are nominal and within the allowable values. The maximum calculated stress is 8.3 ksi, which occurs in an upper grid member of the structure. The fundamental frequency of vibration of the fuel storage rack is 9.5 cps.

The results of the analysis for load case 5 indicate that the drop of a fuel assembly onto a fuel storage cell is bounded by the analysis of a drop of the refueling canal gate onto the fuel storage racks. Any buckling of the cells as a result of a fuel assembly drop would be limited to the top flared region of the cells. The predicted strains in the cells are not sufficient to alter the storage rack geometry after being subjected to a fuel assembly drop from 42 inches. Therefore, there will be no effect on keff of fuel stored in the rack as a result of a fuel assembly drop.

It could not be concluded directly from this analysis that perforation of the quarter-inch stainless steel spent fuel pool liner would not occur as a result of a fuel assembly drop. In the event that the liner is perforated as a result of a fuel assembly drop, the leak rate from the pool would be less than the makeup capability to the pool and fuel stored in the racks would not be uncovered as a result. Perforation of the spent fuel pool liner is addressed in the discussion of the Fuel Cask Trolley in Section 9.12.4.13.

The seismic and structural analysis shows that the deflections and/or stresses in the rack structure resulting from the various loadings meet the deflection and stress acceptance criteria for Seismic Class I structures.

The maximum stress values are given in Table 9A-1 for load combinations 1 through 4.

A summary of stresses of the supporting pool structure is provided in Table 9A-2.

The following load combinations were considered:

1. Hydrostatic + dead load + live load.
2. Hydrostatic + dead load + live load + operating-basis earthquake.
3. Hydrostatic + dead load + live load + safe-shutdown earthquake.
4. Hydrostatic + dead load + live load + high-density racks.

The allowable stresses are based on the minimum sampled coupon strength of 43,600 psi and the acceptance criteria stated in ACI 318-63. It should be noted that with the new high-density fuel storage racks, the mat loadings are lower than those originally calculated. This is due to the different analytical model used. For the high-density fuel storage rack loadings, the model accounted for the detailed location of both the pilings and the fuel rack embedments in the mat. This resulted in a significant portion of the load due to spent fuel being transmitted to the pilings without inducing mat bending. In the analysis for the original loading, the rack loads were spread uniformly over the mat, and the pilings were lumped at discrete locations that were further apart than the actual pile spacing. The method used to calculate the mat loadings from the new high-density fuel storage racks represents the as-built condition at Surry.

As given in Section 9.5, the spent-fuel pool temperature will be maintained at or below the original limits of 140°F (normal case) and 170°F (abnormal case). Therefore, the maximum temperature of the thermal gradient in the pool walls and the base slab as originally designed will not be exceeded.

9A.3.2 Nuclear Analysis

A detailed nuclear analysis was performed to demonstrate that for all anticipated normal and abnormal configurations of fuel assemblies within the fuel storage racks, the k_{eff} of the system is substantially subcritical ($k_{eff} < 0.95$). Certain conservative assumptions about the fuel assemblies and racks were used in the calculations. These assumptions are described in Section 9A.3.2.1.

The reference configuration which is the basis of the criticality calculations consists of an array of square stainless steel boxes (9.12 inches o.d. with a wall thickness of 0.090 inch) spaced 14.0 inches on centers with fuel assemblies centrally located within the boxes. Variations from this reference configuration were also studied and included the effects of dimensional and spacing variations, fuel enrichment changes, water temperature increases and mislocations of fuel assemblies and boxes. A description of the calculational method and codes is presented in Section 9A.3.2.3, and the results of the criticality analysis are presented in Section 9A.3.2.4.

The analysis of the Surry spent fuel racks followed the methodology described in Reference 9 and approved by the NRC in Reference 10. Differences between this approved methodology and the Surry analysis are described in Section 9A.3.2.3.1. Criticality calculations were performed using BONAMI and NITAWL-II codes for cross section generation, and the KENO-V.a Monte Carlo code for reactivity determination. Sensitivity calculations for normal and abnormal conditions were performed using the Westinghouse PHOENIX-P code.

9A.3.2.1 Design Criteria and Assumptions

The criticality design criterion established for the Surry Power Station spent-fuel racks is that the multiplication constant (k_{eff}) shall be less than 0.95 for all normal and abnormal configurations, as confirmed by transport theory.

The following conservative assumptions were used in the criticality calculations performed to verify the adequacy of the rack design with respect to the rack design criteria:

1. The pool water has no soluble poison.
2. The fuel assemblies have no burnable poison.
3. The fuel is fresh and of a specified nominal enrichment as high or higher than that of any fuel available.
4. No credit is taken for structural material other than the fuel can.
5. All fuel cans are assumed to be 0.090 inches thick, the minimum allowable thickness.

9A.3.2.2 Configurations Analyzed

The various configurations of fuel within racks that are possible are classed as either normal or abnormal configurations. Normal configurations result from the placement of fuel within racks and the variation in rack dimensions permitted in fabrication. Abnormal configurations are typically the results of accidents or malfunctions such as seismic events, malfunction of the fuel pool cooling system, etc.

9A.3.2.2.1 Normal Configurations

The normal configurations analyzed were: a reference configuration consists of an infinite array of storage cells having nominal dimensions each containing a 15 x 15 Westinghouse fuel assembly of nominal 4.25 weight percent enrichment positioned centrally within the cell. The 15 x 15 designed fuel assemblies were selected for reference configuration because racks with the 15 x 15 fuel assemblies are slightly more reactive than the rack with the 17 x 17 designed fuel assemblies with equal enrichment. The storage cells are 9.12 inches in outside dimensions, have 0.090-inch walls, and are spaced 14.0 inches on centers. The spent fuel pool water is assumed to be 170°F, which is the upper bound of normal operating temperatures. The effects of variations in material characteristics and physical dimensions are statistically incorporated into the keff for the spent fuel storage racks.

9A.3.2.2.2 Abnormal Configurations

Two types of accidents can typically occur in the spent fuel rack which can cause reactivity to increase. The first accident type involves a pool water temperature change, which involves an increase or decrease in the spent fuel pool water temperature and density. The second accident type involves a fuel assembly misplacement, where restrictions on location, enrichment, or burnup are not satisfied. Fuel assembly misplacement accidents include a fuel assembly drop on top of a rack, and a fuel assembly drop between rack modules or between a rack module and the spent fuel pool wall. It is also possible for a dropped fuel assembly to enter a box cleanly and impact directly on the fuel stored in the box. The effect of this type of fuel drop incident was considered from a criticality viewpoint in the initial evaluation for the high density fuel racks (Reference 3) by assuming that the stored assembly would be compressed axially. A calculation based on axial compression of 2 feet yielded a 0.06 decrease in k_{inf} of the fuel cell. Therefore, this type of fuel misplacement accident would reduce k_{eff} and was not considered further.

For Surry, a fuel storage cask handling accident was also evaluated. This accident scenario assumes a fuel storage cask rotates and falls against the fuel storage racks next to the cask loading area. To evaluate this accident, the spent fuel pool is divided into two regions. Region 1 comprises the first three rows of fuel storage racks (324 locations) adjacent to the fuel building trolley load block, which is susceptible to the storage cask handling accident. The remainder of the Surry spent fuel pool (Region 2) is unaffected by this accident.

The seismic impact on criticality calculations was also considered in the initial evaluation for the high density fuel racks. These analyses indicated that the maximum rack structure deflections will be very small (less than 0.120 inches). These deflections have a negligible effect on k_{eff} since they do not change the center-to-center spacing between the storage cells or boxes significantly. The maximum deflection of the storage cells or boxes due to a seismic event occurs at the middle of the box and is less than 0.050 inches. The effect of box deflections on k_{eff} is negligible since the average center-to-center spacing between cells or boxes will not change appreciably if the boxes deflect independently in random directions or act together in a single direction. As the seismic contributions were determined to be negligible, the effect of this type of abnormal condition on the criticality calculations was not considered further.

9A.3.2.3 **Calculational Methods**

9A.3.2.3.1 Analytical Methods

The design method which insures that a subcritical condition is maintained in the spent fuel storage racks is similar to the NRC-approved Westinghouse Owners Group (WOG) methodology, which is described in References 9 and 10. The analysis of the Surry spent fuel pool incorporated the following exceptions to the WOG methodology:

1. The WOG methodology assumed a nominal UO_2 density of 95.0% T.D. The Surry spent fuel pool analysis used a nominal UO_2 density of 95.5% T.D., based on actual as-built fuel assembly uranium-loading information for Surry

2. The WOG methodology assumed a UO_2 density variation of ±2.0% T.D. about the nominal reference density, and variation in the fuel pellet dishing fraction from 0% to twice the nominal pellet dishing fraction. The analysis for the Surry spent fuel pool assumed a ±1.5% T.D. variation in fuel pellet density, based on the fuel manufacturing specifications and as-built fuel assembly uranium-loading information.
3. The WOG methodology used 227 group ENDF/B-V cross sections. These cross sections have not been made available to Virginia Power by Oak Ridge National Laboratory. Therefore, the Surry spent fuel pool analysis used 238 group ENDF/B-V cross sections, which have been extensively benchmarked.
4. The Surry spent fuel pool analysis does not require any boron credit. Therefore, the WOG boron credit methodology is not applicable.
5. The WOG methodology uses a nominal temperature of 68°F and pressure of 14.7 psia. In the analysis for the Surry spent fuel pool, the nominal temperature was set to the most conservative value over the typical temperature range, which was determined to be 170°F. The nominal pressure was set to 28 psia to account for the effects of the spent fuel pool water depth.
6. Although the NRC-approved WOG methodology does not require consideration of the effect of the axial burnup distribution on fuel assembly reactivity, an axial burnup gradient reactivity bias was applied to the evaluation of the Surry spent fuel pool.
7. The WOG methodology includes B^{10} self-shielding bias for spent fuel pools with poison panels. The Surry spent fuel storage cells do not include any poison panels, so this bias is not necessary in the Surry analysis. In addition, the Surry reactivity and tolerance calculations do not account for any poison panels

The design method uses the BONAMI and NITAWL-II codes for cross section generation, and the KENO-V.a code for reactivity determination. The 238-group ENDF/B-V cross section library is the starting point for all cross sections used for the KENO-V.a calculations. BONAMI (Reference 4) performs a resonance self-shielding calculation based on the Bondarenko method, and produces problem dependent master data sets. NITAWL-II (Reference 5) performs problem dependent resonance shielding calculations by applying the Nordheim Integral Treatment. These multigroup cross section sets are then used as input to KENO-V.a, which is a three dimensional Monte Carlo theory program designed for reactivity calculations (Reference 8). KENO-V.a calculations are always performed with sufficient neutron histories to assure convergence.

Two different KENO-V.a models were used. One model represented an infinitely reflected single spent fuel storage cell, while the other model represented the entire Surry spent fuel storage pool. The storage cells in the full pool model are placed in arrays to model each fuel storage rack, which are placed in their appropriate fuel pool location along with the fuel transfer canal and concrete buttress. This configuration is then surrounded with the stainless steel liner and concrete walls and floor.

9A.3.2.3.2 Benchmark Calculations

In order to establish the accuracy of the computer codes used for this analysis, the KENO-V.a code and cross sections were compared to critical experiment data for fuel assemblies similar to those for which the Surry spent fuel racks were designed. These benchmarking data, which represents fifty-nine validation criticality test cases for UO_2 lattices, are sufficiently diverse to establish that the method bias and uncertainty will apply to the rack conditions covered by this analysis.

The benchmark critical experiments resulted in an average KENO-V.a k_{eff} of 0.99643, which compared to a critical k_{eff} of 1.0 gives a KENO-V.a model bias of 0.00357 Δk. On a 95% confidence level, there is a 95% probability that the uncertainty in reactivity due to the method is not greater than 0.00099 Δk.

Reactivity equivalencing and tolerance calculations were performed using the Westinghouse PHOENIX-P code. The benchmarking performed for the WOG methodology covers a range of lattice parameters and configurations encompassing present fuel storage configurations. Based on the NRC acceptance of PHOENIX-P and their approval of the WOG methodology described in Reference 9, further benchmarking was not performed for the Surry spent fuel pool analysis.

9A.3.2.4 **Analysis Results**

9A.3.2.4.1 Normal Configurations

KENO-V.a calculations were performed for the reference configuration using both the infinitely reflected single storage cell model and the full spent fuel pool model. It was determined that use of the single storage cell KENO-V.a model is slightly conservative for this analysis. The k_{eff} for the single storage cell model was. 0.92950.

The effects of possible variations in material characteristics and mechanical/construction dimensions on spent fuel pool reactivity were performed using Westinghouse's PHOENIX-P code. These calculations included the effects of:

1. Fuel enrichment tolerance.
2. Variation in UO_2 density.
3. Variation of the fuel pellet dishing fraction.
4. Tolerance about the nominal reference storage cell inner dimension.
5. Tolerance about the nominal storage cell center-to-center pitch.
6. Tolerance about the nominal reference storage cell material thickness.
7. Asymmetric positioning of fuel assemblies within the storage cells.

The impact of each of these factors on the calculated k_{eff} is given in Table 9A-3. The total uncertainty associated with material characteristics, mechanical construction, and the KENO-V.a methodology is determined by statistically combining the effects of these tolerances with the calculational uncertainty. The combined uncertainty is 0.01064, as shown in Table 9A-3.

The 95/95 k_{eff} for the Surry spent fuel storage racks was then derived from:

$k_{eff} = k_{nominal} + B_{method} + B_{temp} + B_{uncert}$

where:

$k_{nominal}$ = nominal conditions KENO-V.a k_{eff} (0.92950)

B_{method} = method bias determined from benchmark critical comparisons (0.00357)

B_{temp} = temperature bias (0.0)

B_{uncert} = uncertainty associated with material characteristics, mechanical construction, and KENO-V.a method (0.01064)

The resulting spent fuel pool k_{eff} is 0.94371.

9A.3.2.4.2 Abnormal Configurations

As discussed in Section 9A.3.2.2, one type of accident which can cause reactivity to increase in the spent fuel rack involves an increase or decrease in the spent fuel pool water temperature and density. The normal conditions analysis, which covered a normal temperature range from 50°F to 170°F, showed that k_{eff} is less than 0.95 with no boron present in the spent fuel pool. The double contingency principle of ANSI/ANS 8.1-1983 states that protection against a criticality accident does not require assumption of two unlikely, independent, concurrent events. The presence of soluble boron in the spent fuel pool storage water can therefore be assumed as a realistic initial condition, since the lack of boron in the pool would be the result of a second unlikely event (i.e., a boron dilution accident). It was determined that an increase in pool temperature from 170°F to 246.4°F, the temperature at which boiling would be expected to occur in the spent fuel pool, increases the spent fuel pool k_{eff} less than the worth of the boron normally present in the spent fuel pool. Therefore, the 0.95 k_{eff} limit will be met for a pool water temperature increase.

The second type of accident which can affect reactivity in the spent fuel pool involves the placement of a fuel assembly into a position for which any restrictions on location, enrichment, or burnup are not satisfied. The normal conditions evaluation assumed a spent fuel storage rack configuration containing all fresh fuel at the maximum permissible proposed Surry fuel enrichment, with no restrictions on assembly location. Therefore, fuel assembly misplacement under normal handling conditions is already bounded by the reference non-accident analysis.

Two additional fuel assembly misplacement accidents that were considered were determined to have no impact on reactivity. These accidents include a fuel assembly drop on top of a rack, and a fuel assembly drop between rack modules or between a rack module and the spent fuel pool wall. A fuel assembly which drops onto the top of the fuel racks will impact the flared tops of the fuel storage rack cells. While minor deformation of the flared tops may occur, the close proximity of the upper grid structure to the impact point will preclude significant lateral displacement of the storage cells, so the rack structure pertinent for criticality control is not excessively deformed by the fuel assembly. KENO-V.a sensitivity cases confirmed that a dropped assembly which comes to rest either horizontally or vertically on top of the rack has sufficient water separating it from the active fuel height of stored assemblies to preclude neutron interaction, so the effect on k_{eff} is negligible. For the second scenario, PHOENIX-P sensitivity cases showed that placing an assembly outside of the racks per the second accident scenario is bounded by the normal conditions analysis.

To ensure that the spent fuel pool k_{eff} remains less than or equal to 0.95 during a fuel storage cask handling accident, limitations must be placed on the initial enrichment and burnup of the fuel assemblies which may be stored in Region 1 of the Surry spent fuel pool.

To evaluate the impact of a storage cask handling accident on spent fuel pool criticality, the deformed fuel and the associated storage racks were assumed to be at the optimum pitch. KENO-V.a calculations were run to determine the maximum fresh fuel enrichment that meets the 0.95 k_{eff} limit, including all applicable uncertainties and tolerances. The same methodology employed for the 95/95 k_{eff} calculations for the normal configurations was used for these calculations. It was determined that any fuel with an initial U^{235} enrichment less or equal to 1.9 weight percent may be loaded into Region 1 of the Surry spent fuel pool.

To allow the loading of fuel with higher initial enrichments in Region 1 of the Surry spent fuel pool, credit must be taken for the fuel burnup. A series of reactivity calculations were performed using the PHOENIX-P code and following the methodology outlined in Reference 9 to identify fuel assembly initial enrichment-discharge burnup pairs, which all yield equivalent k_{eff} values for the Surry spent fuel storage racks. These burnup credit cases incorporated the following conservatisms and uncertainties:

1. Fuel depletions were performed at a conservatively high boron concentration to enhance the predicted buildup of plutonium.
2. Burnup credit cases assumed no xenon.
3. A PHOENIX-P code uncertainty was applied.
4. An axial burnup gradient reactivity bias was applied.
5. A reactivity bias was applied to account for changes in optimum pitch due to burnup and enrichment changes.

6. An uncertainty was also applied to assembly burnup to reflect uncertainties in burnup measurements.

The results of these burnup credit reactivity equivalencing calculations were used to define a curve of assembly burnup versus initial fuel enrichment, which is included in the Surry Technical Specifications as Figure 5.4-1. Use of fuel with a burnup and enrichment combination which falls above this curve in Region 1 of the Surry spent fuel pool ensures that the spent fuel pool keff remains less than or equal to 0.95 during a fuel storage handling accident.

FUEL POOL STRESS POINT LOCATIONS FOR TABLE 9A-2

Intentionally Blank

Appendix 9B
Movement of Heavy Loads

Intentionally Blank

APPENDIX 9B MOVEMENT OF HEAVY LOADS

9B.1 HEAVY LOADS OVER SPENT FUEL

This section describes the movement of heavy loads over the reactor core or the spent fuel storage pool. A fuel assembly is not defined as a heavy load, and the movement of fuel assemblies is not controlled under NUREG-0612.

NUREG-0612, *Control of Heavy Loads at Nuclear Power Plants,* (Reference 1) defines a heavy load as a load greater than the combined weight of a single fuel assembly and its handling tool. A fuel assembly weighs approximately 1470 lb and the spent fuel handling tool weighs approximately 350 lb, therefore, this heavy load definition is:

Fuel Assembly	1470
Handling Tool	+ 350
	1820

During refueling operations, a heavy load is defined as 110% of the weight of a fuel assembly (not including the fuel handling tool). This heavy load weight definition is:

Fuel Assembly	1470	
100%		x 1.1
	1617	

Using a single value that bounds both of these definitions, a heavy load subject to NUREG-0612 controls is a load greater than 1600 lb.

9B.1.1 Reactor Vessel Head

The reactor vessel head is lifted by the containment polar crane. Its movement path includes a vertical lift from the reactor vessel, a horizontal movement, and a vertical descent to the head storage area in the basement. The head is returned to the reactor vessel using the reverse sequence. The containment equipment locations can be seen on Reference Drawings 1 and 3. The size and shape of the head are shown on Reference Drawing 3. The weight of the head and lifting device is provided in Table 9B.2-1.

A reactor vessel (RV) head drop analysis based on the guidance and acceptance criteria in NEI 08-05, *Industry Initiative on Control of Heavy Loads* (Reference 17), has been performed to establish limits on load height, load weight, and medium present under the load. Procedures are used to control the lift and replacement of the reactor vessel head, which ensure the limits established in the RV head drop analysis are maintained.

9B.1.2 Reactor Vessel Upper Internals

The reactor vessel upper internals are removed from the reactor vessel by the containment polar crane and are placed in the upper internals lifting rig storage stand. This involves a vertical lift from the reactor vessel, a horizontal movement, and a vertical descent to the storage stand. The upper internals are returned to the vessel using the reverse sequence. The weight of the upper internals and lifting rig is provided in Table 9B.2-1. The upper internals are described in Chapter 3.

9B.1.3 Reactor Irradiation Sample Shipping Casks

In accordance with the reactor vessel radiation surveillance program, reactor irradiation sample assemblies are removed from the reactor vessel at intervals as specified in Section 4.1.7. The sample assemblies are removed from the reactor vessel and transferred to the spent fuel storage pool in a sample basket. The samples are then shipped to a contractor laboratory in a shipping cask. Several shipping cask designs can be used, and these casks weigh from approximately 8000 lb to approximately 23,000 lb. These casks may be loaded without placing them in, or moving them over, the spent fuel storage pool. If a cask is loaded in, or moved over, the spent fuel storage pool, an evaluation must be performed to ensure that cask drop analyses remain bounding.

9B.1.4 Fuel Transfer Canal Door

At the end of each fuel transfer canal in the spent fuel storage pool, a door is used to isolate the canal, if needed. These doors are marked “Gate” on Reference Drawing 4. The dry weight of the transfer canal door is approximately 3200 lb. Prior to refueling, the transfer canal door is removed from the canal and moved to a storage position on the side of the spent fuel storage pool. The door is also removed on a periodic basis to perform seal maintenance. Administrative controls are imposed for moving the transfer canal door over fuel assemblies. The controls limit the lift height of the door and prohibit spider-mounted insert components in fuel assemblies in the load path while the door is being moved. These restrictions ensure that fuel assemblies will not be impacted if the transfer canal door were to drop during movement.

9B.1.5 Spent Fuel Casks

Spent fuel cask drop evaluations have been conducted in support of loading and unloading spent fuel casks in the fuel building. The results of these evaluations, and the request for a license amendment to permit movement of spent fuel casks in the fuel building are provided in References 2 and 3. As part of these evaluations, two cask impact pads have been installed in the cask loading area of the spent fuel storage pool. These pads are designed to protect the floor of the spent fuel storage pool from damage in the event a spent fuel cask is dropped from the fuel cask trolley. Fuel assemblies stored in the first three rows of storage racks adjacent to the cask loading area must have decayed at least 150 days after discharge from the reactor, and must also meet the requirements for burnup and enrichment. These requirements ensure that the radiological consequences are bounded by the consequences for a fuel handling accident, and prevent fuel criticality in the event of a cask drop and tip onto the storage racks. A description of the fuel cask trolley and its operation is provided in Section 9.12.4.13.

License amendments permit the movement of spent fuel casks into the fuel building (Reference 4). Cask drop evaluations of the TN-2100 and GNS-5 casks are included in the license amendments. The license amendments concluded the following:

1. The spent fuel storage pool will not be damaged by a worst-case cask drop, and even if the pool liner should be punctured, no significant leakage is expected since the pool walls would not experience through-cracking.
2. Fuel assemblies in the spent fuel storage pool remain sub-critical if storage racks are damaged by a cask drop and tip, and the radiological consequences are well within the guidelines of 10 CFR 100.
3. Damage to spent fuel storage pool piping would not cause the pool to drain. It also confirmed that there are no safe shutdown systems under the travel path of the fuel building trolley.

Subsequent safety evaluations conclude that the cask drop evaluations are bounding for the CASTOR V/21, CASTOR X/33, MC-10, NAC-I/28, TN-32, and NUHOMS OS187H casks. Cask weights, including the lifting device, are from approximately 157,000 lb to approximately 240,000 lb. The cask lifting device weighs approximately 7000 lb, therefore, its movement over the spent fuel storage pool is also controlled as a heavy load. The NUHOMS EOS-TC125 transfer cask was evaluated under the same scenarios as previous casks (Reference 5). It was concluded that the consequences of dropping the EOS-TC125 are bounded by the previously evaluated casks. The EOS-TC125 is described in the NUHOMS EOS System Updated Final Safety Analysis Report.

The drop of cask lids into the spent fuel storage pool has also been evaluated. After fuel assemblies are loaded into a cask, the lid is moved over the spent fuel storage pool and placed onto the cask. Conversely, after a loaded cask is placed in the spent fuel storage pool for unloading, the lid is removed from the cask and carried over the pool. Both of these operations take place over the cask loading area of the spent fuel storage pool. Lid weights vary with spent fuel cask design, so the analysis used the heaviest known lid weight of approximately 14,000 lb. If a lid is dropped while it is over the cask, damage to the fuel assemblies in the cask is bounded by the cask drop consequences in Reference 2. If the lid drops edgewise onto a cask impact pad, it does not perforate the top plate of the pad, and the spent fuel storage pool liner and floor are not damaged. If the lid drifts horizontally through the water and strikes the storage racks adjacent to the cask loading area, the damage to storage racks and fuel assemblies is bounded by the analyses in Reference 2. If the lid drifts horizontally and strikes a wall of the spent fuel storage pool, the structural response is also bounded by the cask drop analyses.

Cask and lid handling over the spent fuel storage pool is controlled by written procedures which limit cask and lid lift heights and cask orientation consistent with the cask and lid drop analyses.

9B.2 HEAVY LOADS OVER SAFE-SHUTDOWN EQUIPMENT

9B.2.1 Introduction/Background

On December 22, 1980, NRC issued a generic letter (unnumbered) which was supplemented February 3, 1981 (Generic Letter 81-07) regarding NUREG-0612, *Control of Heavy Loads at Nuclear Power Plants* (Reference 1) NUREG-0612 presents an overall philosophy that provides a defense-in-depth approach for controlling the handling of heavy loads. The approach is directed toward the safe handling of lifted loads.

The NRC requested that Surry Power Station implement certain interim actions and provide information related to heavy loads. Submittals were requested in two parts; a 6-month response (Phase I) and a 9-month response (Phase II). Phase I responses were to address Section 5.1.1 of NUREG-0612 which covers the following areas:

Guideline 1 - Safe Load Paths

Guideline 2 - Load Handling Procedures

Guideline 3 - Crane Operator Training

Guideline 4 - Special Lifting Devices

Guideline 5 - Lifting Devices (not specially designed)

Guideline 6 - Cranes (inspection, testing, and maintenance)

Guideline 7 - Crane Design

In addition, the Phase I Report was to identify all load handling systems within the plant that are capable of carrying a heavy load. These load handling systems were divided into two groups:

Group I: Heavy load handling systems from which a load drop may result in damage to any system required for plant shutdown or decay heat removal, taking no credit for interlocks, technical specifications, operating procedures, detailed structural analysis or system redundancy.

Group II: Heavy load handling systems excluded from Group I based on determination by inspection that there is sufficient physical separation between any load impact point and any system needed for plant shutdown or decay heat removal.

Phase II responses were to address Sections 5.1.2 thru 5.1.6 of NUREG-0612 which cover the need for electrical interlocks/mechanical stops, or alternatively, single-failure-proof cranes or load drop analyses in the spent fuel pool area, containment building, and other areas of the plant, and the specific guidelines for single-failure-proof handling systems.

On June 28, 1985, NRC issued Generic Letter 85-11 (Reference 2) which rescinded Phase II. It concluded that Phase I implementation had provided sufficient protection such that the risk associated with potential heavy load drops was acceptably small and no further action was required beyond that identified during Phase I. The NRC Safety Evaluation and their consultant's Technical Evaluation Report (TER) (Reference 3) for the six month response (Phase I) were issued in 1984 with program clarifications via Generic Letter 85-11.

The Surry Technical Specifications (TS) also prohibit heavy loads from being moved over spent fuel. Detailed discussion of how the heavy loads program implements this requirement is presented in Section 9B.2.5.

The following sections summarize the commitments that were made by Virginia Power as part of the Phase I submittal with regard to compliance with Section 5.1.1 of NUREG-0612. Any errors made in the Phase I report are noted and corrected. Additions to the heavy loads program that have been incorporated since the issuance of the Phase I report are also included. Program deletions are detailed within the References. Each of the seven guidelines of Section 5.1.1 of NUREG-0612 along with the definition of a heavy load subject to NUREG-0612 and the list of the handling systems that are capable of moving heavy loads subject to NUREG-0612 are discussed in detail below.

On September 14, 2007, the nuclear industry's Nuclear Strategic Issues Advisory Committee approved an industry initiative to address NRC staff concerns regarding the interpretation and implementation of regulatory guidance associated with heavy load lifts (Reference 16). In response to the industry initiative, reliance on a reactor vessel head drop analysis was included into the safety basis for the control of heavy loads at Surry Power Station. Further discussion on this is provided in Section 9B.1.1.

On September 5, 2008, the NRC issued a Safety Evaluation Report for the methods presented in NEI 08-05, Industry Initiative on Control of Heavy Loads (Reference 17), concluding that the guidelines contained in NEI 08-05, Revision 0, are acceptable for implementation of the industry initiative on control of heavy loads. NEI 08-05 was also endorsed by the NRC in RIS 2008-28 (Reference 19).

Heavy load lifts for the Emergency Service Water Pumps and associated equipment are considered lifts subject to the requirements of NUREG-0612. Alternate methodologies for evaluating these heavy load lifts have been used that consider Risk Management Actions in accordance with NEI 08-05 coupled with consideration of the lifts as configuration management activities with administrative controls established in accordance with 10CFR50.65(a)(4) to establish the safety basis.

Previous controls implemented by station commitments to NUREG-0612 Phase I Guidelines and the use of the Risk Management Actions in accordance with NEI 08-05 make the risk of a load drop and adverse consequences very unlikely. The evaluation of the heavy load lifts for the Emergency Service Water Pumps and their associated components evaluates the NUREG-0612 Criterion IV consequence considerations within the Maintenance Rule 10CFR50.65(a)(4) program through existing procedural guidance and requirements.

9B.2.2 Heavy Loads

NUREG-0612 defines a heavy load as any load that weighs more than the combined weight of a single spent fuel assembly and its associated handling tool. Surry's Phase I report established this load as 2000 pounds; however, a lower weight of 1600 pounds has been adopted in recognition of the more restrictive definition given in Technical Specifications (TS). A load is subject to NUREG-0612 if it exceeds 1600 pounds and is carried over irradiated fuel, safe shutdown equipment or decay heat removal equipment.

9B.2.3 Overhead Heavy Load Handling Systems

The following load handling systems are subject to compliance with NUREG-0612:

1. Reactor Containment Polar Cranes
2. Reactor Containment Annulus Monorail
3. Containment Jib Cranes
4. Fuel Building Motor Driven Platform
5. Auxiliary Building 10-ton Monorail (27' level)
6. Auxiliary Building 5-ton Monorail (13' level)

7. RHR Pump Motor Lifting Lugs
8. Spent Fuel Crane

The RHR pump motor lifting lugs were plant modifications completed after the TER was issued. A jib crane in each containment was mentioned in the TER; this crane is included in heavy loads procedures. The TER included other handling systems as originally being subject to NUREG-0612 that are no longer included in the heavy loads program. Reference 5 discusses those handling systems and the justification for their elimination. A listing of heavy loads per handling system is tabulated in Table 9B.2-1.

9B.2.4 NUREG-0612, Section 5.1.1 Guidelines

9B.2.4.1 **Safe Load Paths**

Safe load paths for the movement of heavy loads have been developed which follow, to the extent practical, structural floor members, beams, etc., such that if the load is dropped, the structure is more likely to withstand the impact. Either a sketch or description of the load paths have been incorporated into lifting procedures. Safe load paths do not require specific lift height restrictions other than to keep the load as low as practical while maintaining adequate vertical clearances over obstructions in the load path. Maximum lift height limits and load drop studies were part of the Phase II requirements that were rescinded by the NRC (Reference 2).

Safe load paths are discussed during the pre-job briefing and loads are guided along the safe load path during the lift operation. Also, restricted areas are used in the containment structure for several heavy loads such as concrete floor plugs that are routinely shuffled to several laydown areas during an outage. These restricted areas include: over the reactor, steam generators, and main steam/feedwater riser area. Drawings are available which indicate operating floor capacities that are used during outages to control laydown space in conjunction with the Heavy Loads Program.

Safe load path sketches are used to control the movement of the fuel transfer canal gates in the fuel pool.

9B.2.4.2 **Load Handling Procedures**

Station maintenance procedures have been developed for performing heavy load lift operations. The procedures identify the following items:

1. Equipment identification.
2. Required equipment inspections and acceptance criteria prior to performing lift and movement operations.
3. Approved safe load paths.
4. Safety precautions and limitations.

5. Special tools, rigging hardware, and equipment required for the heavy load lift.
6. Rigging arrangement for the load.
7. Adequate job steps and proper sequence for handling the load.

9B.2.4.3 Crane Operators Training

NUREG-0612 requires that crane operators be trained, qualified and conduct themselves in accordance with Chapter 2-3 of ANSI B30.2-1976, *Overhead and Gantry Cranes* (Reference 6). Station administrative procedures ensure that crane operators are qualified.

9B.2.4.4 Special Lifting Devices

As indicated in the TER (Reference 3):

> [The following special lifting devices in use at Surry Units 1 and 2 were identified as being subject to compliance with the criteria of NUREG-0612 and ANSI N14.6-1978:
>
> a. reactor vessel head lifting device (RVHLD)
>
> b. internals lifting rig (ILR)
>
> c. reactor coolant pump motor sling (RCPLS)
>
> The original manufacturer of these devices (Westinghouse) performed a detailed comparison of the ANSI criteria and records that document the original design, manufacture, inspection, and testing of the special lifting devices. Results of this review indicate that the devices meet the intent of the ANSI Standard for design, fabrication, and quality assurance, but are not in strict compliance with criteria for maintenance, acceptance testing, or continuing compliance.
>
> Design, fabrication, and quality assurance requirements for these devices were defined on detailed manufacturing drawings and purchase orders. A stress report was prepared, applying the design margin criteria of 3 (yield) and 5 (ultimate) on stress, and results indicate that all devices possess acceptable limits for tensile and shear stress with the following exceptions for the internals lifting rig: (1) tensile and shear stresses in the side plates; (2) thread shear stresses in the leg adaptor; and (3) the tensile stress at the minimum section of the engaging screw. For these exceptions, it was noted that the actual margin is slightly less than the specified criterion of 3 on yield stress, whereas all components satisfy the criterion of 5 on ultimate stress. It is therefore concluded that the existing design is adequate.
>
> In addition, manufacturing surveillance of hold points, procedure review, and personnel qualification which adequately meet ANSI requirements were also provided by the manufacturer during the fabrication and assembly of these devices. Load tests to 100% have been performed for each of the devices, although documentation is

available for the reactor vessel head lifting device only. Although load tests in excess of 100% have not been performed, it is felt that such tests are not necessary since proof of workmanship can be documented through use of existing load tests, adequate design margins, and documentation of procedures that were actually used during the manufacture of these devices. Maintenance procedures require visual examinations of the special lifting devices prior to each refueling and each containment maintenance period if use of the device is anticipated. These visual inspections include inspections of all critical welds and bolted joints or connections, and results are appropriately documented. In addition, a load cell is used during lifts by the reactor vessel head lifting device and the internals lifting rig to provide continuous monitoring to prevent overstressing of either device. To ensure an even higher level of confidence and acceptability of these devices, a nondestructive examination (NDE) program is established. This program includes inspection and NDE of all critical welds and critical parts of the lifting devices over the in-service inspection period of 10 years.]

Five additional special lifting devices have been identified that were not included in the TER:

8. Spent filter cask spreader beam
9. Spent fuel cask lifting yoke
10. Long cask lid lifting tool
11. Short cask lid lifting tool
12. Alternate lift rig for the SFP transfer canal gates.

These lifting devices have been included in station administrative procedures as special lifting devices and will be visually inspected prior to use and immediately after lifting the load. These devices will also be inspected under the 10-year Inservice Inspection Program using NDE methods.

The Reactor Vessel Head Stud Racks have been identified for inclusion under the guidelines of NUREG-0612 at Surry. These special lifting devices were not previously mentioned in the TER nor were they included with the subsequent group of five, as listed above in (8) through (12):

13. Reactor vessel head stud racks

The stud racks are not, however, in strict compliance with ANSI N14.6-1978 for design, fabrication, quality assurance, maintenance and continuing compliance, as noted in the following exceptions:

1. Stud racks were fabricated without official design calculations. To reconstitute a design basis, an engineering evaluation was performed, following the design criteria of ANSI N14.6-1978. The stud racks were conservatively assumed to be fabricated out of carbon steel materials, with strength properties at least comparable to that of ASTM A 36.
2. Stud racks were fabricated without fabrication or quality assurance records. Each of these stud racks has received a post-modification load test to 150% of their rated load capacities. A visual inspection was performed to further assess the quality of construction. Following the modifications, baseline nondestructive examinations were performed on all critical welds and critical parts to provide documented evidence of quality construction.
3. Annual testing per ANSI N14.6-1979 requires that either a 150% load test or dimensional, visual and nondestructive testing be performed. However, plant procedures presently require that each device, its welds, and any bolted joints be visually inspected prior to use and immediately after lifting the load. Therefore, the ANSI annual testing requirements have been waived in lieu of the prior-to-use visual inspections. To ensure more reliability and a higher level of confidence in the continuing compliance with ANSI N14.6-1978, Surry has instituted a nondestructive examination (NDE) program, which will provide for inspection and NDE of all critical welds and critical parts over a normal service interval of 10 years.

Based on the above, it is concluded that:

1. All tensile and shear stresses meet ANSI N14.6-1978 design criteria.
2. The ANSI requirements for design, fabrication, and quality assurance are generally in agreement with those used for these special lifting devices.
3. Although not in strict compliance with ANSI requirements, the load tests and nondestructive testing performed following assembly demonstrates the acceptability of these special lifting devices. Present station procedures meet the intent of ANSI N14.6-1978 regarding verification of continuing compliance.

In addition to the previously stated lifting devices, an intermediate lift ring, supplied by Framatome ANP, was installed during the installation of the SPS Unit 1 replacement closure head. Installation of the intermediate lift ring will utilize the existing lift rod lower clevises, along with the lift ring lower adapter blocks and lift pins, to attach the lift ring to the lifting rig assembly and the replacement closure head lifting lugs. The lift ring components were tested to 150% of the design load (i.e. 483,000 lb) for a minimum of ten (10) minutes, which meets the requirements of ANSI N14.6-1978. After this load-test, non-destructive and visual examinations were performed for surface indications, evidence of permanent deformation, and other nonconformances. Surfaces of the intermediate lift ring, adapter blocks, bolts, and lift pins were examined utilizing PT with acceptance criteria as established by NF5350 of the ASME Section III 1995 Edition with Addenda through 1996. Furthermore, post load-test visual examinations and dimensional checks for evidence of permanent deformation of the intermediate lift ring, adapter blocks, bolts, and lift pins were conducted. These examinations have demonstrated that the intermediate lift ring is acceptable for lifting operations (Reference 14).

9B.2.4.5 **Lifting Devices Not Specially Designed (Slings)**

A Surry station administrative procedure requires that slings used for heavy load lifts meet the requirements specified for slings in accordance with ANSI B30.9-1971 (Reference 7).

As stated in the TER (Reference 3), evaluation of sling capacity indicates that dynamic load constitutes a small percentage of the total load imposed on the slings; therefore, the sling's ratings can be safely expressed in terms of the maximum static load only.

9B.2.4.6 **Cranes (Inspection, Testing, and Maintenance)**

Cranes subject to NUREG-0612 requirements are inspected, tested, and maintained in accordance with Chapter 2-2 of ANSI B30.2-1976, *Overhead and Gantry Cranes*, Chapter 11.2 of ANSI B30.11-1973, *Monorail Systems and Underhung Cranes*, or Chapters 16-1.2.1 and 16-1.2.3 of ANSI B30.16-1973, *Overhead Hoists* (References 6, 8 & 9), with the exception that tests and inspections may be performed prior to use for infrequently used cranes. Inspections and testing following modifications to the Unit 1 and Unit 2 containment polar cranes, that were required to increase the capacity of each main hoist from 125 tons to 140 tons for reactor head replacement, were done in accordance with ASME B30.2-2001, which is the latest version of the above referenced code. Only the modified portions of the uprated cranes were required to be tested and inspected. Prior to making a heavy load lift, an inspection of the crane is made in accordance with the above applicable standards.

9B.2.4.7 **Crane Design**

NUREG-0612, Section 5.1.1 (Reference 1), requires "the cranes be designed to meet the applicable criteria and guidelines of Chapter 2-1 of ANSI B30.2-1976, *Overhead and Gantry Cranes* (Reference 6) and of CMAA-70, *Specifications for Electric Overhead Traveling Cranes* (Reference 11). An alternate to a specification in ANSI B30.2 or CMAA-70 may be accepted in lieu of specific compliance if the intent of the specification is satisfied."

CMAA-70 and ANSI B30.2-1976 apply to the reactor containment polar cranes and the spent fuel crane. These cranes were designed and fabricated in accordance with Electric Overhead Crane Specification #61 (Reference 12) prior to the issuance of the above reference standards. The Nine-Month Report (Reference 4) provided the results of a review of existing crane design with the recommendations contained in CMAA-70 and Chapter 2-1 of ANSI B30.2-1976. The NRC concluded in the TER that the design of the containment polar cranes and the spent fuel crane is consistent with the guidance in Section 5.1.1 of NUREG-0612 (Reference 1). Modifications to the Unit 1 and Unit 2 containment polar crane that were required to increase the capacity of each main hoist from 125 tons to 140 tons for reactor head replacement, were done in accordance with CMAA-70 and ASME B30.2-2001.

The reactor containment jib cranes were designed and fabricated in accordance with ANSI B30.16-1973 and ANSI B30.11-1973 (References 9 & 8). The reactor containment annulus monorails and 10-ton Auxiliary Building monorail systems, and motor-driven platform and hoists were designed in accordance with EOCI 61. It was concluded in the TER that these cranes and monorails meet the requirements of ANSI B30.11 and ANSI B30.16, and these load handling systems meet the intent of NUREG-0612.

The Auxiliary Building 13'-0” Elevation 5-ton hoist is designed to ANSI B30.16. Additionally, the hoist complies with ASME HST-4, *Performance Standard for Overhead Electric Wire Rope Hoists*. These two documents ensure the same level of design, testing and inspection as specified in the TER and compliance with NUREG-0612 requirements.

9B.2.5 Technical Specifications (TS)

Loads exceeding 110% of the weight of a fuel assembly are prohibited by TS from being lifted over spent fuel in the reactor vessel and the spent fuel pool with an explicit exception for the transfer canal door. The NUREG-0612 heavy loads program is used to implement the TS load restriction for loads greater than 1600 pounds; fuel handling procedures are used to implement the restriction which prevents handling more than one fuel assembly at a time over the reactor or spent fuel pool. Fuel handling is outside the scope of the NUREG-0612 program. NUREG-0612 heavy load procedures are used to control lifting of the transfer canal gate and additional exceptions associated with reactor vessel assembly and disassembly as discussed below.

- Movement of the spent fuel pool transfer canal doors are controlled by a NUREG-0612 heavy loads procedure which allows lifting over spent fuel in accordance with the TS.

- Movement of heavy loads over spent fuel in the reactor vessel are allowed for lifts that service the reactor such as the Unit 1 CRD missile shield, the cavity seal ring, the Unit 1 reactor head, the Unit 2 reactor head and head assembly upgrade package, and the reactor upper internals. These lifts are controlled by NUREG-0612 heavy loads procedures.

- Other loads exceeding 1600 pounds are not lifted over spent fuel in the reactor and spent fuel pool as required by TS. Movement of loads greater than 1600 pounds over spent fuel in the reactor and spent fuel pool are prohibited by NUREG-0612 heavy loads procedures which identify the reactor and the spent fuel storage area of the pool as restricted areas over which these loads shall not be lifted.

- The polar crane bottom block and hook are not considered as either a TS or NUREG-0612 heavy load because it is an integral part of the polar crane which is inspected and maintained by procedures in compliance with NUREG-0612 requirements. The unloaded failure of the lower block and hook is not considered a credible accident.

Lifting procedures do not prevent the unloaded block's movement over spent fuel whether it is in the core or being moved via the fuel handling system.

NOTES TO TABLE 9B.2-1:

1. The loads in the table have been taken from the TER (Reference 3) or subsequent evaluation. Whether or not a specific lift (or a load not listed) will be subject to NUREG-0612 is determined by standards and procedures which address Virginia Power's implementation of NUREG-0612 commitments. All weights and capacities are for reference only, are not controlled and are considered approximate.

2. The crane load block is not subject to NUREG-0612 and does not have a lift procedure since it is an integral part of the crane. To ensure that the load block is not dropped, the redundant hoist limit switches are performance tested prior to use.

3. The recirc. spray cooler and regen. heat exchanger were listed in the TER as subject to NUREG-0612; however, existing maintenance procedures for these items do not permit lifting of the entire heat exchangers. If such lifts are planned in the future, new procedures must be written. Compliance with NUREG-0612 commitments will be determined on a case-by case basis and depends upon whether or not the reactor is defueled and containment systems are isolated from an operating unit during the lift.

4. The RHR heat exchanger was listed in the TER as subject to NUREG-0612. Existing station procedures address performing maintenance which will only be performed while the reactor vessel is defueled; therefore, this lift is not subject to NUREG-0612.

5. Several loads handled by the six-ton monorail in the Aux. Building were listed in the TER as being subject to NUREG-0612. Certain lifts (as footnoted) are not subject to NUREG-0612 since procedural controls prevent loads from being moved over adjacent operational safe shutdown equipment.

6. Spent filter cask not listed in the TER; however it is classified as subject to NUREG-0612 since it is lifted over safe shutdown equipment.

7. Lifts of the reactor head lifting rig (tripod), the reactor internals lifting rig, and RCP motor lifting rig are listed above since each rig weighs more than 1600 pounds; these items were not listed individually in the TER.

8. The lift of the spent fuel cask lid was not included in the TER and is subject to NUREG-0612.

9. Lifts of the spent resin container and its cask are performed in the decontamination building where NUREG-0612 is not applicable.

10. Intermediate lift ring was designed, fabricated, and initially load tested to meet the requirements of NUREG-0612 and ANSI N14.6-1978. Refer to Section 9B.2.4.4 for compliance with the requirements.

Appendix 9C
Flood Control System

Intentionally Blank

APPENDIX 9C FLOOD CONTROL SYSTEM

9C.1 DESIGN BASIS FLOODING

Evaluation of design basis flooding considers the postulated failure of a non-Category I (non-seismic) system resulting in the potential for internal plant flooding, which could affect safety related equipment. Postulated failures were considered in the fire protection system and the non-Category I portions of the circulating water and service water systems. Several design features exist to mitigate the effects of flooding and protect safety related equipment from malfunction. Additionally, consideration was also given to consequence of a potential failure of the short section of exposed Category I circulating water (CW) piping immediately upstream of the condenser CW inlet isolation valve. (See Section 10.3.4.3.)

9C.1.1 Features to Protect Safety Related Equipment Against Failure in the CW/SW Systems

Several design features exist to provide sufficient time for an operator to identify and isolate a postulated flood source prior to it affecting safety related equipment. These features include control room annunciation of high water level in select service water (SW) valve pits, flood water storage volume, safety related equipment flood protection, flood flowrate reduction, and automatic isolation, as applicable.

Dikes

Dikes are installed to provide a barrier to minimize the passage of flood water into areas where safety related components are located. These dikes are two feet high and are located as described below.

The SW valve pits are protected with dikes to prevent flooding of the service water supply motor-operated valves for the recirculation spray (RS), bearing cooling, and component cooling heat exchangers, and the Unit 2 turbine building service water subsystem. These dikes, which are constructed of removable metal plates, encompass the pits as well as separate the two RS SW trains.

The pit which provides entrance to the auxiliary building pipe tunnel is protected with a concrete dike. This dike prevents turbine building floodwaters from entering the auxiliary building.

A removable metal plate dike is located inside the entrance to mechanical equipment room #3 (MER3, MCR Chiller Room) to prevent water flow from MER3 to the emergency switchgear room (ESGR). Additionally, the pipe tunnel from MER3 to the ESGR has been sealed to prevent the passage of floodwater to the ESGR.

A removable metal plate dike is also located at the entrance to the ESGR to restrict turbine building floodwater from entering the ESGR.

A removable metal plate dike is located at the entrance to mechanical equipment room four (MER4) to restrict turbine building floodwater from entering MER4 and potentially affecting the charging pump service water pumps.

A removable metal plate dike is located at the entrance to mechanical equipment room five (MER5) to restrict turbine building floodwater from entering MER5 and potentially affecting the MCR/ESGR chillers.

Amertap Pit

One of the four checkered plates covering each unit's Amertap (CW outlet MOV) pit was replaced with open grating to allow floodwater to freely flow into this pit. This provides additional floodwater storage volume and a more prompt actuation of the Amertap pit high level alarms in the event of turbine building flooding.

Circulating Water Flooding Alarm and Trip System

Level sensing devices are located in the CW intake pit (south side of condenser), the CW outlet pit (north side), and the Amertap pit of both units to actuate a high level annunciator in the main control room. In the event the flooding source is not manually controlled, a separate set of three water level sensing devices will automatically close the CW inlet MOVs when two out of three devices sense a water level of nine inches above the basement floor elevation. These trip probe are located on the floor elevation at the south side and at the northeast and northwest corners of the condenser.

Circulating Water and Service Water Expansion Joints

Each of the circulating water inlet, intermediate outlet, and outlet expansion joints (twelve per unit) and bearing cooling water heat exchanger service water supply and discharge expansion joints (six per unit) is enclosed by a removable flow restriction shield. These shields act as a passive flow restraint to limit water flowrate in the event of a ruptured expansion joint.

Floor Drain Isolation

Two floor drains in the electrical tunnels, two floor drains in the emergency switchgear and relay rooms, three floor drains in mechanical equipment room #3, and the single floor drain in mechanical equipment room #4 have backflow preventors installed to prevent a backflow of water from the turbine building into these areas via the floor drain system. The equipment drain inside the concrete dike in the turbine building near column line C-7 is sealed to prevent backflow of water into the auxiliary building.

9C.1.2 Features to Protect Safety Related Equipment Against Failure in the Fire Protection System

Flooding, caused by failure in the fire protection system, in general, does not adversely affect safety related equipment. Large floodwater storage volumes and the many floor drains and sumps throughout the plant provide adequate time for an operator to identify and isolate a fire protection system flood source before reaching a significant water level. The system of alarms in the fire protection system and area sumps provides the means to alert the operators to a possible fire protection system flood situation. Following source identification, fire protection lines in each building may be readily isolated by a single manual isolation valve located at the supply header to each building. For features which prevent flooding during fire fighting activities see Section 9.10.2.

Specific fire protection system design basis flooding features are discussed in the following paragraphs.

Fuel Building Trip Valve

For the fuel building, a normally closed, fail-open trip valve was installed just outside the building in the six-inch supply header to address potential internal flooding.

The fuel building does not have sufficient floodwater storage volume or sufficient drainage to contain the water which could leak from a catastrophic failure in the fire protection system. The supply line trip valve maintains the system within the fuel building in a dry, depressurized state. The two hose racks within the fuel building each are equipped with a remote control station to open the trip valve when needed. (See Section 9.10.4.14.)

Charging Pump Cubicle Dikes

A two foot high concrete dike prevents floodwater flowing across the auxiliary building Elevation 13 foot floor from entering the charging pump cubicles.

Fire Main Deflector

A six-inch fire protection line runs along the turbine building north wall above the mezzanine level near the ESGR opening. To prevent water from spilling into the ESGR side of the dike located at the ESGR entrance, a flow directing pipe sleeve around the six inch line directs water to either end of the dike surrounded area.

Water Level Monitoring System

In addition to the circulating water flooding alarm and trip system, an alarm system monitors the water level in the auxiliary building, fuel building, main steam valve house, emergency switchgear and relay room, Amertap pits, and the service water valve pits. Upon a high water level signal, an annunciator will sound in the control room. The master flood monitor panel can then be used to determine the location of the flooding area. This system is powered from vital bus circuits to provide reliable indication in the event of a loss of offsite power.

9C.2 INDIVIDUAL PLANT EXAMINATION INTERNAL FLOODING

An Individual Plant Examination (IPE) was performed for Surry in response to Generic Letter 88-20, *Individual Plant Examination for Severe Accident Vulnerabilities*. The purpose of an IPE is to systematically identify plant-specific vulnerabilities to severe accidents and, if justified, define modification of hardware and/or procedures to reduce the probability of core damage. This evaluation is based on plant specifics without regard to component safety classification or qualifications and, therefore, goes beyond the licensing basis in its assessment.

The IPE for Surry identified a vulnerability to internal flooding which warranted changes to the plant and procedures beyond the design basis specified above in Section 9C.1, Design Basis Flooding. Hardware modifications and procedural changes made to address the internal flooding vulnerability include those items discussed in the following paragraphs.

The most significant flood sources identified by the IPE were RWST piping in the auxiliary and safeguards buildings, SW system in MER3, and CW/SW systems in the turbine building.

Failure of the safety-related RWST suction piping to the containment spray, charging (HHSI), and low head safety injection pumps may cause significant flooding of the safeguards or auxiliary buildings. Floodwater from the safeguards building would propagate to the auxiliary building through interconnecting pipe tunnels. Flooding the auxiliary building would subsequently affect the component cooling water pumps and charging pumps once the water depth reached approximately eighteen inches. Loss of both of these systems could lead to RCP seal failure due to loss of seal injection and loss of thermal barrier cooling.

Backflow preventors have been installed in each charging pump cubicle's floor drain to minimize the probability of common mode flooding of both unit's pumps via the common auxiliary building floor drain system. The pipe penetrations into the charging pump cubicles which could be submerged during a flooding event are sealed to minimize passage of floodwater.

Rupture of the CW/SW system in the turbine building can lead to a spectrum of potential floodrates. The lower probability—but higher consequence—flood events, if not isolated, can lead to flooding of the ESGR and subsequent core damage. Plant design features associated with Design Basis Flooding (Section 9C.1) were considered in the IPE. Additional plant modifications were implemented to reduce the overall probability of core damage. One of these modifications was the installation of removable flow restriction shields around the rubber expansion joints immediately downstream of the service water isolation MOVs serving the bearing cooling heat exchangers (both units) and the component cooling heat exchangers. Another plant modification was implemented to limit the potential effects of a SW failure in MER3. A watertight door at the entrance to MER3 was installed to delay the progression of flooding originating in MER3 into the ESGR. The door assembly includes a two foot tall bottom panel (dike) which permits access to MER3 during flooding events (until flood level reaches two feet) and is removable to permit access for heavy equipment during maintenance activities. The upper door section is normally closed and sealed (unless personnel are in MER3). The door assembly is designed for seismic or hydrostatic loadings (non-simultaneous). The north, south (adjacent to MER4), and west wall penetrations in MER3, which could be submerged during a flooding event, were modified by applying a watertight sealant.

Additionally, operation of the turbine building sump pumps can delay or prevent floodwater from entering the ESGR. To ensure availability of these pumps, an administrative limit for minimum number of functional pumps has been instituted, as well as surveillance testing and preventive maintenance. The turbine building sump pumps remove floodwaters resulting from ruptures in the turbine building which flow via the floor drain system into the sump. To enhance removal of water associated with overflow of the floor drains in the turbine building, the checkered plate manhole covers over each sump were replaced with open grating.

Although these modifications were not quantified in terms of reduction in the overall probability of core damage, two enhancements were also implemented to address the internal flooding vulnerability. These two enhancements are:

1. Turbine building flooding which occurs as a result of a rupture in the CW or SW system upstream of the first canal isolation valve can be isolated by installing the seal plates at the high level intake structure. Rollers have been added to the plates to enhance their ability to slide into place under flow conditions without binding. (The rollers were later removed as part of an improvement of the stop log guide structure.)
2. To enhance the ability to isolate flow to the condenser waterboxes or downstream rupture during flooding conditions, the motor operators for the inlet valves have been modified for operation while submerged.

Procedures have been revised to reflect sensitivity related to potential turbine building flooding resulting from certain maintenance activities. Where appropriate, maintenance procedures require that a flood watch be posted during the maintenance evolution and that double isolation be established prior to initiation of the maintenance effort.

CHAPTER 10 STEAM AND POWER CONVERSION

10.1 GENERAL DESCRIPTION

Note: As required by the Subsequent Renewed Operating Licenses for Surry Units 1 and 2, issued May 4, 2021, various systems, structures, and components discussed within this chapter are subject to aging management. The programs and activities necessary to manage the aging of these systems, structures, and components are discussed in Chapter 18.

This chapter describes the systems and equipment that are required to convert steam energy to electrical energy. The following sections describe separate equipment and systems required for each unit:

10.3.1 Main steam system

10.3.2 Auxiliary steam system

10.3.3 Turbine generator

10.3.5 Condensate and feedwater system

10.3.6 Condenser

10.3.7 Lubricating-oil system

10.3.9 Bearing cooling water system

The following sections describe those systems that are shared in the operation of both units:

10.3.4 Circulating water system

10.3.8 Secondary vent and drain system

The potential for radioactive contamination of the secondary steam system is discussed in Chapter 11.

Intentionally Blank

10.2 DESIGN BASES

The design bases of the steam and power conversion equipment and systems are largely derived from past design experience with fossil-fueled stations, and have evolved over a long period of time. Specifically, the design bases are oriented to a high degree of operational reliability at optimal thermal performance. The performance of the collective equipment and systems is a function of environmental conditions and the selection of design options. Therefore, the principal design basis is represented by the design heat balances, which incorporate all of the applicable design considerations.

Figure 10.2-1 and Reference Drawing 1 shows the heat balance for the extended rating equivalent to 2558 MWt.

The conventional design bases have been modified in order to provide suitability for nuclear application, and these include provisions for specific earthquake, tornado, and missile protection as further described in other sections.

Turbine building Reference Drawings 2 through 9 show equipment locations.

A steam generator repair program was completed at the Surry Power Station in 1980 and 1981 for Units 2 and 1, respectively. The purpose of the program was to repair degradation caused by corrosion-related phenomena and to restore the integrity of the steam generators to a level equivalent to new equipment. The repair program basically consisted of replacing the steam generator lower assembly and refurbishing the upper assembly. New primary moisture separation equipment was installed in the upper assembly. The steam generators are described in Section 4.2.2.3 (primary-side characteristics) and Section 10.3.1.2 (secondary-side characteristics).

10.2 REFERENCE DRAWINGS

The list of Station Drawings below is provided for information only. The referenced drawings are not part of the UFSAR. This is not intended to be a complete listing of all Station Drawings referenced from this section of the UFSAR. The contents of Station Drawings are controlled by station procedure.

10.3 SYSTEM DESIGN AND OPERATION

10.3.1 Main Steam System

The main steam system is shown on Figure 10.3-1 and Reference Drawing 1. The turbine generator heat balance for a bounding NSSS power of 2602 MWt is shown on Figures 10.2-1 through 10.2-4 and Reference Drawing 10. A review of the effects of the power uprate to a core power of 2589.3 MWt was conducted and the main steam system was found to be adequate.

10.3.1.1 **Design Basis**

Each of the three main steam pipes is designed in accordance with the ASME Code for Pressure Piping, ANSI B31.1, for a flow of 3,722,641 lb/hr of steam at 1085 psig, 555°F. The pipes are each 30-inch o.d. ASTM A-155, Class 1, Gr. CMS-75 carbon steel, 1-inch nominal wall thickness, and join to form a common 36-inch o.d. header. Additional discussion of main steam piping materials may be found in Section 14B.5.1.6.3. Steam flows from this header through four 28-inch o.d. pipes to the stop trip valves and the turbine.

The steam dump system is sized to take the excess steam flow associated with a 50% load reduction. The steam dump system in conjunction with the reactor control system, mitigates a 50% load reduction transient without tripping the reactor. The steam dump system has a capacity of between 28 and 43%, which ranges from approximately 3,336,000 to 4,654,000 lb/hr. This flow can be divided equally through the eight bypass control valves, with each valve having a maximum capacity of 890,000 lb/hr at full load steam conditions.

The 4200-rpm turbine-driven auxiliary feedwater pump is designed to deliver 700 gpm of auxiliary feedwater to the steam generators at main steam pressures from 600 psig to 1100 psig. The turbine-driven auxiliary feedwater pump will also operate at main steam pressures from 600 psig down to less than 120 psig and deliver the required auxiliary feedwater flow to the steam generators to support Reactor Coolant System (RCS) decay heat removal prior to placing the residual heat removal system in service. A main steam pressure of 120 psig corresponds to the approximate RCS conditions at which the residual heat removal system can be placed in service to remove decay heat. Steam traps drain condensate from upstream of the inlet control valves to prevent water slugs from entering the turbine. Removal of this condensate minimizes the risk of water slugs entering the turbine, flashing, and causing a pump trip on turbine overspeed.

The main steam piping supports were initially analyzed for turbine trip forces as well as for seismic forces. Since the turbine trip results in a more severe shock to the piping system than the design-basis earthquake, as set forth in Section 2.5, the turbine trip data were used in the design of the piping supports. In addition, the system was stress-analyzed for the forces and moments that result from thermal growth. The main steam piping within the containment annulus was reviewed for possible pipe rupture, and sufficient supports and guides were provided to prevent damage to the containment liner and adjacent piping. Stresses in the main steam piping inside containment have been reviewed and, in accordance with NRC Generic Letter 87-11, are sufficiently low that only terminal end breaks need be postulated.

As a result of IE Bulletin 79-14 (Reference 1), the main steam piping and supports were reanalyzed in accordance with updated regulatory requirements. Minor support modifications were made to satisfy analytical load limits. Pipe stresses were within allowable limits, so no piping modifications were necessary. The reanalysis of safety-related piping systems and supports is discussed in Appendix 15A.

10.3.1.2 **Description**

Each loop of the reactor coolant system contains a vertically mounted U-tube steam generator. The secondary-side characteristics of the steam generators are described below. The primary-side characteristics are described in Chapter 4. Steam generator design data are given in Table 4.1-4.

The steam generators, as shown on Figures 10.3-2 and 10.3-3, consist of two integral sections: an evaporator section and a steam drum section. The evaporator section consists of a U-tube heat exchanger, while the steam drum section houses moisture-separating equipment. The steam drum section is located in the upper part of the steam generator. In general, the steam generators are designed and manufactured in accordance with Sections II, III, and IX of the ASME Boiler and Pressure Vessel Code. The lower assemblies are designed and manufactured in accordance with the 1974 Edition of the ASME Code, including Addenda through Winter 1976. All components are designed to meet Section XI, *Rules For Inservice Inspection of Nuclear Power Plant Components*. The steam generator lower assemblies bear the applicable ASME Code stamp.

Feedwater enters the unit through the nozzle located on the upper shell and is distributed by a feedwater ring into the downcomer annulus formed by the tube wrapper and steam generator shell. The feedwater mixes with recirculation flow and enters the tube bundle near the tubesheet.

The circulation ratio, which is defined as the total tube bundle flow divided by the feedwater flow and is directly proportional to the steam quality exiting the tube bundle, is approximately 3.8. As circulation ratio increases, certain parameters of the steam generator, such as lateral velocity, steam quality, void fraction, and number of tubes exposed to sludge, change in a favorable direction. Low steam quality in the bundle reduces tube exposure to local steam blanketing. This also reduces the number of potential areas of concentration for chemical impurities. In addition, higher circulation ratios increase the flow exiting the downcomer and sweeping across the tubesheet to the center of the bundle. The point of highest steam quality and thus the lowest density is the center of the tube bundle, though, and is thus more susceptible to chemical concentration and sludge deposition. It is for this reason that the blowdown intake is located in this region.

A set of sixteen 20-inch-diameter centrifugal moisture-separators, located 13 inches above the tube bundle, removes most of the entrained water from the steam. Steam dryers are employed to increase the steam quality to a minimum of 99.75% (0.25% moisture). The steam drum has two bolted and gasketed access openings for inspection and maintenance of the dryers, which can be disassembled and removed through the opening.

The lower assemblies are constructed with four additional 6-inch access ports and two 2-inch access ports in the area of the tubesheet. Four 6-inch access ports are located slightly above the tubesheet 90 degrees apart, with two located on the tube lane. Two additional 6-inch access ports are located on the tube lane, between the flow distribution baffle and the first support plate. At this same elevation, 90 degrees away, are two 2-inch access ports. The addition of these access ports improves and promotes inspection of the tubesheet and flow distribution baffle and assists in the sludge-lancing procedure. The steam generator wrapper is designed to discourage flow in the tube lane yet allow clear access from the access ports.

Feedwater exiting from behind the wrapper in the vicinity of the tube lane will tend to preferentially channel to this path of less resistance and bypass part of the tube array. In order to prevent this flow channeling, a series of plates are placed in the tube lane. These plates block the flow into the tube lane and prevent channeling. These plates are arrayed so that there will be no interference with the sludge-lancing procedure.

A flow distribution baffle is located approximately 18 inches above the tubesheet. This baffle has a cutout center section and quatrefoil tube holes. The increased circulation ratio provides a greater lateral flow across the tubesheet surface. The baffle plate will assist in redirecting the flow across the tubesheet, then up the center of the bundle through the center cutout. The design is sized to minimize the number of tubes exposed to sludge. Consistent with this purpose, the design causes the sludge to deposit in and near the center of the bundle at the blowdown intake. The flow distribution baffle plate material is SA-240 type 405 ferritic stainless steel.

The tube support plates are SA-240 type 405 ferritic stainless steel. This material is ASME Code approved and is resistant to corrosion with the chemistry expected during the operation of the steam generator. In addition, SA-240 has a low wear coefficient when paired with Inconel and has a coefficient of thermal expansion similar to carbon steel. Corrosion of SA-240 results in an oxide which has approximately the same volume as the parent material, whereas corrosion of carbon steel results in oxides that have a greater volume than the parent material. Type 405 also has material properties important to fabrication that are equivalent to carbon steel.

The quatrefoil tube support plate design, as shown on Figure 10.3-4, consists of four flow lobes and four support lands. The lands provide support to the tube during all operating conditions, while preventing wear or fretting. This design has a lower pressure drop than the most current circulation hole designs. This low secondary pressure drop will cause a high circulation ratio which, when combined with other improvements, translates into higher sweeping velocities and fewer tubes exposed to a low steam quality at the tubesheet. This design directs the flow along the tubes, which limits steam formation and chemical concentrations at the tube-to-tube support plate intersections.

Each steam generator has two 2-inch, schedule 40 Inconel internal blowdown pipes. The blowdown rate from the steam generator is varied as required by chemistry conditions in the feedwater and as monitored in the blowdown. Maintenance of the steam-side water chemistry is assisted through the use of the blowdown system. Therefore, a continuous blowdown is preferred to intermittent blowdown. Continuous blowdown of the steam generator provides a dynamic system that is constantly removing impurities from the steam generator. During hot standby and hot functional testing, blowdown is employed as needed to maintain the steam generator chemistry within specification. The blowdown intake location is coordinated with the baffle plate design so that the intake is located where the greatest amount of sludge deposition is expected to occur. The design of the steam generators allows the use of an efficient sludge removal system; a typical system is shown on Figure 10.3-5. A permanent sludge removal system is not installed. A review of the effects of the power uprate to a core power of 2587 MWt was conducted and the main steam generator blowdown system was found to be adequate.

Steam-generator blowdown is discharged from the steam generators through two 2-inch schedule 40 Inconel internal blowdown pipes. The steam generators are designed to allow blowdown rates up to 7.4% of the feedwater flow rate; however, much of this is excess capacity because the blowdown system has a capacity of 1% of the feedwater flow rate.

A 3-inch line downstream of each steam generator blowdown containment isolation valve carries the blowdown effluent from the auxiliary building into the turbine building. Each blowdown line has a manual isolation valve, with a bypass valve provided for system start-up. Each blowdown line has a heat exchanger located adjacent to the east wall of the respective turbine building.

The system is designed for a maximum continuous blowdown from each steam generator of 70 gpm at 750 psig and 510°F, and reduces the blowdown water to a maximum temperature and pressure of 130°F and 60 psig.

During power operation, after the blowdown is cooled, it is normally directed to the condenser hotwell. The blowdown, along with condensate in the condenser, is filtered and treated by condensate polishing prior to being returned to the steam generators. Alternately, steam generator blowdown may be released to the discharge canal through the condenser outlet waterbox. This activity is described in Section 10.3.5.2. Releasing to the discharge canal is normally limited to unit start-up operation.

A pressure control valve (PCV) and a hand control valve (HCV) are provided downstream of each heat exchanger assembly. The PCV will maintain a constant nominal pressure of 250 psig upstream of the HCV. If pressure upstream of the PCV decreases below 250 psig, the valve will travel to the full-open position. The PCV will fail closed on a loss of control air, blowdown flow greater than 75 gpm, or heat exchanger assembly outlet temperature greater than 145°F. The HCV is provided for remote/manual control of the steam generator blowdown rate. A remote control station is provided in the control room to position the HCV. The HCV is sized for a maximum blowdown rate of 70 gpm with an upstream pressure of 250 psig and a downstream pressure of 50 psig. A pressure relief valve, set for approximately 200 psig, is provided to protect the system downstream of the HCV from overpressurization. A manually operated bypass valve is provided around both the PCV and the HCV to allow manual control of the blowdown flow. Two flow elements are provided between the heat exchanger assembly and the PCV for high-range and low-range flow indication.

Main condensate is used as the cooling medium for the heat exchangers. Approximately 1260 gpm per unit (three heat exchangers) is supplied through an 8-inch supply header and isolation valve. The supply connection from the condensate system is located on the 24-inch condensate header between the gland exhaust condenser and the flash evaporator. The return line ties into the condensate system at the cross-connect line between the fourth and fifth point feedwater heaters. Manual isolation valves are provided on each heat exchanger assembly. The outlet isolation valve is a globe valve to permit throttling of the cooling water flow. Thermometers are installed in the cooling water lines at the outlet of the heat exchanger assemblies to monitor condensate return temperature. A relief valve is provided for each heat exchanger assembly between the isolation valves. The differential pressure across the drain coolers, fifth, and sixth point heaters will provide sufficient head for condensate flow through the steam generator blowdown (SGBD) heat exchangers. To increase the condensate cooling capacity of the SGBD heat exchangers during low main condensate flow conditions, an independent SGBD heat exchanger condensate return divert line is added. The diverted heat exchanger condensate return flow is controlled by a temperature controlled valve (TCV) which allows the diverted flow to be discharged to the main condenser when the heat exchangers' blowdown exit temperature reaches 135°F.

Codes and standards applied to the steam generator blowdown system are listed in Table 10.3-1. The piping from the 3-inch connection downstream of the steam generator blowdown containment isolation valves to the heat exchanger assemblies is classified as high-energy piping. This portion of the steam generator blowdown system is not safety related and has no seismic or tornado design requirements, except that its failure must not cause a functional loss of any safety-related equipment. Postulated breaks have been analyzed, and restraints added to prevent pipe whip or jet impingement damage to systems in the auxiliary building that are required for safe shutdown.

A blowdown sampling system is provided in the Unit 1 turbine building. The system is used to analyze a cooled blowdown sample before the blowdown stream is discharged to the discharge canal through the condenser waterbox outlet.

A 2-inch nozzle in the upper shell facilitates the wet layup of the steam generators during the periods of inactivity. The wet layup nozzle can be used for addition of chemicals during these periods to prevent any excursions of the water quality in the steam generator. The nozzle can also be used in conjunction with other systems to circulate water through the steam generator during periods of layup to prevent localized chemical concentrations. These same connections can also be used for chemical cleaning.

A steam generator recirculation and transfer system is provided to protect the steam generator internals from corrosive attack during inactive periods by enabling the water chemistry to be controlled during such periods. The system is used in conjunction with the steam generator nitrogen system described below to ensure the exclusion of oxygen from the steam generator internals during wet layup conditions. Each steam generator has an independent external recirculation loop with 150-gpm pumping capacity, which provides a complete volume turnover approximately every 4 hours. The recirculation and transfer system pump takes suction from the steam generator upper shell. The pump discharges to the steam generator through the blowdown pipe via a connection to the steam generator blowdown system. Each circulation loop has a cross connect to facilitate the transfer of a steam generator’s contents to either of the other two steam generators, the liquid waste system, or the circulating water discharge. During normal plant operation, the system will be isolated from the steam generator by double isolation valves. A typical wet-layup system is shown in Figure 10.3-6.

The steam generator nitrogen system is utilized in conjunction with the steam generator recirculation and transfer system to protect the steam generators during long layup periods from corrosive attack by ensuring the exclusion of oxygen from the secondary side of the steam generators. The system includes a vacuum pump to enable the air to be evacuated from the steam generator before nitrogen is introduced from a nitrogen supply. However, the vacuum pump is no longer used. Connection to the secondary side of the steam generator is made by a 2-inch line connected to the 6-inch main steam trip valve bypass line in the main steam valve house. An isolation valve is provided to isolate this system from the steam system during unit operation. This system is a quality group B system from the bypass line up to and including the isolation valve, with the rest of the system being quality group E.

A loose parts monitoring system has been installed and provides the ability to monitor the primary system and secondary side of the steam generators for the presence of loose circulating parts and other foreign objects. See Section 4.2.10 for further information.

All pressure-containing parts, with the exception of the Inconel tubes, are made of carbon or low-alloy steel. The stainless steel insulation of the steam generator is designed to facilitate removal for maintenance and inservice inspection activities.

Steam is conducted from each of the three steam generators through a steam flowmeter (venturi), a swing disk-type valve and an angle-type nonreturn valve into a common header outside the containment. The steam passes from the header to the turbine stop-trip valves and then to the governor valves. The steam flowmeter sends a signal to the feedwater control system.

The swing disk-type trip valves in series with the nonreturn valves contain swinging disks that are normally held up and out of the main steam flow path by air cylinder operators. Three-way solenoid-operated air control valves function to hold the trip valves open when air pressure is applied. The valves are designed to close on release of air pressure, but are not dependent on air pressure to assist closure. When the air pressure is vented, the valve discs shut rapidly due to spring pressure and the steam flow differential pressure. The air cylinders are equipped with rupture discs to prevent damage to valve and actuator parts from being overstressed due to the rapid cylinder pressure increase when the valves shut at high steam flow rates. Air is normally available at 100 psig, but the equipment is designed to operate at a minimum air pressure of 70 psig. Electrical power to the solenoid-operated air control valves is available at 125V dc.

The main steam-line trip valve circuitry has been modified to ensure that the trip valves will not return to their non-safety position (open) following the resetting of the consequence limiting safeguards (CLS) system signal when power to train A or B is lost. The modification required the installation of an additional contact deck to each trip valve selector switch located at the benchboard in the control room and the installation of a new limit switch to each trip valve. This modification provides a seal-in function in the train B control circuitry similar to that existing in the train A portion of the circuit. As a result, when resetting a CLS signal, if power is lost in either train A or B, the valve will not return to its non-safety position. All electrical equipment installed due to the above modification that could experience a harsh environment is qualified to IEEE 323-1974, IEEE 344-1975, and IEEE 383-1974.

The trip valves close following receipt of an excess flow signal from the steam flowmeter to the solenoid-operated air control valves. The electrical signal positions the air control valves to release air pressure on the air cylinder operators, and spring action causes the trip valve disks to move into the steam path and trip closed. The operating mechanisms are designed and constructed to withstand the pressures and temperatures that result from dashpot action after the valve disk has moved into the steam path. Rapid closure of the trip valves prevents flashing of the water on the shell side of the steam generators, which in turn prevents a rapid decrease in reactor coolant temperature on the tube side of the steam generators.

In addition to the three-way solenoid-operated air control valves described in this section, two solenoid-operated valves have been added to each main steam line trip valve to provide an alternate means of closure at either the control room (in the event of a fire in the emergency switchgear room) or at the emergency switchgear room (in the event of a fire in the control room). The cables, solenoid valves, control switches, and battery/battery chargers required to power the two additional SOV’s are qualified to meet or exceed the normal environmental conditions for the areas where they will be installed. The cables that supply the two SOVs are environmentally qualified in accordance with IEEE 323-1974. See Section 9.10.4.1 for information on 10 CFR 50 Appendix R requirements in relation to this modification.

The air operators are also used to open the trip valves. With 70 psig applied to both operators, the trip valves will open with a maximum differential pressure of 4 psi across the valve seat. Manually operated bypass valves permit pressure to be balanced across the valve before reopening.

The motor-operated nonreturn (stop-check) valves automatically prevent reverse flow of steam in the case of accidental pressure reduction in any steam generator or its piping, and also provide a shut-off of steam from its respective steam generator.

A total of five ASME Code safety valves are located on each main steam line outside the reactor containment and upstream of the trip valves. Four 6-inch by 10-inch valves and one 4-inch by 6-inch valve are provided, for a total relieving capacity of 3,842,454 lb/hr.

Excess steam generated by the residual and sensible heat in the core and the reactor coolant system is normally bypassed directly to the condensers by means of two 14-inch steam dump lines, which provide a total bypass capacity of 40% of normal full-load steam flow. Each steam dump line contains a bank of four steam dump control valves arranged in parallel. These valves are controlled by reactor coolant average temperature with provisions to control a portion of the valves with steam pressure. An uncontrolled unit cooldown caused by a single valve sticking open is minimized by the use of a group of valves installed in parallel.

All or several of the steam dump valves open under the following conditions, provided a condenser vacuum permissive interlock is satisfied:

1. On a large step load decrease, the steam dump system creates an artificial load on the steam generators, thus enabling the nuclear steam supply system to accept a 50% load rejection from the maximum capability power level without reactor trip. An error signal exceeding a set value of reactor coolant T_{avg} minus T_{ref} will fully open all valves in 5 seconds. T_{ref} is a function of load and is set automatically. The temperature-controlled valves close automatically as reactor coolant conditions approach their programmed set-point for the new load.
2. On a turbine trip with a reactor trip, the pressure in the steam generators rises. To prevent overpressure without main steam safety valve operation, the steam dump valves open and discharge to the condenser for several minutes, to provide time for the reactor control system (Section 7.3) to reduce the thermal output of the reactor without exceeding acceptable core and coolant conditions.
3. After a normal orderly shutdown of the turbine generator leading to unit cooldown, the steam dump valves are used to release steam generated from the residual and sensible heat for several hours. Unit cooldown is controlled to minimize thermal transients and is based on residual and sensible heat release. It is effected by manual control of the steam dump valves until the cooldown process is transferred to the residual heat removal system (Section 9.3).

4. During start-up, hot standby service, or physics testing, the steam dump valves are operated from the control room. The Steam Header Pressure Controller can be used in the Automatic or Manual control mode while maintaining the plant at no load conditions or during start-up with power less than approximately 15%.

All steam dump valves are prevented from opening on loss of condenser vacuum, and excess steam pressure is relieved to the atmosphere through the steam generator power operated relief valves or the main steam safety valves. Interlocks are provided to reduce the probability of spurious opening of the steam dump valves.

An interlock is also provided to close all steam dump valves by venting the valve actuators whenever the reactor coolant system temperature in two out of three loops falls below 543°F (nominal). This interlock is redundant down to two solenoids per steam dump valve, which vent the valve actuator. This interlock ensures that any failure in the steam dump control system occurring in the normal operating temperature range above 543°F (nominal) can cause a cooldown only to 543°F (nominal) at which point all valve actuators are vented and, thus, all valves are closed.

A steam generator power operated relief valve with an adjustable setpoint is provided on each main steam safety valve header, upstream of the trip valve outside the containment. The relieving pressure of these valves, normally 1035 psig, is individually controlled from the control room, and each valve has a capacity of 373,000 lb/hr. A key lock selector switch EMERG CLOSE—NORMAL has been added to the existing analog circuit of the associated controls for each of the three power operated atmospheric relief valves. This provides the operator with the ability to close the relief valves by interrupting the analog signal, which normally controls the position of the relief valves. These selector switches are located in the cable vault and tunnel where the operator can operate the relief valves in the event of a fire in the control room or the emergency switchgear room. These valves which are equipped with quick-connect instrument air fittings can be operated locally with a portable air source if required. The steam generator power operated relief valves are equipped with a backup bottled air system so that they can be operated from within the containment spray pump house in the event of loss of offsite power. Additionally, a beyond design basis (BDB) backup air bottle system also exists for operating the steam generator (SG) power operated relief valves (PORV) during a beyond design basis external event (BDBEE) resulting in damage to the backup air bottle system. This BDB backup air bottle system is contained inside the Main Steam Valve House (MSVH), which is a safety related, seismic structure that is tornado missile protected. This system also provides a means to connect an external air source, such a a portable air compressor.

Steam leaving the high pressure turbine passes through four moisture separator-reheater units in parallel to the inlets of the low pressure turbine cylinders. Each of the four steam lines between the reheater outlet and LP turbine inlet is provided with a crossover stop valve and an intercept valve in series. These valves, operated by the turbine control system, function to control turbine overspeed. Six ASME code safety valves are installed on each crossunder line between the high pressure turbine exhaust and the moisture separator inlet to protect the separators and crossunder system from overpressure. The valves are sized to pass the flow resulting from closure of the crossover stop and intercept valves with the main steam inlet valves wide open. Although this event is unlikely, the valves discharging to atmosphere prevent equipment damage.

Steam is supplied to the turbine drive for the auxiliary feedwater pump from each steam line upstream of the main steam trip valves. The steam lines to the turbine are continuously under steam generator pressure up to the shut-off valves located at the turbine drive. The air-operated steam supply valves for the auxiliary feedwater pump are operable from the control room or the auxiliary shutdown panel. Operation of these valves is also initiated automatically from a loss of power signal or on a low-low level signal in two of three steam generators. Indication of operating conditions is provided in the control room to enable the operator to adjust feedwater flow with any of the six motor operated valves shown on Reference Drawing 6.

Temperature flow probes are installed on the discharge side of the 15 main steam safety valves to monitor safety relief valve position on the main steam system. Valve position is indirectly “measured” by comparing discharge temperatures with respect to ambient temperatures with the valve closed. This indirectly determined valve status is transmitted through the ERFDAS (Emergency Response Facility Data Acquisition System) which provides the control room operator with a CRT display on the open or closed valve status for each of the main steam safety relief valves.

10.3.1.3 **Performance Analysis**

The steam generator repairs effected in 1979 and 1981 incorporated design features to eliminate various forms of tube degradation. The design features combined with inservice inspections will help ensure that tube integrity is maintained. The acceptability of the repaired steam generators is discussed in detail in a safety evaluation by the Office of Nuclear Reactor Regulation dated December 15, 1978 (Reference 2).

Design criteria for the steam generator lower assemblies require that tube vibration, tube fatigue, and tube support plate hole enlargement be within acceptable limits. As a result, flow-induced tube vibration caused by turbulence, fluid elastic excitation, and vortex shedding has been evaluated. The evaluation shows that the maximum alternating bending stress in a tube is 1.2 ksi. The code allowable number of cycles at this stress level is infinite and the fatigue usage factor is zero. Furthermore, the wear coefficient of SA-240 type 405 stainless steel, when paired with Inconel tubing at normal operating temperatures, is lower than that for carbon steel; therefore, initial tube clearances will be maintained and tube support conditions will not change noticeably during the lifetime of the steam generator.

If a main steam pipe rupture occurs, a flow signal measured by the venturi flowmeter located in that main steam line causes the swing check trip valves in all three main steam lines to trip closed. The trip valves are assumed to close within 10 seconds from the time the process variable reaches the trip setpoint. This time is comprised of three components: one second for the instrument response time delay from the time the setpoint is reached until bleed off of instrument air pressure is initiated, a maximum of 4 seconds to bleed off the instrument air pressure from the main steam trip valve operating cylinders, and a maximum of 5 seconds as closure time for the valve. If the rupture occurs downstream of the trip valves, valve closure stops the flow of steam through the pipe rupture, thus checking the sudden and large release of energy in the form of main steam. This prevents rapid cooling of the reactor coolant system and an ensuing positive reactivity insertion. Trip valve closure also ensures a supply of steam to the turbine drive for the steam-driven auxiliary feedwater pump described in Section 10.3.5.

If a steam line breaks between a trip valve and a steam generator, the affected steam generator continues to blow down. The nonreturn valve in the ruptured line prevents blowdown from the other steam generators. Steam-break accidents are discussed in Section 14.3.2.

10.3.1.4 **Secondary Plant All-Volatile Chemistry Treatment**

Phosphate chemistry was used prior to 1975, but both units changed to all-volatile treatment (AVT) in January 1975. A chemistry monitoring program has been implemented to inhibit steam generator tube degradation. Discussion of the monitoring system is provided in Section 9.6, Sampling System.

Condenser inleakage, contaminants from condensate polishing, and condensate/feedwater system corrosion products are the major sources of chemical agents that have the potential for accumulating as sludge on the steam generator tubesheet, producing deposits on steam generator heat transfer surfaces. The feedwater is the means by which these chemical agents are transported to the steam generator. AVT chemistry provides no buffer against the effects of condenser inleakage; it is incapable of preventing the formation of scale should the chemical agents that have the propensity for scale formation be present, and the ammonium hydroxide or the amines added to the system for feedwater pH control have minimum effectiveness as steam generator pH control agents at the operating temperature in the steam generator. Therefore, to accomplish the goal of maintaining the secondary system in an all-volatile chemistry environment that is innocuous to the steam generator materials, it is necessary to minimize the introduction of contaminants and corrosion products to the system. In addition to providing the proper environment for the steam generator, a well-maintained AVT chemistry program will accomplish the following:

1. Maintain the integrity of system components.
2. Minimize turbine deposits due to carryover from the steam generators.
3. Minimize sludge in the steam generators.
4. Minimize scale deposits on the steam generator heat transfer surfaces.
5. Minimize feedwater oxygen content prior to entry into the steam generators.
6. Minimize corrosion of the condensate/feedwater system materials.

7. Maintain chemistry near neutral in steam generator crevices.
8. Maintain desired dissolved oxygen level.

These objectives can be achieved by exercising chemistry control over the systems, including sampling and analysis, chemical injection at selected points, continuous system blowdown from the steam generator, and effective protection of the steam generator and feedwater train internals during periods of inactivity. The objectives are accomplished by meeting steam generator control parameters specified by the Nuclear Plant Chemistry Program. The specifications are based on the EPRI, PWR Secondary Water Chemistry Guidelines, including:

1. The use of approved amine(s) for feed water and steam pH control (ammonium hydroxide, morpholine, ethanolamine, and cyclohexylamine are acceptable).
2. The use of an approved oxygen scavenger in the feedwater train.
3. Continuous blowdown and continuous chemical addition.
4. Limiting the concentrations of contaminants in the feedwater and in the steam generator.

For corrosion prevention, the ingress of oxygen into the steam generators should be controlled. Oxygen should be less than 0.005 ppm in the blowdown under any operating or test condition. Oxygen is reduced by the addition of an oxygen scavenger. During hot standby, the concentration of oxygen in the feedwater can be 0.1 ppm or less, provided the concentration of oxygen scavenger injection into the steam generator is within recommended limits.

The concentration of oxygen scavenger in the steam generators during hydro and wet layup must be adequate to minimize dissolved oxygen and passivate the covered metal surfaces.

When controlling steam generator chemistry on AVT chemistry, it must be recognized that (1) AVT provides no buffering capacity for contaminants entering the steam generator, and (2) the steam generator bulk water pH is at or slightly in excess of the neutral pH for water at the operating temperature of the steam generator. The absence of alkalinity in the steam generator at its operating temperature is due to the low ionization of the feedwater pH control amines at these temperatures. Therefore, contaminants entering the steam generator that are more strongly ionized than the feedwater pH control amines have the potential for producing perturbations to the bulk water either in the form of free hydroxide (from fresh waters) or acidity (sea water or treated circulating water). The objectives of the steam generator chemistry control parameters are to provide a means for controlling the steam generator crevice chemistry to minimize corrosion of the steam generator and turbine cycle materials, and to provide a means whereby perturbations to the steam generator chemistry from sources such as condenser inleakage can be recognized.

In the recirculating steam generator, the only bulk water losses from the steam generator are the blowdown and the moisture that is entrained in the steam. Therefore, any contaminant entering the steam generator will tend to concentrate until corrective action is taken.

Based on the type of steam generator degradation that has been observed at pressurized water reactors (PWRs) cooled by seawater and brackish water, emphasis should also be placed on the control of sodium. Inconel 600 steam generator tubing is susceptible to caustic induced IGA/IGSCC, and because of this, every effort must be made to exclude free hydroxide from the steam generator environment. Operational control of the steam generator sodium to chloride molar ratio is recommended to achieve near-neutral chemistry in the steam generator crevices. The controlled addition of chloride may be warranted to counter excess sodium ions.

Protection of the steam generators during inactive periods due to maintenance and refueling requires placing the steam generators in a layup condition. To ensure the long-term performance of the steam system, the same degree of chemical control exercised during normal operation should be exercised during shutdown conditions.

Periods of hot shutdown and hot standby operation require that steam be released from the steam generators to release heat in the reactor coolant system due to heat input from reactor core decay heat and reactor coolant pump heat. Chemistry control is applied during such operations similar to that exercised during normal operating conditions.

Secondary-water chemistry specifications should be adhered to during all phases of unit operation. When specifications are exceeded, operator action is taken as recommended in the station’s chemistry control program.

10.3.1.5 **Tests and Inspections**

The turbine overspeed protection is checked during normal unit start-up. The steam dump system also functions during unit start-up. Operation of the steam generator power operated relief valves is checked at start-up and also periodically during normal operation.

The turbine-driven auxiliary feedwater pump is tested in accordance with the Technical Specifications.

Safety-related main steam components are tested in accordance with Technical Specifications.

During unit shutdown, the tripping mechanisms for the trip valves are tested for proper operation. The nonreturn valves are also tested to verify that they are functional.

10.3.2 Auxiliary Steam System

An auxiliary steam system is provided as shown in Figure 10.3-7 and Reference Drawings 2 and 3. All piping is designed in accordance with the ASME Code for Pressure Piping, ANSI B31.1. A review of the effects of the power uprate to a core power of 2589.3 MWt was conducted and the auxiliary steam system was found to be adequate.

10.3.2.1 **Design Basis**

Steam from the secondary system is reduced in pressure and supplied to the auxiliary steam system for space heating, process system heat exchangers, and process system air ejectors. Nearly all secondary steam used in the auxiliary steam system is condensed, returned to the condensate system, and then sent to either the condensate storage tank or the main condenser. A small quantity of secondary steam used in the auxiliary steam system for the after condenser air ejectors and containment vacuum ejectors is not returned to the condensate system for reuse. Auxiliary steam used in the after-condenser air ejectors is condensed and drained to the storm sewage system or returned to the condenser. Auxiliary steam used in the containment vacuum ejectors is ejected to the atmosphere through the roof of the auxiliary building.

The auxiliary steam system supplies 150 psig saturated steam throughout the station for auxiliary services.

Turbine building uses of auxiliary steam are as follows:

1. Main condenser air ejector.
2. Space heating.
3. Gland seal steam.

Auxiliary building uses of auxiliary steam are as follows:

1. Boron recovery system heat exchangers.
2. Chemical and volume control system (boric acid batch tank heating).
3. Containment vacuum ejectors.
4. Space heating.

Auxiliary steam is used in the yard for the following purposes:

1. Boron recovery tank heating.
2. Primary-grade water tank heating.

Auxiliary steam is used for space heating in the following additional areas:

1. Fuel building.
2. Decontamination building.
3. Safeguards area.
4. Service building area.
   a. Shops.
   b. Mechanical equipment rooms 1 and 2.

c. Emergency generator rooms.

d. Boiler room.

The service building, including locker rooms, laboratories, offices, instrument shop, mechanical room, assembly room, and first-aid room are heated by steam coils in air-handling and air-conditioning units that serve these areas. All of these air-handling units are installed in the mechanical equipment rooms 1 and 2.

No auxiliary steam is used in the operations administration building. It is heated by hot water and steam-heated ventilation air. The hot water converter and the air-conditioning unit containing the steam coil for ventilation heating are installed in the turbine building.

10.3.2.2 **Description**

Normally, the auxiliary steam supply header receives its steam requirements from the second point extraction lines. During periods of low load operation when second point extraction steam pressure drops below approximately 140 psig, steam is supplied from the main steam header through a pressure-reducing valve. When both reactors are shut down, steam is supplied by the heating boilers.

The containment vacuum system steam ejectors are used only during start-up periods to initially evacuate the containment. During normal operation, two mechanical vacuum pumps maintain the vacuum, as described in Section 5.3.4.

Two heating boilers, each rated at 80,000 lb/hr of steam, are provided for preliminary and shutdown operation. Each boiler is the packaged water tube type and is equipped with motor-driven fuel-oil pumps, deaereator, and feedwater pumps. Number 2 fuel oil is supplied to the boilers from the main oil storage tanks.

10.3.2.3 **Performance Analysis**

A loss of normal ac power will shut down the heating boilers. No services supplied by auxiliary steam are required to function as part of engineered safeguards during a loss of station power.

10.3.2.4 **Tests and Inspections**

Routine inspections are performed on a periodic basis.

10.3.3 Turbine Generator

The turbine-generator heat balance for a bounding NSSS power of 2602 MWt is shown in Figures 10.2-1 through 10.2-4 and Reference Drawing 10.

10.3.3.1 **Turbine**

The turbine is a conventional 1800-rpm, tandem-compound unit (ALSTOM Retrofit), consisting of one single-flow high-pressure cylinder and two double-flow low-pressure cylinders. The high pressure turbine disks are 12% Cr-Mo-V and low pressure turbine disks are 2% Cr-Ni-Mo. Periodic inservice inspections are conducted to verify the integrity of the internal components of the turbines. An analysis of turbine missile risk is provided in Section 14.2.13. The inspections are conducted at a frequency consistent with the methodology specified in Reference 7. The inspection interval of the low pressure turbine blading is dictated by the Technical Requirements Manual.

The Unit 1 turbine is expected to achieve a maximum capability of 879.11 MWe gross with inlet steam condition of 769.5 psia and 0.25% moisture exhausting to 3.57 inch Hg (absolute) with feedwater temperature of 438.1 deg F and 0.0% makeup. The Unit 2 turbine is expected to achieve a maximum capability of 878.48 MWe gross with inlet steam conditions of 775.4 psia and 0.25% moisture exhausting to 3.56 inch Hg (absolute) with a feedwater temperature of 438.5°F and 0.0% makeup. The turbine is provided with six stages of feedwater heating and four moisture-separator reheaters located between the high-pressure and low-pressure cylinders.

Each high-pressure steam line to the high-pressure cylinder contains a stop-trip valve and a governor control valve. Stop valves and intercept valves are provided at the discharge of the moisture-separator reheaters to the low-pressure turbine cylinders.

A gland steam sealing system is provided to prevent air inleakage and steam outleakage along the turbine shaft. All necessary piping, controls, and a gland steam condenser are provided.

The turbine oil systems include a conventionally designed electro-hydraulic-controlled governing-trip system. There is also a low-pressure bearing lubrication system, discussed in Section 10.3.7.

Overspeed protection is provided through use of an overspeed trip mechanism that consists of an eccentric weight mounted in a transverse hole in the turbine rotor extension shaft. Centrifugal force moves the weight outward against spring compression. When the turbine overspeeds to a point at which the mechanism is set to operate, the spring compression is overcome by the centrifugal force of the rotor speed, and the weight moves out to strike a trigger, which trips the overspeed trip valve and releases the auto-stop oil and operating fluid to drain.

Additional turbine overspeed protection utilizes the output of magnetic pickups mounted adjacent to the turbine shaft. A toothed wheel on the shaft provides a fluctuation magnetic coupling for the speed transducer pickups. The speed transducer senses fluctuations and translates them into a sine wave whose frequency is proportional to turbine speed. This signal is fed to the auxiliary governor. If the control subsystem senses an overspeed condition (103% speed), and the generator is not in parallel with the grid or if electrical output is less than 5%, then the auxiliary governor provides a control signal to SOVs in the EHC subsystem which depressurizes the governor valve emergency trip header. This trips the governor and intercept valves closed while the overspeed signal is present in an attempt to limit the overspeed and prevent an overspeed trip. Once the turbine speed decreases below 103% of rated speed, the solenoids close and the intercept valves start to reopen immediately followed by the governor valves after five seconds. When the generator is in parallel with the grid and electrical output is greater than 5% then the auxiliary governor's overspeed function is disabled. This is because this protection is not needed when these conditions are met due to the fact that synchronous generators in parallel must operate at grid frequency and physically can not overspeed.

The Reverse Power protection system provides two forms of turbine protection. Excessive heat damage to the turbine is prevented during generator motoring by tripping the generator breakers 40 seconds after sensing the reverse power condition. Additional turbine overspeed protection is provided by using the reverse power relay to provide sequential tripping.

Sequential tripping is the inclusion of a reverse power relay in series with any trip circuits using steam valve close position switches. This will provide security against possible overspeed by ensuring that all sources of steam to the turbine are reduced below the amount required to produce overspeed before the generator breakers and excitation breakers are tripped. In addition, the reverse power relay provides a time delayed backup trip in the case of failed or misadjusted valve position switches.

This protection will not override the generator or switchyard protection that instantaneously opens the generator breaker when an electrical fault occurs that might cause serious and certain damage to the generator or switchyard equipment.

10.3.3.2 **Generator**

The hydrogen inner-cooled generator rating is 1,055,000 kVA at 75 psig hydrogen gas pressure, 0.90 pf, three-phase, 60 Hz, 22 kV, and 1800 rpm. The Unit 1 generator has a 0.540 SCR, while the Unit 2 generator has a 0.559 SCR. The Unit 1 and Unit 2 generator will be operated in accordance with their respective capability curves from the station curve book. The capability curves show the generator capacity for various combinations of power factor and hydrogen pressure.

Primary protection of the main generator is provided by differential current and field failure relays. Protective relays automatically trip the turbine stop valves and electrically isolate the generator.

A rotating rectifier (brushless) exciter with a response ratio of 0.5 is provided for both units. The exciter rating is 4700 kW, 570V dc, and 1800 rpm. The exciter consists of an ac alternator coupled directly to the generator rotor. The alternator field winding is stationary, and control of the exciter is applied to this winding. The alternator armature output is rectified by banks of diodes that rotate with the armature. This direct current output is carried through a hollow section of the shaft and is applied directly to the main generator field.

The 22-kV generator terminals are connected to the main step-up transformer and the unit station service transformers by 22-kV aluminum conductors, each rated at 29,500A. Each aluminum conductor is enclosed in a self-cooled, isolated-phase bus duct. Further discussion of the interconnection between the generator and the transmission system is contained in Section 8.3.

Hydrogen seal-oil pumps are furnished to provide seal oil to the generator shaft seals for the prevention of hydrogen leakage from the generator. An ac motor-driven high-pressure hydrogen seal-oil back-up pump and a dc motor-driven, air side seal-oil backup pump are provided. A continuous bypass-type oil purification system removes water and other contaminants from the oil.

Since a mixture of hydrogen and air is explosive over a wide range of proportions (from about 4 to 70% hydrogen by volume), the design of the generator and the specified operating procedures are such that explosive mixtures are not possible under normal operating conditions. In order to provide for some unforeseen condition brought about by the failure to follow the correct operating procedure, it is necessary to design the frame to be explosion-safe. The intensity of an explosion of a mixture of air and hydrogen varies with the proportions of the two gases present. A curve on which the values of intensity are plotted against the proportions of gases will approximate a sine wave, having zero values at 5 and 70% hydrogen and reaching a maximum intensity at a point half way between these limits. The term “explosion-safe” is intended to mean that the frame will withstand an explosion of this most explosive proportion of hydrogen and air at a nominal gas pressure of 2 or 3 psig without damage to life or property external to the machine. This nominal pressure of 2 or 3 psig is that which might be obtained if hydrogen were accidently admitted during the purging operation instead of carbon dioxide, as specified. Such an explosion might, however, result in damage or dislocation of internal parts of the generator. When changing from one gas to another, the generator is vented to the atmosphere, so that a positive pressure of more than 2 or 3 psig will not be built up.

10.3.4 Circulating Water System

The circulating water system, Reference Drawing 4, provides cooling water for the main condensers and the service water systems of both units. A review of the effects of the power uprate to a core power of 2589.3 MWt was conducted and the circulating water system was found to be adequate.

10.3.4.1 **Design Basis**

To prevent the direct recirculation of the heated circulating water discharge, the system is designed to take water from the James River on the east end of the site and to discharge to the James River on the west end of the site. The shoreline distance between the intake and discharge points is about 5.7 miles, and the overland distance across the peninsula is about 1.9 miles.

Each unit requires 840,000 gpm of river water to supply condensing and service water needs. To provide operational flexibility, system reliability, and station economy, the water requirement for each unit is supplied by four 220,000-gpm pumps. These pumps discharge to the common high-level intake canal that conveys the circulating water to the station area. Coarse trash is removed from the circulating water by trash racks at the river intake structure, and finer trash is removed at the river intake and at the entry-bay and station ends of the intake canal by two sets of traveling water screens. The circulating water flows by gravity from the high-level intake canal through four buried parallel lines to each condenser and then through four separate lines to a concrete tunnel for each unit. The tunnels terminate at seal pits located at the edge of the circulating water discharge canal, which is common to both units.

The discharge canal conveys the flow to the James River. The discharge channel within the river is provided with rock groins along each side to control sedimentation and to maintain exit velocities of the circulating water to achieve desired dilution effects of the heated effluent.

Some components of the circulating water system are used for handling service water, and are therefore designed as Seismic Category I structures and components. These components are:

1. The circulating water intake structure at the river.
2. High-level intake canal.
3. High-level intake structure.
4. Buried circulating water piping and valves between the high-level intake canal and the circulating water discharge tunnel.
5. Circulating water discharge tunnel.
6. Seal pits.
7. Intake canal low-level isolation level switches (1-CW-LS-102 & 103, 2-CW-LS-202 & 203).

10.3.4.2 **Description**

The circulating water is withdrawn from the James River through a channel dredged in the river bed. The original channel invert was 150 feet wide at Elevation -13.3 ft. It extended a distance of approximately 5000 feet to the main river channel. A natural river channel bisects the dredged channel approximately 2000 feet from the shore. This inner portion of the dredged channel is periodically monitored and dredged as necessary to support plant operations. The combination of the natural channel and the dredged channel is also used for shipping materials and equipment to the permanent dock on the east side of the site.

The circulating water intake structure is located at the shore end of the river intake channel and is an eight-bay reinforced-concrete structure. The exposed deck of the structure is at Elevation +12 ft. The invert of the intake structure is at -25.25 feet. Each bay houses one of the eight circulating water pumps for the two units. These pumps are rated 220,000 gpm at 28 feet total dynamic head when running at 220 rpm. Each pump is driven by a vertical, solid-shaft, 2000-hp, induction motor. The pumps are of the nonpullout type and are serviced using mobile hoisting equipment. Before entering the pumps, river water passes through a trash rack and travelling screen at the mouth of each bay. The travelling screens are provided with deflector flaps and screenwash pumps for low-pressure water spray. The deflector flaps ensure that fish dumped from the screens are deflected into a trough for transport via an effluent flume back to the James River. The low pressure spray ensures more efficient washing of fish from the screens into the fish collector trough. The trash rack is serviced by a movable trash rack rake that discharges collected trash to a receptacle where it accumulates until trucked off-site for disposal. In the event of a power failure, accumulated trash can be removed by manual raking. This process could continue indefinitely; however, it is expected that any power failure at the station low-level intake would be of relatively short duration.

Each circulating water pump discharge line is a 96-inch diameter steel pipe that conveys the water over the embankment of and into the high-level intake canal. At the crest of the canal embankment, the crown of the pipe is provided with a pair of active vacuum breakers (valves) and a tap for the vacuum priming system. The vacuum priming system prevents air accumulation in the pump discharge line while the pump is operating. This system is isolated when the circulating water pumps are de-energized. The active vacuum breakers open when the circulating water pump is de-energized. These vacuum breakers prevent loss of water from the high-level intake canal by siphoning through idle pumps. A passive vacuum breaker, designed to conserve intake canal water in the event of a failure of the paired active vacuum breaker valves, is located on the discharge end of each 96-inch diameter pipe. The passive vacuum breaker consists of a 20-inch diameter low profile vertical pipe protection which extends to Elevation +25 ft. of the intake canal. The passive vacuum breakers are designed to interrupt the postulated siphon action prior to reaching the technical specification limitation for canal water level.

The high-level intake canal is about 1.7 miles long and is designed to convey the circulating water flow to the station. The canal is paved with 4.5 inches of reinforced concrete, to allow velocities that would otherwise erode the earthen materials through which the canal is constructed. Since these earthen materials have low permeabilities, significant loss of water through the canal lining and into the substrata is not considered probable. The bottom width along most of the length of the canal is 32 feet, and the canal has side slopes of 1.5 feet horizontal to 1 foot vertical. The invert elevation varies from Elevation +5 ft. at the station end of the canal to Elevation +6.8 ft. at the river end of the canal. The berm along each bank of the canal is at Elevation +36 ft.

The water levels in the canal are controlled by the piping system friction losses within the power station and the prevailing river level. The normal water elevation at the power station end of the canal will vary between Elevation +26 ft. and Elevation +30 ft., depending upon the tide. A minimum freeboard greater than four feet is maintained between the canal water surface and the berm at Elevation +36 ft. during hurricane flooding of the river. This freeboard is adequate to contain surges in the canal that could occur with a loss of station power when the river is in flood and is maintained by progressively reducing the number of pumps in operation by manual control as the James River rises above Elevation +5 ft.

A reinforced-concrete, high-level intake structure is provided in the high-level intake canal at each power station unit. Each structure contains four bays, and each bay contains a trash rack, a traveling screen, and an inlet to a 96-inch-diameter condenser intake line. Steel plates can be placed on the stop log supports to permit dewatering of individual bays of the structure. Screenwash water is supplied by two pumps, each rated at 850 gpm at a 220-feet TDH.

Level sensors (1-CW-LE-102 & 103, 2-CW-LE-202 & 203) are installed in four of the screenwell bays (B & D for Unit 1 and A & C for Unit 2) between the trash rack bars and the travelling screens. Each sensor is positioned at Elevation 23-ft. 6-in. and will initiate a low level isolation channel assigned to two independent trains of 3-out-of-4 actuation logic when the canal level decreases to or below that elevation.

The four 96-inch diameter lines connecting the condenser and the high level intake structure are reinforced concrete in the station yard and welded steel encased in concrete under the station. Service water system taps are made in the steel portion of these lines.

Electric motor-operated butterfly valves are provided at the condenser inlets and outlets. The discharge lines terminate at the reinforced-concrete discharge tunnel, which then carries the water to the common circulating water discharge canal. This tunnel is 12 ft. 6 in. by 12 ft. 6 in. in cross section. The circulating water system total energy gradient in the discharge system is maintained at proper elevation to ensure a full condenser discharge water box by a seal weir at the termination of the discharge tunnel.

On each unit’s discharge tunnel, upstream of the vacuum priming house, is a 12-inch manually operated butterfly valve which is no longer used and has been abandoned in place.

The discharge canal is excavated in earth and is designed to carry the flow of the two units with a velocity of about 2.2 fps at mean low water. The invert of the canal is at Elevation -17.5 ft. and the sides slope at 2 feet horizontal to 1 foot vertical; this slope is stable under the design basis earthquake condition. The bottom width of the canal varies between 20 feet and 65 feet.

The discharge canal extends about 1200 feet into the James River. This extension has rock-filled groins along each side to minimize siltation. The opening between the groins is sized to ensure proper mixing of the discharge water with the James River. A timber pile trestle having five 10-foot-wide bays in which timber gates may be placed extends about half-way across the opening in the groin. The timber gates may be installed in this structure using mobile hoisting equipment to reduce the net area of the opening between groins and increase terminal flow velocity if determined necessary. Since terminal flow velocity is no longer considered a necessary parameter for thermal effluent control and is not required in the existing VPDES permit, the timber gate feature has effectively been abandoned in place.

10.3.4.3 **Performance Analysis**

All four circulating water pumps for each unit should normally be in service. If a circulating water pump is out of service, unit operation can be continued, but the station operator must maintain a satisfactory water level in the high-level intake canal by throttling the condenser outlet valves.

The condenser inlet and outlet valves are normally controlled from the control room. When a consequence-limiting safeguard-initiation occurs and there is a loss of station power, both inlet and outlet valves receive automatic close signals so that if one fails to close, the other will close. The valves are closed to conserve water in the high-level intake canal for cooling the recirculation spray heat exchangers. When a loss of power occurs without a consequence-limiting safeguard initiation signal, the condenser outlet valves are throttled to conserve water in the intake canal for the bearing cooling heat exchangers and component cooling heat exchangers, and to provide a minimum flow required by the steam dump system. If the water level in the high-level intake canal drops to Elevation 23-ft. 6-in., both the condenser inlet and outlet valves are closed to conserve water in the high-level intake canal for subsequent use. Two air-operated vacuum breaker valves are mounted on each condenser outlet waterbox at the highest point in the circulating water system. These valves are designed to interrupt the siphon action of circulating water flowing through the condenser and conserve intake canal water during a postulated Appendix ‘R’ event which prevents closure of the condenser inlet and outlet valves. As mentioned in Section 10.3.4.1, certain components of the circulating water system are designed as Seismic Category I structures to preclude system failure during an earthquake, and are also designed to withstand a tornado in order to ensure a supply of service water in the event of an accident. The traveling water screens have been sized to prevent trash from plugging critical heat exchangers in the service water system.

Automatic operation of the condenser inlet and outlet valves and the valves in the service water system under various accident or event conditions are listed in Table 9.9-1.

A single-ended rupture of one of the 96-inch diameter main circulating water system lines upstream of the condenser isolation valve will not lead to unacceptable consequences. Within the turbine and service building, the postulated break could only occur at Elevation 5 ft. 6 in. in the valve pit in front of the condensers. In this area, the 96-inch diameter steel pipes are exposed above the concrete encasement for a height of approximately 28 inches. A 96-inch-diameter motor-operated isolation valve and an expansion joint connect this section of the pipe directly to the condenser. The pipelines in question have been analyzed to ensure that failure will not occur as a result of a design-basis earthquake.

The circulating water pipe enters the turbine building through a concrete pipe chase. As it nears the main condenser it makes a 90-degree turn upward and exits the concrete pipe chase adjacent to the main condenser. After the motor-operated isolation valve and expansion joint, the pipe immediately takes a 90-degree turn to the main condenser water box. A break in the circulating water pipe that would permit the equivalent flow of a complete single-ended rupture into the turbine building is not credible. The pipe chase confines the movement of the pipe below the valve, the valve permits stopping flow if the break is after the valve, and the short run of exposed pipe after leaving the pipe chase prohibits side movement of the pipe to clear the break and permit full unrestricted flow.

Because of these restraints on the movement of the circulating water piping, it is not considered likely that a crack will develop in the approximate 28-inch section of exposed pipe. In the unlikely event that a crack as wide as 1/8 inch developed around as much as one half of the circumference of the pipe, the flow through the crack would be approximately 2000 gpm, which would not exceed the capacity of the turbine building floor drain sump pumps. There are three floor drain sumps for both units, each equipped with three pumps rated at 1300-gpm, for an individual sump rated capacity of 3900 gpm.

Stop logs at the inlet end of the intake structure are employed to seal off the circulating water lines upstream from the isolation valves. Long-term cooling water canal integrity provided by installing these stop logs ensures a continued ability to remove decay heat.

There are separate takeoffs from two of the four circulating water lines to supply service water to the equipment needed during an emergency.

Isolation of one of the circulating water lines containing these connections would not result in interruption of emergency service water supply.

Two 300-gpm submersible makeup water pumps for the Gravel Neck Facility have been installed in the intake canal. The supports for these pumps have been designed so that the pumps cannot take suction below the minimum canal level in Technical Specifications. This ensures that design basis calculations for canal level drawdown following a loss of offsite power, are not affected by makeup pump operation. Since these makeup pumps are only rated at 300 gpm, they have an insignificant impact on total circulating water flow during normal station operation.

Automatic operation of the condenser and service water motor-operated valves, as described in Table 9.9-1, are checked during initial operation and at frequent intervals thereafter.

Intake canal level instrumentation calibration and alarm setpoints are checked periodically. The level sensor channels and logic trains are calibrated and tested in accordance with the Technical Specifications.

10.3.5 Condensate and Feedwater Systems

The condensate and feedwater systems are shown on Figures 10.3-8 and 10.3-9 and Reference Drawings 5 and 6, and the heat balance used for station design is shown on Figures 10.2-1 through 10.2-4 and Reference Drawing 10. A review of the effects of the power uprate to a core power of 2589.3 MWt was conducted and the following systems were found to be adequate: condensate system, feedwater system, feedwater heaters, moisture separator and high pressure heater drain system, low pressure heater drain system and the extraction steam system.

10.3.5.1 **Design Basis**

The condenser hotwell is designed to operate at a normal level such that about 4 minutes of condensate flow is available to supply the condensate pumps. A 300,000-gallon condensate storage tank floats on the system. Each of the three vertical barrel-type condensate pumps is rated at 9000 gpm and 1070 feet TDH. Minimum flow through the pumps and gland steam condenser is maintained by an orifice-measuring device downstream of the gland steam condenser. The orifice-measuring device operates the recirculation valve.

Two steam generator feedwater pumps, each rated at 13,800 gpm and 1700 feet TDH, are furnished to supply feedwater to the three steam generators. Each feedwater pump is equipped with two electric motor drivers in tandem. Minimum flow through each pump is maintained by flow nozzles in the discharge lines. The recirculation valve opens when the flow drops to 4300 gpm.

A turbine-driven auxiliary feedwater pump, rated at 700 gpm and 2730 feet TDH, and two motor-driven auxiliary feedwater pumps, rated at 350 gpm and 2730 feet TDH, receive suction from a separate 110,000-gallon-capacity emergency condensate storage tank. The feedwater pumps are located outside the containment in a tornado-missile-protected enclosure near the main steam line and feedwater line containment penetration. The emergency condensate storage tank is also tornado missile protected, as is the suction piping leading from the storage tank to the pumps. The system design is based on the following conditions:

1. Integrated residual heat release from a full-power equilibrium core.
2. Feedwater inventory of the steam generators operating at normal minimum feedwater level.
3. Minimum allowable steam generator feedwater level permitted to prevent thermal shock or other damage.
4. The temperature of the feedwater that is supplied from the condensate storage tank. This temperature was assumed as 32°F when considering thermal shock, and 120°F when considering feedwater enthalpy.

The auxiliary feedwater system has been designed, constructed, and maintained to withstand a design-basis earthquake, utilizing methods and acceptance criteria consistent with those applicable to other safety-grade systems in the plant. All areas of the auxiliary feedwater system (i.e., pumps/motors, piping, valves/actuators, power supplies, water sources, instrumentation and control systems, and structures having and supporting the auxiliary feedwater system) are seismically qualified to the design-basis earthquake level.

The pump discharge piping of the auxiliary feedwater systems installed in Units 1 and 2 is cross-connected to ensure that, in the event of a postulated high energy line break in the Main

Steam Valve House or a fire that disables the auxiliary feedwater pumps, the unaffected system will have the ability of maintaining both units in a shutdown condition. The cross-connect line originates downstream of each unit's auxiliary feed pump discharge valve on the auxiliary feed system two main branch lines. Motor-operated valves are installed on each of the two cross-connect branches to provide remote control. A manual valve upstream of the motor-operated valves provides manual control of that specific branch of the cross-connected feed system.

The pumps, drives, piping, and 110,000-gallon emergency condensate storage tank have all been designed as Seismic Category I components (Section 15.2.1).

10.3.5.2 **Description**

The condensate and feedwater systems are shown on Figures 10.3-8 and 10.3-9 and Reference Drawings 5 and 6. Condensate is withdrawn from the condenser hotwells by two of the three half-size motor-driven condensate pumps. The pumps discharge into a common 24-inch header and then through a 24-inch manually operated gate isolation valve to the condensate polishing building. There the water is purified and sent back through another 24-inch manually operated gate isolation valve to the condensate header. From there the condensate continues through two parallel steam jet ejector condensers and through one gland steam condenser. A 24-inch motor-operated gate valve allows for bypassing the gate isolation valves when the system is not in use. The common header divides into two 18-inch lines that carry condensate through a pair of heater drain coolers and the tube side of two parallel trains of five low-pressure feedwater heaters to the suction of two half-size steam generator feedwater pumps. The steam generator feedwater pumps discharge through two parallel No. 1 feedwater heaters to an 18-inch discharge header for distribution to the steam generators through three individual feedwater flow control valves, positioned by the three-element feedwater control system for each steam generator. A remotely operated small bypass valve is provided in parallel with each of the feedwater flow control valves for manual control of feedwater flow to maintain steam generator levels, primarily during low-power operation or hot shutdown. Each bypass line has the capability to provide flow rate indication when aligned to the branch connection downstream of its associated feedwater flow venturi (see Figure 10.3-9). An ultrasonic flow meter is installed in each of the feed water lines of the steam generator feedwater system. The ultrasonic flow meter system measures feedwater flow, feedwater temperature, and UFM localized feedwater pressure information for input into the secondary calorimetric calculation (see Figure 10.3-9).

Drains from the moisture-separators, reheaters, and the No. 1 and No. 2 feedwater heaters are collected in the high-pressure heater drain tank and pumped into the suction of the steam generator feedwater pumps by one of two full-size high-pressure feedwater heater drain pumps.

The principal controls of the condensate and feedwater systems are located in the control room. The system is arranged for automatic or manual control.

Impure condensate in the condenser hotwells is either routed to a condensate polishing system, where it is purified and reused, or is discharged under administrative control through a double-valve connection to the circulating water discharge canal. The double-valved connection with telltale drain prevents inadvertent releases. Planned releases of hotwell condensate to the discharge canal are infrequent, since they are needed only when there has been a major upset in condensate-feedwater chemistry. The condensate is manually sampled to determine if activity levels will permit a safe release. Blowdown line sampling and monitoring is conducted during such releases to ensure that an increase in condensate activity is detected in sufficient time to permit operator action to avoid an uncontrolled release of radionuclides to the environment. Additional indication is provided by radiation monitors installed at the seal pit of the circulating water discharge tunnel.

Two condensate storage tanks, one per unit, are provided for makeup and can be cross connected if necessary. The amount of makeup is controlled by low hotwell level. A recirculation control to the hotwell returns condensate at low generator loads and provides the minimum amount of water for the air ejector condensers and the gland steam condenser. In an emergency, backup water for fire protection can be obtained from the condensate storage tanks.

A condensate cleanup line allows cleaning of the condensate piping and components prior to unit start-up. The condensate pumps can be used to recirculate condensate through the entire condensate system up to the suction of the main feed pumps, through the cleanup line, and back to the condenser hotwell. The condensate is cleaned by filtration through the condensate polishing system demineralizers.

A mixed-bed full-flow condensate polishing system removes dissolved salts and suspended solids from the condensate system. Design and operating information are given in Table 10.3-2.

Each unit's condensate polishing system consists of an independent set of condensate demineralizers supplied from the main condensate header downstream of the condensate pumps. Each set consists of seven demineralizers (six on-line, one spare) with each demineralizer containing mixed resins of cation resin and anion resin. As condensate passes through the resin, impurities are removed by interaction with the resin beads or by the filtration action of the overall resin bed. Each demineralizer discharge then passes through a resin trap, which prevents resin from entering the condensate stream, to an effluent header for return to the condensate system. At the inlet to each trap, an instrumentation penetration supplies a sample source to individual conductivity cells and to local sample valves. A sample is taken before a demineralizer is allowed to supply the condensate stream.

Demineralizer resin is transferred to an external regeneration system for separation and chemical regeneration. Each unit has an independent regeneration system consisting of a separator, separator feed tank, cation regeneration tank, an anion regeneration tank, and a resin mix tank. Air for resin transfer operations is supplied at 40 psig and 100 psig from the service air header of the instrument and service air system. Interlocks are provided to prevent inadvertent operations of influent and effluent valves during resin transfer operations.

Following regeneration, the anion and cation resin is transferred to a resin mix tank in preparation for its eventual return to the condensate demineralizers. Wastes generated by the regeneration process are treated and discharged by the waste neutralization system. Waste is discharged to the settling pond or to the discharge tunnel, and is discharged via waste filters if radiation is present. The waste filters may be bypassed if the total suspended solids have been analyzed to be less than the limits provided in the VPDES permit. Demineralizer and waste systems are remotely controlled from control panels in the condensate polishing building, which is located at the east end of the Unit 2 turbine building.

Condensate polishing system instrumentation is provided to monitor level, pressure, temperature, and flow parameters. This information allows for manual or automatic operation of the system. The instrumentation is tested in accordance with station requirements for existing Category II instrumentation.

Fire protection measures associated with the condensate polishing building are described in Chapter 9. Normal and emergency lighting is provided in the condensate polishing building.

Chemical feed equipment (Figure 10.3-10 and Reference Drawing 7) is provided for chemical treatment of feedwater based on the AVT concept. Hydrazine is added to control residual oxygen content. Ammonium hydroxide, morpholine, ethanolamine, or cyclo-hexylamine can be added to maintain an elevated pH. These chemicals act as corrosion inhibitors to reduce pickup of metal by the feedwater. Solutions are pumped into the main condensate and steam generator recirculation and transfer systems by motor-driven, positive-displacement pumps with manually adjustable strokes. If AFW is used to supply the steam generators during startup of the Unit, Carbohydrazide as well as Hydrazine may be used to control residual oxygen. In this situation, temporary chemical feed equipment may be used to treat the main steam condenser hotwell and inject Hydrazine into the suction of the AFW pumps.

An air in-leakage subsystem is provided to allow accurate establishment and monitoring of air bleed rates into the Condensate (CN) System. It has been determined that having dissolved oxygen (DO) in the CN system facilitates the formation of a passive corrosion layer on wetted secondary piping surfaces. This passive corrosion layer inhibits pipe-wall thinning and iron transport to the steam generators. This is accomplished by allowing air to be vacuum bled into Main CN Pump suction piping through flow controlling/measuring equipment.

An auxiliary steam turbine-driven feedwater pump supplies feedwater to the steam generators during a complete loss of station power. During periods of start-up, and for core residual heat removal, two auxiliary feedwater pumps, driven by electric motors connected to the station emergency busses, can be used.

Each of the three pumps discharges into two headers, aligned by manual valves. There are three lines from each header. Each line has a motor-operated valve with a downstream stop-check valve located inside containment. The lines join downstream of the stop-check valves and form a common discharge to supply each steam generator via the associated main feed line. Check valves in the main feedwater lines prevent loss of auxiliary feedwater should a main feedwater line rupture outside containment. The common discharge line to each steam generator has a cavitating venturi installed to restrict flow to the steam generator in the event of a ruptured steam line. A strainer is also installed upstream of each cavitating venturi to prevent blockage of the venturi throat by debris. In the event of failure of one header, the supplies from the pumps may be isolated by manually operated valves to ensure steam generator water flow from the other header. The motor-operated valves required to establish a flow path from the discharge of these pumps to the steam generators are configured such that AFW Flow path to one of the steam generators shall be limited with the plant between 350 degrees F/450 psig and Hot Shutdown (HSD). Under this configuration, two AFW MOVs (same steam generator) will be procedurally controlled with their Auto-open circuit defeated via operator controlled selector switches between 350 degrees F/450 psig and 535 degrees F and will be procedurally opened prior to Hot Shutdown. This alignment ensures that the turbine driven and motor driven pumps are not damaged by an unanalyzed high flow and potentially inadequate Net Positive Suction Head available (NPSHa) margin condition when a single AFW pump was delivering flow to three low pressure steam generators. The discharge valves fail as-is. Steam generator level is controlled manually from either the control room or the auxiliary shutdown panel by operating the appropriate motor-operated valve in the auxiliary feedwater line. During startup of the Unit using AFW, the AFW MOVs may remain in the partially throttled position up to and including Hot Zero Power (HZP). The throttling is controlled by procedure. Two (2) of the AFW MOVs have been modified to include 1-hour fire rated control cable between the Motor Control Center, Transfer Relay Cabinet, and Main Control Room. This as well as procedure controls ensures at least one MOV is maintained open for safe shutdown during an Appendix R Fire event.

The steam for the steam-driven auxiliary feedwater pump is supplied from the three main steam lines upstream of the main steam trip valves. Check valves in the steam supply lines prevent steam from flowing into a ruptured main steam line so that an adequate supply of steam will reach the turbine for the steam-driven pump. This steam enters the turbine-driven pump through two parallel air operated valves. These parallel air operated valves are controlled by double acting piston actuators that normally hold the valves closed. On a loss-of-power to the air supply solenoid, the pneumatic double acting piston actuator fails the valves open. A bottled nitrogen system is installed to provide control of the air operated valves for a minimum of 2 hours independent of instrument air.

The auxiliary feedwater system discharge lines of both units are cross connected but are isolated by normally closed motor-operated valves. Operator action will permit the auxiliary feedwater system of one unit to supply water to the steam generators of the other unit. These motor-operated valves are remote manual valves and require operator action to open. They are powered from an emergency bus and are controlled manually from the control room. Check valves are installed in each of the two cross-connect branch lines to the respective auxiliary feedwater header inside each containment to maintain the redundancy of these headers.

Each pump is provided with a full flow recirculation line to facilitate pump periodic testing. The return flow path to the emergency condensate storage tank is normally isolated by two valves in series, with valve position controlled by the plant operating procedures. The full flow recirculation may also be used during unit startup if AFW is used to feed the steam generators.

Permanent BDB piping connections exist on the AFW pump discharge headers. These normally isolated piping connections allow for a portable pump to inject water into the SGs during a beyond design basis event. A permanent BDB piping connection also exists on the suction line from the ECST to the TDAFW pump. This normally isolated piping connection allows for a portable pump to either refill the ECST or utilize the ECST as a suction source, based on the configuration of the pump, during a beyond design basis external event (BDBEE).

10.3.5.3 **Performance Analysis**

The auxiliary feedwater system, as described below, is the portion of the condensate and feedwater systems required for certain accident scenarios. A review of the effects of the power uprate to a core power of 2589.3 MWt was conducted and the auxiliary feedwater system was found to be adequate.

The auxiliary feedwater system is designed as a safety-related system except for the initiating signals of the reactor coolant buses undervoltage feature, the main feedwater pump breaker trip feature, the loss of reserve station power feature, and the AMSAC feature. The initiating circuitry incorporates both automatic and manual system start capability, including manual initiation of the system from the control room. Manual initiation capability is provided independent of automatic initiation, and the design of the automatic safety-related initiation circuitry is such that a single failure cannot result in total loss of the system function. The design of the safety-related portions of the auxiliary feedwater systems incorporates testability, and the system is powered from reliable emergency buses as specified in NUREG-0578, including automatic actuation of ac motor-driven pumps and valve loads onto the emergency buses. Although the MOVs feeding the Steam Generators are powered from the emergency buses, the automatic actuation feature for these valves for one Steam Generator is able to be defeated thru operator controlled selector switches. The position and automatic actuation features of these MOVs are procedurally controlled to ensure proper AFW system operation.

The auxiliary feedwater system consists principally of a turbine-driven auxiliary feedwater pump rated for 700 gpm, two motor-driven auxiliary feedwater pumps rated for 350 gpm, a 110,000-gallon storage tank, and associated piping, valves, and controls. The turbine-driven pump and the electrically-driven pumps represent two diverse pumping systems that operate automatically to supply auxiliary feedwater to the steam generator.

The turbine-driven auxiliary feedwater pump can be used for residual heat dissipation as long as adequate main steam is available. The steam supply lines to the turbine are continuously under main steam pressure to keep them warm and to prevent the formation of water droplets on turbine start-up. Steam traps are provided in lines to ensure that any condensate formed as a result of cooling is removed; however, the turbine is a single-inlet, single-stage unit, and any drops of water forming will not damage or impair its operation.

When main steam pressure is no longer adequate to provide sufficient cooldown, the need for residual heat removal has also been reduced to a level where one of the motor-driven auxiliary feedwater pumps can be used as necessary. The motor-driven pumps are powered from the 4160V emergency buses.

A reduction in the capability of the secondary system to remove the heat generated in the reactor core occurs if a loss of normal feedwater flow (LONF) condition exists. Section 14.2.11, Loss of Normal Feedwater, contains an evaluation of this event for cases with and without the reactor coolant pumps operating and a conservative core residual heat generation. If this event occurs, a reactor trip signal is generated due to a low-low steam generator level. To prevent water relief from the pressurizer and to ensure long-term decay heat removal subsequent to the reactor trip, adequate auxiliary feedwater flow is required. This is provided by use of either the turbine-driven or motor driven auxiliary feedwater pumps. The required amount of auxiliary feedwater depends on the status of the reactor coolant pumps and the core residual heat generation. With the reactor coolant pumps operating, more heat is added to the reactor coolant system which requires slightly more auxiliary feedwater for heat removal. The decay heat in current LONF analyses is based on 100% of the ANS 1979 Decay Heat Standard with 2-sigma uncertainty. Both types of auxiliary feedwater pumps are designed to start within 1 minute, even if a loss of offsite ac power occurs simultaneously with a loss of normal feedwater flow. These pumps ensure that there is adequate capacity to cool down the reactor.

Each unit's auxiliary feedwater pumps take suction from a tornado and missile protected 110,000-gallon emergency condensate storage tank (ECST), which is maintained above 96,000 gallons during unit operation. Each ECST (1/2-CN-TK-1) has redundant level indicators that provide for safety-grade indication, and alarming functions associated with tank level. The transmitters are seismically qualified, and are powered from a safety-related Class 1E vital bus. These components are not subject to harsh environmental conditions. Control room indication is provided with alarms set at or above the minimum Technical Specification limit of 96,000 gallons for tank level and also at a lower level to indicate when there is a 20-minute water supply remaining for the highest volume auxiliary feedwater pump.

Operation of the auxiliary feedwater pumps provides residual heat removal capability for up to 8 hours using the ECST. Each unit also has a non-safety-related emergency condensate makeup subsystem, consisting of a 100,000-gallon in-ground emergency condensate makeup tank (1/2-CN-TK-3) with auxiliary feedwater booster pumps, which can supply additional feedwater for additional heat removal capability. In addition, for Appendix R and environmental qualification considerations, both unit's auxiliary feedwater pumps are cross-connected at the pump discharge. Each unit's ECST is maintained above 60,000 gallons to support cross-tie capability for the opposite unit. An emergency source for necessary feedwater is the fire protection system. The three auxiliary feedwater pumps with redundant means of motive power and associated piping are installed in a tornado-protected area adjacent to the containment so that their use can be relied upon during any loss-of-station power accident.

The automatic initiation signals and circuits for the auxiliary feedwater system comply with the single-failure criterion of IEEE Standard 279-1971, with exceptions. The following signals are used for automatic initiation of the auxiliary feedwater system:

1. Turbine-driven auxiliary feed pump
    a. Low-low steam generator level (two out of three)
    b. Undervoltage on the reactor coolant pump buses (two out of three)
    c. AMSAC initiation
2. Motor-driven auxiliary feed pumps
    a. Low-low level from any one steam generator
    b. Loss of reserve station power (station blackout)
    c. Trip of both main feedwater pumps
    d. Safety injection
    e. AMSAC initiation

The steam generator level signals and the input signals from the safety injection system are both redundant and independent. Undervoltage on the reactor coolant pump buses, main feed pump breaker trip, and loss of reserve station power are considered operational signals for economic (non-public safety) protection and are therefore not required to meet the single failure criterion of IEEE Standard 279-1971.

The AMSAC signal is provided as a means, diverse from the reactor protection system, to automatically initiate the auxiliary feedwater system. This back-up signal was provided in accordance with the requirements of 10 CFR 50.62. The AMSAC logic circuit power supplies are normally powered from non-safety related sources independent of the RPS and are capable of operating on a loss of offsite power. They can be powered from EDG #1 (Unit 1) and EDG #2 (Unit 2) by manual action. (Section 7.2.3.2.7)

The motor-driven auxiliary feedwater pumps are part of the emergency diesel generator sequencing scheme. This feature functions on a loss of offsite power concurrent with or subsequent to a safety injection. The EDG load sequencing scheme will trip the motor-driven auxiliary pumps, if running, and delay the motor-driven auxiliary feedwater pump restart for 10 seconds on SI or 140 seconds on hi-hi CLS (Section 8.5).

The operating bypasses associated with the automatic initiation logic circuitry (including sensors used for automatic initiation) during start-up or operation of the reactor are as follows:

1. The steam generator low-low level initiation circuitry is always active and can be bypassed by placing a particular channel in the test position. This action is restricted by the Technical Specifications. Since these channels are always active, a bypass removal mechanism is not needed.
2. Safety injection initiation circuitry is provided with a bypass for start-up purposes and is separately alarmed in the control room. This bypass (block) is automatically unblocked and requires no operator action.
3. During start-up, the circuit breakers for the motors of at least one main feed pump are closed in the test position to allow the motor-driven auxiliary feedwater pumps to be placed in the automatic mode when required by Technical Specifications. The breakers are procedurally taken out of the test position when the second main feed pump is placed in operation.
4. The auxiliary feedwater pumps may be prevented from starting by placing the pump controls in the PULL-TO-LOCK position. The auxiliary feedwater control is procedurally returned to the AUTO position prior to exceeding RCS temperature and pressure limits of 350°F and 450 psig.
5. Reactor coolant system loop isolation valves provide a signal, when closed, that prevents automatic start of auxiliary feedwater pumps from a steam generator low-low water level signal in the affected loop. This signal is automatically reinstated upon reopening of the valves. In the event this block is initiated, a permissive status light is lit in the control room to alert the operator of the condition. This is, however, not considered an operating bypass, since the plant operation is restricted to three-loop operation and at no time would it be operated with a loop isolated.
6. The reactor coolant pump undervoltage channels that sense the voltage on the station service buses A, B, and C are not provided with bypass capability during start-up or operation.

   No bypass capability is provided for the station blackout signal, which senses the voltage on the station transfer buses.

The automatic safety-related initiation circuitry for the auxiliary feedwater pumps originates in the engineered safeguards and reactor protection systems, which are designed in accordance with IEEE 279-1971. Portions of the automatic initiation circuitry, from the reactor coolant buses, main feedwater breakers trip, the loss of reserve station power, and the AMSAC initiation circuitry are not required to completely comply with IEEE 279-1971 because these initiation circuits are needed only as a backup or non-safety-related safeguards feature. Manual capability to initiate auxiliary feedwater operation from the control room has also been retained.

Safety-related initiating signals and circuits are powered from emergency buses, with testability an integral feature of the design.

The auxiliary feedwater motor-driven pumps can be locked out by placing pump control in the “pull-to-lock” position. This action prevents automatic initiation of the pump and, therefore, the auxiliary feedwater motor-driven pump overload trip annunciator actuates when the pump control switch is in the “pull-to-lock” position. In addition, a white status light for each auxiliary feedwater pump control switch indicates that its associated breaker is racked into the “connect” position and the breaker has closing control power available.

Safety-grade auxiliary feedwater flow instrumentation is provided in the control room. The instrumentation is powered from the emergency buses and meets regulatory requirements for diversity. Auxiliary feedwater flow to each of the three steam generators is indicated in the control room. Steam generator level instruments back up the flow instruments to satisfy the single-failure criterion. Each steam generator has three narrow-range and one wide-range level instrument loops, which read out in the control room and are energized from vital instrument buses. The auxiliary feedwater flow indication is testable from the transmitter back to the indicator. The total accuracy of the auxiliary feed flow loop is ±4% or better of span for normal operating conditions.

In response to NUREG-0737, it has been confirmed that the ECST has sufficient capacity to provide 700 gpm of auxiliary feedwater flow from the turbine-driven auxiliary feedwater pump for at least 2 hours independent of any AC power source. Auxiliary feedwater pump lube oil cooling is also independent of AC power because the lube oil coolers are cooled by a flow path from the pump discharge back to the pump suction. Emergency dc lighting provides sufficient lighting to manually control the turbine-driven auxiliary feedwater pump and discharge valves. Sound-powered phone communication capability is available in the vicinity of the auxiliary feedwater pumps and discharge valves.

Two parallel, pneumatic valves enable automatic control of the steam supply to the turbine-driven auxiliary feedwater pump, independent of any AC power. Each pressure control valve (PCV) is controlled by a DC-powered solenoid valve. A nitrogen tank with a regulator and a check valve has been added to the instrument air supply line to provide control of the PCVs for a period of 2 hours. The tank and check valve are necessary because the normal instrument air supply would not be available upon loss of all ac power.

Cavitating venturis (flow restrictors) have been installed in the 3-inch auxiliary feedwater lines leading to each steam generator. They are designed to limit the runout flow to approximately 350 gpm for the loop which has been affected by a main steam line break (MSLB) or main feedwater line break (MFLB). Correspondingly, this will permit the minimum required flow to be delivered to the unaffected steam generators.

The venturi design is based on the loss of the turbine driven AFW pump and the availability of two electric driven AFW pumps. Under the design conditions, the minimum required total flow of 350 gpm to the intact loops is met for core residual heat removal requirements.

Procedures are provided to assist the operators in manually starting the auxiliary feedwater system and controlling feed flow to the steam generators under a variety of operating conditions. Since the Surry Power Station has the capability of cross-connecting the two units' auxiliary feedwater systems, procedural guidance is provided on how to utilize the other unit's auxiliary feedwater system, if necessary.

Operability requirements for the auxiliary feedwater system and associated instrumentation are prescribed by the Technical Specifications.

The feedwater piping at the Surry Power Station incorporates several design features to reduce the likelihood of secondary-system fluid flow instability, i.e., water hammer:

1. Loop seals at the feedwater inlets to the steam generators are provided to reduce the length of piping that could be filled with steam if the steam generator feedring were to drain into the steam generator.
2. Top discharge feedwater spargers (J-tubes) reduce the likelihood of feedring drainage. The flow conditions to which the J-tubes are subjected are not severe, and J-tube stiffness is very high. The design has been evaluated for the expected service conditions and the integrity of the attachment weld will be maintained for the expected plant lifetime.
3. A full penetration weld between the steam generator feedwater inlet nozzle and the feedring prevents leakage from the feedring when steam generator water level is below the feedring.
4. The steam generator feedrings are offset approximately 2.5 inches in elevation above the center line of the feed nozzle to further delay draining of the feedwater piping.

During normal operation, the water level in the steam generator is maintained above the feedring and therefore steam cannot enter the feedring to react with cold feedwater. However, in the event of a transient that results in uncovering the feedring, the design features of the feedring and feedwater piping as discussed above will maintain the feedring full of water while flow to the steam generator is interrupted. Therefore, these design features preclude draining of the feedring and reduce the possibility of water hammer in the feedwater system.

10.3.5.4 **Tests and Inspections**

The auxiliary steam generator feedwater pumps and drives are tested in accordance with the Technical Specifications by admitting steam to the turbine drive or energizing the motor drivers. During these tests, verification of flow from the emergency condensate storage tank to the steam generators from each of the auxiliary feedwater pumps verifies proper alignment of the required auxiliary feedwater flowpaths. Periodic testing is staggered to test the motor-driven and steam-driven auxiliary feedwater pumps at different times to reduce the potential for inadvertently leaving closed the discharge valves of all pumps after a test. While a periodic test is being performed, the affected AFW pump is declared inoperable and the applicable Technical Specification limiting condition for operation is placed in effect.

10.3.6 Condenser

Two single-pass, divided water-box condensers are provided. Each condenses steam from one of the two low-pressure turbine exhausts, and steam from the turbine steam bypass valves, as described in Section 10.3.1.

10.3.6.1 **Design Basis**

The design parameters for each condenser are listed in Table 10.3-3.

10.3.6.2 **Description**

The condensers are of conventional design, manufactured by Ecolaire-Rand Company, and have a neoprene-lined rubber belt-type expansion joint in the neck. They also have steam and condensate crossover ducts to equalize pressure, and impingement baffles to protect the tubes. The tubes are made of titanium, which provides relative immunity from tube-end erosion/corrosion and reduces circulating water inleakage. The waterboxes have a 3/16-inch neoprene lining to provide protection and reduce maintenance. The tubesheet material is aluminum-bronze-D, ASTM B171, Alloy 614. In the event that excessive galvanic corrosion is experienced at the tube/tubesheet interface, an epoxy coating can be added to help minimize any corrosive effect of the electrochemical potential between the tubes and tubesheets. The material is a nonaging, nonshrinking, non-hygroscopic, nontoxic, non-water solution that will withstand corrosion, galvanic action, and cavitation. Internal tube support plates are spaced 24 inches apart. One No. 5 feedwater heater and one No. 6 feedwater heater are located in each condenser neck.

The condenser hotwell is of the deaerating type capable of reducing the oxygen content to less than 0.005 cm^3/liter. The deaerating capability is necessary, as there is no deaerating feedwater heater in the feedwater cycle. Hotwell division plates segregate the condensate from each tube bundle, with sample connections provided for each region. Samples are pumped to the turbine building for analysis.

Two twin-element, two-stage, steam jet air ejector units, each complete with tubed inter-condenser and after-condenser, are provided for removing noncondensable gases from the condenser shells. For normal air removal, one element of each ejector unit is operated per condenser shell. The ejectors function by using auxiliary steam and discharge to the atmosphere. A radiation monitor is installed in the common discharge line from the two air ejectors as described in Section 10.3.8. For initial condenser shell-side air removal, a noncondensing priming ejector is provided for each shell. These ejectors function by using steam from the auxiliary steam system (Section 10.3.2).

10.3.6.3 **Performance Analysis**

Loss of normal ac power causes the four 96-inch condenser outlet valves to partially close. This closure permits the minimum flow of circulating water to continue through the condenser for the main steam bypass system, and conserves water in the intake canal for the recirculation spray coolers.

10.3.6.4 Tests and Inspections

Circulating water and those service water isolation valves, which are required to close to conserve intake canal inventory following a design basis accident, are periodically verified that the total leakage flow from these sources are limited to less than the leakage assumptions of the canal inventory analysis.

10.3.7 Lubricating Oil System

A pressure lubricating oil system is provided to perform the following functions:

1. Store lubricating oil.
2. Supply oil to and receive oil from the turbine-generator oil reservoir.
3. Purify a side stream of oil from the turbine-generator oil reservoir on a continuous-bypass basis.
4. Clean and reclaim used oil from the storage tanks, pumping it from the used-oil storage tank via the purifier to the clean-oil storage tank.

10.3.7.1 Design Basis

The lubricating oil system consists of a 21,000-gallon reservoir, two 22,000-gallon horizontal all-welded steel storage tanks, an oil purifier, and two identical motor-driven transfer pumps. The two gear-type positive displacement transfer pumps are each capable of two-sided operation at 108 and 48 gpm to accomplish the various batch cleaning, transfer, and circulating operations. The variable speed oil conditioner pump for each unit is rated up to 100 gpm.

10.3.7.2 Description

A turbine shaft-driven oil pump normally supplies all lubricating oil requirements to the turbine-generator unit. An ac motor-driven turning gear oil pump is installed for supplying lubricating oil during start-up, shutdown, and standby conditions. An emergency dc motor-driven oil pump, operated from the black battery, is also available to ensure lubricating oil to the bearings.

Cooling water from the bearing cooling water system (Section 10.3.9) is used for the turbine lube-oil coolers. The two 22,000-gallon storage tanks are normally designated “clean” and “used,” but are interchangeable and are located inside a fireproof room equipped with water sprays and vent fans. The transfer pumps and piping are arranged so that oil can be processed from the oil reservoir or either of the two storage tanks. The processed oil can be returned to either of the other two. A vapor extractor purges oil fumes from the reservoir and exhaust to the atmosphere outside of the turbine building. Piping and valves in the system are of welded steel, and high-pressure bearing oil piping is enclosed in a guard pipe.

10.3.7.3 **Performance Analysis**

The dc motor-driven oil pump is designed to function during a loss of station power to supply lubricating oil to the turbine-generator bearings. The black battery provides an uninterrupted source of power to this pump.

10.3.7.4 **Tests and Inspections**

The dc bearing oil pump is tested periodically.

10.3.8 Secondary Vent and Drain Systems

Because the steam and power conversion system is normally nonradioactive, vents and drains are arranged in much the same manner as those in a fossil-fueled power station. However, because air ejector vents and steam generator blowdown can possibly become contaminated and because they discharge to the environment, they are monitored and discharge under controlled conditions as described in Chapter 11.

The air ejector vent subsystem is shown in Reference Drawing 2. The steam generator blowdown system is shown in Reference Drawing 8.

10.3.8.1 **Design Basis**

Each of the condenser steam jet air ejectors (two per shell) is designed to remove 12.5 cfm of free air. Each ejector normally uses about 800 lb/hr of steam at a 140 to 200 psig from the auxiliary steam header, while using 900 gpm of condensate for cooling. Separate hogging or vacuum priming jets are used to reduce condenser vacuum to 1 to 3 inches Hg absolute during start-up.

10.3.8.2 **Description**

Generally, secondary plant piping drains to the condenser.

Vent gases removed from the condensers by the air ejectors are normally discharged through a radiation monitor (Section 11.3) to the atmosphere. If a steam generator tube ruptures, with subsequent contamination of the steam, the radioactive noncondensable gases would be detected by the radiation monitor located in the air ejector effluent line. The related accident analysis is covered in Section 14.3.1. When the radioactivity level reaches the alarm setpoint of the monitor, trip valves in the air ejector effluent line will automatically actuate to divert the effluent flow to the containment and shut off the vent to atmosphere. Other vents from the turbine generator that handle carbon dioxide, hydrogen, oil vapor, and other nonradioactive gases are discharged directly to the atmosphere outside the turbine building.

As discussed above, the condenser air ejector discharge line is a potentially radioactive release point and is therefore required to have high-range radiation monitoring per the requirements of NUREG-0578, Section 2.1.8.b. For this reason, two manual isolation valves have been installed and the air ejector discharge lines have been rerouted to have connections upstream of ventilation vent no. 2 high-range effluent monitor for use during accident conditions. If a condition were to exist such that a radiation monitor (low range) alarms and the containment is under a phase I isolation mode, the air ejector isolation valves would shut and secure all flow from the air ejector vent. However, this modification provides a method for maintaining condenser vacuum, if necessary, by allowing the operator to manually establish condenser-air ejector flow through the new discharge line and the high-range vent stack monitor, as well as the low-range effluent monitor. Both of the manual isolation valves are under administrative control. The high-range effluent monitor isolation valve is normally shut and the low-range effluent monitor manual isolation valve is open.

10.3.8.3 **Performance Analysis**

Loss of power or air causes both diversion valves in the air ejector line to fail closed, thus preventing possible radioactive contaminants in the condenser steam space from reaching the atmosphere. In addition, the air-operated shut-off valves in the steam supply lines to the air ejectors will also go closed on a loss of power or air.

Radiation monitoring and alarm initiation are unaffected by loss of power, but a signal from the containment isolation system (Section 5.2) causes the trip valves on the outside of the containment wall to close.

10.3.8.4 **Tests and Inspections**

The vent and drain systems are in continual use and require no special testing and inspection. However, the trip valves installed in these systems, which are part of the containment isolation system, are tested in accordance with Section 5.2.

10.3.9 Bearing Cooling Water System

The bearing cooling water system supplies cooling water to the steam and power conversion system equipment and is a closed cycle system using pumped condensate quality water as cooling water. The heat removed by the cooling water is transferred to service water in the bearing cooling heat exchangers, as described in Section 9.9. A review of the effects of the power uprate to a core power of 2589.3 MWt was conducted and the bearing cooling water system was found to be adequate.

The bearing cooling water system is shown schematically in Figure 10.3-11 and Reference Drawing 9.

10.3.9.1 **Design Basis**

The turbine plant equipment is designed for full load operation with cooling water supplied at a maximum temperature of 105°F. The bearing cooling water heat exchangers consist of three half-size units capable of maintaining the cooling water supply temperature below 105°F at all river water temperatures.

The principal equipment served by the bearing cooling water is listed in Table 10.3-4.

The full-size 13,000-gpm motor-driven pumps circulate the cooling water through the above equipment and the bearing cooling heat exchangers.

10.3.9.2 **Description**

The cooling water flowing through the major equipment coolers, such as the hydrogen and oil coolers, is controlled manually to maintain constant temperature of the cooled fluid.

A head tank is provided to maintain a positive pressure at all points on the system. Makeup to this tank is normally from the water supply and treatment system header; however, when this system is not in operation, makeup is provided from the condensate system (Section 10.3.5).

The bearing cooling water system is chemically treated to inhibit corrosion.

10.3.9.3 **Performance Analysis**

The bearing cooling water system supplies cooling water to steam and power conversion system equipment, for heat removal. The bearing cooling water system is non-safety-related and is not relied upon for accident mitigation or safe-shutdown of the nuclear plant.

CHAPTER 11 RADIOACTIVE WASTES AND RADIATION PROTECTION

11.1 GENERAL DESCRIPTION

Note: As required by the Subsequent Renewed Operating Licenses for Surry Units 1 and 2, issued May 4, 2021, various systems, structures, and components discussed within this chapter are subject to aging management. The programs and activities necessary to manage the aging of these systems, structures, and components are discussed in Chapter 18.

Waste disposal systems are provided to separate, treat, and dispose of radioactive liquid, gaseous, and solid waste materials. The liquid, solid, and gaseous waste disposal systems are common to both reactor units and designed to serve both units simultaneously. These systems incorporate one or more of the following basic processes:

1. Filtration, to remove particulate matter.
2. Evaporation, to concentrate and remove contaminants.
3. Demineralization, to remove dissolved material.
4. Compaction, to reduce the volume of compressible wastes.
5. Natural decay of radioactive isotopes.
6. Dilution, to reduce concentration.

Liquid, gaseous, and solid waste materials originate in the reactor coolant system, the auxiliary and emergency systems, the waste disposal system, and as a result of operation and maintenance procedures. Waste materials enter the waste disposal system directly from their source or via the vent and drain system (Section 9.7).

Adequate sampling, analysis, and monitoring of the waste disposal system are provided to comply with the design criteria. Process radiation monitors and flow-measuring equipment are provided for the surveillance of various station and radwaste effluents and process streams to ensure compliance with applicable regulations and to provide early indications of possible malfunctions and hazardous conditions.

Sufficient shielding is provided to reduce radiation to acceptable levels for normal operation and incident conditions. Allowable dose rates are based on applicable regulations, expected frequency, and the duration of exposure to radiation.

Area radiation monitoring equipment, health physics facilities, environmental programs, and administrative controls are provided for the surveillance and control of radiation exposure levels. These ensure radiation protection for plant personnel and the general public in accordance with applicable criteria.

Radiological and chemical respiratory protection equipment approved by the National Institute for Occupational Safety and Health/Mine Safety and Health Administration (NIOSH/MSHA) is provided. Equipment not tested and certified by NIOSH/MSHA requires specific authorization by the NRC and an approved exemption from 10 CFR 20.1703(a)(1), 10 CFR 20.1703(c), and certain parts of 10 CFR Part 20, Appendix A, Protection Factors for Respirators, Footnote d.2.(d) before use. Authorization has been received and appropriate exemption granted for the use of MSA Model Firehawk M7 SCBA, ultralite respirator, and 4500 psi tank charged with 35% oxygen and 65% nitrogen. All units are to be equipped with rubber face-pieces. Regulator use is not to be initiated at temperatures >135°F. Units may be used in areas where temperatures exceed 135°F if regulator use is initiated prior to entry into those areas. Breathing gas quality and composition, including hydrocarbon exclusion, are insured by strict controls and maintained in accordance with the latest revision of the United Stated Pharacopeia (USP) - The National Formulary (NF).

Prior to Unit 1 operation, a radiological study of the environs was performed (Section 11.3.5). It included an investigation of the background radiology relating to various forms of the aquatic and terrestrial environment. The nature and extent of the postoperational environmental survey were determined from the results of the preoperational study.

11.2 RADIOACTIVE WASTE SYSTEMS

11.2.1 Design Bases

It is Vepco's waste management policy to maintain radioactive waste effluent from the Surry Power Station at the lowest practical level. In keeping with this policy, the Radioactive waste disposal system is designed, to the extent possible in accordance with maintenance practices, to maintain releases of radioactive material and radiation exposures to unrestricted areas as far below the limits of 10 CFR 20[1] as is practical. Normally, no radioactive waste stream will be discharged from the station without having first been processed through the waste disposal system.

The liquid, solid, and gaseous waste disposal systems are common to both reactor units. Each waste disposal system is designed to accommodate radioactive wastes produced during simultaneous operation of the two units. Both units are assumed to be operating on a daily load follow cycle using boric acid between 100% and 50% power.

The systems are also designed to accommodate the corrosion products originating in the reactor coolant system, and not removed in other systems.

11.2.2 System Design

The waste disposal system and radiation monitoring system are designed to satisfy the applicable sections of the general design criteria of Section 1.4. In addition, these systems are designed to limit the discharge of radioactive materials from the station so as not to exceed the limits of 10 CFR 20 or the suggested criteria of 10 CFR 100, and so as not to endanger the health of station operating personnel. The transportation of radioactive materials from the station is carried out in such a manner as to conform with applicable Federal, state, and local ordinances. Design data are given in Table 11.2-1. An evaluation of the waste disposal systems in accordance with the requirements of 10 CFR 50, Appendix I, is provided in Appendix 11A.

The liquid waste disposal system is described in detail in Section 11.2.3. This system has been designed to ensure that the release of radioactivity to the environment will be kept at the lowest practical level.

All normally radioactive waste gases from the gaseous waste disposal system, the gas stripper in the boron recovery system, the vent and drain system, various pressure relief valves, and the containment vacuum system are regulated before discharge by the process vent subsystem, as described in Section 11.2.5.1. All these sources of gaseous effluent are, before discharge collected; diluted; filtered through charcoal filters; monitored for flow rate, pressure, temperature, and particulates and gaseous activity; and then released through the process vents.

---

1. Virginia Power implemented the revised 10 CFR 20 on January 1, 1994. However, as allowed by the NRC, the calculational methodology used for the design analyses is based on the revision of 10 CFR 20 to which the plant was originally licensed.

Gas stripped from liquids entering the boron recovery system is stored in decay tanks as discussed in Section 11.2.5. The process vents and the process vent blowers are sized such that the minimum exit velocity is approximately 100 fps, which prevents any significant downdrafting of the effluent.

Radioactive waste gases may also be present in the Radwaste Facility (RF) ventilation system. Minor amounts of noble gases may be entrained in the liquid waste being processed by the RF. If evaporation of the liquid waste is the process method used, these gases will be released to the RF ventilation system. The RF ventilation system is designed to process and monitor these gases and any other airborne activity produced in the facility process areas. All tanks and process equipment vents which have radioactive contents are connected to the tank vent system. This system has a demister, a charcoal filter, and high-efficiency particulate air (HEPA) filter bank. The general area ventilation for the radiological controlled areas passes through a HEPA filter bank prior to discharge. Both the general area and the tank vent ventilation systems discharge through the RF vent stack and are continuously monitored. The exit velocity of the RF vent stack is in excess of 3200 fpm.

Other gaseous effluents will normally not be radioactive during operation; however, ventilation exhaust from some primary plant areas is subject to comparatively slight radioactive contamination from such limited sources as pump gland or pipe weepage. Features are incorporated in these exhaust systems to protect the environment from these relatively remote contamination possibilities. Three filter banks (two common and one stand alone) are capable of handling the largest possible exhaust ventilation flow rate that can be aligned through the individual filter bank(s). Each filter bank consists of roughing, HEPA, and charcoal filters. Exhaust bypass arrangements for selective filtration of any exhaust add to the flexibility of the system. All bypass and filter dampers are remote manually operated from the control room as required. Ventilation exhaust trains for the safeguards areas and charging pump cubicles automatically realign on a safety injection signal as discussed in Section 9.13.4.1.

The process vent, ventilation vents, and the RF vent are continuously monitored so that the effluent activity release rates result in concentrations considerably less than those limits provided by 10 CFR 20 at the site boundary. The gaseous waste disposal system is designed to provide adequate radioactive decay storage time for the waste gases prior to discharge through the process vent and, in addition, provides sufficient capacity to allow adequate holdup of these gases even when high-flow letdown is required.

The estimated releases from the gaseous waste disposal system are based on assumptions, discussed in Section 11.2.5, regarding the operation of the system. These assumptions were developed during the original plant design in order to generate estimates of gaseous effluent releases. These estimates were used to demonstrate compliance with effluent release regulations as part of the original licensing basis. Adherence to the gaseous waste effluent requirements is monitored by procedures in accordance with the Offsite Dose Calculation Manual (ODCM). Monitoring gaseous effluents in accordance with the ODCM ensures that the composite results of the variations in gaseous waste inputs and processing on the actual releases are within the accepted current licensing basis for the gaseous waste disposal system as specified in the acceptance criteria of the ODCM.

An analysis of the estimated curies of each radionuclide released from the station gaseous waste disposal system via the waste gas decay tanks has been made to demonstrate that 10 CFR 20 will be met. This analysis is presented in Section 11.2.5, and, as can be seen from Tables 11.2-2 and 11.2-3, the yearly dose at the site boundary with the recombiner operating is about 0.007 rem and is about 0.019 rem without the recombiner. These values are 1.4% and 3.8% (with and without the recombiner, respectively) of the unrestricted area dose of 0.5 rem specified in the revision of 10 CFR 20 to which the plant was originally licensed.

11.2.3 Liquid Waste Disposal System

The liquid waste disposal system for Units 1 and 2 is shared, except for the primary drain transfer tanks and the gaseous drain system in each containment. Two systems currently exist for treating liquid wastes. These are the boron recovery system and the liquid waste disposal system. The boron recovery system, which is described in detail in Section 9.2, treats effluents collected in the primary drain tank from the vents and drains system, as well as letdown from the primary coolant that is diverted from the chemical and volume control system (CVCS). The liquid waste disposal system treats the liquid wastes originating from containment, auxiliary building, fuel building, safeguards, radwaste facility and decontamination building sumps, and from laboratory drains. Steam generator blowdown may be transferred via the component cooling heat exchanger pit sump to the liquid waste disposal system as discussed in Section 11.2.3.2.2. Liquid waste originating from the containment, auxiliary building, fuel building, safeguards, component cooling water heat exchanger, and decontamination sumps and from the laboratory drains are collected in either the low-level waste drain tank or the high-level waste drain tank depending on the valve lineup in the primary vent and drain system. Liquid wastes are normally transferred to one of the two 30,000-gallon RF liquid waste collection tanks for processing through the RF evaporator system or are processed in the RF liquid waste reverse osmosis and demineralizer system. Liquid waste originating in the radwaste facility itself is collected in sumps and pumped directly to the RF liquid waste collection tanks or through filters to the laundry drain monitor tanks. An additional 60,000 gallons of transfer/storage capacity is available via the RF liquid waste surge tanks. The RF evaporator system is available for use during high liquid waste generation periods or as a backup to the RF liquid waste reverse osmosis and demineralizer system. Processed liquid waste is sent to the liquid waste monitor tanks. An inclined plate suspended solids/oil separator is in-line for either the evaporation or reverse osmosis and demineralization process options.

Laundry waste and personnel decontamination showers and sink wastes are collected in the contaminated waste drain tanks. These tanks are pumped to the RF for processing. Some large particulate liquid wastes originating in the radwaste facility are collected in the sumps and pumped to the laundry waste system for processing. Waste is processed with a laundry pre-filter and the laundry waste filter, then collected in the laundry drains monitor tank. Processed laundry waste and RF waste can be sampled and released or mixed with other station liquid waste.

Liquid and laundry wastes discharged to the circulating water system via the RF are monitored. The liquid effluent radiation monitor is an on-line monitor with automatic isolation of the effluent discharge when a high radiation alarm is received.

The Steam Generator Storage Facility sump is periodically pumped out and processed via the Laundry Drain System if contaminated.

Table 11.2-4 presents information regarding the originally licensed Surry liquid waste treatment system. This information provides parameters used as input into the calculation of radiation exposure to the public presented in Appendix 11A. With respect to the present Radwaste Facility, the information in Table 11.2-4 is conservative when compared to the RF radwaste volumes, DFs, and hold-up capacity. Therefore, the original evaluation of radiation exposure to the public presented in Appendix 11A bounds the design of the RF. Reference Drawings 1 through 3 and Figures 11.2-1, 11.2-2, 11.2-3, and 11.2-4 depict the liquid and laundry waste systems in the RF and their tie-ins to the station collection points.

11.2.3.1 **Components**

11.2.3.1.1 High-Level Waste Drain Tanks

Two high-level waste drain tanks are provided. Each tank has a usable capacity of approximately 2000 gallons. Level indicators are provided. These are stainless steel tanks designed according to Section III.C of the ASME Boiler and Pressure Vessel Code.

11.2.3.1.2 Low-Level Waste Drain Tanks

Two low-level waste drain tanks are provided. Each tank has a usable capacity of approximately 1785 gallons. Level indicators are provided. These are stainless steel tanks designed according to Section III.C of the ASME Code.

11.2.3.1.3 Contaminated Drain Tanks

Two contaminated drain tanks are provided. Each tank has a usable capacity of approximately 1045 gallons. Level indications are provided. These are stainless steel tanks designed to Section VIII of the ASME Boiler and Pressure Vessel Code.

11.2.3.1.4 Waste Disposal Evaporator and Auxiliaries (Installed But No Longer Used)

One forced-circulation evaporator with a feed capacity of 6 gpm is provided. The evaporator shell is fabricated from a high-nickel alloy in accordance with Section III.C of the ASME Code. Internals are fabricated from an austenitic stainless steel not susceptible to stress cracking.

The external heat source is a shell and tube steam reboiler fabricated on the tube side from a high-nickel alloy and on the shell side from carbon steel. Distillate is condensed in a water-cooled shell and tube condenser fabricated from austenitic stainless steel. The reboiler, shell, and tube condenser are all fabricated in accordance with Section III.C of the ASME Code, and TEMA Standards. (The external heat source steam lines have been cut and capped to preclude steam and/or water leakage.)

The condensed distillate is held in the distillate accumulator. This tank is fabricated from austenitic stainless steel in accordance with Section III.C of the ASME Code.

A distillate cooler is provided to further cool the distillate. The tube side of the distillate cooler is fabricated from austenitic stainless steel and the shell side from carbon steel, in accordance with Section III.C of the ASME Code.

11.2.3.1.5 Waste Disposal Evaporator Test Tanks (Installed but no longer used)

Two waste disposal evaporator test tanks, each of 3000-gallon capacity, with level indicators, are provided. These tanks are stainless steel and designed according to Section VIII of the ASME Code.

11.2.3.1.6 Pumps

Centrifugal frame-mounted pumps with single or double mechanical seals are provided. The waste disposal evaporator bottoms pump is a canned pump. One pump is provided for each tank with cross ties where appropriate, such as on high-level waste drain tank pumps. External cooling and seal water is supplied to radioactive pump seals as required.

11.2.3.1.7 RF Liquid Waste Evaporator System

The evaporator system consists of a 30-gpm forced circulation evaporator system. The evaporator is designed to concentrate waste up to a boron concentration of 24,500 ±5% ppm or the total solids concentration of 25 weight percent.

Normal feed to the evaporator is from a liquid waste transfer pump after the SPI oil/SS remover. Clean liquid effluent from the evaporator is transferred to the evaporator distillate demineralizer for further processing prior to transfer to the liquid waste monitoring tanks. The evaporator concentrates are forwarded to the bitumen solidification system for volume reduction, solidification, and packaging, or stored for later shipment in liquid form.

The evaporator is a forced circulation system utilizing a mechanical vapor recompression (MVR) system. The MVR evaporator operates on a heat pump principle. The process vapors are compressed to a higher pressure so they will condense at a higher temperature. The hot compressed vapors condense in the heater. The liberated heat causes boiling in the evaporator vapor body. Desuperheating water is added to the vapors to recover the superheat as sensible heat.

The liquor entering the vapor body flash boils to release heat in the form of water vapor. As the water is driven from the system in to vapor phase, the liquor contained in the vapor body is further concentrated. When the boron concentration reaches 24,500 ±5% ppm or the total solid concentration of 25 weight percent, a portion is removed by gravity to the Evaporator Bottoms Tank. The amount of concentrates removed is replaced by an increase in the feed rate, thus the solids concentration in the evaporator is decreased again.

The vapor leaving the vapor body passes through an entrainment separator. In the separator, the vapor flows upward through percolated trays and mesh pads. These remove droplets entrained in the vapor to protect the compressor wheel from erosion and to insure clean condensate.

The vapor from the separator is compressed by a high speed centrifugal compressor. The compressed vapors exit the compressor with a large amount of superheat, which is desuperheated to bring the vapor temperature close to saturation temperature and recover the superheat as sensible heat.

The vapor from the compressor is condensed on the shell side of the heater. The distillate flows by gravity to the distillate flash tank, where it is first flashed to the entrainment separator to recover heat. Then it is pumped through a distillate subcooler to the distillate demineralizer.

Concentrated waste from the evaporator is periodically discharged to the evaporator bottoms tank. The bottoms tank vent is connected to the tank vent system after passing through a vent cooler.

The major components of this subsystem are the vapor body, the heater, the recirculation pump, the entrainment separator, the vent gas cooler, a motor driven vapor compressor, a bottoms tank and bottoms tank pump. Design information on these components are given in Table 11.2-1.

11.2.3.1.8 RF Liquid Waste Reverse Osmosis and Demineralizer System

The RF liquid waste reverse osmosis (RO) and demineralizer system is designed to remove radioactivity and dissolved solids from the liquid waste process prior to collection in the liquid waste monitor tanks where liquids are sampled and discharged or reused. The RF liquid waste reverse osmosis and demineralizer system is normally in service to process liquid waste streams.

The RF liquid waste reverse osmosis and demineralizer system is designed to remove total suspended solids to < 25 ppm, and oil and grease to < 15 ppm prior to entering the liquid waste monitor tanks.

The system consists of demineralizer vessels and a Thermex RO unit. The RO concentrates are recirculated while the permeate is directed to the liquid waste monitoring tanks. The content of the process feed tank is directed to a collection tank when concentrate limits have been met.

The demineralizer vessels are designed and constructed per ASME VIII. The reverse osmosis skid was designed per ANSI B31.1.

11.2.3.1.9 Postaccident Radiation Waste Connection

The capability for processing highly radioactive postaccident liquid waste has been incorporated into the liquid waste disposal system. A flanged connection (Reference Drawing 1) is located in the vicinity of the boron recovery tanks for the purpose of discharging radioactive liquids to an external process system without requiring personnel to enter high radiation areas. The external process system would be brought onsite, if needed, following an accident. The postaccident radiation waste connection also has an isolation valve that can be operated by reach rod to further minimize personnel exposure.

11.2.3.1.10 RF Laundry Waste System

The RF laundry waste system receives waste from the contaminated drain tanks and from the RF building drain system sump pumps via a cross-connect line. The RF laundry systems consist of laundry drain prefilters and the main laundry drain filter.

The two laundry drain prefilters are installed in parallel with one operational to remove large solid matter such as cotton fibers to extend the service cycle of the downstream laundry drain filter. The filters are designed to operate at 50 gpm. The filtration media element is a bag type constructed of artificial fiber cloth. The filter media will be periodically removed manually and transferred to the dry activated waste (DAW) area for drying and volume reduction at the Radwaste Facility or packaged for offsite processing. The filter housing is constructed of 304 stainless steel.

The laundry drain filter is designed to remove particulate matter from the incoming laundry drain stream. The filter is designed to operate at a rate of 50 gpm. It is designed to remove suspended solids with a filtration media of polyethylene fiber balls. The expended filter media will be removed manually and transferred to the DAW compaction area for drying and volume reduction at the Radwaste Facility or packaged for offsite processing.

The filter vessel is designed and constructed in accordance with ASME VIII. The principal material of construction is 304 stainless steel.

Laundry waste and RF building drain system waste processed by this system is sent to the laundry waste monitor tanks for sampling prior to monitored discharge.

11.2.3.1.11 RF Monitor Tanks

The RF liquid waste evaporator, reverse osmosis, and/or demineralization process systems send their processed waste to one of two liquid waste monitor tanks. These tanks are 15,000 gallons, vertical tanks. Each tank has level indication and recirculation capability. They are constructed of 304 stainless steel and have an atmospheric pressure design. The tanks are designed and constructed to ASME Section III.

Laundry waste processed through the RF is sent to one of two laundry waste monitor tanks. These tanks are 7500 gallons, vertical tanks. Each tank has level indication and recirculation capability. They are constructed of 304 stainless steel and have an atmospheric design. The tanks are designed and constructed to ASME Section III.

11.2.3.2 Processing Steam Generator Blowdown

The steam generator blowdown system is described in Section 10.3.1.2. A review of the effects of the power uprate to a core power of 2546 MWt was conducted and the steam generator blowdown system was found to be adequate.

A steam generator blowdown treatment system, located in the Condensate Polisher Building, was utilized to remove impurities from the blowdown stream. The system contained prefilters, demineralizers, and postfilters. The blowdown treatment system was designed to be used during normal operation and following steam generator tube leakage. Subsequently, the system was determined to be incompatible with changes made in secondary water chemistry. As a result, the blowdown treatment system is no longer used for blowdown treatment and blowdown is untreated, except as described below.

11.2.3.2.1 Normal Operation

During startup and power operations, blowdown is either released to the discharge canal or returned to the condenser hotwell as described in Section 10.3.1.2. During outages, the steam generators may be gravity drained through the blowdown lines to a waste neutralization sump located in the condensate polishing building. Water in the waste neutralization sump can be treated, recirculated, sampled and discharged to either the settling pond or the circulating water discharge. During discharge, the water may be directed through a filter or the filter can be bypassed.

11.2.3.2.2 Operation Following Steam Generator Tube Leak

If a steam generator tube leak occurs and shutdown is desired, station procedures provide guidance on evaluating contamination potential and determining appropriate actions for processing blowdown. Depending on activity levels, blowdown may be directed to the condenser hotwell or may need to be processed through the Surry Radwase Facility (SRF). If it is decided to process the blowdown through the SRF, procedures direct that the inventory from the affected steam generator be transferred to the component cooling (CC) heat exchanger (HX) pit sump using blowdown hose connections. Steam generator pressure will provide the motive force for transfer from the affected steam generator to the sump, but gravity transfer is possible. The CC HX pit sump pump transfers water in the sump to the combined containment and safeguard area sump pump discharge header where it can be processed by the liquid waste disposal system (Section 11.2.3). The flow rate into the sump from the affected steam generator will be limited to less than 25 gpm so that it will not exceed the pumping capacity of the CC HX pit sump pump. The flow rate can be controlled from the main control room by use of an HCV in the blowdown line.

Controls are in place to minimize the airborne activity levels in the vicinity of the CC HX pit. Hose connections will be monitored for leakage. Water entering the sump from the blowdown lines will be cooled by the steam generator blowdown coolers to a subcooled condition to preclude flashing. Flow rates into the CC HX pit sump will be limited to below the capacity of the CC HX pit sump pump so that the water level remains in the sump and does not enter the pit. This minimizes the liquid surface area and would allow for an exhaust hood to be installed over the sump if needed to reduce airborne activity levels. Health Physics will monitor the radiation levels in the areas of the routed hose and the radiation and airborne levels around the CC HX pit.

11.2.4 Solid Waste Disposal System

The solid waste disposal system provides logging, packaging, and storage facilities for scheduled shipment off the site and ultimate disposal of radioactive waste material. Materials handled as solid waste include concentrated liquid sludge, water, spent resin, spent filter cartridges, solid noncompactible and compactible trash, and other miscellaneous materials resulting from station and RF operation and maintenance. The operation of the system is described below.

11.2.4.1 **Solid Waste Handling Operations**

11.2.4.1.1 Expended Filter-Cartridge Handling Operations

Radioactive liquid service filters are removed from the system when the pressure drop across the filters becomes excessive or when the radiation level exceeds a predetermined maximum. The filter housing is surveyed prior to any opening or removal. After this is completed, the filter cover is remotely opened and removed by personnel using appropriate tools and protected by a filter removal shield, when required. A lead cask is placed over the filter housing and the filter is then moved upward into the lead cask. A drip pan is then secured to the bottom of the cask and the entire assembly is transported to the Surry Radioactive Waste Facility (SRF). The filter is placed in an approved container. The filter and container remain in the SRF until shipment to the burial site.

Surveys are conducted on the filter when the filter housing is opened, in the shielded casks, and when the container is transported to the Radwaste Facility or removed for shipment. The transport vehicle undergoes a complete radiological survey before leaving the site.

11.2.4.1.2 Spent Resin Handling Operations

A spent resin catch tank and spent resin blend tank are provided to receive spent resin from the station’s ion exchangers located in the Auxiliary Building. A transfer pump is associated with each tank. Spent resin is transferred from the blend tank to a high-integrity container for shipment to a burial facility. A shipping container may be sent to the Radwaste Facility for staging prior to shipment offsite.

Primary plant resins are directed to the spent resin catch tank. Resins from the catch tank are slurried to the blend tank to produce a mixture of resin whose contents may be shipped in a high integrity container. As an option, resin from the spent resin catch tank can be sluiced to a mobil resin transfer vessel (MRTV) for shielded transport to the Radwaste Facility. Subsequent to the processing operations, the lines are flushed with primary grade water.

Spent low-activity resins from the condensate polishing system are typically dewatered to acceptable strong tight containers and sent offsite for disposal. If the activity in these resins becomes high enough that the disposal site would not accept them in drums, the resins would be slurried to high integrity containers (HICs) and then dewatered prior to shipment to an offsite radwaste burial site. There is also an option to transport the spent condensate polishing resins to the Radwaste Facility. From the Radwaste Facility, condensate polishing resins can be sent to the bitumen solidification system, sent to a high integrity container filling and dewatering station, or proportionately blended with other resins for the purpose of lowering the dose rate of some higher activity resins.

11.2.4.1.3 Evaporator Concentrate Operations

Solids that are concentrated in the evaporator are discharged to the evaporator bottoms tank. These concentrates are at 25% by weight solids or at 24,500 ±5% ppm boron. Additionally, sludge from the suspended solids separator is periodically pumped to the bottoms tank.

The concentrates and sludges in the bottoms tank may be pumped to the waste batch tanks through heat traced lines where the concentrate waste is pretreated for processing by the solidification system.

In order to preclude plugging of the concentrates transfer piping, redundant heat tracing circuits are installed. Clean, hot water flushing connections are included to clean each line following concentrates transfer.

11.2.4.1.4 Solidification Operations (Installed but no longer used)

The bitumen solidification system incorporates a chemical and physical process for reducing the volume of radwaste and for incorporating the radwaste into a solidified bitumen matrix. The process uses a LUWA thin-film evaporator operating at a waste product outlet temperature of approximately 320°F. This results in the evaporation of free water from waste effluents and the remaining solids are incorporated in a bitumen matrix. Solidification of the end product occurs upon the natural cooling of the binder.

The system is capable of processing waste which includes evaporator concentrates and spent bead resin. Waste to be processed is collected in one of two waste batch tanks. The waste is sampled and chemically pretreated to prepare it for processing.

The conditioned waste is fed at a controlled rate to a thin film evaporator. Molten bitumen is simultaneously fed into the evaporator through a second feed nozzle. The evaporator is heated by means of hot thermal fluid flowing through an external jacket. As the waste flows downward through the evaporator, the water is evaporated and the water vapor flows counter-currently upward and out of the evaporator. The waste solids are mixed with molten bitumen and exit the bottom of the evaporator, flowing into a waste container. Upon cooling, the waste/bitumen mixture solidifies into a freestanding, monolithic solid with free liquids less than 0.5 percent by volume of the waste form.

The water vapor leaving the thin film evaporator is condensed in a shell and tube condenser. The condensate flows into the distillate oil separator. When this tank is filled, the distillate is pumped to a liquid waste collection tank.

The bituminized waste product flows from the discharge valve of the thin film evaporator into a 55-gallon steel drum. Once filled and cooled, drums are inspected for free liquid, capped, smeared and surveyed. The drums are then transferred to the RF storage area to await shipment to a licensed disposal contractor.

Figure 11.2-5 depicts the solidification process flow.

11.2.4.1.5 Ultimate Disposal Operations

All packages containing radioactive nonfissionable material, and the procedures used to prepare these for offsite shipment, are in accordance with U. S. Department of Transportation regulations. The Radwaste Facility, Low-Level Waste Storage Facility and Sea Van Storage Pad are facilities used for the storage of radioactive material. All waste material is transferred either to a licensed disposal or processing contractor or to common carrier for delivery to a licensed disposal or processing contractor. Radwaste shipments fall under the purview of Vepco's procedures and quality assurance program.

11.2.4.2 **Components**

All components listed below except the spent resin catch tank, the spent resin blend tank, and their associated pumps are located within the Radwaste Facility.

11.2.4.2.1 Spent Resin Catch Tank
Spent Resin Blend Tank

One of each tank is provided. Each tank is installed in a separate cubicle on Elevation 6 ft. 10 in. in the Decontamination Building. The normal operating volume (high level to low level) is approximately 214 ft^3. Total usable volume is approximately 245 ft^3. Vessels are designed to ASME Section VIII.

11.2.4.2.2 Spent Resin Catch Tank Transfer Pump
Spent Resin Blend Tank Transfer Pump

One of each pump is provided. Pumps are of the progressive cavity design. Each pump is designed to deliver 27.7 gal/100 rpm at 0 psi.

11.2.4.2.3 Evaporator Bottoms Tank

The evaporator bottoms tank is a 5000-gallon, 11-foot diameter, vertical tank with a dished bottom and a flat top. The tank is constructed of Inconel 625 and is equipped with a mixing eductor and a demineralizer water flush header, level indication, and heat tracing. The heat tracing prevents concentrates from solidifying in the tank.

11.2.4.2.4 Spent Resin Collection Tanks

There are four spent resin collection tanks in the Radwaste Facility. These tanks are 1020-ft^3 capacity, vertical tanks with a 10-foot diameter. Each tank is constructed of 304 stainless steel and is designed for atmospheric pressure. Each tank is equipped with mixing lines, flush lines, decant lines and an overflow. Each of the two mixing lines is attached to internal mixing eductors.

11.2.4.2.5 Spent Resin Collection Tank Pumps

There are two spent resin collection tank pumps each of which is capable of pumping from any of the four spent resin collection tanks. Each pump is rated at 440 gpm at a total dynamic head of 86 psi. Parts of the pumps in contact with the radioactive resin/water slurry are made of stainless steel.

11.2.4.2.6 Waste Batch Tanks

There are two 1000-gallon waste batch tanks. Each tank is constructed of 316L stainless steel and is equipped with external heating elements to prevent the solidification of evaporator concentrates. Each tank has mechanical agitators for mixing.

11.2.4.2.7 Bitumen Storage Tank

The bitumen storage tank is a horizontal 6000-gallon carbon steel tank. The tank has an internal electric heater and is heavily insulated. The tank is equipped with instrumentation for tank level and temperature.

11.2.4.2.8 Bitumen Metering and Transfer

Bitumen is metered by a gear type metering pump capable of accurate control of the bitumen feed between 0.04-0.92 gpm. The piping from the storage tank to the thin film evaporator are not heat traced. Instead, transfer lines are jacketed pipes using the heating oil from the thin film evaporator heating system to maintain flow of the bitumen feed.

11.2.4.2.9 Thin Film Evaporator

The thin film evaporator is a LUWA design capable of a 52-gal/hr evaporation rate. The body of the evaporator is made of 316L stainless steel. The internal paddle assembly in the evaporator continuously spreads the feed material into a thin film along the vessel walls to assist in the evaporation. The constant action of the paddle assembly also assures adequate and uniform mixing of the waste and the bitumen binder. The paddle assembly is turned by a 15 hp electric motor.

11.2.4.2.10 Distillate Oil Separator Tank

Water vapor from the thin film evaporator is condensed and collected in the distillate oil separation tank. Due to the use of bitumen in this process, small amounts of light weight oils are volatilized during the evaporator process. These oils are separated in the distillate oil separation tank and are skimmed off for separate treatment. The condensed water in the tank sent to the liquid waste collection tanks via the distillate transfer pump.

11.2.5 Gaseous Waste Disposal System

The process vent subsystem regulates the discharge of potentially high-activity waste gases to the atmosphere. The ventilation vent subsystem described in Section 9.13 and the RF vent described in 11.2.2 regulate the discharge of potentially low-activity air streams to the atmosphere. Radioactive waste discharges from these subsystems are monitored by particulate and gas monitors that are part of the process radiation monitoring system described in Section 11.3.3. Limitations on gaseous releases, and associated reporting requirements, are included in the Technical Specifications and the Offsite Dose Calculation Manual.

Waste gases, primarily hydrogen, nitrogen, and minor amounts of fission product gases, such as xenon and krypton, are removed from reactor coolant letdown by the stripper in the boron recovery system. The stripped gases are processed in the gaseous waste disposal system.

The gaseous waste disposal system is designed to provide adequate radioactive decay storage time for the waste gases and, in addition, provide long-term holdup of these gases when high-flow letdown is required.

Gases pass from the stripper to the stripper surge tank, where they are compressed. From the surge tank, the gases are bled off to the waste gas surge drum. At a pressure of approximately 1 atm, the waste gas diaphragm compressor transfers the gases to one of two waste gas decay tanks.

When released, effluent from the waste gas decay tanks is mixed with dilution air, effluent from the containment vacuum system, and the aerated vents from the vent and drain system. The combined gaseous waste is filtered through charcoal and high-efficiency particulate air (HEPA) filters before being released to the atmosphere. The process vent blowers maintain a small vacuum in the charcoal filters to prevent outleakage from the filter assembly. The decay tank contents are sampled before any release to the process vent.

11.2.5.1 **Process Vent Subsystem**

Gaseous wastes enter the process vent subsystem from the gaseous waste disposal system, the stripper in the boron recovery system, the vent and drain system, various pressure relief valves, and the containment vacuum system, as shown in Reference Drawings 4 and 5.

A catalytic recombiner system is installed (but not used) as part of the gaseous waste disposal system. A summary description of the catalytic recombiner is provided in Section 11.2.5.3.1.

Two double-walled waste gas decay tanks are provided. Each tank is buried beneath the Waste Gas & Boron Recovery Pump House and receives tornado protection from this building within its footprint. Where the tanks extend outside the footprint of this building, tornado protection is provided by the depth of burial in soil. The inner tank is fabricated from austenitic stainless steel in accordance with Section III.C of the ASME Code, and the outer tank from carbon steel, in accordance with Section VIII of the ASME Code. Sampling connections are provided for the tank contents and for leakoff in the annular intercept space between the tanks. The decay tanks have piping connections for parallel operation with alternate feed and bleed.

Overpressure relief protection is provided at the waste gas decay tanks in accordance with Section III.C of the ASME Code. The protective devices consist of bellows-sealed pressure relief valves followed by rupture disk assemblies. The use of bellow seals and rupture disks precludes the leakage of the waste gas to the environment during normal operation of the gaseous waste disposal system. The piping downstream of the protective devices relieves to the process vent through the radiation monitor station.

Effluent from the waste gas decay tanks is mixed with dilution air, effluent from the containment vacuum system, and the aerated vents from the vent and drain system. The combined gaseous waste is filtered through charcoal filters before being released to the atmosphere. The process vent blowers maintain a small vacuum in the charcoal filters to prevent outleakage from the filter assembly. The decay tank contents are sampled before any release to the process vent.

The entire discharge stream of radioactive letdown gas and dilution air is monitored for flow rate, pressure, temperature, and particulate and gaseous activity before release through the process vents. The total flow is regulated by a flow control valve on the process vent blower. The ratio of dilution air to waste gas letdown flow is such that the mixed streams never enter the flammability region of the air-steam-hydrogen phase diagram.

The process vent and the process vent blowers are sized such that the minimum exit velocity is approximately 100 fps. This exit velocity prevents any significant downdrafting of the effluent. The process vent terminates at an elevation approximately 22 feet above the top of one of the containment structures.

The process vent monitors are set such that the effluent activity release rate results in concentrations less than those limits provided in the revision of 10 CFR 20 to which the plant was originally licensed. In the event that the activity of the effluent stream exceeds the setting of the monitors, the process vent control station automatically terminates the release of waste effluents from the waste gas decay tanks and isolates the containment vacuum system from the process vent sub system. The monitor also activates an alarm in the control room before valve closure if the activity approaches a preset value. Subsequent restart of the system is manual, in accordance with procedures. The discharge of gases from the waste gas decay tanks is initiated and controlled separately.

The gaseous waste disposal system is designed to provide adequate radioactive decay storage time for the waste gases and, in addition, to provide long-term holdup of these gases when high-flow letdown is required.

The combined volume of the two waste gas decay tanks is sized to process the gas stripped from the estimated annual average letdown flow of 17 gpm, based on simultaneous operation of two reactor units.

The average gas stripping rate is a function of the average letdown flow rate, and this flow rate is dependent on the assumed plan of operation as described in Section 9.2.

On this basis, the total annual letdown volume for two units is 8.94×10^6 gal, and the average annual letdown flow rate for two units is 17 gpm.

If the hydrogen volume is assumed to be 35 cm^3/kg and 90% of the total gas volume, then the hydrogen stripping rate at an annual average of 17-gpm letdown is 0.0792 scfm and the total gas stripping rate is 0.088 scfm.

The gas decay tanks are sized so that a 17-gpm letdown rate with the recombiner not operating gives an average holdup time equivalent to approximately 5 half-lives of Xe-133 (30 days).

Assuming 1% failed fuel, the estimated curies of each radionuclide released from the station via the gaseous waste disposal system for the original plant design are listed in Tables 11.2-2 and 11.2-3. Table 11.2-2 is for a waste gas cycle with the recombiner not operating, which is the design basis for the system, and Table 11.2-3 is for a waste gas cycle with the recombiner operating. With the recombiner not operating, the gas cycle is 30 days of feed/20 days of decay/10 days of bleed; most of the gas is hydrogen. With the recombiner operating, the feed portion of the waste gas cycle can vary between 30 days and approximately 300 days, the time needed to reach maximum design pressure in the tank. To be conservative, 300 days of feed was chosen as the basis for Table 11.2-3, and the waste gas cycle considered was 300 days of feed/20 days of decay/10 days of bleed.

In each case, it is assumed that all of the gases and 0.1% of the iodines are removed at the gas stripper and sent to the waste gas decay tanks except for hydrogen in the case with the recombiner operating. The system is operated so that one tank is on the feed portion of the cycle while the other is on the decay and bleed portion.

The equilibrium reactor coolant activity is a function of the waste gas removal rate by the gas stripper. Using the parameters listed in Table 9.1-5 and a 17-gpm letdown rate to the gas stripper, the equilibrium coolant activity for each radionuclide was calculated. These are also listed in Tables 11.2-2 and 11.2-3.

As can be seen from these tables, the yearly dose at the site boundary is about 0.019 rem for continuous operation with a 30 days of feed/20 days of decay/10 days of bleed cycle, and about 0.007 rem for the 300 days of feed/20 days of decay/10 days of bleed cycle. Both of these values are well below the member of the public dose limit of 0.5 rem/yr set forth in the revision of 10 CFR 20 to which the plant was originally licensed.

11.2.5.2 Ventilation Vent Subsystem

The ventilation vent subsystem is considered to be a portion of the gaseous waste disposal system only for purposes of radiological surveillance, and it is designed on this basis. However, since it handles air streams of very low activity levels, and since the gases to be handled are predominantly of nonradioactive origin, this subsystem has been considered as an auxiliary system for the purpose of this report. A full description of this subsystem is included in Section 9.13.

11.2.5.3 Components

The major components of the gaseous waste disposal system are described below.

11.2.5.3.1 Catalytic Recombiner (Installed But Not Usable)

One skid-mounted catalytic recombiner system is provided. The system includes duplicate full-capacity recycle compressors, duplicate full-capacity electrical preheaters, duplicate full-capacity catalytic recombiners, one aftercooler condenser, one moisture separator, one electrical reheater, duplicate hydrogen analyzers of the thermal conductivity type for the recombiner influent and effluent, duplicate oxygen analyzers of the paramagnetic type on the recombiner effluent, a single oxygen analyzer on the recombiner influent, and one bleed stream cooler. The recombiner system operates at approximately 22 psia and has a feed capacity of approximately 1.14 scfm. The diluent is nitrogen. The catalytic recombiner system is designed according to Section III.C of the ASME Code.

The recycle compressors are rotary positive blowers designed to circulate 40 cfm at 8 psig discharge pressure. They are of gas-tight construction, with three mechanical shaft seals in series between the circulating gas and the outside atmosphere. The end bell of the compressor is pressurized with nitrogen as a further precaution against outward leakage.

The preheaters are stainless steel pipes with external electrical heating elements and are used to raise the temperature of the recycle stream to 300°F before the recycle stream enters the catalyst bed.

The catalytic recombiners are all-metal, low-halogen catalysts. Each bed contains miles of crimped-nickel alloy ribbon coated with catalytically activated precious metals, mainly palladium and platinum.

The aftercooler condenser is a pipe-within-a-pipe heat exchanger, with the recycle gas flowing through the inner pipe and component cooling water flowing through the outer pipe. The aftercooler condenser condenses the water vapor by cooling the recycle gas stream and lowering the water vapor in it to a dewpoint of 75°F.

The moisture separator is a centrifugal separator with an automatic drain operated by a level controller and has high- and low-level alarms. Moisture from the moisture separator drains to a high-level waste drain tank.

The reheater is similar to the preheaters, and raises the temperature of the recycle stream to 120°F.

The hydrogen analyzers are of the thermal conductivity type; the oxygen analyzers are of the paramagnetic type.

11.2.5.3.2 Waste Gas Surge Tank

One waste gas surge tank with a 15.7 ft^3 capacity is provided. This tank is operated at a pressure of approximately 10 to 20 psia. The tank is fabricated from austenitic stainless steel in accordance with Section III.C of the ASME Code.

11.2.5.3.3 Waste Gas Compressor

Two waste gas compressors of the diaphragm type are provided. Each has a rated capacity of 1.5 scfm at a discharge pressure of 120 psig. The compressor heads are leak tested to ensure that the leakage does not exceed a predetermined amount.

11.2.5.3.4 Waste Gas Decay Tank

Two buried waste gas decay tanks are provided. These tanks have double-wall construction with feed and bleed lines; sample, nitrogen purge, drain, and relief valve lines to the inner tank; and sample, nitrogen purge, drain, and relief valve lines from the outer tank. An access opening is provided to the inner tank. In addition, adequate grounding and corrosion protection are provided. The inner tank is fabricated from stainless steel in accordance with Section III.C of the ASME Code, and the outer tank from carbon steel in accordance with Section VIII of the ASME Code.

To ensure an explosive gas mixture does not develop in the tanks, samples are taken via the oxygen analyzer. Compressors have been installed as sample pumps but are normally isolated and bypassed. The differential pressure between the waste gas decay tank and the waste gas surge drum is used to induce flow through the oxygen analyzer.

11.2.5.3.5 Process Vent Blowers

Two full-capacity dilution air blowers of 300 cfm capacity at 2 psia are provided. The blowers are of a centrifugal type, located in a field fabricated box with the blower suction from the box’s interior. Some inleakage is tolerated.

11.2.5.3.6 Charcoal Filters

Two charcoal filter beds are provided to service approximately 300-scfm radioactive gas. The filters are maintained at a subatmospheric pressure.

11.2.5.3.7 Postaccident Radiation Waste Connection

The capability for processing highly radioactive postaccident gaseous waste has been incorporated into the gaseous waste disposal system. A flanged connection (Reference Drawings 4 & 5) is located in the vicinity of the boron recovery tanks for the purpose of discharging radioactive gases to an external process system without requiring personnel to enter high radiation areas. The external process system would be brought onsite, if needed, following an accident. The postaccident radiation waste connection also has an isolation valve that can be operated by reach rod to further minimize personnel exposure.

11.2.6 Tests and Inspections

11.2.6.1 Construction and Fabrication

During the manufacturing period, Vepco's inspectors inspected all equipment periodically, as required, to ensure that all equipment had been provided in strict accordance with specifications. Shop hydrostatic and performance tests of principal equipment were witnessed by Vepco's inspectors. Certified code inspection data sheets were provided by manufacturers for all equipment covered by ASME or other applicable codes.

During the construction period, all pressure systems were subjected to field hydrostatic or pneumatic tests to verify the integrity of welded connections and to ensure that the system as a whole functioned as intended.

During the preliminary operation period, all equipment in the waste disposal system was tested to verify conformance with specification performance requirements. All control systems and interlocks were tested and operated to ensure satisfactory functional performance and reliability.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

On February 9 and 10, 1971, a performance test of the waste disposal system catalytic recombiner was conducted to demonstrate the actual catalyst performance over a range of operating conditions. Tests were rerun at three hydrogen inlet concentrations: test 1, 2.0% hydrogen; test 2, 0.5% hydrogen; and test 3, 3.2% hydrogen.

The specified test requirements at each test condition were to maintain the outlet oxygen concentration at no more than 1% and to have less than 100 ppm of hydrogen in the outlet.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

The catalyst efficiency was greater than 99.5% over the range of hydrogen flow rates and concentrations tested. The outlet hydrogen and oxygen concentrations were well within the stated limits. The tests confirmed the capability of the recombiner to operate over the range of operating conditions expected during normal operations.

11.2.6.2 **Operation**

The basic function of the waste disposal system is to release controlled amounts of radioactivity to the environment with no undue effects on the health and safety of the general public. This is accomplished by ensuring that all releases from the station are at less than the maximum levels of radioactivity set by applicable regulatory agencies, as given in Section 11.2.1.

The following is a list of the types and areas monitored to ensure the proper functioning of the waste disposal system:

1. Continuous Process Monitoring: As described in Section 11.3.3, process radiation monitors continuously monitor certain key systems where radioactive material may exist. These monitors give an indication of the waste-processing requirements of certain systems.
2. Batch Sample Process Monitoring: As described in Section 9.6, batch samples, obtained from certain subsystems, provide information on the effectiveness of ion exchangers, filters, and evaporators. This gives an indication of the effectiveness of the various waste processing subsystems. The monitoring of the gas in the waste gas holdup tanks avoids the storage of excessive activity.
3. Continuous Monitoring of Discharge Effluents: As described in Section 11.3.3, radiation monitors continuously monitor discharges from the process and ventilation vent systems and RF systems and the liquid waste disposal and service water systems. These monitors give an indication of liquid and gaseous radiation discharges to the environment and provide alarms with automatic valve closure when radiation levels exceed a preset level, thus terminating discharge.
4. Radiation Survey of Radioactive Waste/Material Containers: Radiation surveys and smear samples are taken of shipping casks, drums, etc., that contain radioactive waste/material to ensure that such waste/material is properly contained and meets transportation regulations.
5. Environmental Monitoring: As described in Section 11.3.5, environmental samples are taken to indicate the effect of liquid and gas discharges on the environment and the compliance of these discharges with applicable regulations.

To ensure that the performance of the waste disposal systems is meeting design criteria, the following checks are made:

1. Standardized laboratory radiochemical analytical procedures are used to verify decontamination factors.
2. Radiation monitors are periodically checked with remotely operated check sources. The Local Processing Units (LPUs) of the MGP Instruments (MGPI) monitors perform various self checks automatically. Their electrical self check introduces a known and fixed level of pulses into the electronics excluding the detector and verifies that the response is correct, otherwise a fault is generated. Additionally, the electronics continuously monitor the detector for a minimum countrate, otherwise a fault alarm is generated. In addition, samples are withdrawn from the process streams being monitored and analyzed to ensure compliance with regulatory limits. Those monitors that actuate control valves by a high radiation signal are periodically tested to ensure the valves activate on alarm signal.
3. Portable survey instruments and laboratory analytical instruments are periodically calibrated with known radiation sources in accordance with station health physics procedures.
4. Radiation levels on the outside of components, pumps, valves, and piping in the waste disposal systems are monitored periodically to avoid inadvertent discharge of activity that may accumulate with time.

11.2 REFERENCE DRAWINGS

The list of Station Drawings below is provided for information only. The referenced drawings are not part of the UFSAR. This is not intended to be a complete listing of all Station Drawings referenced from this section of the UFSAR. The contents of Station Drawings are controlled by station procedure.

11.3 RADIATION PROTECTION

11.3.1 Design Bases

Radiation protection, including radiation shielding, was designed to ensure that the criteria specified in 10 CFR 20[1] are met during normal operation and that the guidelines in 10 CFR 50.67 are met in the event of the design-basis loss of coolant accident (Section 14.5.5). Maximum dose limits for design-basis accident conditions are given in Table 14.5-11.

Allowable dose rates are based on the expected frequency and duration of occupancy. Occupancy time and dose rates are such that no personnel shall receive in excess of those doses recommended in 10 CFR 20. All dose rate calculations are based on 1% failed fuel elements. Allowable dose rates for typical locations are given in Table 11.3-1.

11.3.1.1 **Leak Reduction Program**

A leak reduction program has been established to minimize leakage from systems outside containment that would or could contain highly radioactive fluids during transients or accidents. The following systems, which are described in detail elsewhere in the FSAR, are at least partially located outside containment and are expected to contain potentially radioactive fluids immediately following an accident:

1. Safety injection system.
2. Containment and recirculation spray systems.
3. CVCS (those portions associated with safety injection).
4. Boron recovery system.
5. Resin waste disposal system.
6. Sampling system.
7. Containment vacuum system.
8. Containment purge system.

Several plant systems have been excluded from the leak reduction program. Their exclusion is justified because their unavailability would not eliminate any of the options for cooling the reactor core, nor would it prevent the use of any safety system. The excluded systems are the following:

1. CVCS (those portions not associated with safety injection).
2. Purification system.

---

1. Virginia Power implemented the revised 10 CFR 20 on January 1, 1994. However, as allowed by the NRC, the calculational methodology used for the design analyses is based on the revision of 10 CFR 20 to which the plant was originally licensed.

3. Gas stripper system.
4. Vent and drain systems.
5. Liquid waste disposal system.
6. Reactor cavity purification system.
7. Spent-fuel pool cooling and purification systems.

The letdown portion of the CVCS is normally used for reactor coolant system inventory control, reactor coolant pump seal injection, and reactor coolant system purification. After an accident, the safety injection system using the refueling water storage tank or containment sump would provide the necessary inventory control and seal injection functions. Coolant purification would be deferred until some time after the accident and would probably be performed using a temporary system. Since CVCS letdown will not be used after an accident, the gas stripper system and the vent and drain systems are not needed to support the associated vent. The containment sump would be used for liquid waste storage in place of the liquid waste storage system. The reactor cavity purification system is used during refueling outages. The spent-fuel pool cooling and purification system is not connected to the reactor coolant system or to containment.

A preventive maintenance program, including periodic leak tests, has been established for the systems in the leak reduction program. This program uses administrative controls and procedures as outlined by the plant quality assurance program.

11.3.2 Shielding Design and Evaluation

11.3.2.1 **Primary Shielding**

Primary shielding is provided to limit radiation emanating from the reactor vessel. The radiation consists of neutrons diffusing from the core, prompt fission gammas, fission product gammas, and gammas resulting from the slowing down and capture of neutrons.

The primary shielding is designed to:

1. Attenuate neutron flux to prevent excessive activation of unit components and structures.
2. Reduce the contribution of radiation from the reactor to obtain a reasonable division of the shielding function between primary and secondary shields.
3. Reduce residual radiation from the core to a level that does not limit access to the region between the primary and secondary shields at a reasonable time after shutdown.
4. Postaccident shielding considerations are discussed in Section 11.3.2.9.

The primary shield consists of a water-filled neutron shield tank with a radial dimension of approximately 3 feet, surrounded by 4.5 feet of reinforced concrete. The neutron shield tank is designed to prevent overheating and dehydration of the concrete primary shield wall and to prevent activation of the plant components within the reactor containment. A thermosiphon cooling system is provided for cooling the water in the shield tank.

A 2-inch-thick cylindrical lead shield that is approximately 15-foot-high is located beneath the neutron shield tank to protect station personnel servicing the neutron detectors during reactor shutdown.

A 3-1/2-inch thick stainless steel radiation shield is provided at the 12-inch diameter incore sump room drain to protect station personnel during normal power operation and refueling outage. The drain is designed to convey the held up water, in excess of the invert elevation of the Incore Sump Room drain, from the Incore Sump Room to the containment sump strainer. This additional water facilitates submergence of the containment sump strainer for RS and LHSI pumps for post-LOCA operation.

lncore instrumentation guide tube shielding is provided in the form of a vertical wall and horizontal table installed in the lncore Sump Room. Each shield consists of 1-1/2-inches of lead wrapped in coated carbon steel. The shielding protects personnel during refueling outages.

To maintain the integrity of the primary shield, streaming shields fabricated from both masonite Benelex 70 and steel are provided in the annular gap between reactor vessel flange and the primary shield concrete. In addition, masonite Benelex 401 and steel streaming shields located outside the primary concrete shield are provided around all of the reactor coolant pipe penetrations.

The primary shield arrangement is shown in Figures 11.3-1 and 11.3-2. The shield materials and thicknesses are listed in Table 11.3-2.

11.3.2.2 Secondary Shielding

Secondary shielding consists of reactor coolant loop shielding, reactor containment shielding, fuel handling shielding, auxiliary equipment shielding, and waste storage shielding.

Nitrogen-16 is the major source of radioactivity in the reactor coolant during normal operation and establishes the combined thickness of the crane and containment walls. Activated corrosion and fission products in the reactor coolant system establish the shutdown radiation levels in the reactor coolant loop areas. Tables 9.1-4 and 11.3-3 list the activities that were used in designing the containment secondary shielding. Table 9.1-4 lists the fission product activities in the reactor coolant system with 1% failed fuel. Table 11.3-3 lists the activated corrosion product activities and the N-16 activity at the reactor vessel outlet nozzle.

Activated corrosion and fission products from the reactor coolant system are the radioactive sources for which shielding is required in the auxiliary and waste disposal systems.

Auxiliary steam used for space heating and other purposes throughout the station may become contaminated due to primary-to-secondary leakage. The estimated dose rate at the surface of a 6-inch, 15-psig auxiliary steam supply header is 2×10^{-6} mrem/hr. The estimated dose rate at 3 feet is 1.25×10^{-7} mrem/hr. The dose rate estimates are based on 1% failed fuel activities (Table 9.1-4), 25% steam flow, 1000 cm^3/hr total steam generator leakage, and zero decay time. All noble gases and 1% of the halogens are assumed to leak into the steam generator. Based on these assumptions, the dose received by an individual in the vicinity of the auxiliary steam piping is insignificant.

11.3.2.3 **Reactor Coolant Loop Shielding**

Interior shield walls separate reactor coolant loop, pressurizer, incore instrumentation, and containment access sectors. This shielding allows access to the incore instrument sector during normal operation and facilitates maintenance in all sectors during shutdown. The crane support wall provides limited access protection in the annulus between the crane wall and the reactor containment wall and provides part of the exterior shielding required during power operation. Shield walls are provided around each steam generator above the charging floor to a height required for personnel protection. The shielding arrangement is shown in Figures 11.3-1 and 11.3-2. The shield materials and thicknesses are listed in Table 11.3-2.

11.3.2.4 **Reactor Containment Shielding**

The containment shielding consists of the steel-lined, steel-reinforced concrete cylinder and hemispherical dome, as further described in Chapter 5. This shielding, together with the crane support wall, attenuates radiation during full-power operation at the outside surface of the containment to less than 0.75 mrem/hr. In addition, it attenuates the dose rate from the design-basis accident to design levels.

11.3.2.5 **Fuel Handling Shielding**

Fuel handling shielding is designed to facilitate the removal and transfer of spent fuel assemblies from the reactor vessel to the spent-fuel pool. It is designed to protect personnel against the radiation emitted from the spent fuel and control rod assemblies.

The refueling cavity above the reactor vessel is flooded to Elevation +45-1/3 ft. to provide a temporary water shield above the components being withdrawn from the reactor vessel. The water height is thus approximately 27 feet above the reactor vessel flange. This height ensures that more than 84 inches of water is present above a withdrawn fuel assembly at its highest point of travel. Under these conditions, the dose rate is less than 50 mrem/hr at the water surface.

The fuel is removed from the reactor vessel to the spent-fuel pool by the fuel transfer mechanism via the refueling canal.

The spent-fuel pool in the fuel storage building is permanently flooded to provide more than 84 inches of water above a fuel assembly when it is being withdrawn from the fuel assembly transfer basket. Water height above stored fuel assemblies is at least 24 feet. The sides of the spent-fuel pool, three of which also form part of the fuel storage building exterior walls, are 6-foot-thick concrete to ensure a dose rate of no more than 2.5 mrem/hr outside the building.

Sixteen feet of earth shielding is provided above the fuel transfer tube between the reactor containment and the fuel storage pool wall.

11.3.2.6 **Auxiliary Equipment Shielding**

The auxiliary components exhibit varying degrees of radioactive contamination due to the handling of various fluids. The function of the auxiliary shielding is to protect personnel working near the various auxiliary system components, such as those in the CVCS, the boron recovery system, the waste disposal system, and the sampling system. Controlled access to the auxiliary building is allowed during reactor operation. Each equipment compartment is individually shielded so that compartments may be entered without having to shut down and, possibly, decontaminate the entire system. Ilmenite concrete is used in certain areas where substantial shielding is required and space is at a premium, such as the primary drain tank compartment and the mixed-bed demineralizer compartments.

Ion exchangers and the most highly contaminated filters are located in the ion-exchange structure along the north wall of the auxiliary building. Each ion exchanger or filter is enclosed in a separate, shielded compartment. The concrete thicknesses provided around the shielded compartments are sufficient to reduce the surrounding area dose rate to less than 2.5 mrem/hr, and the dose rate of any adjacent cubicle to less than 100 mrem/hr. The shielding thicknesses around the mixed-bed demineralizers are based on a saturation activity that gives a contact radiation level of nearly 11,000 rem/hr.

Ion exchangers and potentially contaminated filters are also associated with the steam generator blowdown treatment system (no longer used) located in the condensate polisher building.

In many areas, tornado missile protection in the form of thick concrete affords more shielding than that required for radiation protection.

11.3.2.7 **Waste Storage Shielding**

The waste storage and processing facilities in the auxiliary building and decontamination building, the RF, and the waste storage tanks are shielded to provide protection of operating personnel in accordance with the radiation protection design bases set forth in Section 11.3.1.

Periodic surveys by health physics personnel using portable radiation detectors ensure that radiation levels outside the shield walls meet design specifications, and establish access limitations within the shielded cubicles. In addition, continuous surveillance is provided at the Radwaste Facility drumming area and control area and the RF compactor area by area radiation monitors (Section 11.3.4).

Area and process monitoring also ensure that any accidental radioactivity release would be detected within a reasonable period of time. The largest accidental radioactivity release from the waste disposal system would be the rupture of one of the waste gas decay tanks. An analysis of this accident is provided in Section 14.4.2. Furthermore, periodic samples of the gas in the waste gas decay tanks are analyzed by health physics personnel to ensure that the activity level in these tanks is never above the design level used in the accident analysis.

11.3.2.8 **Accident Shielding**

Accident shielding is provided by the reactor containment, which is a reinforced concrete structure lined with steel. For structural reasons, the thicknesses of the cylindrical walls and dome are 54 and 30 inches, respectively. These thicknesses are more than adequate to meet the requirements of 10 CFR 100 at the exclusion boundary.

Additional shielding is provided for the control room. This, together with the shielding afforded by its physical separation from the containment structure, ensures that an operator would be able to remain in the control room for 30 days after an accident and not receive an integrated whole-body dose in excess of 5 rem. The calculational methods and radiation sources used in designing the control room shielding are discussed in Section 11.3.6.

In addition, the control room will serve as a fallout shelter with a protection factor of better than 500, as defined by the Office of Civil Defense.

11.3.2.9 **Postaccident Shielding Review**

A postaccident shielding review was conducted during the 1979 to 1980 time period using the Stone & Webster GAMTRAN1 computer code with inputs developed from the ACTIVITY-2 and RADIOISOTOPE computer codes. NRC-specified source terms were used. The review assumed that the postaccident period was divided into two phases: the mitigation phase and the recovery phase.

The mitigation phase, which was assumed to last 6 months, experiences radiation levels resulting from the operation of the recirculation portion of the safety injection and recirculation spray systems and the postaccident sampling system. This phase also experiences radiation levels from the auxiliary building sump and from the drain lines from the discharge of the auxiliary building and safeguard building sump pumps to the low-level liquid waste tank, as well as to the containment.

The recovery phase has been identified as the period beginning 6 months after the accident, when cleanup and plant recovery is performed. The recovery phase is a controlled evolution that will be planned and carried out to meet the specific recovery requirements of the particular accident.

All essential system piping and equipment that are required to mitigate the effects of a loss-of-coolant accident (LOCA), and that contain or could contain highly radioactive fluids, were considered as sources in the shielding review. These systems included the high-head safety injection system, the low-head safety injection system, the recirculation spray system, the sample system, and the containment atmosphere cleanup (hydrogen recombiner) system. In addition, other systems that are not required to mitigate a LOCA, but that could contain significant radioactivity, were considered, such as drain lines and standing water in sumps and waste tanks. All branch connections to and from these systems were considered as sources to the first isolation valve. Other sources, such as the shine from the containment dome, shine through containment penetrations, and shine through the personnel hatch, were considered. The location of field run pipe, which is part of the systems listed above, was considered in this analysis. The routing and location of radioactive piping is such that the piping is in shielded areas. The exact routing of field run pipe is not critical in the production of radiation zone maps. The highest activity level in each zone is calculated, and that level is considered for the entire zone. For instance, the highest activity may be 12 inches from a pipe, regardless of its exact location within the zone.

Indirect radiation was not considered as a source. Buildup factors in shield walls are considered, but scatter over walls or through labyrinth doorways was not considered. Airborne activity was not considered as a source in the shielding review.

All vital areas were also considered during the review. Vital areas for personnel exposure are defined as those areas that require continuous or frequent occupancy in order to control, monitor, and evaluate the accident. These areas include the control room, technical support center, the counting lab/health physics area, the operational support center, and the security control center. In addition, any area to which access is required to perform manual operation of equipment in systems that are used to mitigate the accident was considered. Vital areas for equipment qualification include all areas in which mitigating equipment is located. Nonvital areas include the entire auxiliary building, main steam valve house, quench spray pump house, safeguards building, service building, and selected areas in the yard.

11.3.2.9.1 Mitigation Phase

The integrated radiation dose calculated for this phase is comprised of the original license period of 40-year normal dose and a 6-month mitigation phase dose. The safety equipment required to operate during the mitigation phase is the same as that equipment tabulated in Chapter 7 for NRC I&E Bulletin 79-01 (Reference 1). The source term developed to calculate the 40-year normal operating dose is based on the assumptions in Chapter 11. The source terms assumed to calculate the 6-month mitigation phase dose are based on TID-14844 (Reference 2) and Regulatory Guide 1.4 (Reference 3), and are listed in Table 11.3-4. The impact of increased integrated dose associated with an additional 40 years of normal operation is small and is accounted for in the environmental qualification of equipment applied to the mitigation phase.

The exact course of an accident is unpredictable. It is impractical to determine the dose rate and shielding requirements for every possible location and time duration associated with each possible failure, or incident, that requires personnel access. Therefore, radiation “zone maps” have been developed for use as postaccident administrative guidelines. These maps show estimated worst-case gamma rates in various areas of the plant as a function of time. The zone maps are used to help plant operators plan access and egress routes, and to help evaluate the relative benefits of delaying certain actions to allow for radioactive decay. The gamma dose rates on the zone maps are based on worst-case source terms, but do not consider an airborne source term. Depending on the severity of the situation, actual dose rates may be smaller. The zone maps are used only as guidelines, and actual radiation levels will be determined through actual postaccident surveys. In addition, the dose rates on the zone maps are based on the highest, or one of the highest, dose rates in that area. The dose rates at other locations within that area may be lower.

11.3.2.9.2 Recovery Phase

The design basis for certain systems and their associated shielding did not consider postaccident recovery operations, that is, postaccident cleanup of highly radioactive fluids. These are the waste disposal system, the boron recovery system, the containment purge system, and the letdown and charging portions of the CVCS. As a result, these systems will not be used for postaccident cleanup operations.

The activity levels (based on Regulatory Guide 1.4 and TID-14844) of the influent to the liquid waste disposal system or to the boron recovery system are approximately 2×10^3 μCi/cm^3 after 6 months of radioactive decay. The area radiation dose rates from concentrated waste and from waste storage tanks would severely limit access to parts of the auxiliary building and would hinder the operation of both units. Since the radioactive waste disposal systems are common to both Units 1 and 2, the use of these systems for the cleanup of waste in the accident-affected unit would preclude the normal use of the radioactive systems for the non-accident-affected unit.

There is extensive piping for the above-listed systems throughout the auxiliary building. The resulting dose rate if all these systems operated simultaneously would severely limit freedom of access for required operations. Shielding for the piping and components would be very difficult, and in some cases impossible, to install, because of the physical arrangement of the piping and components.

11.3.2.9.3 Postaccident Sampling Capability

The Surry Power Station has the capability to sample the reactor coolant, containment sump, and the containment atmosphere. The reactor coolant sample can be taken and analyzed within approximately 3 hours of the decision to sample. A containment atmosphere sample can also be taken with the high radiation sample system. Provisions are included for personnel exposure control. A detailed discussion of the postaccident sampling system is contained in Chapter 9.

11.3.2.10 **Steam Generator Storage Facility**

The Steam Generator Storage Facility is a reinforced concrete structure located within the station but outside the protected area. Major components housed in the facility include the original Steam Generator lower assemblies and the original Reactor Vessel Closure Heads. The facility has no interface with any permanent plant structures and is a restricted area. It is included in the Radiological Survey Program.

The radionuclide inventory of a steam generator as it is removed from the containment has been estimated about 1400 curies. This will decay to about 2-20 curies in 30 years and 0.0027 to 0.027 curies in 80 years. At the end of station life, it can be conservatively assumed that the total inventory of 12-120 curies of Cobalt-60 for the 6 steam generators will represent less than 0.1% of the total activity on site, exclusive of fuel and control rods. The lower shells could be handled easily as part of station decommissioning activities.

The facility is an above ground concrete structure on a poured structural slab. The exterior walls are as thick as necessary to meet the 40 CFR 190 requirement of 25 millirem/year. The facility is designed as an 80 year structure. It is not necessary that the facility be a seismic category I structure. The facility is designed with a dose rate criteria of radiation Zone I for the contact dose.

The original steam generator lower shells are tracked for decay and the radiation safeguards of the storage building is maintained. The exterior walls of the facility are periodically measured for low-level radiation dose.

The Steam Generator Storage Facility sump is periodically pumped out and taken to the Laundry Drain System for processing if contaminated. Table 11.3-6 list the Laundry Facility Continuous Effluent Particulate and Iodine.

11.3.3 Process Radiation Monitoring System

The process radiation monitoring system continuously monitors selected lines containing, or possibly containing, radioactive effluents. Lines through which waste liquids and gases are discharged to the environment are also monitored. The function of this monitoring system is to warn personnel of increasing radiation levels that could result in a radiation health hazard and to give early warning of a system malfunction. An audible alarm in the control room has been incorporated to indicate the loss of power to the monitor cabinet. The process radiation monitoring system serving both units is comprised of the channels listed in Table 11.3-5.

Each radiation monitoring channel is designed to provide continuous information about the process or effluent stream being monitored. Continuous, as used to describe the operation of the process and effluent radiation monitoring systems, means that a monitor provides the required information at all times with the following exceptions: (1) the system is not required to be in operation because of specified plant conditions per the Technical Specifications, or (2) the system is out of service for testing or maintenance and approved alternate monitoring, sampling, or recording methods are in place.

With the exception of the monitoring channels from the Laundry and Radwaste Facilities, each channel has a readout in the control room, and selected channels, as indicated in Table 11.3-5, have a readout at the detector location. The Laundry Facility monitors all readout locally and the Radwaste Facility monitors readout in the Radwaste Facility control room as well as locally. In addition, each channel has an audible and visual alarm for radiation levels in excess of preset values, as well as a visual alarm for detector malfunction. The output from all channels is recorded on recorders that produce a continuous record of radiation levels and radioactive discharges from the station. Each channel has its own power supply and check source thus making it completely independent of any other channel. Each channel check source is remotely operated from the main control room except the process monitors in the Radwaste Facility, the Laundry Facility, and the High-Range Effluent monitors. The normal/high range Process Vent and Vent Stack No. 2 (MGPI) effluent monitors do not have a check source. The High-Range Effluent monitors for the main steam line and the exhaust of the turbine AFW pump have a built-in radioactive source that provides a life-zero signal for testing purposes. The Radwaste Facility and the Laundry Facility check sources are remotely operated from local control panels. The MGPI equipment is continually self-checking that, should the detector output signal drop below some prescribed value, effectively indicating that there is no background signal, the detector will be considered faulty. This monitoring, in conjunction with continual testing of the electronic signal processing circuits by generation and confirmed receipt of test signals, provides assurance that the circuits remain in good health. The adjustment of alarm setpoints, voltage, power, and other variables is made from the control room for all radiation monitors except for the following: 1) monitors in the Radwaste, and 2) monitors in the Laundry Facilities. Adjustments to the Radwaste and Laundry Facility monitors are performed locally. The normal/high range Process Vent and Vent Stack No. 2 MGPI effluent monitors can be adjusted either at the local display unit (LDU) or at the remote display unit (RDU). The High-Range Effluent monitors can be adjusted at the local processing and display unit (LPDU). The entire system is designed with emphasis on system reliability and availability. Certain channels, as indicated in the following text, actuate control valves on a high-activity alarm signal. In the event of a loss of power to these detectors, the system is designed to provide an alarm of the failed condition. Any control functions associated with a high radiation alarm are also initiated.

The expected concentrations of radionuclides in the process streams monitored by the ventilation vent monitors, component cooling water monitors, component cooling heat exchanger service water monitors, condenser air ejector monitors, steam generator blowdown monitors, and recirculation spray cooler heat exchanger service water monitors are natural background radioactivity. The sensitivity of these detectors ensures that abnormal plant conditions will be detected before they cause a hazard to the operators or to the general public.

The use of a single detector is justified in lines used for normal releases from the plant. The surveillance requirements for each of the liquid effluent monitors and gaseous effluent monitors are given in the Offsite Dose Calculation Manual. The liquid and gas waste tanks are sampled and analyzed before and during discharges. Effluent source terms are discussed in Appendix 11A.

Channels monitoring Unit 1 are supplied from the emergency bus for Unit 1. Channels monitoring Unit 2 are supplied from the emergency bus for Unit 2. Channels monitoring systems or areas common to both units can be supplied from the emergency bus for either Unit 1 or Unit 2.

The type of detector, sensitivity, range, background radiation, and other information for each channel are listed in Table 11.3-5. Counting rates are given in Table 11.3-6. A description of each channel is included in the following text.

11.3.3.1 **Process Vent Particulate Monitor**

This channel continuously withdraws a sample from the process vent and passes the sample through a moving filter paper with a collection efficiency of 99% for particle sizes greater than 1.0μ. The amount of deposited activity is continuously scanned by a silicon diode type. A high-activity alarm automatically initiates the closure of the process vent discharge line valves.

A separate isokinetic sampling nozzle used for Health Physics accountability is provided for each unit, as shown in Reference Drawing 2. The nozzles sample the process vent fluid to ensure that a representative sample is taken. Isokinetic sampling is achieved by locating the nozzles in a straight unobstructed piping run of at least five pipe diameters (30 inches). The sampling systems include a pump and a mass flow meter, and supply 1-cfm flow to a sample filter.

11.3.3.2 **Process Vent Gas Monitor**

This channel takes the continuous process vent sample, after it has passed through the particulate filter paper, and draws it through a sealed system to the process vent gas monitor assembly, which is a fixed lead-shielded sampler containing a silicon diode type detector. The sample activity is measured, and is then returned to the process vent. A high-activity alarm automatically initiates the closure of the process vent discharge line valves. A purge system is integral with the gas monitoring system for flushing the sampler with clean air for purposes of calibration.

11.3.3.3 **Ventilation Vent No. 1 Gas Monitor**

This channel withdraws a sample from ventilation vent no. 1 and passes the sample through a particulate and iodine filter assembly. The sample then enters a gas monitor assembly, which is a fixed lead-shielded sampler enclosing a beta scintillation detector. The sample activity is measured, and is then returned to the ventilation vent. A purge system is integral with the gas monitoring system for flushing the sampler with clean air for purposes of calibration. A multi-probe isokinetic sampling nozzle is provided to obtain a representative sample in the duct.

11.3.3.4 **RF Vent Particulate and Gas Monitors**

These two channels continuously sample the RF ventilation stack particulate and gas. The monitors process a sample (approximately 2 scfm) through a replacable fixed 0.3-micron filter. Noble gases are then monitored in a pressure compensated chamber. Sample flows are supplied by an isokinetic probe. This monitor has provisions for a removable silver zeolite iodine sampler cartridge and for a grab sample for tritium analysis.

11.3.3.5 **Component Cooling Water Monitors**

These two channels continuously monitor the component cooling water by means of a gamma scintillation detector enclosed in lead shielding and mounted on the component cooling piping. The complex piping arrangement of this system dictates that two detectors are required to ensure that the system is properly monitored. Activity is indicative of a leak into the component cooling system (Section 9.4) from one of the radioactive systems that exchange heat to the component cooling system.

11.3.3.6 **Component Cooling Heat Exchanger Service Water Monitor**

These four channels continuously monitor the service water effluent from the four component cooling water heat exchangers. Each channel consists of an inline gamma scintillation detector located in a pipe well on the discharge side of the heat exchanger.

11.3.3.7 **Liquid Waste Disposal System Monitor**

The RF has a liquid waste discharge monitor. This channel continuously monitors processed liquid and laundry waste leaving the RF by means of a gamma scintillation detector mounted on a 3-inch discharge pipe. The unit is shielded to ensure the required detector sensitivity. A high-activity alarm automatically initiates closure of a valve that terminates discharges from the RF.

11.3.3.8 **Condenser Air Ejector Monitors**

There are two identical radiation detection channels (1-SV-RM-111 and 2-SV-RM-211 for Units 1 and 2, respectively) for continuously monitoring the normal gaseous effluent from the condenser air ejectors to the atmosphere. The detectors are gamma scintilators mounted in an in-line sampler surrounded by lead shielding. Activity is indicative of a primary-to-secondary system leak. On a high-activity alarm, the flow is automatically diverted to the containment.

If a condition exists such that the normal radiation monitor alarms, but the containment is under Phase 1 isolation (Section 5.2.2), isolation valves 1-SV-TV-102, 102A, and 103 (Unit 1) and 2-SV-TV-202, 202A, and 203 (Unit 2) would shut (Reference Drawing 1) to stop all flow from the air ejector. However, the operator can maintain condenser vacuum by manually establishing air ejector flow through a discharge line to a point upstream of the ventilation vent no. 2 high-range noble gas effluent radiation monitor (Section 11.3.3.14). This monitor provides both normal and high-range effluent radiation detection. If ultimately required, the air ejector effluent can be isolated remotely from the control room.

11.3.3.9 **Steam Generator Blowdown Sample Monitors**

Each of these channels (two channels per unit) monitors the liquid phase of the steam generators for radioactivity indicative of a primary-to-secondary system leak. The three steam generator blowdowns are combined and continuously monitored by the detectors. Upon indication of radioactivity, a valving arrangement enables the steam generators to be individually sampled, in turn, to determine the source of the activity. Once it has been established which steam generator is leaking, one of the detectors monitors only the blowdown from that steam generator, while the other detector monitors the combined blowdown from the other two steam generators. The detectors are gamma scintillation detectors, mounted in liquid samplers surrounded by lead shielding.

11.3.3.10 **Recirculation Spray Cooler Service Water Outlet Monitors**

The recirculation spray coolers, as part of the recirculation spray system (Section 6.3.1), operate only when containment pressure increases to the Hi Hi Consequence Limiting Safeguards (CLS) setpoint.

There are four recirculation spray coolers per unit, and each service water outlet line from the coolers is monitored, thus giving a total of eight channels. Each of these channels is identical. If the recirculation spray system is placed in service, a 5-gpm to 10-gpm sample is drawn out of each service water outlet line by a small pump with a 2-hp motor and passed through an offline liquid sampler, where it is monitored for activity indicative of a leak in the respective recirculation spray cooler. After passing through the liquid sampler, which is located outside the containment, the sample is returned to the service water line. Each monitor consists of a gamma scintillation detector mounted in a standard offline sampler surrounded by 3 inches of lead.

To ensure low background radiation in the event of an accident, the Unit 1 monitors are located in the Unit 2 safeguards building and the Unit 2 monitors are located in the Unit 1 safeguards building.

11.3.3.11 **Reactor Coolant Letdown Gross Activity Monitors**

Each of the units has its reactor coolant continuously monitored by means of a sample taken from the letdown line to the CVCS (Section 9.1). In this system, large variations in activity level are possible in the event of fuel assembly failure. This is a two-stage monitoring system consisting of a low-range channel and a high-range channel. There is one such system for each unit. After being withdrawn from the letdown line, the sample is passed through a delay line to allow N-16 to decay, then enters a sampler consisting of two gamma scintillation detectors surrounded by lead shielding, and is finally discharged to the volume control tank. Both detectors sit on a 1/2-inch removable stainless steel tube, providing flow through the sampler. Shielded lead plugs are used to convert the two detectors into either high- or low-range letdown monitors.

Normally, the low-range detector will be sitting on the 1/2-inch tubing and the high-range detector will be sitting on the shielded lead plug. In the event of a fuel element failure, the activity released could be sufficient to raise the coolant activity level above 1.0 $\mu Ci/cm^3$ gross fission products. This causes the high-range monitor to begin to indicate activity level at 10^{-1} $\mu Ci/cm^3$, providing a one-decade overlap. At this point, the high-range channel provides the activity data, and the low-range monitor can be converted into a high-range monitor by inserting a shielded lead plug.

11.3.3.12 **Circulating Water Discharge Tunnel Monitors**

Each of these identical channels (one per unit) monitors the effluent (service water, condenser circulating water, and liquid waste) in the circulating water discharge tunnel beyond the last point of possible radioactive material addition. A gamma scintillation detector slides into a capped pipe, which is then inserted directly into the discharge tunnel and acts as a well. At the top of the pipe is a waterproof support assembly that encloses a check source. The entire device is waterproof.

11.3.3.13 **Ventilation Vent No. 2 Particulate and Gas Monitors**

The two channels in Ventilation Stack No. 2 continuously sample for particulate and gas in the same way that the two Process Vent channels monitor the process vent sample, except that multi-probe samplers are provided to obtain a representative sample in the duct and both channels are equipped with silicon diode type detectors. In addition the post-accident noble gas and particulate monitor is used to obtain grab samples of the ventilation flow stream. Finally, the operability of the ventilation vent No. 2 particulate and gas monitors is relied upon in conjunction with the fuel pit bridge area monitor and communications to provide a timely and valid indication of a fuel handling accident in the spent fuel pool.

11.3.3.14 **High-Range Postaccident Radiation Monitors**

Methods for monitoring high-level releases of noble gases, iodine, and particulates have been developed and implemented. All potential releases are monitored by instrumenting ventilation vent no. 2, the process vent stack, main steam safety valve and power operated relief valve header, and the auxiliary feedwater pump turbine exhaust. The waste gas decay tank and hydrogen purge exhaust are discharged through the process vent stack. The auxiliary building, decontamination building, fuel building, and safeguards area exhausts are discharged through the auxiliary building ventilation vent no. 2. The containment purge system, which is common to both units, discharges through the ventilation vent no. 2 during outages. The main condenser air ejectors normally discharge to the atmosphere, but flow is diverted to containment if the set radiation level limit is exceeded.

The high-range noble gas radiation monitors on the ventilation and process vents are listed in Table 11.3-8. These monitors have a range of 10^{-7} to 10^{5} $\mu Ci/cm^3$ (Xe-133) under normal background conditions (less than 1 mR/hr). Due to shielding around the detector, the reduction of effluent detector sensitivity under maximum background conditions will not exceed the normal effluent instrument range. A multidetector system with detectors enclosed in lead shielding and sufficient range overlap is provided to ensure complete coverage for all expected background conditions. Shielded effluent detectors are needed to obtain the required sensitivities.

Accident particulate and iodine releases are determined by retrieving fixed filters for laboratory analysis. The filters are shielded to provide personnel protection during removal and reinstallation. Several filters in parallel provide for continuous sampling during filter removal.

High-range monitors, with a usable range of 0.01 mrem/hr to 10,000 R/hr, are installed on all main steam lines and the exhaust of the turbine driven AFW pump. These monitors are listed in Table 11.3-8. The 10,000 R/hr maximum reading corresponds to a noble gas concentration which is significantly greater than the maximum anticipated value, as determined by analysis, for noble gas concentrations following any design basis accident. The main steam monitors will be used in conjunction with secondary system sampling and offsite radiation monitoring.

The control units for the monitors contain the electronics necessary to interpret and display detector readings. Four control units, one for each monitor, are located in the Unit 1 Containment Spray Pump House and four control units are located in the Unit 2 Containment Spray Pump House. The units provide visual alarms for failure, alert, and high radiation. A digital readout of radiation level is also provided.

The detectors are powered from the control units, called LPDUs. The LPDUs are powered from reliable sources.

The Surry Power Station has the capability of monitoring all vital areas through the process vent and ventilation vent stack samples or local grab samples, as appropriate. Accurate monitoring of iodine in the presence of high noble gas concentrations is accomplished by the use of silver zeolite sampling cartridges. The cartridges can be analyzed by the multichannel analyzer system (MCA) that is located in a concrete walled count room for shielding purposes. The MCA detectors are located within lead-lined shields that also contribute to background reduction. This combination of shielding provided in the count room is adequate to provide a low background analysis location under most emergency conditions. If background becomes too high for accurate analysis, samples can be taken to the Radwaste Facility or shipped offsite. Procedures for iodine sampling and analysis are available in the Health Physics office.

Particulate sampling is accomplished in conjunction with radioiodine sampling by using fiber filter patches positioned upstream of the iodine filter. Particulate analysis is accomplished by using a multichannel analyzer.

11.3.3.15 **Storm Drain Radiation Sample System**

The storm drain radiation sample system is used to monitor for radioactive contamination of the effluent from the storm drain system prior to discharge into the James River. Recording flow meters and automatic wastewater samplers are installed at the four final release points of the storm drain system. Access to the equipment is through precast equipment manholes into the buried storm water drainage lines adjacent to the discharge canal. Electrical service to the equipment is provided by 120V ac power outlets in weatherproof enclosures inside the manholes. Samples are automatically drawn on a periodic basis to be sampled by Health Physics personnel for radioactive material content.

11.3.4 Area Radiation Monitoring System

11.3.4.1 General

The area radiation monitors are designed for continuous operation. Continuous, as used to describe the operation of an area radiation monitor, means that the monitor provides the required information at all times with the following exceptions: (1) the monitor is not required to be in operation because of specified plant conditions per the Technical Specifications, or (2) the system is out of service for testing or maintenance.

The area radiation monitoring system reads out and records the radiation levels in selected areas throughout the station and activates alarms (audible and visible) if these levels exceed a preset value or if the detector malfunctions. With the exception of the containment gas and particulate monitors, each detector reads out and activates alarms, both in the control room and at its station location. Each channel is equipped with a check source remotely operated from the control room. The recorders provide a continuous permanent record of radiation levels while the detectors are functioning. Detectors monitoring Unit 1 are supplied with power from the emergency bus for Unit 1. Detectors monitoring Unit 2 are supplied with power from the emergency bus for Unit 2. Detectors monitoring areas common to both units have the capability of being supplied with power from the emergency bus for either Unit 1 or Unit 2.

Additions subsequent to the original station area radiation monitoring system include the spent resin handling area, laundry, and radwaste facilities. These systems are powered from reliable power supplies and are indicated and source tested locally.

The alarm setpoint of each area monitor is variable and is set at a level slightly above the normal background radiation level in the respective area.

The area radiation monitoring system consists of the detectors listed in Table 11.3-7, plus each unit's containment particulate and gas monitors, described below.

Criticality monitors are not required in the spent fuel and new fuel storage and handling areas. An exemption from the criticality monitoring requirements specified in 10 CFR 70.24(a) was received from the NRC for the storage and handling of fuel assemblies enriched up to 4.3 weight percent U-235 (Reference 8). The exemption was based on station design features and procedural controls that are in place to preclude an inadvertent criticality. Area radiation monitors are provided in these areas which would alert personnel to excessive radiation levels and would initiate appropriate response actions.

11.3.4.2 Containment Particulate Monitors

This channel continuously withdraws a sample from the containment atmosphere into a closed, shielded system exterior to the containment. The sample is passed through a moving filter paper with a collection efficiency of 99% for particle sizes greater than 1.0 micron. The amount of deposited activity is continuously scanned by a lead-shielded beta scintillation detector with a sensitivity of 1×10^{-11} μCi/cm^3 for particulates in a background of 2.5 mR/hr. The sample system, which is common to both the particulate and gas monitors, includes a pump with a 0.75-hp motor, a flow meter, automatic pressure protecting valves, a flow regulating valve, and isolation valves. The pump and motor are located outside the containment. A sample point is available for taking a sample of the containment atmosphere after an incident for spectrum analysis in the laboratory. During refueling a high-activity alarm automatically trips the containment purge air supply fans and closes the purge system butterfly valves, thus isolating the purge system. This automatic function is not credited in the fuel handling accident nor is it required to be functional. The operability of the containment particulate monitor is relied upon in conjunction with the containment gas monitor, the manipulator crane area monitor, and communications to provide a timely and valid indication of a fuel handling accident in the containment. The counting rate of the limiting isotopes, I-131 and Cs-137, is nominally 2.6×10^{12} cpm/μCi/cm^3 (2 scfm and 1"/hour tape speed).

11.3.4.3 Containment Gas Monitors

This channel takes the continuous containment atmosphere sample, after it has passed through the particulate filter paper, and draws it through an in-line, easily removable, charcoal cartridge arrangement to the containment gas monitor assembly, which is a fixed-volume, lead-shielded sampler enclosing a beta scintillation detector. The sensitivity of this detector is 1×10^{-6} μCi/cm^3 for noble gases in a background of 2.5 mR/hr. The sample activity is measured, and then the sample is returned to the containment.

During refueling, a high-activity alarm automatically trips the containment purge air supply fans and closes the purge system butterfly valves, thus isolating the purge system. This automatic function is not credited in the fuel handling accident nor is it required to be functional. The operability of the containment gas monitor is relied upon in conjunction with the containment particulate monitor, the manipulator crane area monitor, and communications to provide a timely and valid indication of a fuel handling accident in the containment.

A purge valve arrangement blocks the normal sample flow to permit purging the detector with a clean sample for calibration. Purged gases are discharged to the containment. Protection and isolation are provided as described in Section 11.3.4.2.

The counting rates of the limiting isotopes Xe-133, and Kr-85 are nominally 3.145×10^7, and 1.09×10^8 cpm/μCi/cm^3, respectively.

11.3.4.4 **Other Area Radiation Monitoring Equipment**

This equipment consists of fixed-position, ion-chamber-type gamma detectors and associated electronic equipment. These channels warn personnel of any increase in radiation level at locations where personnel may be expected to remain for extended periods of time. The channels and their ranges are listed in Table 11.3-7.

In addition, if the dose rate at the manipulator crane area monitor exceeds the alarm setpoint during refueling, the alarm automatically trips the containment's purge air supply fans and closes the purge system butterfly valves, thus isolating the purge system. This automatic function is not credited in the fuel handling accident nor is it required to be functional. The operability of the manipulator crane area monitor is relied upon in conjunction with the containment gas and particulate monitors, and communications to provide a timely and valid indication of a fuel handling accident in the containment.

Finally, the operability of the fuel pit bridge area monitor is relied upon in conjunction with the ventilation vent No. 2 particulate and gas monitors and communications to provide a timely and valid indication of a fuel handling accident in the spent fuel pool.

11.3.4.5 **High-Range Postaccident Containment Monitors**

A high-range reactor containment area monitor is located outside the containment structure. The detector is permanently mounted and aimed at the personnel hatch. The monitor has a range of 0.1 to 10^7 mR/hr to measure the expected high gamma dose rate in the containment following a LOCA.

An additional set of two high-range containment radiation monitors is installed at separate locations on the crane wall above the operating deck level inside containment. The monitors are single ion chamber detectors that measure photons over the range of 1 to 10^7 R/hr. The system is sensitive to photon energies from 60 keV to 3 MeV, with ±20% accuracy for 0.1 to 3 MeV photons.

The readout for the in-containment monitors is located in the control room and consists of a rate meter and recorder that starts at a present value. Each redundant monitor is powered by a separate vital instrument bus.

The in-containment monitors meet the Seismic Class 1 requirements of Regulatory Guide 1.100 (Reference 5), will withstand the LOCA conditions specified by Regulatory Guide 1.89 (Reference 6), and have been environmentally qualified in accordance with the requirements of IEEE 323-1974 and Regulatory Guide 1.97, Revision 3.

11.3.4.6 **Technical Support Center Area Monitor**

The Technical Support Center (TSC) radiation monitoring system is a localized system and satisfies the guidelines established in NUREG-0696. The radiation monitoring system components consist of one particulate, iodine, and noble gas monitor, two area monitors and a remote alarm panel.

This monitoring system provides continuous indication of the dose rate and airborne activity in the TSC during an emergency, as well as alerting personnel of adverse conditions. It is totally contained within the TSC and is in no way connected to the control room or any safety-related systems.

11.3.5 Environmental Survey Program

The information in this section gives the programmatic elements of the Radiological Environmental Monitoring Program (REMP) for Surry Power Station. Historical data is provided on the pre-operational radiological surveillance performed in support of the Applicant's Environmental Report. Current requirements of the REMP program contained in Technical Specifications are implemented through the Offsite Dose Calculation Manual (ODCM), which describes the specific elements of the present radiological environmental surveillance program at Surry Power Station.

The Surry Power Station Applicant's Environmental Report contains the preoperational radiological surveillance program covering the period from May 1968 through June 1970.

Comments made by the U.S. Fish and Wildlife Service concerning the preoperational phase of the station were taken into account by:

1. Holding a conference on June 21, 1968, to discuss the pre- and postoperational surveys for the Surry Power Station. Representatives from the following agencies were present:

   a. Federal Water Pollution Control Authority.

   b. Bureau of Commission of Fisheries, Radiobiological Laboratory.

   c. Virginia State Water Control Board.

   d. Commonwealth of Virginia, Bureau of Industrial Hygiene.

   e. Virginia Commission of Game and Inland Fisheries.

   f. U.S. Fish and Wildlife Service, Bureau of Sport Fisheries and Wildlife.

   g. Virginia Institute of Marine Science.

   The meeting adjourned with the understanding that all agencies represented at the meeting were completely satisfied with the Company's program for pre- and postoperational radiological and ecological surveillance programs.

2. Conducting the preoperational radiological surveillance program in such a manner that indigenous species that concentrate radionuclides are routinely sampled and analyzed.

3. Preparing reports on the radiological program for distribution to interested agencies before station operation.

4. Holding discussions with appropriate state officials and personnel from the U.S. Fish and Wildlife Service regarding thermal pollution.
5. Installing of seven platforms in the James River upon which are seven instruments continuously measuring water temperature. (Instruments to measure river salinity were also installed on those same towers.)
6. Working in conjunction with personnel from the Virginia Institute of Marine Science regarding their grant from the AEC concerning thermal pollution of the river.
7. Designing the intake water facility with a 1.0-fps intake velocity at the screen surface so as to prevent significant damage to fishery resources.

A postoperational radiation surveillance program was developed using the knowledge and information obtained from the preoperational surveillance program. The latter was in effect over a 2-year period and served to train plant personnel in sampling and analytical techniques; aid in identifying those “indicator samples” that may be an indication of a slow buildup of radioactivity in the environment; establish the degree of variability between measurements resulting from seasonal changes in the weather (since fluctuations do occur and are expected); generate meaningful environmental data based primarily on scientific and technical requirements; and establish a correlation of data between the consulting service and the station’s laboratory group.

The ultimate objective of the postoperational surveillance program is the verification of the adequacy of radiation source control. Therefore, analytical efforts are directed toward those samples that have the ability to concentrate the radioelements of concern and afford an integrated and sensitive sampling mechanism. Milk, shellfish (oysters, crabs, and clams), and silt are considered indicator samples and are indicative of radioactivity levels in the environment. Commercial and/or recreationally important species of fish (catfish, eel and perch) are selected for sampling in the vicinity of the discharge point. The consumption of fish present a direct ingestion pathway to man. Because certain species of fish, such as bottom feeders, concentrate radionuclides which may be taken up from the water and aquatic sediments or may accumulate in the fish directly via internal deposition, it is important to include these organisms in the radiological environment sampling program. Samples are collected from the environment surrounding the station at various intervals throughout the year. Radioanalysis of these samples indicates conditions both in time and space, and thus a slow buildup of radioactivity can be determined. In addition, comparison in the trends of radioactivity levels are more meaningful, since the biological variation caused by using many different media has been eliminated.

Since the program’s origination, sampling has been expanded to include obtaining representative samples of the sediment, shoreline silt, food products, oysters, fish and clams from the surrounding area. These samples are analyzed for radioisotopes.

11.3.5.1 **Air Monitoring**

To meet the surveillance objective previously stated, it is desirable for the surveillance methods to indicate changes in radioactivity above-background levels. Therefore, continuous-duty air particulate samplers are also used to confirm that the station presents no hazard to the public. An air-sampling station is located at different locations including a control location which provides background data. The establishment of the air particulate network takes into account the following four general considerations:

1. The average meteorological conditions in the vicinity of the site.
2. The current and projected population densities near the station.
3. The proximity of other nuclear facilities.
4. The proximity of the site boundary location of the highest calculated annual average ground level D/Q.

Air particulate matter is accumulated for a 1-week period on appropriate filter media using a low-volume air sampler. The particulate filters are analyzed in accordance with Radiological Environmental Monitoring Program requirements.

11.3.5.2 **Milk**

The dose consequence to an individual is from both a direct and indirect exposure pathway. The direct exposure pathway is from the inhalation of radioactive material and the indirect exposure pathway is from the grass-cow-milk pathway. In this pathway radioactive material is deposited on the plants consumed by the dairy animals. The radioactive material is them passed on to the individual via the milk.

It has been estimated that, since a cow grazes over an area of 160 m^2 per day (Reference 7), cow’s milk affords a good integrated sample. Since milk is one of the best and most direct biosamplers for determining the radiocesium, radiostrontium, and radioiodine levels in the environment, samples are collected from the local dairy farms in the vicinity of the station.

11.3.5.3 **Shellfish, Crabs, and Fish**

Shellfish have the ability to concentrate certain stable elements and radionuclides far above the normal concentrations found in their saline water environment. Oysters and clams, *Crasostrea virginica* and *Mercenaria mercenaria* respectively, found in the James River are thus one of the more sensitive mechanisms for the determination of radioactivity released from the station. Oysters and clams are collected in the vicinity of the station. Crab and fish samples are obtained in the vicinity of the station. Radioanalysis of these sample media are in accordance with the Radiological Environmental Monitoring Program.

Additional aquatic vectors useful as integrating samples have been investigated, but none have proven to be as sensitive or indicative as shellfish.

11.3.5.4 Silt and Sediment

Since shellfish do not concentrate all radionuclides, river bottom sediment samples are collected from downstream areas which have or potentially may have recreational value. Silt samples are obtained in the vicinity of the station. Because of the interaction of a number of mechanisms, radionuclides accumulate in silt and bottom sediments. Because of this, silt is one of the few environmental media in which radioactive effluents from nuclear power stations are usually detected. These samples thus afford an integrated indication of average water concentrations.

11.3.5.5 Water Samples

Water samples are collected for analysis from the following sources: surface water samples from two different locations—one upstream and one downstream from the station and ground (well) water samples, which are collected from various wells in the vicinity of the station. The well water and surface water samples are analyzed in accordance with Radiological Environmental Monitoring Program requirements.

11.3.5.6 Food Products

The dose consequence to an individual from food products is via the ingestion exposure pathway. Samples of food products are obtained from farms in the vicinity of the station and analyzed in accordance with Radiological Environmental Monitoring Program requirements.

11.3.5.7 Equipment

Analytical equipment used for the Radiological Environmental Monitoring Program includes the following:

1. Gas-flow proportional counter (alpha-beta counter).
2. Multichannel gamma spectroscopy analyzer.
3. Liquid scintillation counter.
4. Thermoluminescent Dosimeter (TLD) readers.
5. Other analytical equipment which meet the Lower Limit of Detection (LLD) requirements set forth in the Offsite Dose Calculation Manual.

11.3.5.8 Environmental Dosimetry

Normally, the gaseous wastes discharged from the station consist almost entirely of the noble gases, xenon and krypton. The radiation hazard from these gases, due to their inertness, is external radiation exposure. Therefore, radiation surveillance can be maintained by using devices to measure total external body radiation levels in the station environs. The TLDs measure external radiation exposure from several sources including naturally occurring radionuclides in the air, radiation from cosmic origin, fallout from atomic weapons testing as well as potential radioactive airborne releases from Surry Power Station. An inner ring of TLDs are located in the five mile range from the site with a station in each of the 16 sectors of each ring. Other TLDs are located in special program interest areas (residences, schools, etc.) and in control locations. The TLDs are collected and analyzed for gamma radiation at a frequency which optimizes statistical sensitivity and characterizes seasonal fluctuations.

11.3.5.9 **Interlaboratory Comparison Program**

Surry Power Station participates in an Interlaboratory Comparison Program to ensure that independent checks on the precision and accuracy of measurements of radioactive material in environmental sample matrices are performed as part of the quality assurance program for environmental monitoring. The program is applicable for the radioanalyses performed in support of the Radiological Environmental Monitoring Program.

11.3.6 Control Room

The control area is described in Section 7.7. The design basis for radiation protection in the control room under accident conditions is that the whole body radiation dose to personnel accessing and occupying the control room is limited to less than or equal to 5 rem TEDE for the duration of the accident. This dose includes the 30-day dose from ECCS leakage (including RWST backleakage) and the contribution from the postulated radioactive plume leaking from the containment (as discussed in Section 14.5.5) until engineered safeguards equipment returns the containment to subatmospheric pressure and terminates the leakage.

The control room doses for the design basis LOCA are discussed in Section 14.5.5.3.

The control room walls, which are a minimum of 24-inch thick for tornado missile protection, provide more than adequate shielding from radiation. Special consideration has been given to the design of penetrations and structural details of the control room so as to establish an acceptable condition of leaktightness.

The air conditioning systems are installed within the spaces served and are designed to provide uninterrupted service under accident conditions. Upon a safety injection signal, the normal replenishment air and exhaust systems are isolated automatically from the control room by tight closures in the ductwork. The control and relay rooms are provided with an emergency ventilation system fitted with particulate and impregnated charcoal filters to introduce cleaned outside air into the protected spaces. Within 1 hour of control room envelope isolation, procedures require the alignment of the control room emergency ventilation system to provide a filtered breathing air supply to the control room envelope. This can continue indefinitely to hold the area pressure above atmospheric to ensure outflow leakage.

The radiation level in the control room is measured by a gamma monitor to verify safe operating conditions.

As a secondary precaution, personnel air-packs are available in the control area.

Table 11.3-1
ALLOWABLE DOSE RATES

Zone Description	Maximum Dose Rate (mrem/hr)	Typical Locations
	Full-power operation	
Continuous access (Zone I)	0.75	Control room, outside surface of containment, and all turbine plant and administration areas
Periodic access (Zone II)	2.5	Auxiliary and fuel building passageways in general and inside reactor containment personnel lock
Limited access (Zone III)	15	Outside surface of shielded tank shields
Controlled access (Zone IV)	15	Inside shielded equipment compartments
Access to incore instrumentation	100	Annulus between crane wall and containment wall
Access to incore instrumentation	40	Vicinity of incore instrumentation transfer devices
Access to incore instrumentation	20	Vicinity of incore instrumentation motors
	Hot shutdown (after 15-min decay)	
Limited access (Zone III)	15	Reactor containment above charging floor and outside of crane wall
Controlled access (Zone IV)	15	Inside shielded equipment compartments
	Cold shutdown for maintenance (after 8-hr decay)	
Periodic access (Zone II)	2.5	Reactor containment above charging floor and outside of crane wall
Controlled access (Zone IV)	15	Inside shielded equipment compartments
	Cold shutdown for refueling (after 4-day decay)	
Periodic access (Zone II)	2.5	Reactor containment above charging floor, outside of crane wall, and adjacent to fuel transfer canal near incore instrumentation devices
Controlled access (Zone IV)	15	Inside shielded equipment compartments
Surface of water over raised fuel elements	50	Fuel element above up-ender, and above other fuel elements in fuel building

APPENDIX 11A RADIATION EXPOSURE EVALUATION FOR EXPECTED RADIOACTIVE EFFLUENTS

11A.1 ANALYTICAL BASIS

Surry Units 1 and 2 were analyzed and evaluated using the parameters and methodology set forth in Regulatory Guides 1.109 (Reference 1), 1.111 (Reference 2), and 1.112 (Reference 3), and NUREG-0017 (Reference 4). Maximum individual doses resulting from gaseous and liquid effluents were calculated.

Radioactive source terms, both liquid and gaseous, were calculated in a manner consistent with Regulatory Guide 1.112 and NUREG-0017. Specific data used for the generation of the sources terms are presented in Section 11A.2.1.

Meteorological information used in the calculation of doses was developed consistent with the methodology described in Regulatory Guide 1.111. Information related to the meteorological inputs is contained in Section 11A.2.2. The dispersion factors (χ/Q) and ground depositions factors (D/Q) from the release points at Surry Units 1 and 2 to the various receptions are contained in Section 11A.2.3.

A plant and animal census is provided in Section 11A.3.

Dose calculations were performed in a manner consistent with Regulatory Guide 1.109. The NRC computer codes LADTAP and GASPAR were used to perform the calculations. The results of the analyses presented in Section 11A.4 support the Surry Power Station's capability of keeping the levels of radioactivity in effluents as low as reasonably achievable.

The liquid waste disposal system described Section 11.2.3 reflects changes in the liquid waste design used in the original Appendix I evaluation. Table 11.2-4, however, maintains the parameters used in the evaluation. This table was unchanged because the new liquid waste design was to be, at a minimum, equal to the previous system. In reality, improved performance was expected. Therefore, this analysis represents a conservative evaluation of offsite doses.

The gaseous waste disposal system is as described in 11.2.5.

11A.2 INPUT INFORMATION

General plant information, meteorological information, dispersion factors (χ/Q), and ground deposition factors (D/Q) are given in the following sections.

11A.2.1 General Plant Information

Plant information required by Appendix B of Regulatory Guide 1.112 is contained in Table 11A-1.

11A.2.2 Meteorological Information

Information concerning the onsite meteorological measurements program is found in Section 2.2.1.2.

Joint frequency distributions of wind speed and wind direction by atmospheric stability class are prepared monthly and annually, based on the format of Table 1 in Regulatory Guide 1.23 (Reference 5). Monthly and annual joint frequency distributions of 35-foot wind and $\Delta T_{150\text{ ft.} - 35\text{ ft.}}$ data are used as input for χ/Q and D/Q calculations for ground-level releases. Monthly and annual joint frequency distributions of 150-foot wind and $\Delta T_{150\text{ ft.} - 35\text{ ft.}}$ data are used as input for qualifying elevated release calculations of χ/Q and D/Q. The 2-year (1974-1976) data set was chosen as the most recent representative data set.

The meteorological data for the period 1974-1976 are considered to be representative of atmospheric transport and diffusion conditions of the site region on a long-term basis. The stability distribution based on $\Delta T_{150\text{ ft.} - 35\text{ ft.}}$ for the period March 3, 1974, to March 2, 1975, is consistent with the 2-year data period as used in this report (Table 11A-2). Comparison of annual wind roses for both the 35- and 150-foot levels indicates that the annual 2-year wind roses are consistent with the first year of data and are in general agreement with Richmond and Norfolk wind roses for the period January 1, 1969, to December 31, 1973 (Reference 6). The representativeness of the first year of the 2-year data set to the long-term meteorological conditions is discussed in Reference 6.

11A.2.3 Dispersion Factors and Ground Deposition Factors

Table 11A-3 provides χ/Q and D/Q values for ground-level and mixed-mode releases for the special appropriate distances as indicated in Section 11A.3 for each downwind sector. Tables 11A-4 and 11A-5 provide χ/Q and D/Q values associated with surface-level releases from the containment (considered as entrained in the building wake, and therefore a ground-level release) for the standard population distances. Tables 11A-6 and 11A-7 provide χ/Q and D/Q values associated with a process vent release from 3.048 m above one of the containment structures, or approximately 43 m above grade (considered as a mixed-mode release) for the standard population distances.

Dispersions factors (χ/Q) were calculated using a sector-average, straight-line model specified in Regulatory Guide 1.111. Ground deposition (D/Q) values were calculated according to Regulatory Guide 1.111. The mixed release mode was used as applicable for a release height of 3.05 m above the 40.1-m containment from a 0.08-m-diameter vent at an exit velocity of 30.5 m/s. Qualifying elevation release heights were adjusted for momentum stack downwash, and terrain rise, as described in Regulatory Guide 1.111.

The open terrain correction factor for χ/Q and D/Q values was applied in accordance with Figure 2 of Regulatory Guide 1.111. As described in References 2 and 3 and in Table 11A-8, the terrain is flat and rises to less than about 170 feet out to a distance of 50 miles near Richmond.

Therefore, straight-line airflow trajectory regimes are considered to reasonably represent dispersion conditions as related to annual χ/Q values in the vicinity of the Surry Power Station.

The calculation χ/Q and D/Q values were based on onsite meteorological data during the period March 3, 1974, to March 2, 1975, and May 1, 1975, to April 30, 1976. Representative joint frequency distributions were developed for ground-level or elevated releases from the station as follows:

1. Ground-level release χ/Q and D/Q calculations were based on meteorological tower observations of wind speed and direction at the 35-foot level and of temperature differential (delta T) between the 150- and 35-foot levels. These levels were selected to conservatively represent the transport and diffusion of surface releases in the vicinity of the plant, or for vent releases entrained in the building wake. The σ_z diffusion parameter was based on the curves in Figure 1 of Regulatory Guide 1.111.
2. Qualifying elevated release χ/Q and D/Q calculations were based on meteorological tower observations of wind speed and direction at the 150-foot level and of the same temperature differential (delta T) between the 150- and 35-foot levels, as representing the environment of the plume between its release height and the ground.

11A.3 PLANT AND ANIMAL CENSUS

The plant and animal census is conducted annually in order to determine the current land use of the area surrounding Surry Power Station. The purpose of the census is to locate the distance to the nearest milk cow or other bovine, milk goat, vegetable garden, and residence within 5 miles of the Surry Power Station. The annual land use is detailed in the current radiological environmental monitoring report.

11A.4 DOSE CALCULATIONS

11A.4.1 Doses From Liquid Effluents

Liquid source terms were calculated for two specific cases using the GALE Code: the liquid radwaste system as presently operating and as the system operated with the blowdown treatment system, which is no longer used. These cases are indicated below:

1. Dirty wastes treated by a system consisting of two mixed-bed demineralizers and no treatment of steam generator blowdown.
2. Same as 1 above, only steam generator blowdown treated by two mixed-bed demineralizers. (This equipment is no longer used.)

Inputs to the GALE Code were based on (1) station operating experience, (2) information supplied previously in Chapter 11 and the Environmental Report (ER) (References 8 & 9), and (3) NUREG-0017. Source terms for each of the two cases outlined above are presented in

Tables 11A-9 and 11A-10.

Liquid radioactive wastes from the units are released to the James River via the discharge canal. Possible pathways of exposure for release from the station include ingestion of fish and invertebrates and shoreline activities. The irrigated food pathway does not exist at this location, nor does the potable water pathway. For all pathways, a river dilution factor of 5 was assumed as appropriate per Regulatory Guide 1.109.

Doses from liquid pathways were calculated for the maximum individual, based on the models given in Regulatory Guide 1.109, using the computer code LADTAP. Dose factors, bioaccumulation factors, and shorewidth factors given in Regulatory Guide 1.109 and in the LADTAP code were used, as were usage terms for shoreline activities and ingestion of fish and invertebrates.

Tables 11A-11 and 11A-12 present the LADTAP input data and the maximum individual doses for both cases indicated above.

During normal station operations, doses from liquid effluents are calculated according to the Offsite Dose Calculation Manual (ODCM). Calculations from the ODCM demonstrate compliance with this section.

11A.4.2 Doses From Gaseous Effluents

Gaseous source terms were calculated using the GALE Code, and are presented in Table 11A-13. Inputs to the GALE Code were based on (1) plant operating experience, (2) information supplied in Chapter 11 and the ER, and (3) NUREG-0017.

Doses to the maximum individual from gaseous effluents were calculated by the NRC GASPAR Code, using the models of Regulatory Guide 1.109. Dose factors, annual air intake, intakes of food products, and parameters for calculating radionuclide concentrations in food products as given in Regulatory Guide 1.109 and in the GASPAR Code were used.

Dose contributions from the following pathways were calculated and analyzed in the assessment of the maximally exposed individual:

1. Immersion in the plume.
2. Ground contamination.
3. Inhalation.
4. Consumption of vegetables, meat, and milk.

For dose calculation purposes, the source terms of Table 11A-2 were divided into mixed-mode releases (i.e., those released from the Surry process vent that could be considered to be elevated at certain times and at ground level at others) and ground-level releases (i.e., those released from the ventilation vents, steam generator flash tank, and turbine building). The sources of releases for the Surry process vent are the gaseous waste and containment vacuum systems. For dose calculation purposes, these releases were considered mixed mode, and the χ/Q and D/Q values, as presented in Table 11A-3, reflect this.

The sources of releases from the ventilation vents of the Surry units are the auxiliary, decontamination, and spent fuel buildings, safeguards areas, condenser air ejector, and containment purge systems. For dose calculation purposes, these releases were considered ground level, and the χ/Q and D/Q values, as presented in Table 11A-3, reflect this.

Based on the χ/Q and D/Q values in Table 11A-3, specific locations were analyzed for the location of the maximally exposed individual. When the principal locations were determined, dose calculations were performed, incorporating the pathways specific to each location. By adding the doses resulting from both mixed-mode and ground-level releases for each of the pathways existing at these locations, the location of the maximum individual was determined.

After evaluating the special locations, the maximum organ dose occurred to an infant who resides 3.75 miles north-northwest of the power station and drinks milk from a cow raised at this location. The maximum total body dose occurred to an individual 1.53 miles south of the Surry Power Station. Table 11A-14 presents the doses at the location of the maximally exposed individuals for Surry Units 1 and 2.

Table 11A-15 presents the doses to the above-mentioned individual based on the cooling of steam generator blowdown below 212°F. Operation in this manner eliminates the gaseous releases of I-131 and I-133 from the blowdown vent offgas and results in a reduction of the maximum organ dose by a factor of 5.

During normal station operations, doses from gaseous effluents are calculated according to the Offsite Dose Calculation Manual (ODCM). Calculations from the ODCM demonstrate compliance with this section.

CHAPTER 12 CONDUCT OF OPERATIONS

12.1 ORGANIZATIONAL STRUCTURE OF VIRGINIA ELECTRIC AND POWER COMPANY

12.1.1 Organization

12.1.1.1 Nuclear Participation by Vepco

Vepco has participated in nuclear power activities since the passage of the Atomic Energy Act of 1954. In 1954, Vepco participated in a series of studies with Stone & Webster Engineering Corporation. In 1955, Vepco commenced further studies with Carolina Power & Light Company, Duke Power Company, and South Carolina Electric & Gas Company. In 1956, these four companies formed Carolinas Virginia Nuclear Power Associates, Inc. (CVNPA), a nonprofit, membership organization. Subsequently, under the third-round invitation of the Reactor Demonstration Program, CVNPA built and operated the Carolinas-Virginia Tube Reactor (CVTR), a 65-MWt heavy-water moderated and cooled pressure tube reactor located at Parr, South Carolina. The CVTR achieved criticality for the first time in March 1963. From the early summer of 1964 to 1967, the CVTR produced electric power on a reliable basis. CVNPA, and Westinghouse Electric Corporation as its subcontractor, carried out an extensive research and development program for the NRC both before and after construction of the CVTR. The plant was decommissioned in 1967 after fulfilling the objectives of the program.

Vepco was a significant participant in the work of CVNPA from its incorporation. Employees of Vepco served on the CVNPA Board of Directors and on several of the management committees, including the Steering Committee, the Technical Advisory Committee, and the Manpower Committee. Four Vepco employees were associated with CVNPA on a resident basis and had an integrated total of 22 man-years of project experience in responsible positions relating to design, engineering, construction, operation, maintenance, health physics, and chemistry. Individual periods of resident service with CVTR ranged from 2 to 9 years. In addition, two employees of CVNPA joined the Vepco organization in 1967. These two men had a total of over 7 man-years of experience in the CVNPA organization in positions relating to the operation of the CVTR reactor station. Vepco also participated in the study of the practicality of converting the Savannah River "R" reactor with a member on the study team.

Vepco became affiliated along with many other utilities with the Atomics International Division of North American Rockwell Corporation in a joint effort to promote research and development of the first demonstration liquid-metal fast-breeder facility. In addition, Vepco participated in a study with Gulf General Atomics to develop the gas-cooled fast-reactor concept.

12.1.1.2 Operational Phase

The execution of the Surry Power Station project was solely the responsibility of Vepco. Vepco (hereafter referred to as Virginia Power) engaged Stone & Webster as its agent for engineering and construction and contracted with Westinghouse Electric Corporation for furnishing the nuclear steam supply systems, the nuclear fuel, and the turbine generators.

In addition to these, Virginia Power retained the following consultants:

Site geology, hydrology, and seismology - Dames & Moore, Inc.

Site meteorology, climatology and general nuclear consultation - NUS Corporation

12.1.1.2.1 Virginia Power Organization and Responsibility

The Site Vice President and his organization have full responsibility for maintaining the station as a functional part of the Virginia Power generation system and for operating the station in a reliable, competent manner consistent with the safety of the public, station personnel, and equipment. The station shall be operated in accordance with the license granted by the United States Nuclear Regulatory Commission (NRC), the Technical Specifications, the Updated Final Safety Analysis Report (UFSAR), and the Operational Quality Assurance Program.

The nuclear organization and key individuals' responsibilities are described in Chapter 17 (the Operational Quality Assurance Program). Additionally, station personnel will meet the qualification requirements as specified in the Station Technical Specifications and the Operational Quality Assurance Program.

12.2 TRAINING PROGRAM

12.2.1 General

Personnel to staff the Surry Power Station have been selected to ensure that each individual possesses the educational training and experience necessary to satisfactorily perform his assigned function. To augment the formal education, training and experience of station personnel, training programs have been instituted to familiarize employees specifically with the Surry facility. The training programs are administered by the Corporate Nuclear Training Department, and actual training is performed mainly by site employees, and some by contract personnel from vendor companies.

The principal objectives of the training programs are to ensure initial and continuing qualification of station personnel through effective training, to accommodate future growth, to comply with applicable regulations, and to use the training information contained in relevant guidance documents, including:

1. Administrative Procedures.
2. Title 10 of the Code of Federal Regulations (CFRs), Parts 50 and 55.
3. Surry Power Station Safety Analysis Report documents, including the Updated Final Safety Analysis Report (UFSAR), Facility Operating License (FOL), Technical Specifications, and Operational Quality Assurance Program.
4. OSHA and other applicable regulatory requirements as specified in Titles 29, 40, and 49 of the Code of Federal Regulations.
5. Institute of Nuclear Power Operations (INPO) guidelines and good practices.
6. NRC inspections and INPO evaluations.

12.2.2 Program Description

12.2.2.1 Types of Training

Station personnel may be qualified through a combination of formal job training, on-the-job training, and special training. The types of training include:

1. Occupational training, which includes training efforts intended to develop job knowledge, skills, and employee development required for competent performance of assigned duties. This includes nuclear employee training, technical training, and employee development training.
2. Basic training, which is designed to provide an understanding of fundamentals, basic principles, and procedures involved in the work to which the employee is assigned.
3. Advanced training, which addresses topics typically taught to journeymen or supervisors.

4. Special training, which is site or equipment specific.
5. Periodic continuing training (requalification) designed to maintain the levels of occupational knowledge, skills, and employee development required to perform job duties. The continuing training program reinforces previous training and knowledge, and introduces new information as appropriate.
6. Backfit training, which is designed to remedy deficiencies in an employee's background.

12.2.2.2 **Training Methods**

Training is conducted using one or more of the following methods:

1. Formal job training, which is typically classroom training techniques directed at specific job skills and knowledge.
2. On-the-job training, conducted under the direction of appropriately experienced personnel.
3. Self-study training, where job skills and knowledge may be obtained on an individual basis.
4. Classroom training, which is formal training using a variety of instructional techniques and media and requires the trainees to demonstrate their comprehension of the material through discussions, tests, and/or skills performance.
5. Simulator training, which utilizes a plant-referenced simulator for reinforcement of classroom training and exercise of procedures.
6. Laboratory training, which provides actual hands-on experience in simulated job situations. The laboratory experiences are designed to provide structured and supervised methods of practicing the concepts, principles, and information taught in the classroom. Laboratory training is similar to on-the-job training.
7. Task training, which is designed to assist the trainee in becoming proficient in learning the basic to advanced job tasks.
8. In-house training, which is training conducted by an employee of Virginia Power.
9. Vendor training, which is training conducted by someone external to Virginia Power.

12.2.2.3 **Qualification of Personnel**

The cognizant director or manager is accountable for timely and effective qualification of assigned personnel. He is assisted by the Nuclear Training Department and by the Manager Nuclear Training.

The Nuclear Training Department administers standardized programs to meet station requirements, performs training needs assessments, develops methods and materials in support of nuclear programs, evaluates and arranges for vendor training programs for offsite or onsite presentations, and evaluates the overall effectiveness of the programs.

The station, through the Manager Nuclear Training:

1. Identifies training requirements, schedules, and types of training needed.
2. Schedules training consistent with station and regulatory requirements.
3. Conducts specific training segments on the site.
4. Maintains records of employee qualification, training, and experience.
5. Ensures the training and qualification of station personnel.
6. Makes applications for and maintains licenses and proper certifications required for station personnel.

The Nuclear Training Department, through the Manager Nuclear Training, administers operations staff and Shift Technical Advisor training programs which were originally accredited by the National Academy for Nuclear Training on October 24, 1985.

12.3 EMERGENCY PLANNING

Virginia Power has formulated a comprehensive Station Emergency Plan for coping with all credible emergency situations at the Surry Power Station. The plan and changes thereto are contained in separately bound documents to facilitate future updating independent of the UFSAR.

The Emergency Plans and Implementing Procedures (EPIP) address the design, operation, and staffing of the offsite Corporate Emergency Response Center (CERC) and the onsite Technical Support Center (TSC) and Operational Support Center (OSC) using guidance contained in NUREG-0654 (Reference 1), NUREG-0696 (Reference 2), NUREG-0737 (including Supplement 1) (Reference 3), NEI 99-01 (Reference 7) and SECY-82-111 (Reference 4). The Station Emergency Plan is consistent with the NRC Standard Review Plan (Reference 5) (dated November 1974) and Regulatory Guide 1.101 (Reference 6) (dated November 1975). The Emergency Plan and supporting arrangements for assistance from pertinent Federal, State, and local agencies fully meet the requirements of Appendix E to 10 CFR 50. The Station Emergency Plan also outlines the emergency preparedness training program, including classroom instruction, practical exercises, and demonstrations.

12.4 REVIEW AND AUDIT

Specific review and audit requirements are assigned to various committees in addition to the review and audit requirements assigned to the Virginia Power Nuclear Oversight staff by the quality assurance program for station operation (see Chapter 17). The committees charged with specific review and audit functions are delineated in the facility's Nuclear Facility Quality Assurance Program Description (QAPD).

The Station Nuclear Safety and Operating Committee is charged with first-level review of station operations. The membership of the committee, committee responsibilities and authority, and quorum and meeting requirements are delineated in the QAPD. The members of this committee who are station supervisory personnel meet or exceed the qualification requirements of the QAPD.

Independent review of the safety of nuclear unit operation is performed for the Management Safety Review Committee by its Safety and Compliance Subcommittee. The organization and responsibilities of the Management Safety Review Committee are described in the QAPD.

Maintenance and modifications of safety-related equipment are controlled and documented in accordance with the requirements of a formal quality assurance program for station operation and other administrative controls formulated by written procedures. Audits of quality assurance programs are periodically conducted as delineated in the operational quality assurance program. The quality assurance programs pertinent to station operation are discussed in the QAPD.

Intentionally Blank

12.5 PLANT PROCEDURES

Detailed procedures for the following station operations have been prepared as recommended by Regulatory Guide 1.33 (Reference 1) and associated attachments:

- Administrative Procedures
- General Plant Operations
- System Operations
- Abnormal and Alarm Conditions
- Emergency Operations
- Radioactivity Control
- Measuring and Test Equipment Control
- Maintenance and Preventative Maintenance
- Chemical and Radiochemical Control

Other types of procedures not covered by this list may also be required during plant operation. However, procedures are subject to various controls to ensure that personnel are provided with accurate, usable guidance and information. These controls are discussed in the operational quality assurance program (Chapter 17). Action has also been taken to respond to guidance contained in NUREG-0737 (Reference 3) for evaluation and development of procedures for transients and accidents.

A continuing process of review, training, and practice drills, as detailed in the Technical Specifications and operational quality assurance program, maintain the functional effectiveness of the procedures. In addition, procedures are in place for the feedback of industry operating experience to the plant operations staff. Part of the feedback function is accomplished through the use of the INPO SEE-IN Program (Reference 4), which was endorsed by the NRC staff in Generic Letter 82-04 (Reference 5).

12.6 PLANT RECORDS

Records documenting the nuclear operation and maintenance of and modifications to the station shall be stored at a location approved by Virginia Power and in accordance with requirements in the operational quality assurance program (Chapter 17) governing the storage of Quality Assurance Records. Operating records will be maintained as delineated in regulatory requirements, the administrative controls section of the applicable unit’s Technical Specifications, and the Operational Quality Assurance Program commitments.

Intentionally Blank

12.7 INDUSTRIAL SECURITY

Physical protection of Surry Power Station Units 1 and 2 is based on controlling access to the facility, selecting station operating personnel, monitoring station equipment, designing and arranging station features, and obtaining assistance from local law enforcement authorities. Design of the security plan is guided by 10 CFR 73, Sections 55, 56, 57, Appendices B & C. Implementation of security procedures shall be in accordance with the approved station security plan. Protection of safeguards information is provided as described in 10 CFR 73.21.

Intentionally Blank

12.8 SHIFT PERSONNEL

The positions, qualifications, duties, and responsibilities of station personnel assigned to rotating shifts are described in, and implemented in accordance with, the Technical Specifications and administrative procedures. Technical Specifications and administrative procedures also define minimum shift crew requirements pursuant to guidance contained in NUREG-0737 (Reference 1) and NRC Generic Letter 82-10 (Reference 2). Overtime limits are administratively controlled in accordance with guidance contained in Generic Letter 82-12 (Reference 3).

CHAPTER 13 INITIAL TESTS AND OPERATION

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

13.1 TESTS PRIOR TO INITIAL REACTOR FUELING

The comprehensive testing program ensured that equipment and systems performed in accordance with design criteria prior to fuel loading. As the installation of individual components and systems was completed, they were tested and evaluated according to predetermined and approved written testing techniques, procedures, or check-off lists. Field and engineering analyses of test results were made to verify that systems and components were performing satisfactorily and to recommend corrective action, if necessary.

The program included tests, adjustments, calibrations, and system operations necessary to ensure that initial fuel loading and subsequent power operation could be safely undertaken. In general, the types of tests are classified as hydrostatic, functional, electrical, and operational. Functional tests verified that the system or equipment was capable of performing the function for which it was designed. Operational tests involved actually operating the system and equipment under design or simulated design conditions.

Whenever possible, these tests were performed under the same conditions as experienced under subsequent station operations. During systems tests for which unit parameters were not available and could not be simulated, the systems were operationally tested as far as possible without these parameters.

The remainder of the tests were performed when the parameters were available. Abnormal unit conditions were simulated during testing when such conditions did not endanger personnel or equipment, or contaminate clean systems. The detailed procedure took into account the predicted emergency or abnormal conditions involved in the test program, and appropriate measures were included in the procedure.

During the preoperational tests, piping systems were checked to ensure correct and satisfactory performance under normal operating conditions, including expected routine transients. Any abnormal conditions, such as water hammer, excessive vibration, or displacement were noted and referred to the start-up engineer for investigation. If no abnormal conditions were observed, the system was deemed to be satisfactory and no other action taken. Completed preoperational test procedures are maintained on file at the plant site.

For purpose of illustration, a listing of representative tests required prior to initial reactor fueling is contained in Table 13.1-1. Additional information on the preoperational testing of specific components and systems is contained in the inspection and tests subsections of Chapters 3 through 11. The quality assurance section (15.4.6) contains supplemental information concerning procedural and organizational matters during construction and start-up activities. The operational quality assurance program is discussed in Chapter 17.

Individual systems have system descriptions in which individual equipment tests are listed.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 13.1-1
OBJECTIVES OF SYSTEM TESTS PRIOR TO INITIAL REACTOR FUELING

System Tested	Test Objective
1. Electrical system	To ensure continuity, circuit integrity, and the correct and reliable functioning of electrical apparatus. Electrical tests were performed on transformers, switchgear, turbine generators, motors, cables, control circuits, excitation switchgear, dc systems, annunciator systems, lighting distribution switchboards, communication systems, and miscellaneous equipment. Special attention was directed to the following tests: a. High-voltage switchgear breaker interlock test. b. Station loss of voltage autotransfer test. c. Emergency power transfer test. d. Tests of protective devices. e. Equipment automatic start tests. f. Excitor check for proper voltage buildup. g. Insulation tests.
2. Voice communication system	To verify proper communication between all local stations, for interconnection to commercial phone service, and to balance and adjust amplifiers and speakers.
3. Service water system	To verify, prior to critical operation, the design head-capacity characteristics of the service water system, that the system would supply design flow rate through all heat exchangers, and would meet the specified requirements when operated in the safeguards mode.
4. Fire protection system	To verify proper operation of the system by ensuring that the design intent was met for the fire pumps, to verify that automatic start functions operated as designed, and to verify that level and pressure controls met specifications.
5. Compressed air system	To verify leaktightness of the system, proper operation of all compressors, the manual and automatic operation of controls at design setpoints, design air dryer cycle time and moisture content of discharge air, and proper air pressure to each controller served by the system.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 13.1-1 (CONTINUED)
OBJECTIVES OF SYSTEM TESTS PRIOR TO INITIAL REACTOR FUELING

System Tested	Test Objective
6. Reactor coolant system cleaning	To flush and clean the reactor coolant and related primary systems to obtain the degree of cleanliness required for the intended service. Provisions to maintain cleanliness and protection from contaminated sources were made after system cleaning and acceptance. After systems were flushed clean of soluble and particulate matter, cleanliness of the system was maintained. Coolant was analyzed for chloride content, suspended solids, pH, and conductivity. Oxygen content was analyzed and brought to specifications before exceeding 200°F.
7. Ventilation system	To verify proper operability of fans, controls, and other components of the containment ventilation system and auxiliary ventilation system.
8. Condensate and system feedwater	To verify valve and control operability and set points. An inspection for completeness and integrity was made. Functional testing was performed when the main steam system was available. Flushing and hydrostatic tests were performed where applicable.
9. Auxiliary coolant systems	To verify component cooling flow to components, and to verify proper operation of instrumentation, controllers, and alarms. Specifically, each of the three systems (i.e., component cooling system, including the charging pump cooling system, residual heat removal system, and fuel pit cooling system) was tested to ensure that a. All manually and remotely operated valves were operable manually and/or remotely. b. All pumps performed their design functions satisfactorily. c. All temperature, flow, level, and pressure controllers functioned to control at the required setpoint when supplied with appropriate signals.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 13.1-1 (CONTINUED)
OBJECTIVES OF SYSTEM TESTS PRIOR TO INITIAL REACTOR FUELING

System Tested	Test Objective
9. Auxiliary coolant systems (continued)	d. All temperature, flow, level, and pressure alarms provided alarms at the required locations when the alarm setpoint was reached, and cleared when the reset point was reached. e. Design flow rates were established through the principal heat exchangers.
10. Boron recovery system	To verify valve and control operability and setpoints, flushing and hydrostatic testing were performed as applicable, including inspection for completeness and integrity. Functional testing was performed when a steam supply was available.
11. Chemical and volume control system	To verify, prior to critical operation, that the chemical and volume control system functioned as specified in the system description and appropriate manufacturers' technical manuals. More specifically, that a. All manually and remotely operated valves were operable manually and/or remotely. b. All pumps performed to specifications. c. All temperature, flow, level, and pressure controllers functioned to control at the required setpoint when supplied with appropriate signal(s). d. All temperature, flow, level, and pressure alarms provided alarms at the required locations when the alarm setpoint was reached and cleared when the reset point was reached. e. The reactor makeup control regulated blending, dilution, and boration as designed. f. The design seal-water flow rates were attainable at each reactor coolant pump. g. Chemical addition subsystem functioned as specified.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 13.1-1 (CONTINUED)
OBJECTIVES OF SYSTEM TESTS PRIOR TO INITIAL REACTOR FUELING

System Tested	Test Objective
12. Safety injection system	To verify, prior to critical operation, response to control signals and sequencing of the pumps, valves, and controllers of this system as specified in the system description and the manufacturers' technical manuals; and to check the time required to actuate the system after a safety injection signal was received. More specifically, that a. All manually and remotely operated valves were operable manually and/or remotely. b. For each pair of valves installed for redundant flow paths, disabling one of the valves did not impair operation of the other. c. All pumps performed their design functions satisfactorily. d. The proper sequencing of valves and pumps occurred on initiation of a safety injection signal. e. The fail position on loss of power for each remotely operated valve was as specified. f. Valves requiring initiating signals to operate did so when supplied with these signals. g. All level and pressure instruments were set at the specified points and provided appropriate alarms and resets. h. The time required to actuate the system was within the design specifications.
13. Containment spray system	To verify, prior to critical operation, response to control signals and sequencing of the pumps, valves, and controllers as specified in the system description and the manufacturers' technical manuals; and to check the time required to actuate the system after a containment high-pressure signal was received. More specifically, see the test objective listing for the safety injection system above.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 13.1-1 (CONTINUED)
OBJECTIVES OF SYSTEM TESTS PRIOR TO INITIAL REACTOR FUELING

System Tested	Test Objective
14. Fuel handling system[a]	To show that the system design was capable of providing a safe and effective means of transporting and handling fuel from the time it reaches the station until it leaves the station. In particular, the tests were designed to verify that a. The major structures required for refueling, such as the reactor cavity, refueling canal, new-fuel and spent-fuel storage, and decontamination facilities were in accordance with the design intent. b. The major equipment required for refueling, such as the manipulator crane, fuel-handling tools, and spent-fuel transfer system, operated in accordance with the design specifications. c. All auxiliary equipment and instrumentation functioned properly.
15. Radiation monitoring systems	To verify the calibration, operability, and alarm setpoints of all area radiation monitors, air particulate monitors, gas monitors, and liquid monitors that were included in the process radiation monitor system and the area radiation monitor system.
16. Reactor control and protection system	To verify calibration, operability, and alarm settings of the reactor control and protection system; to test its operability in conjunction with other systems. As an example, the nuclear instrumentation system tests are detailed below.
17. Nuclear instrumentation system	To ensure that the instrumentation system was capable of monitoring the reactor leakage neutron flux from source range through 120% of full power and that protective functions were operating properly. In particular, tests were designed to verify that a. All system equipment, cabling, and interconnections were properly installed.

a. Tests were conducted with a dummy fuel element.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 13.1-1 (CONTINUED)
OBJECTIVES OF SYSTEM TESTS PRIOR TO INITIAL REACTOR FUELING

System Tested	Test Objective
17. Nuclear instrumentation system (continued)	b. The source-range detector and associated instrumentation responded to neutron level changes and that the source-range protection (high-flux-level reactor trip), as well as alarm features and audible count rate, operated properly. c. The intermediate-range instrumentation operated properly; the reactor protective and control features, such as high-level reactor trip and high-level rod stop signals, operated properly; and the permissive signals for blocking source-range trip and source-range high-voltage-off operated properly. d. The power-range instrumentation operated properly; the protective features, such as the overpower trips, permissive, and dropped-rod functions, operated with the required redundancy and separation through the associated logic matrices; and the nuclear power signals to other systems were available and operating properly. e. All auxiliary equipment, such as the start-up rate channel, recorders, and indicators, operated properly. f. All instruments were properly calibrated and all setpoints and alarms were properly adjusted.
18. Radioactive waste system	To verify satisfactory flow characteristics through the equipment, to demonstrate satisfactory performance of pumps and instruments, to check for leak-tightness of piping and equipment, and to verify proper operation of monitors, alarms, and controls. More specifically, that a. All manual and automatic valves were operable. b. All instrument controllers operated to control the system at required values.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 13.1-1 (CONTINUED)
OBJECTIVES OF SYSTEM TESTS PRIOR TO INITIAL REACTOR FUELING

System Tested	Test Objective
18. Radioactive waste system (continued)	c. All alarms were operable at required locations. d. All pumps performed their design functions satisfactorily. e. All pump indicators and controls were operable at required locations. f. All waste gas compressors and blowers operated as specified. g. The gas analyzers and recombiners operated as specified. h. The waste evaporator operated as specified.
19. Sampling system	To verify that a quantity of representative fluid could be obtained safely from each sampling point. In particular, the tests were designed to verify that a. All system piping and components were properly installed. b. All remotely and manually operated valving operated in accordance with the design specifications. c. All sample containers and quick-disconnect couplings functioned properly.
20. Emergency power system	To demonstrate that the system was capable of providing power for operation of vital equipment under power failure conditions. In particular, the tests were designed to verify that a. All system components were properly installed. b. Each emergency diesel functioned according to the design intent under emergency conditions. c. The emergency units were capable of supplying the power to vital equipment as required under emergency conditions. d. All redundant features of the system functioned according to design intent.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 13.1-1 (CONTINUED)
OBJECTIVES OF SYSTEM TESTS PRIOR TO INITIAL REACTOR FUELING

System Tested	Test Objective
21. Hot functional tests	Using pump heat, the reactor coolant system was tested to check heatup and cooldown procedures to demonstrate satisfactory performance of components that were exposed to the reactor coolant temperature; to verify proper operating of instrumentation, controllers, and alarms; and to provide design operating conditions for checkout of auxiliary systems. The chemical and volume control system was tested to determine that water could be charged at rated flow against normal reactor coolant system pressure; to check letdown flow against design rate for each pressure reduction station; to determine the response of the system to changes in pressurizer level; to check procedures and components used in boric acid batching and transfer operations; to check operation of the reactor make-up control; to check operation of the excess letdown and seal-water flow path; and to verify proper operation of instrumentation controls and alarms. The sampling system was tested to determine that a specified quantity of representative fluid could be obtained safely and at design conditions from each sampling point. The component cooling system was tested to evaluate its ability to remove heat from systems containing radioactive fluid and other special equipment under varied service water conditions; to verify component cooling flow to all components; to verify that the charging pumps cooling water subsystem functioned as designed; and to verify proper operation of instrumentation, controllers, and alarms. Following this hot function test, the reactor internals were examined for evidence of vibration.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 13.1-1 (CONTINUED)
OBJECTIVES OF SYSTEM TESTS PRIOR TO INITIAL REACTOR FUELING

System Tested	Test Objective
22. Pressurizer level control system	To ensure that the system was capable of monitoring the full range of pressurizer level and to verify alarms and setpoints. Also to verify that the system, in conjunction with the chemical and volume control system, controlled pressurizer level.
23. Rod position indication system	To check the system's response to test signals and to verify correct indicating and control functions. After fuel loading and after the position indication coils were installed, a calibration check and a complete operational check were performed by operating individual control rod drive mechanisms.
24. Reactor thermocouple instrumentation	To check and calibrate the system and compare thermocouple readings with other temperature instrumentation indications up to the maximum allowable temperature.
25. Auxiliary steam generator feedwater pumps.	To verify that all pumps performed their design functions satisfactorily.
26. Primary system safety and relief valves	To verify correct relief and lift pressures as necessary.
27. Cold hydrostatic tests	To verify the integrity and leaktightness of the reactor coolant system and auxiliary primary systems with the performance of a hydrostatic test at the specified test pressure.
28. Main steam trip valves	To verify that the valves would terminate steam flow to the turbine by testing at steam temperature and pressure associated with hot functional conditions.
29. Heat tracing check	To verify operations of the circuits and controls of the heat tracing system and safety-related equipment and to obtain a set of equilibrium data under static flowing and nonflowing conditions.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 13.1-1 (CONTINUED)
OBJECTIVES OF SYSTEM TESTS PRIOR TO INITIAL REACTOR FUELING

System Tested	Test Objective
30. Pressurizer relief tank	To verify that the system responded accurately to low- and high-level and high-pressure setpoints; that the nitrogen cover gas system will maintain a nitrogen atmosphere at the required pressure; that the oxygen content of the gas space can be reduced and maintained within chemistry requirements; that the remotely operated valves for maintaining tank level operate correctly.
31. Residual heat removal system	To verify that the valve interlocks, flow controls, alarms, and indications operate properly.
32. Containment isolation valves test	To verify that the valves that provide containment isolation during accident conditions operate as designed.
33. Containment leakage test	To prepare the containment for the structural test and to provide a pre-operational containment leakage rate.
34. Containment personnel air lock and equipment hatch	To verify the leaktightness of the system.
35. CLS “Hi” and “Hi-Hi” system operation	To verify the proper operation of the systems. The test verified that all relays associated with the CLS “Hi” operated properly and that all signals were generated and all “logic” verified; the CLS “Hi-Hi” test verified the initiation of start signals to No. 2 and No. 3 EDGs and that the lockout circuitry to No. 3 EDG functioned properly.
36. Charging pump control circuit	To verify breaker interlocks, charging pump start signals, and breaker trip signals in the system.
37. Incore movable detector system	To provide an initial calibration of the upper and lower limit stop setpoints for the flux thimbles, and establish the slipping torque for the slip clutch.
38. Reactor coolant loop isolation valves	To verify that the interlocks associated with the reactor coolant isolation valves performed as designed.
39. Reactor coolant pump initial check	To verify reactor coolant pump operating valves and to establish a correlation between seal-water flow and the thermal barrier differential pressure

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 13.1-1 (CONTINUED)
OBJECTIVES OF SYSTEM TESTS PRIOR TO INITIAL REACTOR FUELING

System Tested	Test Objective
40. Reactor coolant system thermal expansion	To verify that all piping and components within the test boundary would expand freely and operate without interfering with other systems, components, and structures.
41. Operation from the auxiliary shutdown panel	To verify the capability of maintaining hot shutdown conditions from outside the control room at the auxiliary shutdown panel for a minimum of 4 hours.
42. Electric hydrogen recombiner	To demonstrate the performance of the electric hydrogen recombiner by running it at a set power and recording the temperatures reached and measuring the air flow through the recombiner.

13.2 FINAL STATION PREPARATION

Fuel loading began when all prerequisite system tests and operations were satisfactorily completed and the facility operating license was obtained. Upon completion of fuel loading, the reactor upper internals and pressure vessel head were installed, and additional mechanical and electrical tests were performed. The purpose of this phase of activities was to prepare the system for nuclear operation and to establish that all design requirements necessary for operation had been achieved. The core-loading and postloading tests are described below.

13.2.1 Core Loading

The overall responsibility and direction for the initial core loading was exercised by the Station Manager, assisted by the Superintendent - Station Operations.

The overall process of initial core loading was normally directed from the operating floor of the containment structure.

Standard procedures for the control of personnel and the maintenance of containment security were established prior to fuel loading.

Westinghouse provided technical advisors to assist during the initial core-loading operation.

The as-loaded core configuration was specified as part of the core design studies conducted in advance of station start-up, and as such was not subject to change at start-up.

The core was assembled in the reactor vessel, submerged in water containing enough dissolved boric acid (at least 1500 ppm boron) to maintain a core effective multiplication factor (K_{eff}) of 0.90 or lower.

The refueling cavity was dry during initial core loading.

Core moderator chemistry conditions (particularly boron concentration) were prescribed in the core-loading procedure document and were verified periodically by chemical analysis of moderator samples taken before and during core loading.

Core-loading instrumentation consisted of two permanently installed source range (pulse type) nuclear channels, two temporary incore source range channels, and a third temporary channel that could be used as a spare.

The permanent channels were monitored in the control room by licensed station operators; the temporary channels were installed in the containment structure and monitored by reactor engineering personnel.

At least one channel and one temporary channel were equipped with audible count range indicators. Both channels and both regular temporary channels displayed neutron count rates on count-rate meters and strip-chart recorders.

Minimum count rates of two counts per sec, attributable to core neutrons, were required on at least two of the four available nuclear channels at all times during core-loading operations.

Two artificial neutron sources were introduced into the core at appropriate specified points in the core-loading program to ensure a neutron population large enough for adequately monitoring the core.

Fuel assemblies, together with inserted components (control rod assemblies, burnable poison inserts, source spider, or thimble plugging devices), were placed in the reactor vessel one at a time according to a previously established and approved sequence that was developed to provide reliable core monitoring with minimum possibility of core mechanical damage.

The core-loading procedure documents included a detailed tabular check sheet that prescribed and verified the successive movements of each fuel assembly and its specified inserts from its initial position in the storage racks to its final position in the core.

Multiple checks were made of component serial numbers and types at successive transfer points to guard against possible inadvertent exchanges or substitutions of components.

An initial nucleus of eight fuel assemblies, the first of which contained an activated neutron source, was the minimum source-fuel nucleus that would permit subsequent meaningful inverse count-rate monitoring. This initial nucleus was determined by calculation and previous experience to be markedly subcritical (K_{eff} = 0.90) under the required conditions of loading.

Each subsequent fuel addition was accompanied by detailed neutron count-rate monitoring to determine that the just-loaded fuel assembly had not excessively increased the count rate and that the extrapolated inverse count-rate ratio was not decreasing for unexplained reasons.

The results of each loading step were evaluated by Vepco before the next prescribed step was started.

Criteria for safe loading required that loading operations stop immediately if:

1. The neutron count rates on all responding nuclear channels doubled during any single loading step after the initial nucleus of eight fuel assemblies had been loaded.
2. The neutron count rate on any individual nuclear channel increased by a factor of five during any single loading step.

An alarm in the containment and main control room was coupled to the source range channels with a setpoint at five times the current count rate. This alarm would have automatically alerted the loading operation to an indication of high count rate and would have required an immediate stop of all operations until the incident was evaluated by Vepco and by technical advisors.

If the licensed station operation in the control room had determined that an unacceptable increase in count rate was being observed in any or all responding nuclear channels, he would have executed one or a combination of the prepared special procedures that involved withdrawing fuel from the core, manually actuating the containment evacuation alarm, or charging concentrated boric acid into the moderator. In actuality, no difficulties were encountered on either Unit 1 or Unit 2, and core loading was satisfactorily completed in accordance with applicable procedures.

Core-loading procedures specified alignment of fluid systems to prevent inadvertent dilution of the reactor coolant, restricted the movement of fuel to preclude the possibility of mechanical damage, prescribed the conditions under which loading could proceed, identified chains of responsibility and authority, and provided for continuous and complete fuel and core component accountability.

13.2.2 Postloading Tests

Upon completion of core loading, the reactor upper internals and the pressure vessel head were installed and additional mechanical and electrical tests were performed prior to initial criticality.

The final hydrostatic tests were conducted after filling and venting were completed.

Mechanical and electrical tests were performed on the control rod drive mechanisms under both cold and hot conditions. These tests included a complete operational checkout of the mechanisms.

Checks were made to ensure that the control rod assembly position indicator coil stacks were connected to their position indicators. Similar checks were made on control rod drive mechanism coils.

Tests were performed on the reactor trip circuits to test manual trip operation, and actual control rod assembly drop times were measured for each control rod assembly.

By use of dummy signals, the reactor control and protection system was made to produce trip signals for the various unit abnormalities that required tripping.

At all times that the control rod drive mechanisms were being tested, the boron concentration in the coolant-moderator was large enough (approximately 1500 ppm boron) that criticality could not be achieved with all control rod assemblies out.

Furthermore, the number of control rod assemblies operated at any one time was restricted to no more than approximately half the total number of assemblies.

A complete functional electrical and mechanical check was made of the incore nuclear flux mapping system at the operating temperature and pressure.

Intentionally Blank

13.3 INITIAL TESTING IN THE OPERATING REACTOR

After satisfactory completion of fuel loading and final station tests, nuclear operation of the reactor was begun. The final phase of start-up and testing included initial criticality, initial unit verification testing, zero power testing, and power level escalation. The purpose of these tests was to establish the operational characteristics of the unit and core, to verify design predictions, to demonstrate that license requirements had been met, and to ensure that the next prescribed step in the test sequence could be safely undertaken. A brief description of the testing is presented in the following sections. Table 13.3-1 summarizes the tests that were performed from the initial core loading to rated power.

13.3.1 Initial Criticality

Initial criticality was established by sequentially withdrawing the shutdown and control groups of control rod assemblies from the core, leaving the last withdrawn control group inserted far enough in the core to provide effective control when criticality was achieved, and then slowly and continuously diluting the heavily borated reactor coolant until the chain reaction was self-sustaining.

Successive stages of control rod assembly group withdrawal and of boron concentration reduction were monitored by observing changes in neutron count rate, as indicated by the regular source range nuclear instrumentation, as functions of control rod assembly group position and, subsequently, of primary-water addition to the reactor coolant system during dilution.

Primary safety reliance was based on inverse count-rate ratio monitoring as an indication of the nearness and rate of approach to criticality of the core during control rod assembly group withdrawal and during reactor coolant boron dilution. The rate of approach was reduced as the reactor approached extrapolated criticality to ensure that effective control was maintained at all times.

Written procedures specified alignment of fluid systems to allow controlled start and stop and adjustment of the rate at which the approach to criticality could proceed, indicated values of core conditions under which criticality was expected, specified allowed deviations in expected values, and identified chains of responsibility and authority during reactor operations.

13.3.2 Initial Unit Verification Tests

Upon establishment of criticality, a series of tests was initiated to determine the overall unit behavior and to check out the system under operating conditions. The initial tests consisted of selected zero-power physics measurements and power escalation tests to ensure safe reactor operation while performing the overall unit checkout.

The selected zero-power measurements were made at or near operating temperature and pressure, and consisted of measurements of control rod assembly group reactivity worth, boron concentration reactivity worth, isothermal temperature coefficient, and the boron concentration and power distribution with all control rod assemblies out. Concurrent tests were conducted on the unit instrumentation, including the source and intermediate range nuclear channels. Control rod assembly operation and the behavior of the associated control and indicating circuits were demonstrated under zero-power operating conditions. The results of these tests and measurements were compared to the expected design behavior and the results were reported for each unit as an appendix to each start-up test report (References 1 & 2). The remainder of the initial station verification tests were performed during power escalation to no more than 40% of full power.

The purpose of the above nuclear tests was to survey overall station performance and to determine the adequacy of the design and the integrity of the systems used.

Detailed procedures specified the sequence of tests and measurements conducted and the conditions under which each was performed. If deviations from design predictions had existed or if apparent anomalies had developed, the testing would have been suspended and, prior to resumption of testing, the situation would have been reviewed by Vepco to determine whether a question of safety was involved. In actuality, no difficulties were encountered on either Unit 1 or Unit 2, and initial unit verification was satisfactorily completed in accordance with applicable procedures.

13.3.3 Zero-Power Testing

A prescribed program of reactor physics measurements was undertaken to verify that the basic static and kinetic characteristics of the core were as expected and that the values of the kinetic coefficients assumed in the safeguards analysis were indeed conservative.

The measurements were made at zero power and primarily at or near operating temperature and pressure. The measurements included verification of calculated values of control rod assembly group and unit reactivity worths, of isothermal temperature coefficient under various core conditions, of differential boron concentration reactivity worth, and of critical boron concentrations as functions of control rod assembly group configuration. Relative power distribution checks were made in normal and abnormal control rod assembly configurations.

Detailed procedures were prepared to specify the sequence of tests and measurements to be conducted and the conditions under which each was to be performed to ensure both safety of operation and the relevance and consistency of the results obtained.

13.3.4 Power Level Escalation

When the operating characteristics of the reactor and unit were verified by the preliminary zero-power tests, a program of power level escalation in successive stages brought the unit to its full rated power level. Both reactor and unit operational characteristics were closely examined at each stage and the relevance of the safeguards analysis was verified before escalation to the next programmed level was effected.

Reactor physics measurements were made to determine the magnitudes of reactivity effects, of control rod assembly group differential reactivity effects, of control rod assembly group differential reactivity worth, and of relative power distribution in the core as functions of power level and control rod assembly group position.

Concurrent determinations of primary and secondary heat balances ensured that the several indications of power level were consistent and provided bases for calibration of the power range nuclear channels. The ability of the reactor control and protection system to respond effectively to signals from primary and secondary instrumentation under a variety of conditions encountered in normal operations was verified.

At prescribed power levels the response characteristics of the reactor coolant and steam systems to dynamic stimuli were evaluated. The responses of system components were measured for 10% loss of load and recovery, 50% loss of load and recovery, turbine trip, and the trip of a single control rod assembly.

After the rated power level was achieved, a series of load follow tests was performed at selected power level escalation steps. The results of these tests gave actual reactor and unit behavior under operating conditions and were used to verify predicted load-follow capabilities.

Adequacy of radiation shielding was verified by gamma and neutron radiation surveys inside the containment and the outside area immediately adjacent to the containment.

The sequence of tests, measurements, and intervening operations was prescribed in the power escalation procedures, together with specific details relating to the conduct of the several tests and measurements. The measurement and test operations during power escalation were similar to normal operations.

13.3.5 Poststart-Up Surveillance and Testing Requirements

Poststart-up surveillance and testing requirements are designed to provide assurance that essential systems, including equipment components and instrument channels, are always capable of functioning in accordance with their original design criteria. These requirements can be separated into two categories:

1. The system must be capable of performing its function, i.e., pumps deliver at design flow and head, and instrument channels respond to initiating signals within design calibration and time responses.
2. Reliability is maintained at levels comparable to those established in the design criteria and during early station life.

The testing requirements, as described in the Technical Specifications, establishing this reliability and, in addition, provide the means by which this reliability is continually reconfirmed. Verification of operation of complete systems is checked at refueling intervals. Individual checks of components and instrumentation are made at more frequent intervals, as outlined in the Technical Specifications.

The techniques used for the testing of instrument channels included a preoperational calibration that confirmed values obtained during factory test programs. These reconfirmed calibration values became the reference for recalibration maintenance at refueling intervals during station life. Periodic testing, as defined in the Technical Specifications, includes the insertion of a predetermined signal that will trip the channel bi-stable. Indication of the operation is confirmed and recorded.

Testing of components is initiated through manual actuation. If response times are important, they are measured and recorded. The capability to deliver design output is checked by instrumentation and compared against design data. Allowable discrepancies are established in the Technical Specifications. The component is operated sufficiently long to allow the equalization of operating temperatures in bearings, seals, and motors. Checks are made on these parameters. The component is surveyed for excessive vibration. Readings are recorded.

It is believed that testing in accordance with the above described program provides a realistic basis for determining maintenance requirements, and, as such, ensures continued system capabilities, including reliability equal to that established in the original criteria.

Table 13.3-1
INITIAL TESTING SUMMARY

Tests	Conditions	Objectives	Acceptance Criteria
Control rod assembly drop tests	a. Cold shutdown b. Hot shutdown	To measure the drop time of control rod assemblies under full-flow and no-flow conditions	Drop time less than value in Technical Specifications
Thermocouple/ RTD inter-calibration	Various temperatures during system heatup at zero power	To determine in-place isothermal correction constants for all core exit thermocouples and reactor coolant RTDs	Sensors showing excessive deviations from average were removed from service or replaced
Nuclear design check tests	All two-dimensional control rod assembly group configurations at hot zero power	To verify that nuclear design predictions for endpoint boron concentrations, isothermal temperature coefficients, and power distributions were valid	Within limits established in FSAR for $\delta\rho/\Delta T$ and $F_{\Delta H}$
Control rod assembly group worth	All control rod assembly groups at hot zero power	To verify that nuclear design predictions for control rod assembly group differential worths with and without partial length control rod assemblies were valid	Within limits established in FSAR for $\Delta p/\Delta h$, p/h, $\delta/\Delta h$, and $\Delta p/h$
Power and Doppler coefficient measurement	0 to 92% of rated power	To verify that nuclear design predictions for differential power coefficients and Doppler reactivity coefficients were valid	Technical Specification limiting values
Power and Doppler reactivity defects	0 to 92% of rated power	To verify that nuclear design predictions for power and Doppler reactivity defects were valid	Technical Specifications limiting values

Table 13.3-1 (CONTINUED)
INITIAL TESTING SUMMARY

Tests	Conditions	Objectives	Acceptance Criteria
Automatic control system	Approximately 30% of rated power	To verify control system response characteristics for: 1) Steam generator level control system 2) Control rod assembly automatic control system 3) Turbine control system	Applicable FSAR criteria
Load swing test	10% steps at 35, 75, and 100% of rated power	To verify reactor control performance	Applicable unit performance criteria
Station trip	Full-load rejection from 50 and 100% of rated power	To verify reactor control performance	Applicable unit performance criteria
Pressurizer spray effectiveness test	Hot shutdown	To verify that pressurizer pressure is reduced at the required rate by pressurizer spray actuation	Applicable unit performance criteria
Minimum shutdown verification	Hot zero power	To verify the nuclear design prediction of the minimum shutdown boron concentration with one stuck control rod assembly	Stuck control rod assembly shutdown criteria
Static rod insertion and rods-out-of-position test	50% of rated power	To verify that a single control rod assembly inserted fully or part-way below the control bank is detected by ex-core nuclear instrumentation, core exit thermocouples under typical operating conditions, and to provide bases for adjustment of protection system setpoints	Inserted control rod assembly detectable with station instrumentation

Table 13.3-1 (CONTINUED)
INITIAL TESTING SUMMARY

Tests	Conditions	Objectives	Acceptance Criteria
Step load reduction test	Reduction from 75% to 25% of rated power Reduction from 100% to 50% of rated power	To verify operation of reactor control system	Applicable unit performance report criteria
Dynamic control rod assembly drop test	45% of rated power	To verify automatic detection of dropped control rod stop and turbine cutback	Required power reduction and control rod assembly withdrawal block accomplishment
Turbine-generator start-up tests	Pre- and postsynchronization	To verify that the turbine-generator unit and associated controls and trips were in good working order and ready for service	Successful completion of all mechanical, electrical, and control functional checks
Turbine generator	0 to 75% of rated power	To verify normal trouble-free performance of the turbine generator at low power	Performance within manufacturer's limitations
Acceptance run	100 hr at rated power	To verify reliable steady-state full-power capability	100 hr equilibrium operation at full power
Station blackout test (loss of offsite power only)	Unit 1: 10% of rated power Unit 2: 37% of rated power	To verify the ability of the station control and protection systems to bring the plant safely to the hot shutdown condition following the loss of power to the 4160-V emergency buses	Emergency diesel generators start and restore power to emergency buses; both reactor and turbine are tripped; relays and breakers respond properly to de-energize the emergency buses on under-voltage and re-energize them from the diesel generators

Table 13.3-1 (CONTINUED)
INITIAL TESTING SUMMARY

Tests	Conditions	Objectives	Acceptance Criteria
Steam generator moisture carryover	Unit 1: 90%/100% of rated power Unit 2: 90, 95, and 100% of rated power	To verify that moisture carryover (averaged over all three steam generators) is less than 0.25%	Less than 0.25% moisture carryover (averaged over all three steam generators)
Rod drive mechanism stepping test	a. Cold shutdown b. Hot shutdown	To verify that each individual rod could be properly stepped from one position to another	Rod speeds and movement within Technical Specification limits
Part-length rod mechanism brake test	Shutdown	To ensure engagement of brake mechanism on application of current	Smooth operation of the engagement and disengagement of the part-length rod brake mechanism
Rod control system	Shutdown	To verify that the full-length rod control system performed properly	Smooth operation with rod position indicators and step counters verifying proper rod motion when in both “bank select” and “manual” mode of operation
Reactor coolant system flow measurement	Shutdown	To verify that the actual flow rates were equal to or greater than design flow rates	Applicable flow rate criteria
RTD bypass loop flow verification	Hot shutdown	To verify adequate flows through the RTD bypass loops	Applicable flow rate criteria
Containment shielding test	Hot zero power, 30, 50, 75, and 92%	Obtain actual radiation levels at specified locations and power levels	Levels are within design criteria

Table 13.3-1 (CONTINUED)
INITIAL TESTING SUMMARY

Tests	Conditions	Objectives	Acceptance Criteria
Ex-core detector behavior	Various power levels	To develop curves of incore/ex-core axial offsets for each ex-core detector and to develop plots of the sum of top and bottom detector currents versus power and full-power normalized detector currents versus axial offset	Within design specifications
Overpower and overtemperature delta T calibration	Hot shutdown, start-up, 75 and 92%	To ensure protection against excessive power levels and to protect the core against DNB	System calibrated to Technical Specifications
Delta flux calibration	Shutdown	To calibrate the reactor core power axial offset contribution to overpower and overtemperature delta T setpoints	Set to Technical Specification limits
Static rod drop measurement	48% power	To determine effect of the dropping of a full-length control rod assembly on the hot-channel factors	Within design limits
Rod ejection measurements	Hot, zero power, 32% Unit 1, 50% Unit 2	To confirm that the control rod insertion limits are satisfactory	Within design limits
Power distribution measurements	Hot, zero power, 75%	To obtain the core power distribution and flux maps	Within design criteria
Flow coastdown	Hot shutdown	To obtain reactor coolant flow coastdown rates	Within limits specified in FSAR
Nuclear design check	Hot shutdown	Determine differential and integral worth of the controlling RCC bank and differential boron worth over the range of controlling RCC bank	Applicable design criteria

Intentionally Blank

13.4 OPERATING RESTRICTIONS

13.4.1 Safety Precautions

The measurements and test operations during zero power and power escalation were similar to normal station operations at power, so that normal safety precautions were adequate.

13.4.2 Initial Operation Responsibilities

Vepco had overall responsibility for supervising and directing all phases of testing. Technical responsibility for each individual phase of actual start-up resided with the functional group most directly concerned with the results of the phase. Stone & Webster and Westinghouse had onsite representatives of supporting functional groups to provide technical advice, provide recommendations and assistance in planning, and execute the respective phases of unit start-up. Specific responsibilities during each phase of testing are discussed in preceding sections.

All system operations in the testing program were performed by station operators in accordance with the approved written procedures. These procedures included such items as the delineation of administrative procedures and test responsibilities, equipment clearance procedures, test purpose, conditions, precautions, limitations, and sequence of operations.

The methodology used in the preparation, review, approval, and revision of initial operating procedures is briefly described below.

The initial draft of each operating procedure was written by a member of the station staff knowledgeable in the operation of the system under consideration. After review by the Superintendent - Station Operations, the Operating Supervisor, or the Supervisor - Engineering Services, the procedure was submitted to the Station Nuclear Safety and Operating Committee for review and approval. The purpose of this was to ensure that the procedure was in accordance with other established procedures, clear in content, met the design criteria specified, and met the safety requirements for sound operating practices. If a procedure was found to be unsatisfactory by the committee, the necessary correction was made by the individual(s) originally preparing the procedure wherever possible, to provide continuity. All procedures approved by the committee were signed and dated by the committee chairman before implementation by the Operating Department.

Any minor procedural change found necessary after initial committee approval was obtained was to be forwarded through the Operating Supervisor and Superintendent - Station Operations for comment. Further review and approval was to be obtained from the Station Manager before the minor procedural change was implemented.

Any significant change was to be handled in the same manner as the approval required for the initial operating procedure.

Test procedures stating the test purpose, conditions, precautions, limitations, and criteria for acceptance were prepared for each test by station personnel with assistance from Westinghouse and Stone & Webster technical advisors. Before implementation, all such procedures were reviewed and approved by Vepco's senior personnel in accordance with approved standard administrative procedures.

As part of the precautions, all licensed senior reactor operators and manufacturer's representatives whose equipment was being tested were instructed to stop a test or a portion of a test if the test was not being performed safely or in accordance with the written test procedure. The test procedure was reviewed and approved by the Station Manager or his representative. If substantial revision was required, however, the Station Manager reviewed the change, using the same approach as that used for a new test procedure, before approving continuation.

If the results of preoperational tests, fuel loading, post-fuel-loading tests, or initial operation indicated that system modifications and/or procedural changes were required, the proposed changes were discussed with the Vepco engineering staff at the General Office in Richmond, Virginia. The station staff normally made recommendations or offered solutions before this time, and these accompanied the request for the change as an Engineering Deficiency Report.

Any changes that could alter the operation of the station were to be handled under the following three categories:

1. Changes not affecting the approved design or operation of the station, but considered primarily for convenience or improvement to operations, could be handled at the station level with the approval of the Station Manager. A report of all such changes was to be forwarded to the Superintendent - Production Operations and the Supervisor - Nuclear Design.
2. Changes that could alter the arrangement or function of a system from the intended approved design were to be reviewed by the Station Nuclear Safety Committee. If approved by the committee, the recommendation was forwarded to the System Nuclear Safety Committee for final approval. If there was no requirement to amend the FSAR, the proposed change was implemented through the Director of Power Station Design.
3. Design changes that would incorporate changes to approved design prints and would affect the operation of the station as described in the FSAR, either by description or drawings, were to be approved by the Station Nuclear Safety Committee and the System Nuclear Safety Committee. The recommended change was forwarded to the Manager of Power Production and the Vice President - Power, respectively. If approved, the Vice President - Power informed the Atomic Energy Commission (AEC) of the requested change. When changes of this type were considered, a full review of the Technical Specifications was conducted, and appropriate approved changes were handled as above through amendments to the Technical Specifications.

Vepco had overall responsibility during plant start-up, including precriticality tests, approach to criticality, and postcriticality operation. The station staff was assisted by the supplier of the nuclear steam supply system, Westinghouse Electric Corporation. Experienced Westinghouse reactor engineers were assigned to the station from fuel loading, through power ascension, until completion of the 100-hr full-load test. These reactor engineers had previously participated in reactor start-ups of similar units and were qualified and knowledgeable in reactor operations. At least one reactor engineer was at the site during all shifts when the reactor was operating. The responsible shift reactor engineer reported directly to the Shift Supervisor and received instructions from him. The reactor engineer acted in an advisory capacity only; Vepco retained responsibility and control of the unit. Reactor specialists (e.g., control engineers) were available and utilized as required.

The results of preoperational and start-up testing were reported to the Atomic Energy Commission in reports dated May 1, 1973 (Unit 1 Start-up Test Report), July 31, 1973 (Unit 2 Start-up Test Report), and July 1, 1976 (Supplement to Surry Units 1 and 2 Start-up Reports).

Intentionally Blank

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

13.5 STEAM GENERATOR POSTREPAIR START-UP TEST PROGRAM

An extensive steam generator repair program was completed in 1979 for Surry Unit 2 and in 1981 for Surry Unit 1. In both cases, a postrepair integrated start-up test program was performed as described below. Refer to Section 10.3.1 for further details on the steam generator repair program.

The subject test program consisted of three phases: construction tests, preoperational tests, and start-up tests. The format of the program followed the intent of Regulatory Guide 1.68, Revision 2 (Reference 1).

The tests in the construction test phase were designed to provide assurance that the construction and installation of new, modified, or replaced equipment in the station were accomplished properly and in accordance with requirements.

The tests in the preoperational test phase were designed to provide assurance that the components and subsystems of new, modified, and original systems function safely within established design criteria. The preoperational tests on new or modified systems were conducted after the successful completion of construction tests and before fuel loading. This test phase also allowed the plant operating staff to become familiar with the operation of a new or modified system and to verify by trial use, to the extent practical, that the operating procedures were adequate.

The tests in the start-up test phase were designed to provide assurance that systems previously demonstrated as functioning safely, and new or modified systems, will function to (1) provide for safe normal operation and high tolerance for system malfunctions and transients; (2) ensure that, in the event of errors, malfunctions, and abnormal conditions, the reactor protection systems and other design features will arrest the event or limit its consequences to defined and acceptable levels; and (3) ensure that adequate safety margins exist for events of extremely low probability or for arbitrarily postulated hypothetical events without substantial reduction in the safety margin for the protection of public health and safety. The start-up tests were performed during and after fuel loading to confirm the design basis and demonstrate that the plant will continue to operate in accordance with design.

Per Criterion 1 of Appendix A to 10 CFR 50, all structures, systems, and components were tested or demonstrated operable to levels commensurate with the importance of their safety function. In addition, the extent of testing varied directly with the amount of construction done to and around the particular equipment or system. The sequence of tests was conducted so that the safety of the plant was never totally dependent on the performance of untested structures, systems, or components.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

13.5.1 Test Phases

Each phase of the integrated start-up test program was composed of a series of tests, as described below.

13.5.1.1 **Construction Test Phase**

The construction test phase consisted of nondynamic instrument, electrical, and mechanical tests included in design change packages for new or modified systems or components.

The installed components and systems were tested and evaluated according to approved design change test procedures. Construction tests were performed to ensure the quality implementation of the design change.

This phase also included the testing of any rework associated with deficiencies found by testing or quality control in the construction test, preoperational test, or start-up test phases.

All safety-related equipment or systems removed for maintenance work underwent instrument, electrical, and mechanical tests included in the maintenance procedure, as applicable. All maintenance tests were conducted by station personnel.

13.5.1.2 **Preoperational Test Phase**

The preoperational test phase consisted of functional tests on new, modified, and affected original equipment and systems. This phase included tests, adjustments, calibrations, and system operations necessary to ensure that the subsequent testing would be safely undertaken. This phase also included a walkdown of systems adjacent to construction work. Any repairs and subsequent testing of equipment were accomplished by a field change to the design change.

Preoperational tests are listed in Table 13.5-1. The actual sequence of individual tests was formulated before the performance of the tests, considering equipment and system availability, and was maintained on an integrated start-up test schedule.

In instances where the performance of components or systems deviated from predicted results, further engineering evaluations, rework, and/or retesting were performed to resolve the discrepancies before the test was considered satisfactory. Systems that had to be modified as a result of the preoperational tests were retested to verify acceptable performance. Components and systems were tested and evaluated according to approved testing procedures. Preoperational tests were performed to verify as nearly as possible the performance of the system under actual operating conditions. Where required, simulated signals or inputs were used to verify the full operating range of the system and to calibrate and align the systems and instruments at these conditions.

13.5.1.3 **Start-Up Test Phase**

The major testing milestones during the start-up test phase are identified and discussed below. Major start-up tests are listed in Table 13.5-2.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

13.5.1.3.1 Post-Fuel-Loading Tests

Systems that are not used during normal plant operation but must be in a state of readiness to perform safety functions were tested or demonstrated operable before plant conditions required them to be available, as defined in the Technical Specifications. Abnormal unit conditions were simulated during testing as required and when such conditions did not endanger personnel or equipment, or contaminate systems whose cleanliness had been established. Fuel loading began when all prerequisite system tests and operations were satisfactorily completed. Upon completion of fuel loading, the reactor upper internals and pressure vessel head were installed. Additional mechanical and electrical tests were performed on the rod control system, rod position indication system, and incore movable detection system. The purpose of this segment of the start-up test phase was to prepare the system for nuclear operation and to establish that all design requirements necessary for operation were achieved.

13.5.1.3.2 Hot Functional Tests

Before initial criticality, the following hot functional tests were performed: heatup of the primary system, thermal expansion testing of affected systems, vibration testing of construction-affected equipment, reactor coolant pump coastdown time check, and steam generator water-hammer testing (auxiliary feed). The final pressure test was conducted in accordance with the Technical Specifications.

13.5.1.3.3 Criticality and Low-Power Physics Tests

On completion of hot functional tests, nuclear operation of the reactor was begun. These final segments of start-up testing included criticality and low-power physics testing. The purpose of these tests was to verify the operational characteristics of the unit and core, to acquire data for the proper calibration of setpoints, and to ensure that operation was within license requirements. The actual sequence of tests was formulated by station engineering and operating personnel, considering test requirements and equipment availability.

Procedures were prepared to specify the sequence of tests and measurements conducted and the conditions under which each was to be performed to ensure safety of operation and consistency of the results obtained. If significant deviations from design calculations existed, or if unacceptable behavior was revealed, or if apparent anomalies developed, the testing was suspended and the situation was reviewed to determine whether a question of safety was involved before the resumption of testing.

13.5.1.3.4 Power Level Escalation Testing

When the operating characteristics of the reactor and unit were verified by low-power physics testing, a program of power level escalation in successive stages was used to bring the unit to its full rated power level. Both reactor and unit operational characteristics were examined at each stage of the power escalation program.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

13.5.1.3.5 At-Power Testing

On completion of power level escalation testing, the following at-power tests were performed: final steam generator carryover testing, final recirculation ratio testing, secondary plant heat balance determination, condensate-polishing chemistry performance testing, and load rejection testing with the condensate polisher.

13.5.2 Extent of Testing

Because of the various amounts of construction done to and around each system, a graded approach for the extent of testing was employed. The tests required for individual components within a system were developed by the Start-up Group and listed on a test matrix for that system.

In areas such as containment, where extensive work had been performed, all equipment and systems were checked during the construction testing, preoperational testing, or start-up testing phase. In areas such as the auxiliary building, where little work had been performed, selected system walkdowns were employed in conjunction with normal station start-up procedures to verify the operability of the equipment.

Systems that were new or had undergone major design-basis changes were subjected to complete component testing and performance testing to verify design and installation.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 13.5-1

POST-STEAM-GENERATOR REPAIR, LIST OF PREOPERATIONAL TESTS AND CHECKS

Test or Check	Plant Condition/Prerequisite	Test Objective
	I. PLANT INSTRUMENTATION	
1. Nuclear instrumentation	Before core loading	Nuclear instruments were aligned and source range detector response to a neutron source checked as the primary source was loaded.
2. Process instrumentation	Ambient and/or at temperature	Required equipment was aligned per station procedures.
	II. REACTOR COOLANT SYSTEM	
1. Pressure boundary integrity		
a. Hydrostatic test	Below 200°F (after verification of cleanliness and fill of system)	Cold hydrostatic testing of each reactor coolant system loop was performed at test pressures as specified by ASME standards for the system. Before pressurization, the affected portions of the system were heated above the minimum temperature for pressurization. The pressure was then increased in increments, and at each increment inspections were made for leakage. Leaky valves or mechanical joints were not a basis for rejecting the test. Overpressure protection was provided during testing.
b. Baseline data for inservice inspection	During preoperational testing	Systems and components that require inspection in accordance with Section XI of the ASME Code were examined for baseline data. Data from these inspections provide baseline data for subsequent inservice inspections.
2. Component tests		
a. Pressurizer safety valve	Ambient pressure	The setpoints of the safety valves were verified using existing station procedures.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 13.5-1 (CONTINUED)

POST-STEAM-GENERATOR REPAIR, LIST OF PREOPERATIONAL TESTS AND CHECKS

Test or Check	Plant Condition/Prerequisite	Test Objective
	III. REACTIVITY CONTROL SYSTEM	
1. Automatic reactor power control test systems	Preoperational testing	The system alignment was verified at pre-operational operational conditions to demonstrate response of the system to simulated inputs. These tests were performed to verify that the systems would operate satisfactorily at power.
	IV. REACTOR PROTECTION SYSTEMS	
1. Reactor protection system	Before core loading	Before core loading, the reactor protection system was tested to demonstrate operability, proper logic, redundancy, and coincidence. The protection channels were verified through to tripping of the reactor trip breakers.
2. Engineered safety features	Before core loading	Before core loading, the engineered safety features logic systems were tested to demonstrate operability, proper logic, redundancy, and coincidence.
	V. POWER CONVERSION SYSTEM	
	Done under startup testing	

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 13.5-1 (CONTINUED)

POST-STEAM-GENERATOR REPAIR, LIST OF PREOPERATIONAL TESTS AND CHECKS

Test or Check	Plant Condition/Prerequisite	Test Objective
	VI. AUXILIARY SYSTEMS	
1. Residual heat removal system	Before core loading	This system was tested by verifying pressure and flow characteristics of the pumps and operation of the isolation valves.
2. Containment instrument air system	Before core loading	The instrument air system, including air receivers and compressors, was tested to verify proper operation.
3. Neutron shield tank cooling system	Before core loading	The system was operationally checked out to verify heat-exchanger operability.
4. Leak detection system	Before and during pre-operational tests	Temperature detectors in the drain lines from pressurizer safety valves and the reactor vessel head seal and their alarm functions were checked. Pressurizer relief tank level and temperature sensors were calibrated, and the associated alarms were checked.
	VII. ELECTRICAL SYSTEM	
1. Emergency power systems	Before core loading	The automatic starting and loading of the diesel generators was demonstrated under loss of emergency bus ac power.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 13.5-1 (CONTINUED)

POST-STEAM-GENERATOR REPAIR, LIST OF PREOPERATIONAL TESTS AND CHECKS

Test or Check	Plant Condition/Prerequisite	Test Objective
	VIII. CONTAINMENT SYSTEMS	
1. Reactor containment	Before core loading	Containment type A leakage tests were performed in accordance with an NRC-approved topical report,[a] which provides for a reduced-duration test. Containment type B and C leakage tests were performed in accordance with Appendix J to 10 CFR 50.
2. Containment isolation	Before core loading	The operation of actuation systems and components used for containment isolation was verified.
	IX. GASEOUS RADIOACTIVITY REMOVAL SYSTEMS	
	Done under start-up testing	
	X. EMERGENCY CORE COOLING SYSTEM	
1. High-pressure safety injection	Before core loading	This system was operationally tested to verify pressure/flow values. Tests were also conducted to check pump operating characteristics. More specifically, the tests checked that a. Valves installed for redundant flow paths operated as designed. b. Pump operating characteristics were verified.

a. BN-TOP-l, Revision J.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 13.5-1 (CONTINUED)

POST-STEAM-GENERATOR REPAIR, LIST OF PREOPERATIONAL TESTS AND CHECKS

Test or Check	Plant Condition/Prerequisite	Test Objective
	X. EMERGENCY CORE COOLING SYSTEM (continued)	
1. High-pressure safety injection (continued)		c. Valves and pumps operated on operator initiation and/or automatically on initiation of a safety injection signal. d. Level and pressure instruments were properly calibrated.
2. Low-pressure safety injection	Before core loading	The low-head safety injection system was checked to verify design flow, flow paths, and pump operating characteristics. More specifically, the system was checked to ensure that a. Valves installed for redundant flow paths operated as designed. b. Pump operating characteristics were verified with the reactor coolant system at ambient conditions. c. Valves and motors operated on operator initiation and/or automatically on initiation of a safety injection signal. d. Level and pressure instruments were properly calibrated. In addition a 100-hr endurance test was performed, and the pump was disassembled and inspected.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 13.5-1 (CONTINUED)

POST-STEAM-GENERATOR REPAIR, LIST OF PREOPERATIONAL TESTS AND CHECKS

Test or Check	Plant Condition/Prerequisite	Test Objective
	XI. FUEL STORAGE AND HANDLING SYSTEM	
1. Refueling equipment (hand tools and power equipment, including protective interlocks)	Before core loading	Tests were performed before core loading to demonstrate the functioning of the fuel transfer system.
	XII. REACTOR COMPONENTS HANDLING SYSTEM	
	Done during start-up	
	XIII. RADIATION PROTECTION SYSTEM	
1. Criticality and area monitors	Before core loading	The radiation alarms associated with core loading were checked out and the alarm setpoints verified.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 13.5-2

LIST OF START-UP TESTS AND CHECKS

Test or Check	Plant Condition/Prerequisite	Test Objective
I. PLANT INSTRUMENTATION		
1. Nuclear instrumentation (out of core)	Before criticality	Just before criticality, all channels were checked to verify high-level trip functions, alarm setpoints, audible count rates where applicable, operation of strip-chart recorders, and any auxiliary equipment.
2. Process instrumentation (temperature, pressure, level, and flow instruments)	Ambient and/or at temperature	Equipment was aligned per station procedures.
II. REACTOR COOLANT SYSTEM		
1. Vibration and amplitude	After fuel loading	Vibration sensors were placed on the main coolant pumps and main coolant piping in order to check for excessive vibration while starting and stopping the pumps.
2. Expansion and restraint	During plant heatup	During the heatup to operating temperature, selected points on components and piping of the reactor coolant system were checked at various temperatures to verify unrestricted expansion. Points of interference detected during the heatup were corrected before increasing the temperature.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 13.5-2 (CONTINUED)

LIST OF START-UP TESTS AND CHECKS

Test or Check	Plant Condition/Prerequisite	Test Objective
II. REACTOR COOLANT SYSTEM (continued)		
3. Integrated hot functional	Heatup and at-temperature hydrostatic testing has been satisfactorily completed and reactor coolant system instruments are aligned and operational. Associated auxiliary systems shall be operational to the extent required to support hot functional testing.	The reactor coolant system was tested using tests pump heat to reverify heatup procedures to demonstrate satisfactory performance of components and systems exposed to reactor coolant system temperature. Proper operation of instrumentation, controllers, and alarms was checked against design operating conditions of auxiliary systems, and setpoints were verified. Among the demonstrations performed were a. To check that water could be charged by the chemical and volume control system at rated flow against normal reactor coolant pressures. b. To check letdown design flow rate for each operating mode. c. To check response of system to a change in pressurizer level. d. To check operation of the excess letdown and seal-water flow paths. e. To check steam generator level instrumentation response to level changes.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 13.5-2 (CONTINUED)

LIST OF START-UP TESTS AND CHECKS

Test or Check	Plant Condition/Prerequisite	Test Objective
II. REACTOR COOLANT SYSTEM (continued)		
3. Integrated hot functional tests (continued)		f. To check thermal expansion of selected system components and piping. g. To perform isothermal calibration of resistance temperature detectors and incore thermocouples. h. To operationally check out the residual heat removal system.
4. Component tests		
a. Pressurizer	At operating temperature	During the hot functional testing, the pressure-controlling capability of the pressurizer was demonstrated to be within the controlling band. With reactor coolant pumps operating and with full spray, the pressure-reducing capability of the pressurizer was verified. With the spray secured and all heaters energized, the pressure-increasing capability of the pressurizer was verified. Pressurizer relief valves were functionally checked.
b. Reactor coolant pumps and motors	At ambient conditions and during heatup and at temperature	As the pumps and motors were placed in operation, they were checked for a. Direction of rotation (initial start only). b. Vibration. c. Power requirements. d. Lubrication. e. Cooling. f. Megger and hi-pot test (as applicable).

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 13.5-2 (CONTINUED)

LIST OF START-UP TESTS AND CHECKS

Test or Check	Plant Condition/Prerequisite	Test Objective
II. REACTOR COOLANT SYSTEM (continued)		
		g. Overload protection.
		h. Correct power supply voltage.
c. Steam generators	At ambient conditions and during heatup and at temperature	The proper operation of instrumentation and control systems of steam generators were checked during heatup and at temperature. The heat transfer capability of the steam generators was demonstrated. The functioning of the blowdown system was checked.
5. Pressure test of reactor coolant system	Before criticality	After core loading and installation of the reactor vessel head and torquing of the reactor vessel head studs, pressure testing was performed in accordance with Technical Specifications.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 13.5-2 (CONTINUED)

LIST OF START-UP TESTS AND CHECKS

Test or Check	Plant Condition/Prerequisite	Test Objective
II. REACTOR COOLANT SYSTEM (continued)		
6. Chemical tests (to establish water quality)	Before heatup during start-up test	Water for reactor coolant system fill and makeup was analyzed for chloride content, conductivity, total suspended solids, pH, clarity, and fluorides to requirements specified by the chemistry manual for the nuclear steam supply system. After core loading and before exceeding 250°F, hydrazine was added to scavenge oxygen before critical operation. Before criticality, at criticality, and during power escalation, chemical analysis was performed to verify requirements.
7. Reactor coolant flow test	Before criticality	After core loading, measurements were made of elbow tap differential pressures to make a relative comparison. At hot shutdown conditions after core loading, measurements of loop elbow differential pressure drops were made. Using these data with the reactor coolant pump performance curve, the calculated flow was verified to the design flow. Flow coastdown and transients after reactor coolant pump stoppages were also determined at shutdown conditions after core loading.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 13.5-2 (CONTINUED)

LIST OF START-UP TESTS AND CHECKS

Test or Check	Plant Condition/Prerequisite	Test Objective
III. REACTIVITY CONTROL SYSTEMS		
1. Chemical and volume control system	At ambient and/or at operating conditions; system components are operationally checked out	Makeup and letdown operations were conducted with the chemical and volume control system to check out the different modes of dilution and boration and to verify flows in the different modes. The adequacy of heat tracing to maintain the required boric acid concentration in solution was verified. The ability to adequately sample was demonstrated.
2. Emergency boration system	During hot functional testing	The pressure/ flow characteristics of the emergency boration system were verified by pumping into the reactor coolant system.
3. Incore monitor system		
a. Incore thermocouples	During heatup and at temperature	During heatup and at temperature, the incore thermocouples were calibrated to the average of the reactor coolant system resistance temperature detectors. All readout and temperature-compensating equipment was checked during the calibration, and isothermal corrections for the operative thermocouples were determined.
b. Movable detector system	At ambient conditions after core loading and critical testing	After core loading, the installation checkout of the movable detector system was completed.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 13.5-2 (CONTINUED)

LIST OF START-UP TESTS AND CHECKS

Test or Check	Plant Condition/Prerequisite	Test Objective
III. REACTIVITY CONTROL SYSTEMS (continued)		
4. Control rod system		
a. Rod control system	Ambient conditions after core loading and critical testing	During the installation check of this system, it was energized and operationally checked out with mechanisms connected to each power supply. The ability of the system to stop the mechanism was verified, the alarm and inhibit functions were checked out, and the values of system parameters were adjusted to specified values. After core loading, the operation of each rod over its full range of travel was demonstrated.
b. Rod drop	Cold and hot plant conditions after core loading	At cold and hot plant conditions after core loading, the drop times of the full-length rods were measured. The drop time is measured from the release of the rod until the rod enters the top of the dashpot. This time was verified to be less than the maximum value specified in the Technical Specifications.
c. Rod position indication	At ambient conditions and at temperature after core loading	During rod control system tests, the position indication system was aligned to provide rod movement indication. Rod bottom setpoints were adjusted during these tests. After plant heatup, individual rod positions were calibrated to within tolerances specified by the test procedure.
IV. REACTOR PROTECTION SYSTEM		
	Done during preoperational testing	

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 13.5-2 (CONTINUED)

LIST OF START-UP TESTS AND CHECKS

Test or Check	Plant Condition/Prerequisite	Test Objective
V. POWER CONVERSION SYSTEM		
1. System tests		
a. Vibration frequency and amplitude	Hot functional testing and/or plant heatup after criticality	When the main turbine was rolled, vibration readings were monitored. (Turbine vibrations were also monitored throughout the power escalation program.) Major equipment (e.g., feedwater pumps and condensate pumps) was operated as it became available and was observed for indications of excessive vibration.
b. Expansion and restraint	During heatup and at temperature	During heatup to operating temperature, selected points on the components and piping of the systems were checked at various temperatures to verify that they could expand unrestricted.
2. Components and individual systems		
a. Steam generator pressure relief and safety valves	Pressure conditions	The setpoint of safety valves was verified by in-plant tests at pressure and temperature conditions when the unit was shut down. Setpoints were checked by using a pressure-assist device that adds to the force due to pressure. Once the valve left the seated position, the assist device was vented, allowing the valve to reset immediately. Steam relief valve setpoints were checked during instrument alignment.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 13.5-2 (CONTINUED)

LIST OF START-UP TESTS AND CHECKS

Test or Check	Plant Condition/Prerequisite	Test Objective
V. POWER CONVERSION SYSTEM (continued)		
2. Components and individual systems (continued)		
b. Auxiliary feedwater system	Before criticality	During hot functional testing before criticality, the auxiliary feedwater system was checked out to verify its ability to feed the steam generators. Automatic starting was checked during the safeguards logic system tests.
c. Turbine control and bypass valve	Hot functional testing and/or power operation after criticality	During hot functional testing, the turbine control system was demonstrated by turbine operation up to and including a period of operation at synchronous speed. The turbine bypass valves to the condenser and their associated control systems were operationally checked out during hot functional testing.
d. Feedwater and feedwater control system	Hot functional testing and at power	The feedwater and condensate pumps were operationally checked out during hot functional testing. During power escalation the power was increased and the ability of the feedwater pumps and control system to maintain level in the steam generators was verified.
e. Condenser circulating water	Before hot functional testing	Before hot functional testing, the main circulating water system valves were tested to verify operability.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 13.5-2 (CONTINUED)

LIST OF START-UP TESTS AND CHECKS

Test or Check	Plant Condition/Prerequisite	Test Objective
V. POWER CONVERSION SYSTEM (continued)		
2. Components and individual systems (continued)		
f. Makeup water and chemical treatment system	During steam generator fill, hot functional testing, and start-up testing	The makeup system to the system generators was checked out during hot functional testing and at power. The chemical treatment system was checked out when chemicals were added to the steam generators at heatup to steaming conditions.
VI. AUXILIARY SYSTEMS		
1. Reactor coolant system makeup test (CVCS)		See Section III, Item 1.
2. Seal and pump cooling water test (CVCS)	Before heatup and at temperature	Before reactor coolant pump operation and with the system pressurized, flow to the pump seals and cooling water was set, and flow was adjusted to specified values using installed instruments. During hot functional testing when at operating temperature and pressure, seals and cooling flows and temperatures were checked.
3. Secondary vent and drain system	During hot functional testing	During hot functional testing after core loading, the secondary system was vented while pressurizing the secondary system. Secondary drains were tested for unrestricted flow in accordance with operating procedures.
4. Component cooling system	Ambient and/or hot plant conditions	Component cooling flow to the various components in the affected systems was adjusted, the system operationally checked out, and setpoints verified.
5. Residual heat removal system	Before and during hot functional testing	Heat removal capability was demonstrated.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 13.5-2 (CONTINUED)

LIST OF START-UP TESTS AND CHECKS

Test or Check	Plant Condition/Prerequisite	Test Objective
VI. AUXILIARY SYSTEMS (continued)		
6. Service water system	Before hot functional testing	The system was operationally checked out to verify pressure and flow. Service water flow to components in the system was verified.
7. Control rod drive mechanism and rod position indication coil cooling system	Before and/or during hot functional testing	The system was operationally checked out to verify air flow, temperatures, and motor current.
8. Primary sampling system	Before and/or during hot functional testing	Operations were performed to a. Demonstrate that liquid and gas samples could be obtained from sample points. b. Demonstrate that valves, instruments, and controls functioned properly. c. Verify proper functioning of the sample cooler.
9. Primary pressure relief system	Before hot functional testing and at pressure conditions	The pressurizer relief tanks, associated valves, and instrumentation were checked out to verify performance of design functions. For testing of pressurizer relief and safety valves see Section II.
VII. ELECTRICAL SYSTEM TESTS		
	Done during preoperational testing	

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 13.5-2 (CONTINUED)

LIST OF START-UP TESTS AND CHECKS

Test or Check	Plant Condition/Prerequisite	Test Objective
VIII. CONTAINMENT SYSTEMS		
1. Containment ventilation system	Before and/or during hot functional testing	The system was operated to balance air flows and to verify the ability to maintain temperatures below maximum allowable limits.
2. Postaccident heat removal system (containment sprays)	Before criticality	Tests were performed to verify pump operating characteristics, response to control signals, and sequencing of the pumps, valves, and controller (and to ensure that spray nozzles were unobstructed).
IX. GASEOUS RADIOACTIVITY REMOVAL SYSTEMS		
	Done during preoperational testing	
X. EMERGENCY CORE COOLING SYSTEM		
1. Accumulator	During hot functional testing	Flow through the accumulator lines was initiated to demonstrate that the check valves were free to open. Tests were also made to verify that accumulator pressure could be maintained.
XI. FUEL STORAGE AND HANDLING SYSTEM		
1. Spent-fuel storage radiation monitoring equipment	Before plant start-up	Refer to Table 13.5-1, Section XIII, Item 1.
XII. REACTOR COMPONENT HANDLING SYSTEM		
1. Reactor component handling system (polar crane)	Before use for installation of components within the containment	Testing was conducted on the polar crane in accordance with standard crane testing procedures during steam generator replacement.
XIII. RADIATION PROTECTION SYSTEM		
	Done during preoperational testing	

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 13.5-2 (CONTINUED)

LIST OF START-UP TESTS AND CHECKS

Test or Check	Plant Condition/Prerequisite	Test Objective
	XIV. INITIAL CRITICALITY AND LOW-POWER TESTS	
1. Initial criticality	Plant at hot shutdown	The objective was to bring the reactor critical from the plant conditions specified. Before the start of rod withdrawal, the nuclear instrumentation had been aligned, checke0d, and conservative reactor trip setpoints made per procedures. At preselected points in rod withdrawal, data were taken and inverse count rate plots made to enable extrapolating to the expected critical rod position. In addition, the following tests associated with modified systems were performed: steam generator water-hammer test, blowdown system capability test, and thermal expansion monitoring.
	XV. POWER ASCENSION	
1. Power ascension	Criticality	Normal postrefueling testing applied for power ascension. In addition, the following design tests associated with modified systems were performed: a. Steam generator carryover tests. b. Steam generator recirculation ratio test. c. Steam generator thermal and hydraulic performance verification. d. Steam generator water level stability and control demonstration. e. Condensate polishing performance testing. f. Load-rejection testing with condensate polisher.

CHAPTER 14 SAFETY ANALYSIS

An assessment of the impact of using inputs and acceptance criteria derived from the latest fuel performance models and methods was performed for the Surry Non-LOCA safety analyses. This assessment concluded that the results generated using the RETRAN-3D computer code remain valid for most Non-LOCA analyses, even with the effects of Thermal Conductivity Degradation (TCD) included through the use of the latest fuel performance models and methods. One analysis determined to require reanalysis using updated fuel performance inputs was the RCCA Ejection accident. The results of the new analysis demonstrate that the applicable acceptance criteria continue to be met with consideration of TCD using the latest fuel performance models and methods.

14.1 GENERAL

This chapter evaluates the safety aspects of the station and demonstrates that the station can be operated safely and that exposures from credible accidents are less than or equal to the limits of 10 CFR 50.67 or Regulatory Guide 1.183, as applicable.

This chapter is divided into sections, each dealing with a different behavior category. The sections are as follows:

1. Core and Coolant Boundary Protection Analysis, Section 14.2.

   The incidents presented in Section 14.2 are associated with an individual unit within the station.

2. Standby Safeguards Analyses, Section 14.3.

   The accidents presented in Section 14.3 are steam generator tube rupture, steam-line break, and control-rod ejection. High-energy line breaks outside containment are discussed in Appendix 14B (Reference 1).

3. General Station Accident Analysis, Section 14.4.

   The accidents presented in Section 14.4 are associated with shared systems and facilities that may cause the release of radioactive material to the environment.

4. Loss-of-Coolant Accident (including the design-basis accident), Section 14.5.

   The loss-of-coolant accident, or the rupture of a reactor coolant pipe, is the worst accident case and is the primary basis for the unit design requirements. It is shown that even this accident meets the limits of 10 CFR 50.67, assuming that the core has been operating at 2605 MWt. This core power level is conservative compared to 100.38% of the rated power level of 2587 MWt (i.e., 2596.9 MWt).

All accident analyses were originally performed assuming the use of Zircaloy fuel rod cladding. The impact of the use of ZIRLO as an alternate cladding material was evaluated by Westinghouse (Reference 2). The properties of these two zirconium-based alloys are essentially identical except for the temperature at which the alpha to beta phase change occurs, and its related effect on the thermophysical properties (particularly the specific heat over the phase transformation temperature range). Therefore, the use of ZIRLO does not affect the analyses of non-LOCA accidents for which the clad temperature remains below the ZIRLO phase change temperature (1380°F). This includes all Condition I and Condition II events. The only non-LOCA accident analyses in which the clad temperatures are predicted to reach 1380°F or greater are the locked rotor analysis (Section 14.2.9.2) and the rupture of a control rod mechanism housing (Section 14.3.3). The effect of the use of ZIRLO cladding is discussed in the applicable sections for these accident analyses. The impact of the use of the ZIRLO alloy on the large break LOCA (Section 14.5.1) and the small break LOCA (Section 14.5.2) analyses was also assessed.

Topical Report VEP-NE-2-A (Reference 3) describes the calculation of "retained DNBR margin" as the difference between the DNBR design limit (i.e., Safety Analysis Limit) and the Statistical Design Limit (SDL). The available retained DNBR margin is evaluated for each reload core, considering DNBR penalties for generic fuel design issues (e.g., fuel rod bow), cycle-specific violations of limits (e.g., fuel rod power census), and plant operating conditions. Surry UFSAR Section 3.4.3.5 also summarizes the applicable uses of retained DNBR margin.

The Surry Improved Fuel (SIF) is no longer in use at Surry. While the basis for most transient analyses of the Chapter 14 events were performed with the SIF design and were demonstrated to be applicable to the Westinghouse 15x15 Upgrade fuel, the DNBR analyses of record have been updated explicitly to reflect the 15x15 Upgrade fuel design.

For the implementation of the Westinghouse 15 x 1 5 Upgrade fuel design at Surry, all accident analyses were reviewed for potential impact upon the NSSS predictions. The 15 x 15 Upgrade fuel assembly is described in Section 3.3 of the UFSAR. The change in cladding from ZIRLO to Optimized ZIRLO (Reference 5) as approved by the NRC (Reference 8) does not significantly change the cladding material properties. Furthermore, there are no significant changes in fuel properties between the 15 x 15 SIF product and the 15 x 15 Upgrade fuel design. Since the changes in material properties are negligible, no transient reanalysis for the non-LOCA events (UFSAR Sections 14.2 and 14.3) was performed for the 15 x 15 Upgrade fuel design.

The implementation of the 15 x 15 Upgrade fuel design has an impact on the calculated DNBR results for the Chapter 14 accident analyses. The DNBR analyses were conducted using the VIPRE-D thermal-hydraulic code (Reference 6) and the WRB-1 and W-3 CHF correlations. In Reference 7, the NRC approved the use of the VIPRE-D/WRB-1/W-3 code/correlation pairs and the supporting DNB statepoint calculations for the 15 x 15 Upgrade fuel design. VIPRE-D/WRB-1 together with the Virginia Power Statistical DNBR Evaluation Methodology (Reference 3) has been applied to the accidents listed in Section 3.2.3. Statepoints for applicable DNB events were analyzed with VIPRE-D/WRB-1 at 2589.3 MWt for full-power, statistically-treated events. All statistically-treated DNB events show acceptable DNB performance for the Westinghouse 15 x 15 Upgrade fuel design at 2589.3 MWt core thermal power. The analyzed core power is bounding for the measurement uncertainty recapture (MUR) uprated core power of 2587 MWt. The deterministic events (see Section 3.2.3) analyzed with VIPRE-D/W-3 code/correlation pair are not impacted by the MUR (Reference 4).

Subsequent to the implementation of the Westinghouse 15 x 15 Upgrade fuel design, the ABB-NV and WLOP DNB correlations were approved for use as a replacement for the W-3 DNB correlation. Consistent with the implementation of the 15 x 15 Upgrade fuel design, a DNBR analysis for the affected events (Rod Withdrawal from Subcritical and Main Steamline Break) was performed using the ABB-NV and WLOP DNB correlations. In Reference 9, the NRC approved the use of the VIPRE-D/ABB-NV and VIPRE-D/WLOP code correlation pairs and the supporting DNB statepoint calculations for the Westinghouse 15 x 15 Upgrade fuel design at Surry.

The safety analyses described in Chapter 14 have been updated to support the following DNB analysis configurations:

- Westinghouse 15x15 Upgrade fuel with VIPRE-D/WRB-1 correlation pair with a full power $F\Delta H$ limit of 1.56 for statistical DNB calculations and VIPRE-D/W-3 code correlation pair with a full power $F\Delta H$ limit of 1.62 $F\Delta H$ for deterministic DNB calculations
- Westinghouse 15x15 Upgrade fuel with VIPRE-D/WRB-1 correlation pair with a full power $F\Delta H$ limit of 1.635 for statistical DNB calculations and VIPRE-D/ABB-NV or VIPRE-D/WLOP code correlation pairs with a full power $F\Delta H$ limit of 1.70 $F\Delta H$ for deterministic DNB calculations

The ability of the automatic rod control system to withdraw rods from the core has been eliminated (Chapter 7). This prevents addition of positive reactivity by rod withdrawal in response to transient event conditions thereby resulting in lower power during the event. Automatic rod control cases are retained herein for the Excessive Heat Removal Due to Feedwater System Malfunctions (Section 14.2.7) and Excessive Load Increase Incident (Section 14.2.8) events, even though they are no longer credible, as they continue to bound the current plant design.

14.2 CORE AND COOLANT BOUNDARY PROTECTION ANALYSIS

14.2.1 Uncontrolled Control-Rod Assembly Withdrawal From a Subcritical Condition

A control-rod assembly withdrawal incident is defined as an uncontrolled addition of reactivity to the reactor core by the withdrawal of control-rod assemblies, resulting in a power excursion. While the probability of a transient of this type is extremely low, such a transient could be caused by a malfunction of the reactor control or control rod drive systems. This could occur with the reactor either subcritical or at power. The “at power” case is discussed in Section 14.2.2.

Reactivity is added at a prescribed and controlled rate in bringing the reactor from a shutdown condition to a low-power level during start-up by control-rod withdrawal. Although the initial start-up procedure used the method of boron dilution, the normal start-up is with control-rod assembly withdrawal. Control-rod assembly motion can cause much faster changes in reactivity than can be made by changing boron concentration.

The control-rod drive mechanisms are wired into preselected banks, and these bank configurations are not altered during core life. The assemblies are therefore physically prevented from being withdrawn in other than their respective banks. Power supplied to the rod banks is controlled such that no more than two banks can be withdrawn at any time. The control-rod drive mechanism is of the magnetic latch type and the coil actuation is sequenced to provide variable-speed rod travel. The maximum reactivity insertion rate is postulated in a detailed analysis assuming the simultaneous withdrawal of the combination of the two rod banks of the maximum combined worth at maximum speed.

Should a continuous control-rod assembly withdrawal be initiated from subcritical or low power conditions, the transient will be terminated by the following automatic safety features:

1. Source range flux level trip—actuated when either of two independent source range channels indicates a flux level above a preselected, manually adjustable value. This trip function may be manually bypassed when either intermediate-range flux channel indicates a flux level above the source range cutoff power level. It is automatically reinstated when both intermediate-range channels indicate a flux level below the source range cutoff power level.
2. Intermediate-range control-rod stop—actuated when either of two independent intermediate-range channels indicates a flux level above a preselected, manually adjustable value. This control-rod stop may be manually bypassed when two out of the four power range channels indicate a power level above approximately 10% of full power. It is automatically reinstated when three of the four power range channels are below this value.
3. Intermediate-range flux level trip—actuated when either of two independent intermediate-range channels indicates a flux level above a preselected, manually adjustable value. This trip function may be manually bypassed when two of the four power range channels are reading above approximately 10% of full power and is automatically reinstated when three of the four channels indicate a power level below this value.

4. Power range flux level trip (low setting)—actuated when two out of the four power range channels indicate a power level above approximately 25% of full power. This trip function may be manually bypassed when two of the four power range channels indicate a power level above approximately 10% of full power and is automatically reinstated when three of the four channels indicate a power level below this value.

5. Power range control-rod stop—actuated when one out of the four power range channels indicates a power level above a preset setpoint. This function is always active.

6. Power range flux level trip (high setting)—actuated when two out of the four power range channels indicate a power level above a preset setpoint. This trip function is always active.

Reactor protection for subcritical and low power rod withdrawal events has traditionally been assumed to be provided by the Power Range high flux trip (low setpoint) for events initiated both above and below permissive P-6. Source Range protection was assumed to not be available, since the Source Range channel lacked the redundancy required to assume trip availability in UFSAR accident analyses. Technical Specifications require two available Source Range Channels below permissive P-6. In conjunction with Source Range trip bistable operability testing to verify Source Range channel response characteristics, this validates the assumption of Source Range trip availability in accident analyses. Technical Specifications also impose an allowable Source Range channel outage time for power levels below P-6. This ensures start-up protection by providing confirmation of the availability of the Source Range channel.

Rod withdrawal from subcritical events may be initiated from above or below permissive P-6. Below P-6, one or two reactor coolant pumps may be operating, or reactor coolant system (RCS) cooling may be provided by the Residual Heat Removal (RHR) system. For any operating condition below P-6, Source Range protection or open trip breakers provide reactor protection against a rod withdrawal from subcritical event. Additional protection is provided by the other operable reactor protection system circuitry, including the Intermediate Range and Power Range (low setpoint) reactor trips. As was demonstrated in the North Anna Core Uprating submittal (Reference 27) and subsequent responses to NRC questions (References 28 & 29) events initiated from allowable operating conditions below P-6 will not result in significant power generation of core heat flux when a reactor trip is actuated on the Source Range channel. This conclusion is also applicable to Surry. Therefore, reactor protection is provided for all operating conditions below P-6, including one-RCP, two-RCP, and RHR operation.

The nuclear power response to a continuous reactivity insertion originating above P-6 is characterized by a very fast rise terminated by the reactivity feedback effect of the negative fuel temperature coefficient. This self-limitation of the initial power burst results from a fast negative fuel temperature feedback (Doppler effect) and is of prime importance during a start-up incident since it limits the power to a tolerable level before external control action. After the initial power burst, the nuclear power is momentarily reduced and then if the incident is not terminated by a reactor trip, the nuclear power increases again, but at a much slower rate.

The termination of the start-up incident by the above protection channels prevents core damage. In addition, the reactor trip from high reactor pressure serves as a backup to terminate the incident before an overpressure condition could occur.

14.2.1.1 **Method of Analysis**

The rod withdrawal from subcritical event was analyzed using the RETRAN computer code and the associated Virginia Power reactor system transient methodology (Reference 12). The analysis includes the simulation of the plant neutron kinetics, and the core thermal and hydraulic feedback equations. The RETRAN code calculates nuclear power, core heat flux, average fuel, clad and coolant temperatures. The MDNBR for the 15 x 15 Upgrade fuel design was determined at the statepoint for the DNB limiting case of the transient using the VIPRE-D computer code (Reference 36).

The analysis assumes the operation of all three reactor coolant pumps. Technical Specification 3.1.A.1.a prohibits achieving criticality with less than three reactor coolant pumps operating. The following additional assumptions were made to provide conservative results for this analysis:

1. Since the magnitude of the nuclear power peak reached during the initial part of the transient, for any given rate of reactivity insertion, is strongly dependent on the Doppler power reactivity coefficient, a conservative fuel-temperature-dependent Doppler coefficient was used.

2. The contribution of the moderator reactivity coefficient is negligible during the initial part of the transient because the heat transfer time constant between the fuel and the moderator is much longer than the nuclear flux response constant. However, after the initial nuclear flux peak, the succeeding rate of power increase is affected by the moderator reactivity coefficient. A conservative value of +6 pcm/°F was used in the analysis since the positive value yields the maximum peak core heat flux (1 pcm = 10^{-5} $\Delta k/k$).

3. The reactor is assumed to be at hot zero power with a T_{avg} of 547°F. This assumption is more conservative than that of a lower initial system temperature. The higher initial system temperature yields a larger fuel-to-water thermal conductivity, a larger fuel thermal capacity, and a less negative (smaller absolute magnitude) Doppler coefficient. The less negative Doppler coefficient reduces the Doppler feedback effect, thereby increasing the nuclear flux peak. The high nuclear flux peak combined with a high fuel thermal capacity and large thermal conductivity yields a larger peak heat flux. Initial multiplication (k_o) is assumed to be 1.0 since this results in the maximum nuclear power peak.

4. The most adverse combination of instrument and setpoint errors, as well as delays for trip signal actuation and control-rod assembly release, are taken into account. A 10% increase has been assumed for the power range flux trip setpoint, raising it from the nominal value of 25% to 35%. The rise in nuclear flux is so rapid that the effect of errors in the trip setpoint on the actual time at which the rods are released is negligible.

5. The rate of negative reactivity insertion corresponding to the trip action is based on the assumption that the highest worth control rod assembly is stuck in its fully withdrawn position. A conservatively low value was assumed for the total trip reactivity from zero power.

6. The maximum positive reactivity insertion rate assumed (112.5 pcm/sec) is greater than that for the simultaneous withdrawal of the combination of the two control banks having the greatest combined worth at maximum speed (45 in/min).

7. The initial power level was assumed to be below the power level expected for any shutdown condition. The combination of highest reactivity insertion rate and lowest initial power produces the highest peak heat flux.

8. The delayed neutron fraction (β_{eff}) was assumed to be at its maximum value, as that would maximize the thermal energy released into the coolant.

9. On the secondary side, the condenser dump valves are assumed closed, thus causing a pressure buildup that would contribute to the heatup of the primary system.

10. Since this event is evaluated at hot zero power conditions (0% rated core power), the UFSAR analysis of record is unaffected by the MUR power uprate to 2587 MWt.

For the pressure-limiting case, to conservatively overestimate the pressurization in the RCS, the following additional assumptions are made:

1. Initial pressurizer pressure is 2280 psia (30 psi above the nominal).
2. Initial pressurizer level is 5% above the nominal.
3. PORVs and pressurizer sprays that would mitigate the pressurization are not credited.
4. The PSV loop seals are filled with water. Displacing the liquid in the loop seal causes a delay in the opening of the PSVs, thus driving the primary system pressures higher.

In the DNB-limiting case, the following specific assumptions are made to decrease the primary pressurization and increase the energy released into the coolant, thus minimizing the calculated margin to DNB:

1. Initial pressurizer pressure and level are held at their nominal values.
2. Pressurizer sprays and PORVs are credited, thereby mitigating system pressurization.
3. For the MDNBR calculation, conservative values for the pressurizer pressure, RCS flow and the bypass flow fraction are used.

14.2.1.2 **Results**

Figure 14.2-2 shows the effect of the initial power level on peak heat flux for various reactivity insertion rates from 20 to 60 pcm/sec. It shows that peak heat flux initially decreases with increasing initial power level and then, depending on the rate, it increases again and approaches 35% of full power (reactor trip is assumed to be initiated at this value). It can also be seen that for the faster insertion rates, which result in the greatest energy addition, the flux peak is greatest for the lowest initial power level.

Figures 14.2-1, 14.2-3 and 14.2-4 show the transient behavior for a DNB-limiting case, with the incident terminated by reactor trip at 35% power. As seen in Figure 14.2-1, the nuclear power increases to the trip setpoint in 6.8 seconds. The power then overshoots to approximately 966%, but only momentarily. Therefore, the energy release and the fuel temperature increase are moderate. The thermal flux response, of interest for DNB considerations, is shown in Figure 14.2-3. The beneficial effect of the inherent thermal lag of the fuel is evidenced by a peak heat flux of only 53% of 2546 MWt (52% of 2587 MWt). There is an adequate margin to DNB during the transient since the rod surface heat flux remains below the design value, and there is a high degree of subcooling at all times in the core. Figure 14.2-4 shows the response of the average fuel, cladding and coolant temperatures. The average fuel temperature peaks at 956°F which is much lower than the nominal full power value of 1311°F. The average coolant temperature rises to only 566.4°F while the clad temperature peaks at 597°F. A VIPRE-D calculation for the 15 x 15 Upgrade fuel design using a statepoint with adjustments to the thermal-hydraulic input variables gives a MDNBR above the applicable SAL listed in Section 3.2.3.

The pressure-limiting case results in a pressurizer pressure peak of 2656 psia at 11.6 seconds, while the overall primary system peaks at 2720 psia in the cold leg at 11.8 seconds.

14.2.1.3 **Conclusion**

It is concluded that, in the unlikely event of a control rod assembly withdrawal incident from subcritical conditions, the core and reactor coolant system are not adversely affected, as the peak thermal power and the peak coolant temperature in the DNB-limiting case are well below their nominal full power values. An explicit statepoint calculation using very conservative assumptions results in a minimum DNBR above the design limit.

In the case that examines primary system pressure, it can be shown that the peak RCS pressure will be less than 110% of design pressure.

14.2.2 Uncontrolled Control-Rod Assembly Withdrawal at Power

The Uncontrolled Rod Cluster Control Assembly (RCCA) Bank Withdrawal at Power (RWAP) event is characterized by a reactivity increase resulting from the withdrawal of one or more RCCA banks from the core during power operation. The initiating event is a postulated single failure in a control system such as the rod control system or the reactor control system or faulty action by a reactor operator. The addition of reactivity to the core tends to be distributed uniformly, due to the RCCA bank arrangement. The energy removal capabilities of the secondary system tend to lag behind the core power increase resulting from the rod bank withdrawal. This energy mismatch causes the Reactor Coolant System (RCS) pressure and temperature to increase.

The possibility exists that the core heat flux could exceed the ability of the RCS fluid to conduct the heat from the fuel, potentially leading to a Departure from Nucleate Boiling (DNB) and subsequent cladding failure. The RCS temperature and pressure transients can be limited by the operation of RCS and main steam (MS) pressure relief valves; however, the power excursion generally continues until terminated by the addition of negative reactivity from the safety control rod banks due to a reactor trip. The limiting event conditions occur shortly after safety control bank insertion, when the minimum DNB ratio (MDNBR) occurs. The Reactor Coolant Pumps (RCPs) remain operational throughout the event so that, in the absence of DNB, sufficient RCS flow exists to adequately handle the transfer of energy from the fuel to the reactor coolant.

As stated above, maintaining the fuel cladding integrity is the primary concern for the RWAP event. However, maintaining the RCS as a fission product barrier is also a concern. Specifically, the heating of the RCS fluid during a RWAP event causes the fluid density to decrease, resulting in a volumetric expansion of the fluid. Operation of the pressurizer sprays and Power Operated Relief Valves (PORVs) can mitigate the effects of the subsequent pressure increase, but do not counteract the volumetric expansion. Should the expansion of the RCS fluid continue uncontested, the potential exists for discharge of liquid through the PORVs or Pressurizer Safety Valves (PSVs). For the rod withdrawal at power event, the reactor protection system terminates the heatup of the reactor coolant system before any liquid relief occurs.

Provided the integrity of the fission product barriers is not compromised, sensible and decay heat can be removed by steaming to the condenser through the steam bypass system, to the atmosphere through the MS PORV or the Main Steam Safety Valves (MSSVs), or any combination of the three methods. Feedwater remains available to the steam generators (SGs) from either the Main Feedwater (MFW) system or the Auxiliary Feedwater (AFW) system to replenish the secondary coolant. Shortly after reactor trip, the energy removal capability of the SGs will exceed the RCS sensible and decay heat levels, and the reactor operators/automatic control systems will function to maintain the plant at the new equilibrium condition.

The automatic features of the reactor protection system that prevent core damage in a control-rod assembly withdrawal incident at power include the following:

1. Nuclear power range instrumentation actuates a reactor trip if two out of the four channels exceed an overpower setpoint.
2. Reactor trip is actuated if any two out of three delta T channels exceed an overtemperature delta T setpoint. This setpoint is automatically varied with axial power distribution and coolant temperature and pressure to protect against DNB.
3. Reactor trip is actuated if any two out of three delta T channels exceed an overpower delta T setpoint. This setpoint is automatically varied with axial power distribution and coolant temperature to ensure that the allowable heat generation rate (kw/ft) is not exceeded.
4. A high-pressure reactor trip, actuated from any two out of three pressure channels, is set at a fixed point. This set pressure is less than the set pressure for the pressurizer safety valves.

5. A high pressurizer water level reactor trip, actuated from any two out of three level channels, is actuated at a setpoint. This affords additional protection for control-rod assembly withdrawal incidents. The Technical Specifications require that the reactor be maintained subcritical by some minimum amount until normal water level is established in the pressurizer.

6. In addition to the above-listed reactor trips, there are the following control-rod assembly withdrawal blocks:

   a. High nuclear power (one out of four).

   b. High overpower delta T (two out of three).

   c. High overtemperature delta T (two out of three).

The manner in which the combination of overpower and overtemperature delta-T trips provides protection over the full range of reactor coolant system conditions is described in Chapter 7 and in Figure 14.2-5. Figure 14.2-5 illustrates reactor coolant loop average temperature and delta-T for the design power distribution and flow as a function of primary coolant pressure. The boundaries of operation defined by the overpower delta-T trip and the overtemperature delta-T trip are represented as “protection lines” on this diagram. The protection lines are drawn to include all adverse instrumentation and setpoint errors so that under nominal conditions a trip would occur well within the area bounded by these lines. This diagram is useful in that the limit imposed by any given DNBR can be represented as Reactor Core Safety Limit lines. The DNB lines represent the locus of conditions for which the DNBR equals the limit value. All points below and to the left of a DNB line for a given pressure have a DNBR greater than the limit value. The diagram shows that DNB is prevented for all cases if the area enclosed with the maximum protection lines is not traversed by the applicable DNBR line at any point.

The region of permissible operation (power, pressure, and temperature) is completely bounded by the following reactor trips: nuclear overpower (fixed setpoint), high pressure (fixed setpoint), low pressure (anticipatory rate dependent setpoint), and overpower and overtemperature delta T (variable setpoints). These trips are designed to prevent a DNBR less than the applicable SAL (Section 3.2.3).

The analysis presented below shows that no fuel damage occurs by demonstrating that the DNBR limit is met for the rod withdrawal event. Also shown is that the RCS and MS system pressure relieving devices have sufficient capacities to ensure the safety of the unit without relying on the mitigating capabilities of the pressurizer pressure control or MS bypass systems.

14.2.2.1 **Method of Analysis**

The RWAP transient is analyzed with the RETRAN computer code (Reference 12) and the detailed core thermal/hydraulic analysis is performed with the VIPRE-D computer code (Reference 36) for the 15 x 15 Upgrade fuel design. The RETRAN system code simulates the neutron kinetics, Reactor Coolant System, pressurizer, pressurizer relief and safety valves, pressurizer spray, steam generator, and steam generator safety valves. The code computes pertinent plant variables, including temperatures, pressures, and power level. The VIPRE-D code is used to calculate the DNBR for the transient using the WRB-1 CHF correlation.

For the DNBR evaluation cases, the initial power level, pressurizer pressure, and RCS average temperature are assumed to be at values consistent with the conditions at 2589.3 MWt, which bounds the MUR uprated nominal power of 2587 MWt. The effects of normal control system variations and measurement uncertainties associated with these parameters are treated statistically and incorporated into the statistical design limit (SDL) (Section 3.2.3) in accordance with Virginia Power's Statistical DNBR Methodology (Reference 17). The calculation of the DNBR is consistent with the current Technical Specifications Core Operating Limit Report limit on $F\Delta H$ as modified by a 0.3 part power multiplier.

For cases where reactor coolant system pressures are of primary interest, the initial reactor power, pressurizer pressure and RCS average temperature are assumed to be at the maximum values consistent with steady state full power operation, including allowances for calorimetric and other instrument errors. In addition these cases are performed with the pressurizer pressure relieving devices (pressurizer spray and PORVs) disabled.

All cases incorporate the assumption of 15% steam generator tube plugging. To obtain conservative results the following assumptions are made:

1. Reactivity coefficients - two cases are analyzed:
    a. Minimum reactivity feedback. A positive moderator temperature coefficient of +6.0 pcm/°F in conjunction with a least negative Doppler temperature coefficient is used in the analysis.
    b. Maximum reactivity feedback. A conservatively large negative moderator coefficient -45.0 pcm/°F and a large (in absolute magnitude) negative Doppler temperature coefficient are assumed.
2. The reactor trip on high neutron flux is assumed to be actuated at a conservative value of 118% of conditions at 2589.3 MWt, which bounds the MUR uprated nominal power of 2587 MWt. The delta T trips include all adverse instrumentation and setpoint errors, while the delays for the trip signal actuation are assumed at their maximum values.
3. The RCCA trip insertion characteristic is based on the assumption that the highest worth assembly is stuck in its fully withdrawn position.
4. A spectrum of reactivity insertion rates is analyzed. The maximum positive reactivity insertion rate is greater than the maximum rate of two sequential control rod banks moving at the maximum speed with normal overlap.

The effect of rod cluster assembly movement on the axial core power distribution is accounted for by causing a decrease in overtemperature and overpower delta-T trip setpoints proportional to a decrease in margin to DNB.

14.2.2.2 **Results**

Figure 14.2-6 shows the minimum DNBR for the 15 x 15 SIF product as a function of reactivity insertion rate from initial full power operation of 2589.3 MWt (which bounds the MUR uprated nominal power of 2587 MWt) for the minimum and maximum reactivity feedback. It can be seen that the high-neutron flux and overtemperature delta-T trip setpoints provide protection over the whole range of reactivity insertion rates since the minimum DNBR for all insertion rates is greater than the applicable SAL listed in Section 3.2.3.

Figures 14.2-7 and 14.2-9 show the response of nuclear power, pressurizer pressure, and average coolant temperature to the limiting DNBR case initiated from 2589.3 MWt (0.4 pcm/sec insertion rate). The slow rod withdrawal allows for a sufficient rise in temperature and pressure to cause a trip on overtemperature delta-T. The minimum DNBR for the 15 x 15 SIF product for this case remains well above the limit as indicated by Figure 14.2-6.

Figures 14.2-10 and 14.2-11 show the minimum DNBR for the 15 x 15 SIF product as a function of reactivity insertion rate for the rod withdrawal event starting at 60% and 10% of 2546 MWt, respectively. The results are similar to the 100% of 2589.3 MWt (100.1% of 2587 MWt) power case, except that as the initial power is decreased, the range over which the overtemperature delta-T trip is effective is increased. In all cases, the DNBR is greater than the applicable SAL (Section 3.2.3).

Figures 14.2-12 and 14.2-14 show the nuclear power, RCS average temperature, and cold leg pressure response to the limiting overpressure rod withdrawal incident. Sensitivity cases performed to maximize RCS pressure indicate that limiting results occur for an assumed initial power of 12% of 2546 MWt with a reactivity insertion rate of 55 pcm/sec and minimum reactivity feedback. The reactor trips on high flux at 12.63 seconds. The cold leg pressure reaches a peak value of 2699.00 psia at 13.8 seconds into the transient.

Cases performed to maximize the main steam pressure (maximize the RCS average temperature prior to trip) show that the maximum main steam pressure occurs for rod withdrawal events initiated at 60% of 2546 MWt. The cases providing the maximum main steam pressure are those which allow a gradual but large rise in the RCS average temperature. These are cases with low insertion rates and minimum reactivity feedback or relatively high insertion rates with maximum reactivity feedback. These cases trip on overtemperature delta-T and achieve approximately the same RCS temperature.

Therefore, the maximum main steam pressure is fairly constant (1190 psia) over a range of insertion rates. The analyses support up to 15% steam generator tube plugging.

The MDNBR for the 15 x 15 Upgrade fuel design was determined for the RWAP event at the statepoints for the DNB-limiting cases of the transient using the VIPRE-D computer code (Reference 36). It was determined that the MDNBR for all RWAP cases was above the applicable SAL (Section 3.2.3).

14.2.2.3 **Conclusions**

This analysis indicates that for an uncontrolled rod withdrawal at power event, the following criteria are met:

1. The minimum DNBR remains above the applicable SAL (UFSAR Section 3.2.3).
2. Pressure at the most limiting RCS location is less than 110% of RCS design pressure, or 2750 psia (the Emergency Condition Stress Limit specified in Section III of the ASME Code).
3. Pressure at the most limiting Main Steam System (MSS) location is less than 110% of MSS design pressure, or 1210 psia (the Emergency Condition Stress Limit specified in Section III of the ASME Code).

14.2.3 Malpositioning of the Part Length Control Rod Assemblies

The part length control rod assemblies have been removed from the core.

14.2.4 Control-Rod Assembly Drop/Misalignment

Control-rod misalignment accidents include (1) dropped full length assemblies, (2) dropped full-length assembly groups, and (3) statically misaligned assemblies.

Each control-rod assembly has a rod position indicator channel that displays the position of the assembly. The displays of assembly position are grouped for the operator's convenience. Fully inserted assemblies are further indicated by rod bottom indicators on the redundant rod position flat panel displays. Bank (demand) position is also indicated. Except during start-up physics testing and control-rod exercise testing, the assemblies are moved in preselected banks and the banks are moved in the same preselected sequence.

The dropping of a control-rod assembly could occur only when the drive mechanism is de-energized. This would result in a power reduction and an increase in the hot-channel factor. If no protective action occurred, the reactor control system would restore the power to the level that existed before the incident. This would lead to a reduced safety margin or possibly DNB, depending on the magnitude of the hot-channel factor.

Dropped assemblies or banks are detected by:

1. A sudden drop in the core power level.
2. Asymmetric power distribution as seen on ex-core neutron detectors (Reference 1) or core exit thermocouples.

3. Rod bottom indicators on the redundant rod position flat panel displays.
4. A rod deviation alarm.

The rod bottom condition signal from the rod position indication system is provided for each control-rod assembly. The initiation of this signal is independent of lattice location, reactivity worth, or power distribution changes inherent with the dropped control-rod assembly. The other independent indication of a control-rod assembly drop is obtained by using the ex-core power range channel signals. This rod drop detection circuit is actuated upon the sensing of a rapid decrease in local flux such as could occur from the depression of flux in one region by a dropped control-rod assembly. This detection circuit is designed such that normal load variations do not cause it to be actuated.

A rod drop signal from any control-rod assembly position indication channel, or from one or more of the four power range channels, initiates alarms in the main control room.

Misaligned assemblies are detected by:

1. Asymmetric power distribution as seen on ex-core neutron detectors or core exit thermocouples.
2. A rod deviation alarm.

The resolution of the rod position indicator channel is ±5% of span (±12 steps) under steady state conditions. The deviation of any assembly from its bank by twice this distance (10% of span or 24 steps) will not cause power distributions worse than the design limits. The rod deviation alarm alerts the operator to rod deviation in excess of 10 steps or 4.3% of span.

If one or more of the rod position indicator channels should be out of service, detailed operating instructions in accordance with Technical Specification requirements are followed to ensure the alignment of the nonindicating assemblies.

14.2.4.1 **Methodology of Analysis**

The dropped RCCA(s) event is conservatively evaluated. This evaluation consists of three analyses, transient, nuclear, and thermal/ hydraulic. These analyses provide (l) statepoints, i.e., the reactor power, pressure, and temperature at the most limiting time in the transient, (2) the radial peaking factor at the most limiting conditions in the transient, and (3) the DNB analysis at the conditions determined by 1 and 2.

These analyses are performed using a parametric approach so that cycle specific conditions may be evaluated using the data generated from the three analyses above. On a reload basis an analysis is made using two key cycle specific parameters (the rod worth available for withdrawal and the moderator temperature coefficient) to determine the radial peaking factor prior to the dropped RCCA(s) event necessary to produce the applicable SAL (Section 3.2.3) during the transient for a range of dropped RCCA(s) worths. This range covers those which could be expected for a three loop plant like Surry. These predrop radial peaking factors are compared to the reload design predictions to confirm that the limiting predrop conditions for DNB do not occur during the cycle.

The transient response is calculated using either the LOFTRAN (Reference 4) or the RETRAN (Reference 12) code. These codes simulate the neutron kinetics, reactor coolant system, pressurizer, pressurizer relief and safety valves, pressurizer spray, steam generators, and steam generator safety valves. Nuclear models are used to obtain hot channel factors consistent with the primary system conditions at the statepoints generated by the transient simulation. The DNB design basis is shown to be met using the VIPRE-D code (Reference 36) for the 15 x 15 Upgrade fuel design by combining the primary conditions from the transient analysis with the hot channel factor from the nuclear analysis. The transient response, nuclear peaking factor analysis, and DNB design basis confirmation are performed in accordance with the methodology described in Reference 18.

A DNBR penalty of 3.0% will be applied to account for the increased bypass flow due to the conversion to upflow configuration. This DNBR penalty is conservative and applicable to all DNB events and will be deducted from the retained margin for the Westinghouse 15x15 Upgrade fuel product during the core reload thermal-hydraulic evaluation in accordance with NRC approved methodology in VEP-NE-2-A (Reference 17).

The ability of the automatic rod control system to withdraw rods from the core has been eliminated. This prevents addition of positive reactivity by rod withdrawal in response to transient event conditions thereby resulting in lower power during the event. The event cases with automatic rod control are no longer credible and are therefore not considered.

14.2.4.2 **Results**

For the dropped RCCA(s) event, power may be reestablished either by reactivity feedback or control bank withdrawal.

Following a dropped RCCA(s) in manual rod control, the plant will establish a new equilibrium condition. The drop will insert negative reactivity which causes the core power level to fall. The mismatch in power between that demanded by the turbine and that generated by the reactor core causes the reactor temperature to fall. The falling temperature in turn causes the reactor coolant pressure to fall. The plant will be tripped on low pressurizer pressure before the DNBR falls to the applicable SAL (Section 3.2.3). This process without control system interaction is monotonic, thus removing power overshoot as a concern and establishing the automatic rod control mode of operation as the limiting case.

The automatic rod withdrawal feature of the rod control system has been disabled. Therefore, following a dropped rod event the plant will establish a new equilibrium condition, and a power overshoot is not predicted. Figures 14.2-15 and 14.2-16 are generic curves for a typical transient response to a dropped RCCA (or RCCAs) without automatic rod withdrawal.

Uncertainties in the initial conditions are included in the DNB evaluation as described in Reference 17. On a reload basis, it is shown that the minimum DNBR remains greater than the applicable SAL (Section 3.2.3)

14.2.4.3 **Conclusions**

For all cases the DNB design basis is met by demonstrating that the DNBR is greater than the applicable SAL (Section 3.2.3).

14.2.5 Chemical and Volume Control System Malfunction

14.2.5.1 **Identification of Causes and Accident Description**

Reactivity can be added to the core by feeding primary grade water into the reactor coolant system via the reactor makeup portion of the chemical and volume control system. Boron dilution is a manual operation under strict administrative controls with procedures calling for a limit on the rate and duration of dilution. A boric acid blend system is provided to permit the operator to match the boron concentration of reactor coolant makeup water during normal charging to that in the reactor coolant system. The chemical and volume control system is designed to limit, even under various postulated failure modes, the potential rate of dilution to a value which, after indication through alarms and instrumentation, provides the operator sufficient time to correct the situation in a safe and orderly manner.

The opening of the primary water makeup control valve creates a dilution flow path to the reactor coolant system. Inadvertent dilution from this source can be readily terminated by closing the control valve. For makeup water to be added to the reactor coolant system at pressure, at least one charging pump must be running in addition to a primary grade water transfer pump.

The boric acid from the boric acid tank is blended with primary grade water in the blender; the composition is determined by the preset flow rates of boric acid and primary grade water on the control board. Two separate operations are required to dilute: (l) The operator must-switch from the automatic makeup mode to the dilute mode; (2) The blender switch must be turned to the "on" position. Omitting either step prevents dilution, making the possibility of an inadvertent dilution very remote.

Information on the status of the reactor coolant makeup is continuously available to the operator. Lights are provided on the control board to indicate the operating condition of the pumps in the chemical and volume control system. Alarms are actuated to warn the operator if boric acid or demineralized water flow rates deviate from preset values as a result of system malfunction.

14.2.5.2 **Method of Analysis**

To cover all phases of plant operation, boron dilution during Refueling Shutdown, Cold Shutdown, Intermediate Shutdown, Hot Shutdown, Reactor Critical, and Power Operation are considered. Explicit analyses are performed for Reactor Critical and Power Operation. Analyses are not performed for the shutdown operating modes as discussed in Section 14.2.5.3. The case of an inadvertent dilution during a planned dilution or makeup activity is not considered here as an accident analysis, since evaluation of such dilutions is not required by the Standard Review Plan. Boron dilution during start-up of an inactive loop is discussed in UFSAR Section 14.2.6.

The following parameter value ranges were considered in the boron dilution analyses for Power Operation and Reactor Critical operating modes:

1. Steam Generator Tube Plugging Fraction (SGTPF): 0% to 15% SGTP. The effective RCS Volume excludes the pressurizer, reactor vessel upper head, and plugged steam generator tube volumes.
2. Maximum Dilution Flow Rate. When the reactor coolant system is pressurized and the plant is in Power Operation or Reactor Critical mode, the rate of addition of unborated water is limited by the capacity of the charging pumps. The maximum dilution flow rate of 165 gpm, corresponding to the maximum charging flow rate of a single charging pump to a pressurized RCS, is assumed in the analysis when in Reactor Critical or Power Operation modes when Technical specifications do not require Primary Grade water isolation.
3. Bounding values of dilution flow density and RCS Water Density were assumed (maximum dilution density and minimum RCS density).
4. Minimum Shutdown Margin at Power: 1.77% $\Delta K/K$.

14.2.5.3 **Boron Dilution in Shutdown Operating Modes**

Technical Specifications require that the PG makeup water flow path be closed during Refueling Shutdown, Cold Shutdown, Intermediate Shutdown and Hot Shutdown, thereby preventing a high flow rate boron dilution event from occurring during these operating conditions. To satisfy this requirement, manual valve 1-CH-233 (2-CH-233 for Unit 2), the PG makeup water isolation valve, is secured in the closed position. As an alternative, Technical Specifications allow that manual valves 1-CH-212, 1-CH-215 and 1-CH-218 (2-CH-212, 2-CH-215, and 2-CH-218 for Unit 2) may be secured in the closed position if for any reason it is desired that 1-CH-223 (2-CH-223) be maintained open. This alternative combination of valve closures has the same effect as closing valve 1-CH-223 (2-CH-223). The PG makeup water flow path isolation is also required to be closed within 15 minutes following a planned dilution in all shutdown operating modes. (Allowances are provided in the Technical Specifications for relaxing PG water isolation requirements during approach to critical and immediately after shutdown.) Compliance with Technical Specification requirements for closing the PG water flow path ensures that the highest capacity source of PG water is isolated from the reactor coolant system. Therefore, a high flow rate boron dilution event is not credible in the shutdown operating modes.

It is recognized that there are many paths for dilution of the moderator. The rationale behind isolating the main primary grade water flow path is to preclude dilutions that would cause a rapid, uncontrolled decrease in shutdown margin. Low dilution flow rates have a high probability of being identified and corrected before a significant loss of shutdown margin occurs.

There are a number of plant features that provide diagnostic indication of an inadvertent low flow rate boron dilution in the shutdown modes. These indications include audible count rate and high flux at shutdown alarm from the source range nuclear instruments. Reload core design checks have been implemented to ensure that the source range nuclear instruments provide effective indication of changes in core reactivity in subcritical conditions. In addition, RCS letdown divert valve position, VCT level, PG tank levels and PG header flow rate all provide indication in the Main Control Room of a potential mismatch between charging and letdown and unexpected usage of PG water.

14.2.5.4 **Boron Dilution at Reactor Critical and Power Operation**

The analysis of the boron dilution event at reactor critical conditions indicates that at least 15 minutes are available from positive indication of a dilution in progress (alarm or reactor trip) to loss of shutdown margin for corrective operator action. The analysis conservatively assumed a minimum of 1.77% shutdown margin at the beginning of the dilution.

The boron dilution at power event has been analyzed for the rods in automatic and manual control cases. The results of the analysis indicate that 15 minutes are available after positive indication of a dilution in progress (reactor trip) for corrective operator response before a return to criticality.

The “rods in automatic control” case was shown to be bounded by the “rods in manual control” case. To illustrate, if an initial boron concentration, a dilution flow rate, and a boron worth are assumed, the “rods in manual” case will result in a reduction of shutdown margin potentially beyond that of the minimum shutdown margin required by Technical Specifications. If rods are in automatic, rod insertion due to T_{avg} -T_{ref} deviation will result in a rod insertion limit (indicating dilution is in progress) before the rod bank reaches rod insertion limit, the point at which minimum shutdown margin is defined. Therefore, the “rods in manual” case is assumed to consume a portion of minimum shutdown margin resulting in an operator response time which is always less than that of the corresponding “rods in automatic control” case. The automatic control case is therefore bounded by the manual control case. With either automatic or manual rod control, boron dilution events initiated at or below 100% power will result in an RCS temperature increase and, ultimately, in a high RCS temperature alarm. Positive indication of a dilution in progress in the analyzed boron dilution at power case (100% power; manual rod control), is assumed to be provided by the OTΔT reactor trip. In this analysis case, the high RCS temperature alarm is conservatively assumed to not actuate.

The reactivity transient resulting from an inadvertent boron dilution is essentially identical to that of a control rod assembly withdrawal accident. The reactivity insertion rates used in the analysis are well within the range of reactivity insertion rates considered in UFSAR Section 14.2.2, *Uncontrolled Control-Rod Assembly Withdrawal at Power*. If the reactor is in manual control and the operator takes no action to correct an inadvertent boron dilution, the power and temperature will rise to the overtemperature delta-T trip setpoint. Before the overtemperature delta-T trip, an overtemperature delta-T alarm and turbine runback would be actuated. The time to trip varies with the reactivity insertion rate (which is a function of boron concentration and boron worth) and with the temperature and power reactivity feedback of the core (which are largely functions of burnup). It was shown that 15 minutes are available after a reactor trip before the reactor can return to critical, conservatively assuming a minimum of 1.77% shutdown margin at the beginning of the dilution.

The results of the reactor critical and both the automatic and manual control cases of the boron dilution at power analyses indicate that at least 15 minutes are available, from positive indication of a dilution in progress (alarm or reactor trip) to loss of shutdown margin, for corrective operator response to an unplanned boron dilution.

14.2.5.5 **Conclusions**

Because of the procedures involved in the dilution process and the Technical Specification PG water isolation requirement, a high flow rate boron dilution is not considered credible in the shutdown operating modes. Numerous alarms and indications are available to alert the operator to any unintended low flow rate boron dilution in sufficient time for detection and corrective action prior to loss of shutdown margin.

For Reactor Critical and Power Operation modes, reload cores are designed and analyzed to ensure at least 15 minutes are available between positive indication (alarm or reactor trip) and loss of shutdown margin for corrective operator action in response to a boron dilution.

14.2.6 Start-Up of an Inactive Loop (SUIL) Accident Analysis Design Basis

14.2.6.1 **Event Description**

The SUIL accident analysis considers reactivity additions due to inadvertent introduction of cold and/or unborated water from an isolated (or previously isolated) loop. Because loop stop valve operations are prohibited at conditions other than COLD SHUTDOWN and REFUELING SHUTDOWN, inadvertent reactivity additions due to introduction of cold or unborated water at INTERMEDIATE SHUTDOWN, HOT SHUTDOWN, REACTOR CRITICAL, or POWER OPERATION are not considered.

An SUIL event is defined as an uncontrolled reduction in coolant temperature and/or boron concentration in the core region resulting from either the start-up of a reactor coolant pump (RCP) on an idle loop (the loop stop valves open case), or recirculation through a loop stop valve bypass line on an isolated loop (the loop stop valves closed case) when a reduced coolant temperature or boron concentration exists in the idle (or isolated) loop. A loop is considered idle when its hot and cold leg loop stop valves are open, but the reactor coolant pump on the loop is not operating. When no coolant temperature or boron concentration differential exists between the idle (or isolated) loop and the active portion of the reactor coolant system (RCS), the start-up of an RCP does not result in reactivity insertion, erosion of shutdown margin (SDM), power excursion, or reduction in margin to a departure from nucleate boiling (DNB) condition. Under these conditions, start-up of an RCP is simply a start-up procedure, and does not represent an SUIL event.

Because starting an RCP is a deliberate action under operator control, the initiator for an SUIL event is postulated to be multiple administrative errors. If a significant coolant temperature or boron concentration differential existed between the idle (or isolated) loop and the active portion of the RCS, starting the RCP on the idle (or isolated) loop could result in a reactivity insertion, erosion of SDM, and a power excursion. If the core heat flux exceeded the ability of the RCS fluid to conduct the heat from the fuel, the power excursion could lead to DNB and subsequent cladding failure at localized hot spots. Further, coolant expansion in the core region could lead to overpressurization of the RCS. Administrative controls governed by Technical Specifications ensure that, prior to starting an RCP, the differential coolant temperature and boron concentration between the idle (or isolated) loop and the active portion of the RCS are less than those which could result in complete loss of shutdown margin.

If the administrative controls governed by Technical Specifications are circumvented, and a differential coolant temperature and boron concentration beyond that ensured by the administrative controls is achieved, the start-up of an RCP could result in fuel cladding failure due to the onset of DNB, and potential overpressurization of the RCS. The DNB response of the fuel would be governed primarily by the core power and RCS temperature transient responses. The major contributors to the core power response are the change to the RCS boron concentration and the change to the RCS fluid temperature. Power changes induced by changing the RCS temperature are driven by the magnitude and direction of the moderator reactivity feedback. For example, the moderator temperature coefficient (MTC) is negative throughout most of the fuel cycle and thus acts to increase the total reactivity of the reactor core, i.e. reactor power, as the RCS temperature decreases. Finally, the fuel Doppler coefficient also plays a minor role in the determination of the transient core power response because the reactivity feedback caused by the heating of the fuel inherently limits the power peaking.

The consequences of an SUIL event would be mitigated by operating RCPs or residual heat removal (RHR) pumps, which would remain operational throughout the event to transfer energy from the fuel to the reactor coolant. Although the RCS temperature and pressure transients would be limited by the operation of RCS and main steam (MS) pressure relief valves, the power excursion would ultimately be terminated by either (a) the addition of negative reactivity from the safety control rod banks due to a reactor trip, (b) aborting the RCP start-up, or (c) manual initiation of safety injection. A reactor protection signal and reactor trip would be generated by one of the following reactor trip system (RTS) functions: source range neutron flux, power range neutron flux (low setpoint), power range neutron flux (high setpoint), overtemperature delta-T, overpower delta-T, loss of flow, or manual reactor trip.

After operator or automatic action to stabilize the RCS conditions, sensible and decay heat would be removed by steaming to the condenser through the steam bypass system, to the atmosphere through the MS power operated relief valves (PORVs) or the main steam safety valves (MSSVs), or any combination of the three methods. However, the desirability of a given method is based on system availability and the extent to which the fission product barriers have been compromised. In all scenarios, feedwater would remain available to the steam generators from the auxiliary feedwater (AFW) system to replenish the secondary coolant. At this point in the transient, the reactor operators or automatic control systems would function to maintain the plant at shutdown conditions.

14.2.6.2 **Accident Evaluation**

An SUIL event is defined as an uncontrolled reduction in coolant temperature or boron concentration in the region of the core resulting from either the start-up of an RCP on an idle loop (loop stop valves open case), or recirculation through a loop stop valve bypass line on an isolated (loop stop valves closed case) loop, when a reduced coolant temperature or boron concentration exists in the idle (or isolated) loop. A loop is considered idle when its hot and cold leg loop stop valves are open, but the RCP on the loop is not operating. The ultimate goal of the accident analysis is to demonstrate that a DNB condition is not reached during the accident and, hence, fuel failure is not predicted to occur.

A high level of confidence that a DNB condition will not be reached is demonstrated by consideration of the Technical Specification requirements for loop stop valve operation, and for filling drained and isolated loops. Technical Specifications and associated procedures ensure that the preconditions necessary for significant reactivity insertion during an SUIL event (i.e., reduced temperature and boron concentration in an isolated or idle loop) cannot be achieved under credible circumstances.

A calculation has been performed to verify that an SUIL event with the maximum credible temperature differential between an idle loop and the active portion of the RCS at COLD SHUTDOWN or REFUELING SHUTDOWN will not result in complete loss of shutdown margin. This calculation is described in Section 14.2.6.2.4. In addition, a calculation was performed to determine the reactivity insertion rate and time to loss of shutdown margin assuming isolated loop recirculation is being performed with 0 ppm boron in the isolated loop. This calculation is described in Section 14.2.6.2.5.

14.2.6.2.1 Loop Configurations Permitted by Technical Specifications

The Technical Specifications permit the following RCS and RHR loop configurations to be achieved:

1. Two RCS Loops Operating, and One RCS Loop Idle (Unisolated)
2. Two RCS Loops Operating, and One RCS Loop Isolated
3. One RCS Loop Operating, and Two RCS Loops Idle (Unisolated)
4. One RCS Loop Operating, One RCS Loop Idle (Unisolated), and One RCS Loop Isolated

5. One or Two RHR Loops Operating, Three RCS Loops Idle (Unisolated)
6. One or Two RHR Loops Operating, Two RCS Loops Idle (Unisolated), and One RCS Loop Isolated
7. One or Two RHR Loops Operating, One RCS Loop Idle (Unisolated), and Two RCS Loop Isolated
8. Two RHR Loops Operating, Three RCS Loops Isolated

In cases 1 through 4, RHR may or may not be in operation. Of the above configurations, only those with an idle, unisolated loop are possible loop configurations for the loop stop valve open case (i.e., configurations 1, 3, 4, 5, 6, and 7). Similarly, only configurations 2, 4, 6, 7, and 8 are possible loop configurations for the loop stop valves closed case. As described below, achievement of these configurations in combination with a reduced idle (or isolated) loop temperature and reduced boron concentration would involve a non-credible combination of operator errors.

14.2.6.2.2 Procedural Requirements for Returning Isolated and Filled Loops to Service

To preclude the possibility of inadvertent reactivity insertion due to boron concentration or temperature mismatch between isolated and active portions of the RCS, Technical Specification 3.17 establishes requirements for loop stop valve operations:

1. Loop stop valves must remain open except during COLD SHUTDOWN or REFUELING SHUTDOWN. (An exception is made for short-term maintenance activities.)
2. When a reactor coolant loop is isolated, the loop stop valves must be de-energized, and their circuit breakers must be locked open.
3. An operable source range nuclear instrumentation channel with audible indication must be continuously monitored when returning an isolated loop to service. The loop stop valves must be closed if the source range count rate doubles.
4. Before opening the hot leg loop stop valve, the boron concentration in the isolated loop must be verified to be greater than or equal to the boron concentration corresponding to the shutdown margin requirements for the active volume of the Reactor Coolant System.
5. Before opening a cold leg loop stop valve, the hot leg loop stop valve must be open, and a relief line flow rate of at least 125 gpm must be established for at least 90 minutes. This time period and flow rate is sufficient to equilibrate the boron concentration and temperature of the isolated and active portions of the RCS. Further, the cold leg temperature of the isolated loop must be verified to be at least 70°F, and within 20°F of the highest cold leg temperature of the active loops. Verification of this condition must be completed within 30 minutes prior to opening the cold leg loop stop valve in the isolated loop. Finally, the boron concentration of the isolated loop must be greater than or equal to the boron concentration corresponding to the shutdown margin requirements for the active volume of the Reactor Coolant System.

Concerning the above requirements for loop stop valve operation, the Basis for Technical Specification 3.17 states: "The return to service of an isolated and filled loop is done in a controlled manner that virtually precludes the possibility of an uncontrolled positive reactivity addition from cold water or boron dilution." The recirculation activity described above is performed under strict administrative controls. Therefore, this activity itself does not constitute a boron dilution event.

14.2.6.2.3 Procedural Requirements for Filling Isolated and Drained Loops

In order to return an isolated and drained loop to service, Technical Specification 3.17 requires that the following conditions be met:

1. The isolated loop must be verified to be drained. Verification must be completed within 2 hours prior to partially opening the hot or cold leg loop stop valve in the isolated loop.
2. The RCS level must be at least 18 feet during the opening of the loop stop valves and during filling of the isolated loop. This requirement is established to ensure that the RCS water level does not drop below mid-nozzle level, thereby ensuring adequate suction conditions for the RHR pumps.
3. A source range nuclear instrument channel is required to be monitored to detect any unexpected positive reactivity addition.

Concerning the return of isolated and drained loops to service, the Basis for Technical Specifications 3.17 states: "An initially isolated and drained loop may be returned to service by partially opening the cold leg loop stop valves and filling the loop in a controlled manner from the Reactor Coolant System. To eliminate numerous reactor coolant pump jogs to completely fill a drained loop, a partial vacuum may be established in the isolated loop prior to commencing filling from the active volume of the Reactor Coolant System. The vacuum-assist loop fill evolution requires initiating seal injection to the reactor coolant pump to permit establishing an adequate vacuum in the isolated loop. A portion of the reactor coolant pump seal injection enters the isolated loop. To eliminate the reactivity concerns associated with the water injected into the isolated and drained loop from the seal injection, a water source of known boron concentration is used."

By returning isolated and drained loops to service in the manner described above, achievement of reduced idle loop temperature and reduced boron concentration would involve a non-credible combination of operator errors.

14.2.6.2.4 Inactive Loop Start-Up with Temperature Mismatch

A bounding calculation has demonstrated that an SUIL event with the maximum credible temperature differential between an idle loop and the active portion of the RCS during COLD SHUTDOWN or REFUELING SHUTDOWN will not result in complete loss of shutdown margin. This calculation assumes that the boron concentration in the idle loop is equal to the concentration in the active portion of the RCS, but that the idle loop temperature is 150°F lower than the active portion of the RCS. Based on this calculation, it is concluded that the reactivity insertion driven only by temperature differential will not result in erosion of SDM, power excursion, or reduction in margin to a DNB condition. Development of a significant boron concentration differential between an idle loop (i.e., loop stop valves open) and the active portion of the RCS is not considered credible.

14.2.6.2.5 Isolated Loop Recirculation with Boron Mismatch

The start-up of an inactive reactor coolant loop with the loop stop valves initially closed has been analyzed. The analysis assumes the inactive loop is at a boron concentration of 0 ppm, while the active portion of the system is at 1500 ppm, a conservatively high value for the beginning of core life. The flow through the relief line is assumed to be at its maximum value of 400 gpm. Even with the assumption that administrative procedures are violated to the extent that an attempt is made to open the loop stop valves with 0 ppm in the inactive loop while the remaining portion of the system is at 1500 ppm, the dilution of the boron in the core region is slow. The initial reactivity insertion rate is calculated to be 3.2×10^{-5} Δk/sec, considerably less than the reactivity insertion rates considered in the Rod Withdrawal at Power and Rod Withdrawal at Subcritical accident analyses. The operator will recognize a high source range count rate signal, and will terminate the dilution by turning off the pump in the inactive loop or by borating to counteract the dilution.

14.2.6.3 **Conclusion**

The Technical Specifications and associated procedural requirements for unisolation of an isolated loop ensure with a high degree of confidence that the RCS and RHR loop configurations presented above cannot achieve the preconditions (i.e., boron concentration and temperature in the isolated loop) necessary for a significant reactivity insertion due to unisolated loop start-up. The recirculation activity which constitutes the loop stop valves closed case is an operating procedure performed under strict administrative control, and does not by itself constitute a reactivity insertion accident. An SUIL event with the maximum credible temperature differential (and no boron concentration differential) between an idle loop and the active portion of the RCS will not result in complete loss of shutdown margin.

14.2.7 Excessive Heat Removal Due to Feedwater System Malfunctions

14.2.7.1 **Identification of Causes and Accident Description**

Reductions in feedwater temperature or additions of excessive feedwater can result in an increase of core power above full power. Such transients are attenuated by the thermal capacity in the secondary plant and in the reactor coolant system. The overpower overtemperature protection (nuclear overpower and delta T trips) prevents any power increase that could lead to a DNBR of less than the applicable SAL (Section 3.2.3).

A feedwater temperature reduction and subsequent reactor coolant system load increase can be initiated by any of the following events: the inadvertent opening of a high-pressure feedwater heater bypass valve which diverts flow around a first-point feedwater heater, the inadvertent opening of a low-pressure feedwater heater bypass valve which diverts flow around the second-, third-, and fourth-point feedwater heaters, or the isolation of extraction steam to the first-point feedwater heaters. Inadvertent bypass valve opening or extraction steam isolation results in a sudden reduction in feedwater inlet temperature to the steam generators. The increased subcooling creates a greater load demand on the RCS. The feedwater heater bypass valves can only be opened manually.

A second example of excessive heat removal is a transient associated with the accidental full opening of feedwater regulating and bypass valves in one or more steam generator loops due to control system malfunction or operator error. The sudden increase in feedwater flow would increase the subcooling of the primary system resulting in a higher core power due to reactivity feedback.

14.2.7.2 **Method of Analysis**

The feedwater temperature reduction event is evaluated by determining a conservative feedwater temperature reduction for the initiating events described in Section 14.2.7.1. The resulting feedwater temperature reduction from each initiating event is shown to be less than the temperature reduction required to generate a primary system load increase of 10% of full power. The event was explicitly analyzed at 2546 MWt for a bounding, 60°F feedwater temperature reduction with the transient analysis code RETRAN (Reference 12), which simulates the reactor coolant system, core kinetics, and the feedwater and steam systems. DNBR analysis for the SIF product was performed with the thermal-hydraulic code COBRA (Reference 13) or the VIPRE-D code (Reference 36) for the 15 x 15 Upgrade fuel design. The analysis incorporates the Statistical DNBR Evaluation Methodology (Reference 17).

The feedwater temperature reduction transient analysis was performed at nominal values consistent with steady-state full power operation: initial pressurizer pressure of 2250 psia, RCS average temperature of 573°F, and full power at 2546 MWt. The use of nominal conditions is consistent with the Virginia Power Statistical DNBR Methodology (Reference 17). The limiting case had a Doppler temperature coefficient of -1.2 pcm/°F, a moderator temperature coefficient of -45 pcm/°F, and automatic rod control enabled.

A DNBR penalty of 3.0% will be applied to account for the increased bypass flow due to the conversion to upflow configuration. This DNBR penalty is conservative and applicable to all DNB events and will be deducted from the retained margin for the Westinghouse 15x15 Upgrade fuel product during the core reload thermal-hydraulic evaluation in accordance with NRC approved methodology in VEP-NE-2-A (Reference 17).

Excessive feedwater addition due to a feedwater control system malfunction or operator error, which allows a feedwater control valve to open fully, was also explicitly analyzed. The analyses were performed using the transient simulation code RETRAN. The excessive feedwater flow transient was analyzed for the 15 x 15 SIF product using deterministic conditions consistent with steady-state full power operation to allow for calibration and instrument errors.

In the 15x15 Upgrade statistical DNBR submittal using VIPRE-D to the NRC (Reference 37), it was stated that the Feedwater malfunction event would be analyzed using statistical methods. With NRC approval (Reference 38) of the LAR in Reference 37, the excessive feedwater flow transient will be analyzed using statistical conditions for the 15 x 15 Upgrade fuel design.

The maximum capacity of the feedwater pumps at Surry is no more than 125% of nominal full power flow. However, the excess feedwater transient was analyzed at 125%, 150%, and 200% of nominal flow. The multi-loop cases assumed equal flows in all three secondary loops. The analyses show that the multi-loop transients experience a lower DNBR than the corresponding single-loop cases. Transients with automatic rod control were shown to have a slightly lower DNBR than the manual rod control cases. The limiting case is the multi-loop analysis with 150% feedwater flow and automatic rod control.

The ability of the automatic rod control system to withdraw rods from the core has been eliminated. This prevents addition of positive reactivity by rod withdrawal in response to transient event conditions thereby resulting in lower power during the event. The event cases with automatic rod control are retained herein, even though they are not credible, as they continue to bound the current plant design.

14.2.7.3 **Results**

14.2.7.3.1 Excessive Feedwater Flow Transient

Figures 14.2-17 through 14.2-21 show the multiple loop 150% feedwater transient with reactor control. The positive reactivity feedback from the sudden increase of feedwater at 0.001 second results in an increase of core power which levels off at 106% of 2546 MWt at about 22 seconds into the transient. The excessive feedwater addition to the steam generators causes an overcooling of the reactor coolant system, resulting in a decrease in pressurizer pressure and RCS average temperature. The analysis results demonstrate that no rods have a calculated MDNBR less than the applicable SAL listed in Section 3.2.3. The mismatch between feedwater flow and steam flow causes the steam generator level to rise until the SG high-high level setpoint is reached, actuating feedwater isolation at 115 seconds. With the feedwater flow reduced to zero, the primary system heats up causing a rise in RCS temperature and pressurizer pressure and a decrease in core power due to negative moderator temperature feedback. The steam generator inventories continue to boil off to dissipate the core power that is still being generated. Eventually, the SG inventory drops to the low-low level setpoint, tripping the reactor at 207 seconds, followed by a turbine trip 2 seconds later.

14.2.7.3.2 Feedwater Temperature Reduction Event

The feedwater temperature reduction event was analyzed with RETRAN and VIPRE-D computer code (Reference 36) for the 15 x 15 Upgrade fuel design for a 200-second duration, which was adequate to demonstrate a new steady-state condition well beyond the point of the event minimum DNBR. Feedwater temperature reduction, normalized nuclear power, change in pressurizer pressure, change in RCS loop ΔT and change in RCS average temperature as a function of time are illustrated in Figures 14.2-22 through 14.2-26. The reduction in feedwater temperature causes a cooldown of the reactor coolant system resulting in a decrease in coolant average temperature and pressurizer pressure. The reduction in coolant average temperature results in an increase in core power from the large negative moderator temperature coefficient present at end of cycle. This increase in core power balances the RCS cooldown so that the system reaches a new steady-state condition at 109% of 2546 MWt, with T_{avg} 2.3°F below nominal and RCS loop ΔT 5.7°F above nominal. The reactor does not trip under these conditions. Pressurizer pressure decreases to 25.6 psi below nominal before recovering due to pressurizer heater actuation. The analysis results demonstrate that no rods have a calculated MDNBR less than the applicable SAL listed in Section 3.2.3. Analysis results confirm that the excessive load increase event evaluated in Section 14.2.8 is more limiting with respect to DNBR.

14.2.7.3.3 Excessive Feedwater Flow Hot Zero Power

Multiple loop excessive flow malfunction is not considered credible at no load conditions. The Feedwater Control System (FWCS) would be in manual mode at start-up and low power. Thus, a series of operator actions inadvertently opening the main and bypass control valves in more than one loop simultaneously would be extremely improbable. At full power, the FWCS is in automatic and a multiple loop control system malfunction becomes more credible. However, the possibility of single loop malfunction at hot zero power has been considered and is discussed below.

The reactivity insertion rate at no load following an excessive feedwater accident has also been calculated, with the following assumptions:

1. A step increase in feedwater flow to one steam generator from 0 to the nominal full-load flow.
2. The most negative reactivity moderator coefficient at the end of life. The value used in the calculation was for a rodded core. The value when just critical at no load will be less negative.
3. A constant feedwater temperature of 70°F.
4. Neglect of the heat capacity of the reactor coolant system and the thick metal of the steam generator shell.
5. Neglect of the energy stored in the fluid of the unaffected steam generators.

The maximum reactivity insertion rate was calculated to be 3.9×10^{-4} delta k/sec, which is less than the maximum reactivity insertion rate analyzed in Section 14.2.1, *Uncontrolled Control-Rod Assembly Withdrawal From a Subcritical Condition*. It should be noted that if the incident occurs with the unit just critical at no load, the reactor may be tripped by the power range flux level trip at a low setting (approximately 25%). As shown in Section 14.2.1 there is a large DNB margin with the above-calculated reactivity insertion rate.

The continuous addition of cold feedwater after a reactor trip is prevented since the reduction of the reactor coolant system temperature, pressure, and pressurizer level leads to the actuation of safety injection on low-low pressurizer pressure. The safety injection signal trips the main feedwater pumps and closes the feedwater pump discharge valves as well as the main feedwater control valves.

14.2.7.4 **Conclusions**

Primary system load increase due to the inadvertent opening of a feedwater heater manual bypass valve or the isolation of extraction steam to both first-point feedwater heaters is bounded by that assumed for the excessive load increase event presented in Section 14.2.8. The excessive load increase event evaluates the consequences of a 10% step load increase from full power. The feedwater temperature reduction event is shown to be bounded by the excessive load increase event.

Representative transient results for excessive load increases due to reduced feedwater temperature and excessive feedwater flow indicate that a core power increase is accompanied by a reactor coolant system average temperature decrease. This has the effect of maintaining an adequate margin to the applicable SAL (Section 3.2.3). It has been shown that the maximum reactivity insertion rate that occurs at no load following excessive feedwater addition is less than the maximum value considered in the analysis of a control rod assembly withdrawal incident from a subcritical condition. It has further been shown that automatic action occurs to prevent the continuous addition of cold feedwater after a unit trip. The event acceptance criteria (DNBR greater than the applicable SAL, reactor coolant system and main steam system pressures less than 110% of design limits, no event propagation) are satisfied for the feedwater malfunction that results in either an increase in feedwater flow or a decrease in feedwater temperature.

14.2.8 Excessive Load Increase Incident

An excessive load increase (ELI) incident is defined as a rapid increase in steam generator flow that causes a power mismatch between the reactor core power and the steam generator load demand. The reactor control system is designed to accommodate a 10% step-load increase or a 5% per minute ramp-load increase, without a reactor-trip, in the range of 15% to 100% of full power. Any loading rate in excess of these values may cause a reactor trip to be actuated by the reactor protection system. If the load increase exceeds the capability of the reactor control system, the transient is terminated in sufficient time to prevent the DNBR from being reduced below the SAL (Section 3.2.3), since the core is protected by the combination of the nuclear overpower and the overpower-overtemperature trips discussed in Chapter 7, although the analysis conservatively does not credit the latter trip. An excessive load increase incident could result from either an administrative violation, such as excessive loading by the operator, or an equipment malfunction in the steam bypass control or turbine speed control.

For excessive loading by the operator or by system demand, the turbine load limiter keeps the maximum turbine load from exceeding 100% rated load.

During power operation, steam bypass to the condenser is controlled by reactor coolant condition signals; high reactor coolant temperature indicates a need for steam bypass. A single controller malfunction does not cause steam bypass; an interlock blocks the opening of the valves unless a large turbine load decrease or a turbine trip has occurred.

14.2.8.1 **Method of Analysis**

Three cases were analyzed to demonstrate the unit behavior for a 10% step increase from 2546 MWt. The first two cases were at end-of-life (EOL) conditions, when the moderator temperature coefficient (MTC) for the core is assumed to be at its most negative limit of -45 pcm/°F, with and without automatic rod control. The third case was at beginning-of-life (BOL), with the MTC at its least negative limit of 0.0 pcm/°F and automatic rod control. Previous analyses indicate that a BOL case without automatic rod control is bounded by the other cases. The analyses were performed using the RETRAN code to provide a detailed simulation of the RCS, core kinetics, and the feedwater and steam systems. Following the RETRAN calculation of the RCS transient initiated from nominal conditions, the VIPRE-D computer code was used to compute the MDNBR at the limiting statepoints for the 15 x 15 Upgrade fuel design from the RETRAN forcing functions as a function of time.

A DNBR penalty of 3.0% will be applied to account for the increased bypass flow due to the conversion to upflow configuration. This DNBR penalty is conservative and applicable to all DNB events and will be deducted from the retained margin for the Westinghouse 15x15 Upgrade fuel product during the core reload thermal-hydraulic evaluation in accordance with NRC approved methodology in VEP-NE-2-A (Reference 17).

The ability of the automatic rod control system to withdraw rods from the core has been eliminated. This prevents addition of positive reactivity by rod withdrawal in response to transient event conditions thereby resulting in lower power during the event. The event cases with automatic rod control are retained herein, even though they are not credible, as they continue to bound the current plant design.

14.2.8.2 **Results**

Figures 14.2-27, 14.2-28, 14.2-29, and 14.2-30 illustrate the results of the ELI transient with the reactor in manual control at EOL conditions, while Figures 14.2-31, 14.2-32, 14.2-33, and 14.2-34 represent the same event under automatic control. As expected, in the manual control case the decrease in RCS pressure and temperature is much more pronounced due to the high moderator temperature feedback. Under automatic control, rod movement will significantly retard the decrease in pressure and temperature. The nuclear power levels off at approximately 110% of 2546 MWt in both cases to balance the steam flow; but it does so sooner under automatic control. The transient DNBR decreases initially and flattens out as the power equilibrium is reached. Rod control has only a minimal effect on the magnitude of the minimum DNBR.

The third case, at BOL under automatic control with enhanced rod worth, is represented in Figures 14.2-35, 14.2-36, 14.2-37, and 14.2-38. The behavior is similar to that of the second case above. As the moderator feedback is assumed to be negligible at BOL, the reactivity to counteract the overcooling effect comes entirely from the control rods. Although RCS pressure and temperature drop initially, they recover and rise to a comparable level later in the transient, and are expected to reach an equilibrium, if the transient is followed long enough.

14.2.8.3 **Conclusions**

The three cases analyzed have considerable margin to the applicable SAL (Section 3.2.3). It is concluded that unit integrity is maintained throughout lifetime for the excessive load increase incident.

14.2.9 Loss of Reactor Coolant Flow

14.2.9.1 **Flow Coastdown Incidents**

A loss-of-coolant-flow incident can result from a mechanical or electrical failure in a reactor coolant pump or from an interruption in the power supply to these pumps. If the reactor is at power at the time of the incident, the immediate effect is a rapid increase in coolant temperature.

This increase could result in DNB with subsequent fuel damage if the reactor is not tripped promptly. The following trip circuits provides the necessary protection against any loss-of-coolant-flow incident:

1. Low reactor coolant flow.
2. Reactor Coolant Pump motor circuit breaker opening,
3. Low voltage on pump power supply busses, and
4. Low frequency on pump power supply busses (opens RCP supply breakers).

Of these, only the low reactor coolant flow reactor trip is assumed in the analysis. The low frequency and low voltage signals are not credited for reactor protection, but are assumed to trip the RCPs at their appropriate setpoints. They provide diverse backup protection for loss of flow accidents. Even though these reactor protection system inputs do not meet IEEE-279 requirements, no credible failure mechanism has been identified which would impact the operability of the reactor protection system.

The reactor trip setpoints and their redundancy are further described in UFSAR Section 7.2, *Reactor Protection System*.

The simultaneous loss of electric power to all reactor coolant pumps at full power is the most severe credible loss-of-coolant-flow condition. For this condition, reactor trip together with flow sustained by the inertia of the coolant and rotating pump parts will be sufficient to prevent reactor coolant system overpressure and the DNBR from being reduced below the applicable SAL (Section 3.2.3).

The following discussion presents the loss-of-flow analysis performed for operation at 2546 MWt. This analysis does not include cases for two loop operation.

14.2.9.1.1 Method of Analysis

The two limiting cases that were analyzed are as follows:

1. Loss of three out of three RCPs from a power level of 2546 MWt, due to an undervoltage condition.
2. Loss of three out of three RCPs from a power level of 2546 MWt, due to a frequency decay condition (-5 Hz/sec).

Partial losses of flow from the loss of fewer than three reactor coolant pumps are protected by the same low flow reactor trip. Because of the identical protection setpoint, and correspondingly higher coolant flow rates throughout the transient, the partial loss of flow events are less limiting than the complete loss of flow events. Therefore, the partial loss of flow events are bounded by the complete loss of flow analyses and no specific partial loss of flow analyses are run.

The above analyses assume core characteristics associated with the 15 x 15 SIF fuel product. The analysis incorporates the *Statistical DNBR Evaluation Methodology* (Reference 17).

The normal power supplies for the pumps are three buses supplied by the generator. Each bus supplies power to one pump. When a generator trip occurs, the pumps are automatically transferred to a bus supplied from external power lines, and the pumps continue to supply coolant flow to the core. The simultaneous loss of power to all reactor coolant pumps is a highly unlikely event. Following any turbine trip, where there are no electrical faults that require tripping the generator from the pump supply network, the generator remains connected to the network for approximately 30 seconds. The reactor coolant pumps remain connected to the generator, thus ensuring full flow for approximately 30 seconds after the reactor trip before any transfer is made. Since each pump is on a separate bus, a single-bus fault would not result in the loss of more than one pump.

A full unit simulation with RETRAN (Reference 12) is used in the analysis to compute the core average and hot-spot heat flux transient responses, including flow coastdown, temperature, reactivity, and control-rod assembly insertion effects.

These data are then used in a detailed thermal-hydraulic computation to compute the DNB margin. This computation solves the continuity, momentum, and energy equations of fluid flow, together with the WRB-1 DNB correlation discussed in Section 3.4.2. The assumptions made in the calculations are discussed below. The VIPRE-D computer code was used to compute the MDNBR and DNBR margin for the LOFA statepoint for the 15 x 15 Upgrade fuel design using the initial conditions specified in 14.2.9.1.2.

A DNBR penalty of 3.0% will be applied to account for the increased bypass flow due to the conversion to upflow configuration. This DNBR penalty is conservative and applicable to all DNB events and will be deducted from the retained margin for the Westinghouse 15x15 Upgrade fuel product during the core reload thermal-hydraulic evaluation in accordance with NRC approved methodology in VEP-NE-2-A (Reference 17).

14.2.9.1.2 Initial Operating Conditions

The initial conditions which are assumed in the analysis are presented below. They are consistent with the statistical treatment of key analysis parameters for the 15 x 15 SIF analysis. (See Section 3.4.3.2).

1. Key thermal/hydraulic parameters used in analysis - 3 loops operating - 15 x 15 SIF:

Power	2546 MWt
Pressure	2249.7 psia
Inlet Temperature	541.9°F
Minimum Measured Flow	273,000 gpm

2. Thermal/Hydraulic Conditions used for the analysis of 15 x 15 Upgrade Fuel Design

Power	2589.3 MWt
Pressure	2250.0 psia
Inlet Temperature	540.7°F
RCS Flow Rate	273,000 gpm

14.2.9.1.3 Reactivity Coefficients

A least negative Doppler Temperature Coefficient (-1.0 pcm/°F) and most positive Moderator Temperature Coefficient (+6 pcm/°F) were assumed since these result in higher heat flux at the time of minimum DNBR. The sensitivity to the effective delayed neutron fraction was evaluated. A minimum delayed neutron fraction was used because it produced the most limiting DNBR.

14.2.9.1.4 Reactor Trip

Following the loss of flow induced by underfrequency or undervoltage, the reactor is assumed to trip on low flow in any loop. This trip meets the IEEE-279 criterion and therefore cannot be negated by a single failure. Neither the low voltage nor low frequency trip circuits meet the IEEE-279 criterion from sensor to trip and are therefore considered backup trips. The low flow trip setting is 90% of full loop flow; the trip signal is assumed to be initiated at 87% of minimum measured flow, allowing 3% for instrumentation errors. It is also assumed that, upon reactor trip, the most reactive control rod assembly is stuck in its fully withdrawn position, resulting in a minimum insertion of negative reactivity. The assumed trip reactivity was 4.0% $\Delta k/k$, which is confirmed to be bounding for each reload cycle.

14.2.9.1.5 Flow Coastdown

Reactor coolant flow coastdown curves for the limiting undervoltage and underfrequency induced loss of flow accidents are shown in Figures 14.2-39 and 14.2-40, respectively. The flow profile for the undervoltage transient includes an initial 2% flow penalty to account for the potential of a “back EMF” phenomenon prior to the trip of the RCP. The RCP will maintain flow at or above 98% for undervoltage conditions less severe than the undervoltage trip setpoint. This is modeled by a prompt drop in flow from 100% to 98% of minimum measured flow followed by a five second delay prior to the RCP trip on (undervoltage). The reactor is not assumed to trip until the low flow setpoint has been reached.

14.2.9.1.6 Results

Both the underfrequency and the undervoltage trip events were analyzed. The two events were found to have nearly identical values of minimum DNBR. The minimum DNBRs for the two accidents showed a considerable margin to the applicable SAL (Section 3.2.3).

The transient responses of power, inlet temperature, average temperature, and pressurizer pressure are plotted in Figures 14.2-41 through 14.2-44 for the undervoltage case and 14.2-45 through 14.2-48 for the underfrequency case.

14.2.9.1.7 Conclusions

The analyses performed have demonstrated that for the above loss of flow incidents, the DNBR does not decrease below the applicable SAL (Section 3.2.3) at any time during the transient. Thus, no fuel or clad damage is predicted, and all applicable acceptance criteria are met.

14.2.9.2 **Locked Rotor Incident**

14.2.9.2.1 Identification of Causes and Accident Description

The Locked Rotor/Sheared Shaft events are characterized by the rapid loss of forced circulation in one Reactor Coolant System (RCS) loop. A Locked Rotor event is defined as the seizure of a Reactor Coolant Pump (RCP) motor due to a mechanical failure. The Sheared Shaft event is defined as the separation of the RCP impeller from the motor due to the severance of the impeller shaft. For both the Locked Rotor and the Sheared Shaft events, the postulate RCP failure causes the reactor coolant flow rate to decrease more rapidly than a normal RCP coastdown.

During power operation the reduction in RCS flow caused by a Locked Rotor or Sheared Shaft event results in degradation of the heat transfer between the fuel and the reactor coolant, and between the reactor coolant and the secondary coolant in the steam generator (SG). As a result of the reduced fluid velocity, the core differential (ΔT) and average temperatures (T_{avg}) increase. The reduced heat transfer to the secondary fluid also contributes to the reactor coolant temperature increase. The expansion of the RCS fluid that accompanies the temperature increase causes an insurge of coolant into the pressurizer, and thus an increase in the reactor coolant system pressure. The reduced fluid velocity and subsequent temperature rise also act to reduce the heat transfer from the fuel, causing the fuel temperature to increase. Fuel damage could then result if specified acceptable fuel damage limits are exceeded during the transient, i.e., if the fuel experiences a Departure from Nucleate Boiling (DNB). Due to the severe nature of these postulated failures, there is a possibility that a limited number of fuel rods will experience DNB. Thus, timely actuation of the Reactor Protection System (RPS) is required to help limit the number of potential fuel failures.

The immediate core power response during a Locked Rotor or Sheared Shaft event will change in accordance with the RCS temperature and pressure based on the magnitude and direction of the moderator reactivity feedback. As such, a Locked Rotor or Sheared Shaft event occurring in the presence of a positive Moderator Temperature Coefficient (MTC) will see an increase in core power at the RCS temperature increases. Conversely, the presence of a negative MTC will cause the core power to decrease as the RCS temperature increases. If the Rod Control System is in automatic, movement of the control rods will generally be in a direction such that a power reduction occurs.

The core power response is also influenced by the magnitude of the fuel Doppler coefficient. The reduced capability of the reactor coolant to remove energy from the reactor core causes the fuel temperature to increase. In the presence of a negative fuel Doppler coefficient, a fuel temperature increase contributes negative reactivity to the core, which acts to diminish the core power increase.

The potential for a Locked Rotor or Sheared Shaft event is present during all modes of operation where at least one RCP is functioning to provide forced circulation. However, the consequences of a Locked Rotor or Sheared Shaft event are reduced dramatically when the reactor is not at power. During subcritical or zero power operation, natural circulation is more than adequate to remove decay heat following the loss of forced circulation. Thus, the potential for exceeding the specified fuel design limits is nearly zero when the reactor is not at power.

Maintaining the fuel cladding integrity is a primary concern for the Locked Rotor/Sheared Shaft event, although integrity may not be maintained for all fuel rods. Therefore, maintaining the RCS as a fission product barrier becomes more significant. Specifically, RCS integrity may be challenged as a result of the volumetric expansion of the fluid caused by the heating of the RCS fluid. Operation of the pressurizer sprays and Power Operated Relief Valves (PORVs) can help limit the impact of the subsequent pressure increase, but cannot counteract the volumetric expansion of the RCS fluid. In general, the short duration of the Locked Rotor event acts in concert with the functioning of the Pressurizer Safety Valves (PSVs), to prevent excessive RCS pressurization. Thus, timely actuation of the RPS is also required to help limit the RCS pressure response.

Sensible and decay heat can be removed by steaming to the condenser through the steam bypass system, to the atmosphere through the Main Steam (MS) PORV or the Main Steam Safety Valves (MSSVs), or any combination of the three methods. However, the desirability of a given method is based on system availability and the extent to which the fission product barriers have been compromised. In all scenarios, feedwater remains available to the Steam Generators (SGs) from either the Main Feedwater (MFW) System or the Auxiliary Feedwater (AFW) System to replenish the secondary coolant. Shortly after the reactor is shut down, the energy removal capability of the SGs will exceed the RCS sensible and decay heat levels, and the reactor operators/automatic control systems will function to maintain the plant at the new equilibrium condition.

The use of the ZIRLO and Optimized ZIRLO (References 31 and 39) alloy in Surry fuel assemblies has a negligible effect on the number of rods in DNB or the peak RCS pressure, and has a negligible effect on the total Zirconium/water reaction compared to Zircaloy. Therefore, the analysis for the 15 x 15 SIF product or the 15 x 15 Upgrade fuel design remains applicable, and reanalysis of the locked rotor event was not required for the implementation of this cladding material.

14.2.9.2.2 Method of Analysis

14.2.9.2.2.1 General. To cover all applicable phases of plant operation, Locked Rotor and Sheared Shaft events during Cold Shutdown, Intermediate Shutdown, Hot Shutdown, Reactor Critical (manual rod control), and Power Operation (automatic and manual rod control modes) are considered. A transient analysis is only required for the Locked Rotor and Sheared Shaft events at full power with manual rod control. The results for a Locked Rotor or Sheared Shaft event at any of the remaining operating conditions are bounded by those of the full power manual rod control case.

Except where otherwise noted, the following assumptions are made in the Locked Rotor/Sheared Shaft transient analysis:

1. The DNB analysis employs a statistical treatment of key analysis uncertainties; the transient cases are initiated from the condition listed in Section 14.2.9.1.2.
2. The main steam and RCS overpressurization analyses employ a deterministic treatment of key analysis uncertainties (102% of 2546 MWt or 100.38% of 2587 MWt; nominal T_{avg} +4°F; nominal pressurizer pressure +30 psi; and Thermal Design Flow).
3. Reactor protection is assumed to be provided by the low coolant loop flow rate reactor trip at 87% of the applicable analysis flow rate. A 1.0-second trip delay is assumed.

4. The analysis supports a moderator temperature coefficient (MTC) core design limit of +6.0 pcm/°F from 0% to 50% power and a linearly decreasing limit to 0.0 pcm/°F at 100% power. The analysis is non-limiting at EOC.

5. Unaffected reactor coolant pumps were assumed to trip 2.0 seconds after reactor trip on low loop coolant flow. The inertia of the unaffected pumps was conservatively reduced by 10% from the design value.

6. In the DNB transient analyses, the turbine trip following reactor trip was conservatively assumed to not function. In the main steam and RCS overpressurization transient analyses, the turbine trip following reactor trip was conservatively assumed to actuate.

7. Manual rod control was assumed.

8. In the DNB transient analyses, the pressurizer sprays and PORVs are conservatively assumed to be operable. In the main steam and RCS overpressurization transient analyses, the pressurizer sprays and PORVs are conservatively assumed to not actuate.

9. The RCS overpressurization analysis assumes 50% bypass flow. The high degree of bypass flow in the overpressurization cases compensates for the uncertainty associated with the thermal/hydraulic behavior of the core due to coolant voiding during a locked rotor event.

14.2.9.2.2.2 Transient Analysis for DNB. The transient analysis for DNB considerations utilizes the RETRAN transient analysis code (Reference 12) and the VIPRE-D detailed core thermal/hydraulics code (Reference 36). The WRB-1 critical heat flux correlation (Reference 30) is used in the analysis.

The transient analysis for DNB is performed to determine the number of fuel pins that experience DNB as a result of a Locked Rotor or Sheared Shaft event. A fuel pin is assumed to fail if the predicted MDNBR is less than the applicable SAL (Section 3.2.3). The Locked Rotor DNB event scenario is therefore designed to produce the most limiting DNB response. From an analytical perspective, this goal is achieved by choosing initial conditions and analysis assumptions that will maximize coolant temperature and the power-to-flow ratio and minimize pressure during the event.

The analysis results demonstrate that no rods have a calculated MDNBR less than the applicable SAL (Section 3.2.3). Therefore, no fuel damage is predicted to occur during the event. Figures 14.2-49 through 14.2-51 provide transient results for core inlet mass flow rate, core heat flux and core inlet temperature from the limiting DNBR analysis case.

A DNBR penalty of 3.0% will be applied to account for the increased bypass flow due to the conversion to upflow configuration. This DNBR penalty is conservative and applicable to all DNB events and will be deducted from the retained margin for the Westinghouse 15x15 Upgrade fuel product during the core reload thermal-hydraulic evaluation in accordance with NRC approved methodology in VEP-NE-2-A (Reference 17).

14.2.9.2.2.3 Transient Analysis for RCS and Main Steam Overpressurization. The transient analysis for RCS and main steam overpressurization considerations also utilizes the RETRAN transient analysis code. The transient analysis for overpressurization considerations verifies that the peak RCS pressure (intact cold leg pump exit pressure) and peak main steam pressure (intact loop steam generator pressure) remain below 110% of RCS and main steam design pressure (2750 psia and 1210 psia, respectively). The Locked Rotor overpressurization event scenario is designed to produce the most limiting overpressurization response. From an analytical perspective, this goal is achieved by choosing initial conditions and analysis assumptions that will minimize RCS energy removal and maximize core coolant expansion during the transient.

Figures 14.2-52 and 14.2-53 provide transient results for RCS pressure and steam generator pressure from the limiting pressurization analysis cases.

14.2.9.2.3 Conclusions

For the scenarios for which a transient analysis was performed, the following conclusions are applicable:

1. Acceptable offsite dose consequences are ensured, since the analysis demonstrates that the fraction of fuel rods predicted to experience Departure from Nucleate Boiling (DNB) is less than that which provides acceptable offsite dose analysis results.
2. Reactor Coolant System (RCS) integrity is maintained throughout the transient as demonstrated by analysis of transient RCS pressure. Specifically, the maximum RCS pressure, which occurred in the intact cold leg pump exit, remained below 2750 psia throughout the transient.
3. Main Steam System (MSS) integrity is maintained throughout the transient as demonstrated by analysis of transient MSS pressure. Specifically, the maximum main steam pressure, which occurred in the intact loop steam generator, remained below 1210 psia throughout the transient.

14.2.9.2.4 Environmental Consequences of Locked Rotor Accident (LRA)

The environmental consequences of the Locked Rotor Accident are not explicitly calculated for Surry Power Station. In accordance with RG 1.183 Appendix G.2., the dose consequences of the LRA are bounded by the MSLB analysis if no fuel damage is postulated for the limiting event. Fuel damage, defined as rods that experience departure from nucleate boiling (DNB), is not predicted during the design basis LRA transient analysis. As such, an analysis of the radiological dose consequences for the LRA event is not explicitly conducted for Surry Power Station.

14.2.10 Loss of External Electrical Load

14.2.10.1 **Identification of Causes and Accident Description**

The loss of external electrical load may result from an abnormal variation in network frequency or other adverse network operating conditions. It may also result from a trip of the turbine generator or the opening of the main breaker from the generator that fails to cause a turbine trip but causes a large, rapid nuclear steam supply system load reduction by the action of the turbine control.

The unit is designed to accept a step loss of load from 100% to 50% without actuating a reactor trip. The automatic steam bypass system, with 40% steam dump capacity to the condenser, is able to accommodate this load rejection by reducing the severity of the transient imposed on the reactor coolant system. The reactor power is reduced to the new equilibrium power level at a rate consistent with the capability of the rod control system. The pressurizer relief valves may be actuated, but the pressurizer safety valves and the steam generator safety valves do not lift for the 50% step loss of load with condenser steam dumps.

In the event the steam bypass (condenser dump) valves fail to open following a large load loss or in the event of a complete loss of load with the steam dump operating the steam generator safety valves may lift and the reactor may be tripped on a high pressurizer pressure, high pressurizer level, or overtemperature delta-T signal. The steam generator shell-side pressure and reactor coolant temperatures will increase rapidly. The pressurizer safety valves and steam generator safety valves are, however, sized to protect the reactor coolant system and main steam systems, respectively, against all load losses, including a complete loss of steam load without the bypass system (condenser dumps) or atmospheric dumps (main steam PORVs) available. The steam dump valves will not be opened for load reductions of 10% or less. For larger load reductions they may open.

The most likely source of a complete loss of load on the nuclear steam supply system is a trip of the turbine generator. In this case, there is a direct reactor trip signal (unless below approximately 10% power) derived from either the turbine autostop oil pressure or a closure of the turbine stop valves. Reactor coolant temperatures and pressure do not significantly increase if the steam bypass system and pressurizer pressure control system are functioning properly. However, in this analysis, the behavior of the unit is evaluated for a complete loss of load from full power without direct reactor trip. The analysis, presented below, shows the adequacy of the pressure relieving devices to prevent Main Steam System and Reactor Coolant System overpressurization and to show that no fuel damage occurs. The latter is demonstrated by conservatively requiring that the applicable SAL (Section 3.2.3) is met for the hottest rod in the core.

As will be shown, the reactor coolant system and Main Steam System pressure relieving devices have sufficient capacities to ensure the safety of the unit without relying on the mitigating capabilities of the Automatic Rod Control, Pressurizer Pressure Control or Main Steam Bypass Systems.

14.2.10.2 **Method of Analysis**

The complete loss of load transients are analyzed with the Virginia Power RETRAN (Reference 12) and VIPRE-D detailed core thermal/hydraulics code (Reference 36) at the limiting statepoint.

The RETRAN model is used to perform the overall Reactor System transient analysis. The model describes the neutron kinetics, Reactor Coolant System including the pressurizer and pressurizer safety and relief valves and spray, and the Main Steam System including the steam generators and main steam safety valves. Outputs of the RETRAN analysis include reactor power level, temperatures and pressures at various points in the Reactor Coolant System, pressurizer water volume and Main Steam System pressure.

The VIPRE-D models are used to calculate the detailed subchannel thermal conditions, including a time and position dependent Departure from Nucleate Boiling Ratio (DNBR) for the 15 x 15 Upgrade fuel design.

A DNBR penalty of 3.0% will be applied to account for the increased bypass flow due to the conversion to upflow configuration. This DNBR penalty is conservative and applicable to all DNB events and will be deducted from the retained margin for the Westinghouse 15x15 Upgrade fuel product during the core reload thermal-hydraulic evaluation in accordance with NRC approved methodology in VEP-NE-2-A (Reference 17).

14.2.10.3 **Initial Operating Conditions**

The following assumptions are made in the DNBR cases:

1. The behavior of the unit is evaluated for a complete loss of steam load from power at (2589.3 MWt for the 15 x 15 Upgrade fuel design) - without a direct reactor trip to demonstrate core protection margins. A statistical treatment of key DNBR analysis parameter uncertainties is employed. Therefore, nominal initial RCS conditions are assumed, and allowances for calibration and instrument errors are incorporated into the limiting DNBR value as described in Statistical DNBR topical report (Reference 17).
2. A positive moderator temperature coefficient conservative for BOC conditions and a least negative Doppler temperature coefficient are assumed.
3. Credit is taken for the effect of pressurizer spray and power operated relief valves in reducing or limiting the coolant pressure.
4. Main feedwater flow is isolated at the time of the turbine trip for the DNB case only.

The following assumptions are made in the Non-DNBR (RCS Pressure) case:

1. The behavior of the unit is evaluated for a complete loss of steam load from full power without a direct reactor trip to demonstrate the adequacy of the pressure-relieving devices. A deterministic treatment of uncertainties in initial RCS operating conditions [e.g. pressure, temperature, flow, and core power (102% of 2546 MWt or 2597 MWt (i.e., 100.38% of 2587 MWt))] is used in the analysis.
2. A zero moderator temperature coefficient and a most negative Doppler temperature coefficient are assumed.
3. The reactor is assumed to be in manual control, which is conservative from the standpoint of maximum pressure attained.
4. Main feedwater flow is isolated at the time of the reactor trip.
5. The pressurizer safety valve tolerance is modeled with +3% PSV tolerance and 0.1 second delay. (Only the results of the overpressure transients are sensitive to the safety valve tolerance. The DNBR results are not sensitive to these parameters.)
6. No credit is taken for the effect of pressurizer spray and power operated relief valves in reducing or limiting the coolant pressure.

The following assumptions are made in both the DNBR case and non-DNBR case:

1. No credit is taken for the operation of the steam dump system, steam generator power operated relief valves, or direct reactor trip on turbine trip. The reactor is tripped on high pressurizer pressure. The steam generator pressure rises to the safety valve setpoint, where steam release through safety valves limits secondary steam pressure to less than design limit.
2. No credit is taken for auxiliary feedwater flow since a stabilized plant condition will be reached before auxiliary feedwater initiation is normally assumed to occur. The auxiliary feedwater flow would remove core decay heat following plant stabilization.
3. All cases examined assumed reactor is in manual rod control mode. This provides the limiting initial reactor power response to the event. In addition, all cases incorporate the assumption of 15% steam generator tube plugging.

14.2.10.4 **Results**

Only the BOC cases are presented here, since they provide the limiting results with respect to the analysis acceptance criteria of interest.

14.2.10.4.1 DNBR Case

Transient results for the RETRAN DNBR case are presented in Figures 14.2-54 to 14.2-58. These are discussed as follows:

Figure 14.2-54 - Nuclear power initially increases in the presence of the RCS heatup and the assumed positive moderator coefficient. Peak power reaches about 114% of 2546 MWt (112% of 2587 MWt) before the effects of reactor trip on high pressurizer pressure dominate.

Figure 14.2-55 - RCS inlet temperature increases by about 39°F prior to the excursion being terminated by reactor trip.

Figure 14.2-56 - Pressurizer liquid volume responds to the RCS heatup by increasing from 804 cubic feet to a maximum of about 1153 cubic feet leaving about 147 cubic feet of minimum steam space.

Figure 14.2-57 - Cold leg pressure follows a similar trend, reaching a peak value of 2674 psia at 15 seconds.

Figure 14.2-58 - Main steam pressure reaches a maximum value of 1174 psia (36 psia margin to the design limit) at 20 seconds. This case is expected to be limiting for main steam pressure.

The Hot Channel DNBR is shown to have considerable margin to the SAL (Section 3.2.3).

14.2.10.4.2 Non-DNBR (RCS Pressure) Case

This is the limiting RCS overpressure case. The results are presented in Figures 14.2-59 to 14.2-63. These are discussed as follows:

Figure 14.2-59 - Nuclear power does not exceed the initial value of 102% of 2546 MWt (100.38% of 2587 MWt) before decreasing in response to the reactor trip on high pressurizer pressure.

Figure 14.2-60 - RCS inlet temperature increases by about 30°F. Again the temperature increase is less than for the pressure control case because of the earlier trip.

Figure 14.2-61 - Pressurizer liquid volume responds to the RCS heatup by increasing from 854 cubic feet to a maximum of about 991 cubic feet leaving about 309 cubic feet of minimum steam space.

Figure 14.2-62 - Cold leg pressure follows a similar trend, reaching a peak value of 2669 psia (about 81 psi margin to the analysis limit) at 9 seconds.

Figure 14.2-63 - Main steam pressure reaches a maximum value of 1161 psia (49 psi margin to the design limit) at 17 seconds or slightly less than the primary pressure control case, as expected.

14.2.10.5 **Conclusions**

The analysis indicates that for a complete loss of external electrical load without a direct or immediate reactor trip the following criteria are met:

1. The minimum transient DNBR remains above the applicable SAL (Section 3.2.3).
2. Pressure at the most limiting RCS location is less than 110% of RCS design pressure, or 2750 psia (the Emergency Condition Stress Limit Specified in Section III of the ASME Code).
3. Pressure at the most limiting Main Steam System (MSS) location is less than 110% of MSS design pressure, or 1210 psia (the Emergency Condition Stress Limit specified in Section III of the ASME Code).

14.2.11 Loss of Normal Feedwater

A loss of normal feedwater (from a pipe break, pump failures, valve malfunctions, or loss of offsite ac power) results in a loss in the capability of the secondary system to remove the heat generated in the reactor core. If the reactor were not tripped during this incident, reactor core damage could possibly occur from a sudden loss of heat sink. If an alternative supply of feedwater were not available for the unit, residual and sensible heat following reactor trip would heat the reactor coolant system water to the point at which water relief from the pressurizer relief valves occurs. A loss of significant water from the reactor coolant system could conceivably lead to core damage. A special case of this event is a main feedwater line break in the main steam valve house (outside containment). The transient is described in Section 14B.6.

The following provides the necessary protection against a loss of normal feedwater:

1. Reactor trip on low-low water level in any steam generator, unless the RCS loop stop valves are closed, or on water level below the AMSAC (ATWS Mitigation System Actuation Circuitry) setpoint in two steam generators after a time delay, providing the C-20 permissive is satisfied.
2. Reactor trip on a main steam flow-feedwater flow mismatch coincidental with a low water level in any steam generator.
3. The operation of two motor driven auxiliary feedwater pumps (350 gpm design flow for each), which can be started either automatically or manually. They are started automatically on:
   a. A low-low water level in one of three steam generators as sensed by two of three channels on that steam generator, unless the RCS loop stop valves for that steam generator are closed.
   b. The opening of one of two feedwater pump breakers on two of two main feedwater pumps.

c. Any safety injection signal.

d. The loss of all ac power, as indicated by an undervoltage on the two transfer buses corresponding to that unit's emergency buses.

e. AMSAC initiation.

4. The operation of one turbine-driven pump (700 gpm), which can be started automatically or manually. It is started automatically on:

   a. A low-low level in two of three steam generators as sensed by two of three channels for each steam generator unless the loop stop valves for those steam generators are closed.

   b. Undervoltage on two of three 4160V ac station service buses for greater than 5 seconds.

   c. AMSAC Initiation.

The motor-driven auxiliary feedwater pumps are supplied by the diesel generators if a loss of outside power occurs, and the turbine-driven pump uses steam from the steam generators. The turbine exhausts the steam to the atmosphere. The auxiliary feedwater pumps take suction directly from the 110,000-gallon emergency condensate storage tank for delivery to the steam generators.

The above provides functional diversity in equipment and control logic to ensure that reactor trip and automatic auxiliary feedwater flow will occur following any loss of normal feedwater, including that caused by a loss of ac power.

14.2.11.1 **Method of Analysis**

A detailed analysis using the RETRAN Code (Reference 12) was performed to obtain the plant transient following a loss of normal feedwater (LONF). The LONF analysis includes sensitivities on the operation of pressurizer heaters, sprays, and power operated relief valves for the effect on the pressurizer fill and RCS overpressure criteria.

The following assumptions were made:

1. Reactor trip occurs when the steam generator water level reaches the narrow range low-level tap in the steam generator.
2. The plant is operating at 102% of 2546 MWt (100.38% of 2587 MWt).
3. The core residual heat generation is based upon long-term operation at the initial power level preceding the trip.
4. The loss of alternating current power case assumes offsite power becomes unavailable at the time reactor trip occurs. The reactor coolant pumps are tripped off coincident with reactor trip.

5. For offsite power available - two motor-driven auxiliary feedwater pumps are available 1 minute after the accident. The pumps are capable of providing 250 gpm of auxiliary feedwater per pump. The turbine driven auxiliary feedwater pump is assumed inoperable.

   For loss of offsite power - one motor-driven auxiliary pump is available 1 minute after the accident. The pump is capable of providing 300 gpm of auxiliary feedwater. The turbine driven auxiliary feedwater pump is assumed inoperable and the second motor-driven auxiliary feedwater pump is not readily available, within the 1 minute timeframe.

6. Auxiliary feedwater is distributed to the steam generators through a common header.

7. Secondary system steam relief is achieved through the self-actuated safety valves. Note that steam relief is typically through the power-operated relief valves or condenser dump valves for most cases of loss of normal feedwater. However, for conservatism, these components are assumed unavailable.

8. The initial reactor coolant average temperature is 4°F higher than the nominal value, since this results in a greater expansion of reactor coolant system water during the transient and a higher water level in the pressurizer.

9. An uncertainty of 8.5% in the full-power programmed pressurizer level is assumed. It should be noted with regard to this incident that even if the pressurizer does fill, the low surge rate would not cause an excessive pressure rise.

10. Initial pressurizer pressure is 30 psi above its nominal value.

11. The analysis is performed with and without alternating current power to the station auxiliaries.

14.2.11.1.1 Case 1 - Offsite Power Unavailable

Figures 14.2-64 through 14.2-67 show the unit parameters following a loss of normal feedwater incident according to the assumptions listed above. Following the reactor and turbine trip, the water level in the steam generators will fall because of a reduction of the steam generator void fraction and because steam flow through the safety valves continues to dissipate the stored and generated heat. For the limiting case, one minute following the initiation of the low-low level trip, one auxiliary feedwater pump is automatically started, reducing the rate of water level decrease. The capacity of the auxiliary feedwater pump is such that the water level in the steam generators being fed does not recede below the lowest level at which sufficient heat transfer area is available to dissipate core residual heat without water relief from the primary system relief or safety valves.

The loss of alternating current power (LOAC) is a special case of the LONF event from an analysis standpoint. The LONF event followed by a reactor coolant pump trip on low-low steam generator water level conservatively bounds the LOAC event. Figures 14.2-64 through 14.2-67 present pressurizer pressure, pressurizer water volume, RCS loop temperature, and core inlet flow rate, respectively, for a case assuming the pressurizer heaters are operational. The analysis of the loss of normal feedwater event demonstrates that the auxiliary feedwater system will remove the stored and residual heat, thus preventing overpressurization and liquid relief of RCS inventory through the pressurizer safety valves or pressurizer power operated relief valves.

14.2.11.1.2 Case 2 - Offsite Power Remains Available

The offsite power available case assumes continuous operation of the reactor coolant pumps. All other assumptions are consistent with those cited earlier. Figures 14.2-68 through 14.2-71 present pressurizer pressure, pressurizer water volume, RCS loop temperature, and core inlet flow rate, respectively, for a case assuming the pressurizer heaters are operational. This case demonstrates the adequacy of the long-term heat removal capability of the AFW System.

14.2.11.2 **Conclusions**

The loss of normal feedwater does not result in any adverse condition in the core, because it does not result in water relief from the pressurizer relief or safety valves, nor does it result in an uncovering of the tube sheets of the steam generators being supplied with water. A long term decrease in the pressurizer water volume is shown, peak RCS pressure does not exceed 2750 psia, main steam pressure is less than 1210 psia, and the total secondary liquid inventory of the three steam generators does not decrease below 15,000 lbm.

14.2.12 Loss of All Alternating Current Power to the Station Auxiliaries

In the event of a complete loss of offsite power and a turbine trip, there would be a loss of power to the unit auxiliaries (i.e., the reactor coolant pumps, main feedwater pumps, etc.). The events following a loss of ac power with turbine trip are as follows:

1. Unit vital instrument loads are supplied by the emergency power sources.
2. As the steam system pressure increases, the steam system power-operated relief valves are automatically opened to the atmosphere. (Steam bypass to the condenser is assumed to be unavailable, since the steam bypass is not required for reactor protection.)
3. If the steam flow rate through the power-operated relief valves is not sufficient (or if the power relief valves are not available), the steam generator self-actuated safety valves may lift to dissipate the sensible heat of the fuel and coolant plus the residual heat produced in the reactor.
4. As the no-load temperature is approached, the steam power-operated relief valves (or self-actuated safety valves if the power-operated relief valves are not available for any reason) are used to dissipate the residual heat and to maintain the unit in the hot-shutdown condition.
5. The emergency diesel generators will start on a loss of voltage on the emergency 4160V buses to supply unit vital loads.

The auxiliary feedwater system is started automatically as discussed in Section 14.2.11. The steam-driven auxiliary feedwater pump uses main steam and exhausts to the atmosphere. The motor-driven auxiliary feedwater pumps are supplied by power from the diesel generators. The pumps take suction directly from the 110,000-gallon emergency condensate storage tank for delivery to the steam generators. The auxiliary feedwater system ensures a feedwater supply of at least the 300 gpm value assumed in the analysis upon loss of power to the station auxiliaries.

The auxiliary steam turbine-driven feedwater pump has a nominal capacity of 700 gpm and the motor driven auxiliary feedwater pumps have a nominal capacity of 350 gpm each.

The steam-driven pump can be tested at any time by admitting steam to the turbine driver. The motor-driven pumps also can be tested at any time. The valves in the system can be operationally tested at any time.

Upon the loss of power to the reactor coolant pumps, coolant flow necessary for core cooling and for the removal of residual heat is maintained by natural circulation in the reactor coolant loops. The natural circulation flow was calculated for the conditions of equilibrium flow and maximum loop flow impedance. The results given by the model are within 15% of the measured flow values obtained during natural circulation tests conducted at the Yankee-Rowe plant and confirmed at San Onofre and Connecticut Yankee. The natural circulation flow ratio as a function of reactor power is given in Table 14.2-1.

It is shown in Section 14.2.11 that a loss of normal feedwater from any cause, including a loss of offsite ac power, does not result in water relief from the pressurizer relief or safety valves.

The loss of ac power to the station auxiliaries does not cause any adverse condition in the core since it does not result in water relief from the pressurizer relief or safety valves.

14.2.13 Likelihood of Turbine-Generator Unit Overspeed

A turbine missile can be generated by a rotor fracture releasing fragments capable of causing significant damage. A large rotor fragment is interpreted to be a sector of a rotor disk forging, of between 90° and 180° included angle, separated by fracture along several radial-axial planes and rupture of the welds.

The material used for the six disk forgings of each LP rotor is a 2%Cr-Ni-Mo steel. The absence of defects of any significant size from the disk forgings, as purchased, is ensured by stringent ultrasonic inspection. The rotors are of welded construction designed to ensure long-term integrity. Each rotor consists of six separate forgings, joined at their outside diameters by submerged-arc welding. In each of the opposed flows, a center disk carries the first six stages of moving blades, the intermediate disk carries the penultimate stage blades and the last disk carries the last stage blades. The improved welded rotor design characteristics include low yield strength material, no shrunk-on disks, homogeneous properties due to small volume of each disk, and verification of absence of material defects by high resolution ultrasonic inspection performed on small size of each forging. These design features contribute to the elimination of the risk of rotor fracture.

There are two quite different circumstances in which the risk of rotor fracture may arise, which are categorized as high-speed burst and low-speed burst events.

The high-speed burst could occur if there is an accidental loss of electrical load concurrent with the failure of turbine protection system components. If the HP turbine governor valves were not automatically closed then the rotor would accelerate to a speed approaching twice the normal running speed. At this speed there is a high probability that LP rotors would fracture, releasing fragments. The low probability of such an event is determined by the low probability of this overspeed ever occurring. The probability of a high-speed burst is unaffected by the turbine retrofit due to the high reliability of the control system components.

A low-speed burst could occur due to a mechanism of deterioration leading to the progressive weakeninq of the rotor which may fail at normal speed, or at a low overspeed. This includes 10 percent above normal speed during periodic overspeed trip tests at no load and 20 percent above normal speed following loss of electrical load and an overspeed trip. The low probability of such an event is determined by design of the rotors to ensure long-term integrity and by periodic inspection to detect any sign of deterioration.

The Alstom Power methodology for the turbine missile generation probability calculation is included in Alstom Standard STD0010572, Reference 40.

The methodology used in this report is the same methodology used by ABB (now Alstom) in the missile analysis report for the Maine Yankee Unit and several others for US utilities. This missile generation probability methodology was the basis for the change in the turbine rotor inspection frequency requested in Maine Yankee Technical Report Amendment 134 to the NRC. The NRC approved Maine Yankee Amendment 134 and stated in their approval that the ABB's probability analysis (turbine missile generation probability calculation) is consistent with NRC approved methodology.

Alstom Standard STD0011103, Reference 44, confirmed that the missile generation probability methodology in Alstom Standard ST0010572 that is used for Surry Power Station is the same missile generation probability methodology as that approved for Maine Yankee.

Therefore, use of the Alstom Power methodology for turbine missile generation probability calculations included in Alstom Standard ST00010572 is consistent with the NRC requirements included in NUREG 0800 for turbine missile generation probability calculations.

This methodology used by Alstom is for estimating the probability of low-speed rotor fracture and/or missile generation due to stress corrosion cracking. The following two failure modes were evaluated:

1. Growth of an Initial Defect by Fatigue

The ultimate inspection standards ensure that any initial defect of significant size is detected and rejected. A conservative assumption is made that, despite this, a large embedded defect of 0.4 inch diameter remains in the disk in a location subject to the highest tangential stress. The evaluation indicates that the margin between a large extended defect size and the minimum critical crack size is a factor of more than 10, and there is no credible failure by this mechanism.

2. Initiation and Growth of Cracks due to Stress Corrosion Cracking (SCC)

   Design procedures developed using the Alstom Power Threshold Stress Approach (TSA), as described in Reference 41, indicate that any risk of stress corrosion cracking Surry retrofit LP rotors is eliminated by design and materials selection. LP rotors of welded construction type indicate no SCC in the relevant radial-axial plane which could extend to release large rotor fragments. Despite the fact that a rotor fracture has never occurred on an Alstom welded rotor, the residual risk of missile generation has been evaluated by probabilistic methods.

   The probability of rotor fracture has been determined by assigning probability distributions to the values of SCC growth rate, stress, and crack geometry. A Monte Carlo analysis was performed to determine the probability of failure. The calculation method and results of estimating the probability of missile generation resulting from the initiation and growth to a critical size of a SCC is described in the following sections:

   a. Crack Initiation

      The initiation probability is taken as a constant value calculated on the basis of the statistics of SCC cracks found in Alstom Power welded rotors during inspections after periods of service. The statistics are based on long-term service but no credit is assumed for design procedures introduced to eliminate susceptibility to SCC initiation as described in Reference 41.

      Using the methodology of Reference 43, the best estimate of the probability of SCC initiation, for 50 percent confidence, is 0.00125. There have been a small number of SCC cracks which have initiated at the internal corners of the blade root slots. In the limited number of cases where this cracking has been observed, the rotors were produced before the application of the Alstom Power TSA, and the calculated stresses at the locations of the cracking have been found to exceed those permitted by TSA. No SCC cracking has been observed at a location where the calculated stress satisfies the requirements of the Alstom Power TSA, to which the Surry retrofit LP rotors have been designed.

   b. Crack Growth Rate

      Stress corrosion cracks appear after an initial period of exposure to stress in the presence of wet steam. It is conservatively assumed that any crack that initiates does so immediately on entering service and begins to grow immediately.

Based on the available data for stress corrosion cracks found in the power-industry service and determined from laboratory tests, the rate of crack growth under steady load can be described (Reference 43) as a log-normally distributed function of temperature and material yield stress.

The probability distribution of stress corrosion crack growth is illustrated in Figure 14.2-72. The rate of crack growth is independent of the crack stress intensity, and therefore independent of applied stress. The decrease in rate at low stress intensities is neglected in this analysis. The increase in rate at high stress intensities is dealt by assuming, very conservatively, that if the crack stress intensity reaches 100 ksi. $\sqrt{\text{in}}$ (ksi square root inches is a unit in the category of fracture toughness, ksi. $\sqrt{\text{in}}$ has a dimension of $\sigma\sqrt{L}$ where σ is applied stress in ksi and L is the crack length in inches) then the acceleration is so great that the fracture follows almost immediately. This is equivalent to reducing the assumed fracture toughness to 100 ksi. $\sqrt{\text{in}}$ in calculating critical crack size at normal speed, as discussed below.

c. Critical Crack Size

The critical crack size at which rotor fracture will occur is dependant on crack geometry factor, rotor disk fracture toughness, and applied stress.

The minimum rotor disk fracture toughness guaranteed by the property specification of the most vulnerable rotor disks, the center disks, is 154 ksi. $\sqrt{\text{in}}$, and the actual values achieved are likely to be significantly higher. However, the calculation is performed by substituting lower value of 100 ksi. $\sqrt{\text{in}}$.

The crack geometry factor has limiting values of 1.99 for a parallel sided crack and 1.26 for a semi-circular crack. These values are appropriate to planar cracks and, conservatively, neglect any increase in critical crack size that might result from crack branching. Between these limits the geometry factor is assumed to be uniformly distributed, so that any value in this range is equally probable. The probability distribution is shown in Figure 14.2-73.

The applied stress is taken to be the mean tangential stress acting over the critical crack depth, determined from the tangential stress contours of Figure 14.2-74. For a given value of crack geometry factor, the mutually compatible values of crack depth and mean tangential stress over that crack depth which satisfy the condition that the crack tip stress intensity equals the limit of 100 ksi. $\sqrt{\text{in}}$ for stable crack propagation are calculated. The variation of this critical crack depth with the crack geometry factor is shown in Figure 14.2-75.

The distribution of tangential stress shown in Figure 14.2-74, which was determined by finite element analysis, is conservatively assumed to be subject to a calculational error of ±10% in line with Reference 43, and is assumed to be distributed linearly around the calculated value. The probability distribution and the corresponding cumulative probability distribution are shown in Figure 14.2-76.

d. Failure Probability

The probability of failure, i.e., that a stress corrosion crack grows to a size that could cause fast fracture of the rotor after any specified period of service, assuming immediate initiation, was determined using a Monte Carlo analysis. For each period of service, ranging from 60,000 hours to 150,000 hours, a large number of trial calculations were carried out in which each of the three variable parameters (SCC growth rate, crack geometry factor, and rotor tangential stress) were randomly selected from its associated probability distribution using randomly generated numbers between zero and one.

The probability of a rotor disk fracture due to SCC initiation and growth is determined as a function of time (Reference 42). Alstom recommends major rotor inspection intervals of 100,000 operating hours. The calculated probability of rotor fracture per unit year during the final year of operation prior to reaching 100,000 hours is 6.96×10^{-8}.

Alstom missile analysis (Reference 40) has concluded that the probability of lowspeed fracture for Surry Power Station LP turbine retrofit rotors is 6.96×10^{-8} per unit year which is less than one hundredth of the acceptable limit of 1×10^{-5} permitted for unfavorably orientated plants by the NRC guidelines. The LP turbine rotor will be inspected per Dominion's inspection program based on the manufacturer's recommendations (Reference 42). This inspection verifies that the rotor will continue to meet the required design safety limit.

Dominion inspection requirements for LP rotors during major overhaul ensure that any indications of SCC which could develop to cause rotor fracture will be detected. The inspection includes a thorough visual inspection for erosion and corrosion damage and magnetic particle examination of selected areas to detect any cracking at the rotor surfaces. In the very unlikely event of surface indications being detected, additional ultrasonic examinations would be performed.

Alstom Power evaluated the probability of missile generation for Surry turbine using the methodology which was previously used for Maine Yankee unit. The methodology was approved by the NRC in Maine Yankee Amendment 134 Safety Evaluation Report. This methodology complies with the SRP Acceptance criteria of NUREG 0800 Section 3.5.1.3, Turbine Missiles.

The probability of missile generation from either unit is so low that it can be discounted and there is no missile strike envelope.

Because of the redundant means of overspeed protection and reliability of the turbine control protection system and of the main steam system, the possibility of unit speeds above the design value (120%) is very remote.

A description of the electro-hydraulic governing system and its operation is given in Section 10.3.3.

In addition to design provisions associated with the turbine control and protection system, the governor and main stop valves are exercised on a periodic basis during unit operation to further reduce the possibility of valve stem sticking. Analyses of oil samples are performed regularly.

The turbine is periodically oversped to check the tripping speed. The remaining tripping devices are routinely checked.

14.3 STANDBY SAFEGUARDS ANALYSIS

14.3.1 Steam Generator Tube Rupture

14.3.1.1 Identification of Causes and Description of Accident

The accident examined is the complete severance of single steam generator tube at the limiting break location. It is assumed that the accident takes place at full power and while the reactor coolant is contaminated with the maximum concentrations allowable by the Technical Specifications, including the effects of pre-accident iodine spiking. The accident leads to the contamination of the secondary side due to the leakage of radioactive coolant from the Reactor Coolant System and, in the event of a coincidental loss of offsite power, a discharge of activity to the atmosphere through the steam generator safety valve and/or power operated relief valves and turbine driven AFW pump exhuast. The analysis presented here conservatively assumes a single power operated relief valve on the header closest to the ruptured generator sticks open following reactor trip with continued operation of the turbine driven AFW pump.

The steam generator tube material is Inconel 600, and, as the material is highly ductile, it is considered that the complete severance of a tube is extremely conservative. Surry Unit 1 and 2 steam generator tube bundles were replaced in 1979 and 1980, respectively, and operating experience since then has been extremely good.

The more probable mode of tube failure would be one or more minor leaks of undetermined origin. Activity in the Steam and Power Conversion System is subject to continual surveillance, and primary to secondary leakage during unit operation is limited to a value that is much lower than that associated with a full tube rupture. For RCS leaks in excess of 50 gpm with indications of secondary activity, the reactor is tripped, and an abnormal procedure for large steam generator tube leak is implemented which directs the operator to (a) identify and isolate secondary release paths from the ruptured generator, (SG PORVs, steam flow to the turbine driven AFW pump, etc.), (b) align the condenser air ejector discharge to containment and (c) commence unit cooldown.

Once the operator has determined a tube rupture has occurred, his first priority is to identify and isolate the affected steam generator as soon as possible in order to minimize the contamination of the secondary system and ensure the termination of any activity discharge to the atmosphere. The recovery procedure can be carried out on such a time scale as to ensure that break flow to the secondary system is terminated before the water level in the affected steam generator can rise into the main steam pipe. Sufficient indications and controls are provided to enable the operator to perform these functions satisfactorily. Training on the tube rupture accident is a significant emphasis of the licensed operator requalification program.

The following sequence of events is initiated by a tube rupture:

1. Pressurizer low pressure and low-level alarms are actuated, and, before unit trip, charging pump flow increases in an attempt to maintain the pressurizer level. On the secondary side there is a steam flow-feedwater flow mismatch before the trip as feedwater flow to the affected steam generator is reduced owing to the additional break flow that is now being supplied to that steam generator.

2. The loss of reactor coolant inventory leads to falling pressure and level in the pressurizer, and eventually a reactor trip signal is generated by overtemperature ΔT or low pressurizer pressure. Automatic unit cooldown following a reactor trip leads to a rapid change of pressurizer level, and the safety injection signal, initiated by low pressurizer pressure, follows soon after the reactor trip. The safety injection signal automatically terminates the normal feedwater supply and initiates the addition of auxiliary feedwater.

3. The steam generator blowdown liquid monitor and the air ejector radiation monitor alarm, indicating the passage of reactor coolant into the secondary system. The air ejector radiation monitor high alarm causes the air ejector exhaust from the condenser to be discharged to the containment, thereby terminating any direct atmospheric release.

4. The unit trip automatically shuts off the steam supply to the turbine and, if offsite power is available, the condenser bypass valves open to permit steam dump to the condenser. In the event of a coincidental station blackout, and loss of condenser vacuum, the condenser bypass valves would automatically close to protect the condenser. The steam generator pressure would rapidly increase and discharge steam to the atmosphere through the steam generator safety valves and/or power-operated relief valves as well as the turbine driven AFW pump exhaust.

5. Following a unit trip, the continued auxiliary feedwater supply and borated safety injection flow (supplied from the refueling water storage tank) provide a heat sink that eventually absorbs decay heat. Thus, steam bypass to the condenser, or, in the case of the loss of condenser vacuum, steam relief to the atmosphere, is discontinued on a time scale that is dependent on the exact amount of emergency equipment (safety injection pumps and auxiliary feedwater pumps) operating.

6. Safety injection flow results in an increasing pressurizer water level. The time after trip at which the operator can clearly see the returning level in the pressurizer is also dependent on the amount of operating auxiliary equipment.

14.3.1.2 **Method of Analysis and Description of the Accident**

A. Thermal-Hydraulic Analysis (Loss of Offsite Power Case)

The thermal hydraulic portion of the tube rupture accident is simulated with the Virginia Power RETRAN model (Reference 12). Key analysis assumptions were as follows:

1) A double ended tube rupture was modeled. Break flow was calculated by explicitly modeling friction losses in both segments of the ruptured steam generator tube and unchoked flow at the rupture site. This model overpredicts the actual break flows observed in the 1987 North Anna Unit 1 steam generator tube rupture. The resultant decrease in RCS pressure eventually reduces the overtemperature ΔT trip setpoint to the full power value resulting in a reactor and turbine trip.

2) Following reactor trip on overtemperature ΔT, the condenser dumps are assumed unavailable, and the secondary side pressurizes to steam generator power operated relief valve (PORV) setpoint following turbine trip.

3) The PORV on the main steam header nearest the ruptured generator is assumed to remain fully open from the time of PORV actuation until 30 minutes after event initiation. Additionally, the turbine drive AFW pump is assumed to start coincident with PORV actuation. Thus, atmospheric releases are assumed over this interval. For the normal case of condensers available, a high air ejector radiation signal diverts the air ejector exhaust to containment. Following safety injection, this exhaust path is also isolated. When offsite power and the condenser are available, the volatile species undergo two stages of partitioning (i.e., in the steam generator and the condenser) prior to being released to the atmosphere. Loss of offsite power results in loss of the condenser and in coastdown of the reactor coolant pumps, which increases the break fluid flashing fraction. Flashed break flow is a major contributor to the release of radioisotopes, as discussed in Section 14.3.1.4. Thus, the case of loss of offsite power is the limiting case from the standpoint of site boundary dose, and the analysis for this case assumes loss of the condenser and coastdown of the reactor coolant pumps after reactor trip.

4) After reactor and turbine trip, the Reactor Coolant System continues to depressurize to the safety injection setpoint. Two high head safety injection pumps are assumed to operate. The Reactor Coolant System pressure stabilizes at the point where break flow and safety injection flow are essentially equal.

5) Reactor power level used in this analysis was set at 102% of 2546 MWt or 100.38% of 2587 MWt.

B. Thermal-Hydraulic Analysis—Control Room Dose (Offsite Power Available) Case

The thermal/hydraulic analysis performed to support the calculation of control room dose is similar to that presented above. However, the calculated control room dose is more limiting under the assumption of offsite power continuing to remain available. Continued availability of offsite power would result in a potentially larger forced intake of unfiltered air from the normal control room air inlets prior to control room isolation than the case of concurrent loss of offsite power.

Therefore, the thermal/hydraulic analysis used to develop the control room calculation assumes continued operation of the reactor coolant pumps after reactor trip. However, no credit is taken for operation of the condenser dumps. As with the previous case, releases are assumed to be via a stuck open PORV on the main steam header leading from the ruptured generator along with the TDAFW exhaust.

14.3.1.3 **Results**

The thermal hydraulic results are shown in Figures 14.3-1 through 14.3-7 for the loss of offsite power case with a complete severance of a SG tube on the hot side just above the tubesheet:

Figure 14.3-1—RCS Average Temperature: Following the rupture, RCS temperature is relatively stable until the unit trips on overtemperature ΔT at 73 seconds. The turbine stop valves are assumed to close within the next 2 seconds. Temperature continues to decrease in response to addition of cold safety injection water (safety injection occurs in response to low pressurizer pressure at 223 seconds) and the release of steam through the stuck open PORV (the PORV opens at 80 seconds). In actual operating practice, additional cooldown would be imposed by the operators as directed by the emergency procedures to support primary side depressurization to reduce the break flow (assuming the affected SG's PORV was manually isolated).

Figure 14.3-2—Ruptured Loop Steam Pressure: After the reactor and turbine trip, pressure in the steam generator initially increases. The expected response would be an increase followed by stabilization at the no-load pressure of about 1005 psig, but since the analysis assumes a steam generator PORV sticks open, there is a gradual depressurization. Flow through the stuck open PORV not shown in this figure follows the same trend as the ruptured loop steam pressure in Figure 14.3-2. The flow through the stuck open PORV represents the primary potential source of radioactivity transport to the environment. Figures 14.3-4 and 14.3-5 show the integrated mass flow rate out of the faulted SG and the intact SG through the stuck open PORV and MSSV.

Figure 14.3-3—Pressurizer Pressure: The initial drop in pressurizer pressure results from excess of tube rupture flow over the charging flow. The pressurizer level controller, which would increase charging flow and tend to retard this initial depressurization, is not modeled. Immediately following reactor trip, the depressurization rate is accelerated. Safety injection is initiated on low pressurizer pressure, the depressurization drops significantly as a result.

Figures 14.3-4 and 14.3-5 – Intact and Ruptured Steam Generator Integrated Steam Releases: These figures show the integrated mass flow rate out of the faulted SG and intact SG through the open PORV, MSSV and turbine driven AFW pump exhaust. This represents the primary potential source of radioactivity transport to the environment.

Figure 14.3-6—Break Flow: The initial break flow through the two ends of the ruptured steam generator tube is about 90 lbm/sec. The flow drops off quickly in response to the RCS depressurization until safety injection is initiated. Then the flow stabilizes, as equilibrium between the break flow and safety injection is established, at about 65 lbm/sec. The slight increasing trend in mass flow beyond this point is a result of increased fluid density due to the RCS cooldown.

Figure 14.3-7—Integrated Break Flow: At one-half hour after initiation of the event, approximately 122,000 lbm of fluid has been transferred from the RCS to the secondary side of the ruptured steam generator.

14.3.1.4 Environmental Consequences of Steam Generator Tube Rupture (SGTR)

A steam generator tube rupture (SGTR) is a break in a tube carrying primary coolant through the steam generator. This postulated break allows primary liquid to leak to the secondary side of the steam generator with an assumed release to the environment through the steam generator Power Operated Relief Valves (PORVs) or the steam generator safety valves. Steam is assumed to be discharged from the affected generator to the environment until the generator is isolated at 30 minutes. The SGTR analysis used the alternative source term and followed the guidance of Regulatory Guide 1.183. Consistent with Regulatory Guide 1.183 the analysis assumed both a pre-accident iodine spike and a concurrent iodine spike.

14.3.1.4.1 SGTR Analysis Assumptions

It has been determined that tube bundle uncovery can affect doses from a Steam Generator Tube Rupture (SGTR). SGTR dose calculations follow the Westinghouse Owners Group (WOG) developed methodology (Reference 39) for this analysis. This methodology of dose calculations consists of four components:

1. Releases from secondary liquid boiling including allowance for a partition factor of 0.01 for iodine between secondary liquid and steam.
2. Releases from the fraction of primary liquid break flow that flashes to steam. A partition factor of 1 is assumed for this flashing fraction.
3. Releases from primary liquid bypassing the secondary side.
4. Releases caused by secondary moisture carryover.

As shown in Reference 39, releases from a SGTR are dominated by the first two terms above for a case with a stuck open PORV. A stuck open PORV also produces a larger radionuclide release than a cycling PORV or a PORV that fails closed, and causes the steam generator safety valves to open to relieve secondary side pressure. The RADTRAD-NAI computer model for the SGTR analysis includes terms 1, 2, and 4 discussed above.

Uncovery of the tube bundle in a SGTR does not significantly increase radionuclide releases for the stuck open PORV case. If the tube bundle is uncovered in a SGTR and the PORV is stuck open, the third release term described above increases, but it is still only a small part of the total release.

14.3.1.4.2 Initial Radioisotope Concentrations

The analyses of the SGTR accidents indicate that no additional fuel rod failures occur as a result of this transient. Thus, radioactive material releases are determined by the radionuclide concentrations initially present in primary liquid, secondary liquid and secondary steam, plus any releases from fuel rods that have failed before the transient. The analyses considered both pre-accident iodine spike cases and concurrent iodine spike cases. The discussion regarding the determination of the pre-accident and concurrent iodine spikes found in Section 14.3.2.4.2 is applicable to the SGTR as well as the main steam line break. The radionuclide inventories and concentrations for the concurrent and pre-accident iodine spike cases are shown in Tables 14.3-10 and 14.3-11, respectively.

14.3.1.4.3 Determination of χ/Q Values

The exclusion area boundary (EAB) and low population zone (LPZ) χ/Q values given in Table 14.3-13 were determined based on Regulatory Guide 1.145 methodology using meteorological data from 2009 to 2013.

During a SGTR, the condenser is conservatively assumed to be unavailable, causing the steam generators to release steam through the secondary system PORVs. Along with contaminated steam being released through the PORVs, steam is also released from the Turbine Driven Auxiliary Feed Water (TDAFW) pump exhaust. The control room χ/Q values for releases from the two steam generator release pathways to the control room normal and emergency air inlets were determined based on Regulatory Guide 1.194 methodology (Reference 34) and are given in Table 14.3-13. The control room utilizes the normal air inlet χ/Q values until the control room is isolated. After operator action is taken to actuate the emergency ventilation system, the emergency air inlet χ/Q values are used.

14.3.1.4.4 Steam Generator Tube Rupture RADTRAD-NAI Models

The RADTRAD-NAI computer code system (References 29) with Federal Guidance Report 11 and 12 dose conversion factors (References 7 & 41) was used to model the SGTR. Several RADTRAD-NAI models were created to calculate the radiological dose consequences of two cases: the pre-accident iodine spike and the concurrent iodine spike. The two cases are identical except for the initial radioisotope inventories and the inclusion of modeling of an iodine release from the fuel rods for eight hours for the concurrent iodine spike case.

The primary system mass, steam generator mass, and control room volume for the SGTR are given in Table 14.3-12. The release of the radionuclides in the steam from the intact steam generators was modeled as essentially a puff release occurring when the PORVs open. The affected steam generator release was modeled using integrated values over the time period of release (30 minutes).

The primary coolant leakage to the intact steam generators was assumed to be 1 gpm, which is conservative with respect to Surry Technical Specifications. The maximum leakage allowed by Technical Specifications is 150 gpd through any one steam generator.

For conservatism, all of this leakage was assumed to occur into the two intact steam generators. This assumption is conservative because the intact generators release steam to the environment for 10.5 hours compared to 30 minutes for the affected generator.

The break flow rates through the ruptured tube to the affected steam generator were based on the thermal hydraulic analysis of a complete double-ended tube rupture. To be consistent with the guidance in Regulatory Guide 1.183 (Reference 32), the liquid and steam break flows are modeled separately. The break flow rates and release rates to the environment are summarized in Tables 14.3-7 and 14.3-8 for the cases with and without continued availability of offsite power.

The liquid break flow through the primary system is modeled as mixing with the secondary liquid in the affected steam generator. The flow from the secondary liquid to the secondary steam is then modeled assuming a partition factor of 0.01 for iodine and moisture carryover of 1% for particulates. The fraction of the break flow that flashes to steam is modeled as being transferred to the affected steam generator steam space with no credit for scrubbing by the steam generator liquid, i.e., equivalent to tube uncovery. Once in the steam generator steam space, the radionuclides in this part of the break are almost immediately released to the environment. This technique for modeling a SGTR with uncovery of the tube bundle was developed in a generic study by the Westinghouse Owners Group (Reference 39).

The primary and secondary system releases are replaced with safety injection and auxiliary feedwater flows. Therefore, the mass of the primary and secondary liquids remains relatively constant during this transient.

The radionuclide inventory in the steam generators is modeled based on the initial inventory, the primary to secondary leakage, and the break flow rates and release rates to the environment that are discussed above. Flow through the condenser was not modeled because it was unavailable for the loss of offsite power case and because modeling the condenser reduces dose consequences.

The model for the control room ventilation system for the SGTR is set up to accurately model the timing of the sequence of events of the SGTR accident. The start of the accident is the tube rupture itself. The PORV on the faulted steam generator was determined to open 80 seconds after the break, and the SI signal is generated at 182 seconds for the case assuming continued availability of offsite power. For the case assuming loss of offsite power, the PORV on the faulted steam generator was determined to open 80 seconds after the break, and the SI signal is generated at 223 seconds. The timing of these events was extracted from the thermal-hydraulic analysis.

Prior to the isolation of the control room with offsite power available, the control room is being supplied via the normal ventilation system with a 3300 cfm intake air flow rate until loss of offsite power or control room isolation, whichever is earlier. The control room isolates automatically 20 seconds after the initiation of the SI signal. Emergency ventilation is assumed to provide a filtered breathing air supply of 900 cfm within 1 hour of the SGTR until the end of the accident. An unfiltered leakage of 0 or 250 cfm is assumed for the entire time the control room is isolated. The control room intake filter efficiency assumed is 90% and 70% for elemental and organic iodine, respectively. All other non-noble gas isotopes modeled are filtered at 99% efficiency.

14.3.1.4.5 Results of Dose Calculations for SGTR

Both pre-accident and concurrent iodine spike cases were analyzed for the steam generator tube rupture. The limiting case for the control room dose was determined to be a pre-accident iodine spike with continued availability of offsite power. This dose is shown in Table 14.3-9 and corresponds to 0 cfm of unfiltered control room inleakage. For 250 cfm of unfiltered control room inleakage the calculated dose is demonstrated to go down slightly. This result is attributed to the decreased average residence time for radionuclides in the control room with the higher inleakage.

Table 14.3-9 also shows a comparison of the doses calculated for the limiting SGTR accident scenario with the GDC-19 criteria. All calculated control room doses for the Surry steam generator tube rupture remain below the GDC-19 criteria.

The limiting case for the EAB and LPZ was determined to be a concurrent iodine spike with loss of offsite power. The EAB and LPZ doses shown in Table 14.3-9 are less than the Regulatory Guide 1.183 limits for concurrent iodine spike cases.

14.3.1.5 **Recovery Procedure**

The immediately apparent symptoms of a tube rupture accident, such as falling pressurizer pressure and level and increased charging pump flow, can also be symptoms of small steam-line breaks and loss-of-coolant accidents. It is therefore important that the operator determine that the accident is the rupture of a steam generator tube in order to carry out the correct recovery procedure. This accident is uniquely identified by a condenser air ejector radiation alarm or a steam generator blowdown radiation alarm, and the operator does not proceed with the following recovery procedure unless these alarms are observed. In the event of a relatively large rupture, such as that analyzed above and shown in Figures 14.3-1 to 14.3-6, it is clear soon after the trip that the level in one steam generator is rising more rapidly than those in the others. This indication is used in identifying the affected steam generator.

The analysis described above takes no credit for operator action for the first 30 minutes. In an actual event, within 30 minutes the operators would be expected to achieve the following:

1. Ensure that power is available to the emergency buses and that safety injection and auxiliary feedwater are actuated. Verify that main feedwater is isolated.

2. Control the reactor system cooldown to maintain no-load temperature. Stop the reactor coolant pumps if safety injection flow to the core is indicated and the minimum required RCS subcooling is not maintained.
3. If not already completed, identify the ruptured steam generator by rising water level or high steam line radiation indications and isolate flow from this steam generator. Adjust auxiliary feedwater flow to maintain the specified water levels in the affected and intact steam generators.

Completion of these steps terminates the release of radioisotopes. For the analysis case discussed above, following termination of flow from the stuck PORV in the ruptured generator, more than 15 additional minutes would elapse prior to repressurizing the steam generator to the nominal PORV relief setpoint (Reference 40), assuming no additional operator actions. In practice, upon completion of identification and isolation of the ruptured generator, the following additional actions are performed:

1. Initiate RCS cooldown through the intact steam generators by dumping steam to the main condenser or through the steamline PORV (depending on the availability of offsite power). Following a loss of offsite power, the steam generator PORVs can not be operated remotely from the main control room because the control circuits are powered from a semi-vital source. However, a backup bottled air system has been provided so that the SG PORVs can be operated from within the Containment Spray Pump House. A second backup bottled air system is also provided inside the Main Steam Valve House, which is a safety-related, seismic structure that is tornado missile protected.
2. Depressurize the RCS to minimize break flow and refill the pressurizer using the pressurizer spray or the pressurizer PORVs. Maintain the RCS pressure within the pressure-temperature limit curve for the Reactor Coolant System.
3. Terminate safety injection flow upon meeting the SI termination criteria.
4. Establish normal letdown and charging functions and control RCS pressure to minimize primary-to-secondary leakage.
5. Initiate appropriate post-SGTR cooldown procedures.

These additional actions limit the potential for any additional releases from the affected generator following the isolation step.

The generic analyses of Reference 40 show that the stuck PORV case yields higher releases than the case where the PORV on the affected generator cycles normally. For cases where less than a full double-ended tube rupture occurs, it may take the operator longer to perform the RCS depressurization step. However, for this case, the break flow rate will also be lower. Therefore, although in specific event scenarios some limited additional relief from cycling of the affected generator's PORV might occur beyond 30 minutes, the analysis cases presented here are bounding in terms of total integrated release and therefore radiological consequences. Based on observation of the relative releases cited for the stuck PORV, cycling PORV and cycling main steam safety valves in Section 9 of Reference 40, the stuck PORV analysis presented here bounds the following scenarios:

1. SGTR with the ruptured SG's PORV cycling at its nominal setpoint; releases terminated at approximately 37 minutes.
2. SGTR with the ruptured SG PORV isolated and the associated main steam safety valve(s) cycling at the nominal setpoint. Releases terminated well beyond 1 hour.
3. Any case above with a break area corresponding to less than a double-ended tube rupture (initial break flow rate of 800 gpm).

14.3.2 Rupture of a Main Steam Pipe

A rupture of a main steam pipe (the pipes that carry steam from the steam generators to the main turbine) is assumed to include any accident that results in an uncontrolled steam release from a steam generator. The release can occur as a result of either a break in a pipe line or a valve malfunction. The steam release results in an initial increase in steam flow, which decreases during the accident as the steam pressure falls. The energy removal from the reactor coolant system causes a reduction of reactor coolant temperature and pressure. With a negative moderator temperature coefficient, the cooldown results in a reduction of the core shutdown margin. If the most reactive control-rod assembly is stuck in its fully withdrawn position, there is a possibility that the core will become critical and return to power, even with the remaining control-rod assemblies inserted. A return to power following a main steam pipe rupture is a potential problem mainly because of the high hot-channel factors that exist when the most reactive rod is stuck in its fully withdrawn position. Assuming the worst combination of circumstances that could lead to the resumption of power generation following a main steam line break, the core is ultimately shut down by the boric acid in the safety injection system.

The analysis of a main steam pipe rupture is performed to demonstrate that:

1. Assuming a stuck control-rod assembly with or without offsite power, and assuming a single failure in the engineered safety features, there is no consequential damage to the primary system and the core remains in place and intact.
2. There will be no DNB or clad perforation resulting from any single active failure in the main steam system. The single active failure is the opening, with failure to close, of the largest of any single steam bypass, relief, or safety valve.
3. Energy release to containment from the worst steam pipe break does not cause failure of the containment structure.

Although DNB and possible clad perforation following a steam pipe rupture are not necessarily unacceptable, the following analysis shows that no DNB occurs for any rupture, even in the event that the most reactive control-rod assembly is stuck in its fully withdrawn position.

The following systems provide the necessary protection against a main steam pipe rupture:

1. Safety injection system actuation by any of the following (see Chapter 7 for logic details):
    a. Two out of three pressurizer low pressure signals.
    b. Two out of three differential pressure signals between any main steam line and the main steam header.
    c. High steam flow in two out of three main steam lines (one out of two per line) in coincidence with either low reactor coolant system average temperature (two out of three) or low main steam line pressure (two out of three).
    d. Three out of four high containment pressure signals.
    e. Manual intervention.
2. The overpower reactor trips (neutron flux and delta T) and the reactor trip occurring upon actuation of the safety injection system.
3. Redundant isolation of the steam generator feedwater lines. Sustained high feedwater flow would cause additional cooldown; thus, in addition to the normal control action that closes the main feedwater valves, any safety injection signal rapidly closes all feedwater control valves, trips the steam generator feedwater pumps, and closes the feedwater pump discharge valves.

    The feedwater isolation function is primarily accomplished by safety grade feedwater control valves and feedwater control valve bypass valves. The feedwater isolation design does not include safety grade back-up isolation capability. However, the automatic trip of the main feedwater pumps and closure of the feedwater pump isolation valves accomplishes the back-up feedwater isolation function. The reliance upon commercial grade isolation equipment as back-up feedwater isolation has been accepted as a generic industry position as documented in NUREG-0138. The failure of a feedwater control valve or bypass valve to close upon a feedwater isolation signal has been evaluated and shown to be bounded by the assumptions in the limiting analysis described in this section.
4. The trip of the fast-acting main steam line trip valves (designed to close within 10 seconds from the time the process variable reaches the trip setpoint) on:
    a. High steam flow in two out of three main steam pipes (one out of two per line) in coincidence with either low reactor coolant system average temperature (two out of three) or low steam line pressure (two out of three).
    b. Three out of four high containment pressure signals.

Each main steam line has a fast-closing trip valve and a nonreturn valve. These six valves prevent the blowdown of more than one steam generator for any break location in a main steam pipe, even if one valve fails to close. For example, for a break upstream from the trip valve in one line, the closure of either the nonreturn valve in that line or the trip valves in the other lines prevents the blowdown of the other steam generators.

All Surry steam generators are equipped with integral flow restrictors at the generator outlet. The restrictors have a smaller flow area than the main pipe and serve to reduce the largest effective break area which must be considered to 1.4 ft^2.

A special case of this event is a main steam line break in the main steam valve house (outside containment). The transient is described in Section 14B.6.

14.3.2.1 **Method of Analysis**

The analysis of the main steam pipe rupture has been performed to determine:

1. The core heat flux and reactor coolant system temperature and pressure resulting from the cooldown following the steam-line break. The analysis was performed with the RETRAN (Reference 12) computer code. The calculation describes the plant neutron kinetics, the reactor coolant system including natural circulation, the pressurizer, steam generators and feedwater system. The digital program computes pertinent variables including the break flow rate, core power and point kinetics reactivity and primary coolant temperatures.
2. The thermal and hydraulic behavior of the core following a steam-line break. The 15 x 15 Upgrade fuel design was analyzed to determine if DNB has occurred using the VIPRE-D code (Reference 42) for the core conditions computed in 1 above. These calculations solve the continuity, momentum, and energy equations of fluid flow in the core, and with the Westinghouse W-3 (Reference 2) or WLOP (Reference 42) correlations determines the DNB margin.

The following assumptions were made:

1. A 1.77% delta k/k shutdown reactivity from all but one control rod assembly at no-load conditions. This is the end-of-life design value, including design margins for the case in which the most reactive control-rod assembly is stuck in its fully withdrawn position. The actual shutdown capability is expected to be significantly greater.
2. The negative moderator coefficient corresponding to the end-of-life core with all but the most reactive control-rod assembly inserted. The variation of the coefficient with temperature has been included. In computing the power generation following a steam-line break, the local reactivity feedback from the high neutron flux in the region of the core near the stuck control-rod assembly has been included in the overall reactivity balance. The local reactivity feedback is composed of Doppler reactivity from the high fuel temperatures near the stuck control-rod assembly and moderator feed back from the high water temperature near the stuck control-rod assembly. The Doppler reactivity feedback corresponds to a most negative hot zero power Doppler temperature coefficeint. For the cases in which steam generation occurs in the high flux regions of the core, the effect of void formation on the reactivity has also been included. The effect of power generation in the core on overall

reactivity is shown in Figure 14.3-8. The curve assumes end-of-life core conditions with all control-rod assemblies in except the most reactive control-rod assembly, which is assumed to be stuck in its fully withdrawn position (completely removed from the core).

3. Minimum safety injection capability corresponding to the operation of only one high head safety injection pump. The most restrictive single failure corresponds to the flow delivered by one charging pump delivering its full flow to the cold leg header. A boron concentration of 2300 ppm was assumed in the Refueling Water Storage Tank (RWST), from which the safety injection pumps take suction. Boron enters the safety injection system after the charging pump suction switches over from the volume control tank to the refueling water storage tank upon safety injection actuation.

   The assumed single failure for the steamline break analysis is the failure of one safeguards train to function, thus maximizing the delay time for boron to reach the core. Other failures that could affect the severity of the transient are bounded by the failure of a safeguards train.

   The initial boron concentration in the Boron Injection Tank (BIT) and the associated safety injection piping is assumed to be zero. The time delays incurred prior to the delivery of the 2300 ppm boron have been included in the analysis. These time delays are conservatively based on the SI system design which included a 900-gallon boron injection tank (BIT). The BIT has been subsequently removed from the SI system on both units (Reference 4). An evaluation of this change against the criteria of 10 CFR 50.59 showed that the main effect of removing the BIT was to significantly reduce the time delay required to sweep unborated water from the SI piping following a safety injection signal, which would be a benefit from a safety analysis standpoint. Thus, the steamline break analyses based on a BIT at 0 ppm are conservative and bound the current condition with the BIT removed.

4. Hot-channel factors corresponding to one stuck control-rod assembly, i.e. the control-rod assembly giving the highest factor at the end of life. The hot-channel factors account for the void existing in the locality of the stuck control-rod assembly at the pressure that occurs during the return-to-power phase following the steam break. This void, in conjunction with the large negative moderator coefficient, partially offsets the effect of the stuck control-rod assembly. The hot-channel factors depend on the core temperature, pressure, and flow, and are therefore different for each case studied. The calculations used to obtain the hot-channel factors again assume end-of-life core conditions with all control-rod assemblies in except the most reactive control-rod assembly.

5. Three combinations of break sizes and initial unit conditions were considered in determining the core power and reactor coolant system transient:

   a. The complete severance of a main steam pipe, initially at no load conditions with offsite power available. The presence of the integral flow restrictors in the steam generators will control the steam release rates for all break locations, both inside and outside the containment.

b. Case A above with loss of offsite power immediately before the steam break.

c. A break larger than or equal to the capacity of any single steam dump or safety valve from one steam generator with offiste power available (credible break).

All the cases above assume initial hot-shutdown conditions with the control-rod assemblies inserted (except for one stuck control-rod assembly) at time zero. Should the reactor be just critical or operating at power at the time of a main steam line break, the reactor is tripped by the normal overpower protection system when the power level reaches a trip point or by the safety injection signal from the steamline break protection functions. Following a trip at power, the reactor coolant system contains more stored energy than at no load, the average coolant temperature is higher than at no load, and there is appreciable energy stored in the fuel. Thus, the additional stored energy is removed via the cooldown caused by the main steam line break before the no-load conditions of reactor coolant system temperature and shutdown margin assumed in the analyses are reached. After the additional stored energy has been removed, the cooldown and reactivity insertions proceed in the same manner as in the analysis that assumes a no-load condition at time zero. However, since the initial steam generator mass is greatest at no load, the magnitude and duration of the reactor coolant system cooldown are less for main steam line breaks occurring at power.

1. In determination of the critical flux at which burnout could occur, the W-3 or WLOP Correlation may be used. This was considered to be the correlation that most accurately represented the range of parameters produced in the transients analyzed.
2. In computing the steam flow during a steam-line break, the Moody Critical Flow Model (Reference 3) was used.

14.3.2.2 **Results**

The results presented are a conservative indication of the events that would occur assuming a main steam line rupture, since it is postulated that all of the conditions above occur simultaneously.

14.3.2.2.1 Core Power and Reactor Coolant System Transient

Figures 14.3-9 through 14.3-13 show the reactor coolant system transient and core heat flux following a main steam pipe rupture (complete severance of a pipe) at initial no-load conditions (Case A). The break assumed is the largest break that can occur anywhere in the system. Offsite power is assumed available such that full reactor coolant flow exists. The transient shown assumes that the control-rod assemblies are inserted at time 0 (with one control-rod assembly stuck in its fully withdrawn position) and steam is released from only one steam generator after closure of the steamline trip valves. Should the core be critical at near zero power when the rupture occurs, the initiation of safety injection by high differential pressure between any steam generator and the main steam header or by high steam flow signals in coincidence with either low reactor coolant system temperature or low steam-line pressure. The current bounding main steam line break analysis assumes a 5-second delay from the time the measured process variables (e.g., steam line flow, steam line pressure) reach the main steam line setpoints to the initiation of main steam trip valve motion, followed by an additional 5-second ramp closure of the valves.

The acceptance criteria for a satisfactorily full closure test of a trip valve is defined in the Basis of Technical Specification 4.7-2 (Reference 26). With the high flow existing during a main steam line rupture, the valves will close considerably faster since their closure is flow assisted.

Tables 14.3-1 through 14.3-3 outline the sequence of events and Tables 14.3-4 and 14.3-5 the transient statepoint parameters for the three main steamline break cases. Figures 14.3-9 through 14.3-23 plot the transient results for several key parameters in the offsite power case, loss of offsite power case, and credible break case, respectively.

As shown in Figure 14.3-9 through 14.3-13, the core attains criticality with the control-rod assemblies inserted (with the design shutdown, assuming one stuck control-rod assembly) before boron solution enters the reactor coolant system from the safety injection system. The delay time consists of the time to receive and actuate the safety injection signal and the time to completely open or realign valve trains in the safety injection lines. The safety injection pumps are then ready to deliver flow. At this stage a further delay time is incurred before boron solution can be injected to the reactor coolant system, due to 0% boron concentration water being swept from the safety injection lines. No credit was taken for any boron in the safety injection lines entering the reactor coolant system prior to the 2300 ppm boric acid from the refueling storage tank. The case attains a peak core power well below the nominal full power value.

The calculation assumes the boric acid is mixed with and diluted by the water flowing in the reactor coolant system before entering the reactor core. The concentration after mixing depends on the relative flow rates in the reactor coolant system and in the safety injection system. The variation of mass flow rate in the reactor coolant system due to water density changes is included in the calculation, as is the variation of flow rate in the safety injection system due to changes in the reactor coolant system pressure. The safety injection system flow calculation includes the line losses in the system as well as the pump head curve.

Figures 14.3-14 through 14.3-18 show the responses of the core parameters for Case B, which corresponds to the case discussed above with loss of offsite power at the time the main steamline break occurs. The safety injection system delay time includes 10 seconds to start the diesel and 10 seconds for the safety injection pump to reach full speed. Criticality is reached later in the transient and the core power increase is slower than in the similar case with offsite power available. The ability of the emptying steam generator to extract heat from the reactor coolant system is reduced by the decreased flow in the reactor coolant system. The peak core power remains well below the nominal full power value.

It should be noted that, following a main steam-line break, only one steam generator blows down completely. Thus, two steam generators are still available for the dissipation of decay heat after the initial transient is over. In the case of loss of offsite power, this heat is removed to the atmosphere, the atmospheric safety valves having been sized to cover this condition.

Figures 14.3-19 through 14.3-23 show the responses of the core parameters resulting from a steam release with an initial steam flow typical of the capacity of any single steam dump or safety valve. In this case, safety injection is initiated automatically by low pressurizer pressure. The limited cooldown resulting from the stuck open valve results in the transient reaching criticality much later in the transient than in the other cases. Sufficient negative reactivity remains to limit the peak heat flux to approximately 7% of the rated power. With the reactor coolant pumps still providing full flow, the case is bounded in terms of minimum DNBR by the offsite power case in Case A, severance of a main steam pipe.

The evaluation of Reference 5 demonstrates that even with 0 ppm boron in the BIT, the containment design bases are met for steam line break. As discussed previously, removal of the BIT provides an analysis benefit with respect to the case of 0 ppm in the BIT, by reducing the time delay for introducing borated water to the core. This reduced time delay will result in a more rapid shutdown and, therefore, reduced mass and energy release to the containment.

14.3.2.3 **Margin to Critical Heat Flux**

Using the transients shown in Figures 14.3-9 through 14.3-23, the 15 x 15 Upgrade fuel design is analyzed with the VIPRE-D/W-3 code/correlation pair or the VIPRE-D/WLOP code/correlation pair (Reference 42) to determine the margin to DNB. Carefully chosen points from each transient were examined, and the results showed that all three cases have a minimum DNBR greater than the applicable SAL (Section 3.2.3). The power and flow statepoint conditions are shown together with pressure and inlet core temperature in Table 14.3-4 and 14.3-5.

14.3.2.4 **Environmental Consequences of a Main Steam-Line Break (MSLB)**

A Main Steam Line Break (MSLB) involves the postulated double ended failure of one of the steam lines carrying steam from a steam generator to the turbine generator. Two cases have to be considered: Loss of Offsite Power (LOOP) and Offsite Power Available (no-LOOP). Both cases assume that the break occurs in the turbine building to maximize does consequences. The no-LOOP case models the turbine building as recirculating the air in the building at the maximum capability of the emergency exhaust fans. The LOOP case assumes that the exhaust fans do not have power in order to operate. Therefore, only natural recirculation is modeled in the LOOP case. The MSLB analysis used the alternative source term and followed the guidance of Regulatory Guide 1.183.

Because the MSLB releases are assumed to occur in the turbine building, the normal χ/Q methodology used for the control room does not apply. χ/Q is used to determine the concentration of a radioisotope χ in Ci/m^3 from the release rate Q in Ci/sec. The control room χ/Q is normally determined with the methodology of Reference 34 based on the distance between release and receptor points and site meteorology. Depending on the type of release, building wake effects may also be considered. For the MSLB, the releases occur in the same building as the control room emergency inlet, so the ARCON96 χ/Q methodology does not apply. Therefore, the direct pathway from the steam line break to the turbine building was modeled along with the intake of control room air from the turbine building.

14.3.2.4.1 MSLB Analysis Assumptions

There is no control room χ/Q defined for a situation when the releases are into the same building where the inlet to the control room is located. Therefore, for the MSLB it was necessary to use a different approach to model the transport of radioactive steam releases from the broken steam line to the control room. (Normal χ/Q methodology is applicable to the modeling of the releases through the intact steam generators.)

The control room is modeled in the RADTRAD-NAI computer code as having three intakes: two intakes from the environment (filtered and unfiltered) and one directly from the Turbine Building. The intake pathways from the environment utilize time-dependent χ/Q values, while the intake pathway from the Turbine Building does not. This modeling approach accounts for the assumption that the release is in the same building as the inlet to the control room.

As a starting point for the MSLB analysis, the concentrations of each radioisotope in the primary and secondary liquid were determined. Radionuclides are released with the steam from these sources through the break. These MSLB release rates are shown in Table 14.3-14.

The flow rates used in this analysis considered the volume expansion that occurs when pressurized liquid or steam is discharged from the steam generator to the turbine building. The flow rate from the steam generator to the turbine building was based on the density of steam or liquid inside the steam generator, while the flow rate from the turbine building to the environment was based on the expansion of steam to atmospheric pressure inside the turbine building. This MSLB model is summarized below.

14.3.2.4.2 Initial Radioisotope Concentrations

For the MSLB, the radioactive material releases are determined by the initial radionuclide concentrations present in primary and secondary liquid, plus any releases from failed fuel rods. The amount of activity in the primary and secondary coolant at the initiation of the MSLB is assumed to be the maximum levels allowed by the plant Technical Specifications.

Consistent with RG 1.183 (Reference 32), both a pre-accident iodine spike and a concurrent iodine spike were considered for the MSLB. For Surry, the maximum iodine concentration allowed in Surry Technical Specifications for an iodine spike is 10 μCi/gm dose equivalent I-131. RG 1.183 defines a concurrent iodine spike as an accident initiated increase in the release rate of iodine from failed fuel rods to a value 500 times the release rate corresponding to the Technical Specification dose equivalent iodine limit for normal operations. (For the SGTR accident, the concurrent spike release rate of iodine from failed fuel rods is set to a value 335 times the release rate corresponding to the Technical Specification dose equivalent iodine limit for normal operations.) In addition to the Technical Specification dose equivalent iodine concentrations and to bound the release rate expected during normal operations; the release rate was determined assuming hot full power conditions, a letdown flow rate of 120 gpm, a primary system leak rate of 11 gpm (10 gpm identified and 1 gpm unidentified), primary-to-secondary leakage of 450 gpd (150 gpd per steam generator) and a letdown decontamination efficiency of 100%. The concurrent iodine spike term of 500 times the release rate is also known as the concurrent iodine spike appearance rate. A concurrent iodine spike is more likely than a pre-accident spike since the pressure change caused by an accident can increase iodine releases from failed fuel rods. A pre-accident iodine spike is unlikely, since some independent event would have had to occur shortly before the accident to cause the spike.

The primary coolant Technical Specification activity concentrations are given in Table 14.3-10. The total primary and secondary radionuclide inventories are derived from these values using the masses of the respective systems. The secondary coolant radionuclide concentrations are assumed to be 10 percent of the primary coolant activity. This accounts for the secondary coolant activity Technical Specification limit being a factor of 10 less than the primary Technical Specification limit. The pre-accident spike activity and the concurrent iodine spike rate are given in Table 14.3-11. The secondary side activity levels are initially the same (at the Technical Specification secondary activity limit) for the pre-accident and concurrent spike cases. Only the primary liquid activities differ. The concurrent iodine spike case assumes the primary coolant activity is initially at the steady state activity limit of 1 μCi/gm dose equivalent I-131 shown in Table 14.3-10, with iodine added at the appearance rates shown in Table 14.3-11. The pre-accident spike case assumes the primary coolant iodine activity is initially at the short term Technical Specifications limit of 10 μCi/gm dose equivalent I-131 and the remainder of the primary coolant isotopes are at the steady state activity limit of 1 μCi/gm dose equivalent I-131 shown in Table 14.3-10. The isotopic concentrations and iodine spike values in Tables 14.3-10 and 14.3-11 are derived from RCS 1% Failed Fuel concentrations shown in Table 14.3-16, which are based on a core power of 2605 MWt and nominal 18 month operating cycles, by normalizing to the Technical Specifications limits for primary and secondary liquid dose equivalent I-131 using CEDE dose conversion factors from FGR 11. These inventories were input to the RADTRAD-NAI code system to calculate doses from an MSLB. The masses of the primary liquid, secondary liquid and secondary steam used in this MSLB dose analysis are listed in Table 14.3-12.

14.3.2.4.3 Determination of χ/Q Values

The EAB and LPZ atmospheric dispersion factors (χ/Q) are given in Table 14.3-13 and were determined based on Regulatory Guide 1.145 methodology using meteorological data for 2009 to 2013.

The intact steam generators are assumed to release steam through the secondary system steam relief valves and Turbine Driven Auxiliary Feed Water (TDAFW) pump exhaust. Using the ARCON96 methodology, the control room χ/Q values shown in Table 14.3-13 were determined for releases from the intact generators.

14.3.2.4.4 Main Steam Line Break RADTRAD-NAI Models

The RADTRAD-NAI computer code system (Reference 29) with Federal Guidance Report 11 and 12 dose conversion factors (References 7 & 41) was used to model the MSLB. RADTRAD models were created to calculate the radiological dose consequences of two cases: the pre-accident Iodine spike and the concurrent accident spike. The two models are identical except for the initial radioisotope inventories and the inclusion of modeling of an iodine release from the fuel rods for eight hours for the concurrent iodine spike case.

The flow rates from the primary coolant to the steam generators prior to the start of the accident were based on conservatively assumed leak rates with respect to Technical Specifications. The maximum leakage from one generator was assumed to be 500 gpd into the generator affected by the steam line break. The maximum leak rate allowed by the Technical Specifications is 150 gpd through any one steam generator.

The affected steam generator was modeled as discharging through the turbine building, while the other two generators were modeled as discharging directly to the environment. The flow rates from the affected steam generator liquid to the turbine building and from the turbine building to the environment are summarized in Table 14.3-14.

All of the iodine being released is conservatively assumed to be airborne. In practice, some of the steam generator discharge would be as water, which would retain some of the iodine in the liquid phase.

The mass release in thirty minutes (Table 14.3-14) is several times the initial mass of the affected steam generator. The mass released from the affected steam generator to the turbine building was increased above the calculated values to ensure that substantially all of the radionuclides initially present in the affected steam generator were released.

Because the affected steam generator is essentially emptied of liquid during the MSLB, no partitioning of iodine between the liquid and steam is assumed for discharges from the affected generator. A partition factor of 0.01 for the iodine isotopes and a moisture carryover of 1% for the particulate isotopes were assumed for the intact generators. The flow rate from the turbine building to the environment considered the expansion of the steam as the pressure is reduced to atmospheric in the turbine building. In addition, because the turbine building is not a sealed building, air flow through the building was considered. The building has a forced ventilation system capable of approximately one volume exchange every six minutes.

However, this forced ventilation system would not function after a loss of offsite power. One volume exchange per hour is a reasonable air flow rate for the turbine building without forced ventilation. For conservatism, the LOOP case assumed a 0.2 volume/hour air flow rate. A forced ventilation of 12 volumes/hour was used in the no-LOOP case when forced ventilation is available.

The model for the control room ventilation system for the MSLB is set up to accurately model the timing of the sequence of events of the MSLB accident. The start of the accident is the steam line break itself. Steam is released from the intact steam generators safety relief valves during the first 11 seconds of the MSLB. The SI signal is generated at 16 seconds for the case assuming continued availability of offsite power and at 19 seconds for the case assuming loss of offsite power. The timing of these events was extracted from the thermal-hydraulic analysis.

Prior to the isolation of the control room with offsite power available, the control room is being supplied via the normal ventilation system, with a 3300 cfm intake air flow rate. The control room isolates automatically 20 seconds after the initiation of the SI signal. For the LOOP case, the normal ventilation system is assumed to not be operating. Emergency ventilation is assumed to provide a filtered breathing air supply of 900 cfm within 1 hour of the MSLB until the end of the accident. An unfiltered inleakage of 250 cfm is assumed for the entire control room is isolated. The control room intake filter efficiency assumed is 90% and 70% for elemental and organic iodine, respectively. All other non-noble gas isotopes modeled are filtered at 99% efficiency.

14.3.2.4.5 Results of Dose Analysis for MSLB

The control room, EAB and LPZ doses calculated for the MSLB are shown in Table 14.3-15. The limiting accident scenario for the calculation of the doses was determined to be a concurrent iodine spike case. The calculated control room dose from a MSLB is below the GDC-19 criteria. The doses calculated for a MSLB at the EAB and LPZ are less than the RG 1.183 limits for concurrent iodine spike cases.

14.3.2.5 **Conclusions**

Although DNB and possible clad perforation (no clad melting or zirconium-water reaction) following a steam pipe rupture are not necessarily unacceptable, the above analysis, in fact, shows that DNB does not occur for any rupture, assuming the most reactive rod stuck in its fully withdrawn position.

The minimum DNBRs determined in the analysis of the steamline break are greater than the applicable SAL (Section 3.2.3).

14.3.3 Rupture of a Control Rod Drive Mechanism Housing (Control Rod Assembly Ejection)

14.3.3.1 **Identification of Causes and Accident Description**

This accident is defined as the mechanical failure of a control rod mechanism pressure housing, resulting in the ejection of a rod cluster control assembly and drive shaft. The consequence of this mechanical failure is a rapid reactivity insertion together with an adverse core power distribution, possibly leading to localized fuel rod damage.

14.3.3.1.1 Design Precautions and Protection

Certain features in Westinghouse pressurized water reactors are intended to preclude the possibility of a rod-ejection accident, or to limit the consequences if the accident were to occur. These include a sound, conservative mechanical design of the rod housings, a thorough quality control (testing) program during assembly, and a nuclear design that lessens the potential ejection worth of rod cluster control assemblies and minimizes the number of assemblies inserted at power.

14.3.3.1.1.1 Mechanical Design. The mechanical design is discussed in Section 3.5. Mechanical design and quality control procedures intended to preclude the possibility of a rod cluster control assembly (RCCA) drive mechanism housing failure sufficient to allow a rod cluster control assembly to be rapidly ejected from the core are listed below:

1. Each Unit 1 control rod drive mechanism housing is completely assembled and shop-tested at 3450 psig. Each Unit 2 control rod drive housing is hydrostatically tested at the shop at 3107 psig.
2. The mechanism housings are checked during the system leak test of the reactor coolant system.
3. Stress levels in the mechanisms are not affected by anticipated system transients at power, or by the thermal movement of the coolant loops. Moments induced by the design-basis earthquake can be accepted within the allowable primary working stress range specified by the ASME Code, Section III, for Class A components.
4. The Unit 1 latch mechanism housing and rod travel housing are each a single length of forged type 304 stainless steel. The Unit 2 latch mechanism housing and rod travel housing are each a single length of forged type 316 stainless steel. These materials exhibit excellent notch toughness at all temperatures that will be encountered.

The Unit 1 joints between the latch mechanism housing and head adapter, and between the latch mechanism housing and rod travel housing, are threaded joints reinforced by canopy-type rod welds. The Unit 2 joints between the latch mechanism housing and head adapter housing are threaded joints reinforced by canopy type welds. The Unit 2 joints between the latch mechanism housing and rod travel housing are butt welds. Administrative regulations require periodic inspections of these (and other) welds.

14.3.3.1.1.2 Nuclear Design. Even if a rupture of a rod cluster control assembly (RCCA) drive mechanism housing is postulated, the operation of a plant using chemical shim is such that the severity of an ejected rod cluster control assembly is inherently limited. In general, the reactor is operated with the RCCAs inserted only far enough to permit load follow. Reactivity changes caused by core depletion and xenon transients are compensated for by boron changes. Further, the location and grouping of control rod banks are selected during the nuclear design to lessen the severity of a RCCA-ejection accident. Therefore, should a rod cluster control assembly be ejected from its normal position during full-power operation, only a minor reactivity excursion, at worst, could be expected to occur.

However, it may occasionally be desirable to operate with larger than normal insertions. For this reason, a rod insertion limit is defined as a function of power level. Operation with the rod cluster control assemblies above this limit guarantees adequate shutdown capability and acceptable power distribution. The position of all rod cluster control assemblies is continuously indicated in the control room. An alarm will occur if a bank of rod cluster control assemblies approaches its insertion limit or if one assembly deviates from its bank. There are low-low-level insertion monitors with visual and audio signals.

14.3.3.1.1.3 Reactor Protection. The reactor protection in the event of a rod-ejection accident has been described in Reference 13. The protection for this accident is provided by the high-neutron-flux trip (high and low setting). This protection function is described in detail in Section 7.2.

14.3.3.1.1.4 Effects on Adjacent Housings. A control-rod drive mechanism assembly is shown in Chapter 3. The operating coil stack assembly of this mechanism has a 10.718-inch by 10.718-inch cross section and is 39.875 inch in length. The position indicator coil stack assembly is located above the operating coil stack assembly. It surrounds the rod travel housing over nearly its entire 163.25-inch length. The rod travel housing outside diameter is 3.75 inch and the inside and outside diameters of the position indicator coil stack assembly are 3.75 and 7 inches, respectively. This assembly consists of a Micarta tube surrounded by a continuous stack of copper-wire coils. This assembly is held together by two end plates, an outer sleeve, and four axial tie rods.

14.3.3.1.1.4.1 Effects of Rod Travel Housing Longitudinal Failures. Should a longitudinal failure of the rod travel housing occur, the region of the Micarta tube opposite the break would be stressed by the reactor coolant pressure of 2250 psia. The most probable leakage path would be the radial deformation of the position indicator coil assembly, resulting in the growth of axial flow passages between the rod travel housing and the Micarta tube. The development of a radial free-water jet would be unlikely because of the small clearance between the Micarta tube and the rod travel housing, and the considerable resistance of the combination of the Micarta tube and the position indicator coils to internal pressure.

Calculations based on experimental data on the mechanical properties of Micarta and copper at reactor operating temperature show than an internal pressure of at least 2500 psia would be necessary for the combination of the Micarta tube and the coils to start leaking in a radial direction between the Micarta glass filaments.

The normal operating environment of the Micarta tube is strictly controlled during unit operation, and thus no deterioration of the Micarta is expected. Should for unknown reasons the mechanical strength of the Micarta tube be reduced and a longitudinal crack occur in a control-rod assembly housing, weepage flow between the Micarta filaments and the copper coil wires might take place, but no free jet should be formed. The formation of a free jet implies a cracking of the Micarta tube, which could occur only with internal pressure substantially in excess of reactor operating pressure. Prolonged exposure to hot water might cause a deterioration of the Micarta and radial leakage might increase; even under these conditions, however, a net radial free jet would be improbable.

A position indicator coil assembly has to maintain its integrity after a housing failure only until the remaining control-rod assembly can be tripped into the core. Should for unknown reasons a failure of the position indicator coil assembly occur after reactor trip, the resulting free radial jet from the failed housing could cause the housing to bend and come into contact with adjacent rod travel housings. If the adjacent housings were on the periphery, they could conceivably bend outward from their bases. The housing material is quite ductile and plastic hinging without cracking could be expected. Rod travel housings adjacent to a failed housing in locations other than the periphery would not be bent because of the rigidity of multiple adjacent housings.

14.3.3.1.1.4.2 Effect or Rod Travel Housing Circumferential Failures. If a circumferential failure of a rod travel housing were to occur, the broken-off section of the housing would be ejected vertically because the driving force is vertical. The position indicator coil stack assembly and the drive shaft would tend to guide the broken-off piece upward during its travel. Travel would be limited to less than 3 feet (Unit 1) or about 15 inches (Unit 2, due to the integral missile shield) by the missile shield, thereby limiting the projectile acceleration. When the projectile reached the missile shield, it would partially penetrate the shield and dissipate its kinetic energy. The water jet from the break would continue to push the broken-off piece against the missile shield.

If the broken-off piece of the rod travel housing were short enough to clear the break when fully ejected, it would rebound after impact with the missile shield. The top-end plates of the position indicator coil stack assemblies would prevent the broken piece from directly hitting the rod travel housing of a second drive mechanism. Even if a direct hit by the rebounding piece were to occur, the low kinetic energy of the rebounding projectile would not be expected to cause significant damage.

14.3.3.1.2 Limiting Criteria

Due to the extremely low probability of a RCCA-ejection accident, limited fuel damage is considered an accepatable consequence.

Comprehensive studies of the threshold of fuel failure and of the threshold of significant conversion of the fuel thermal energy to mechanical energy have been carried out as part of the SPERT project by the Idaho Nuclear Corporation (Reference 14). Extensive tests of Zirconium-clad UO_2 fuel rods representative of those in pressurized-water-reactor-type cores have demonstrated failure thresholds in the range of 240 to 257 cal/gm. However, other rods of a slightly different design have exhibited failures as low as 225 cal/gm. These results differ significantly from the TREAT (Reference 15) results, which indicated a failure threshold of 280 cal/gm. Limited results have indicated that this threshold decreases by about 10% with fuel burnup. The clad failure mechanism appears to be melting for zero burnup rods and brittle fracture for irradiated rods. Also important is the conversion ratio of thermal to mechanical energy. This ratio becomes marginally detectable above 300 cal/gm for unirradiated rods and 200 cal/gm for irradiated rods; catastrophic failure (large fuel dispersal, large pressure rise), even for irradiated rods, did not occur below 300 cal/gm.

In view of the above experimental results, conservative criteria are applied to ensure that there is little or no possibility of fuel dispersal in the coolant, gross lattice distortion, or severe shock waves. These criteria are:

1. Average fuel pellet enthalpy at the hot spot below 225 cal/gm for unirradiated fuel and 200 cal/gm for irradiated fuel.
2. Peak clad temperature at the hot spot below the temperature at which clad embrittlement may be expected (2700°F). (Reference 25).
3. Peak reactor coolant pressure less than 3000 psi, which is much less than that which would cause damage to the reactor coolant system.
4. Fuel melting limited to less than 10% of the fuel volume at the hot spot even if the average fuel pellet enthalpy is below the limits of criterion 1 above.

14.3.3.2 **Analysis of Effects and Consequences**

14.3.3.2.1 Method of Analysis

Previous analyses of this event are documented in the original FSAR, and in References 9 and 16 through 21 and 27. The initial FSAR analysis was performed by Westinghouse. The calculation was done in two stages: an average core calculation, and then a hot region calculation. The nuclear power transients for the average core calculation were calculated using the CHIC-KIN code developed by the Bettis Atomic Power Laboratory (Reference 22) to solve the point kinetics equations. A detailed heat transfer code, which employed the Tong, Sandberg and Bishop correlation (Reference 23) to determine the film boiling heat transfer coefficient after DNB, was then used for the hot region calculations.

References 16 and 17 updated the original analysis to accommodate the higher end of life (EOL) ejected rod worths and peaking factors realized for Cycle 2 operation at both units.

The Reference 18 analysis was performed to reflect a positive moderator temperature coefficient at beginning of cycle (approximately 3 pcm/F at zero power, decreasing to 1.5 pcm/F at full power). These calculations were done by Westinghouse using the TWINKLE code for the nuclear power transient and the FACTRAN code for the hot spot heat transfer calculations. The method of analysis is given in WCAP-8117 (Reference 24), and the basis for the calculation and the Westinghouse limit criteria is given in WCAP-7588 (Reference 10).

These same models and methods were used for the reanalyses in References 19 and 20. These evaluations were performed because the Cycle 3 reload core design for each unit resulted in violations of one or more of the following design limits: the ratio of the rod worths to the delayed neutron fraction, the peaking factors; maximum ejected rod worths, or minimum delayed neutron fractions.

The analysis in Reference 9 was performed to establish new design limits when the minimum delayed neutron fractions for the Surry 1 Cycle 5 reload design were less than the applicable limits. The Westinghouse models and methods were again used for this analysis.

The rod ejection analysis in Reference 21 was performed to evaluate the impact of the increased drop time associated with the SIF assemblies.

The rod ejection analysis in Reference 27 was performed to establish new design limits to accommodate trends toward higher peaking factors. For the analysis of the rod ejection event, it was determined that the use of ZIRLO cladding results in a small reduction in both the fraction of fuel melting at the hot spot and the fuel peak stored energy when compared with the results for Zircaloy clad fuel (Reference 28). The use of Optimized ZIRLO cladding associated with the 15 x 15 Upgrade fuel design has a negligible effect on the results as compared to ZIRLO cladding (Reference 43). The analysis described below is therefore applicable for all of these clad materials.

A rod ejection analysis was performed to establish design limits for the moderator temperature coefficient. A subsequent rod ejection analysis was performed to support the implementation of Integral Fuel Burnable Absorber (IFBA) fuel. The implementation of IFBA fuel core loading patterns at Surry resulted in several core physics parameters exceeding values previously analyzed. The current analysis employs increased key core physics parameter inputs which accommodate the predicted core behavior for IFBA core reload patterns. The current analysis is applicable for both IFBA and non-IFBA fuel types at Surry and is bounding for the 15 x 15 Upgrade fuel design. Also, consistent with the PAD5 fuel performance code, WCAP-17642-P-A, Rev. 1, (Reference 30), the effects of fuel thermal conductivity degradation with burn up are accounted for in the current analysis.

The analysis of the RCCA ejection accident is performed in two stages: first, an average core nuclear power transient calculation, and then a hot-spot heat transfer calculation. The average core power calculation is performed using point neutron kinetics methods to determine the average power generation with time, including the various total core feedback effects, i.e., Doppler reactivity and moderator reactivity. Enthalpy and temperature transients in the hot spot are then determined by multiplying the average core power generation by the hot-channel factor and performing a fuel rod transient heat transfer calculation. The power distribution calculated without feedback is conservatively assumed to persist throughout the transient.

A detailed discussion of the method of analysis can be found in Reference 25.

14.3.3.2.1.1 Average Core Analysis. The point kinetics model of the RETRAN computer code (References 12 and 25) is used to perform the average core transient analysis. This code includes the simulation of prompt and delayed neutrons (using the six group model), the thermal kinetics of the fuel and moderator and the balance of the NSS primary and secondary coolant system. Thermal feedback effects are modeled via temperature dependent reactivity coefficients with a detailed multiregion, transient fuel-clad-coolant heat transfer model. Reactivity insertion from the ejection of the control rod and the subsequent reactor trip are accounted for.

Since both the axial and radial dimensions are missing, it is necessary to use very conservative methods (described below) of calculating the ejected-rod worth and hot-channel factor.

14.3.3.2.1.2 Hot-Spot Analysis. The average core energy addition, calculated as described above, is multiplied by the appropriate hot-channel factors, and the hot-spot analysis is performed using a detailed fuel and clad transient heat transfer model of the RETRAN code termed the Hot Spot Model (Reference 25). This model calculates the transient temperature distribution in a cross section of a metal-clad UO_2 fuel rod and the heat flux at the surface of the rod, using as input the nuclear power versus time and the local coolant conditions. The zirconium-water reaction is explicitly represented, and all material properties are represented as functions of temperature. A parabolic radial power generation is used within the fuel rod.

The RETRAN Hot-Spot Model uses the Thom subcooled boiling correlation to determine the film heat transfer before departure from nucleate boiling, and the Bishop-Sandberg-Tong correlation (Reference 23) to determine the film-boiling coefficient after departure from nucleate boiling. The DNB heat flux is not calculated; instead, the code is forced into departure from nucleate boiling by specifying a conservative DNB heat flux. The gap heat transfer coefficient is adjusted to force the full-power steady-state temperature distribution to agree with that predicted by design fuel heat transfer codes presently used by Westinghouse.

For full-power cases, the design initial hot-channel factor (Fqt) is input to the code. The hot-channel factor during the transient is assumed to increase from the steady-state design value to the maximum transient value in 0.1 second and remain at the maximum for the duration of the transient. This is conservative, since detailed spatial kinetics models show that the hot-channel factor decreases shortly after the nuclear power peak due to the power flattening caused by the preferential feedback in the hot channel (Reference 10).

14.3.3.2.1.3 System Overpressure Analysis. Because safety limits for the fuel damage specified earlier are not exceeded, there is little likelihood of fuel dispersal into the coolant. The pressure surge may therefore be calculated on the basis of conventional heat transfer from the fuel and prompt heat generation in the coolant.

The pressure surge is calculated by first performing the fuel heat transfer calculation to determine the average and hot-spot heat flux versus time. Using these heat flux data, a THINC calculation is conducted to determine the volume surge. Finally, the volume surge is simulated in a plant transient computer code. This code calculates the pressure transient, taking into account fluid transport in the system, heat transfer to the steam generators, and the action of the pressurizer spray and pressure relief valves. No credit is taken for the possible pressure reduction caused by the assumed failure of the control rod pressure housing (Reference 10).

Due to the very conservative method of analysis, the peak surge rate is high enough to cause the reactor coolant pressure to exceed the pressurizer safety valve actuation pressure. However, this condition exists only for a few seconds; consequently, the pressurizer water volume does not change significantly (less than 150 ft^3). Therefore, the transient is not sensitive to the initial pressurizer level, and the programmed value is used.

14.3.3.2.2 Calculation of Basic Parameters

Input parameters for the analysis are conservatively selected on the basis of values calculated for this type of core. The more important parameters are discussed below. Table 14.3-6 presents the parameters used in this analysis. The MUR uprate does not impact 0% power initial condition case results and is bounded by analysis at 102% of 2546 MWt or 100.38% of 2587 MWt initial core power.

14.3.3.2.2.1 Ejected-Rod Worths and Hot-Channel Factors. The values for ejected-rod worths and hot-channel factors are calculated using a synthesis of one-dimensional, two-dimensional and three-dimensional calculations. Standard nuclear design codes are used in the analysis. No credit is taken for the flux-flattening effects of reactivity feedback. The calculation is performed for the maximum allowed bank insertion at a given power level, as determined by the rod insertion limits. Adverse xenon distributions are considered in the calculations.

The total transient hot-channel factor, Fqt, is then obtained by combining the axial and radial factors.

Appropriate margins are added to the results to allow for calculational uncertainties, including an allowance for nuclear power peaking due to fuel densification.

14.3.3.2.2.2 Reactivity Feedback Weighting Factors. The largest temperature rises, and hence the largest reactivity feedbacks, occur in channels where the power is higher than average. Since the weight of a region is dependent on flux, these regions have high weights. This means that the reactivity feedback is larger than that indicated by a simple single-channel analysis. Physics calculations were carried out for a large number of radial temperature distributions. Reactivity changes were compared and effective weighting factors determined. These weighting factors take the form of multipliers that, when applied to single-channel feedbacks, correct them to effective whole-core feedbacks for the appropriate flux shape. In this analysis, although a point kinetics method is used, only a radial weighting factor is applied. In addition, no weighting is applied to the moderator feedback. This very conservative radial weighting factor is applied to the Doppler reactivity feedback of the fuel as a function of the post-ejection radial power peaking factor to account for the missing spatial effect. This weighting factor has been shown to be conservative compared to three-dimensional analysis (Reference 25).

14.3.3.2.2.3 Moderator and Doppler Coefficient. The critical boron concentration at the beginning of cycle (BOC) and end of cycle (EOC) were adjusted in the nuclear code to obtain moderator density coefficient curves that are conservative compared to actual design conditions for the plant. As discussed above, no weighting factor is applied to this coefficient.

The Doppler reactivity coefficeint is determined as a function of fuel temperature using a two-dimensional steady-state computer code with a Doppler weighting factor of 1.0. The resulting coefficient is conservative compared to design predictions for this plant. The weighting factor will increase under accident conditions as discussed above. The transient weighting factor used in the analysis is presented in Table 14.3-6.

14.3.3.2.2.4 Delayed Neutron Fraction, Beff. The accident is sensitive to Beff if the ejected-rod worth is nearly equal to or greater than Beff, as in zero-power transients. To allow for future fuel cycles, conservative estimates of Beff of 0.54% at beginning of cycle and 0.43% at end of cycle were used in the analysis.

14.3.3.2.2.5 Trip Reactivity Insertion. The trip reactivity insertion is assumed to be 4% from 102% of 2546 MWt or 100.38% of 2587 MWt and 1.77% from hot zero power, including the effect of one stuck rod, (i.e., the ejected rod). The shutdown reactivity is simulated by a conservative curve of trip reactivity insertion versus time after trip. The start of the rod motion occurs 0.5 second after the high-neutron-flux point is reached. This delay is assumed to consist of 0.2 second for the instrument channel to produce a signal, 0.15 second for the trip breaker to open, and 0.15 second for the coil to release the rods. The analyses presented are applicable for a rod insertion time of 2.4 second from coil release to entrance of the rod at the dash pot, although measurements indicate that this value should be closer to 1.8 second. The choice of such a conservative insertion rate means that there is over 1 second after the trip point is reached before significant shutdown reactivity is inserted into the core. This is a particularly significant conservatism for hot full-power accidents.

14.3.3.2.3 Results

The value of parameters used in the analysis, as well as the results of the most recent analysis are presented in Table 14.3-6 and discussed below.

14.3.3.2.3.1 Beginning of Cycle, Full Power. Control bank D was assumed to be inserted to its insertion limit. The ejected-rod worth, hot-channel factor, maximum fuel pellet average temperature, maximum fuel center temperature, maximum clad temperature, maximum fuel stored energy and percent of fuel melt are presented in Table 14.3-6.

14.3.3.2.3.2 Beginning of Cycle, Zero Power. For this condition, control bank D was assumed to be fully inserted and control bank C was at its insertion limit. The ejected-rod worth, hot-channel factor, maximum fuel pellet average temperature, maximum fuel center temperature, maximum clad temperature, maximum fuel stored energy and percent of fuel melt are presented in Table 14.3-6.

14.3.3.2.3.3 End of Cycle, Full Power. Control bank D was assumed to be inserted to its insertion limit. The ejected-rod worth, hot-channel factor, maximum fuel pellet average temperature, maximum fuel center temperature, maximum clad temperature, maximum fuel stored energy and percent of fuel melt are presented in Table 14.3-6.

14.3.3.2.3.4 End of Cycle, Zero Power. For this condition, control bank D was assumed to be fully inserted and control bank C was at its insertion limit. The ejected-rod worth, hot-channel factor, maximum fuel pellet average temperature, maximum fuel center temperature, maximum clad temperature, maximum fuel stored energy and percent of fuel melt are presented in Table 14.3-6.

A summary of the cases presented above is given in Table 14.3-6. The nuclear power and hot-spot fuel and clad temperature transients for the EOC full-power and zero-power cases are presented in Figures 14.3-24 through 14.3-27.

14.3.3.2.3.5 Fission Product Release. It is assumed that fission products are released from the gaps of all fuel rods entering DNB. Fission product release fractions, which show the expected fraction of the core inventory that is released to the gap, are summarized in Appendix 14A. These fractions are based on the steady-state fuel temperatures expected at full-power operation, and they include the effect of high fuel temperatures at the hot spot, using the design hot-channel factor. As a result of the rod ejection accident, the hot-spot fuel temperatures will increase, leading to an increase in the fraction of activity released to the gap. However, the results of the rod ejection analysis showed that even at the hot spot there is limited metal-water reaction and the clad is not expected to fail. Even if the rods entering DNB were to fail, only a small portion of the core is affected because of the strong localized peak typical of rod ejection accidents. For example, a fuel census performed from the results of a static, three-dimensional ejected-rod calculation (Figure 14.3-28) shows that, for this typical case, 90% of the fuel volume is operating at a power level less than half that at the hot spot. For this reason, less than 10% of the core enters DNB and a much smaller fraction will experience a fuel temperature nearly as high as that of the hot spot. Since there will be no massive failure of the fuel rods, the position with regard to fission product release, even taking into account the increased fuel temperatures in the area of the rod ejection, is that less than 10% of the core will release fission products. A gap-type release is expected. However, even assuming that a TID-14844-type release (100% of the noble gases and 50% of the halogens) occurs in less than 10% of the core, this release is much less than that for the double-ended severance of a reactor coolant pipe, in which 100% of the total core noble gases and 50% of the total core halogens are assumed to be released.

14.3.3.2.3.6 Pressure Surge. It is shown that there is no danger of fuel dispersal into the coolant. The pressure surge may therefore be calculated on the basis of conventional heat transfer from the fuel and prompt heat generation in the coolant. The most severe excess addition of energy to the coolant occurs for the high-power and end-of-life case. In order to estimate the magnitude of this pressure transient, average channel and hot-spot heat transfer calculations were performed using a high gap conductance and without assuming DNB. The power curves used for these calculations represented a limiting case in which center melting was initiated at the hot spot. Using these heat flux data, a THINC 3 run was conducted to determine the volume surge without the benefit of pressure feedback. This volume surge was subsequently used as the basis-for a pressure calculation. The results indicated that, starting at 2250 psia, a peak pressure of about 2340 psia occurs some 1.5 seconds after a control-rod assembly ejection.

14.3.3.2.3.7 Lattice Deformation. A large temperature gradient will exist in the region of the hot spot. Since the fuel rods are free to move in the vertical direction, differential expansion between separate rods cannot produce distortion. However, the temperature gradients across individual rods any produce a force tending to bow the midpoint of the rods toward the hot spot. Physics calculations indicate that the net result of this would be a negative reactivity insertion. In practice, no significant bowing is anticipated, since the structural rigidity of the core is more than sufficient to withstand the forces produced. Boiling in the hot-spot region would produce a net flow away from that region. However, the heat from the fuel is released to the water relatively slowly, and it is considered inconceivable that cross flow will be sufficient to produce significant lattice forces. Even if massive and rapid boiling, sufficient to distort the lattice, is hypothetically postulated, the large void fraction in the hot-spot region would produce a reduction in the total core moderator-to-fuel ratio and a large reduction in this ratio at the hot spot. The net effect would therefore be a negative feedback. It can be concluded that no conceivable mechanism exists for a net positive feedback resulting from lattice deformation. In fact, a small negative feedback may result. The effect is conservatively ignored in the analysis.

14.3.3.3 **Conclusions**

Even on a pessimistic basis, the analyses indicate that the described fuel and clad limits are not exceeded. It is concluded that there is no danger of sudden fuel dispersal into the coolant. Since the peak pressure does not exceed that which would cause stresses to exceed the faulted condition stress limits, it is concluded that there is no danger of further consequential damage to the primary loop. The analyses have demonstrated that the upper limit in fission product release as a result of a number of fuel rods entering departure from nucleate boiling amounts to 10%.

14.4 GENERAL STATION ACCIDENT ANALYSIS

14.4.1 Fuel-Handling Accidents

The following fuel-handling accidents are evaluated:

1. A fuel assembly becomes stuck inside the reactor vessel.
2. A fuel assembly becomes stuck in the containment penetration valve (fuel transfer tube).
3. A fuel assembly becomes stuck in the transfer carriage or the carriage becomes stuck.
4. A fuel assembly in the reactor cavity becomes damaged (fuel-handling accident in containment).
5. A fuel assembly in the spent-fuel pool becomes damaged (fuel-handling accident in the spent-fuel pool).
6. A spent-fuel shipping cask is dropped into the cask laydown area of the spent-fuel pool (cask-drop accident).

14.4.1.1 **Accident Prevention or Mitigation**

The possibility of a fuel-handling accident is remote because of the stringent administrative controls and physical limitations imposed on fuel-handling operations. All refueling operations are conducted in accordance with prescribed procedures under the direct surveillance of a supervisor technically trained in nuclear safety. Also, before any refueling operations begin, the verification of complete control-rod assembly insertion is obtained by tripping the control-rod banks and obtaining indication of rod drop and disengagement from the control-rod drive mechanisms. The boron concentration in the reactor coolant is raised to the relatively high refueling concentration and verified by sampling. The refueling boron concentration is sufficient to maintain the clean, cold, fully loaded core subcritical with all control-rod assemblies withdrawn. The refueling cavity is filled with water meeting the same boric acid specifications. As the vessel head is raised, a visual check is made to verify that the control-rod assembly drive shafts are free in the mechanism housing.

After the vessel head is removed, the control-rod assembly drive shafts are removed from their respective assemblies using the manipulator crane hoist and the shaft unlatching tool. A spring scale is used to indicate that the drive shaft is free of the control-rod assembly as the lifting force is applied.

The fuel-handling manipulators and hoists are designed so that fuel cannot be raised above a position that provides adequate shield water depth for the safety of operating personnel. This safety feature applies to handling facilities in both the containment and the spent-fuel pool area. In the spent-fuel pool, the design of storage racks and manipulation facilities is such that:

1. Fuel at rest is held in position by positive restraints in a safe, always subcritical, geometrical array, with no credit for boric acid in the water.

2. Fuel can be manipulated only one assembly at a time.
3. A violation of procedures by placing one fuel assembly in juxtaposition with any group of assemblies in racks will not result in criticality.
4. Crane facilities do not permit the handling of heavy objects, such as a spent-fuel shipping cask, above the fuel racks.

Adequate cooling of spent-fuel during underwater handling is provided by convective heat transfer to the surrounding water. The fuel assembly is immersed continuously while in the refueling cavity or spent-fuel pool.

Even if a spent-fuel assembly becomes stuck in the transfer tube, natural convection maintains adequate cooling. The fuel-handling equipment is described in detail in Chapter 9.

Two nuclear instrumentation system source range channels are continuously in operation and provide a warning of any approach to criticality during refueling operations. This instrumentation provides a continuous audible signal in the containment, and it would annunciate a local horn and a horn and light in the control room if the count rate increased above a preset low level.

The refueling boron concentration is sufficient to maintain the clean, cold, fully loaded core subcritical by at least 5% delta k/k with all control-rod assemblies inserted (Reference 8). At this boron concentration the core would also be subcritical with all control-rod assemblies withdrawn. The refueling cavity is filled with water meeting the same boric acid specifications.

All these safety features make the probability of a fuel-handling accident very low. Nevertheless, it is possible that a fuel assembly could be dropped during the handling operations. Therefore, this accident is analyzed both from the standpoint of radiation exposure and accidental criticality.

Special precautions are taken in all fuel-handling operations to minimize the possibility of damage to fuel assemblies during transport to and from the spent-fuel pool and during their installation in the reactor. All irradiated fuel-handling actions are conducted under water. The handling tools used in the fuel-handling operations are conservatively designed and the associated devices are of a fail-safe design.

In the fuel storage area, the fuel assemblies are spaced in a pattern that prevents any possibility of a criticality accident. The motions of the cranes that move the fuel assemblies are limited to a relatively low maximum speed. Caution is exercised during fuel-handling to prevent a fuel assembly from striking another fuel assembly or structures in the containment or fuel building.

The fuel-handling equipment suspends the fuel assembly in the vertical position during fuel movements, except when the fuel is moved through the transport tube.

The design of the fuel assembly is such that the fuel rods are restrained by grid clips that provide a total restraining force of approximately 60 lb on each fuel rod. If the fuel rods are in contact with the bottom plate of the fuel assembly, any force transmitted to the fuel rods is limited by the restraining force of the grid clips. The force transmitted to the fuel rods during fuel-handling is not sufficient to breech the fuel-rod cladding. If the fuel rods were not in contact with the bottom plate of the assembly, the rods would have to slide against the 60-lb friction force. This would absorb the shock and thus limit the force on the individual fuel rods.

Considerable assembly deformation would have to occur before the rod would make contact with the top plate and place any appreciable load on the fuel rod. In view of the above, it is unlikely that any damage would occur to the individual fuel rods during handling. If one assembly is lowered on top of another, no damage to the fuel rods would occur that would affect the integrity of the cladding.

If during handling the fuel assembly were to strike against a flat surface, the loads would be distributed across the fuel assembly and grid clips and essentially no damage would be expected in any fuel rods.

If the fuel assembly were to strike a sharp object, it would be possible for the sharp object to damage the fuel rods with which it comes in contact, but a breech of the cladding would be unlikely. On this basis, assuming the failure of an entire row of fuel rods (15) is a conservative upper limit.

Preliminary analyses in support of the initial FSAR assumed three extremely remote situations: a fuel assembly is dropped 14 feet and strikes a flat surface; one assembly is dropped onto another; and one assembly strikes a sharp object. The analysis of a fuel assembly assumed to be dropped and striking a flat surface considered the stresses the fuel cladding was subjected to and any possible buckling of the fuel rods between the grid clip supports. The results showed that the axial load at the bottom section of the fuel rod, which would receive the highest loading (approximately 100 lb) was below the critical buckling load (250 lb) and the stresses were relatively low and below the yield stress. For the case where one assembly is dropped on top of another fuel assembly, the loads would be transmitted through the end plates and the control-rod assembly guide tubes of the struck assembly before any of the loads reached the fuel rods.

The end plate and guide thimbles absorb a large portion of the kinetic energy as a result of bending in the lower plate of the falling assembly. Also, energy is absorbed in the struck assembly top end plate before any load can be transmitted to the fuel rods. The results of this analysis indicated that the buckling load on the fuel rods was below the critical buckling loads and the stresses in the cladding were relatively low and below yield.

The experience that has been gained in Westinghouse reactor refueling operations indicates that fuel cladding integrity failures would not be expected to occur during fuel-handling operations.

For the initial FSAR, the rupture of one complete outer row of fuel rods in a withdrawn spent-fuel assembly was assumed as a conservative limit for evaluating the environmental consequences of a fuel-handling accident. The remaining fuel assemblies are protected by the storage rack structure so they are not subjected to lateral bending loads. No damage resulted from the axial application of a load of 2200 lb to a fuel assembly. The maximum load expected to be experienced in service is approximately 1000 lb. This information was used in the fuel-handling equipment design to establish the limits for inadvertent axial loads.

The spent fuel cask drop analysis is discussed in Reference 1 and Reference 22. The fuel handling accident in the containment and the fuel handling accident in the spent fuel pool are described below in more detail. These analyses were performed as part of implementing the alternate source term that is described in RG 1.183 (Reference 13). It should be noted that Surry Power Station has been licensed for fuel burnups up to 62,000 MWD/MTU lead rod burnup beginning with Surry Improved Fuel Assemblies with ZIRLO cladding (Reference 20). Older fuel assemblies with Zircaloy-4 cladding are limited to a lead rod average burnup of 60,000 MWD/MTU (Reference 20). The Optimized ZIRLO cladding was approved by the NRC for use at Surry in Reference 21 as part of the 15 x 15 Upgrade fuel design for lead rod average burnups up to 62,000 MWD/MTU. For this extended burnup it has been shown that the radiological consequences of the fuel handling accidents discussed below remain unchanged (References 2, 3, 4, 19, & 20).

Virginia Power conducted a spent fuel cask drop evaluation in support of the use of spent fuel casks in the fuel building area (References 5 & 6). As a result of this evaluation, cask impact pads were installed in the cask loading area of the spent fuel pool, and the spent fuel pool was divided into two regions for the storage of spent fuel (Reference 7). Region 1 comprises the first three rows of fuel racks (324 storage locations) adjacent to the Fuel Building Trolley Load Block. Region 2 comprises the remainder of the fuel racks in the fuel pool. During spent fuel cask handling, Region 1 is limited to storage of spent fuel assemblies which meet the criteria delineated in Surry Power Station Technical Specification 5.3, *Fuel Storage*.

14.4.1.2 **Fuel-Handling Accident in the Containment**

The fuel handling accident (FHA) in the containment has three postulated release paths. These three pathways are the ventilation system (through Vent Stack No. 2), the open personnel airlock, and the open equipment access hatch. The analysis models the release flow and atmospheric dispersion factors to bound the radiological effects of release from any combination of the three release paths and from penetrations that terminate in the Auxiliary Building and Safeguards. Filtration of the containment release to atmosphere is not credited in the FHA analysis.

14.4.1.2.1 Assumptions

During refueling, the containment purge system may be aligned to exhaust through either the non-safety related or safety-related ventilation filters in the Auxiliary Building or a combination thereof, but no filtration is credited in the analysis. If exhaust is being filtered, more than one filter bank may be on line because the fuel building exhaust could also be aligned through the filters. The containment purge design flow rate to the non-safety-related filters is 20,000 cfm. The design flow rate through a safety-related filter is 36,000 cfm. The containment was modeled arbitrarily as a 1 ft^3 volume with a 500 cfm release flow rate in order to bound all credible releases, maximize dose consequences, and complete the release in 2 hours as required by RG 1.183. The fuel building modeling assumptions are discussed in Section 14.4.1.3.1. The analysis results are not sensitive to release flow rates of the various ventilation systems.

While the purge system is in operation, the air flow in the containment is as follows. Air enters the containment through two 14,500-cfm fans and two 36-inch butterfly supply valves, and is dispersed through the ring header outside the crane wall at Elevation 39 ft. 6 in. The air is continuously recirculated inside the containment by three 75,000-cfm recirculation fans. The air is purged from the containment through the ring header at Elevation -20 ft. outside the crane wall. The air discharges through two 36-inch butterfly valves in series. The air then passes through the auxiliary building filter banks and the two 36,000 cfm filter exhaust fans. Air is also assumed to flow through the personnel airlock, equipment access hatch, and other containment penetrations (if these are open).

The worst single failure would be either the inability to close one of the hatches or the loss of the valve-closing circuit that closes the valves and secures the purge fans on an alarm from either the manipulator crane monitor or the containment gas and particulate monitors. The two output relays are sufficiently redundant to secure purge flow; however, a loss of power to this circuit would cause them not to function. Failure to isolate containment or establish containment closure could cause a release to the atmosphere with a boundary dose as calculated below. Even though containment isolation, containment closure, and filtering of the release are not credited in the analysis, the dose is still within allowable limits (Table 14.4-5).

The transit time for any released activity from the radiation detection point to the control room normal ventilation system intake is calculated to be two minutes and the control room manual isolation was modeled as occurring ten minutes after radioactive material reached the control room air inlet. The control room isolation dampers close within 20 seconds of manual isolation. This progression relies upon the operability of the manipulator crane area monitor and the containment gas and particulate monitors in conjunction with communications to provide a timely and valid indication of a FHA.

Within 1 hour of initiation of the event, procedures require the alignment of the control room emergency ventilation system to provide a filtered breathing air supply to the control room envelope. This analysis considered that one fan was operational which provides a control room intake flow rate of 900 cfm from 1 hour through the end of the 30-day dose calculation period. Operation of additional fans will not increase the consequences of the FHA. An unfiltered inleakage of 250 cfm is assumed when the control room is isolated (0-30 days). Normal ventilation flow into the control room is modeled at 3300 cfm. Before isolation, 250 cfm of unfiltered inleakage is added to the normal ventilation flow.

The control room χ/Q values were determined with ARCON96 (Reference 11) methodology and meteorological data for the 2009 through 2013 time period. These values are listed in Table 14.4-3. The control room occupancy factors in Table 14.4-4 were also incorporated into the dose calculations to reflect that personnel would not be exposed to the released activity 100% of the time over the entire 30 day period. The breathing rate used for the control room dose calculations was 3.5×10^{-4} m^3/sec.

More specific conservative assumptions are:

1. A release of fission gases contained in the fuel rod gap occurs as the result of the rupture of all the fuel rods in a fuel assembly in the reactor fuel cavity. The release volume is modeled as a one cubic foot volume with a 500 cfm exhaust flow rate. The release is assumed to occur linearly over a 2-hour duration and is assumed to homogeneously mix within the conservatively small release volume and immediately begins to exhaust into the environment at the indicated flow rate.

2. The manipulator crane area monitor is gamma radiation sensitive, so that it is not necessary for it to be immersed in a radioactive cloud to detect radioactivity. Its position above the fuel cavity (approximately 10 feet), unshielded from direct gamma rays from the cavity, enhances its capability to detect an accident release immediately.

3. The containment closure is not credited even though the equipment hatch and the personnel airlock will be capable of being closed, and all other containment penetrations will either be closed, capable of being closed, or have an operable isolation valve.

4. The delay time from reactor shutdown to the initiation of fuel assembly transfer operations is at least 100 hours.

5. The assembly radial peaking factor is 1.70, which is the appropriate peaking factor, including uncertainties, for events (e.g., FHA) that do not employ the Statistical DNBR Evaluation Methodology. This value is a multiplier applied to the core average isotopic activity to determine bounding activity. The core average activity per fuel assembly was multiplied by this peaking factor and then by the gap fractions prescribed in PNNL-18212 Revision 1. After applying appropriate decontamination factors from the pool, the result is the activity released to the atmosphere of the release volume.

6. The number of fuel assemblies in the core is 157.

7. Eight percent of the fuel assembly Iodine-131 activity is assumed to be released into the reactor cavity water, as are nine percent of Iodine-132 activity, and five percent of the other iodine isotopes present in the fuel assembly, 99.85% being elemental and 0.15% in the organic form. The effective decontamination factor for a depth of water of 23 feet or greater above the damaged fuel rods is 200, as prescribed in RG 1.183 and DG-1199 Revision 1.

8. Eight percent of each of the noble gases present in the fuel assembly is released to the reactor cavity pool, with the exception of Kr-85; 38% of Kr-85 is released. The DF of the water for noble gases is 1.

9. The calculational method includes dose conversion factors for each isotope.

10. The χ/Q values used in the offsite dose analysis were calculated using the PAVAN (Reference 10) methodology and are based on site specific meteorological data for the 2009 through 2013 time period. These χ/Q values are listed in Table 14.4-2.

11. The breathing rate for the LPZ calculation was 3.5×10^{-4} m^3/sec for the first 8 hours, 1.8×10^{-4} m^3/sec from 8-24 hours, and 2.3×10^{-4} m^3/sec from 24 hours until the end of the accident. The breathing rate for EAB dose calculation was 3.5×10^{-4} m^3/sec for the entire event.

12. The distance from the possible release point to the site boundary varied from a minimum of 1640.4 feet to a maximum of 5059.1 feet.

The activity for the limiting fuel assembly is calculated using the following equation:

Fuel assembly activity (Ci) = Total activity in the core at core-average power after a 100-hr decay $\times \frac{1}{157} \times 1.70$.

14.4.1.2.2 Results

The results of the FHA dose calculations are shown in Table 14.4-5. The doses in Table 14.4-5 are a composite of the worst doses from an FHA in either the containment or the fuel building. A fuel-handling accident in the containment will not lead to EAB and LPZ doses exceeding the dose limits as specified in Regulatory Guide 1.183. Also, the control room doses will not exceed the 10 CFR 50.67 dose limit.

14.4.1.3 **Fuel-Handling Accident in the Spent-Fuel Pool**

If a fuel assembly is dropped in the spent-fuel pool in the fuel building, the increase in radiation level as these radionuclides mix with the fuel building air will be detected by the two radiation monitors located in the ventilation vent no. 2 or by the fuel pool bridge area monitor.

The fuel building exhaust may be diverted through the particulate and activated charcoal filter banks during refueling operations but no filtration is credited in the analysis (Section 9.13). The monitors alarm on a high radiation level to indicate a possible dropped-fuel-assembly incident.

14.4.1.3.1 Assumptions

To determine the quantity of radioactive material available for release, it is conservatively assumed that the fuel assembly with the peak fission product inventory is the one damaged. The inventory is based on maximum full power operation at the end of core life immediately preceding shutdown and a conservative radial peaking factor which is applied to all fuel rods in the assembly. Only that fraction of the fission products which migrates from the fuel matrix to the gap and plenum regions of the fuel rods during normal operation is considered to be available for immediate release into the water in the event of clad damage. The quantity of radioactive material released subsequent to the immediate release is considered to be negligible compared to the quantity released immediately after the Fuel Handling Accident (FHA).

The fuel radionuclide inventory was based on a core power level of 2605 MWt. This core power level is conservative compared to 100.38% of the uprated power level of 2587 MWt (i.e., 2596.9 MWt).

For analyses employing alternative source terms, the FHA is discussed in Section 15.0.1 of the NRC's Standard Review Plan and Regulatory Guide 1.183. The following assumptions were made for the evaluation of the Surry control room and offsite doses due to a FHA.

1. The accident occurs 100 hours after shutdown. Surry Technical Specification 3.10 requires a minimum 100-hour period between the shutdown of a unit and initiation of fuel movement, so the use of a 100-hour time period is conservative. Radioactive decay of the fission product inventory during the 100-hour interval between shutdown and the assumed commencement of fuel handling is incorporated into the analysis.
2. The minimum water depth between the top of the damaged fuel rods and the water surface is 23 feet.
3. All of the gap activity in the damaged rods at the time of the accident is released. The gap activity consists of 38% of the Kr-85, 8% of the noble gases other than Kr-85, 8% of the I-131, 9% of the I-132 and 5% of the radioactive iodine other than I-131 and I-132 in the rods.
4. The values assumed for individual fission product inventories are calculated assuming full power operation at the end of core life immediately preceding shutdown.
5. The iodine gap inventory is composed of 99.85% inorganic species and 0.15% organic species.
6. The pool effective decontamination factor is 200 (i.e., 99.5% of the total iodine released from the damaged rods is retained by the water).

   This difference in decontamination factors for inorganic and organic iodine species results in the iodine above the fuel pool being composed of 70% elemental and 30% organic species.
7. The retention of the noble gases in the water is negligible.
8. A release of fission gases contained in the fuel rod gap occurs as the result of the rupture of all the fuel rods in a fuel assembly in the spent fuel pool. The release volume is modeled as a one cubic foot volume with a 500 cfm exhaust flow rate. The release is assumed to occur linearly over a 2-hour duration and is assumed to homogeneously mix within the conservatively small release volume (1 ft3) and immediately begins to exhaust into the

environment at the indicated flow rate. No credit was taken for filtration via the ventilation exhaust system.

The amount of radioactive material which is released to the fuel building or containment during a FHA at 100-hour period of decay is determined from this core inventory using the following assumptions:

1. All rods in one fuel assembly are damaged.
2. There are 157 fuel assemblies in the Surry core.
3. The assembly radial peaking factor is 1.70, which is the appropriate peaking factor, including uncertainties, for events (e.g., FHA) that do not employ the Statistical DNBR Evaluation Methodology. This value is a multiplier applied to the core average isotopic activity to determine bounding activity. The core average activity per fuel assembly was multiplied by the peaking factor and then by the gap fractions prescribed PNNL-18212 Revision 1. After applying appropriate decontamination factors from the pool, the result is the activity released to the atmosphere of the release volume.
4. Gap fractions as defined above.
5. Decontamination factors as defined above.

The resulting activities released to the fuel building or containment are given in Table 14.4-1.

The RADTRAD-NAI computer code system (Reference 9) was used to calculate doses for the FHA.

The χ/Q values which were used to calculate the exclusion area boundary (EAB) and low population zone (LPZ) doses were calculated using the PAVAN (NUREG/CR-2858) methodology and were based on site specific meteorological data for the 2009 through 2013 time period. The χ/Q values are listed in Table 14.4-2.

The transit time for any released activity from the radiation detection point at the water surface to the control room normal ventilation system intake is calculated to be two minutes and the control room manual isolation was modeled as occurring ten minutes after the radioactive material reached the control room air inlet. The control room isolation dampers close within 20 seconds of manual isolation. This assumption relies upon the operability of the fuel pit bridge area monitor and the ventilation vent No. 2 gas and particulate monitors in conjunction with communications to provide a timely and valid indication of a FHA.

Within 1 hour of initiation of the event, procedures require the alignment of the control room emergency ventilation system to provide a filtered breathing air supply to the control room envelope. This analysis considered that only one fan was operational which provides a control room intake flow rate of 900 cfm from 1 hour through the end of the 30-day dose calculation period. An unfiltered inleakage of 250 cfm is assumed when the control room is isolated

(0-30 days). Normal ventilation flow into the control room is modeled at 3300 cfm. Before isolation, 250 cfm of unfiltered inleakage is added to the normal ventilation flow.

The control room χ/Q values were determined with the ARCON96 (Reference 11) methodology and meteorological data for the 2009 through 2013 time period. These values are listed in Table 14.4-3. The control room occupancy factors in Table 14.4-4 were also incorporated into the dose calculations to reflect that personnel would not be exposed to the released activity 100% of the time over the entire 30 day period. The breathing rate used for the control room dose calculations was 3.5×10^{-4} m^3/sec which is consistent with Reference 13.

14.4.1.3.2 Results

The results of the FHA dose calculations are shown in Table 14.4-5. The doses in Table 14.4-5 are a composite of the worst doses for an FHA in either the containment or the fuel building.

The EAB and LPZ doses for a FHA are less than the dose limits presented in Regulatory Guide 1.183 as shown in Table 14.4-5. The control room doses for the FHA are less than the 10 CFR 50.67 limit, which is also indicated in Table 14.4-5.

14.4.1.3.3 Analysis for High-Density Spent-Fuel Racks

The use of high density fuel racks does not affect the dose consequences resulting from a fuel handling accident in the spent fuel pool. Therefore the analysis provided in the Fuel Handling Accident in the Spent Fuel Pool in Section 14.4.1.3 remains bounding for the use of high density fuel storage racks.

14.4.2 Radioactive Gas Release

The concentration of radioactive waste gases in the primary and auxiliary systems is a function of the rate of fission gas release to the coolant from defective fuel and the rate of gas removal by auxiliary systems. The components that retain significant concentrations of radioactive gases are the volume control tank and the waste gas decay tanks. The radioactive release analysis considers the rupture of the volume control tank and a waste gas decay tank with an instantaneous release of the radioactive gas inventories of each tank to the environment.

14.4.2.1 **Volume Control Tank Rupture**

In this analysis, the volume control tank (VCT) is assumed to rupture and release to the atmosphere all the gases that have collected in the vapor space of the tank. Also released are all the gases in the liquid inventory of the tank and in the volume of liquid that continues to flow into the tank until it is isolated. Isolation is assumed to take 25 minutes, and the flow rate of the entering liquid is assumed to be 160 gpm, a conservatively high letdown flow rate.

The maximum activities of the gases in the vapor space with 1% failed fuel are listed in Table 14.4-6. The activities of the gases in the liquid are based on the reactor coolant equilibrium activities with 1% failed fuel as listed in Table 14.3-16. For the accident analysis, activities in the liquid have been corrected for density. The analysis follows the guidance of NRC Branch Technical Position ETSB (Effluent Treatment Systems Branch) 11-5.

Using these sources and an atmospheric dispersion factor of 9.43×10^{-4} sec/m^3, and assuming a puff ground level release, the two-hour whole-body dose at the EAB is below the 10 CFR 100 limit, and below the 0.5 REM limit contained in Branch Technical Position 11-5.

14.4.2.2 **Waste Gas Decay Tank (WGDT) Rupture**

Surry has two Waste Gas Decay Tanks that collect the gases stripped from the primary coolant system by the primary coolant clean-up systems. One tank is charged with waste gases being removed from the primary system while the other tank is used to hold up the gases for decay and controlled release. The analysis of doses from rupture of a WGDT assumes rupture of a WGDT with the release of the maximum inventory allowed by Technical Specifications.

14.4.2.2.1 WGDT Analysis Assumptions

The whole body EAB dose from the rupture of a WGDT was determined based on a puff release as the product of the (l) curies released, (2) dose conversion factor for Xe-133 and (3) EAB χ/Q. This analysis does not require any computer code. As explained in Reference 15, the WGDT control room dose was bounded by doses determined for other accident conditions. Although some iodine may be present in the tank, the amount are orders of magnitude below those considered for other accidents.

14.4.2.2.2 Dose Analysis for WGDT Rupture

The maximum WGDT inventory allowed by Surry Technical Specification 3.11 is 24,600 curies, (considered as Xe-133). The χ/Q for the EAB is 9.43×10^{-4} sec/m^3. The whole body dose conversion factor for Xenon-133 is 9.316×10^{-3} rem-m^{-3}/Ci-sec. A puff release of the maximum WGDT inventory allowed by Technical Specifications results in a whole body EAB dose less than 0.5 Rem.

14.4.3 Radioactive Liquid Release

Accidents in the auxiliary systems that could result in the release of waste liquids must necessarily involve the rupture or leaking of various pipelines, valves, tanks, and pumps.

All liquid processing components are located within the auxiliary building, fuel building, decontamination building, radwaste facility, and station yard area. Any liquid leakage or release from these components is collected in sumps and pumped to the liquid waste disposal systems (Section 11.2.3) or flows directly to the vent and drain system (Section 9.7). The auxiliary building and fuel building are of Class I design. The below ground levels of the radwaste facility are seismically designed to the requirements of RG 1.143.

The boron recovery tanks are located in the station yard area in separately diked enclosures, each of which is of sufficient capacity to retain the total liquid volume resulting from the rupture of one boron recovery tank without any overflow to areas outside the enclosure. The collected liquid is pumped either to the unruptured boron recovery tanks or to the liquid waste disposal systems. The diked enclosure is of Class I design.

Piping running between the auxiliary building and the reactor containment, between the auxiliary and fuel buildings, between the fuel building and the tanks in the yard area, and between the auxiliary building and the radwaste facility is situated below grade in concrete trenches or in special piping conduits. Liquids spilled or released from such piping are collected in sumps and pumped into the liquid waste disposal system. Accordingly, a release of waste liquids would be contained within the station and would not result in an uncontrolled release to the environment.

Xe-135m	5.081E-01

Table 14.4-2
ATMOSPHERIC DISPERSION FACTORS (χ/Qs) FOR OFFSITE CALCULATIONS

Receptor	Time Period	χ/Q value
EAB	0-2 hr	1.02E-03
LPZ	0-8 hr	5.66E-05
	8-24 hr	3.84E-05
	24-96 hr	1.66E-05
	96-720 hr	4.95E-06

Table 14.4-3
ATMOSPHERIC DISPERSION FACTORS (χ/Qs) FOR CONTROL ROOM CALCULATIONS

	Normal Intake		Emergency Intake	
Time Period	Containment Release χ/Q Value [ab]	Fuel Building Release χ/Q Value [ac]	Containment Release χ/Q Value [a]	Fuel Building & Release χ/Q Value [c]
0-2 hours	2.67E-03	8.47E-04	9.03E-04	6.55E-04
2-8 hours			6.83E-04	4.93E-04
8-24 hours			2.90E-04	2.03E-04
24-96 hours			2.05E-04	1.44E-04
96-720 hours			1.56E-04	1.08E-04

a. In this AST model, it is assumed the radioactivity reaches the control room before manual isolation of the control room takes place. Thus, normal control room intake χ/Q values need to be used during this time.

b. A release from containment uses the χ/Q values for the West Louver, as this release point had the most conservative value, maximizing dose consequence for this case.

c. A release from the fuel building uses the χ/Q values for Vent #2, as this release point had the most conservative value, maximizing dose consequence for this case.

Table 14.4-4
CONTROL ROOM OCCUPANCY FACTORS

0-8 hours	1.0
8-24 hours	1.0
24-96 hours	0.6
96-720 hours	0.4

	2.7	3.2	0.2
Regulatory Guideline Value [a]	5.0	6.3	6.3

a. 10 CFR Part 50.67 establishes TEDE dose limits for the EAB, the outer boundary of the LPZ, and for the control room for use with the alternate source term. The specified offsite dose limits are stated for evaluating reactor accidents of exceedingly low probability of occurrence and low risk of public exposure to radiation, e.g., a large-break LOCA. For events with a higher probability of occurrence, e.g., FHA postulated EAB and LPZ doses should not exceed the limits established in RG 1.183. The 10 CFR 50.67 control room criterion applies to all accidents.
b. Composite results from the limiting or worst case containment and fuel building releases.

14.5 LOSS-OF-COOLANT ACCIDENT

14.5.1 Major Reactor Coolant System Pipe Ruptures (Large Break Loss-of-Coolant Accident)

14.5.1.1 General

The **FULL SPECTRUM™ LOCA** (**FSLOCA™**) Evaluation Model (EM) (Reference 5) was developed to address the full spectrum of loss-of-coolant accidents (LOCAs) which result from a postulated break in the reactor coolant system (RCS) of a pressurized water reactor (PWR). The break sizes considered in the Westinghouse FSLOCA EM include any break size in which break flow is beyond the capacity of the normal charging pumps, up to and including a double ended guillotine (DEG) rupture of an RCS cold leg with a break flow area equal to two times the pipe area, including what traditionally are defined as Small and Large Break LOCAs.

The break size spectrum is divided into two regions. Region I includes breaks that are typically defined as small-break LOCAs (SBLOCAs). The Region II includes break sizes that are typically defined as large-break LOCAs (LBLOCAs). The Region II analysis simulations only include breaks above 1.0 ft^2 break area and provide coverage to a maximum size of a DEG break. Only the Region II (LBLOCA) analysis was performed for this application of the FSLOCA EM. A Region I (SBLOCA) analysis was not performed.

The FSLOCA EM explicitly considers the effects of fuel pellet thermal conductivity degradation (TCD) and other burnup-related effects by initializing fuel rod conditions to fuel rod performance data input generated by the PAD5 code (Reference 4), which explicitly models TCD and is benchmarked to high burnup data. The fuel pellet thermal conductivity model in the WCOBRA/TRAC-TF2 code used in the FSLOCA EM explicitly accounts for pellet thermal conductivity degradation.

Three of the Title 10 of the Code of Federal Regulations (CFR) 50.46 criteria (peak cladding temperature (PCT), maximum local oxidation (MLO), and core-wide oxidation (CWO)) are considered directly in the FSLOCA EM. A high probability statement is developed for the PCT, MLO, and CWO that is needed to demonstrate compliance with 10 CFR 50.46 acceptance criteria (b)(1), (b)(2), and (b)(3) (Reference 62) when employing realistic methods to account for uncertainty. The MLO is defined as the sum of pre-transient corrosion and transient oxidation consistent with the position in Information Notice 98-29 (Reference 63). The coolable geometry acceptance criterion, 10 CFR 50.46 (b)(4), is met by compliance with acceptance criteria (b)(1), (b)(2), and (b)(3), and demonstrating that fuel assembly grid deformation due to combined seismic and LOCA loads does not extend to the in-board fuel assemblies, thus ensuring that a coolable geometry is maintained.

The FSLOCA EM has been generically approved by the Nuclear Regulatory Commission (NRC) for Westinghouse 3-loop and 4-loop plants with cold leg Emergency Core Cooling System

(ECCS) injection (Reference 5). Since Surry Units 1 and 2 are Westinghouse designed 3-loop plants with cold leg ECCS injection, the approved method is applicable.

This section summarizes the application of the Westinghouse FSLOCA EM to Surry Units 1 and 2. The application of the FSLOCA EM to Surry Units 1 and 2 is consistent with the NRC-approved methodology (Reference 5), with the corrections and changes reported in Reference 64 pursuant to 10 CFR 50.46, with the exception of only including an analysis for Region II. After completion of the analysis for Surry Units 1 and 2, two errors were discovered in the WCOBRA/TRAC-TF2 code. The first error was regarding the calculation of radiation heat transfer to liquid, which could be incorrectly calculated under certain conditions. The second error was regarding vapor temperature resetting, where under certain conditions the vapor temperature could incorrectly be reset to the saturation temperature for heat transfer calculations. These errors were found to have negligible impact on the FSLOCA EM analysis results as described in Reference 68.

An additional error regarding the gamma energy redistribution multiplier was identified after completion of the analysis for Surry Units 1 and 2. The treatment for the uncertainty in the gamma energy redistribution is discussed on pages 29-75 and 29-76 of Reference 5, and the equation for the assumed increase in hot rod and assembly relative power is presented on page 29-76. The power increase in the hot rod and hot assembly due to energy redistribution in the application of the FSLOCA EM to Surry Units 1 and 2 was calculated incorrectly. This error resulted in a 0% to 5% deficiency in the modeled hot rod and hot assembly rod linear heat rates on a run-specific basis, depending on the as-sampled value for the multiplier uncertainty. The effect of the error correction was evaluated against the application of the FSLOCA EM to Surry Units 1 and 2.

The error correction has only a limited impact on the power modeled for a single assembly in the core. As such, the error correction has a negligible impact on the system thermal-hydraulic response during the postulated LOCA. For the Region II analysis, parametric PWR sensitivity studies, derived from a subset of uncertainty analysis simulations covering various design features and fuel arrays, were examined to determine the sensitivity of the analysis results to the error correction. The PCT impact from the error correction was found to be different for the transient phases (i.e., blowdown versus reflood) based on the PWR sensitivity studies and existing power distribution sensitivity studies. Based on the results from the PWR sensitivity studies, the correction of the error is estimated to increase the Region II analysis PCT by 31°F, leading to an analysis result of 1848° for the Region II analysis assuming loss-of- offsite power and 1875 °F for the Region II analysis assuming offsite power available. All of the analysis results, including the error correction, continue to demonstrate compliance with the 10 CFR 50.46 acceptance criteria.

The major plant parameter and analysis assumptions used in the Surry Units 1 and 2 analysis with the FSLOCA EM are provided in Tables 14.5-1, 14.5-2, 14.5-4 and 14.5-5. Table 14.5-17 contains a sequence of events for the transient that produced the more limiting analysis PCT result relative to the offsite power assumption.

Subsequent to the completion of the analysis, revised pre-transient oxidation (PTO) data was generated which increased the PTO assumed in the analysis. Due to the substantial conservatisms in the fuel temperature and rod internal pressure methodology, there is no change to the analyzed fuel rod temperature and rod internal pressure data; therefore, there is no impact on the FSLOCA EM analysis transient results (including PCT). However, the updated PTO does impact the total MLO (transient plus pre-transient). The largest difference in upper bound oxidation relative to the data provided in the base LBLOCA analysis was used to conservatively estimate the impact of the revised PTO. The evaluation estimated an increase to the Region II analysis MLO of 2.26%. Analysis results continue to demonstrate compliance with the 10 CFR 50.46 acceptance criteria.

14.5.1.2 Identification of Cause and Accident Description

A LBLOCA is a hypothetical, design-basis accident that is considered in the sizing of ECCS components. The accident is initiated by an instantaneous rupture of a RCS pipe. The break type considered is either a double-ended guillotine, defined as a complete severance of the pipe resulting in unimpeded flow from either end, or a split break, defined as a partial tear. The break sizes considered vary from 1 ft^2 to two times the cold leg area. A break in the cold-leg piping between the reactor coolant pump and the reactor vessel inlet nozzle has been concluded to be the most limiting location for a large break in a PWR.

A revision to General Design Criterion 4 (GDC-4) was issued by the NRC effective May 12, 1986. In accordance with the revised rule, consideration of the dynamic effects of RCS pipe rupture may be eliminated as a design basis provided the “Leak Before Break” (LBB) analyses demonstrate that any flaw in the RCS primary loop piping which grew would become a through-wall crack with detectable leakage allowing shutdown of the plant long before a rupture would occur. LBB fracture mechanics analyses applicable to Surry have been accepted by the NRC and, in accordance with Amendment 108 to the Surry operating license, consideration of the dynamic effects of a LOCA is no longer part of the design basis. However, this change to the design basis does not affect the ECCS design basis or engineered safety feature system response. Therefore, the pipe rupture LOCA condition will remain as a design basis for safety related systems in the RCS and conservatively envelopes all other accidents.

Should a large break occur, rapid depressurization of the RCS to a pressure nearly equal to the containment pressure occurs in approximately 40 seconds, with a nearly complete loss of RCS inventory. Rapid voiding in the core shuts down the reactor. The SI system is actuated when the low pressurizer pressure setpoint (SI signal) is reached, and the accumulators inject upon RCS depressurization below the accumulator cover pressure, mitigating the consequences of the accident in two ways:

1. The borated water injection complements void formation in causing a rapid reduction in nuclear power to a residual level corresponding to fission product decay heat. The level of RCS mixed boron concentration is sufficient to ensure that the core remains subcritical for

short term post-LBLOCA considerations (long term core cooling considerations are discussed in Chapter 6 and Chapter 9). However, no credit is taken for the insertion of control rods to shut down the reactor in the large break analysis.

2. The injection of borated water provides core cooling and prevents excessive fuel rod cladding temperatures.

Before the break occurs, the reactor is assumed to be in a full power equilibrium condition, i.e., the heat generated in the core is being removed by the steam generators. At the beginning of the blowdown phase, the entire RCS contains sub-cooled liquid which transfers heat from the core by forced convection with some nucleate boiling. During blowdown, heat from fission product decay and stored energy in the fuel pellets continues to be transferred to the fuel rod cladding. After the break occurs, departure from nucleate boiling occurs.

The heat transfer between the RCS and the secondary system may be in either direction, based on the progression of the transient and the relative fluid temperatures. In the case of the large break LOCA, the primary pressure rapidly decreases below the secondary system pressure, and the steam generators become an additional heat source.

As the RCS pressure decreases to the accumulator gas cover pressure, injection of accumulator liquid into the cold leg begins. However, significant accumulator inventory is lost out of the break due to the phenomenon of emergency core cooling bypass. After the initial surge of accumulator inventory is lost out of the break, core bypass breaks down and the remaining accumulator liquid refills the lower portion of the reactor vessel. Reflood of the core and eventual quench of the fuel rods is accomplished by the injection of water from the refueling water storage tank (RWST).

The operation of the low head safety injection pumps supplies water for long term cooling. When the refueling water storage tank is nearly empty, long term cooling of the core is accomplished by switching to the recirculation mode of core cooling, in which the spilled borated water is drawn from the containment sump by the low head safety injection pumps and returned to the reactor vessel. The containment spray system and the recirculation spray system operate to return the containment environment to subatmostpheric pressure.

14.5.1.3 Method of Analysis

FULL SPECTRUM LOCA Evaluation Model Development

In 1988, the NRC Staff amended the requirements of 10 CFR 50.46 (Reference 62 and Reference 65) and Appendix K, "ECCS Evaluation Models," to permit the use of a realistic EM to analyze the performance of the ECCS during a hypothetical LOCA. Westinghouse's previously approved best-estimate LBLOCA EM is discussed in Reference 6. The EM is referred to as the Automated Statistical Treatment of Uncertainty Method (ASTRUM), and was developed following Regulatory Guide (RG) 1.157 (Reference 3).

When the FSLOCA EM was being developed, the NRC issued RG 1.203 (Reference 66) which expands on the principles of RG 1.157, while providing a more systematic approach to the development and assessment process of a PWR accident and safety analysis EM. Therefore, the development of the FSLOCA EM followed the Evaluation Model Development and Assessment Process (EMDAP), which is documented in RG 1.203. While RG 1.203 expands upon RG 1.157, there are certain aspects of RG 1.157 which are more detailed than RG 1.203; therefore, both RGs were used for the development of the FSLOCA EM.

WCOBRA/TRAC-TF2 COMPUTER CODE

The FSLOCA EM (Reference 5) uses the WCOBRA/TRAC-TF2 code to analyze the system thermal-hydraulic response for the full spectrum of break sizes. WCOBRA/TRAC-TF2 was created by combining a 1D module (TRAC-P) with a 3D module (based on Westinghouse modified COBRA-TF). The 1D and 3D modules include an explicit non-condensable gas transport equation. The use of TRAC-P allows for the extension of a two-fluid, six-equation formulation of the two-phase flow to the 1D loop components. This new code is WCOBRA/TRAC-TF2, where “TF2” is an identifier that reflects the use of a three-field (TF) formulation of the 3D module derived by COBRA-TF and a two-fluid (TF) formulation of the 1D module based on TRAC-P. This best-estimate computer code contains the following features:

1. Ability to model transient three-dimensional flows in different geometries inside the reactor vessel
2. Ability to model thermal and mechanical non-equilibrium between phases
3. Ability to mechanistically represent interfacial heat, mass, and momentum transfer in different flow regimes
4. Ability to represent important reactor and plant components such as fuel rods, steam generators (SGs), reactor coolant pumps (RCPs), etc.

A detailed assessment of the computer code WCOBRA/TRAC-TF2 was made through comparisons to experimental data. These assessments were used to develop quantitative estimates of the ability of the code to predict key physical phenomena for a LOCA. Modeling of a LOCA introduces additional uncertainties which are identified and quantified in the plant-specific analysis. The reactor vessel and loop noding scheme used in the FSLOCA EM is consistent with the noding scheme used for the experiment simulations that form the validation basis for the physical models in the code. Such noding choices have been justified by assessing the model against large and/or full-scale separate effect and integral effect test facility experiments (Reference 5).

14.5.1.4 Description of Representative Transient

A large-break LOCA transient can be divided into phases in which specific phenomena are occurring. A convenient way to divide the transient is in terms of the various heatup and cooldown phases that the fuel assemblies undergo. For each of these phases, specific phenomena and heat transfer regimes are important, as discussed below.

Blowdown – Critical Heat Flux (CHF) Phase

In this phase, the break flow is subcooled, the discharge rate of coolant from the break is high, the core flow reverses, the fuel rods go through departure from nucleate boiling (DNB), and the cladding rapidly heats up and the reactor is shut down due to the core voiding.

The regions of the RCS with the highest initial temperatures (upper core, upper plenum, and hot legs) begin to flash during this period. This phase is terminated when the water in the lower plenum and downcomer begins to flash. The mixture level swells and a saturated mixture is pushed into the core by the intact loop RCPs, still rotating in single-phase liquid. As the fluid in the cold leg reaches saturation conditions, the discharge flow rate at the break decreases significantly.

Blowdown – Upward Core Flow Phase

Heat transfer is increased as the two-phase mixture is pushed into the core. The break discharge rate is reduced because the fluid becomes saturated at the break. This phase ends as the lower plenum fluid mass is depleted, the fluid in the loops becomes two-phase, and the RCP head degrades.

Blowdown – Downward Core Flow Phase

The break flow begins to dominate and pulls flow down through the core as the RCP head degrades due to increased voiding, while liquid and entrained liquid flows also provide core cooling. Heat transfer in this period may be enhanced by liquid flow from the upper head. Once the system has depressurized to less than the accumulator cover pressure, the accumulators begin to inject cold water into the cold legs. During this period, due to steam upflow in the downcomer, a portion of the injected ECCS water is bypassed around the downcomer and sent out through the break. As the system pressure continues to decrease, the break flow and consequently the downward core flow are reduced. As the ECCS bypass phenomenon breaks down the break mass flow rate temporarily reduces to almost zero from 20 to 40 seconds after transient initiation due to the combination of the rapidly falling system pressure and the initial penetration of subcooled ECCS inventory. The system pressure approaches the containment pressure at the end of this last period of the blowdown phase.

During this phase, the core begins to heat up as the system approaches containment pressure, and the phase ends when the reactor vessel begins to refill with ECCS water.

Refill Phase

The core continues to heat up as the lower plenum refills with ECCS water. This phase is characterized by a rapid increase in fuel cladding temperature at all elevations due to the lack of liquid and steam flow in the core region. The water completely refills the lower plenum and the refill phase ends. As ECCS water enters the core at the end of the refill phase, the fuel rods in the lower core region begin to quench and liquid entrainment begins, resulting in increased fuel rod heat transfer.

Reflood Phase

During the early reflood phase, the accumulators begin to empty and nitrogen is discharged into the RCS. The nitrogen surge forces water into the core, which is then evaporated, causing system re-pressurization, illustrated by the temporary increase in RCS pressure, and a temporary reduction of pumped ECCS flow. During this time, core cooling may increase due to vapor generation and liquid entrainment, but conversely the early reflood pressure increase results in loss of mass out through the broken cold leg.

The pumped ECCS water aids in the filling of the downcomer throughout the reflood period. As the quench front progresses further into the core, the PCT elevation moves increasingly higher in the fuel assembly.

As the transient progresses, continued injection of pumped ECCS water refloods the core, effectively removes the reactor vessel metal mass stored energy and core decay heat, and leads to an increase in the reactor vessel fluid mass. Eventually the core fluid inventory increases enough that liquid entrainment is able to quench all the fuel assemblies in the core.

A second cladding heatup transient may occur due to boiling in the downcomer. The mixing of ECCS water with hot water and steam from the core, in addition to the continued heat transfer from the hot vessel and vessel metal, reduces the subcooling of ECCS water in the lower plenum and downcomer. The saturation temperature is dictated by the containment pressure. If the liquid temperature in the downcomer reaches saturation, subsequent heat transfer from the vessel and other structures will cause boiling and level swell in the downcomer. The downcomer liquid will spill out of the broken cold leg and reduce the driving head, which can reduce the reflood rate, causing a late reflood heatup at the upper core elevations.

14.5.1.5 Analysis Results

The Surry Units 1 and 2 Region II analysis was performed in accordance with the NRC-approved methodology in Reference 5, with exceptions identified in Section 14.5.1.1. The analysis was performed assuming both loss of offsite power (LOOP) and offsite power available (OPA), and the results of both the LOOP and OPA analyses are compared to the 10 CFR 50.46 acceptance criteria. The most limiting ECCS single failure of one ECCS train is assumed in the analysis as identified in Table 14.5-1. The results of the Surry Units 1 and 2 Region II LOOP and OPA uncertainty analyses are summarized in Table 14.5-3, and include the impact of the gamma energy redistribution error correction and the revised pre-transient oxidation data.

Table 14.5-17 contains a sequence of events for the transient that produced the more limiting analysis PCT result relative to the offsite power assumption. Figure 14.5-1 through Figure 14.5-14 illustrate the key response parameters for this transient. The containment pressure is calculated for each LOCA transient in the analysis using the COCO code (Reference 67 and Reference 7). The COCO containment code is integrated into the WCOBRA/TRAC-TF2 thermal-hydraulic code. The transient-specific mass and energy releases calculated by the thermal-hydraulic code at the end of each timestep are transferred to COCO. COCO then calculates the containment pressure based on the containment model (the inputs are summarized in Table 14.5-2 and Table 14.5-5) and the mass and energy releases, and transfers the pressure back to the thermal-hydraulic code as a boundary condition at the break, consistent with the methodology in Reference 5. The containment model for COCO calculates a conservatively low containment pressure, including the effects of all the installed pressure reducing systems and processes assuming all trains of containment spray are operable. The containment backpressure for the transient that produced the analysis PCT result is provided in Figure 14.5-8.

14.5.1.6 Compliance with 10 CFR 50.46

It must be demonstrated that there is a high level of probability that the following criteria in 10 CFR 50.46 are met:

(b)(1) The analysis PCT corresponds to a bounding estimate of the 95th percentile PCT at the 95-percent confidence level. Since the resulting PCT is less than 2,200°F, the analysis with the FSLOCA EM confirms that 10 CFR 50.46 acceptance criterion (b)(1), i.e., “Peak Cladding Temperature does not exceed 2,200°F,” is satisfied.

The results are shown in Table 14.5-3 for Surry Units 1 and 2.

(b)(2) The analysis MLO corresponds to a bounding estimate of the 95th percentile MLO at the 95-percent confidence level. Since the resulting MLO is less than 17 percent when converting the time-at-temperature to an equivalent cladding reacted using the Baker-Just correlation and adding the pre-transient corrosion, the analysis confirms that 10 CFR

50.46 acceptance criterion (b)(2), i.e., “Maximum Local Oxidation of the cladding does not exceed 17 percent,” is satisfied.

The results are shown in Table 14.5-3 for Surry Units 1 and 2.

(b)(3) The analysis CWO corresponds to a bounding estimate of the 95th percentile CWO at the 95-percent confidence level. Since the resulting CWO is less than 1 percent, the analysis confirms that 10 CFR 50.46 acceptance criterion (b)(3), i.e., “Core-Wide Oxidation does not exceed 1 percent,” is satisfied.

A detailed CWO calculation takes advantage of the core power census that includes many lower power assemblies. Because there is significant margin to the regulatory limit, the CWO value may be conservatively chosen as that calculated for the limiting hot assembly rod. A detailed CWO calculation is therefore not needed because the outcome will always be less than the hot assembly rod.

The results are shown in Table 14.5-3 for Surry Units 1 and 2.

(b)(4) 10 CFR 50.46 acceptance criterion (b)(4) requires that the calculated changes in core geometry are such that the core remains in a coolable geometry.

This criterion is met by demonstrating compliance with criteria (b)(1), (b)(2), and (b)(3), and by assuring that fuel assembly grid deformation due to combined LOCA and seismic loads is specifically addressed. Criteria (b)(1), (b)(2), and (b)(3) have been met for Surry Units 1 and 2 as shown in Table 14.5-3.

It is discussed in Section 32.1 of the NRC-approved FSLOCA EM (Reference 5) that the effects of LOCA and seismic loads on the core geometry do not need to be considered unless fuel assembly grid deformation extends to inboard assemblies beyond the core periphery (i.e., deformation in a fuel assembly with no sides adjacent to the core baffle plates). Inboard grid deformation due to combined LOCA and seismic loads is not calculated to occur for Surry Units 1 and 2.

(b)(5) 10 CFR 50.46 acceptance criterion (b)(5) requires that long-term core cooling be provided following the successful initial operation of the ECCS.

Long-term cooling is dependent on the demonstration of the continued delivery of cooling water to the core. The actions that are currently in place to maintain long-term cooling are not impacted by the application of the NRCapproved FSLOCA EM (Reference 5).

Based on the analysis results for Region II presented in Table 14.5-3 for Surry Units 1 and 2, it is concluded that Surry Units 1 and 2 comply with the criteria in 10 CFR 50.46.

14.5.1.7 Post Analysis of Record Evaluations

In addition to the analyses presented in this section, evaluations and reanalyses may be performed as needed to address computer code errors and emergent issues, or to support plant changes. The issues or changes are evaluated, and the impact on the Peak Cladding Temperature (PCT) is determined. The resultant increase or decrease in PCT is applied to the analysis of record PCT. The PCT, including all penalties and benefits is presented in Table 14.5-6 for the large break LOCA. The current PCT is demonstrated to be less than the 10 CFR 50.46(b) requirement of 2200°F.

In addition, 10 CFR 50.46 requires that licensees assess and report the effect of changes to or errors in the evaluation model used in the large break LOCA analysis. These reports constitute addenda to the analysis of record provided in the UFSAR until the overall changes become significant as defined by 10 CFR 50.46. If the assessed changes or errors in the evaluation model results in significant changes in calculated PCT, a schedule for formal reanalysis or other action as needed to show compliance will be addressed in the report to the NRC.

Finally, the criteria of 10 CFR 50.46 requires that holders and users of the evaluation models establish a number of definitions and processes for assessing changes in the models or their use. Westinghouse, in consultation with the PWR Owner's Group (PWROG), has developed an approach for compliance with the reporting requirements. This approach is documented in WCAP-13451, Westinghouse Methodology for Implementation of 10 CFR 50.46 Reporting (Reference 30). Dominion provides the NRC with annual and 30-day reports, as applicable, for Surry Power Station. Dominion intends to provide future reports required by 10 CFR 50.46 consistent with the approach described in Reference 30.

14.5.2 Loss of Reactor Coolant From Small Ruptured Pipes or From Cracks in Large Pipes, Which Actuates Emergency Core Cooling System (Small Break Loss-of-Coolant Accident Analysis)

14.5.2.1 General

An analysis of the Emergency Core Cooling System (ECCS) performance for the postulated small-break LOCA (SBLOCA) has been performed in compliance with Appendix K to 10 CFR 50. The results of this analysis are in compliance with 10 CFR 50.46. The analysis was performed in accordance with the NRC-approved S-RELAP5 methodology described in Reference 26 as supplemented by Reference 27 and approved in Reference 61.

14.5.2.2 Identification of Causes and Accident Description

A LOCA can result from a rupture of the reactor coolant system (RCS) or of any line connected to that system up to the first isolation valve. Ruptures of small cross section will cause expulsion of the coolant at a rate that can be accommodated by the charging pumps. A spectrum of cold leg break sizes were analyzed with the S-RELAP5 computer code, ranging from 1.0 inches to 8.7 inches in diameter. A rupture in the reactor coolant system results in the discharge to the containment of reactor coolant and associated energy. The result of this discharge is a decrease in coolant pressure in the reactor coolant system and an increase in containment temperature and pressure. The reactor trip signal subsequently occurs when the pressurizer low pressure trip setpoint is reached. A safety injection system (SIS) signal is actuated when the pressurizer low-low pressure setpoint is reached, activating the high head safety injection pumps. The SIS actuation and subsequent activation of the Emergency Core Cooling System, which results from the SIS signal, assumes the most limiting single failure of ECCS equipment.

Before the break occurs, the unit is assumed to be in an equilibrium condition, (i.e., the heat generated in the core is being removed via the secondary system). In the small break LOCA, the blowdown phase of the small break occurs over a long time period. Thus for a small break LOCA, there are three characteristic stages: (1) a gradual blowdown in which the decrease in water level is checked by the inventory replenishment associated with safety injection, (2) core recovery, and (3) long-term recirculation. The heat transfer between the reactor coolant system and the secondary system may be in either direction, depending on the relative temperature. For the case of continued heat addition to the secondary side, the secondary side pressure increases and the main steam safety valves may actuate to reduce the pressure. Makeup to the secondary side is automatically provided by the auxiliary feedwater system. Coincident with the safety injection signal, normal feedwater flow is stopped by closing the main feedwater control valves and tripping the main feedwater pumps. Emergency feedwater flow is initiated by starting the auxiliary feedwater pumps. The secondary side flow aids in the reduction of RCS pressure. When the reactor coolant system depressurizes to approximately 600 psia, the accumulators begin to inject borated water into the reactor coolant loops. Reflecting the loss of offsite power assumption, the reactor coolant pumps are assumed to be tripped at the time of reactor trip, and the effects of pump coastdown are included in the blowdown analysis.

14.5.2.3 Analysis Assumptions

As required by Appendix K of 10 CFR 50, certain conservative assumptions were made for the Small Break LOCA-ECCS analysis. The assumptions pertain to the conditions of the reactor and associated safety system equipment at the time that the LOCA is assumed to occur and include such items as the core peaking factors, core decay heat, and the performance of the Emergency Core Cooling System. Table 14.5-12 presents the values assumed for several key parameters in this analysis. Assumptions and initial operating conditions that reflect the requirements of Appendix K to 10 CFR 50 have been used in this analysis. These assumptions include:

- The break is located in the cold leg between the pump discharge and the vessel inlet.
- Safety injection occurs both in the intact loops and the broken loop.
- Accumulator injection occurs both in the intact loops and the broken loop.
- 120% of 1971 ANS decay heat is assumed following reactor trip.
- Initial power is 2597 MWt, which is 102% of 2546 MWt (100.38% of 2587 MWt) to account for the calorimetric uncertainty
- 7% tube plugging in each steam generator.
- Safety injection system delivers borated water to the reactor coolant system 40 seconds after actuation of the SIS signal. The 40-second delay includes sufficient time to allow startup of the emergency diesel generators and loading of the charging pumps onto the emergency buses.
- Minimum assumed auxiliary feedwater flow is provided to three steam generators.

The following assumptions have been incorporated into the SBLOCA analysis described below to provide margin in key input parameters.

The analysis assumed a peak Heat Flux Hot Channel Factor, FQ(z), value of 2.50 and a peak Nuclear Enthalpy Hot Channel Factor, FΔh, value of 1.70, inclusive of uncertainties, and a K(z) equal to 1 for all core heights. K(z) is a multiplier on the allowable 3-D peaking factor FQ, and by nature cannot exceed 1.0. The power shape used is consistent with these technical specifications and was selected to yield limiting SBLOCA results. These values bound the current and anticipated power peaking limits.

The flow rates for the HHSI are provided by an engineering model of the HHSI subsystem that is based on the system configuration and measured data from the plant. This model includes allowances for imbalance between the separate injection lines, HHSI pump degradation, and instrument accuracy. The HHSI pump curves used in the model are based on the actual measured plant data for the installed HHSI pumps in each unit. For the calculated HHSI flows, it is assumed that the HHSI flow recirculation line is open. This is consistent with previous assumptions used to calculate HHSI flow rates versus RCS pressure for small break LOCAs. Other assumptions regarding HHSI system configuration, such as water levels and back pressures, are set to provide limiting conditions for the specified test condition. HHSI flow testing performed during refueling outages assesses the condition of the HHSI pumps to ensure that the actual system performance is bounded by the assumptions in the current analysis. Table 14.5-13 and Table 14.5-14 provide the HHSI and LHSI flow rates used in the break spectrum analysis.

The analysis assumes representative fuel design and material characteristics and is applicable to the Westinghouse 15x15 Upgrade fuel product.

14.5.2.4 Analysis of Effects and Consequences

14.5.2.4.1 Method of Analysis

The SBLOCA analysis is a Fuel-vendor Independent application of the NRC-approved S-RELAP5 EMF-2328 methodology described in Reference 26 as supplemented by Reference 27 and approved in Reference 61. The methodology incorporates the appropriate conservatisms, as prescribed by Appendix K of 10 CFR 50 (Reference 28) and is applicable to W- and CE-designed plants. The application analyzes a 15x15 fuel product with non-fuel related plant-specific details. The EMF-2328 SBLOCA evaluation model for event response of the primary and secondary systems and the hot fuel rod used in this analysis is based on the use of two computer codes:

1. The RODEX2-2A code was used to determine the burnup dependent initial fuel rod conditions for the system calculations.

2. The S-RELAP5 code was used to predict the thermal-hydraulic response of the primary and secondary sides of the reactor system and the hot rod response.

A complete spectrum of cold leg break sizes was considered, ranging from 1.0 inches in diameter to 8.7 inches in diameter. In addition, sensitivity studies were performed to consider delayed reactor coolant pump (RCP) trip, attached piping breaks, and different ECCS fluid temperatures. The results described in Section 14.5.2.4.2 are applicable to the current 15x15 fuel product with ZIRLO or Optimized ZIRLO cladding.

14.5.2.4.2 Results

The Surry break spectrum analysis for SBLOCA includes breaks of varying diameter up to 10% of the flow area for the cold leg. The limiting PCT from the break spectrum is 1673ºF. The maximum value from the break spectrum for the transient maximum local oxidation (MLO) is 1.43%. The transient MLO does not include the pre-transient oxidation which is dependent on cladding type. The maximum core wide oxidation (CWO) is less than 0.06%.

The limiting PCT case was determined to be the 2.6 inch break with a PCT of 1673ºF. The sequence of events is shown in Table 14.5-15. The transient progression is shown in Figure 14.5-15 through Figure 14.5-33:

- Cladding Temperature at the PCT Location: Figure 14.5-15
- Break Flow Rate: Figure Figure 14.5-16
- Break Void Fraction Figure 14.5-17
- System Pressures: Figure 14.5-18
- Reactor Power: Figure 14.5-19
- RCS and RV Masses: Figure 14.5-20
- Downcomer Level: Figure Figure 14.5-21
- Hot Assembly Collapsed Level:Figure 14.5-22
- Hot Assembly Mixture Level: Figure 14.5-23
- Cold Leg Mass Flow Rates: Figure 14.5-24
- HHSI Mass Flow Rates: Figure 14.5-25
- LHSI Mass Flow Rates:Figure 14.5-26
- Accumulator Mass Flow Rates: Figure 14.5-27
- Loop Seal Upside Collapsed Levels: Figure 14.5-28
- SG Upside Tube Collapsed Level: Figure 14.5-29
- Secondary Mass:Figure 14.5-30
- MFW Mass Flow Rates:Figure 14.5-31
- AFW Mass Flow Rates: Figure 14.5-32
- MSSV Mass Flow Rates: Figure 14.5-33

The ECCS must also cope with breaks in attached piping. The Surry plant has a separate line for the accumulator and the pumped SI injection connected to each cold leg. The high head and low head system share a common short length of pipe before joining to the cold leg. Both the accumulator and SI line break were analyzed. The accumulator line break resulted in a PCT of 1292ºF and a transient MLO of 0.06%. The SI line break resulted in a PCT of 934ºF and transient MLO of less than 0.01%. The results are less limiting than those of the break spectrum analysis.

14.5.2.5 Post Analysis of Record Evaluations

In addition to the analyses presented in this section, evaluations and reanalyses may be performed as needed to address computer code errors and emergent issues, or to support plant changes. The issues or changes are evaluated, and the impact on the PCT is determined. The resultant increase or decrease in PCT is applied to the analysis of record PCT. The PCTs, including all penalties and benefits, are presented in Table 14.5-16 for the small break LOCA. The resultant PCT is demonstrated to be less than the 10 CFR 50.46(b) requirement of 2200°F.

As discussed in Section 14.5.1.7, 10 CFR 50.46 requires that licensees assess and report the effect of changes to or errors in the evaluation models used in LOCA analyses. The requirements discussed in Section 14.5.1.7 are also applicable to the small break LOCA analysis.

14.5.2.5.0.1 Conclusions. The calculated peak clad temperature for the limiting 2.6-inch break is 1673°F, which is less than the 2200°F limit. The maximum transient local metal-water reaction for the limiting 2.5-inch break is 1.43%. Including pre-transient oxidation, the total local metal-water reaction is less than the embrittlement limit of 17%. The total core-wide metal-water reaction is less than the 1% limit. The results show that the clad temperature transient has peaked and sufficiently stabilized while the core is still amenable to cooling. Consequently, it is concluded that the Surry ECCS will be capable of mitigating the effects of a small break LOCA with a maximum F_Q of 2.50 and a $F\Delta h$ of 1.70, inclusive of uncertainties, at a thermal core power of 2597 MWt, with the current 15x15 fuel product.

An evaluation performed for a transition from 15 x 15 SIF with ZIRLO cladding to 15 x 15 Upgrade fuel with Optimized ZIRLO cladding concluded that there is no significant impact on the SBLOCA analysis results and all pertinent 10 CFR 50.46 acceptance criteria continue to be satisfied (see Section 14.5.2.5).

For the small break LOCA, the emergency core cooling system will thus meet the acceptance criteria as presented in 10 CFR 50.46, as follows:

1. The calculated peak fuel element clad temperature provides margin to the limit of 2200°F.
2. The amount of fuel element cladding that reacts chemically with water or steam does not exceed 1% of the total amount of Zircaloy in the reactor.
3. The clad temperature transient is terminated at a time when the core geometry is still amenable to cooling. The localized cladding oxidation limit of 17% is not exceeded.
4. The core remains amenable to cooling during and after the break.
5. The core temperature is reduced and decay heat is removed for an extended period of time, as required by the long-lived radioactivity remaining in the core.

14.5.3 Core and Internals Integrity Analysis

The methodology presented in Sections 14.5.3.1 through 14.5.3.4 has been replaced in part by the methodology of WCAP-9401. Also, the BLODWN-2 program has been replaced in part by the MULTIFLEX computer code. Refer to Section 14.5.3.3.4 for a description of the MULTIFLEX code and its use in blowdown and force models and the WCAP-9401 methodology.

14.5.3.1 Internals Evaluation

The forces exerted on the reactor internals and the core following a LOCA are computed by employing the BLODWN-2 digital computer program developed for the space-time-dependent analysis of multiloop PWR plants.

14.5.3.2 Design Criteria

Following a LOCA, the basic requirement is that the plant shall be shut down and cooled down in an orderly manner so that fuel cladding temperature is kept within the specified limits. This implies that the deformation of the reactor internals must be kept sufficiently small so that the core geometry remains substantially intact to allow core cooling and insertion of a sufficient number of control-rod assemblies.

After the break, the reduction in water density greatly reduces the reactivity of the core, thus shutting down the core independent of the control-rod assemblies. In other words, the core is shut down whether or not the control-rod assemblies are tripped. (The subsequent refilling of the core by the emergency core cooling system uses borated water to maintain the core in a subcritical state). Therefore, insertion of most of the control-rod assemblies gives further assurance of the ability to shut the unit down and keep it in a safe-shutdown condition. Note that the methodologies of Reference 45 and Reference 52 have been used to verify acceptability for crediting control rod insertion following a cold leg break in the assessment of long term core cooling.

Maximum allowable deflection limitations are established for those regions of the internals that are critical for unit shutdown. Allowable stress limits are adopted to ensure physical integrity of the components.

In the event of a sudden double-ended reactor coolant system pipe rupture[1] (complete severance in a few milliseconds), pressure waves are produced in the reactor, causing vertical and horizontal excitation of the components. A study has been made to analyze the response of the reactor vessel internal structures under these conditions.

14.5.3.3 Blowdown and Force Models

14.5.3.3.1 Blowdown Model

BLODWN-2 is a digital computer program used for calculation of local fluid pressure, flow, and density transients that occur in the reactor coolant system during a LOCA. This program applies to the subcooled, transition, and saturated two-phase blowdown regimes. This is in contrast to programs such as WHAM (Reference 9), which are applicable only to the subcooled region and which, due to their method of solution, could not be extended into the region in which large changes in the sonic velocities and fluid densities take place.

1. As discussed in Section 15.6.2, it is no longer necessary to consider the dynamic effects of a postulated rupture of the primary reactor coolant loop piping. However, pipe ruptures of reactor coolant branch lines are still postulated.

BLODWN-2 is based on the method of characteristics, wherein the resulting set of ordinary differential equations obtained from the laws of conservation of mass, momentum, and energy, are solved numerically using a fixed mesh in both space and time.

Although one-dimensional conversation laws are employed, the code can be applied to describe three-dimensional system geometries through the use of the equivalent piping networks. Such piping networks may contain any number of pipes or channels of various diameters, dead ends, branches (with up to six pipes connected to each branch), contractions, expansions, orifices, pumps, and free surfaces (such as in a pressurizer). System losses such as friction, contraction, expansion, etc., are considered.

14.5.3.3.2 Comparison With Experimental Data

BLODWN-2 predictions have been compared with data obtained by Phillips Petroleum Company from their loss-of-flow test (LOFT) semi-scale and 1/4-scale blowdown experiments.

An example of these comparisons is shown in Figure 14.5-75, which illustrates the pressure history in the blowdown pipe for the semi-scale test #522. This was a bottom blowdown test for the “Bettis Flask No. 1” geometry, with initial uniform fluid conditions of 1268 psia and 445°F. It can be seen that the BLODWN-2 digital computer program gives good agreement in both the subcooled and the saturated regimes.

14.5.3.3.3 Force Model

BLODWN-2 evaluates the pressure and velocity transients for a maximum of 2400 locations throughout the system. These pressure and velocity transients are stored as a permanent tape file and are made available to the program FORCE, which uses a detailed geometric description in evaluating the loading in reactor internals.

Each reactor component for which force calculations are required is designated as an element and assigned an element number. Forces acting upon each of the elements are calculated, summing the effects of:

1. The pressure differential across the element.
2. Flow stagnation on, and unrecovered orifice losses across, the element.
3. Friction losses along the element.

Input to the code, in addition to the BLODWN-2 pressure and velocity transients, includes the effective area of each element on which the force acts due to the pressure differential across the element, a coefficient to account for flow stagnation and unrecovered orifice losses, and the total area of the element along which the shear forces act.

14.5.3.3.4 Method of Blowdown Re-Analysis

Re-analysis of the blowdown forces on the reactor vessel and internals structures for Units 1 and 2, such as the one performed for the vessel head replacements and the control rod insertion analysis following a cold leg break (Reference 45), has made use of the MULTIFLEX (References 46 & 47) computer code, rather than BLODWN-2 described above, and the methodology of WCAP-9401 (Reference 48). MULTIFLEX is an extension of the BLODWN-2 code and includes mechanical structure models and their interactions with the thermal-hydraulic system. Both versions of the MULTIFLEX code share a common hydraulic modeling scheme, with the differences confined to a more realistic downcomer hydraulic network, and a more realistic core barrel structural model that accounts for non-linear boundary conditions and vessel motion. Generally, this improved modeling results in lower, more realistic, but still conservative hydraulic forces on the core barrel. The NRC staff has accepted (References 49, 50, & 53) the use of MULTIFLEX (including MULTIFLEX 3.0) for calculating the hydraulic forces on reactor vessel internals, including the reactor core (References 51 & 52). MULTIFLEX is used in the analysis to calculate the thermal-hydraulic transient (primarily transient pressures) within the reactor vessel. The re-analysis uses the FORCE2 computer code (described in Reference 46) to post process MULTIFLEX hydraulic transient results into vertical forces as described above for the FORCE code. Lateral forces are computed using the LATFORC code (described in Reference 46). The WCAP-9401 methodology utilizes a 3-dimensional structural model of the reactor vessel, internals, reactor core, and vessel support mechanism. LOCA forces acting on internals components are generated using the calculated transient pressures from the MULTIFLEX computer code and the FORCE2 and LATFORC codes. Horizontal and vertical responses are calculated simultaneously from the 3-dimensional model for both LOCA and seismic loading conditions.

14.5.3.4 Response of Reactor Internals to Blowdown Forces

14.5.3.4.1 Reactor Equipment System Model - LOCA Analysis

The response of reactor internals components due to an excitation produced by complete severance of a branch line pipe is analyzed. Assuming a pipe break occurs in a very short period of time of 1 millisecond, the rapid drop of pressure at the break produces a disturbance that propagates along the primary loop and excites the internal structures.

The LOCA break considered for Surry Units 1 and 2 consist of breaks located at the accumulator (ACC) line, pressurizer surge (PZR) line, and the residual heat removal (RHR) line. The LOCA hydraulic forcing functions (horizontal and vertical forces) that were used in the analyses were generated using MULTIFLEX 3.0 computer code described by Reference 47.

Mathematical Model of the Reactor Pressure Vessel (RPV) System

The mathematical model of the RPV system is a three-dimensional nonlinear finite element model, which represents the dynamic characteristics of the reactor vessel/internals/fuel in the six geometric degrees of freedom. The RPV system model was developed using the WECAN (Westinghouse Electric Computer Analysis) computer code. The WECAN finite element model consists of three concentric submodels connected by the nonlinear impact elements and stiffness matrices. The first submodel represents the reactor vessel shell and associated components. The reactor vessel is restrained by reactor vessel supports and by the attached primary coolant piping. The reactor vessel support system is represented by stiffness matrices.

The second submodel represents the reactor core barrel assembly (core barrel and thermal shield), lower support plate, tie plate, and secondary core support components. This submodel is physically located inside the first, and is connected to it by a stiffness matrix at the internals support ledge. Core barrel to vessel shell impact is represented by nonlinear elements at the core barrel flange, core barrel nozzle, and lower radial support locations.

The third and innermost submodel represents the upper support plate, guide tubes, support columns, upper and lower core plates, and the fuel. This submodel includes the specific properties of the Westinghouse 15 x 15 Upgraded fuel assemblies. The third submodel is connected to the first and second by a stiffness matrices and nonlinear elements.

The WECAN computer code, which is used to determine the response of the reactor vessel and its internals, is a general purpose finite element code. In the finite element approach, the structure is divided into a finite number of members or elements. The inertia and stiffness matrices, as well as the force array, are first calculated for each element in the local coordinates. Employing appropriate transformation, the element global matrices and arrays are then computed. Finally, the global element matrices and arrays are assembled into the global structural matrices and arrays, and used for dynamic solution of the differential equation of motion for the structure:

$$[M]\{\ddot{U}\}+[D]\{\dot{U}\}+[K]\{U\}=\{F\}$$

Where,

$[M]$ = Globalinertia matrix
$[D]$ = Global damping matrix
$[K]$ = Global stiffness matrix
$\{\ddot{U}\}$ = Acceleration array
$\{\dot{U}\}$ = Velocity array
$\{U\}$ = Displacement array
$\{F\}$ = Force array, including impact, thrust forces, hydraulic forces, constraints and weight.

WECAN solves the above equation using the nonlinear modal superposition theory. An initial computer run is made to calculate the eigenvalues (frequencies) and eigenvectors (mode shapes) for the mathematical model. This information is stored, and is used in a subsequent computer run which solves the equation. The first time step performs a static solution of the equation to determine the initial displacements of the structure due to deadweight and normal operating hydraulic forces. After the initial time step, WECAN calculates the dynamic solution of the equation. Time-history nodal displacements and impact forces are stored for postprocessing.

The following typical discrete elements from the WECAN finite element library are used to represent the reactor vessel and internals components:

- Three-dimensional elastic pipe
- Three-dimensional mass with rotary inertia
- Three-dimensional beam
- Three-dimensional linear spring
- Concentric impact element
- Linear impact element
- 6 x 6 stiffness matrix
- 18 Card stiffness matrix
- 18 Card Mass matrix
- Three-dimensional friction element

During performance of analysis Westinghouse converted the reactor equipment system model (RESM) from WECAN to ANSYS as follows:

The reactor equipment system model (RESM) is used to determine the dynamic response of the RPV and internal system when subjected to loss -of-coolant accident (LOCA) excitations and seismic excitations. The mathematical model of the RPV system is a three-dimensional non-linear finite element model that represents the dynamic characteristics of the reactor vessel/ internals/ fuel in the six geometric degrees of freedom.

For the upflow conversion, the RPV system model was developed using ANSYS computer code. The ANSYS finite element model consists of three concentric structural sub-models connected by non-linear impact elements and stiffness matrices.

The first sub-model represents the reactor vessel shell and associated components. The RPV is restrained by reactor vessel supports and by the attached primary coolant piping. The reactor support system is represented by stiffness matrices.

The second sub-model represents the reactor core barrel assembly (core barrel and thermal shield), lower support plate, tie plates, and secondary core support components. The sub-model is physically located inside the first and is connected to it by a stiffness matrix at the internal support ledge. Core barrel to vessel shell impact is represented by nonlinear elements at core barrel flange, core barrel nozzle and lower radial key support locations.

The third sub-model represents the upper support plate, guide tubes, support columns, upper and lower core plates and fuel. The sub-model includes the specific properties of the Westinghouse 15x15 upgrade fuel. The third sub-model is connected to the first and second sub-models by stiffness matrices and non-linear elements.

The following typical discrete elements from ANSYS finite element library are used to represent the reactor vessel and internal components:

- Three-dimensional elastic pipe
- Three dimensional mass and rotary inertia
- Three dimensional beam
- Three-dimensional linear spring
- Concentric impact element
- Linear impact element
- 6x6 card stiffness matrix
- 18-card stiffness matrix
- 18-card mass matrix
- Three-dimensional friction element

The RESM analyses are completed using ANSYS parametric macro and the results are post processed to generate the following:

- Component interface loads (force in nonlinear elements)
- Core plate motions
- Vessel motions
- Closure head acceleration response spectra

The LOCA loads were generated considering the combination of upflow conversion and implementation of ELBB resulting in lower magnitude LOCA loads.

Analytical Methods

The RPV system finite element model as described above was used to perform the LOCA analysis. Following a postulated LOCA pipe rupture, forces are imposed on the reactor vessel and its internals. These forces result from the release of the pressurized primary system coolant. The release of the pressurized coolant results in the traveling depressurization waves in the primary system. These depressurization waves are characterized by a wavefront with low pressure on one side and high pressure on the other. The wavefront translates and reflects throughout the primary system until the system is completely depressurized. The rapid depressurization results in transient hydraulic loads on the mechanical equipment of the system.

The LOCA loads applied to the reactor vessel system consist of (a) reactor internal hydraulic loads (vertical and horizontal), and (b) reactor coolant loop mechanical loads. All of the loads are calculated individually and combined in a time-history manner.

RPV Internal Hydraulic Loads -

Depressurization waves propagate from the postulated break location into the reactor vessel through either a hot leg or a cold leg nozzle.

After a postulated break in cold leg, the depressurization path for the waves entering the reactor vessel is through the nozzle into the region between the core barrel and reactor vessel. This region is called the downcomer annulus. The initial wares propagate up, around, and down the downcomer annulus, then up through the region circumferentially enclosed by the core barrel; that is the fuel the region.

The region of the downcomer annulus close to the break depressurizes rapidly; however, because of the restricted flow areas and finite wave speed (approximately 3,000 feet per second), the opposite side of the core barrel remains at a high pressure. This results in a net horizontal force on the core barrel and reactor pressure vessel. As the depressurization wave propagates around the downcomer annulus and up through the core, the barrel differential pressure reduces, and similarly, the resulting hydraulic forces drop.

In the case of the postulated break in the hot leg, the waves follow a dissimilar depressurization path, passing through the outlet nozzle and directly into the upper internals region, depressurizing the core and entering the downcomer annulus from the bottom exit of the core barrel. Thus, after a break in the hot leg, the downcomer annulus would depressurize with very little difference in pressure across the outside of the diameter of the core barrel.

A hot leg break produces less horizontal force because the depressurization wave travels directly to the inside of the core barrel (so that the downcomer annulus is not directly involved) and internal differential pressures are not as large as for a cold leg break. Since the differential pressure is less for a hot leg break, the downcomer annulus would be depressurized with very little difference in the pressure across the outside diameter of the core barrel.

Reference 47 describes how the MULTIFLEX computer code calculates the hydraulic transients within the entire primary coolant system. It considers subcooled, transition, and two-phase (saturated) blowdown regimes. The MULTIFLEX program employs the method of characteristics to solve the conservation laws, and assumes one-dimensionality of flow and homogeneity of the liquid-vapor mixture.

The MULTIFLEX code considers a coupled fluid structure interaction by accounting for the deflection of the constraining boundaries, which are represented by separate spring mass oscillator systems. A beam model of the core support barrel has been developed from the structural properties of the core barrel; in this model, the cylindrical barrel is vertically divided into various segments and the pressure as well as the wall motions are projected onto the plane parallel in the broken inlet nozzle. Horizontally, the barrel is divided into 10 segments; each segment consists of three separate walls. The spatial pressure variation at each time step is transformed into 10 horizontal forces, which act on the 10 mass points of the beam model. Each flexible wall bounded on either side by a hydraulic flow path. The motion of the flexible walls is determined by solving the global equations of motion for the masses representing the forced vibration of an undamped beam.

Reactor Coolant Loop Mechanical Loads

The reactor coolant loop mechanical loads are applied to the RPV nozzles by the primary coolant loop piping. The loop mechanical loads results from the release of normal operation forces present in the pipe prior to the separation as well as transient hydraulic forces in the reactor coolant system. The magnitudes of the loop release forces are determined by performing a reactor coolant loop analysis for normal operating loads (pressure, thermal, and deadweight). The loads existing in the pipe at the postulated break location are calculated and are “released” at the initiation of the LOCA transient by application of the loads to the broken piping ends. These forces are applied with a ramp time of 1 millisecond because of the assumed instantaneous break opening time. For breaks in the branch lines, the force applied at the reactor vessel would be insignificant. The restraints on the main coolant piping would eliminate any force to the reactor vessel caused by a break in the branch line.

Results of the Analysis

The severity of a postulated break in a reactor vessel is related to three factors: the distance from the reactor vessel to the break location, the break opening area, and the break opening time. The nature of the decompression following a LOCA, as controlled by the internals structural configuration previously discussed, results in larger reactor internal hydraulic forces pipe breaks in the cold leg than in the hot leg (for breaks of similar area and distance from the RPV). Pipe breaks farther away from the reactor vessel are less severe because the pressure wave attenuates as it propagates toward the reactor vessel. The LOCA hydraulic and mechanical loads described in the previous sections were applied to the WECAN model of the reactor pressure vessel system.

The results of LOCA analysis include time-history displacements and nonlinear impact forces for all major components. The time-history displacements of upper core plate, lower core plate, and core barrel at the upper core plate elevation are provided as input for the reactor core evaluations. The impact forces calculated at the vessel-internals interfaces are used to evaluate the structural integrity of the reactor vessel and its internals. Using appropriate postprocessors, component linear forces are also calculated.

ANSYS: Westinghouse upgraded/ refined computer analysis by converting the Reactor Equipment System Model (RESM) from WECAN computer code to ANSYS computer code during the upflow conversion analysis. See Section 14.5.3.4.1 for detailed description of the model.

RPV Sliding Foot Support Analysis

For analysis of the RPV sliding foot supports for both Unit 1 and 2, an NRC approved methodology (References 55, 56, & 57) is used which credits increased break opening times for RCS branch line breaks in order to better characterize LOCA forces acting on the sliding foot supports. Using these alternatively developed LOCA forces, combined with existing design basis loads, the RPV sliding foot supports are capable of supporting postulated design basis loads without the need for crediting any of the twenty cap screws between the socket plate and the nozzle pad. The alternative methodology approach utilized is described in more detail below.

For purposes of lowering LOCA forces acting on the RPV sliding foot supports, increased break opening times (BOT) shown in Table 14.5-18 are developed using an NRC approved methodology described in References 55, 56, & 57. Crediting these increased BOTs, a new thermal-hydraulic model coded in AREVAs CRAFT2 software (Reference 58) is used to develop pressure and force time-histories corresponding to postulated breaks at the following RCS branch line connections: [1] 14” residual heat removal (RHR) line (Loop 1 Hot Leg); [2] 12” safety injection (SI) line (Loop 1 Cold Leg); and [3] 12” pressurizer surge (PZR) line (Loop 3 Hot Leg). AREVAs CRAFT2 software (Reference 58) is a thermal hydraulic code that is functionally equivalent to Westinghouse’s MULTIFLEX software. Asymmetric cavity pressure (ACP) force time histories acting on the reactor coolant pumps and steam generators are also developed. AREVAs BWHIST software (Reference 59) is used to develop LOCA force time histories from the pressure time histories developed from the CRAFT2 thermal-hydraulic model and the ACP analysis. AREVAs BWHIST program (Reference 59) is used to develop LOCA force time histories from the pressure time histories developed from the CRAFT2 thermal-hydraulic model and the ACP analysis. AREVAs BWHIST program (Reference 59) is a postprocessor of CRAFT2 that converts the CRAFT2 results to input for AREVAs BWSPAN structural analysis software (Reference 60), which is functionally equivalent to Westinghouse’s WECAN software. BWSPAN is used to model the RPV and three reactor coolant loops (including large bore piping, reactor coolant pumps, steam generators, and supports) and LOCA loads at the RPV sliding foot support (and at other major RCL equipment supports) are generated. These revised LOCA forces are combined with other design basis loads and the RPV support is re-evaluated in order to demonstrate that the aforementioned twenty cap screws are no longer required to be credited. Note that LOCA reaction forces developed for major RCL equipment supports (i.e., steam generator and RCP supports) are checked against design basis limitations for these supports to evaluate acceptability for the increased BOT and revised modeling approach. However, the Westinghouse-developed LOCA forces (using the 1 ms BOT) are still valid for the design of the major RCL equipment supports.

ANSYS: Westinghouse upgraded/ refined computer analysis by converting the Reactor Equipment System Model (RESM) from WECAN computer code to ANSYS computer code during the upflow conversion analysis. See Section 14.5.3.4.1 for detailed description of the model.

14.5.3.4.2 Reactor Equipment System Model Seismic Analysis

Nonlinear dynamic seismic analysis of the RPV system (reactor pressure vessel, internals, and fuel) includes the development of the system finite element model and the synthesized time-history accelerations.

The basic mathematical model for seismic analysis is essentially similar to the LOCA model except in that the seismic model includes the hydrodynamic mass matrices in the vessel/barrel annulus to account for the fluid-interactions. The RPV system finite element model for the nonlinear time-history seismic analysis consists of three concentric structural submodels connected by nonlinear impact elements and linear stiffness matrices. The first submodel represents the reactor vessel shell and its associated components. The reactor vessel is restrained by reactor vessel support system in the system finite element model was represented by stiffness matrices.

The second submodel represents the reactor core barrel, thermal shield, lower support plate, tie plates, and the secondary core support components. These submodels are physically located inside the first, and are connected to them by stiffness matrices at the vessel-internals interfaces. Core barrel to reactor vessel shell impact is represented by nonlinear elements at the core barrel flange, upper support plate flange, core barrel outlet nozzles, and the lower radial restraints.

The third and innermost submodel represents the upper support plate assembly consisting of guide tubes, upper support columns, upper and lower core plates, and the fuel. The fuel assembly simplified structural model incorporated in to the RPV system model. The third submodel is connected to the first and second submodel by stiffness matrices and nonlinear elements.

As mentioned earlier, fluid-structure or hydroelastic interaction is included in the reactor pressure vessel model for seismic evaluations. The horizontal hydroelastic interaction is significant in the cylindrical fluid flow region between the core barrel and the reactor vessel annulus. Mass matrices with off-diagonal terms (horizontal degrees of freedom only) attach between nodes on the core barrel, thermal shield, and the reactor vessel. The diagonal terms of the mass matrix are similar to the lumping of water masses to the vessel shell, thermal shield, and core barrel. The off-diagonal terms reflect the fact that all of the water mass does not participate when there is no relative motion of the vessel and the core barrel. It should be pointed out that the hydrodynamic mass matrix has no artificial virtual mass effect and is derived in a straight-forward, quantitative manner.

The matrices are a function of the properties of two cylinders with the fluid in the cylindrical annulus, specifically, inside and outside radius of the annulus, density of the fluid and length of the cylinders. Vertical segmentation of the reactor vessel and the core barrel allows inclusion of radial variations along their heights and approximates the effects of beam mode deformation. These mass matrices were inserted between the selected nodes on the core barrel, thermal shield, and the reactor vessel.

The seismic evaluations are performed by including the effects of simultaneous application of time-history accelerations in three orthogonal directions. The WECAN computer code, which is used to determine the response of the reactor vessel and its internals, is a general purpose finite element code. In the finite element approach, the structure is divided into a finite number of discrete members or elements. The inertia and stiffness matrices, as well as the force array, are first calculated for each element in the local coordinates. Employing appropriate transformations, the element global matrices and arrays are assembled into global structural matrices and arrays, and used for dynamic solution of the system equations.

ANSYS: Westinghouse upgraded/ refined computer analysis by converting the Reactor Equipment System Model (RESM) from WECAN computer code to ANSYS computer code during the upflow conversion analysis. See Section 14.5.3.4.1 for detailed description of the model.

14.5.3.4.3 Allowable Deflection and Stability Criteria

14.5.3.4.3.1 Fuel Assemblies. The limitations for this case are related to the stability of the thimbles in the upper end. The upper end of the thimbles cannot experience stresses above the buckling compressive stresses, because any buckling of the upper end of the thimbles distorts the guide line and could affect the free fall of the control-rod assembly. The buckling stress for the thimbles is 62,300 psi, and the yield stress is 62,500 psi.

14.5.3.4.3.2 Upper Core Package. The local deformation of the upper core plate where a guide tube is located shall be less than 0.100 inch. This deformation causes the plate to contact the guide tube, since the clearance between plate and guide tube is 0.1 inch. This limit prevents the guide tubes from being put in compression.

For a plate local deformation of 0.150 inch, the guide tube is compressed and deformed transversely to the established upper limit, and consequently the value of 0.150 inch. is adopted as the maximum core plate local deformation, with an allowable of 0.100 inch.

14.5.3.4.3.3 Upper Core Barrel. The upper barrel deformation has the following limits:

1. To ensure reactor trip and to avoid disturbing the control-rod assembly guide structure, the barrel cannot interfere with any guide tubes. This condition requires a stability check to ensure that the barrel does not buckle under the accident loads. The minimum distance between guide tube and barrel is 9 inches. This value is adopted as the limit above which “no loss of function” can no longer be guaranteed. An allowable deflection of 4.5 inches has been selected.

2. To ensure core cooling, the outward movement of the upper barrel must be such that the inlet flow from the unbroken cold legs is not impaired. From this condition an outward barrel deflection of 6 inches in front of the inlet nozzle has been established as the no-loss-of-function value. An allowable deflection of 3 inches has been selected.

14.5.3.4.3.4 Control-Rod Assembly Guide Tubes. The guide tubes in the upper core support package housing control-rod assembly required for unit shutdown have the following deflection limit: the maximum horizontal deflection of a beam should not exceed 1.75 inches over the length of the guide tube. An allowable distortion of 1.0 inch has been selected.

14.5.3.4.3.5 Allowable Stress Criteria. The allowable stress criteria fall into two categories depending on the nature of the stress state (membrane or bending). A direct or membrane state of stress has a uniform stress distribution over the cross section. The allowable (maximum) membrane or direct stress is taken to be equal to the stress corresponding to 20% of the uniform material strain or the yield strength, whichever is higher. For unirradiated type 304 stainless steel at operating temperature, the stress corresponding to 20% of the uniform strain is 39,500 psi. For irradiated type 304 stainless steel, the stress limit is higher.

For a bending state of stress, the strain is linearly distributed over a cross section. The average strain value is one-half of the outer fiber strain where the stress is a maximum. Thus, by requiring the average bending stress to satisfy the allowable criterion for the direct state of stress, the average absolute strain may be 20% of the uniform strain. Consequently, the outer fiber strain may be 40% of the uniform strain. The maximum allowable outer fiber bending stress is then taken to be equal to the stress corresponding to 40% of the uniform strain or the yield strength, whichever is higher. For unirradiated type 304 stainless steel operating temperatures, the stress-strain curve gives the maximum stress intensity as 50,000 psi. For irradiated type 304 stainless steel, the stress limit is higher; therefore, it is conservative to use the unirradiated value.

For combinations of membrane and bending stresses, the maximum allowable stress is taken to be equal to the maximum stress corresponding to the strain distribution having the maximum outer fiber strain not in excess of 40% uniform strain and average strain not in excess of 20% uniform strain. Analogous to the uniaxial case, the maximum allowable membrane and total stress intensities for multiaxial stress distributions are 39,500 psi and 50,000 psi.

14.5.3.5 Effects of LOCA and Safety Injection on the Reactor Vessel

The effects of injecting safety injection water into the reactor coolant system following a postulated LOCA have been analyzed. WCAP 7304L gives a description of the program associated with this analysis. Below is a summary of the conditions that were considered.

For the reactor vessel, three modes of failure are considered: the ductile mode, the brittle mode, and the fatigue mode.

14.5.3.5.1 Ductile Mode

The failure criterion used for this evaluation is that there shall be no gross yielding across the vessel wall, using the material yield stress specified in Section III of the ASME Code. The combined pressure and thermal stresses during safety injection through the vessel thickness as a function of time have been calculated and compared to the material yield stress at various times during the safety injection transient.

The results of the analyses showed that local yielding may occur in approximately the inner 12% of the base metal and in the cladding.

14.5.3.5.2 Brittle Mode

The possibility of a brittle fracture of the irradiated core region has been considered from both a transition temperature approach and a fracture mechanics approach.

The failure criterion used for the transition temperature evaluation is that a local flaw cannot propagate beyond any given point where the applied stress remains below the critical propagation stress at the applicable temperature at that point.

The results of the transition temperature analysis showed that the stress-temperature condition in the outer 65% of the base metal wall thickness remains in the crack arrest region at all times during the safety injection transient. Therefore, if a defect were present in the most detrimental location and orientation (i.e., a crack on the inside surface and circumferentially directed), it could not propagate any farther than approximately 35% of the wall thickness, even considering the worst-case assumptions used in this analysis.

Both a local crack effect and a continuous crack effect have been considered, with the latter requiring the use of a rigorous finite element axisymmetric code. The results of the fracture mechanics analysis, considering the effects of water temperature, heat transfer coefficients, and fracture toughness of the material as a function of time, temperature, and irradiation show that the integrity of the reactor vessel is maintained throughout the life of the unit.

14.5.3.5.3 Fatigue Mode

The failure criterion used for the failure analysis is the one presented in Section III of the ASME Code. In this method, the piece is assumed to fail once the combined usage factor at the most critical location for all transients applied to the vessel exceeds the code allowance usage factor of one.

The results of this analysis show that the combined usage factor never exceeds 0.2, even after assuming that the safety injection transient occurs at the end of unit life.

In order to cause a fatigue failure during the safety injection transient at the end of unit life, it has been estimated that a wall temperature of approximately 1100°F is needed at the most critical area of the vessel (instrumentation tube welds in the bottom head).

The design basis of the emergency core cooling system ensures that the maximum cladding temperature does not exceed the clad melting temperature. This is achieved by prompt recovery of the core through flooding, with the passive accumulator and the active injection systems. Under these conditions, a vessel temperature of 1100°F is not considered a credible possibility, and the evaluation of the vessel under such elevated temperatures is a hypothetical case.

For the ductile failure mode, such hypothetical rise in the wall temperature would increase the depth of local yielding in the vessel wall.

The results of these analyses show that the integrity of the reactor vessel is never violated.

The safety injection nozzles have been designed to withstand 10 postulated safety injection transients without failure. This design and associated analytical evaluation were made in accordance with the requirements of Section III of the ASME Code.

The maximum calculated pressure plus thermal stress in the safety injection nozzle during the safety injection transient was calculated to be approximately 50,900 psi. This value compares favorably with the code-allowable stress of 80,000 psi.

These 10 safety injection transients are considered along with all the other design transients for the vessel in the fatigue analysis of the nozzles. This analysis shows the estimated usage factor for the safety injection nozzles to be 0.47, which is well below the code-allowable value of 1.0.

The safety injection nozzles are not in the highly irradiated region of the vessel, and thus they are considered ductile during the safety injection transient.

The effect of the safety injection water on the fuel assembly grid springs has been evaluated and, due to the fact that the springs have a large surface-area-to-volume ratio, and are in the form of thin strips, they are expected to follow the coolant temperature transient with very little lag; hence, no thermal shock is expected, and the core cooling is not compromised.

Evaluations of the core barrel and thermal shield have also shown that core cooling is not jeopardized under the postulated accident conditions.

14.5.4 Containment Iodine Removal by Spray System

The spray system is designed to reduce post-accident containment pressure by condensing steam and to adsorb inorganic or particulate iodine present in the containment atmosphere by chemical spray. The spray system design bases and description are discussed in Section 6.3.1.

The analyses establishing the amount of radioiodine in the containment following a LOCA were approved and documented in Reference 44. The spray removal coefficients used in the analyses for elemental and organic iodine were assumed to be 10 hr^{-1} and 0 hr^{-1}, respectively, consistent with NUREG-0800 (Standard Review Plan) Section 6.5.2 (Reference 15). The spray removal coefficients used in the analyses for particulate iodine and other aerosols were as indicated in Table 14.5-8. The spray removal coefficients in Table 14.5-8 were developed in accordance with the methodology of NUREG/CR 5966 (Reference 14). A maximum decontamination factor of 200 was applied to the elemental iodine. A two-region model was used to calculate the effective spray removal coefficients. The spray is effective over 61% of the containment volume until containment spray is terminated, at which time the sprayed volume is reduced to 18.78%. There is assumed to be a mixing rate of 2 unsprayed volumes per hour.

14.5.5 Environmental Consequences of Loss-of-Coolant Accident (LOCA)

The assumed design basis accident LOCA is defined as the double-ended guillotine failure of a cold leg reactor coolant pipe, the total loss of coolant through such a double-ended failure, a total loss of offsite station power, where that is conservative, the availability of only minimum safeguards, and release of the core fission product inventory indicated in Table 14.5-10 to the reactor containment atmosphere. The core iodines released during the LOCA take the following chemical and physical forms:

1. 4.85% elemental
2. 0.15% organic
3. 95.0% particulate

This section describes the method and results of the radiological analyses for the design basis accident. The analyses include TEDE doses from three sources: dose from the containment leakage plume and the dose due to 30 days of ECCS and RWST leakage following the accident. Doses were calculated at the exclusion area boundary, at the low population zone boundary, and in the control room. The LOCA dose analyses discussed below assume operation at the uprated power.

The methodology used to evaluate the control room and offsite doses resulting from a LOCA was consistent with the NRC Standard Review Plan (References 15, 17, 18, & 34), and the Regulatory Guide 1.183 (Reference 35). Core radionuclide inventory was based on a power level of 2605 MWt which is slightly conservative compared to the uprated power level for Surry of 2587 MWt plus 0.38% for instrument uncertainty.

Regulatory Guide 1.183 (Reference 35), provides detailed guidelines for calculating doses from a LOCA in a PWR. Doses from all postulated release paths to the environment are calculated as described in the SRP, and compared with 10 CFR 50.67 exposure criteria. Radiological consequences of both containment leakage and post-LOCA leakage from Engineered Safety Feature (ESF) system components outside containment, (including backleakage into the RWST) were considered.

To account for manual realignment of the safeguards area ventilation system to filtered exhaust, a 30-minute delay in filtration, which corresponds to the earliest time for recirculation mode transfer, is included in the analysis of doses resulting from a LOCA. Surry Units 1 and 2 share a single fuel building. Prior analyses of the fuel handling accident required that the auxiliary ventilation system be aligned in the refueling mode during fuel handling. This alignment was necessary unless sufficient decay had occurred since reactor shutdown to eliminate the need for filtration of radioiodine releases from postulated fuel handling accidents. With this alignment, a manual action was required to enable filtration of the exhaust from the safeguards area after a safety injection (SI) signal. Currently, air filtration is not required to mitigate a fuel handling accident, and procedural controls have been established to eliminate operating with automatic alignment defeated, but this action is still conservatively modeled. Additionally, while modeled as a 30-minute delay, Reference 54 indicates that realignment of the safeguards area ventilation system is not actually required until just prior to recirculation mode transfer, when contaminated sump water is recirculated outside containment. The Surry core radionuclide inventory was determined from calculations using the ORIGEN-ARP computer code that conservatively modeled a representative Surry core-loading plan.

Surry has a subatmospheric containment system. During the first hour following the accident containment pressure is analyzed to remain less than 45 psig. A 0.1 volume percent per day containment leak rate was used for the first hour after the LOCA, which corresponds to a maximum containment pressure of 45 psig. The original design criterion required that within one hour, containment pressure be calculated to return to subatmospheric conditions. This original design criterion was modified in conjunction with the analyses for implementation of the alternative source term and Generic Letter 2004-02. The criteria were subsequently updated to support an increase in the containment depressurization profile for the alternative source term analyses. The modified criteria require that, following the LOCA, the containment pressure be less than 2.0 psig within 1 hour and less than 0.0 psig within 6 hours. Therefore, from 1 hour to 6 hours after a LOCA, a 0.04 volume percent per day leak rate was assumed, which corresponds to a maximum containment pressure of 2.0 psig. Beyond 6 hours, containment pressure is assumed to be less than 0.0 psig, terminating leakage from containment.

When the containment pressure is subatmospheric, any leakage would be into the containment. Therefore, no containment leakage is assumed after the fourth hour. Surry does not have a vent purge system that has to be considered as a LOCA release pathway.

The following containment spray removal coefficients were used:

Elemental Iodine = 10 per hour

Organic Iodine = 0 per hour

Particulate Iodine and other Particulates = per Table 14.5-8

Sprayed Volume = 61% (reduced to 18.78% at 1.14 hrs)

Mixing Rate = 2 unsprayed volumes/hour

Spray Start Time = 100 seconds (recirculation spray is not credited until 1.14 hrs)

Based on a review of the Basis for Surry Technical Specification 4.20, Regulatory Guide 1.25, and Regulatory Guide 1.52, the following control room and auxiliary building ventilation system filters efficiencies were used for Surry:

Iodine Type	Filter Efficiency

Elemental	90%
Methyl	70%
Particulate	99%

The 90% elemental and 70% methyl iodine removal efficiencies are indicated in Regulatory Guides 1.25 and 1.52 (References 19 & 37) as being appropriate for 2-inch charcoal filters without humidity control. The 99% efficiency for particulate iodine is based on the use of HEPA filters.

The ESF leakage was assumed to be 2 times the total allowable ECCS leakage of 15,000 cc/hour (Section 14.5.5.3) and the total allowable back-leakage into the RWST of 9,000 cc/hour. The RWST release to the atmosphere is modeled at 1000 cfm through the safeguards building and out ventilation vent No. 2. Filtration by the auxiliary building ventilation system was credited for the portion of the ECCS leakage that occurs in the Safeguards Building, primarily the 3,000 cc/hour of Outside Recirculation Spray System leakage identified in Section 14.5.5.3, and the RWST backleakage. The release of radionuclides to the environment was determined both for containment leakage and Engineered Safety Feature components leakage.

For the ECCS leakage dose calculation, forty percent of the core iodine inventory is assumed to be released to the sump. The water in the ESF system at Surry, including RWST back-leakage, is taken from the containment sump at temperatures less than 212°F except for a short period at the beginning of the accident. During the period of time that the water temperature in the sump exceeds 212°F, the flashing fraction is less than 10%. Therefore, Surry meets the requirements for assuming 10% of the iodine in the ESF system leakage becomes airborne (Reference 35). Of the 10% of the iodine that becomes airborne, 97% is modeled as elemental and 3% organic (Reference 35). All of the other radionuclides as indicated in Table 14.5-10 as being in the containment sump remain in the liquid phase (Reference 35) of ESF leakage. Therefore only the airborne iodine portion of radionuclides released through ESF leakage has any consequence for EAB. LPZ, and control room doses.

14.5.5.1 Methodology to Determine Atmospheric Dispersion Factors, Control Room Occupancy, and Breathing Rates

The parameter χ/Q defines the ratio of radionuclide concentration (χ in curies/m^3) to release rate (Q in curies/second). It depends on the site meteorology (average wind speed and atmospheric stability) and distance between source and receptor. The EAB and LPZ atmospheric dispersion factors (χ/Q) are given in Table 14.5-7 and were determined based on the PAVAN (NUREG/CR-2858) methodology (Reference 33) using meteorological data for 2009 to 2013. The “wake-credit not allowed” scenario of the PAVAN results was used, since the closest point of both the EAB and LPZ from the onsite release points is greater than 10 ‘building heights’ of the containment dome (the tallest wake-producing structure).

The control room χ/Q values were determined with the ARCON96 (Reference 32) methodology and meteorological data form the 1982 through 1986 time period. These values are listed in Table 14.5-7. Wake effects were considered in calculating the atmospheric dispersion factors for all the onsite receptor points. For all ARCON96 runs, the default cross sectional area of one of the containment buildings above grade was used to model a wake effect. This is reasonable since all the receptor points modeled would be expected to be in the wake of one of the containment buildings. Additionally, further conservatism was introduced by only considering one containment dome for wake effect impacts. All releases were modeled as ground-level releases even when the source point was elevated (e.g., ventilation vent No. 2).

The control room occupancy factors in Table 14.5-9 were also incorporated into the dose calculations to reflect that personnel would not be exposed to the released activity 100% of the time over the entire 30 day period. These occupancy factors are based on the guidance from Reference 35. The breathing rate used for the control room and EAB dose calculations was 3.5×10^{-4} m^3/sec. The breathing rate for the LPZ dose calculations was 3.5×10^{-4} m^3/sec for the first 8 hours, 1.8×10^{-4} m^3/sec from 8-24 hours, and 2.3×10^{-4} m^3/sec from 24 hours until the end of the accident.

14.5.5.2 RADTRAD-NAI Model for Surry LOCA Analysis

RADTRAD-NAI (Reference 31) was used to model the release of radionuclides for a LOCA at Surry. This computer code system first calculates radionuclide concentrations and releases to the environment. The RADTRAD-NAI computer code system modeled a LOCA at Surry with six volumes: 1) the environment, 2) the containment sump, 3) the portion of the containment covered by the Containment Chemical Spray System, 4) the portion of the containment not covered by the Chemical Spray System, 5) the RWST, and 6) the control room. The volumes used in the computer model were:

	0 - 1.14 hours	> 1.14 hours
Unsprayed containment volume	= 709,410 ft^3	1,477,392 ft^3
Sprayed containment volume	= 1,109,590 ft^3	341,608 ft^3
Sump volume	= 55,986 ft^3	
RWST Volume	= 50,502 ft^3	
Control room volume	= 2.23×10^5 ft^3	

The transport of radionuclides to the environment is modeled by specifying flow rates between the various volumes modeled. The mixing between the sprayed and unsprayed containment volumes was modeled based on 2 unsprayed volumes per hour. The containment leakage to the environment was modeled as 0.1 volume percent per day for the first hour. From 1 hour until 6 hours after the LOCA, a 0.04 volume percent per day leak rate was used. Beyond 6 hours, containment pressure is assumed to be less than 0.0 psig, terminating leakage from containment. The appropriate containment leakage rates, based upon time in the accident, were applied proportionately to both the sprayed and unsprayed containment volumes during the first six hours of the LOCA.

ESF leakage to the environment is modeled at twice the potential leakage rates specified in footnote to Tables 6.2-6 and 6.3-2 and twice the RWST allowable back-leakage of 9,000 cc/hour:

Twice the Allowable Leak Rate

Time Period	ECCS filtered leakage (cc/hour)	ECCS unfiltered leakage (cc/hour)	RWST filtered back-leakage (cc/hour)	Comments
0–0.25 hours	0	0	0	
0.25–0.5 hours	0	6000	0	earliest start of the RS System
0.5–720 hours	6000	24000	18,000	earliest RMT

RWST back-leakage is the modeled ESF system leakage through ECCS check valves into the RWST after switching to the recirculation cooling mode.

RADTRAD-NAI utilizes the χ/Q values discussed in Section 14.5.5.1 to determine the radionuclide concentrations outside the control room and at the EAB and LPZ dose points. Radionuclide transport into the control room is then modeled by specifying flow rates from the environment outside the control room.

The control room ventilation system was modeled consistent with Reference 32 and Surry control room ventilation system design and operation. An unfiltered inleakage of 250 cfm was modeled from time 0 to 30 days. The control room was assumed to be isolated at the start of the event based on a SI signal. After the first hour, a filtered intake of 900 cfm was modeled. Control room ventilation filter efficiencies are indicated in Section 14.5.5.

The RADTRAD-NAI code system calculates radionuclide releases to the environment and radionuclide concentrations versus time in each volume. Dose conversion factors, occupancy factors, and breathing rates are then used along with the radionuclide concentrations to calculate doses. The breathing rates and occupancy factors used for the dose calculations were discussed in Section 14.5.5.1. The RADTRAD-NAI code system uses dose conversion factors based on Federal Guidance Report Nos. 11 and 12 (References 38 & 39) to determine the TEDE doses.

14.5.5.3 Results of Dose Calculations for LOCA

The calculated LOCA doses are given in Table 14.5-11. It should be noted that the control room TEDE dose does not include the dose due to direct shine from containment due to the control room wall thickness being at least 18 inches thick (Reference 17). The calculated doses are less than the 10 CFR 50.67 limits for the EAB and LPZ, and the control room.

Filtration by the auxiliary building ventilation system was credited for the portion of the ECCS leakage that occurs in the Safeguards Building, primarily the Outside Recirculation Spray System leakage and RWST backleakage. Filtration was not credited for the portion of the ECCS leakage that occurs in the Auxiliary Building, primarily the SI and Charging System leakage. However, only certain areas (the charging pump cubicles and safeguards) are provided with dedicated exhaust paths to the filters. This has the potential to lead to releases to the environment that may bypass the auxiliary building filters. However, since no filtration credit is taken (in areas without dedicated exhaust paths to filters) and all atmospheric dispersion factors were modeled as ground releases (Section 14.5.5.1) this analysis remains conservative. The total allowable RWST back-leakage is 9,000 cc/hour. The maximum allowable unfiltered leakage is limited to the SI and Charging Systems leakage of 12,000 cc/hour. The total allowable ECCS leakage of 15,000 cc/hour includes SI and Charging Systems leakage of 12,000 cc/hour and Outside Recirculation Spray System leakage of 3,000 cc/hour.

14.5.6 Summary

For breaks up to and including the double-ended guillotine break of a cold leg reactor coolant pipe, the emergency core cooling system with minimum safeguards will limit the clad temperature to below the melting temperature of the cladding and ensure that the core will remain in place and substantially intact, with its essential heat transfer geometry preserved. The emergency core cooling system design meets the core cooling criteria for all cases. This is confirmed by the results of the limiting cases for the small break and large break LOCA sensitivity analyses. The emergency core cooling system components meet the acceptance criteria throughout the range of break sizes with the high-head safety injection pumps mitigating the smaller breaks and the accumulators in conjunction with the pumped safety injection flow mitigating the larger breaks.

The design of the fuel assemblies and the core support structures is such that the pressure oscillations and flow transients resulting from any LOCA can be accommodated without changes that would affect the capability of the safety injection system to perform its required function.

The calculated TEDE doses at exclusion area boundary, low population zone boundary, and in the control room resulting from a design basis LOCA are within the regulatory limits stated in 10 CFR 50.67.

Table 14.5-1
PLANT OPERATING RANGE ALLOWED BY THE BEST-ESTIMATE LARGE BREAK LOCA ANALYSIS

Parameter	As-Analyzed Value or Range	Operating Range or Target Value
1.0 Plant Physical Description		
a. Dimensions	Nominal	N/A
b. Pressurizer location	On an intact loop	N/A
c. Hot assembly location	Anywhere in core[a]	N/A
d. Hot assembly type	15 x 15 Upgrade fuel design	15 x 15 Upgrade fuel design
e. Steam generator tube plugging level	≤ 7%	0% ≤ SGTP ≤ 7% (in any one SG)
f. Fuel assembly type	15 x 15 Upgrade fuel with Optimized ZIRLO cladding, non-IFBA or IFBA, with IFMs	15 x 15 Upgrade fuel with Optimized ZIRLO cladding, non-IFBA or IFBA, with IFMs
2.0 Plant Initial Operating Conditions		
2.1 Reactor Power		
a. Core power	≤ 100% of 2597 MWt	≤ 2597 MWt
b. Peak heat flux hot channel factor (F_Q)	≤ 2.5	≤ 2.5
c. Peak hot rod enthalpy rise hot channel factor ($F_{\Delta H}$)	≤ 1.7	≤ 1.7
d. Hot assembly radial peaking factor ($\overline{P}_{HA}$)	≤ 1.7/1.04	≤ 1.7/1.04
e. Hot assembly heat flux hot channel factor (F_{QHA})	≤ 2.5/1.04	≤ 2.5/1.04

a. 28 peripheral locations will not physically be lead power assemblies.
b. Minimum Measured flow is verified per Technical Specifications 3.12.F, DNB parameters.
c. Not used.
d. Plant control systems are designed to control these parameters to the stated values.
e. fL/D based on average L/D of 516.2.
f. The analyzed maximum transient operation fraction is the sum of the planned (0.2) and unplanned (0.1) transient operation fractions, plus 0.2, as defined by the approved methodology (Reference 5).
g. Containment response calculated for each transient using transient-specific mass and energy releases.

Table 14.5-1 (CONTINUED)
PLANT OPERATING RANGE ALLOWED BY THE BEST-ESTIMATE LARGE BREAK LOCA ANALYSIS

Parameter	As-Analyzed Value or Range	Operating Range or Target Value
2.0 Plant Initial Operating Conditions (continued)		
2.1 Reactor Power (continued)		
f. Maximum transient operation fraction [f]	≤ 0.5	≤ 0.5
g. Axial flux difference band at 100% power	± 11%	± 5%
h. MTC	≤ 0 at hot full power (HFP)	≤ 0 at hot full power (HFP)
i. Typical cycle length	18 months	18 months
j. Maximum steady state depletion, F_Q	2.0	≤ 2.0
2.2 Fluid Conditions		
a. T_{AVG}	570–5.6°F ≤ T_{AVG} ≤ 576 + 5.6°F	570 to 576°F[d]
b. Pressurizer pressure	2250–60 psia ≤ P_{RCS} ≤ 2250 + 60 psia	2250 psia[d]
c. Loop flow	TDF ≥ 88,500 gpm/loop	MMF ≥ TS Limit[b]
d. Upper head design	T_{HOT}	T_{HOT}
e. Pressurizer level (Nominal)	53.7% of span (694 ft^3)	53.7% of span @ 573°F T_{AVG}[d]
f. Accumulator temperature	89°F ≤ T_{ACC} ≤ 113°F	89.5°F ≤ T_{ACC} ≤ 113°F

a. 28 peripheral locations will not physically be lead power assemblies.
b. Minimum Measured flow is verified per Technical Specifications 3.12.F, DNB parameters.
c. Not used.
d. Plant control systems are designed to control these parameters to the stated values.
e. fL/D based on average L/D of 516.2.
f. The analyzed maximum transient operation fraction is the sum of the planned (0.2) and unplanned (0.1) transient operation fractions, plus 0.2, as defined by the approved methodology (Reference 5).
g. Containment response calculated for each transient using transient-specific mass and energy releases.

Table 14.5-1 (CONTINUED)
PLANT OPERATING RANGE ALLOWED BY THE BEST-ESTIMATE LARGE BREAK LOCA ANALYSIS

Parameter		As-Analyzed Value or Range	Operating Range or Target Value
2.0	Plant Initial Operating Conditions (continued)		
	2.2 Fluid Conditions (continued)		
	g. Accumulator pressure	580 psia $\leq P_{ACC} \leq$ 700 psia	600 psia $\leq P_{ACC} \leq$ 680 psia
	h. Accumulator liquid volume	965 $ft^3 \leq V_{ACC} \leq$ 1035 ft^3	975 $ft^3 \leq V_{ACC} \leq$ 1025 ft^3
	i. Accumulator fL/D	7.227[e]	Current line configuration
	j. Minimum accumulator boron	2250 ppm	≥ 2250 ppm
3.0	Accident Boundary Conditions		
	a. Minimum safety injection flow	Table 14.5-4	≥ Table 14.5-4
	b. Safety injection temperature	37.5°F ≤ SI Temp ≤ 62.5°F	40°F ≤ SI Temp ≤ 60°F
	c. Safety injection delay	25 seconds (with offsite power) 40 seconds (with LOOP)	≤ 25 seconds (with offsite power) ≤ 40 seconds (with LOOP)
	d. Containment modeling	See Figure 14.5-8 and raw data in Tables 14.5-2 and 14.5-5[g]	See Figure 14.5-8 and raw data in Tables 14.5-2 and 14.5-5[g]
	e. Recirculation spray initiation delay	900 seconds	≥ 900 seconds
	f. Single failure	Loss of one ECCS train	Loss of one ECCS train

a. 28 peripheral locations will not physically be lead power assemblies.
b. Minimum Measured flow is verified per Technical Specifications 3.12.F, DNB parameters.
c. Not used.
d. Plant control systems are designed to control these parameters to the stated values.
e. fL/D based on average L/D of 516.2.
f. The analyzed maximum transient operation fraction is the sum of the planned (0.2) and unplanned (0.1) transient operation fractions, plus 0.2, as defined by the approved methodology (Reference 5).
g. Containment response calculated for each transient using transient-specific mass and energy releases.

Table 14.5-2
CONTAINMENT DATA USED FOR REGION II FSLOCA (LBLOCA) CALCULATION OF CONTAINMENT PRESSURE

Parameter	**Value**
Maximum containment net free volume	1,819,000 ft^3
Minimum initial containment temperature at full power operation	102 °F (1)
Refueling Water Storage Tank (RWST) temperature for containment spray	37.5 °F ≤ T_{RWST} ≤ 62.5 °F
Minimum RWST temperature for broken loop spilling SI	37.5 °F
Minimum containment outside air / ground temperature	9 °F
Minimum initial containment pressure at normal full power operation	9.85 psia
Minimum containment spray pump initiation delay from containment high pressure signal time	59 seconds (LOOP and OPA)
Maximum containment spray flow rate from all pumps	4625 gpm
Maximum number of containment fan coolers in operation during LOCA transient	0
Maximum number of containment venting lines (including purge lines, pressure relief lines or any others) which can be OPEN at onset of transient at full power operation	0
Containment walls / heat sink properties	Table 14.5-5

1. One containment heat sink, corresponding to the containment mat and subfloor, is initialized at a lower minimum temperature of 45°F.

Table 14.5-3
REGION II FSLOCA (LBLOCA) ANALYSIS RESULTS

Outcome	Region II Value (OPA)	Region II Value (LOOP)	Criterion
95/95 PCT *	1844°F + 31°F = 1875°F	1817°F + 31°F = 1848°F	≤ 2200 °F
95/95 Total MLO ** [Transient MLO]	6.23% [1.33%]	6.49% [3.57%]	≤ 17%
95/95 CWO	0.37%	0.43%	≤ 1%

* The PCT values presented in the table show the analysis-of-record result, which is the sum of the uncertainty analysis result plus the impact of the energy redistribution error correction. The figures presenting the analysis results correspond to the uncertainty analysis results. The MLO and CWO were confirmed to demonstrate compliance with the 10 CFR 50.46 acceptance criteria with the error correction.

** The MLO values presented in the table show the uncertainty analysis result. However, an evaluation of revised pre-transient oxidation (PTO) data was completed, resulting in a total MLO increase of 2.26% for both OPA and LOOP to 8.49% and 8.75%, respectively.

Table 14.5-4
MINIMUM SAFETY INJECTION FLOW (TOTAL IN INTACT LOOPS)
USED IN REGION II FSLOCA (LBLOCA) ANALYSIS

Pressure (psia)	**High Head Safety Injection (HHSI) Flow (gpm)**	**Low Head Safety Injection (LHSI) Flow (gpm)**

PEAK CLADDING TEMPERATURE INCLUDING ALL PENALTIES AND BENEFITS, REGION II FSLOCA (LBLOCA)

PCT for Analysis of Record (AOR)	1875°F
PCT Assessments Allocated to AOR	
Reactor Vessel Upflow Conversion	46 °F
LBLOCA PCT for Comparison to 10 CFR 50.46 Requirements	1921°F

Table 14.5-7
SURRY CONTAINMENT AND ECCS χ /Q VALUES

Time Period	Control Room χ/Q (sec/m^3) Containment Source	Control Room χ/Q (sec/m^3) ECCS & RWST (Vent No. 2)	EAB χ/Q Value (sec/m^3)	LPZ χ/Q Value (sec/m^3)
0-2 hours	4.67E.04	6.55E-04	1.02E-3	5.66E.05
2-8 hours	3.67E-04	4.93E-04	-	3.84E-05
8-24 hours	1.50E-04	2.03E-04	-	3.84E-05
24-96 hours	1.13E-04	1.44E-04	-	1.66E-05
96-720 hours	8.78E-05	1.08E-04	-	4.95E-06

Table 14.5-8
COMBINED CONTAINMENT AND RECIRCULATION SPRAY AEROSOL (PARTICULATE) REMOVAL COEFFICIENTS

Time (hr)	λ_{mf} (hr^{-1})
2.78E-02	3.59E+00
1.94E-01	3.69E+00
5.56E-01	4.16E+00
1.00E+00	4.40E+00
1.14E+00	3.04E+01
1.80E+00	1.94E+01
1.83E+00	1.35E+01
1.87E+00	7.21E+00
2.02E+00	3.91E+00
2.61E+00	3.43E+00
7.20E+00	0

Table 14.5-9
SURRY CONTROL ROOM OCCUPANCY FACTORS[a]

Time	Occupancy Factor
0 - 8 hr	1.0
8 - 24 hr	1.0
24 - 96 hr	0.6
96 - 720 hr	0.4

a. These values also used for LRA, SGTR, and MSLB accident dose analyses.

Table 14.5-10
CORE FISSION PRODUCT RELEASE FRACTIONS FOR THE LOCA
AS SPECIFIED BY REGULATORY GUIDE 1.183

	Core Release Fraction	
Group	Gap	Early In-Vessel
Noble Gases[b]	0.05	0.95
Halogens	0.05	0.35
Alkali Metals	0.05	0.25
Tellurium	0	0.05
Barium, Strontium	0	0.02
Noble Metals	0	0.0025
Cerium	0	0.0005
Lanthanides	0	0.0002
Duration (hr)[a]	0.5	1.3

a. Release duration and fractions apply only to the Containment release. The ECCS leakage portion of the analysis conservatively assumes that the entire core release fraction is in the containment sump from the start of the LOCA.
b. Noble Gases are not scrubbed from the containment atmosphere and therefore are not found in either the sump or ECCS fluid.

Table 14.5-11
LOCA CONTROL ROOM AND OFFSITE TEDE DOSE CONSEQUENCES COMPARED TO THE TEDE DOSE LIMITS OF 10 CFR 50.67

	Control Room (Rem TEDE)	Exclusion Area Boundary (Rem TEDE)	Low Population Zone (Rem TEDE)
Total Dose Consequences including contributions from containment, ECCS and RWST leakage	4.7	10.6	2.1
10 CFR 50.67 dose limits	5	25	25

a. 10 CFR Part 50.67 establishes TEDE dose limits for the EAB, the outer boundary of the LPZ, and for the control room for use with the alternate source term.

Table 14.5-12
SYSTEM PARAMETERS AND INITIAL CONDITIONS

Parameter	Analysis Value
Reactor Power, MWt	2597 [1]
Total Peaking Factor, F_Q	2.5 [1]
Radial Peaking Factor, $F\Delta h$	1.70 [1]
RCS Flow Rate, gpm	265,500
Pressurizer Pressure, psia	2250

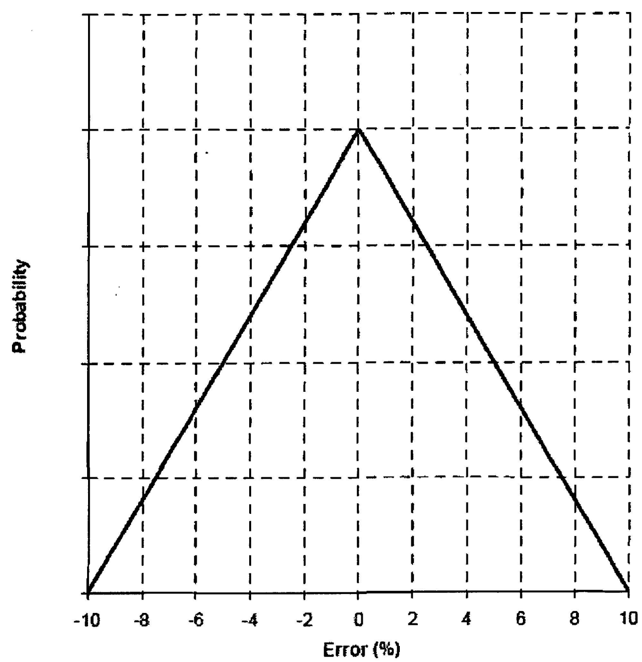
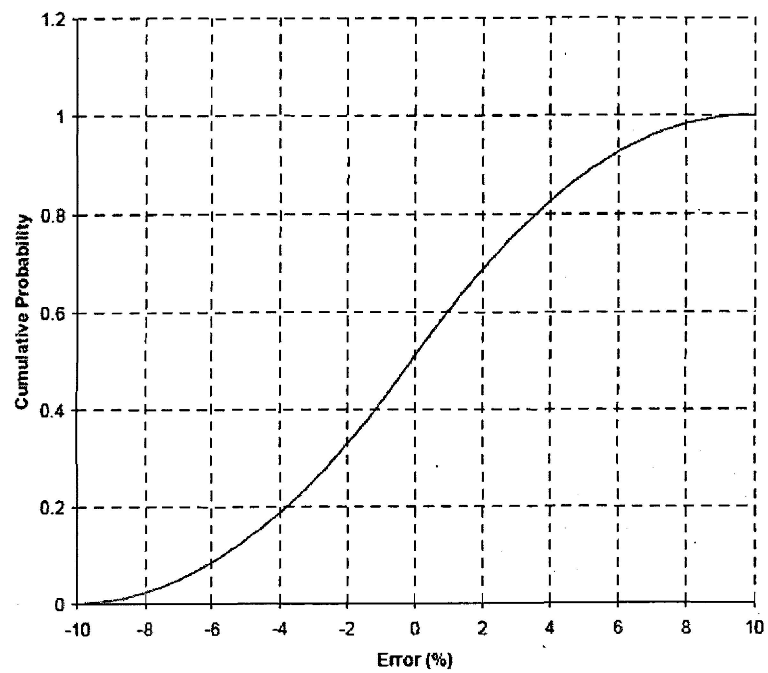
WECAN REACTOR EQUIPMENT SYSTEM MODEL





ANSYS: Westinghouse upgraded/ refined computer analysis by converting the Reactor Equipment System Model (RESM) from WECAN computer code to ANSYS computer code during the upflow conversion analysis. See Section 14.5.3.4.1 for detailed description of the model.

Appendix 14A
Radiation Sources

Intentionally Blank

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

APPENDIX 14A RADIATION SOURCES

14A.1 INTRODUCTION

This appendix presents the quantities of radioactive isotopes present in the core and the fuel rod gap. A general discussion of the derivations is also provided.

14A.2 TOTAL ACTIVITY IN THE CORE

The total core activity calculation is consistent with TID 14844 and data from ORNL-2127 (Reference 1). Numerical values for certain significant isotopes are given in Table 14A-1.

14A.3 ACTIVITY IN THE FUEL ROD GAP

The gap activity is computed based on buildup in the fuel from the fission process and diffusion to the fuel rod gap at rates dependent on the operating temperature. For analysis, the fuel pellets are considered divided into five concentric rings, each with release rate dependent on the mean fuel temperature within that ring. The diffusing isotope is assumed present in the gas gap when it has diffused to the boundary of its ring.

The diffusion coefficient, D', for Xe and Kr in UO_2 varies with temperature in accordance with the following expression:

$$D'(T) = D'(1673)\exp\left[-\frac{E}{R}\left(\frac{1}{T} - \frac{1}{1673}\right)\right]$$

Where:

E = activation energy

D'(1673) = diffusion coefficient at 1673 K = 1×10^{-11} sec^{-1}

T = temperature, K

R = gas constant

The above expression is valid for temperatures above 1473 K. Below 1473 K, fission gas release occurs, mainly by two temperature-independent phenomena, recoil and knock-out, and is predicted by using D' at 1473 K. The value used for D'(1673 K), based on data at burnups greater than 10^{19} fissions/cc, accounts for possible fission gas release by other mechanisms and pellet cracking during irradiation.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

The diffusion coefficient for iodine isotopes is assumed to be the same as for Xe and Kr. Toner and Scott (Reference 2) observed that iodine diffuses in UO_2 at about the same rate as Xe and Kr and has about the same activation energy. Data surveyed and reported by Belle (Reference 3) indicate that iodine diffuses at slightly slower rates than do Xe and Kr.

For a full core cycle at 2546 MWt, the above analysis results in a pellet-clad gap activity of less than 3% of the dose equivalent equilibrium core iodine inventory. The noble gas activity present in the pellet-clad gap is about 2.5% of the core inventory.

The percentage of the total core activity present in the gap for each isotope is also listed in Table 14A-1.

The core temperature distribution used in this analysis is presented in Table 14A-2.

APPENDIX 14B EFFECTS OF PIPING SYSTEM BREAKS OUTSIDE CONTAINMENT

14B.1 INTRODUCTION

14B.1.1 Appendix Coverage and Summary

This appendix is based on Appendix D to the initial FSAR and provides the response to a Commission letter dated December 18, 1972 (Reference 1), which contained a document entitled *General Information Required for Consideration of the Effects of a Piping System Break Outside Containment* (later revised in January 1973).

Since Surry Units 1 and 2 are similar in design, and to avoid unnecessary repetition, the analysis within this Appendix is oriented to Unit 2. However, wherever Unit 1 is unique with respect to Unit 2, an additional analysis is made for the unique portions.

This appendix presents an analysis of the consequences of postulated pipe failures outside the containment. In addition to the direct effects on safety resulting from the postulated break of a high-energy line, it is shown in this analysis that Surry Units 1 and 2 can be shut down and maintained in a shutdown condition. The postulated break of a pipe is shown not to negate any safety function as a result of the postulated failure.

The analysis ensures that the Commission's General Design Criterion 4 is met, i.e., that all structures, systems, and components important to safety are designed to accommodate the effects of and are compatible with the environmental conditions associated with normal operation, maintenance, testing, and postulated accidents, including loss-of-coolant accidents (LOCAs). These structures, systems, and components are protected against dynamic effects, including the effects of missiles, pipe whipping, and discharging fluids that may result in equipment failures and from events and conditions outside the nuclear power unit.

14B.1.2 Appendix Organization

The sectional organization of this Appendix is delineated in Figure 14B-1.

The approach used to analyze the consequences of pipe failure is to identify and locate the high-energy sources, identify and locate the safety-related targets, and determine and evaluate the physical effects. The criteria for determining pipe breaks and methods of analysis are presented in Section 14B.2. The identification and location of high-energy systems are found in Section 14B.3. The safety-related and shutdown equipment is identified, and the location listed in Section 14B.4. Calculation results and the evaluation of the physical effects from a pipe system break are found in Section 14B.5. The conclusions are found in Section 14B.7.

14B.2 CRITERIA FOR PIPE BREAKS AND METHODS FOR ANALYSIS

14B.2.1 General Discussion

High-energy systems that require analysis for the consequences of pipe breaks are identified based on the fluid in the pipe, and the pressure and temperature during normal station operation.

In pressurized water reactors, the fluids are water, steam, and water solutions. High-pressure nonflashing gas lines are not included in this analysis.

The temperatures and pressures used for determination of high-energy systems are the maximum normal operating temperatures and pressures. The type of analysis that is required is based on the temperature and pressure conditions as shown in Figure 14B-2. The lines that are both high-temperature and high-pressure are analyzed for pipe whip and environmental effects. The pipes that are low-pressure and high-temperature, or low-temperature and high-pressure, are postulated to crack and are analyzed for environmental effects.

The analysis of these effects (environmental, pipe whip, steam jets, etc.) involves consideration of the source and the target. The source includes the postulated pipe failure and the resulting reactions of the failure. The target includes components or systems that are considered essential in shutting down and maintaining the reactor in a safe-shutdown condition in the event of a postulated break outside containment of a pipe containing high-energy fluid, and which provide protective functions such that a loss of redundancy can be permitted but a loss of function cannot be permitted. The approach taken involved the determination of the effects of the source on the target.

After the high-energy lines are identified in accordance with the above definition, the function of each line is determined. Failure of lines that do not serve a safety function do not require the plant to be shut down. The criterion to which these lines are analyzed is that all safety functions must be protected. Failure of one out of two redundant components is acceptable if the safety function is not degraded. It is assumed that the plant must be shut down to repair damage to safety equipment in accordance with the Technical Specifications.

Failures in lines that serve a safety function require the plant to be shut down and maintained in a shutdown condition. The criterion under which these lines were analyzed is that all redundant components required to operate to recover from this failure are to be protected, including all redundant equipment required to bring the plant to shutdown and to maintain the plant in the shutdown condition.

To analyze the consequences of the postulated break, the targets must be identified. Targets are identified on the various drawings within this appendix.

After the high-energy break points and targets are located, the consequences of pipe whip and jet impingement are determined. The criteria and methods of analysis for determining these effects are discussed below. As a part of the analysis of each break point, it is determined that either the consequences are acceptable, or pipe whip protection and/or jet impingement protection is required.

14B.2.2 Criteria for Pipe Breaks and Cracks

14B.2.2.1 **Definition of High-Energy Lines**

Design-basis pipe breaks are postulated in piping for which the maximum operating pressure exceeds 275 psig and the maximum operating temperature equals or exceeds 200°F. The critical crack size is taken to be one-half the pipe diameter in length (d/2) and one-half the wall thickness in width (t/2). Pipe cracks (d/2 x t/2) are postulated in piping for which either the operating pressure exceeds 275 psig or the operating temperature equals or exceeds 200°F. If both operating pressure and temperature are below these values, breaks and cracks are not postulated (Figure 14B-2).

Operating temperature and pressure are defined as the maximum temperature and pressure in the piping system, during occurrences that are expected frequently or regularly in the course of power operation, start-up, shutdown, standby, refueling, or maintenance of the plant.

Protection from pipe whip is not provided if any of the following conditions exists:

1. The piping is physically separated by protective barriers or is otherwise isolated from structures, systems, or components important to safety, or is restrained from whipping by plant design features such as concrete encasement.
2. Following a single break, the unrestrained pipe movement of either end of the broken pipe in any possible direction about a plastic hinge formed at the nearest pipe whip restraint cannot impact any structure, system, or component important to safety.
3. The internal energy level associated with the whipping pipe can be demonstrated to be insufficient to impair the safety function of any structure, system, or component to an unacceptable level.

   The internal fluid energy level associated with the pipe break reaction may take into account any line restrictions (e.g., flow limiters) between the pressure source and break location, and the effects of either single-ended or double-ended flow conditions, as applicable. The energy level in a whipping pipe may be considered as insufficient to break an impacted pipe of equal or greater nominal pipe size and equal or heavier wall thickness.

14B.2.2.2 **Pipe Break Criteria**

Design-basis break locations are postulated in accordance with the following pipe whip protection criteria. However, where pipes carrying high-energy fluids are routed in the vicinity of structures and systems necessary for safe shutdown of the nuclear plant, supplemental protection of these structures and systems is provided to cope with the environmental effects (including effects of jet impingement) of a single postulated open crack at the most adverse location with regard to these essential structures and systems, the length of the crack being chosen not to exceed the critical crack size.

1. ASME Section III, Class I piping breaks are postulated to occur at certain locations in each piping run or branch run. Piping is defined as a pressure-retaining component consisting of straight or curved pipe and pipe fittings (e.g., elbows, tees, and reducers). A piping run is defined as piping that interconnects components such as pressure vessels, pumps, and rigidly fixed valves that may act to restrain pipe movements beyond the restraint required for design thermal displacement. A branch run differs from a piping run only in that it originates at a piping intersection, as a branch of the main pipe run.

   The postulated locations of piping breaks are:

   a. The terminal ends.

   b. Any intermediate locations between terminal ends where the primary-plus-secondary stress intensities S_n (circumferential or longitudinal) derived on an elastically calculated basis under the loadings associated with one-half of the safe shutdown earthquake and operational plant conditions exceed 2.0 S_m for ferritic steel and 2.4 S_m for austenitic steel.

      Operational plant conditions include normal reactor operation, upset conditions (anticipated operational occurrences), and testing conditions. S_m is the design stress intensity as specified in Section III of the ASME Code.

   c. Any intermediate locations between terminal ends where the cumulative usage factor (U) derived from the piping fatigue analysis and based on all normal, upset, and testing plant conditions exceeds 0.1.

      U is the cumulative usage factor as specified in Section III of the ASME Code.

   d. At intermediate locations in addition to those determined by l.a and l.b above, selected on a reasonable basis as necessary to provide protection. As a minimum, there are two intermediate locations for each piping run or branch run.

2. ASME Section III, Class 2 and 3, and ANSI-B31.1.0 (1967 Edition) piping breaks are postulated to occur at the following locations in each piping run or branch run:

   a. The terminal ends.

   b. Any intermediate locations between terminal ends where either the circumferential or longitudinal stresses derived on an elastically calculated basis under the loadings associated with seismic events and operational plant conditions exceed 0.8 (S_h + S_A), or the expansion stresses exceed 0.8 S_A.

S_h is the stress calculated by the rules of NC-3600 and ND-3600 for Class 2 and 3 components, respectively, of the ASME Code, Section III, Winter 1972 Addenda. S_A is the allowable stress range for expansion stress calculated by the rules of NC-3600 of the ASME Code, Section III-1971, or the USA Standard Code for Pressure Piping, ANSI B31.1.0-1967.

c. Intermediate locations in addition to those determined by 2.b above selected on a reasonable basis as necessary to provide protection. As a minimum, there are two intermediate locations for each piping run or branch run, selected on the basis of maximum combined primary and secondary stress. For nonseismic piping systems, the intermediate locations are selected on the basis of maximum thermal stress.

3. For systems meeting maximum operating conditions of either pressures greater than 275 psig or temperatures greater than 200°F, piping cracks were postulated at the most adverse points with respect to targets.

14B.2.2.3 Pipe Break Orientation

The criteria used to determine the pipe break orientation at the break locations as specified in Section 14B.2.2.2 above are equivalent to the following:

1. Longitudinal breaks in piping runs and branch runs, 4-inch nominal pipe size and larger, and/or
2. Circumferential breaks in piping runs and branch runs exceeding 1-inch nominal pipe size.

A tee-joint that connects a branch run and main piping is not necessarily a break location for the main piping if it does not qualify as a high-stress and/or high cumulative usage factor location in this main piping run; however, at its welding junction to the branch run, which is a terminal point of the branch run, a break location has to be postulated.

If one of the computed stresses and/or cumulative usage factors of the various points of an elbow (tee or reducer) is high enough to be qualified as an intermediate break location, and the other(s) varies within ±l0% of it, all these points are considered as a single break location.

Longitudinal breaks are parallel to the pipe axis and oriented at any point around the pipe circumference. The break area is equal to the effective cross-sectional flow area upstream of the break location. Dynamic forces resulting from such breaks are assumed to cause lateral pipe movements in the direction normal to the pipe ends.

Circumferential breaks are perpendicular to the pipe axis, and the break area is equivalent to the internal cross-sectional area of the broken pipe. The dynamic (blowdown) forces resulting from a circumferential break act to separate the piping axially; there is no transverse force during a circumferential break event.

14B.2.3 Methods of Analysis and General Results

14B.2.3.1 **Whipping Pipes and Interactions With Concrete Walls**

The velocity of a whipping pipe is dependent on:

1. The blowdown forces.
2. The pipe, break geometry, and size.
3. The distance traveled.

A typical mathematical model is shown in Figure 14B-3. At time zero, before the break occurs, the system is in a state of stress due to internal pressure, but these pressure forces are in static equilibrium with the axial loads in the pipe. As the circumferential crack propagates, the load-carrying metal area decreases, so a force imbalance results (Figure 14B-3, Part A). The axial load at the break is assumed to drop linearly to zero in 1 millisecond. After the break, the forces exerted on the pipe by the fluid are determined by time-dependent pressure and momentum effects. The combined behavior of these two terms is equivalent to a pressure drop to 0.7 of the initial value after the passage of the decompression wave (Reference 2). A wave velocity, assumed to be 1600 fps, results in the forcing functions as shown in Figure 14B-3, Part B.

The results of the above analysis indicate that, during most of the pipe displacement, the applied forces are only 0.7 of the initial forces and that approximately 30% of the energy is dissipated by plastic deformation in the pipe before impact. Due to strain hardening and strain rate effects, a distinct hinge may not form, but rather an extended region of large plastic deformation occurs. The plastic hinge lengths are also determined by this analysis (Table 14B-1) for the initial condition of 1050 psi.

Effects from whipping pipes on concrete walls were analyzed as follows. The local crushing stiffness of the pipe elbow may be readily determined in the elastic range, but only with difficulty once plastic deformation begins. The case of the actual elliptical contact area between the pipe elbow and wall has been considered, as well as an idealized case in which the portion of the elbow near the contact area is modeled as an equivalent sphere. PISCES (Reference 3) computer runs indicate that once crushing (or denting) is initiated, a flat area forms on the elbow. (Without internal pressure, bounce-back or “oil canning” occurs.) The forces transmitted by the wall to the pipe occur mainly at the circumference of the contact area. Thus, analyses presented in the literature for the stiffness of a sphere intersected by a pipe with normal loading may be used to get an approximate stiffness (Reference 4).

The crushing resistance of the elbow is modeled as a spring (connected to ground) in the mathematical model. This is acceptable, since the great inertia of the wall prevents any appreciable movement prior to the moment that the peak forces occur. The peak force in this spring is the maximum load transmitted to the wall during the impact. The effects of the continuing blowdown forces and the inertia of the pipe away from the impact point are automatically included in the analysis. Typical examples of these peak forces as a function of impact velocity are plotted in Figure 14B-4.

Since the load is applied to the concrete wall in a short time compared to the natural period of a concrete wall, the application of a dynamic load factor of two is required when using static design equations. The model used for punch shear is shown in Figure 14B-5. The equation used for punching shear (Reference 5) in a concrete wall is:

$$F = 4\sqrt{f_c}d2\pi\left(r + \frac{d}{2}\right)$$

where:

F = applied force

f_c = compressive strength of concrete

d = wall thickness

r = radius of contact area

In all cases, wall thicknesses employed in normal plant construction are sufficient to stop whipping pipes.

14B.2.3.2 **Fluid Jets and Interactions With Reinforced-Concrete Walls**

14B.2.3.2.1 Assumptions

1. The pipe break location is very close to the pressure reservoir(s). The pressure drop in the pipe due to flow friction is negligible.
2. The total jet force remains constant throughout its traveling distance; i.e., the friction force between the jet stream and ambient air is negligible.
3. The jet stream is totally intercepted by the concrete wall.
4. The jet impingement is a suddenly applied load to the concrete wall.

14B.2.3.2.2 Jet Force

The maximum value of the initial jet pressure from a pipe break can be expressed as:

$$P_J = C_J P_o$$

where:

P_o = fluid pressure inside pipe

C_J = jet coefficient

$C_J = 1.26$ for steam

$C_J = 2.0$ for subcooled nonflashing water

(If the pressure drop due to friction is taken into consideration, the values of C_J can be reduced.)

The total jet force is then:

$F_J = P_J A$

where:

A = pipe break area $= \frac{\pi}{4} D_p^2$

D_p = inside diameter of pipe

As the jet stream progresses away from the pipe break area, the width of the jet increases with the axial distance. The angle of divergence is assumed to be 20 degrees (Reference 6).

14B.2.3.2.3 Punch Shear Failure of Concrete Wall

The punch shear failure mechanism of a concrete wall due to jet impingement from a pipe break is shown in Figure 14B-6. The failure of a concrete wall is a diagonal cracking along the surface of a truncated cone or pyramid around the jet impingement area. The area of the shearing surface is:

$A_s = \pi D_w W$

where:

$D_w = D_P + 2L \tan 10° + W$

W = wall thickness

L = distance between wall and pipe break location

Without shear reinforcement, the shear strength is:

$$V_c = 4\sqrt{f'_c}$$

where:

f'_c = specified compressive strength of concrete

The total shear resistance of the reinforced-concrete wall is:

$R = ø A_s V_c$

where:

ø = capacity reduction factor = 0.85 for shear

The total jet impingement load seen by the wall is:

$F_T = C_D F_J$

where:

C_D = dynamic load factor = 2.0 for suddenly applied load

If R is greater than or equal to F_T, there will be no punch shear failure.

Curves relating dimensionless wall thickness ($X = W/D_P$) and dimensionless distance ($Y = L/D_P$) are shown in Figures 14B-7 and 14B-8 for steam and water lines, respectively. The specified concrete compressive strength, f'_c, is assumed to be 3000 psi.

These curves are extremely conservative. A more realistic analysis to determine the effective jet impingement force requires additional parameters, such as pipe lengths from sources, elbows, and flow restrictors and fluid characteristics. A conservative approach was used in the analysis for this appendix.

14B.2.3.2.4 Fluid Jets and Interaction With Steel Plates

For a fluid jet issuing from a crack (one-half the pipe diameter times one-half the pipe thickness) in a pipe wall, the magnitude of the jet force is small because the break area is small. It can be shown that either a 1-foot reinforced-concrete wall or a 1/8-inch steel plate being hit by a jet from close distance from a crack in a 32-inch, 2300-psi water line will not experience a local failure by punch shear. Therefore, it is not necessary to analyze the local punch shear failure of concrete walls or steel plates due to fluid jets from cracks in pipe walls.

14B.2.3.2.5 Fluid Jet Range

Any safety-related structure, piping component, and equipment located in the fluid jet traveling path is considered susceptible to jet impingement. As the jet propagates away from the pipe break area, it expands at a diverging angle. Therefore, the jet intensity decreases with distance from the break location to the target, whereas the total jet force is assumed to remain constant.

14B.2.3.3 **Pressure and Environment**

The pressure buildup from the postulated break of a high-energy pipe in a compartment or building is calculated using the computer program CUPAT (Reference 7).

14B.2.3.3.1 Introduction

CUPAT is a computer program used to calculate pressure and temperature transients in various nuclear power plant compartments resulting from a postulated high-energy pipe break.

The output is used mainly for design purposes in establishing the peak pressure differentials across the compartment walls.

This program was derived from the LOCTIC computer program (Reference 8) which was used to calculate pressure and temperature transients for the primary containment. Chapter 5 discusses the current method for primary containment analysis. There are two major differences between LOCTIC and CUPAT:

1. LOCTIC includes the effects of heat transfer by providing subroutines to handle sources and sinks. CUPAT assumes a volume that receives heat and mass from a broken piping source and discharges heat and mass to its surroundings, but aside from that there are no other heat sources or sinks (adiabatic assumption).
2. CUPAT allows for flow out of the volume considered as well as flow in. There is no provision in LOCTIC for mass outflow from the containment volume.

In order to calculate the transients within a compartment, CUPAT numerically solves finite difference equations defining heat and mass flows into and out of the compartment. The program uses the same basic assumptions as those used in LOCTIC, namely:

1. Mass and energy added or removed during each small time step are based on rates determined at the start of the time step; i.e., during any time interval, the thermodynamic state is assumed to be steady and the response of the flow out of the volume to changes in the thermodynamic state is instantaneous (quasi-steady-state assumption).
2. The atmosphere in the compartment mixes instantaneously and homogeneously, i.e., at each point in time, the atmosphere is in a state of thermodynamic equilibrium.

A detailed description of the approach to the problem is presented below.

The calculational approach used in CUPAT is summarized in the block diagram shown in Figure 14B-9. Blocks (1) through (5) in the figure are traversed once for each time step.

14B.2.3.3.2 Calculational Approach

14B.2.3.3.2.1 *Quasi-Steady-State Assumption.* The problem of analyzing the transient effects of a LOCA is very complex. The thermodynamic state of the compartment atmosphere is continuously changing. This state depends on the mass and energy flows into and out of the compartment. The flows, in turn, are dependent on the thermodynamic state within the compartment. In order to solve such a problem numerically, some simplifying assumptions must be made.

First, the system is defined as the compartment atmosphere at any given time. This includes any air, steam, and water droplets present, but not the walls, equipment, or internal structure of the compartment itself. If the time step is small enough, the net rate of mass and energy addition to the system will not vary appreciably during the time step. Thus, the flow rates are calculated assuming that the thermodynamic state does not change during the time step, and this assumption eliminates the need to iterate and converge on the inflow and outflow for each time step. This approach was used in LOCTIC (which also includes heat flows) for the primary containment transients, and is also used in CUPAT.

14B.2.3.3.2.2 *Mass and Energy Flow Rates into Compartment.* The mass and energy flow rates into the compartment are supplied as input to the program in tabulated form. These blowdown rates into the compartment may be obtained from the output of a LOCTIC or LOCTVS (Reference 9) computer run or from the assumption of Moody flow (Reference 10) with a known pressure blowdown.

The flow of fluid from a piping break is relatively insensitive to the back pressure in the compartment, since the pressure in the high-energy line is above 275 psig. Thus, the mass and energy inflow data specified as input are close to the actual flow, but are conservatively high.

14B.2.3.3.2.3 *Calculation of the Thermodynamic State of the Compartment.* In each time step of the numerical calculation, equilibrium temperature and pressure in the compartment are determined based on new values of mass and internal energy. Properties of water are obtained from the steam tables. The detailed procedure by which the pressure and temperature of the compartment atmosphere are found from the updated values of mass and internal energy is described below.

Initially the equilibrium state is considered to be a two-phase mixture of air, saturated steam, and saturated liquid. However, if the energy content for the given mass is greater than that required for saturation, a single-phase mixture of air and superheated steam is determined.

To arrive at the correct equilibrium conditions, a curve of internal energy of the air, steam, and liquid in the volume versus temperature is generated. The basis for the curve is that the mass of water present in the compartment is at a saturated equilibrium state for each temperature, and the total internal energy of the system at this temperature is calculated accordingly. The actual total internal energy is then used to enter this curve and find the true temperature. The total pressure is then determined by adding the vapor pressure to the air partial pressure, which is calculated by the ideal gas flow at this temperature.

In the case where the contents form a superheated vapor, the superheat section of the steam tables is used to match the specific volume of the steam and the internal energy to find the equilibrium temperature and pressure.

14B.2.3.3.2.4 *Calculation of Flow Rate Out of Compartment.* The CUPAT computer program uses the LOCTVS vent flow (Reference 11) to determine the flow rate out of the compartment. A homogeneous flow model is used in LOCTVS to calculate flow out of the drywell through the vents of a pressure suppression containment. Although flow through the vents is characterized by slip between the gaseous and liquid phases, a homogeneous model yields lower flow rates and is used for conservatism. The ability of the vent flow model to conservatively predict flow through the vents has been checked against the Bodega and Humboldt Bay pressure suppression tests.

14B.2.4 Protection Against Pipe Whip

A combination of three basic approaches was used for the protection of targets from whipping pipes. These approaches include:

1. Separation of redundant features by distance or location so that at least one feature remains intact.
2. The incorporation of many redundant features into the design of the safety-related systems for assurance of reliability.
3. For the largest main steam and feedwater lines, an extensive inspection program was devised for each postulated break point. By means of ultrasonic and/or radiographic testing in addition to a visual surveillance program, defect propagation can be detected at any early stage and repaired accordingly, thereby ensuring the integrity of each postulated break point.

14B.2.5 Analysis of Seismic Category I Structures

Analysis of Seismic Category I structures for loads other than pipe break in the main steam valve house is given in Section 15.2.

14B.3 HIGH-ENERGY SYSTEMS

14B.3.1 System Identification

The following systems contain high-energy lines, as defined in Section 14B.2:

1. Main steam.
2. Feedwater.
3. High-pressure heater drains and vents.
4. Moisture separator drains.
5. Auxiliary steam.
6. Condensate.
7. Low-pressure heater drains and vents.
8. Boron recovery.
9. Liquid waste.
10. Chemical volume and control.
11. Safety injection.
12. Steam generator blowdown.
13. Extraction steam.

14. Sample.

The high-energy lines in these systems were reviewed in conjunction with safety-related and safe-shutdown equipment (Table 15.2-1) by means of a detailed drawing review and onsite inspection. Those portions of the high-energy lines in proximity to the safety-related and safe-shutdown equipment have been identified. These portions of the high-energy lines are defined as sources and are presented in Table 14B-2.

The safety-related equipment and plant shutdown equipment in proximity to these sources (identified as targets) are listed in Section 14B.4.1.

Table 14B-2 presents a listing of the high-energy line sources with their maximum operating conditions, locations, and seismic classifications. These lines were individually analyzed for adverse effects on targets. Sources such as smaller lines located in the target areas were not individually analyzed, since the sources listed were the worst cases for their respective areas.

14B.3.2 Quality Assurance and Inspection

Piping presently installed was designed and fabricated in accordance with the criteria described in Section 1.4, *Compliance with Criteria*.

14B.3.3 Detection of Failures

As described in Section 7.2 and delineated in Table 7.2-1, reliable and redundant systems have been incorporated into the present plant design for detection of failures in the main steam and feedwater systems.

As described in Section 11.3.4, the area radiation monitoring system is designed to alarm when radiation levels in their associated areas are slightly above background. This system detects pipe failures in systems containing radioactive fluids.

Detection for breaks in lines routed through the Auxiliary Building is discussed in Section 14B.5.3.3.

14B.4 PLANT SHUTDOWN AND SAFETY-RELATED EQUIPMENT

14B.4.1 Introduction

Table 14B-3 lists the systems and major equipment locations that constitute postulated targets among the plant shutdown and safety-related equipment. Associated cables and controls are considered along with this equipment.

14B.4.2 Emergency Procedures

Main steam or feedwater breaks outside the containment are discussed in Section 14B.6. Subsequent to a main steam or feedwater break, assuming offsite power is unavailable, plant shutdown is achieved by actuation of the emergency core cooling system and removal of core decay and sensible heat via steam release through the steam generator power operated relief valves, and maintenance of steam generator water inventories by means of the auxiliary feedwater system.

Section 9.3 details the operation of the residual heat removal system necessary for long-term cooling and cold shutdown of the reactor.

Shutdown equipment is normally controlled from the control room. However, in the event that evacuation of the control room is necessary, shutdown equipment can be controlled from an auxiliary shutdown panel.

Emergency procedures direct the operators to perform mitigating actions in the event of a high-energy line break outside containment. The operator response to a break in the main steam valve house is described in Section 14B.6.

14B.4.3 Relationship of High-Energy Lines to Safe-Shutdown and Safety-Related Equipment

Figures 14B-10 through 14B-17 show the high-energy systems and the safe-shutdown and safety-related equipment.

14B.5 EFFECTS OF PIPE BREAKS AND CRACKS

14B.5.1 Main Steam

14B.5.1.1 Break Locations

Break locations were postulated in the main steam lines from the containment to the turbine building in accordance with Section 14B.2.2. For the main steam line, 0.8 of the allowable thermal stress is 22,500 psi, and 0.8 of the allowable combined primary and secondary stress is 0.8 $(S_A + S_h)$ = 37,500 psi. Since 0.8 of the allowable stresses was not exceeded, the two intermediate locations between terminal points were selected on the basis of maximum primary-plus-secondary stress. Piping downstream of the manifold common to the three steam lines was not analyzed seismically. For this piping, pipe breaks were assumed; however, because of separation, no further analysis is required. At all break points, both circumferential and longitudinal breaks were postulated to occur.

The break points are listed in Table 14B-4 along with the thermal and combined stress levels. The break locations are shown on Figure 14B-10.

Cracks were selected in the vicinity of all targets.

14B.5.1.2 **Separation**

The steam lines in the turbine building were analyzed, and satisfactory separation was found to exist between steam lines and any safety-related features.

The control room and emergency diesel-generator rooms are separated by sufficient distance from all high-energy lines, so that whipping pipes or steam jets will not adversely affect their respective functions. These conclusions were based on results given in Section 14B.2.3.

The auxiliary feedwater modification described in Section 14B.5.1.7 provides a system widely separated from postulated breaks.

14B.5.1.3 **Pipe Whip**

An extensive nondestructive testing program, as described in Section 14B.5.1.6, is used to preclude breaks, thereby making pipe whip a noncredible incident.

Since the guideline referenced in Section 14B.1.1 requires a postulated failure, each postulated main steam line break has been evaluated for the effects of pipe whip. Because feedwater supply to the steam generators is the ultimate requirement for a safe shutdown, the evaluation was based on maintaining the feedwater function. The results of this investigation are shown in Table 14B-5. These results were based on the plastic hinge lengths established in Section 14B.2.3.1 and on discussions with the turbine-driven auxiliary feedwater pump manufacturer indicating that the pump can operate in a steam environment.

Since loss of offsite power must be assumed, and the turbine drives are not environmentally qualified by tests, additional assurance that feedwater will be maintained is obtained by the auxiliary feed cross-connect system. As shown in Table 14B-5, there are no effects on the auxiliary feed cross-connect system, considering all postulated breaks. The auxiliary feed cross connect was a modification to the initial plant design and is discussed in Section 14B.5.1.7.

14B.5.1.4 **Fluid Jet Effects**

Jet impingement loadings on the walls, valves, and pipes inside the main steam valve house have been calculated. The time-history results of jet force from a pipe break at the most adverse location in the steam line within the valve house is calculated as follows (Section 14B.2.3.2):

$F(t) = 1.0\ P_oA$ for $t \leq 0.020$ sec

$F(t) = 0.7\ P_oA$ for $0.020\ \text{sec} < t \leq 0.113$

$F(t) = 0.19\ P_oA$ for $t > 0.113$ sec

The initial jet force on the walls was calculated as:

$F_o = K\ P_o\ A$

where:

K = initial thrust coefficient = 1.0

P_o = hot standby pressure = 1005 psig

A = flow area = 616 in^2

F = 619 kips

For the longitudinal breaks, the break size was taken as 60 x 10.3 inches with the jet diverging at a 20-degree inclusive angle. The impingement areas, jet pressures, and loads corresponding to each of the postulated breaks are indicated in Table 14B-6.

Local damage to the walls and floors was checked based on Section 14B.2.3.2. The conservative calculation, which assumes a dynamic factor of two and no energy loss, indicates that the floor at Elevation 27 ft. 6 in. is subject to some local damage from jet impingement. However, the containment, the walls, and the roof withstand the effects of jet impingement with no punch shear damage.

For breaks of the main steam lines, jet impingement loads on the valves were calculated. The maximum normal force on the valves is given by:

$F_v = C\ P_t\ A_t \cos^2 \alpha/1000$ (kips)

where:

C = shape factor for flow around the valve, cylinder, C = 0.6

P_t = initial jet pressure at the target (psi)

A_t = impingement area (in^2)

α = incident angle

The maximum normal jet forces on the valves are listed in Table 14B-7. It should be noted that these loads drop instantaneously to a fraction of the levels recorded. Available calculations indicate that the nonreturn valve will continue to function as a check valve, preventing blowdown of the undamaged loops. Calculations indicate that jet impingement will not break a main steam trip valve housing, but can cause the valve to fail open. However, with the nonreturn valve operable, a broken line could still be isolated, so that only one steam generator would blow down.

14B.5.1.5 Pressure and Environment

The main steam valve house and the reactor trip switchgear room, as shown in Figure 14B-10, are the only target areas that can be affected by steam following a postulated break or a crack in a main steam line, as discussed in the following sections.

As shown on Figure 14B-10, the reactor trip switchgear room is far removed from the source lines; therefore, the probability of having a steam environment within the room is extremely remote.

With the existence of the nondestructive testing program, as described in Section 14B.5.1.6, only smaller steam-line breaks need to be considered for pressure effects on the main steam valve house. The pressure buildup within the valve house, following a smaller steam-line break, is negligible.

In order to comply with the criteria, as referenced in Section 14B.1.1, the pressure in the main steam valve house has been calculated for the largest steam-line break. Frictionless Moody flow and the CUPAT computer program, as described in Section 14B.2.3.3, were used in these calculations. The results are shown in Figure 14B-18.

The main steam valve house contains many targets, as shown in Table 14B-3. As detailed below, all the targets either fail in the safe position or operate mechanically:

1. Targets that fail in the safe position.
   a. Main steam trip valves (close).
   b. Auxiliary feed pump steam isolation valve (open).
2. Targets that operate mechanically.
   a. Feedwater isolation check valves.
   b. Main steam nonreturn valves.
   c. Main steam safety valves.
   d. Turbine driver for auxiliary feed pump.

Furthermore, all electrical cables considered as targets are the same as the cables used inside the containment. Since this cable has been qualified by test for post-design-basis-accident conditions inside the containment, the cabling is not subject to common mode environmental failure.

The blowdown rates used to obtain the above results were based on blowdown of one steam generator, following the postulated steam-line break. The blowdown of only one steam generator can be justified by taking no credit for the main steam trip valves, but taking credit for the nonreturn valve (NRV-201A, B, C for Unit 2) in the affected steam line. Credit for the nonreturn valve is justified as follows:

1. As described in Section 14B.5.1.4, jet impingement will not affect the intended performance of this valve.
2. There is no instrumentation or electrical component required for operation of the valves. The nonreturn valves require only reverse steam flow for their intended operation.

3. In the worst case, where blowdown is the greatest following the postulated steam-line break, the steam system is in the hot standby condition. Blowdown is greatest for this case, since the steam-line pressures are at a maximum. In this condition, there is little or no steam flow to hold the valve disk in an open position; therefore, the valve is performing its required function even before the postulated failure. In all cases, when the system pressure is high, with respect to the pressure at 100% power, the flow rates are low and the valve is in a nearly closed position before the postulated incident occurs.

14B.5.1.6 **Inspection Program for Large Steam Lines**

An extensive nondestructive testing program is provided for the main steam postulated break points in the main steam valve house. These points, a total of 12 for each unit, are shown in Figure 14B-10.

14B.5.1.6.1 Procedures

A program of periodic examination exceeding the requirements of ASME Section XI, Winter Addenda 1972, as instituted by Regulatory Guide 1.51, was originally provided as follows:

1. A baseline examination was performed including 100% coverage of all subject points.
2. Inservice examinations were performed including 100% coverage of all subject points for the initial 3 years of the 10-year inspection interval as defined by ASME Section XI.
3. Examinations were performed including 100% coverage of all subject points for two subsequent inservice examinations.

Currently, the Augmented Inspection Program includes periodic examinations that meet the requirements of the Technical Specifications and the Technical Requirements Manual. This program requires ultrasonic and surface examinations to be performed on 1/3 of the welds every 40 months, with a cumulative 100% coverage of all welds by the end of the interval. Repairs are made as required. Upon completion of any repairs, the program, as described above, will be reinstated for the repaired postulated break point.

In addition to the above testing program, a visual inspection of the surface of the insulation at the main steam break point locations in question is performed weekly for detection of leaks. If a leak is detected, it is immediately investigated and subsequently repaired if the leakage is caused by a through-wall crack. The investigation allows for evaluation of system functionality to determine if continued plant operation can or cannot be justified, with consideration of the ASME Section XI Code for applicable Class piping, prior to the repair.

14B.5.1.6.2 Methods

The ultrasonic test procedures include the examination of the postulated break points and heat-affected zones. Consideration of weld thickness, geometry, material, and curvature parameters results in establishing the appropriate transducer sizes, optimum beam angles, and frequencies for test reliability and repeatability. Where appropriate, additional techniques are used for evaluating reflectors and obtaining characterization data. Test sensitivity is in accordance with ASME Section XI, which defines reference calibration requirements.

14B.5.1.6.3 Basis for the Inspection Program

As shown in a PVRC report (Reference 12), and a Virginia Power Technical Report (Reference 15), toughness of nuclear power plant piping materials is high enough to prevent brittle fracture at operating conditions. This conclusion can be supported by fracture mechanics calculations.

Furthermore, from the following fracture mechanics techniques and calculations, the critical size of surface and internal flaws far exceeds the thickness of the piping material. Consequently, a surface or an internal flaw will extend through the wall thickness and form a subcritical through-wall crack, which will leak before it reaches its critical size.

The main steam line material is SA155, grade CMS 75, Class 1, outside diameter 30 inches, wall thickness 1 inch. Plate material for piping is SA299. Fittings were fabricated from ASTM A299 steel plate stock, using the ASTM A234 Grade WPB specification. Fitting material equivalent to ASTM A691, Grade CMS 75, Class 32: carbon-manganese-silicon alloy steel can be used as replacement material for the main steam line pipe and fittings.

Feedwater line material is ASTM A106 Grade B: Carbon steel. Fittings are ASTM A234 WPB. ASTM A335 Grade P11 or P22: Chromium-Molybdenum steel can be used as replacement material for feedwater seamless pipe. ASTM A234 WP11 or WP22 can be used a replacement material for fittings.

For both main steam and feedwater piping, the ASME SA equivalent materials can be used as a preferred substitute for ASTM materials.

14B.5.1.6.4 Fracture Mechanics

The application of fracture mechanics techniques allows prediction of the critical flaw size that can cause fast or unstable fracture in a stressed structure.

When the critical flaw size is established for a nominal stress level, it is possible to decide the acceptable defect size. One of the criteria is the leak-before-fracture criterion, which requires that the defect wall propagate slowly through the wall of the pipe and that the pipe will leak before the crack is large enough to trigger the fast fracture.

Fabricated structures usually contain several types of defects, including surface flaws, internal flaws, and through-the-thickness cracks. The critical flaw size will be calculated for each of these flaws using fracture mechanics relationships. These formulas were used in two recently published papers (References 12 & 13) treating similar problems. As emphasized in the PVRC Recommendations on Toughness Requirements for Ferritic Materials (Reference 12), the pipe wall section is usually not thick enough to support plane strain fracture propagation, which can be properly analyzed by the fracture mechanics methods. In other words, the load limits and critical flaw size calculated using fracture mechanics will in general be more conservative for pipe than for the thick section structures where the plane stress conditions can exist. Fracture will occur when the value of the stress intensity factor K_I reaches the critical value K_{IC}. The critical flaw size is related to the K_{IC} in several different formulas depending on geometry of structures, flaws, shape, and environmental factors. In this work, the following assumptions were made about factors affecting the relation between the K_{IC} and the critical flaw size:

1. Material properties (toughness and strength) of the weld metal and the heat-affected zone in the longitudinal and circumferential weldments are the same as in the base material.

2. The lowest and the highest temperatures in the main steam line are 510°F and 547°F. The lowest and the highest temperatures in the feedwater line are 438°F and 450°F. However, only the lowest temperatures are used in calculations of fracture toughness because they give more conservative values for critical crack size.

3. Because of uncertainty involved in evaluating the possible stress state, Irwin's (Reference 14) suggestion was accepted that the membrane stress is equal to the yield strength. For SA106B pipes, Class 1 data are given in Section III. For SA155 (plate SA299) material, the elevated temperature yield strength was not given in Section III, Class 2, and the allowable design stress data for Class 1 were used to get the yield stress.

4. The stress intensity factor of 300,000 psi $\sqrt{\text{in.}}$ was used (Reference 13) for SA106B pipe. In this work, a lower value of 200,000 psi $\sqrt{\text{in.}}$ was accepted, which would correspond to the reference stress intensity factor K_{IR} at the temperature NDT + 180°F. The lowest temperature for SA106B pipe is 438°F, and for SA155 pipe, 510°F, which means that the NDT temperature in the first case would be 438–180 = 258°F, and in the second case, 510–180 = 330°F. This is of course a very conservative assumption, because the NDT temperature for these materials is below room temperature.

Toughness of replacement materials is documented in Reference 15. This reference provides technical justification for use of replacement materials based upon fracture toughness of materials. The replacement materials are assessed using linear-elastic fracture mechanics, elastic-plastic fracture mechanics, and limit load methods.

14B.5.1.6.4.1 *Internal Flaw.* The internal flaw is an ellipsoid, as shown in Figure 14B-19, Part A. The flaw is located in the center of the pipe wall. The flaw can be axial (major axis parallel to the pipe axis) or circumferential (major axis perpendicular to the pipe axis). A further assumption is that the flaw is small compared to the pipe radius. Thus the curvature effect can be neglected and the pipe can be approximated with an infinite plate under uniform applied stress. The stress intensity factor K_I for this model is given (Reference 13) as:

where:

σ = applied stress

$$K_I = \left[\sin^2\beta + \frac{a^2}{b^2}\cos^2\beta\right]^{1/2} \frac{\sigma(\pi a)^{1/2}}{\phi}$$

β = angle at which the stress intensity is calculated

ø = the following elliptical integral:

$$ø = \int_o^{\pi/2}\left[1 - \frac{b^2 - a^2}{b^2}\sin^2\theta\right]^{1/2} d\theta$$

At the tip of the major axis $\beta = 0$, while at the tip of the minor axis, $\beta = \frac{\pi}{2}$.

If it is assumed that the major axis of the ellipsoid is twice as long as the minor axis, the equation for K_I becomes:

$K_{IC} = 0.826\ \sigma\ (\pi a_{cr})^{1/2}$

It has been shown that, for an elongated crack (b>>a), the critical stress intensity factor is given by:

$K_{IC} = 1.2\ \sigma\ (\pi a_{cr})^{1/2}$

Substituting the values for the stress intensity factor and applied stress (yield strength at the temperature) in the first equation for K_{IC} results in the following:

Material	Temperature °F	2 a_{cr}(Critical Flaw Size), in.
SA106B	400	42.0
SA155	500	46.5

Substituting the values for the stress intensity factor and applied stress in the second equation for K_{IC} results in the following:

Material	Temperature °F	2 a_{cr}(Critical Flaw Size), in.
SA106B	400	19.6
SA155	500	22.8

As can be seen, all critical flaw size values are much greater than the wall thickness, which means that the flaws would extend through the wall without becoming critical. In other words, the internal flaw will become a through-the-thickness crack and will leak.

14B.5.1.6.4.2 *Surface Flaw.* The surface flaw is a semi-ellipsoid, as shown in Figure 14B-19, Part B. The flaw can be axial or circumferential, as in the previous case. Again the curvature effect is neglected, and the stress intensity factor is given (Reference 13) as:

$$K_{IC} = 1.12\sigma\,(\pi a_{cr})^{1/2}$$

Material	Temperature °F	a_{cr}(Critical Flaw Size), in.
SA106B	400	11.3
SA155	500	13.2

As in the case of the internal flaw, the surface flaw will penetrate the pipe wall without becoming critical.

14B.5.1.6.4.3 *Axial Through-Wall Crack.* The simplest formula for axial through-wall cracks is obtained when the pipe is assumed to be infinite plate; that is, the diameter is much greater than the thickness. The critical crack size for such a simple case is (Reference 12):

$$\underline{K}_{IC} = \sigma\,(\pi b_{cr})^{1/2}$$

where 2 b_{cr} is the critical crack length. The geometry is shown in Figure 14B-19, Part C. When the pipe diameter decreases, corrections are necessary. As a result of tests at Battelle Memorial Institute on SA106B piping, the critical size of the axial through-wall crack is given (Reference 13) as:

$$b_{cr} = \left\{ \frac{Rt}{1.61}\left[\left(\frac{\sigma^*}{\sigma}\right) -1\right] \right\}^{1/2}$$

where:

b_{cr} = critical half-length

σ^* = flaw stress

R = average pipe radius

t = thickness

Material	Temperature °F	Equation	2 b_{cr} (Critical Flaw Size), in.
SA106B	400	K_{IC}	28.4
SA106B	400	b_{cr}	5.5 (14-inch o.d. Schedule 80)
SA106B	400	b_{cr}	7.5 (18-inch o.d. Schedule 100)
SA155	500	K_{IC}	33.2

Material	Temperature °F	Equation	$2\ b_{cr}$ (Critical Flaw Size), in.
SA155	500	b_{cr}	9.5

Flow stress data were not available for SA155 piping. The strength of this material is higher than the strength of SA106B steel. Consequently its flow stress must be greater than the flow stress of SA106B steel. To calculate b_{cr}, the flow stress value used was based on the ratio of ultimate tensile strength of SA106B material to SA155 material.

14B.5.1.6.4.4 *Circumferential Through-Wall Crack.* It is shown (Reference 13) that the critical length of a circumferential through-wall crack is greater than the critical length of an axial crack.

14B.5.1.6.4.5 *Flaw Growth.* Under the influence of cyclic loads, small defects can grow to critical size. It has been shown that an empirical expression accurately describes the flaw growth:

$$\frac{da}{dn} = C\ (\Delta K)^m$$

where $\frac{da}{dn}$ is the flaw growth rate, ΔK is the change in stress intensity factor per cycle; C and m are constants.

The following calculation (Reference 13) describes the growth of the code allowable internal and surface flaws into through-wall cracks. Since the size of these flaws is small, pipe curvature can be neglected and there is no difference between axial and circumferential flaws. Surface defects in Seismic Category I piping allowed by the code are defects with a maximum depth of 5% of the wall thickness (t). Therefore the maximum flaw depth will be 0.05t. The material constants have values of $C = 1.6 \times 10^{-4}\ in^{-1}$ and $m = 4$ (at 550°F). Note that the value of the exponent m is conservative. The exponent varies between 2 and 4 for different steels and, using its maximum value, the growth rate will be the fastest.

Integration of the previous equation gives the number of cycles:

$$n = \int_{a_i}^{a_f} \frac{da}{C(\Delta K)^4}$$

where $a_i = 0.05$ t is the initial flaw depth (the code allowable defect) and a_f is the final flaw depth. For a surface flaw, the integral becomes:

$$n = \frac{1}{C} \int_{a_i}^{a_f} \frac{da}{[1.12\sigma(\pi a)^{1/2}]^4}$$

If a_f = thickness, then n is the number of cycles to develop a through-wall crack. When the equation for n is applied to SA155 pipe, $a_i = 0.05 \text{ x } 1 = 0.05$ in. and $a_f = 1$ in. σ = yield stress at 550°F (the flaw growth will be faster at higher temperatures).

$$n = 4.13 \times 10^9 \times \frac{1}{(27.7)^4} \left(\frac{1}{0.05} - 1\right) = 132,000 \text{ cycles}$$

The additional growth of this defect to reach critical size is not important because the pipe will leak and the leak will be repaired.

It has been shown that the growth of an internal flaw is even slower than in the above case (Reference 13). The number of cycles during the lifetime of a nuclear power plant can be obtained taking into account daily and weekly power reductions, start-ups, shutdowns, and other changes in pressure. An estimate (Reference 13) gives the number of cycles at about 13,000, which is much smaller than the value for the formation of a through-wall crack. For subsequent license renewal, the allowable number of cycles has been determined to be 70,390 based on the application of the updated stress intensity factor solutions from API-579 and fatigue crack growth from ASME Section XI.

14B.5.1.7 **Modifications**

The following modifications to the initial plant design were made to further ensure safe-shutdown reliability and the operation of plant protective features:

1. The pump discharge piping of the auxiliary feedwater systems in Units 1 and 2 were cross connected so that the unaffected system will have the capability of maintaining both units in a shutdown condition. Furthermore, an additional source of makeup water for the auxiliary feedwater systems was installed. An in-ground 100,000-gallon emergency condensate makeup tank and two booster pumps can supply the suction of the unaffected auxiliary feedwater pumps. These modifications were designed and installed in accordance with ANSI B31.1-1967, Seismic Category I criteria, and are also tornado-protected. These modifications are shown in Figure 14B-20.

   As described in Section 14B.6 one auxiliary feedwater pump is required to remove stored and residual heat. Therefore, no redundancy requirements were lost for either unit since each unit is equipped with two motor driven auxiliary feedwater pumps (350 gpm nominal flow rating) and one turbine driven auxiliary feedwater pump (700 gpm nominal flow rate).

   Since, with the modifications, the unaffected auxiliary feedwater system can be required to supply both units, the residual heat removal capacity from the original 110,000-gallon emergency condensate storage tank is halved. Another reliable source of water is the fire protection system main, which has the capability of supplying 500,000 gallon of water to the suction side of the unaffected auxiliary feedwater pumps. In addition, the 300,000-gallon condensate storage tank used for normal condensate makeup can be used to supply the 110,000-gallon emergency condensate storage tank utilizing gravity flow. The 100,000-gallon emergency condensate makeup tank was added to enhance the reliability of the modified system.

2. The turbine drivers for the containment spray pumps were disconnected from their steam supply lines and the three-inch lines were removed from the containment spray pump room. These modifications eliminated the containment spray pumps as a target.

   Since the turbines were used only as redundant pump drivers for the two full-size containment spray pumps, the pumps with their motor drivers still maintain the redundancy requirements of the containment spray system.

3. In response to an Atomic Energy Commission (AEC) inquiry concerning the ability to shut down the reactor following the postulated loss of the main steam valve house (MSVH), Virginia Power committed to a SI system modification (Reference 16). The AEC's inquiry was made during the original review of FSAR Appendix D (currently Figure 14B). The modification installed a SI system piping cross-connect between the Unit #1 and Unit #2 RWSTs and associated valves and controls (refer to Section 6.2.2.1.4). The modification ensures a supply of RWST water to each unit's SI charging pumps in the event the normal supply line is rendered inoperable due to the postulated loss of the associated main steam valve house. It should be noted that charging pump suction piping from the RWST was not identified as a potential target for a high energy line break (HELB) in the MSVH.

14B.5.2 Feedwater

14B.5.2.1 **Break Locations**

Break locations were postulated in the feedwater lines from the containment to the feedwater pumps in the turbine room in accordance with Section 14B.2.2. For the feedwater lines, 0.8 of the allowable thermal stress was 18,000 psi. For each line considered, none of the calculated thermal stresses exceeded 0.8 of their allowables. Piping upstream of the containment was not analyzed seismically, so that intermediate points were selected on the basis of maximum thermal stress. For piping from the containment to the turbine building, two intermediate locations were selected. Breaks were assumed for piping in the turbine building; however, because of physical separation, no detailed analysis was required. At all break points, both circumferential and longitudinal breaks were considered.

The break points are listed in Table 14B-8 along with thermal stress levels, as calculated. The break locations are shown in Figure 14B-10.

Cracks were selected at all locations in the vicinity of targets.

The environmental impact on the adjacent EQ rooms resulting from the worst case turbine building high energy line break (HELB) have been determined. The temperatures in these rooms were calculated as a function of EQ barrier breach size. These rooms include the control room envelope, MER-5, and the emergency diesel generator rooms. The size of these breaches into the above rooms is limited based on the average internal room temperature of 120°F (see Section 7.7.1).

14B.5.2.2 **Separation**

The same degree of separation provided between targets and a postulated steam-line break is found for the postulated feedwater line break.

14B.5.2.3 **Pipe Whip and Fluid Jet Effects**

The effects of pipe whip and fluid jets from a postulated feedwater line break are similar but less severe than a main steam line break.

Table 14B-9 contains the results of the evaluation for maintaining the feedwater system functional. All the assumptions required for the main steam system as described in Section 14B.5.1.3 also apply to the feedwater system.

14B.5.2.4 **Pressure and Environment**

The main steam valve house will withstand the pressure buildup from a postulated feedwater line break, which is less than the steam-line break pressure buildup. Environmental effects are similar to the main steam line break but less severe.

14B.5.2.5 **Inspection Program for Larger Lines**

An extensive nondestructive testing program was initiated for the main feedwater postulated break points in the main steam valve house. These points, a total of eight for each unit, are shown in Figure 14B-10.

14B.5.3 Other High-Energy Lines That Maintain Maximum Operating Temperatures Greater Than 200°F and Maximum Operating Pressures Greater Than 275 psig

14B.5.3.1 **Break Locations**

Figures 14B-11, 14B-12, and 14B-13 show the break locations that were postulated for circumferential and longitudinal breaks. Postulated break locations were selected in accordance with the criteria specified in Section 14B.2.2. Tables 14B-10 and 14B-11 list the stresses in the piping systems at the postulated break locations. Designated numbers for these high-energy lines are:

1. Steam Generator Blowdown

Unit 1	Unit 2
3"-WGCB-1-601	3"-WGCB-101-601
3"-WGCB-2-601	3"-WGCB-102-601
3"-WGCB-3-601	3"-WGCB-103-601

2. Letdown from Regenerative Heat Exchanger

Unit 1	Unit 2
2"-CH-6-602	2"-CH-306-602

Cracks were postulated throughout the length of the lines for any adverse effects on targets. For computation of crack size, the diameter and wall thickness of these pipes are given in Table 14B-2.

14B.5.3.2 **Pipe Whip and Fluid Jet Effects**

The letdown line and the steam generator blowdown lines will be permitted to whip in the event of a postulated circumferential break. It has been determined by an extensive drawing review, onsite inspection, and pipe break analysis sheets that no additional restraints are required in order to meet the criteria for pipe breaks. An example of the pipe break analysis sheets for these lines is given in Table 14B-12. Target protection is maintained in the following manner:

1. By means of physical separation, including distance, building support columns, concrete walls, and larger sized pipes, and/or
2. By means of the many redundant features originally designed into the existing systems.

In all cases, the postulated pipe break will not jeopardize a safe plant shutdown.

14B.5.3.3 **Pressure and Environment**

For the high energy line break analysis, the flow from the broken letdown line was 60 gpm with an operating temperature of 287°F and a pressure of 289 psig; therefore only local effects were considered. Although the actual letdown flow and pressure may be higher than these values, the conclusions of the analysis remain bounding.

The limiting case for pressure buildup and auxiliary building environmental conditions is the break of a 3-inch steam generator blowdown line. The maximum flow rate through this line is 140 lb/sec at a maximum operating temperature of 515°F and pressure of 775 psig. Calculations were made considering the area in which the blowdown lines are located as the worst case. This area is shown in Figure 14B-11 and extends to the charging pump cubicle walls as shown in Figure 14B-12. Because of the large volume and the large vent areas, there will be negligible pressure buildup within this volume, but the temperature in this area can essentially reach 212°F if blowdown is not stopped. Therefore, temperature sensors are provided in various areas of the Auxiliary Building to provide individual temperature indication and an alarm in the main control room to alert the operators to a potential problem.

An excess flow-measuring device mitigates the consequences of a steam generator blowdown line break outside the containment. This device is located upstream of the inside containment isolation valve. If blowdown line flow exceeds a predetermined value, a signal will close the inside containment isolation valve for that blowdown line. Automatic isolation of the steam generator blowdown lines is accomplished within 30 seconds in the event of a piping break. Also, manual isolation associated with other breaks or cracks must be made within 15 minutes to meet the environmental qualification requirements of certain Class 1E components in the Auxiliary Building.

Also, excess flow is annunciated in the control room. Indication of isolation valve closure presently exists in the control room.

Detection and subsequent isolation of the affected line will inhibit the increase of temperature and humidity of the environment in the areas adjacent to postulated cracks or breaks.

14B.5.4 High-Energy Lines That Maintain a Maximum Operating Temperature of Greater Than 200°F or a Maximum Operating Pressure of Greater Than 275 psig

14B.5.4.1 Break Locations

Figures 14B-11 through 14B-15 show the locations of the high-energy lines in question. In addition, Table 14B-2 gives the maximum operating conditions of each of the lines shown. Cracks were postulated throughout the entire length of each line shown, and evaluated for any adverse effects on targets. The diameter and thickness of these pipes are given in Table 14B-2 for computation of crack size.

14B.5.4.2 Separation

Source lines not located within the confines of the areas shown in Figures 14B-10 through 14B-15 have no adverse effects on targets because of the physical separation provided by the building arrangement. For this reason, high-energy lines outside these areas were not considered as sources.

14B.5.4.3 Local Environmental Effects and Jet Impingement

In many cases, shutdown and other protective features are far enough removed from the lines in question that local effects of a postulated crack will have no effect on even the redundant features.

In other cases, target protection is maintained with the many redundant features designed into the present systems and the separation of these by means of distance, walls, and location. An example of one of the pipe break/mini-crack analysis sheets is shown in Table 14B-13.

Except for minor modifications, as discussed in Section 14B.5.4.4, the plant will always maintain shutdown capability, and at least one each of the redundant protective features will remain operable following a crack in these high-energy lines.

14B.5.4.4 Modifications

In order to ensure a safe cold shutdown, the following modifications to the initial plant design were made:

1. The charging pump cooling water pumps are shielded from direct impingement, in accordance with Figure 14B-21.
2. One of the four component cooling pump cables is rerouted (shown in Figure 14B-14), so that two of the pumps are always available (only one is required for hot standby).

14B.6 TRANSIENT ANALYSIS OF A HIGH-ENERGY LINE BREAK IN THE MAIN STEAM VALVE HOUSE

A break in a main steam or main feedwater (MFW) pipe in the main steam valve house (MSVH) could be postulated to disable the auxiliary feedwater (AFW) pumps, resulting in a loss of all feedwater on the accident unit. The main feedwater line break (MFLB) is shown to be more severe than the steam line break with respect to core cooling and steam generator inventory reduction. The MFLB in the MSVH is assumed to disable all main and auxiliary feedwater to one of the units. The only source of AFW is from the opposite unit via the AFW cross-connect. This is a limiting assumption that requires operator action within a specified time. Emergency procedures direct the operators to perform mitigating actions for this event. A further limiting assumption is that only a single motor-driven AFW pump (most degraded) is available from the other unit.

This transient is characterized by a rise in the reactor coolant system (RCS) temperature and pressure and the pressurizer water volume due to a reduction in the capability of the secondary system to remove the heat generated in the reactor core and by the reactor coolant pumps (RCPs). AFW delivery via the cross-connect becomes the critical factor for maintaining a secondary heat sink and preventing core damage. The key safety analysis parameters for this transient are the core decay heat, time of AFW cross-connect flow delivery to the accident unit’s steam generators, AFW flow rate and enthalpy, and time of RCP trip.

14B.6.1 Method of Analysis

The high-energy line break event is evaluated by modeling a loss of all MFW and AFW to the affected unit and the initiation of AFW via the cross-connect by operator action as directed by the station emergency procedures. The event was explicitly analyzed at hot full power deterministic conditions. The transient analysis code RETRAN (Reference 17) was used to simulate the reactor coolant system, core kinetics, and the feedwater and steam systems. The 1979 ANS decay heat standard with a two-sigma uncertainty was used to calculate post-trip reactor core heat based on long-term operation at the initial power level preceding the trip. An assumed AFW cross-connect flow rate was selected to be conservatively bounded by the design flow rate from the most degraded AFW pump. AFW enthalpy was based on the highest allowable design temperature in the emergency condensate storage tank.

Two cases were analyzed to demonstrate the plant behavior for a loss of all feedwater event. One case provided the limiting results with respect to the fuel integrity and steam generator dryout (i.e., minimum secondary side liquid inventory) criteria. The other case provided the limiting results for the primary and secondary system overpressure criteria. Reactor trip on a low-low water level in any steam generator provides the necessary protection. Simulator verification runs were performed to provide assurance that the operators can satisfy the analysis assumptions to cross-connect AFW from the unaffected unit and trip the RCPs to maintain the secondary heat sink and to ensure a safe plant shutdown. The analyses demonstrate that the event acceptance criteria are met.

14B.6.2 Results and Conclusions

The loss of all feedwater due to a high-energy line break in the MSVH was analyzed to demonstrate a long-term increase in steam generator inventory after AFW was provided and the secondary system heat removal rate exceeded the heat production by the reactor coolant system. The effects of a high-energy line break in the MSVH are mitigated by operator action in accordance with the emergency procedures. The accident analysis meets all event acceptance criteria (no RCS bulk boiling, no steam generator dryout, peak RCS and main steam system pressures less than the limits).

14B.7 CONCLUSIONS

Surry Units 1 and 2 are designed with highly reliable and redundant systems for the purpose of safe shutdown, considering normal and accident conditions. Furthermore, with the modifications described in the text of this appendix, safe plant shutdown is ensured for all postulated failures of high-energy piping outside of the containment.

The control room, which serves Units 1 and 2, will remain habitable and functional following a failure of any high-energy line.

The emergency diesel generators, which are required to satisfy loss-of-offsite-power criteria, will maintain integrity throughout a postulated high-energy piping failure incident.

MOCB-102	26	CB	7.1		Column TH-9' prevents the pipe from whipping in the eastward direction. For movement in other directions the hinge length of 77.4 in. was used to determine "target" damage. There were no "targets" within this distance. The normal charging line 3"-CH-379-1503 and the normal seal injection line for the reactor coolant pumps 3"-CH-313-1503 will not be damaged because of the criteria for whipping pipes. Line 2"-CH-390-1503 is only an alternate seal injection line to the reactor coolant pumps, and is therefore not required.	MOV-2289A MOV-2289B	10 13			Possible damage from direct impingement. These are redundant isolation valves which are normally open and will fail open. Furthermore this line can be isolated at the charging pumps, if necessary. The line which includes these valves is the normal charging path for chemical and volume control. An alternate path is 2"-CH-308-1503 (located at drawing coordinate E-2), could be used to shut the unit down in a normal manner. Therefore, there are no adverse effects on safe shutdown and no analysis on the effects of the two valves is required.	Plant must be shut down and repairs made.
						MOV-2370 MOV-2867C MOV-2867D	8 15 18			Valves are protected from jet impingement by column TH-9', distance, and location. Failure by fluid jets is therefore not credible. The power cables to these motor operated valves could be severed. MOV-2370 is an isolation valve for isolation of normal seal water injection to the reactor coolant pump seals. This valve will fail as is (open). Valve operation is not required for safe shutdown. MOV-2867C & D are redundant isolation valves which require operation only in the event of a loss-of-coolant accident (13A) or a major main steam line rupture. Therefore, there are no adverse effects on safe plant shutdown.	Plant must be shut down and repairs made.

15.2 STRUCTURAL DESIGN CRITERIA

15.2.1 General

The structures, systems, and components of the Surry Power Station, Units No. 1 and No. 2, are classified into groupings requiring seismic, tornado or conventional design. The effects of the Power Uprating to a core power of 2546 MWt on pipe stress and supports were reviewed for the systems listed below. The review determined that the existing piping and support configuration is adequate to withstand the increase in pressure and temperature associated with the Power Uprating.

Systems: Main Steam

Condensate

Extraction System

H. P. Heater Drain

L. P. Heater Drains

Reactor Coolant

Class I design encompasses those structures, systems or components of reactor facilities that are essential to the prevention of accidents that could affect the public health and safety, or to the mitigation of their consequences.

Structures, systems, and components are designed, fabricated, and constructed to performance standards that will enable the facility to withstand, without loss of capability to protect the public, the additional forces that might be imposed by:

1. The operating-basis earthquake and the design-basis earthquake.
2. Tornados and other local site effects including flooding conditions, winds, and ice. Radiation levels that constitute a hazard to the public are defined in 10 CFR 50.67.

A Class I structure is designed for resistance to seismic loadings in accordance with Section 15.2.4 and for tornados, where applicable, in accordance with Section 15.2.3. There are some structures, systems, or components whose loss or failure by earthquake will not affect the public health or safety and will permit safe station shutdown, although their loss could interrupt power generation. These structures, systems, or components are not designed for specific seismic or tornado loadings.

Structures not designed for seismic or tornado loadings are designed according to *Specification for the Design, Fabrication, and Erection of Structural Steel for Buildings* (AISC-1963), and *Building Code Requirements for Reinforced Concrete* (ACI 318-63, Part IVA - *Working Stress Design*).

These structures are designed for dead, live, and normal wind loads using allowable stress levels given in the above codes.

Some structures, systems and components of the station are necessary for a safe and orderly shutdown during a tornado. These structures are designed for tornado loadings, and systems and components are protected by tornado-resistant structures.

A list of the structures, systems, and components designed to satisfy seismic and/or tornado criteria is given in Table 15.2-1.

15.2.2 Normal Wind Loading

All structures were designed to withstand the following wind loads applied to the projected area of all surfaces:

Elevation 26 ft. 6 in. to Elevation 56 ft. 6 in., 30 lb/ft^2

Elevation 57 ft. 6 in. to Elevation 75 ft. 6 in., 35 lb/ft^2

Elevation 75 ft. 6 in. to Elevation 130 ft. 0 in., 45 lb/ft^2

Elevation 131 ft. 0 in. and above, 55 lb/ft^2

Roofs were designed for uplift using 1.25 times the wind load taken at the corresponding elevation of the roof.

Members subject to stresses produced by this wind load combined with live and dead loads were proportioned for stresses 33-1/3% greater than conventional working stresses, provided that the section thus required is not less than that required for the combination of dead and live loads computed without the one-third increase.

15.2.3 Tornado Criteria

Section 2.2 outlines the probability of a tornado occurring at the site. Although no structural damage is known to have resulted to a reinforced concrete building in a tornado (Reference 1), the structures and systems so indicated in Table 15.2-1 are designed to ensure safe shutdown of the reactor when subjected to tornado loadings. The Seismic Class I and Tornado Criterion “T” structures discussed in Sections Section 15.2.3 and Section 15.2.4, respectively, are primarily of reinforced-concrete construction. The principal components that transmit horizontal and vertical loads to the foundation are the reinforced-concrete roof and floor slabs, and both interior and exterior reinforced-concrete walls. Since these components act as diaphragms, tending to minimize stress concentrations that might otherwise occur (in a column, for example), and their thicknesses are usually controlled by requirements for biological shielding or tornado and interior missile protection, stresses and strains are generally not significant. For these reasons, calculated stresses and strains for selected principal structural components have been omitted from this report. In addition, test data and analytical studies, in accordance with Appendix C of

Reference 13, have confirmed that 2-foot thick, reinforced-concrete test specimens, with similar spans and steel reinforcement as those found in SPS Tornado Criterion “T” structures (Table Table 15.2-1), will not experience a ductility ratio, μ, in excess of applicable industry code allowable limits (i.e., $\mu \leq 10$), when subjected to tornado load effects, as described in SPS UFSAR, Section 15.2.3.

The tornado model used for design has the following characteristics:

Rotational velocity	300 mph
Translation velocity	60 mph
Pressure drop	3 psi in 3 sec
Overall diameter	1200 ft
Radius of maximum winds	200 ft

Applicable structures are designed to resist a maximum wind velocity associated with a tornado of 360 mph, which is obtained by adding the rotational and translational velocities. Structures and systems are checked for tornado pressure loading, vacuum loading, and the combination of these two.

The tornado wind velocity is converted to an equivalent pressure, which is applied to the structures uniformly using the formula:

$$P = 0.00256\ V^2$$

where:

P = equivalent pressure, lb/ft^2

V = wind velocity, mph

This pressure is multiplied by applicable shape factors and drag coefficients as given in ASCE Paper No. 3269 by Thomas W. Singell (Reference 2), and applied to the silhouette of the structure.

A reduction of the full negative pressure differential is made when venting of the structures is provided. The amount of the reduction is a function of the venting area provided.

Tornado wind loads are combined with other loads as described in Section 15.5.1.2. Tornado and earthquake loads are not considered to act simultaneously. A uniform wind velocity and a nonuniform atmospheric pressure gradient is incorporated in the design of the containment structure.

Structural design criteria for tornado loading for the containment structure are given in Table 15.5-1 and Section 15.5.1.5.

It is assumed that a tornado could generate either of the following potential missiles:

1. Missile equivalent to a wooden utility pole 40 feet long, 12-inch diameter, weighing 50 lb/ft^3 and traveling in a vertical or horizontal direction at 150 mph.
2. Missile equivalent to a 1-ton automobile traveling at 150 mph.

The design assumes maximum wind forces and partial vacuum to occur simultaneously with the impact of either of the missiles singly. Allowable stresses do not exceed 90% of the certified minimum yield strength of the steel, the capacity reduction factor given in Section 15.5.1.2 times the certified minimum yield strength of the reinforcing steel, and 75% of the ultimate strength of the concrete. The allowable stress limits of 0.9 Fy (steel superstructures) and 0.9 fy and 0.75 f'c (reinforced concrete structures) apply to stresses from the overall structural response due to tornado load effects. These stresses are located away from the tornado missile impact zone and outside any yield-line patterns that may develop during the tornado missile impact.

It is noted that the physical configuration of certain plant components does not provide complete physical protection against tornado-generated missiles. The vulnerable surface area for each component was assessed probabilistically using the Tornado Missile Risk Evaluator Methodology (Reference 12) and it was determined that the risk to the plant is acceptably low, such that the additional missile protection need not be provided. Refer to Table 15.2-1 for identification of these components.

The U.S. NRC approval of the LAR 21-330 (References 14 & 15) demonstrates that the Surry Power Station (SPS) Turbine Building (TB) is a tornado-resistant structure, evaluated under a different methodology and acceptance criteria than other Tornado Criterion "T" structures at SPS, and is therefore classified as a Tornado Criterion "T+" structure in Table 15.2-1. The following bullet items distinguish the tornado evaluation methodology and acceptance criteria of the Tornado Criterion "T+" SPS TB structure, from other Tornado Criterion "T" structures at SPS.

- A nonlinear, static, finite element analysis methodology and associated acceptance criteria demonstrates that the TB is a tornado-resistant structure, which provides protection for safe shutdown and non-isolable water source components located in the basement of the TB during a tornado. Material properties are based on a true-stress, true-strain curve for carbon steel, which was developed based on the method provided in Section VIII, Division 2 of the ASME Boiler and Pressure Vessel Code and using the design basis ASTM A36 material strength and properties. Column stability is based on a 1% maximum drift ratio from ASCE 7-10. The evaluation demonstrates that partial building collapse of the TB, consisting of the failure of the steel roof trusses, is expected during a tornado. The operating and mezzanine decks will remain stable and the TB overhead cranes, their supporting crane rails and steel columns, will not fall during a tornado. The stable operating and mezzanine decks of the TB will provide tornado protection for safe shutdown and non-isolable water source components located below in the basement of the TB. Additionally, partial building collapse of the TB structure during a tornado will not damage any adjacent Tornado Criterion 'T' structure and protected components housed within.

- The maximum tornado wind speed for the TB is established as 250-mph, which is the sum of a 208-mph rotational component and a 42-mph translational component.
- Only local effects of tornado missiles (i.e., penetration) need to be considered for the design of the TB and the 2-foot thick, reinforced concrete slabs at the mezzanine deck elevation, which provide physical tornado missile protection for safe shutdown components located directly below.
- For other safe shutdown and non-isolable water source components located in the basement of the TB, where physical tornado missile protection cannot be provided, adequate tornado missile protection is demonstrated via the Tornado Missile Risk Evaluator (TMRE) methodology and designated by the Tornado Criterion *"P""* protection classification in SPS UFSAR, Table 15.2-1.
- Partial differential pressures will not develop during a tornado in a vented structure such as the TB.
- In accordance with ACI 318-71, the allowable compressive stress limit for the reinforced concrete portions of the SPS TB structure shall not exceed $0.85f'_c$. This concrete compressive stress limit applies to the overall (i.e., global) structural response due to the tornado wind effects.

15.2.4 Seismic Design

Class I structures, systems, and components designed to resist seismic forces are listed in Table 15.2-1. The design is based on two separate seismic criteria: the operating-basis earthquake (OBE) and the design-basis earthquake (DBE), as described in Section 2.5.

The seismic analysis of Class I structures, such as the containment structure, auxiliary building, fuel building, service building (including the control room), and safeguard areas, was based on the modal analysis response spectra technique. Major equipment-supporting structures, such as steam generator supports, reactor coolant pump supports, and pressurizer supports, were treated in an identical manner. Acceleration response spectra for the OBE and DBE are given on Figures 2.5-5 and 2.5-6.

Seismic loading includes the horizontal or vertical responses acceleration or combinations of both where the effects, as measured by the separate acceleration components, of horizontal and vertical accelerations are combined to produce maximum stress intensities, taking into account any potential adverse effect due to phase of the separate accelerations.

Damping factors for the structures, systems, and components are given in Table 15.2-2.

The design of the containment structures is based on ultimate strength design and loading factors as described in Section 15.5.1.2. Maximum allowable stress levels for both the operating-basis earthquake and the design-basis earthquake are based on proportions of the minimum yield strength.

For other Class I structures, the operating-basis earthquake loading is combined with dead, live, and other static loads. Normal wind or tornado loadings are not assumed to occur simultaneously with the earthquake loading. Members are proportioned for stresses 33-1/3% greater than conventional working stresses, provided that the section thus required is not less than that required for the combination of dead and live loads computed without the one-third increase. Allowable soil-bearing values are increased one-third.

For Class I structures other than the containment structure, the design basis earthquake is combined with static loads using loading combinations given in Table 15.5-1. For these structures under the design-basis earthquake loading, the allowable stresses do not exceed 90% of the certified minimum yield strength for structural steel, the capacity reduction factor, given in Section 15.5.1.2, times the certified minimum yield strength for reinforcing steel, and the capacity reduction factor times the specified strength for concrete. Allowable soil bearing values are increased by one-half.

To allow for unimpeded relative motions between structures, a rattlespace is provided between the:

1. Containment structures and the auxiliary building.
2. Containment structures and the fuel building.
3. Containment structures and the containment auxiliary structures around the periphery of each containment.
4. Fuel building and auxiliary building.
5. Auxiliary building and control area.

In general, the periphery of the rattlespace between buildings is arranged to prevent material entering the space, with the inner areas left as a void.

Maximum relative motions between adjoining structures are included in the stress analyses of all piping that extends from one building to another.

Type “A” sand, as described in Section 2.4.3.3, was removed from under the fuel building, auxiliary building, and control area and replaced by a dense graded granular fill material as described in Section 2.4.5.1.

The analytical procedure used for the nuclear steam supply system is described by Section 15A.3 of Appendix 15A.

The reactor protection system, engineered safety feature (ESF) circuits, and the emergency power system are designed so that they will not lose the capability to shut the plant down and maintain it in a safe shutdown condition under operating-basis earthquake or design-basis earthquake conditions. For the design-basis earthquake, permanent deformation of the equipment is allowable, provided that the capability to perform its function is maintained.

Typical protection system equipment is subjected to type tests under simulated seismic accelerations to demonstrate its ability to perform its functions. Type testing was performed using conservatively large accelerations and applicable frequencies. Analyses were done for structures that were not done for the reactor protection system equipment. However, the peak accelerations and frequencies were checked against those derived by structural analyses of operational and design-basis earthquake loadings.

A Westinghouse topical report, WCAP-7397-L, provides the seismic evaluation of safety-related equipment. The type tests covered by this report are applicable to the Surry Power Station, with the exception of the process control equipment, which is covered in a supplement to WCAP-7397-L.

The emergency switchgear has been tested under seismic conditions, and manufacturers' test data are available. The emergency generator and control panels are identical with those used in locomotives, and have been tested under severe conditions, but no seismic tests have been made.

The control board was designed to withstand earthquake conditions, and an analysis was performed to verify the adequacy of the seismic design, but tests were not performed.

The emergency batteries are supported on rigid reinforced concrete pedestals firmly anchored to the floor. Steel retaining members integral with the pedestals prevent the batteries from being dislodged under seismic excitation.

15.2.5 Hydrostatic Loadings

Finish ground grade at the station is at Elevation 26 ft. 6 in. Natural ground water level is at approximately Elevation 4 ft. 0 in.

The exterior wall of the containment structure extends approximately 66 feet below the finished ground level. Water-resistant membrane protection for this structure is defined in Sections 15.5.1.9 and 15.5.1.10. External pumps for reducing the hydrostatic head on the containment structure are described in Section 15.5.1.3. This latter section also discusses the effect of the buoyant pressure on the containment structure.

Exterior surfaces of walls of other Class I structures with floor levels below Elevation 26 ft. 6 in. are covered with a mopped-on bitumastic coating to establish a water-resistant membrane.

The roofs of safety-related structures and select nonsafety-related structures with the potential to impact structures, systems, or components important to safety are evaluated to withstand hydrostatic surcharge loading associated with a Beyond Design Basis (BDB) Local Intense Precipitation (LIP) rainfall event. Roof parapets of the Turbine Building, Service Building, and Condensate Polishing Building feature cutouts to passively limit the hydrostatic surcharge loading induced by the postulated BDB event.

Building penetrations susceptible to flooding from a BDB LIP rainfall event are equipped with flood seals in locations which protect structures, systems, or components important to safety.

Item	Earthquake Criterion	Tornado Criterion	Sponsor[a]	Note

Legend

W - Westinghouse Electric Corporation.

SW - Stone & Webster Engineering Corporation.

I - Refers to Seismic Class I criteria. All Class I components and structures are designed to resist the operating-basis earthquake within allowable working stresses. A check has been made to determine that failure to function will not occur with a design-basis earthquake.

T - Refers to structures that will not fail during the design tornado.

T+ - Refers to the main structural steel members and reinforced concrete slabs of the operating and mezzanine decks of the Turbine Building structure, which will remain stable and not collapse during a tornado with a 250-mph maximum wind speed.

P - Refers to systems and components that will not fail during the design tornado since they are protected by tornado resistant structures or by being buried underground.

P* - Refers to systems and components that are not provided with complete physical protection from tornado-generated missiles, but have been evaluated using the Tornado Missile Risk Evaluator Methodology (Reference 12) and it has determined that the risk to the plant associated with the partially exposed SSC is sufficiently low such that complete physical protection from tornado-generated missiles need not be provided.

NA - Not applicable.

STRUCTURES, SYSTEMS, AND COMPONENTS DESIGNED FOR SEISMIC AND TORNADO CRITERIA

(Refer to the equipment classification list (Q-list) for a more comprehensive list of components. See Note 1.)

Item	Earthquake Criterion	Tornado Criterion	Sponsor[a]	Note

NOTES:

1. CAUTION, this table shall only be used for the classification of structures. Refer to the PAMS database for the classification of systems and components. A list of structures, systems, and components, like those in Table 15.2-1, was provided as part of the licensing application to permit a determination to be made as to the general suitability of the classification given and the design approach applied. Since the time of original plant licensing, an equipment classification listing (Q- List), was developed and subsequently replaced with a database (PAMS) to provide a more comprehensive and up-to-date list of individual components and their classifications than does this table, which only provides a general list of systems and components. According to the SPS current licensing basis, structures required to withstand the effects of a design basis tornado (Tornado Criterion "T") are also required to be designed to Seismic Category I requirements (Seismic Criterion "I"). Hence, all structures classified as "T" must also be classified as "I", but not necessarily vice versa. The Q-List and PAMS database only provide an input field for the more encompassing Seismic Category I classification for structures and do not provide a separate input field to identify those Seismic Criterion "I" structures that must also meet the Tornado Criterion "T" classification. Hence, SPS UFSAR, Table 15.2-1, was updated to be consistent with the SPS current licensing basis to reflect both the Seismic Criterion "I" and Tornado Criterion "T" classifications for structures at SPS in response to US NRC RIS 2015-06. For the classifications of systems and components at SPS, designed to be functional under Seismic Class I, Seismic Criterion "I", refer to the PAMS database.
2. The information in the sponsor column designates the division of responsibility between Westinghouse and Stone & Webster for the original design of listed structures, systems, and components. These designations are considered HISTORICAL and are not intended or expected to be updated for the life of the plant.
3. The extent of the "building collapse" in the Turbine Building, under a 250-mph maximum tornado wind speed, consists of the failure of the steel roof trusses. The overhead cranes and their supporting steel columns will remain in place, The operating deck and mezzanine decks will remain stable to provide tornado protection for safe shutdown and non-isolable water source components located below. Additionally, no damage will occur to any adjacent Criterion "T" structure or the protected components housed within (e.g., Service Building - Control House).

Table 15.2-2
DAMPING FACTORS FOR CLASS I STRUCTURES

Component	Percent of Critical Damping
1. Reactor vessel internals and control rod assembly drives	
a. Welded assemblies	1.0
b. Bolted assemblies	2.0
c. Control rod assembly drives	5.0[a]
2. Reinforced concrete reactor support structure, including the reactor vessel	5.0
3. Vital piping systems	
a. Carbon steel	0.5 OBE, 1.0 DBE[b]
b. Stainless steel	0.5 OBE, 1.0 DBE[b]
4. Containment structure and foundation	5.0
5. Steel framed structures, including supporting structures and foundations	
a. Bolted	2.5
b. Welded	1.0
6. Concrete structures aboveground	
a. Shear-wall type	5.0
b. Rigid-frame type	5.0
7. Mechanical equipment, including pumps, fans, and similar items	2.0

a. For Surry Unit 2 control rod assembly drives, the "Percent of Critical Damping" used is 5% as justified in Mitsubishi Heavy Industries Design Report, Reference 11.

b. In accordance with reference 4, the damping values of ASME Code Case N-411 (reference 5) have been approved for use at Surry as an alternate, for both the operating-basis earthquake and the design-basis earthquake.

The values specifically are: five percent below frequency of 10Hz; linear reduction from five percent to two percent between 10Hz and 20Hz and two percent above 20Hz. These damping values are used in the following situations and with the following additional considerations:

a. For seismic analyses in cases where new piping is added, existing systems are modified, existing systems are re-evaluated for support optimization.

b. For seismic analyses using response spectrum methods and not for seismic analyses using time-history analyses methods.

c. When these damping values are used, the ±15% peak broadening criteria of Regulatory Guide 1.122, *Development of Floor Design Response Spectra for Seismic Design of Floor Supported Equipment or Components*, will be used.

d. When these alternate damping values are used, they are used in a given analyses in their entirety.

Table 15.2-2 (CONTINUED)
DAMPING FACTORS FOR CLASS I STRUCTURES

Component	Percent of Critical Damping
e. When these damping values are used together with changes in the support arrangement that increases the flexibility of piping systems, the predicted maximum displacements are reviewed to ensure that such displacements do not cause adverse interaction with adjacent structures, components or equipments.	

15.3 MATERIAL

15.3.1 Concrete

See Section 15.5.2.4 for the description of the concrete used for the Reactor Pressure Vessel Head Replacement Project.

15.3.1.1 Cement

All cement used was an approved American brand conforming to the specification for Portland cement, ASTM Designation C150, Type II, low alkali. It is suitable for Class I structures because of its lower heat of hydration and improved resistance to sulphate attack. A low-content alkali was specified to minimize the possibility of reaction with aggregates. Certified copies of mill tests, showing that the cement meets or exceeds the ASTM requirements for Portland cement, were furnished by the manufacturer. An independent testing laboratory performed tests on the cement for compliance with the specifications.

15.3.1.2 Admixtures

An air-entraining agent was used in the concrete in an amount sufficient to entrain from 3 to 5% air by volume of the concrete. This agent conformed to the requirements of Standard Specification for Air-Entraining Admixtures for Concrete, ASTM C260, when tested in accordance with Standard Method of Testing Air-Entraining Admixtures for Concrete, ASTM C233.

The air-entraining agent was added separately to the batch in solution in a portion of the mixing water. The solution was batched by means of a mechanical dispenser capable of accurate measurement, and in a manner that ensured uniform distribution of the agent throughout the batch during the specified mixing period.

Water-reducing agents were used when their use was approved in writing. Water-reducing agents were Master Builders NB-100, type R or N, manufactured by Master Builders of Cleveland, Ohio. Type N is normal NB-100 and is used when a normal rate of hardening is required. Type R contains a retarder and is used in warm weather to reduce the rate of hardening and to avoid cold joints.

Calcium chloride was not used under any circumstances.

15.3.1.3 Water

Mixing water was obtained from a deep well and was kept clean and free from injurious amounts of oils, acids, alkalies, salts, organic materials, or other substances deleterious to concrete or steel. The quality of the water was the equivalent of that suitable for drinking. The water was continuously checked and tested for compliance with the above requirements by an independent testing laboratory.

15.3.1.4 **Aggregates**

Fine and coarse aggregates conformed to the requirements of the Standard Specifications for Concrete Aggregates ASTM C33. Aggregates were evaluated for potential chemical alkali reactivity. Aggregates were free from any materials that could have been deleteriously reactive in any amount sufficient to have caused excessive expansion of mortar or concrete. All aggregates were tested for compliance with the above requirements by an independent testing laboratory.

15.3.1.5 **Proportioning**

Proportioning of structural concrete conformed to ACI 301, Chapter 3. Working-stress-type concrete and ultimate-strength-type concrete conformed to the requirements of ACI 301, Paragraph 302. Ultimate-strength-type concrete was used in the construction of the foundation mat, exterior wall, and dome of the reactor containment. In general, working-stress-type concrete was used for other areas. Concrete mixes had a 28-day specified strength of 3000 psi, except as otherwise noted on the engineering drawings.

Proportions of ingredients were determined and tests conducted by an independent laboratory in accordance with the method detailed in ACI 301, Paragraph 308, for combinations of materials established by trial mixes.

The maximum slump of mass concrete, as defined in ACI 301, Chapter 14, in general did not exceed 3 inches. Slump of other concrete conformed to ACI 301, Paragraph 305. The samples for the slump tests were taken at the end of the last conveyor, chute, or pipeline before the concrete was placed in the forms.

The close and complex spacing of reinforcing steel in the heavily reinforced sections surrounding the equipment and personnel hatches results in the use of concrete with a maximum slump of 5 inches. The results of strength tests indicate that the 5-inch slump concrete will have a minimum compressive strength of approximately 4000 psi at 28 days. This is considerably higher than the nominal stipulated value of 3000 psi at 28 days used for design purposes, and demonstrates that the structural strength of the containment would not be jeopardized by the use of concrete with a slump of 5 inches.

15.3.2 Reinforcing Steel

Except for the No. 14 and No. 18 reinforcing bars for the foundation mat, exterior wall, and dome of the containment structure, all reinforcing conforms to Grade 40 (or higher strength steel) of the Standard Specification for Deformed Billet-Steel Bars for Concrete Reinforcement ASTM A615.

For No. 14 and No. 18 reinforcing bars and splices for the foundation mat, exterior wall, and dome of the containment structure, see Section 15.5.1.9. See Section 15.5.2.3 for the description of the reinforcing steel used for the Reactor Pressure Vessel Head Replacement Project.

Mill Test Reports showing chemical and physical properties were obtained and evaluated for each heat of steel used in making all reinforcing steel furnished.

15.4 CONSTRUCTION PROCEDURES AND PRACTICES

See Section 15.5.2 for the description of the restoration of the construction opening used for the Reactor Vessel Head Replacement Project.

15.4.1 Codes of Practice

Materials and workmanship conformed to the following codes and specifications:

ACI 301-66	*Structural Concrete for Buildings* and all specifications of the American Society for Testing and Materials referred to in Section 105 and declared to be a part of ACI 301-66 as is fully set forth therein.
ACI 304	Recommended Practice for Measuring, Mixing, and Placing Concrete.
ACI 305	Recommended Practice for Hot Weather Concreting.
ACI 306	Recommended Practice for Cold Weather Concreting.
ACI 318-63	Building Code Requirements for Reinforced Concrete.
ACI 347	Recommended Practice for Concrete Formwork.

See Section 15.5.2.1 for the description of the codes and specifications used for the restoration of the construction opening used for the Reactor Pressure Vessel Head Project.

Section III of the ASME Boiler and Pressure Vessel Code for Nuclear Vessels was used as a guide in the selection of materials, design stresses, and fabrication of the steel containment liner.

ACI 301-66, *Specifications for Structural Concrete for Buildings,* together with ACI 347-63, *Recommended Practice for Concrete Formwork*, and ACI 318-63, *Building Code Requirements for Reinforced Concrete*, formed the basis for the concrete specifications.

ACI 301-66 was supplemented as necessary with mandatory requirements relating to types and strengths of concrete, including minimum concrete densities, proportioning of ingredients, reinforcing steel requirements, joint treatments, and testing agency requirements.

Admixtures, types of cement, bonding of joints, embedded items, concrete curing, additional test specimens, additional testing services, cement and reinforcing steel mill test report requirements, and additional concrete test requirements were specified in detail.

Concrete protection for reinforcement, preparation, and cleaning of construction joints, concrete mixing, delivering, placing, and curing, with the following exceptions, equaled or exceeded the requirements of ACI 301:

Section 1404 (a) - Maximum slump was generally restricted to 3 inches to permit placing concrete in the heavily reinforced containment structures. The slump was increased to 5 inches in the areas of the containment wall adjacent to the equipment and personnel hatches where the large steel inserts and additional reinforcing steel required a more plastic mix for adequate concrete placement. All concrete mixes were designed and tested before use. All concrete mixes used in the work were fully documented.

Section 1404 (b) - Maximum placing temperature of the concrete when deposited conformed to the requirements of ACI 305-59, *Recommended Practice for Hot Weather Concreting*.

Section 1404 (c) - Minimum placing temperature of the concrete when deposited conformed to the requirements of ACI 306-66, *Recommended Practice for Cold Weather Concreting*.

15.4.2 Concrete

Concrete ingredients were batched in a batch plant and transferred to transit mix trucks for mixing, agitating, and delivering to the point of placement. Water was added to the mix with the other ingredients before the truck left the batch plant area. Batching and mixing otherwise conformed to ACI 301, Chapter 7.

Placing of concrete was by bottom-dump buckets, concrete pumps, or by conveyor belt. Bottom-dump buckets did not exceed 4 yd^3 in size. The discharge of concrete was controlled so that concrete could be effectively compacted around embedded items and near the forms.

For placing of concrete for the wall and dome of the containment structure, see Section 15.5.1.10. See Section 15.5.2.4 for the description of the concrete used for the Reactor Pressure Vessel Head Replacement Project.

Vertical drops greater than 6 feet for any concrete were not permitted, except where suitable equipment was provided to prevent segregation. All concrete placing equipment and methods were subjected to the approval of the structural engineer.

The surfaces of all construction joints were thoroughly treated to remove all laitance and to expose clean, sound aggregate. Surfaces of fresh concrete were roughened by cutting with an air-water jet after the initial concrete set had occurred, but before the concrete had reached its final set. After cutting, the surface was washed and rinsed. Where the use of an air-water jet was not advisable in any specific instance, then that surface was roughened by hacking with hand tools or other satisfactory means to produce the requisite clean surface.

Before placing subsequent concrete lifts, the surfaces of all construction joints were thoroughly cleaned and wetted, and all excess water that was not absorbed by the concrete was removed. Horizontal construction joints were then covered by a 0.50-inch-thick layer of sand/cement grout of the same sand/cement ratio as the concrete, and new concrete was then placed immediately against the fresh grout.

Curing and protection of freshly deposited concrete conformed to ACI 301, Chapter 12, using curing compounds conforming to ASTM C309.

For curing of the top surface of the containment foundation mat, see Section 15.5.1.10.

Concrete strength tests were performed in accordance with ACI 301, Chapter 16, Section 1602 (a), Paragraph 4, supplemented as follows.

No fewer than two sets of compression test specimens for each mix design of concrete placed were taken during the first two days of placing concrete, or at least one set of test specimens for each 250 yd^3 placed. Thereafter, one set of test specimens was taken for each 250 yd^3, or fraction thereof, for each mix design of concrete placed in any one day. In addition, one set of specimens was taken whenever, for any reason, the materials, methods of concreting, or proportioning were changed.

The test specimens for compressive strength were cylinders 6 inches in diameter and 12 inches long. Each set consisted of five specimens, at least one of which was tested at 7 days and three at 28 days age. The remaining cylinder was retained at the laboratory for further tests at 60 days age if the result of the previous tests made such a test desirable.

Concrete strength tests were evaluated by the engineers in accordance with ACI 214-65, *Recommended Practice for Evaluation of Compression Test Results of Field Concrete*, and ACI 301-66, Chapter 17.

Strengths of working-stress-type concrete were considered satisfactory if the average of any five consecutive strength tests of the laboratory-cured specimens at 28-days age was equal to or greater than the specified compressive strength, f'c, of the concrete.

Strengths of ultimate-strength-type concrete were considered satisfactory if the average of any three consecutive strength tests of the laboratory cured specimens at 28-days age was equal to or greater than the specified compressive strength, f'c, of the concrete.

If any tests for individual cylinders or group of cylinders failed to reach the specified compressive strength, f'c, of the concrete, the responsible engineers were immediately notified to determine if further action would be required.

The field tests for slump of Portland cement concrete were in accordance with ASTM C143. Any batch not meeting specified requirements was rejected.

Slump tests were made frequently during concrete placement and each time concrete test specimens were made.

Statistical quality control of the concrete was maintained by a computer program. This program analyzed compression test results reported by the testing laboratory in accordance with methods recommended by ACI 214, *Recommended Practice for Evaluation of Compression Test Results of Concrete*.

15.4.3 Reinforcing Steel

Placing of reinforcing steel conformed to the requirements of Chapter 5 of ACI 301, *Structural Concrete for Buildings*, and Chapter 8 of ACI 318, *Building Code Requirements for Reinforced Concrete*. See Section 15.5.2.3 for the description of the placement of the reinforcing steel used for the Reactor Pressure Vessel Head Replacement Project.

All Cadweld splices were made in accordance with the instructions issued by the manufacturer, Erico Products, Inc., Cleveland, Ohio.

In order to qualify operators for making Cadweld process joints, each operator was required to demonstrate to the Senior Quality Control Engineer his ability to make an acceptable fixed joint using the Cadweld process. Cadwelders were requalified after every 200 Cadwelds. Testing was by tensile testing a Cadweld made under simulated field conditions.

The ends of the reinforcing steel bars to be joined by the Cadweld process were square cut by the fabricator. Ends of the bars were then thoroughly cleaned of all rust, scale, grease, oil, water, or other foreign matter before the joints were made.

Welding was performed using the “Metallic Arc Welding Process” with coated electrodes, or the “Metallic Inert Gas Shielding Welding Process” (MIG) using bare wire. The filler metal for the Metallic Arc Welding Process conformed to ASTM A316, *Coated Arc Welding Electrodes*, Classification E-10016-D2 or E-10018-D2.

The filler metal for the MIG welding process was a spooled bare wire 0.30 inch or 0.35 inch in diameter, Linde or Arcos Type 515. The shielding gas used for the MIG welding process was Linde C-25, a mixture of 75% argon and 25% carbon dioxide.

The ends of the bars to be joined by butt welding were prepared by sawing or flame cutting, and dressing by grinding, where necessary, to form a single vee butt joint.

Mill test reports of the heats of steel used for making the rebars were obtained by the Senior Quality Control Engineer to confirm the grade of steel welded. Where preheating was required, temperatures were checked with Tempilstiks.

In order to qualify welders for work on the reinforcing steel bars, each welder made a reinforcing bar test weld in the horizontal fixed position, welding vertically up. Each test weld was sectioned through the center of the weld by power sawing and machining. The cross-sectioned surface was etched with a 10% solution of nitric acid and water. The etched surface was examined by the field welding supervisor, who determined the qualification of the welding operator.

Tack welding of rebar was not permitted.

Special criteria for placing reinforcement for the containment structure are provided in Section 15.5.1.6.

15.4.4 Construction Procedures

The portion of the site to be covered by structures was cleared, and general excavation performed to the underside of the foundations for the various buildings. In general, this excavation was from elevation +34 to +10, with some building foundations slightly higher or lower. The major Class I structures (except the Fuel Building and main steam valve enclosure structures) are supported on mat foundations; the Fuel Building and the main steam valve enclosure structures are supported on pile foundation. For additional construction procedures for other Class I structures, see Section 15.6.1.

15.4.5 Construction Practice

Vepco maintained quality control personnel on the site at all times to serve as qualified inspectors in all phases of work, so as to ensure and document that all construction operations met the rigid requirements of the specifications as outlined in the quality assurance report. The qualification of welding procedures and welders was performed in accordance with Part A of Section IX of the ASME Boiler and Pressure Vessel Code or, for structural steel, in accordance with American Welding Society requirements.

Concrete was sampled and tested during construction, in accordance with ACI 318, to ensure compliance with the specifications. A competent independent testing laboratory was retained to design the concrete mixes, take samples, perform all tests of aggregates and concrete cylinders, and report to Vepco for approval.

Special practices to be followed for the containment liner are contained in Section 15.5.1.8.

15.4.6 Quality Assurance Program (Construction Phase)

The descriptions of the quality assurance program during the construction phase have been deleted. These activities have been completed and the descriptions are no longer needed for the operational phase. The NRC-approved Operational Quality Assurance Program is described in Chapter 17.

Intentionally Blank

15.5 SPECIFIC CONTAINMENT STRUCTURAL DESIGNS

15.5.1 Containment Structure

15.5.1.1 General

For arrangement of the containment structure, see Reference Drawings 1 through 7.

Each of the reactor containment structures is similar in design and construction to that of the Connecticut Yankee Atomic Power Plant at Haddam, Connecticut. Each is a steel-lined, heavily reinforced concrete structure with vertical cylindrical wall and hemispherical dome supported on a flat base mat. Below grade, the containment structures are constructed inside a cofferdam of steel sheet piling. The structures are soil-supported. The base of the foundation mats is located approximately 66 feet below finished ground grade.

Each containment structure has an inside diameter of 126 ft. 0 in. The spring line of the dome is 122 ft. 1 in. above the top of the foundation mat. The inside radius of the dome is 63 ft. 0 in. The interior vertical height is 185 ft. 1 in., and the base mat is 10 ft. 0 in. thick. The steel liner for the wall is 3/8-inch thick, except over the base mat, where 0.25-inch and 0.75-inch plate is used. The steel liner for the dome is 0.50-inch thick. A waterproof membrane, as shown in Figure 15.5-1, is placed below the containment structural mat and carried up the containment wall to ground level. Attached to and entirely enveloping the part of the structure below grade, the membrane protects the structure from the effects of ground water and the steel liner from external hydrostatic pressure. Ground water immediately adjacent to the containment structure is kept below the top surface of the foundation mat by pumping as required.

Access to the containment structure is provided by a 7 ft. 0 in. i.d. personnel hatch penetration, and a 14 ft. 6 in. i.d. equipment hatch penetration. Other smaller containment structure penetrations include hot and cold pipes, main steam and feedwater pipes, fuel transfer tube, and electrical conductors.

The reinforced concrete structure has been designed to withstand all loadings and stresses anticipated during the operation and life of the unit. The steel lining is attached to and supported by the concrete. The liner functions primarily as a gastight membrane, and transmits incident loads to the concrete. The containment structure does not require the participation of the liner as a structural component. No credit has been taken for the presence of the steel liner in designing the containment structure to resist seismic force or other design loads.

The steel wall and dome liners are protected from potential interior missiles by interior concrete shield walls. CRDM missile protection is provided by a concrete shield on Unit 1 and a steel shield on Unit 2. The base mat liner is protected by a 1.50 to 2-foot thick concrete cover, except where a 0.75-inch-thick liner plate was used beneath the reactor vessel incore instrumentation, and at a drainage trench where floor grating provides additional protection.

As an added precaution against water seepage that might penetrate the waterproofing membrane in small quantities, pipe sumps are provided in each of the instrument observation pits located outside the cylindrical wall of the containment but within the waterproofing membrane. The sumps penetrate the base mat and terminate in the porous concrete immediately below the mat.

Pumps are provided to remove ground water outside the waterproofing membrane, as described in Section 15.5.1.3.

15.5.1.2 **Design Criteria**

The design of the containment structures is based on:

1. Biological shielding requirements.
2. The temperature and pressure generated by the design-basis accident (DBA), Section 14.5.2.
3. The operating and design-basis earthquakes discussed in Section 2.5
4. Severe weather phenomena.
5. The maximum calculated power level of 2597 MWt.

The design-basis accident was selected as the design basis for the containment structure because all other bases would result in lower temperatures and pressures. The containment structure is also designed for the normal subatmospheric operating conditions. Further, the containment structure is designated for a leakage rate not to exceed 0.1% of the contained volume per day at 45 psig.

The minimum operating pressure for the containment is 10.1 psia with about 1.0 psia additional partial water vapor pressure. The resulting total containment pressure is approximately 11.1 ± 0.5 psia. The temperature of the containment air fluctuates between a maximum temperature of 125°F and a minimum of 75°F during normal operation, and 60°F during shutdown, depending upon the ambient temperature of available service water. The normal operating pressure allows accessibility for inspection and minor maintenance during operation without requiring containment pressurization or the use of supplementary breathing equipment for personnel.

The containment structure is designed by ultimate strength methods conforming to ACI 318-63, Part IV-B. Design load criteria based on ACI requirements and others given below conform to current containment design.

The ultimate load capacity of the containment structure as modified by the safety provisions of ACI 318-63, Section 1504, is not less than that required to meet the containment structural loading criteria.

Loads imposed on the containment shell design include:

1. Dead load.
2. DBA pressure.
3. Temperature rise in liner associated with DBA.
4. Normal operating temperature gradients.
5. Earthquake.
6. Wind loads, including tornado winds.

Loads imposed on the containment mat design include:

1. Mat and interior structures during construction.
2. Dead load for complete structure and contents.
3. Dead load and DBA pressure and liner loading.
4. Dead load, DBA pressure, liner loading, and earthquake.
5. Dead load and earthquake.

The ultimate load capacity of the containment structure, as modified by the safety provisions of ACI 318-63, Section 1504, is not less than that required to satisfy the following structural loading criteria, tabulated in Table 15.5-1.

The seismic design coefficients and critical damping factors used in the design of the reactor containment structure are given in Section 15.5.1.4. The average acceleration spectra curves are included in Section 2.5. The earthquake loads include the horizontal or vertical acceleration, or a combination of both where the effects, as measured by the stresses resulting from the separate acceleration components, of horizontal and vertical ground accelerations are combined algebraically.

The load capacity of the tension members is based on the guaranteed minimum yield strength of the reinforcing steel. Load capacities of flexural and compression members are determined in accordance with the *Building Code Requirements for Reinforced Concrete,* ACI 318. The load capacity so determined is decreased by a reduction factor multiplier “ϕ”, to compensate for small adverse variations in material and workmanship. The reduction factors are listed in Table 15.5-2.

The load capacity reduction factor for stresses in concrete produced by tornado-carried missiles, in combination with other tornado-produced stresses as given in Loading Criteria 5, is 0.75.

The dominant design load is the 45-psig containment design pressure, which creates major tensile membrane stresses in the reinforcing steel, coincident with moments at the junction of the containment wall and mat.

The design tornado wind loading and pressure drop criteria are stated in Sections 2.2 and 15.2.3.

Since the DBA pressure load is greater than the negative pressure load of tornadoes, the containment structure is able to maintain its integrity and permit an orderly shutdown on the reactor unit should a tornado strike the structure.

15.5.1.3 **Buoyant Loads**

Yard elevation is at +26 ft. 6 in.; the base of the containment mat is at Elevation -39 ft. 7 in. Six seepage drains are provided to drain the area beneath the containment structure. Four drains extend down to Elevation -65 ft. 0 in., and two drains extend down to Elevation -105 ft. 0 in. These drains terminate in a 12-inch thick, crushed-rock layer placed immediately below the mat and through which water can travel to the edge of the cofferdam. Seepage from these drains, and other seepage into the cofferdam, collects inside the cofferdam around the base of the mat. Two pumps located in a cubicle adjacent to the instrument well remove all subsurface seepage water. To prevent loss of pumping capability, the system design permits access to critical areas, such as the interior drainage header, the pump cubicle, and backwash facilities. This will permit maintenance and continued operation of the drainage system, thereby preventing water levels from reaching the top of the containment base mat and exerting hydrostatic pressure on the top of the mat liner.

The pumps are controlled to maintain the water level in this space between a high of Elevation -32.75 ft. and a low of Elevation -33.4 ft., a range of 0.7 feet which is equivalent to a fluctuation in buoyant pressure under the structure of ± 22 lb/ft^2 from the mean value. A local high level indicator comes in if the water exceeds Elevation -32.6 ft. The dead load of the structure and its contents is 7200 lb/ft^2. This fluctuation in buoyant pressure amounts to 0.31% of the dead load weight.

In the unlikely event of multiple pump failure for a sufficient period of time for the ground water to rise to finished ground grade at Elevation +26 ft. 6 in. the buoyant pressure would increase to a maximum value of 4150 lb/ft^2, which amounts to less than 60% of the dead load structure. Therefore, flotation of the containment is not credible.

15.5.1.4 **Dynamic Analysis**

Analyses were conducted to determine response stresses in the containment structure due to the application of seismic loading. Earthquake ground motion values were applied simultaneously in the horizontal and vertical directions. Vertical ground motions were assigned a magnitude equal to two-thirds of the horizontal motions. The magnitudes of the operating-basis earthquake and the design-basis earthquake are derived and assigned as described in Section 2.5. Design loading conditions combined with seismic loading and allowable stress levels are stated in Section 15.5.1.2.

The earthquake loading was analyzed using a Stone & Webster program, *Container Vessel Seismic Analysis,* based upon the dynamic analysis of a containment structure by Messrs. Hansen, Holley, and Biggs of MIT.

The general analytical model of the containment structure responding to horizontal earthquake forces is a coupled two-mass system in which the wall and dome comprise one mass and the base slab and internals comprise the second mass. This model responds to three degrees of freedom: flexure in the wall and dome, translation, and rocking of the structure as a unit. The model includes the first three modes of vibration.

The stiffness of the wall and dome was obtained through formulas recommended by Professor R. V. Whitman of MIT, based on work by G. N. Bycroft.

The output of the computer program was spot-checked by manual analysis, which confirmed the program basis.

Another independent manual analysis that considered the internals as a third coupled mass resulted in loading values that were not greater than those obtained from the analysis of the two-mass system.

A preliminary analysis of response to vertical earthquake forces using a single-mass system showed that these forces are not controlling factors in the design.

When computing the response of the reinforced concrete containment structure to earthquake forces, the value of 5% of critical damping was used with the design earthquake acceleration of 0.07g. This is an overall value that includes the damping in both the reinforced concrete structure and the soil. The magnitudes of earthquake forces applied to the structure were obtained from the response spectrum for 0.07g at zero period and 5% critical damping at the calculated frequency of the structure, and then distributed over the structure in accordance with the relative motions of the structure as determined by dynamic analysis.

The force derived by use of this damping factor was used for the entire reinforced concrete containment. The value of 5% of critical damping, together with the damping factors for other systems, structures, and equipment, is listed in Table 15.2-2.

The value of 10% of critical damping was used with the design-basis earthquake of 0.15g on the basis of increased cracking in the concrete and increased movement in the concrete and soil.

To verify the damping used for design, an analysis of the soil structure interaction damping was made in accordance with the procedures suggested in *Analysis of Foundation Vibrations,* by

Robert V. Whitman, Proceedings of a Symposium organized by the British National Section of the International Association for Earthquake Emergency.

Damping factors for soil were calculated for the rigid body translation and rocking. Flexure damping was assessed as suggested by Newmark.

For each of the four modes of vibration, energy losses in structural flexure, sliding, and rocking were calculated and proportioned to determine the total system energy loss, thereby defining the damping to be used in spectrum response.

This analysis demonstrated that the damping factors used for design and the resulting seismic response characteristics are conservative.

Earthquake load criteria are included in the loading criteria described in Section 15.5.1.2. Operating and design-basis earthquake factors are each combined with other loads, including the design-basis accident pressure. Resulting shears are computed by the computer program.

Lateral earth pressure under seismic loadings on the containment mat was determined by computing the lateral resistance developed in the soil as the structure responds in flexure, translation, and rocking. In this analysis, the translational restraining force has two components, a shear across the base of the structure and lateral soil pressures on the side wall of the containment structure developed by its displacement relative to its static position.

The “spring constant,” that is, force per unit of lateral displacement by shear, for a circular rigid base on an elastic half space is given by Bycroft (Reference 1) as:

$$k_x = \frac{32\,(1-u)\,Gr_o}{7-8u}$$

where:

G = shear modulus

r_o = radius of base

u = Poisson’s Ratio

Note: Values in consistent units

For usual values of u this reduces approximately to:

$k_x = 5Gr_o$

The horizontal pressure on the side wall of the containment structure can be evaluated from the theories of horizontal subgrade reaction. From Terzaghi (Reference 2) the relation between horizontal deflection and pressure at any point is given by:

$$k_h = \frac{P}{y_h}$$

where:

P = horizontal pressure at soil structure interface

y = horizontal deflection of soil at interface

k_h = coefficient of horizontal subgrade reaction

further:

$$k_h = \frac{n_h z}{B}$$

where:

n_h = coefficient dependent upon physical properties of the soil

z = depth below free surface of soil

B = width of loaded area, which may be taken as diameter of containment structure

For purposes of this analysis, a value of n = 40 tons/ft^3 was selected from tables presented by Terzaghi. This value is appropriate to dense sand above the ground water table. It is a conservative value, since the higher the coefficient, the stiffer the soil, and the greater the loads imposed upon the side walls of the structure.

The rotational, translational, and flexural deflections of the structure were determined from response analysis and added so as to obtain maximum deflections. The lateral soil pressures on the side wall of the structure were then computed for these total deflections using the theory of horizontal subgrade reaction.

In determining these pressures, the side wall of the structure was assumed to be rigid radially, since radial deflection of the side wall would reduce relative soil-structure deflections, and thus the soil forces acting upon the structure.

The analysis was performed for both the operating-basis earthquake of 0.07g and the design-basis earthquake of 0.15g. The analysis for a 0.15-g earthquake indicates a lateral force of 300 lb/ft^2 at Elevation -8 ft. 6 in. which defines approximately the magnitude of this component.

It should be noted that these forces, if included in the seismic loadings on the structure, would reduce the base shear and vertical bending stresses in the shell. Accordingly, they are not included when computing such stresses in the shell and thereby contribute to the conservation of the design.

Rocking motion of the containment structure was considered in the determination of the natural frequency, the distribution of inertia forces, and in the amplitudes of motions.

The containment wales supporting the cofferdam structure do not affect consideration of horizontal pressure under seismic loading on the containment wall.

Four circular concrete wales originally supported the sheet steel cofferdam in which the containment structure is founded. The top wale, Wale A, has been partially removed at several points to permit completion of adjacent structures; in this condition it does not impose any restraint on the containment structure. The bottom wale, Wale D, is in the lower plane of the containment mat and below the plane of the wall, and offers no restraint. Wale C extends from a height of 4 ft. to 8 ft. above the base of the wall. Wale B extends from a height of 17 ft. 6 in. to 21 ft. 6 in. above the base of the wall. These two wales are approximately 3 ft. 9 in. from the containment wall, and the space between the wales and wall is backfilled with pervious fill. Under seismic loading, the distribution of the lateral earth pressure through the cofferdam wales would not have any different effect than if these pressures were applied directly to the structure.

15.5.1.5 **Static Analysis**

The containment structure was analyzed and designed for all loading conditions combined with load factors as outlined in Section 15.5.1.2. The forces, shears, and moments in the structural shell were obtained from a computer program based on *Numerical Analysis of Unsymmetrical Bending of Shells of Revolution*, by B. Budiansky and P. P. Radkowski, published in the American Institute of Aeronautics and Astronautics Journal, dated August 1963.

Forces, moments, and shears in the base slab were obtained from a Stone & Webster computer program, *Flat Circular Mat Foundations for Nuclear Secondary Containment Structures*. The program analyzes a flat circular plate supported on an elastic foundation and computes the discontinuity stresses at the junction of the mat and cylinder, and the soil bearings pressure.

Discontinuity stresses, shears, and moments at the junction of the cylinder and mat were determined using an analogy to the Hardy Cross method for distributing fixed-end moments in continuous frames. The theoretical fixed-end moments obtained from the shell and mat computer analysis were balanced in proportion to the relative stiffness of the mat and cylinder.

An independent, manual computation, based on *Theory of Plates and Shells*, by S. Timoshenko, at a few selected points produces forces, shears, and moments substantially the same as those produced by the computer programs for the shell and the mat.

The containment shell program used to derive stresses in the shell assumes an isotropic material. The program does not include considerations of temperature gradients due to the thermal loadings across the containment wall.

To compute maximum stresses due to the thermal load, six general strain equations were derived, one equation for each of the four principal areas of reinforcing steel and one for each major axis of the steel liner. These equations relate strain to position, temperature, and incident stress for each item considered. To solve these general strain equations, six additional equations were used: four equations for strain compatibility, which equate radial and longitudinal strains, and two equations for load equilibrium. The solution of these equations for incident conditions gives the stress in each of the principal areas of reinforcing steel and the stress on the steel liner.

These equations permit the thermal stresses to be considered separately without modification of the major shell program.

The thermal operating load in the containment concrete wall, combined with incident condition loadings, produces a stress difference of approximately 6000 psi between the reinforcing steel adjacent to the inside face of the wall and the reinforcing steel adjacent to the outside face of the wall. This difference exists in both the longitudinal steel and the hoop reinforcing steel.

To permit the addition of these stresses to those obtained from the containment shell program, without exceeding the maximum, the containment shell program stresses are limited to 3000 psi below the maximum allowable design stress. This approach is considered extremely conservative since it limits the design stress in the interior layers of reinforcing steel to approximately 6000 psi, less than the maximum allowable design stress permitted on the exterior layers of reinforcing steel.

Structural failure cannot occur, however, until the interior reinforcing steel exceeds yield. Up to that point plastic yielding of the outside reinforcing would be controlled by the elastic behavior of the interior steel.

In the solution of the general strain equations, the effect of the concrete has been ignored, since it is assumed to be cracked and incapable of carrying any of the tensile loads considered. The dead load of the concrete is also ignored, as this was found to have little effect on the hoop stresses. This assumption also provides a more conservative result.

The loads exerted on the concrete shell by the thermal effects of the exposed steel liner were obtained from the calculations discussed above. The equivalent pressure, p, equals the hoop stress, f, in the steel liner multiplied by the liner thickness, t, and divided by the radius of the liner, r. The computed equivalent pressure associated with 1.5 times incident pressure equals 5.45 psi.

Stiffness factors were used to distribute computed fixed-end moments derived from an analysis of the containment cylindrical wall, considered as a shell with a fixed-end moment, and from an analysis of the containment mat, considered as a flat circular plate with uniform fixed-edge moment.

Stiffness factors for the cylinders were computed from formulas given in Raymond J. Roark's book, *Formulas for Stress and Strain*, for long, thin-walled cylinders. Stiffener factors for the mat were computed from formulas for circular flat plates with uniform edge moment, from the same source.

Variation of the modulus of elasticity of the concrete to differentiate between uncracked and cracked concrete was not considered in determining the stiffness factors chosen.

Use of such a variable would modify the distribution of the moments and shear forces to some degree, but it is not believed that this would significantly affect the accuracy of the results. The safety factor inherent in the present design would accommodate such small variations.

The actual distribution of the moments and forces at the junction of the wall and mat are a function of the relative stiffness of each member. This is determined by the design approach used. Provided the total forces are distributed between the two areas under consideration, differences of distribution due to theoretical variations of the theoretical value of Young's Modulus for concrete are not considered likely to improve the results beyond the accuracy obtained with the assumptions already used.

The methods for computing soil pressures under the mat were based upon an analogy to E. P. Popov's *Method of Successive Approximations for Beams on an Elastic Foundation,* published in the Proceedings of the ASCE, Separate No. 18, dated May 1950. The program computes the deflection at the center of the mat relative to a point on the mat at the intersection of the center line of the containment shell walls. The elastic curve of the mat deflection is assumed to be parabolic between these two points. Multiplying the deflection by the subgrade spring constant, the program then provides a parabolic soil pressure curve, which is combined with the rectangular soil pressure curves to provide final soil pressures under the mat. The subgrade spring constant is derived from Professor R. V. Whitman's formula:

$$k = \frac{4G}{\pi(1 - U)R}$$

where:

k = Spring constant

G = Shear modulus of subgrade material

R = Radius of mat

U = Poisson's ratio of subgrade material

While the subgrade reaction varies with depth, a single typical value for the reaction was used which is representative of the zone at the level being considered. The shear modulus was computed using a formula developed by Hardin and Black (Reference 3) from observed soil samples, and substantiated by dynamic triaxial tests of the soil. The stiffness of the soil was also based on work by G. N. Bycroft which is referred to in the Section 15.5.1.4.

A variable soil pressure conforming to the deformation of the mat was used in determining the stresses in the structure.

Maximum wind velocity associated with a tornado is given as 360 mph. This velocity was converted to an equivalent pressure using the formula $P = .00256V^2$, where P = equivalent pressure, lb/ft^2 and V = wind velocity, mph. Wind pressure was distributed over the containment dome in accordance with the methods given in *Wind Stresses in Domes,* by P. Gondikas and M. G. Salvadori, published in ASCE proceedings No. 2616, dated October 1960.

Wind pressure was distributed over the containment cylindrical shell in accordance with the methods given in *Wind Forces on Structures*, by T. W. Singell, published in ASCE proceedings No. 1710, dated July 1958.

Tornado wind loads were combined with other loads as described in Section 15.5.1.2.

An analysis of the containment structure indicated that resulting membrane stresses due to tornado wind loading in the dome reinforcing are less than 5000 psi, and that discontinuity stresses at the junction of the dome and cylinder are somewhat less.

The wind loading on the cylindrical shell creates bending, direct and shear stresses. The bending and direct stresses in the horizontal reinforcing equal 16,000 psi.

An investigation of overturning due to wind shows that the resultant (DL + wind) falls within the Kern point radius of the cylinder, indicating that the vertical reinforcing will not be subject to tensile forces from this load.

Containment torsional loadings from wind were considered negligible, in view of the ideal shape of the containment when considered as a torsion resistant shell supplemented by the diagonal reinforcing throughout the walls provided to resist earthquake loads.

The Stone & Webster computer programs for the reactor containment base slab, cylindrical wall, and dome use a constant Young's Modulus of Elasticity and Poisson's Ratio. No attempt was made to assign varying numerical values to these factors to differentiate between the relative amount of cracking in different parts of the structure.

The output of the mat program furnishes the following information:

1. Radial and tangential bending moments and vertical shear at five-foot intervals along horizontal radii from the center of the mat, spaced at 30-degree intervals.

2. Discontinuity stresses at the junction of the mat and cylinder.
3. Soil pressure.

The output of the shell program furnished forces, shears, and moments at 1-foot intervals in the height of the cylindrical wall, and at one-degree intervals in the height of the dome. Similar information is furnished at each of 16 equidistant points on the circumference of the vessel at each level considered.

Scaled load plots obtained from the computer programs for moment, shear, deflection, longitudinal force, and hoop tension are shown in Figure 15.5-2 for each of three design load conditions. The fourth design load condition did not govern design and is not represented.

The following assumptions were made:

a. The dead and live structural loads are included in all three of the design load cases.
b. Pressure load, factored and unfactored, is the dominant load condition.
c. Wind loading replaces earthquake loads where wind loads exceed earthquake loads.
d. Tornado loads are included under the general category of wind loads discussed above.
e. Buoyant water loads as discussed in Section 15.5.1.3 are substantially less than dead loads.
f. Earthquake loads, both for the operating-basis earthquake and the design-basis earthquake, are included in the analysis.
g. Thermal load from the liner is converted into an equivalent pressure and added to the incident pressure load when computing moments, shear, and tension associated with the design-basis accident.
h. Thermal load from the concrete is discussed in Section 15.5.1.5. Stresses resulting from this load are combined with incident pressure load stresses.

15.5.1.6 Reinforcing Steel Arrangement

The foundation mat of the containment structure is reinforced with both top and bottom layers of reinforcing. Bottom mat reinforcing is placed in a rectangular grid pattern with layers at 90 degrees to each other. Reinforcing for the top of the mat consists of concentric circular bars combined with radial bars. The reinforcement pattern for the top of the mat is arranged to permit maintaining a uniform spacing of the vertical wall rebars that extend into the mat. Splices in adjacent parallel rebar in the mat are in general not less than 4 feet apart.

Hoop tension in the cylinder wall is resisted by horizontal bars located near both the outer and inner surfaces of the wall. All horizontal circumferential bars, including those in the dome, have their joints staggered at a minimum of 3 feet apart.

Longitudinal tension in the cylinder wall is resisted by two rows of vertical bars, one near the interior face and the other near the exterior face of the wall. Vertical bars are placed in groups of 20 bars of equal length. These are arranged so that no adjacent group in the same or opposite face of the wall has splices closer than 6 feet vertically.

See Section 15.5.2.3 for the description of the splicing scheme used for the Reactor Pressure Vessel Head Replacement Project.

The dome reinforcing consists of layers of rebar placed radially extending from the vertical reinforcing of the cylindrical wall and horizontal layers of circumferential hoop bars. Layers are located near both the inner and outer faces of the concrete. The radial pattern of the reinforcing steel terminating in the containment dome results in a high degree of redundancy of reinforcing steel in the dome. Bars are terminated beyond a point where there is more than twice the amount of steel required for design purposes. The rate of convergence of these bars, and low-stress requirements dictated by the arrangement, produces a low bond stress. In a limited number of cases where bars are terminated close to the center of the dome, anchorage stresses are more critical, and bars are hooked to provide the required anchorage. Near the crown, the rebars are welded to a concentric ring cast in the concrete.

Radial shear loads generated by internal pressure resulting from the design-basis accident are resisted by rebars inclined at 45 degrees with the horizontal and extending between the surfaces of both the vertical reinforcing closest to the interior and exterior faces of cylinder wall. This radial shear will vary from a maximum at the base of the wall where the foundation mat restrains the independent movement of the wall to zero at some level above the mat. Anchorage bond stresses in these shear bars is kept below allowable stress levels to minimize potential cracking of the concrete. In addition, sufficient longitudinal and circumferential reinforcing is carried to the base of the wall to carry all potential loads without assistance from the radial shear reinforcing.

The tangential shears resulting from the earthquake loading are resisted by rebars inclined at approximately 45 degrees in each direction, in the plane of the wall parallel to the main reinforcing steel.

Minimum concrete cover for all principal reinforcing steel of the containment structure exceeds the requirements of ACI 318, Paragraph 808(d), which states, “Concrete protection for reinforcement shall in all cases be at least equal to the diameter of the bars.” The largest and principal reinforcing bar is No. 18, which requires a minimum cover of only 2-3/8 inches by the code.

15.5.1.7 **Penetration Design**

Penetration through the containment structure is divided into one of the following three categories:

1. Pipe penetrations nine inches in diameter or less.

   No special structural reinforcing is provided for penetrations nine inches in diameter or less. Penetrations in this category are located to avoid interference with the reinforcing steel.

2. Pipe penetrations greater than nine inches and up to 3 ft. 6 in. in diameter.

   For penetrations greater than nine inches, and up to and including 3 ft. 6 in. diameter, supplementary reinforcement is provided in amount and distribution such that area requirements for reinforcement are adequately satisfied.

   At all these size penetrations, reinforcing steel interrupted by the openings is terminated at each side of the opening. Supplementary reinforcing was placed parallel to the interrupted bars to provide bar continuity. Horizontal, diagonal, and vertical bars were used to effectively frame the opening. The total area of reinforcement provided in any plane is not less than twice the area of steel interrupted or cut by the opening, with half of this placed on each side of the opening.

   Additional reinforcing around these openings is not less than 20 feet in length, and of sufficient length to develop the full ultimate strength of the bar in ultimate bond stress to conform to the requirements of ACI 318, Section 1801(C 2). Horizontal bars are considered as top bars for this purpose.

3. Openings larger than 3 ft. 6 in. in diameter.

   The two openings in this category are the 7 ft. 0 in.-diameter personnel access hatch and the 14 ft. 6 in.-diameter equipment access hatch. Details of the additional reinforcement provided around the equipment access hatch and personnel access hatch are shown in Figures 15.5-3 through 15.5-6, inclusive.

These penetrations are analyzed by means of a computer program (Reference 4). This program analyzes a ring beam based on the method of virtual work. The program assumes the ring beam to be isolated from the containment shell and loaded in two planes. The analysis includes the effect of the stiffened ring and the moments introduced by transferring external loads from the shell at the perimeter of the ring to the center line of the beam.

The ring beams are designed to resist biaxial bending moments, axial tension, torsion, and biaxial shear resulting from loading criteria listed in Section 15.5.1.2. The biaxial bending moments and axial tension are assumed to be resisted by the reinforcing bars only, the concrete being neglected. The torsional and biaxial shear stresses are assumed to be resisted entirely by binders placed radially around the penetrations. Torsion is computed by the formulas for torsion in a rectangular beam. The principal circumferential and meridional reinforcing is extended to the inner face of the ring beam and bent at right angles, hereby providing additional shear resistance, the availability of which is considered in the design.

The normal pattern of membrane stress in the cylinder wall is interrupted in the area adjacent to the stiffened openings. This redistribution of stress was investigated by means of a computer program, based upon a paper by B. Budiansky and P. Radkowski (Reference 5). For this investigation, a flat circular plate with a radius equal to three times the distance from the center of the opening to the outside face of the stiffening ring beam was used to establish the stress pattern. The movement of both the stiffened ring and the adjacent shell was compared to determine if significant discontinuity stresses were present. Extra reinforcement was added to regions of marked deviation from the normal pattern to keep the discontinuity effects to the level at which they can be considered negligible. The gross concrete area of the ring section was used to determine the section stiffness and rigidity.

15.5.1.8 **Steel Liner and Penetrations**

The containment structure has an inside diameter of 126 ft. 0 in., and an interior vertical height of 185 ft. 1 in., measured from the top of the foundation mat to the center of the dome. The cylindrical steel wall liner is 3/8 inch thick, the hemispherical dome liner plate is 0.50 inch thick, and the flat base liner is 0.25 inch and 0.75 inch thick.

See Section 15.5.2.2 for the description of the restoration of the steel liner for the Reactor Pressure Vessel Head Replacement Project.

The top of the containment dome at Surry has a 39-inch penetration that was used during construction. This penetration is sealed by a welded plug on the liner side and a bolted plate on the outer end, and is filled with sandbags.

The steel lining is attached to and supported by the concrete; the liner functions primarily as a gastight membrane. The steel wall and dome liner are protected from potential interior missiles by interior concrete shield walls. CRDM missile protection is provided by a concrete shield on Unit 1 and a steel shield on Unit 2. The base liner is protected by a 1.50- to 2-foot-thick concrete mat, except in two areas where 0.75-inch-thick liner plate is used beneath the reactor vessel incore instrumentation, and at a drainage trench where floor grating provides additional protection.

The steel liner is designed to withstand the effects of all temperature, earthquake, and pressure loads, including the effect of the subatmospheric operating pressure.

The liner stress limits and their associated strains are limited to the stress criteria given in Paragraph N-1314 of Section III of the ASME Boiler and Pressure Vessel Code for nuclear vessels, and to basic primary stress levels taken from Table N-421 of that Code. The liner material SA-442-GR60 has a specified NDT that is at least 80°F below the minimum liner operating temperature, and considerably more than 120°F below the design-basis accident temperature. Under either of these conditions, the liner material is able to accommodate at least 60% plastic strain without cracking. A strain of this magnitude is at least 80 times greater than the maximum strain that will be imposed on the liner.

Reference to a generalized fracture analysis diagram shows that the "Crack Arrest Temperature" (CAT) curve crosses the NDT +80°F line at approximately 60% of the span between the "Fracture Temperature Elastic" (FTE) and the "Fracture Temperature Plastic" (FTP) ordinates, indicating that the steel can be strained to 60% of the required strain to fracture without cracking, even in the presence of large flaws.

To demonstrate that this plate material can accommodate plastic strains of this magnitude when biaxially stressed, tests were conducted on samples of 3/8-inch-thick plate of identical specification to the steel to be used in this containment liner, at a temperature of 90°F above the NDT of the steel. In these tests, the plate samples were each laid across a 23-inch-diameter ring, and a 3-5/8-inch-diameter mandrel was forced into the plate at the center line of the ring. In all cases, the mandrel deformed the plate by an amount in excess of 4 inches before shearing through.

The design-basis earthquake can be expected to produce tremors to the extent of not more than 8 to 10 cycles, and the operating-basis earthquake not more than 4 to 5 cycles.

Operating pressure variations from 9.5 psia to 14.7 psia can be expected to occur not more than 200 times during the lifetime of the unit, since personnel access is permitted under subatmospheric conditions. Temperature variations from 70°F to 105°F resulting from seasonal swings and shutdowns of the unit can be expected to occur not more than 800 times during the lifetime of the unit.

The containment liner is designed for 2000 cycles of operating pressure variations, 8000 cycles of temperature variation, and 20 cycles of design-basis earthquake, all simultaneously applied.

The containment liner is also designed for one cycle of design-basis accident pressure, one cycle of design-basis accident temperature, and ten cycles of design-basis earthquake, all considered simultaneously applied.

The containment liner is designed, within allowable working stresses, to withstand a vacuum increase of not less than 1.5 psi. The shell and dome plate liner is capable of withstanding an internal pressure of 3 psia, and the bottom mat liner is capable of withstanding an internal pressure of 8 psia, with reference to standard atmospheric conditions outside the containment.

The change in barometric pressure due to tornadoes is not expected to exceed 3 psig, and the change due to maximum hurricane will be approximately 1.1 psig. These pressure changes will result in a decrease in the atmospheric pressure, which will decrease the differential between atmospheric pressure and the containment structure ambient pressure, thereby decreasing the potential for stresses in the containment.

The accumulated effects of the above are evaluated in accordance with Paragraph N-415.1 of the ASME Boiler and Pressure Vessel Code, Section III, Nuclear Vessels.

The steel containment liner is securely anchored to the concrete wall and dome with Nelson stud-type concrete anchors. Failure could occur by stud failure in shear or tension, by studs pulling out from the concrete, or by studs tearing off from the liner plate. Tests conducted by Northeastern University, Boston, Massachusetts, using 1/2-inch-diameter studs and 3/8-inch-thick plate, show that shear failure occurs in the stud adjacent to the weld connecting the stud to the plate; in no instance was the plate damaged. Tests conducted for the stud manufacturer under the direction of Dr. I. M. Viest indicate that, with the manufacturer's recommended depth of embedment of the stud in concrete, the ultimate strength of the stud material can be developed in direct tension.

The principal design load imposed on the studs is due to the subatmospheric pressure operating condition, with the anchor lattice spacing based on considerations of plate buckling. A safety factor greater than 10 is provided against stud failure in tension.

Shear due to design-basis accident conditions and earthquake will result in stresses less than the allowable working stresses.

In addition to the concrete stud anchors, the wall and base mat sections are anchored and joined at the intersection of the vertical wall and the base mat with a continuous steel skirt embedded and anchored in the concrete.

All anchors are designed so that failure occurs in the anchor, thereby assuring that the leaktightness of the containment liner will be maintained during and after anchor failure.

Probable mode of failure will be one of random stud failure due to poor workmanship during stud attachment. This type of failure will result in separation of the stud from the liner without impairment of the liner ductility or integrity.

Loss of random anchor points will not trigger a chain reaction, since the design load on each stud is low compared with the stud load capability. Design spacing of these studs is such that a group of at least 10 adjacent studs would have to fail to cause a liner plate to reach its yield stress under design operating conditions. Even with this unlikely condition, the loads on the studs adjacent to this area would remain within their safe load capability.

As shown in Figure 15.5-7, the liner was welded to a skirt ring which in turn is embedded and anchored into the concrete mat. The skirt-to-liner juncture and the skirt-to-mat anchorage were proportioned to develop the full strength of the liner. Under DBA conditions, the liner at the base juncture will be under a state of biaxial compressive strain, due primarily to thermal effects.

All thermally hot pipes penetrating the reinforced concrete containment wall pass through individual sleeves that are approximately 1 foot in diameter larger than the pipe, and project inward a distance of approximately 2 feet from the liner. A typical application is shown in

Figure 15.5-10. The pipe is welded to a thick cap that is an integral part of the end of the penetration sleeve.

Each penetration sleeve with a thermally hot pipe penetration is equipped with two water-cooled heat exchangers to limit the temperature of the liner and the concrete in contact with the sleeve. One heat exchanger is located inside the sleeve encompassing its length (inner unit); the other is located outside the penetration sleeve in proximity to the liner. Either of the heat exchangers will provide adequate cooling for the penetration if the other is out of service. The associated component cooling water system has two independent lines. One line circulates water through the outer unit; the other circulates water through the inner unit. The inner unit limits the radial heat flow resulting from convection and thermal radiation from the thermally hot pipe penetration, to keep the temperature of the concrete in contact with the sleeve within allowable limits. In addition, the inner unit controls the longitudinal heat flow resulting from conduction from the same heat source, thus limiting the temperature of the liner and temperature gradient along the sleeve to keep the resulting thermal stresses in the liner and sleeve within the limits set forth in Section III of the ASME Pressure Vessel Code. The outer unit also limits the longitudinal heat flow, providing independent thermal protection of the penetration sleeve and liner.

The circumferential groove in the attachment plate, between the sleeve and penetration with its outside threaded connection, serves as a test chamber for the testing of the welds joining the attachment plate and penetration.

All penetrations are anchored in the reinforced concrete containment wall. The anchor strength is equal to the full yield strength of the pipe with regard to torsion, bending, and shear, and to the maximum possible pipe jet reaction. All stresses induced in the liner by these combinations of loadings are only those reflected by the resulting distortions in the reinforced concrete containment wall, and are minor in intensity. So, loads will not be imposed on the liner, thereby preserving its integrity.

All highly stressed insert plates at penetrations and equipment supports that are welded into the liner to transfer loads into the concrete have been ultrasonically tested to check for possible laminations. Tests were conducted on all plates where analysis showed a higher than average stress field, although all such plates are stressed well below the allowable limits for the materials. These tests show that no faults exist in the insert plates.

The pipes anchored to the containment penetrations between containment isolation valves constitute an extension of the containment, and are designed in accordance with the *USA Standard Code for Pressure Piping - Power Piping,* USAS B31.1.0-1967, with respect to materials and allowable stress. Analyses of stresses due to thermal expansion and shock loadings from earthquake, pipe jet reaction, and other causes were made using established digital computer calculation techniques.

In order to determine the loading combinations that act on a penetration, the pipe line passing through the penetration sleeve was assumed to have failed transversely at several locations along its run. The location at which the reaction of the ensuing jet of fluid flowing from the broken end first causes the pipe to completely yield, in either bending or torsion, was taken as the design case from which all resultant combinations of penetration loading were determined for that particular pipe line. The maximum stress allowed on any individual element of the penetration is 90% of the minimum yield point.

The intent of this criterion is to keep the material assembly components within the elastic range of the material. Under operating conditions of pressure, temperature, and external loads, the stresses in the assembly will be within the limits established in Section III of the ASME Pressure Vessel Code.

As a part of the issues identified in NRC GL 96-06, isolated containment penetration piping with confined fluid was reviewed for susceptibility to thermal over-pressurization following a DBA. The linear elastic analysis criteria stipulated in the 1989 version of the ASME Boiler and Pressure Vessel Code Section III, Appendix F was used for structural integrity evaluation. The internal pressure in piping penetrations during a design basis accident (LOCA or MSLB) was calculated by taking into account the difference in the expansion of the fluid and the pipe, the temperature increase immediately following the DBA and credit for a limited amount of circumferential strain in the pipe. The analysis established that thermally induced over-pressurization of isolated water-filled piping sections in the containment boundary could not jeopardize the ability of the accident mitigating systems to perform their safety functions and could not lead to a breach of containment integrity (Reference 10).

All liner seams were strength-welded. Small steel channels welded continuously along the edges of their flanges to the liner plate cover the plate weld seams, in a manner similar to those installed at the Connecticut Yankee Station. These channels are zoned into test areas by dams welded to the ends of the sections of the channels. Fittings are provided in the channels for periodic testing of the weld seams for leaktightness under pressure. Typical liner details are shown in Figure 15.5-12. Testing of the liner is described in Section 5.5.

To transfer the stress adequately around penetration openings, or to transfer the pipeyield load adequately to the concrete within the limits of this material, whichever is larger, the liner is reinforced in accordance with the rules set forth in the ASME Boiler and Pressure Vessel Code, 1968, Section III, Nuclear Vessels.

All major equipment and pipe loads are carried on the interior concrete structure or by the neutron shield tank. A 1.50- to 2-foot-thick concrete slab placed over the bottom mat steel liner provides anchorage and support for other equipment located in the base of the containment structure. The neutron shield tank skirt is attached to the containment mat by 1.50-inch-diameter anchor bolts. The skirt support was welded to the liner, and the entire weld, including the anchor bolts, covered by test channels. The internal concrete structure is attached to the containment mat by lengths of 3-inch by 6-inch steel bars which, placed horizontally, intersect the steel plate liner as shown in Figure 15.5-8. The main vertical reinforcing steel bars were welded to the top and bottom faces of these bars, thus providing bar continuity without creating multiple penetrations through the liner.

The 1.50-foot-thick concrete slab is anchored through the steel liner plate in a similar manner using 7-inch by 0.50-inch bars, as shown in Figure 15.5-8. These bars, termed bridging bars, form an integral part of the steel liner, and conform to the material and workmanship specifications of the steel liner. All welded joints are covered by test channels and tested as all other liner plate joints.

Access to the containment structure is provided by a 7 ft. 0 in. i.d. personnel hatch and a 14 ft. 6 in. i.d. equipment hatch. Other smaller containment structure penetrations include hot and cold pipes, main steam and feedwater pipes, fuel transfer tube, and electrical conductors.

Electrical conductors penetrating the containment structure range in size from No. 16 AWG thermocouple leads to 1-inch-diameter solid copper rods for 4160V power circuits. Each penetration group passes through 8-inch-diameter steel sleeves. The sleeves were welded into the containment liner with a test channel around the weld for periodic leak testing, as shown in Figure 15.5-9 (Amphenol electrical penetration depicted).

The basic Amphenol electrical penetration consists of an eight-inch steel tube with bolted-on flanges, through which pass the sealed conductors. The hermetically sealed connectors, as shown in Figure 15.5-9, were bench-tested for leaktightness.

Each flange is held tightly in place with eight bolts that draw the flange against a high temperature sealing ring and a backing plate welded to the sleeve. Each flange is tapped for leak testing. A make-up method is used to determine the penetration leakage by applying a test pressure equal to greater than containment design pressure (45 psig) between the o-ring seals. An electrical connector may be replaced, if necessary, without welding or cutting the containment liner or sleeve.

The design and qualifications of the Amphenol electrical mating connectors are based upon the requirements of military specification number MIL-C-5015. Connector design is such that silastic components are provided in the connector to feed through the interface. This type of interface has been proven adequate to meet the environmental requirements of MIL-C-5015. Additional capability to withstand elevated temperatures is provided in the material used for the sealing members.

The original tests conducted at the Amphenol’s shop consisted of the following:

> Connectors installed in the flanges normally operate at ambient conditions of 105°F and 9.75 psia, and were tested for leak rate and tagged for integrity before shipment to the job. A test facility was set up by the manufacturer suitable for 50 psig, with provisions for thermocycling from 32° to 300°F. A thermocycle run of at least three cycles was made on one of each type flange. A time interval of 30 minutes was

> allowed between the thermocycles. The leak rate test after thermocycling was made at 50 psig and 300°F. Each completed flange had a leak rate of less than 1×10^{-6} cc/sec per assembled flange. All flanges were leak tested at 50 psig and 300°F. Helium gas was used in the test facility.

For the Amphenol triaxial cable penetrations a more detailed procedure for the thermocycle test was followed in shop test:

> The type sample consisted of a containment side flange disk with hermetic assemblies welded in place. A thermocouple was installed to monitor disk temperature. The disk was stabilized at 32°F and then placed in an oven heated previously to 280°F. On entrance of the disk, the oven temperature was reduced, straight line, to 150°F over a 60-minute period. The disk was removed and cooled to 100°F, while the oven was reheated to 280°F. The disk was then returned to the oven and the oven temperature reduced to 150°F as before. The highest metal temperature reached during this cycle was recorded and a 50-psig helium leak test was conducted at this metal temperature for all discs of this type.

Each Amphenol penetration assembly, without external cable mating connectors, was tested in the factory to demonstrate insulation resistance of at least 1000 megohms at 1000V dc. In addition, each penetration has passed an overpotential test. After initial installation, each penetration with external cables connected was tested at 1000V dc for 5 minutes.

Containment electrical penetrations now in use at the Surry Power Station were manufactured by either Amphenol Space and Missile Systems, Conax Corporation, or Westinghouse Electric Corporation. Nitrogen pressure is not required for penetration functional capability; however, each penetration is capable of being pressurized with nitrogen for leak detection purposes. RTV-8112, THIOKOL, or POLYSYLFONE are used to provide a tight seal around conductors.

Amphenol penetration electrical connectors were tested by D. G. O'Brien, Inc. in 1972. The purpose of this test was to demonstrate operability during simulated LOCA conditions. The connectors passed the test with no less than 34 megohms internal resistance while retaining complete electrical continuity. The test had no observable physical effect on the connector assembly or cable. No connectors are associated with the CONAX or Westinghouse type penetrations; however, both manufacturer's have provided data regarding the performance of the materials used in their penetrations. This information includes thermal performance, radiation resistance, and chemical resistance tests. All data indicate excellent performance characteristics for a LOCA environment.

All containment structure piping penetrations consist of a basic containment insert, plus additional items, as required for the individual services. Two basic types of penetrations are used for piping systems:

1. Unsleeved - These penetrations consist of piping installed through the containment wall without a sleeve around the outside of the piping. Unsleeved penetrations are used for cold piping systems (temperature of the fluid in the piping is less than 150°F) when only one pipe passes through the penetration.
2. Sleeved - These penetrations have a sleeve around the outside of the piping. Sleeved penetrations are used for all multiple piping systems passing through one penetration and for all thermally hot (over 150°F) piping systems, both single and multiple. Typical piping penetrations are shown in Figure 15.5-10.

The main steam and feedwater penetrations are provided with adequate space between the piping and the sleeve for the necessary pipe insulation, and for a pipe coil outside the insulation through which component cooling water is circulated. This cooling coil reduces the temperature of the sleeve and prevents any excessive heating of the concrete in contact with the sleeve. All welded seams subjected to containment pressure are leaktested by introducing air through each test boss. In addition, the sleeve end is drilled and tapped, as shown in the details, so that any leakage between pipe wall and sleeve end can be detected during periodic containment leakage testing.

The liquid and gas pipe penetration assemblies, in nearly all instances, consist of more than one pipe inside the penetration sleeve. The diameter of the sleeve depends on the number and size of the pipes installed in a given penetration. Each of these penetrations was tested with air using the same procedure as that used for the steam and feedwater penetrations.

A 20-inch o.d. fuel transfer tube penetration is provided for fuel transfer between the refueling canal in the containment structure and the spent-fuel pool in the fuel building. The penetration consists of a 20-inch stainless steel pipe installed inside a 26-inch pipe, as shown in detail in Figure 15.5-10, Sheet 1. The inner pipe acts as the transfer tube, and connects the containment refueling canal with the spent-fuel pool. The outer pipe is welded to the containment liner, and provision is made, by use of a special seal ring, for air leak testing of all welds essential to the integrity of the penetration. Bellows expansion joints are provided on the outer pipe to compensate for any differential movement between the two pipes.

The equipment hatch is a 14-ft. 6-in. single closure penetration. The equipment hatch cover is mounted inside the containment structure and is double gasketed with a leakage test tap between the o-rings. The equipment hatch cover is provided with a hoist with two point suspension and a sliding rail for storage. A positive locking device is furnished to prevent circular swing. The equipment hatch was designed, fabricated, and stamped in accordance with the ASME Boiler and Pressure Vessel Code, Section III, Class B. A removable concrete tornado missile shield protects the equipment hatch and acts as equivalent shielding.

The equipment hatch opening is analyzed in two basic steps, using the actual space curve shape. In the first step, it is assumed that the pattern of stress concentration at the junction of the cylinder and the ring beam is the same as if the cylinder were of infinite radius and the ring and the cylinder were in the same plane; that is, the cylinder wall is assumed to be a flat plate. The forces are imposed on this flat plate at such a distance from the opening that they are not influenced by the opening. These forces are membrane meridional (vertical) loads, circumferential (hoop) loads, and tangential shear loads. An outward longitudinal force is delivered to the inside face of the ring beam by a bearing plate which is welded to the liner plate. This force is caused by incident pressure acting on the hatch.

The first step of analysis is performed by using the Stone & Webster Shell I computer program, which is based on general first-order linear plate theory modified by Sanders. This program is developed from a numerical analysis of shells of revolution as published by Bernard Budiansky and Peter Radkowski in the AIAA Journal, Vol. 1, No. 8, August 1963.

In the second step, the ring is isolated and analyzed, taking into account its actual geometry (curved in two planes). The loads imposed on the ring beam have been obtained at the junction of the ring and normal shell in the first step, plus the incident pressure loads and temperature effects on the ring surface.

The second step of the analysis is performed by means of the Stone & Webster computer program, *Reinforcing Opening in a Cylindrical Structure.* This program analyses structures curved in space about two axes. The loads imposed on the ring are the membrane forces at the juncture of the thickened ring and the normal shell, as obtained from the first step, and a modified incident pressure acting on the ring beam and hatch cover.

The analysis of the isolated ring is based on the theory of curved beams, as demonstrated in Seely and Smith, *Advanced Mechanics of Materials.* Although the theory in this textbook is confined to the one-dimensional, curved beam, the assumptions set forth are extended to the two-dimensional case. These assumptions permit a simplified calculation of the stresses and deformations.

The ring, loaded in two planes, is statically indeterminate to the sixth degree. The analysis for the ring in space consists of cutting the ring, imposing six unknown loads at the cut section, and solving for the six unknown forces by equating differential deflections and rotations on either side of the cut to zero. The six unknown forces are: direct force, a torsional moment, a transverse shear, a radial shear, and bending moments about two axes. The curvature of the ring is considered in obtaining the bending moment strains and effects on total strain energy.

An emergency airlock is provided through the equipment hatch for emergency access to the containment. The airlock is flanged to the outside of the equipment hatch cover utilizing a double o-ring seal, and has an outside diameter of 6 ft 0 in., and a length of 12 ft 8.50 in. A 30-inch-diameter door is located at each end of the air lock. The air lock doors, which swing toward the center of the containment, are interlocked so that one door cannot be operated unless the other is closed. These are mechanical interlocks, and provisions have been made for deliberate violation of the interlock by use of a special tool. This tool shall be kept under administrative control.

Each door is equipped with a valve for equalizing the pressure across the door. At no time can the equalizing valves on both doors be open simultaneously, and in no case can an equalizing valve be open on one door while the other is operating.

The operations required at each station for engagement or release of the interlocks, for operation of the equalizing valve, and for opening or closing the door, are accomplished by rotation of a single handwheel. Provisions have been made to allow operation of the outer door from inside the containment and the inner door from outside the containment, in addition to local operation.

Both doors are designed to withstand the containment test pressure of 52 psig. Each door is also designed to withstand 8.0 psia pressure in the containment structure with full atmospheric pressure outside. The interior door is provided with an additional securing device to facilitate testing the air lock to the maximum test pressure when the containment structure is at 8.0 psia.

All shafts penetrating the door or bulkhead have double packing. A blind flanged emergency air port is provided on the air lock outside containment. A light is provided inside the air lock and is powered near the air lock for communication.

A track is provided for emergency air lock removal via a cart. The track consists of two continuously supported rails that extend through the equipment hatch barrel onto the platform. Chicago Bridge and Iron Company designed and installed the track inside the equipment hatch barrel, and Stone & Webster designed the identical mating rails on the platform.

The tornado missile shield outside the containment equipment hatch has been modified to provide a labyrinth passage to the air lock. The missile shield slabs are fastened to the equipment hatch platform, which consequently has been modified. The equipment hatch platform has sufficient structural steel to withstand tornado wind loads on the attached missile shields.

The design, fabrication, and testing of the emergency air lock was performed by Chicago Bridge and Iron Company according to the ASME Code Section III, Subsection NE, 1971 Edition through the Winter 1972 Addenda. Welder procedures and performance qualifications were controlled under ASME Code Section IX.

The personnel hatch is a 7 ft. 0 in. i.d. double closure penetration as shown in Figure 15.5-11. Each closure head is hinged, double gasketed with a leakage test tap between the o-rings. Both doors are interlocked so that in the event one door is open, the other cannot be actuated. Both doors are furnished with a pressure equalizing connection. The equalizing valves are manually operated by persons entering or leaving the personnel hatch. The personnel hatch was designed, fabricated and stamped in accordance with the ASME Boiler and Pressure Vessel

Code, Section III, Class B. The personnel hatch is externally protected from tornado missiles by concrete shield walls and roof.

An 18-inch-diameter manway on the inner door of the personnel airlock is also provided for emergency egress from the containment. A positive locking device prevents inadvertent opening of the emergency manway. Manway position indication is provided in the control room. Alarm indication is also provided in the control room, and on the control panels on either side of the personnel airlock inner door, to indicate whenever the manway locking bar is not in the proper position to prevent inadvertent opening of the manway.

Material for the liner and penetrations is carbon steel plates conforming to ASTM A442, Grade 60, which has a specified minimum tensile strength of 60,000 psi, a minimum guaranteed yield strength of 32,000 psi, and a guaranteed minimum elongation of 25% in a standard 2-in. specimen. The liner has sufficient ductility to tolerate local deformation without rupture. This material has a nil ductility transition temperature of -20°F, which is 80°F below the normal minimum shutdown temperature given in Section 5.4.1.

Steel items, except backing plates and anchors, gas testing channels, equipment hatch bolts, and equipment hatch nuts are made to fine grain practice and normalized. In addition, steel items other than the above have passed NDT tests performed in accordance with the following:

1. Material 5/8 inch and thicker was tested by the Drop Weight Test method in accordance with ASTM E 208.
2. Material less than 5/8 inch thick was tested by the Drop Weight Tear Test method as developed by the U.S. Naval Research Laboratory (NRL Report 6300).
3. Material 5/8 inch and thicker has an NDT no higher than -20°F.

The liner plates were ordered to conform to standard mill practice with regard to thickness tolerances. Therefore, the 3/8-inch-thick cylindrical shell liner plate ranges in thickness from 0.365 inches to 0.406 inches. The 0.50-inch-thick hemispherical dome liner plate ranges in thickness from 0.490 inches to 0.535 inches, and the 0.25-inch-thick flat base liner plate ranges in thickness from 0.240 inches to 0.285 inches.

Physical and chemical properties of materials used in the construction of the containment liner, weldability tests, and liner thickness were checked by the Stone & Webster Field Quality Control Organization on a random sampling basis.

All welding procedures and tests required in Section IX of the ASME Boiler and Pressure Vessel Code for Welding Qualifications were adhered to in the selection of weld rod material, weld rod flux, heat treatment, and qualification of the welding procedures and the performance of welding machines and welding operators engaged in the construction of the containment liner. The welding qualification included 180-degree bend tests of weld material. These procedures ensure that the ductility of welded seams was comparable to the ductility of the containment liner plate material.

Section III of the ASME Boiler and Pressure Vessel Code for Nuclear Vessels was used as a guide in the selection of materials.

Erection of the steel liner followed completion of the concrete mat. The 3/8-inch-thick steel wall liner was erected to approximately Elevation +60 ft. The 0.25-inch-thick mat liner plate was installed on top of the concrete foundation mat during this period. On completion of the wall liner to Elevation +60 ft. and completion of the mat liner, all welds were checked for compliance with the approved weld inspection and gas test requirements. Work on the liner was then stopped until the containment interior concrete structure was completed, the polar crane was erected, and the concrete containment wall was completed to ground grade (Elevation 26 ft. 6 in.).

The 3/8-inch-thick steel wall liner was erected from Elevation +60 ft. to Elevation +92 ft. 6 in., and the containment liner completed with the construction of the 0.50-inch-thick steel dome liner. A-1 welds were inspected and gas-tested for compliance with the weld requirements.

The reinforced concrete wall, above ground grade, was completed, following as closely as practical the construction of the wall liner.

The reinforced concrete dome was constructed upon completion of the dome liner.

The steel wall liner was braced internally and locally with temporary bracing to prevent distortion during concrete placement. The exterior concrete forms were supported from the placed concrete and tied to form a tension ring.

Cantilevered steel strongbacks were used in the construction of the concrete dome to support the steel dome liner against deformation due to the weight of reinforcing steel formwork and wet concrete. Strongbacks were cantilevered from the completed concrete of the dome.

The containment liner is not a coded pressure vessel, so there was no section of the ASME Boiler and Pressure Vessel Code for Nuclear Vessels directly applicable to its design and construction. However, to ensure that good engineering practices were followed, certain portions of Section III of the Code were reviewed for suggested guidance as to design and construction practices that should be incorporated in the liner specifications. Those sections reviewed for information were:

- N-511 Certification of Materials by Vessel Manufacturer
- N-512 Material Identification
- N-513 Examination During Fabrication
- N-514 Repair of Material by Welding
- N-515 Forming Shell Sections and Heads
- N-518 Attachments

- N-519 Cutting Plates and Other Products
- N-521 Welding Processes
- N-522 Welding Qualifications and Weld Records
- N-523 Precautions for Welding
- N-524 Assembly
- N-526 Finished Longitudinal and Circumferential Joints
- N-527 Miscellaneous Welding Requirements
- N-528 Repair of Weld Defects
- N-531 Preheating
- N-541 Modification of Section IX - Welding Procedure Qualification Requirements
- N-611 Inspection, General
- N-612 Qualification of Inspectors, Engineering Specialists, and Inspection Agencies
- N-613 Access for Inspector
- N-614 Inspection of Materials
- N-615 Marking on Plates and Other Material
- N-616 Final Inspection
- N-620 Inspection of Welding
- N-622 Check of Welder and Welding Operator Performance Qualifications
- N-623 Check of Nondestructive Examination Methods
- N-625 Ultrasonic Examination of Welded Joints
- N-626 Magnetic Particle Examination
- N-627 Liquid Penetrant Examination
- N-713 Pneumatic Test
- N-714 Pressure Test Gauges

The liner attachments are Nelson concrete anchors, welded on a triangular pattern to the wall and dome liner, and cast in the containment concrete as the concrete was poured against the liner. The attachment spacing was determined by the procedure (Reference 6) set forth for buckling of a cylindrical shell under combined axial and uniform lateral pressure where each attachment constitutes a buckling wave nodal point and was so spaced that the critical buckling stress will take place in plastic range of the liner material. The liner dome was treated in a similar manner. Maximum variation from the correct stud location, where relocation was necessary to avoid an obstruction, did not exceed 1.50 inches. The bottom mat liner was covered with 1.50- to 2-foot-thick reinforced concrete slab to protect it from both pressure and temperature loadings, so that it will remain virtually unstressed.

All penetrations are anchored into the concrete containment structure wall with a loading resistance level greater than the plastic strength of the penetration pipe. Openings in the liner plate are reinforced with reinforcing plate, and/or collar, sized to develop the full relief of the liner plate. The stress around each reinforced opening was analyzed in accordance with the appropriate procedure (Reference 7).

Departure from the original specified out-of-roundness tolerance of the reactor containment liners was necessary due to erection difficulties. Attempts were made to obtain the specified tolerance by means of an adjustable ring girder and supplementary anchorage to the cofferdam. As work progressed above the cofferdam level, it was found that it was impractical to obtain the specified liner tolerance.

A thorough review was made of the necessity for this close tolerance, and it was found unnecessarily restrictive.

The liner shell and dome are studded to the concrete and the plate is essentially plane within an equilateral triangle, 12 inches at the base and bounded by studs at the apexes of the triangle. The response of each individual triangular element to its own particular loading system establishes the adequacy of the structure as a whole. Therefore, actual roundness of the shell has no effect on liner performance.

The following revised out-of-roundness tolerances were adopted after a thorough review of the problem.

1. The out-of-roundness tolerance shall not exceed plus or minus 3 inches from the true radius.
2. The maximum plus or minus deviation from a true circular form shall not deviate more than 0.25 inches from a straight line in any 14-inch space in any plane in any location on the liner.

The revised out-of-roundness tolerances have no adverse effect on the buckling strength of the liner, and ensure that plate buckling between studs will not occur in the elastic range.

The adjustable ring girder was found to be of limited value during the erection of the liner, due to the many liner penetrations and the stiffness of the liner shell. Therefore, the ring girder was used for rounding the shell only in areas where its application was found advantageous by the liner fabricator.

15.5.1.9 **Materials**

See Sections 15.5.2.2, 15.5.2.3, and 15.5.2.4 for descriptions of the construction materials used for the Reactor Pressure Vessel Head Replacement Project.

15.5.1.9.1 Concrete

The description of concrete materials is given in Section 15.3.1.

See Section 15.5.2.4 for the description of the concrete used for the Reactor Pressure Vessel Head Replacement Project.

15.5.1.9.2 Porous Concrete

Porous concrete is used under the base mat to provide drainage for the containment structure. The type of concrete is formed by the omission of the fine aggregate from a standard structural concrete mix. The mix was designed to have a 28-day compressive strength greater than 1000 psi.

Water porosity tests were performed earlier in an independent laboratory for porous concrete, using 6-inch by 12-inch cylinders prepared in the laboratory by compacting the material in three layers with standard tamping rods. A varying number of strokes, ranging from 10 to 40 for each layer, were used for different cylinders. After the concrete test cylinders had been properly cured, the amount of water that would flow through the 12-inch length of specimen during a three-minute period with a constant head of 4 inches of water above the top of each cylinder was determined. Results indicated water porosities of from 28 to 47 gpm/ft^2, depending upon the amount of compaction and resulting density of the cylinders.

The porosity determined by the laboratory tests indicated that the four-inch porous concrete layer under the base mat provides adequate drainage, since the leakage through the membrane waterproofing of the container would be minor. This layer serves as the collection means for the seepage removal system in the mat, described in Section 15.5.1.3.

15.5.1.9.3 Reinforcing Steel

Special large-size reinforcing bars, No. 14 and No. 18, used in the construction of the reactor containment structure, are steel of 50,000 psi minimum yield point, conforming to Grade 40 of the *Standard Specification for Deformed Billet-Steel Bars for Concrete Reinforcement,* ASTM A615 as modified to meet the following chemical and physical requirements:

- Carbon 0.35% maximum
- Manganese 1.25% maximum

• Silicon	0.15 to 0.25%
• Phosphorus	0.05% maximum
• Sulphur	0.05% maximum
• Minimum yield strength	50,000 psi.
• Elongation	16% minimum in a 2-inch test sample
• Tensile strength	70,000 to 90,000 psi

For these special chemistry bars, all ingots were identified and all billets were stamped with identifying heat numbers. All bundles of bars were tagged with the heat number as they came off the rolling mill. A special stamp marking was rolled into all bars conforming to this special chemistry, to identify them as processing the chemical and mechanical qualities specified.

See Section 15.5.2.3 for the description of the reinforcing steel used for the Reactor Pressure Vessel Head Replacement Project.

The engineers' quality assurance inspectors witnessed, on a random basis, the pouring of the heats and the physical and chemical tests performed by the fabricator. Bars containing inclusions, or failing to conform to the required chemical and physical requirements, were rejected.

One 12-inch-long test sample was furnished to the engineers from a finished bar from each heat of the special chemistry rebars, to permit independent verification of physical and chemical analysis tests by the engineers.

Test specimens for the special chemistry rebars conformed to Section 10.1.1 of ASTM A615 and were Standard 0.505-inch-diameter specimens with 2-inch gauge length. Rate of loadings was such that the tension-tested sample was brought to the yield point in not less than 2 minutes.

For containment structure, reinforcing steel, consisting of No. 11 bars and smaller, is of 40,000 psi minimum yield point, conforming to Grade 40 of the *Standard Specification for Deformed Billet-Steel for Concrete Reinforcement,* ASTM A615.

The reinforcing steel for structures other than the containment structures is described in Section 15.4.3.

15.5.1.9.4 Cadweld Splices

Cadweld reinforcing steel splices, Type "T" full tension splices, as manufactured by Erico Products, Inc., Cleveland, Ohio, were used to splice 50,000 psi minimum yield point reinforcing bar sizes No. 14 and No. 18. These splices, including the sleeves, develop tensile strengths not less than 90% of the minimum ultimate strength of the reinforcing bar. The average value of two or more successive splices develop at least the minimum ultimate strength of the rebar. Information for splices other than No. 14 and No. 18 reinforcing bars is given in Section 15.4.3.

See Section 15.5.2.3 for the description of Cadwelds, including operator qualification and tensile testing, used for the Reactor Pressure Vessel Head Replacement Project.

15.5.1.9.5 Waterproofing Membrane

The waterproofing membrane is a flexible polyvinyl chloride sheet having a minimum thickness of 40 mils. Associated adhesives and tapes consist of the membrane manufacturer's recommended material for the application conditions.

15.5.1.10 **Construction Procedures and Practices**

After performing the general excavation described in Section 15.4.4, two 149-ft. 5.25-in.-diameter cofferdams were constructed, one for each reactor. The cofferdams consist of interlocking steel sheet piles supported by a system of heavily reinforced concrete internal ring wales. The top of the sheet piles is at Elevation +10 ft. and tip grade is at Elevation -48 ft. The interior of the cofferdams was excavated to approximately Elevation -41 ft. Seepage drains were then driven through a 12-inch layer of crushed stone placed in the bottom of the excavation, as described in Section 15.5.1.3.

A 2-inch-thick concrete leveling slab was placed over the crushed stone and 40-mil-thick vinyl waterproof membrane placed over this concrete. A 4-inch layer of porous concrete was then placed over the membrane to protect the membrane and to serve as an internal drainage system, as described in Section 15.5.1.12.

Porous concrete was also placed around the sides of the cofferdam to fill the space between the cofferdam and the edge of the concrete mat, and to provide a form for the mat concrete. The waterproof membrane was extended vertically in this area, and protected by concrete block.

The reinforcing steel, steel bridging bars as described in Section 15.5.1.8, and other miscellaneous steel inserts required in the containment mat were placed, and the concrete poured. The mat was constructed in six sections.

The 3/8-inch-thick steel wall liner was then erected to Elevation +60 ft on the containment wall. The steel mat liner plates were installed on top of the concrete mat. All welds were checked for compliance with the approved weld inspection and gas test requirements. The containment interior concrete structure was then built on the mat liner. On completion of the interior concrete structure, the polar crane was erected.

The exterior containment concrete wall was constructed to approximately Elevation 24 ft. 6 in. during the construction of the interior concrete. On completion of the concrete substructure, a vinyl waterproof membrane was attached to the exterior concrete surface with adhesives. The membrane completely encloses the containment structure below grade.

The space between the cofferdam and the containment structure was then backfilled with crushed stone compacted in 6-inch layers. A 2-foot-thick layer of compacted impervious fill was placed at Elevation -4.0 ft. to seal the area and to minimize the amount of ground water seeping into the area.

The liner was then completed and finished with the construction of the 0.50-inch-thick steel dome, with all welds inspected and gas-tested. The steel dome liner was supported during erection with open web steel trusses.

See Section 15.5.2.2 for the description of the restoration of the steel liner during the Reactor Pressure Vessel Head Replacement Project.

The reinforced concrete wall above ground grade was completed, following as closely as practical the construction of the wall liner.

The completed steel wall liner was braced internally and locally with temporary bracing to prevent distortion during concrete placement. The exterior concrete forms were supported from the preceding concrete.

Cantilevered steel strongbacks were used in the construction of the concrete dome to support the steel dome liner, reinforcing steel, formwork, and wet concrete against deformation. Strongbacks were cantilevered from the completed concrete of the wall or the dome.

Careful inspection of the dome was maintained during concrete placing and until the concrete had definitely taken initial set. Concrete buckets used during the first two lifts of the dome were limited to 2 yd^3 in size. Bucket sizes were increased after the second lift had set, when placing results of these lifts were satisfactory and warranted such a move.

Concrete in the wall and dome of the containment structure was poured in uniform 6-foot lifts around the entire circumference. Each lift was constructed in approximately 18-inch layers.

See Section 15.5.2.4 for the description of the concrete used for the Reactor Pressure Vessel Head Replacement Project.

Concrete forms were used on the exterior of the concrete dome to a line 50 degrees above the horizontal. The permanent steel liner served as the inner form for pouring concrete. For the area where exterior forms were used, the concrete points were in horizontal planes. Above the 50 degree line, the remainder of the dome concrete was poured as one lift.

Particular care was taken to check the special markings of the No. 14 and No. 18, 50,000-psi minimum-yield rebars for the containment structure.

See Section 15.5.2.3 for the description of welded splices and Cadwelds, including operator qualification and tensile testing, used for the Reactor Pressure Vessel Head Replacement Project.

Welded splices conform to *Recommended Practices for Welding Reinforcing Steel, Metal Inserts, and Connections, in Reinforced Concrete Construction,* AWS D12.1. Bars spliced by metallic arc welding develop not less than 90% of the minimum ultimate strength of the reinforcing bar, and the average of two or more successive splices develop at least the minimum ultimate strength of the bar.

Structural ductility was maintained by staggering critical splices where possible. Full scale pressure tests conducted in May 1967, on a recently completed concrete containment structure (Reference 8) in which similar Cadweld splices and welded splices were used, showed no stress concentrations or lack of structural ductility. Locations of splice groups were not discernible from inspection of the test crack patterns.

All Cadweld Process Type "T" joints were visually inspected. The visual inspection included inspection of the ends of the bars for dryness and cleanliness prior to fitting the sleeve over the ends. It also included inspection of the completed splice for properly filled joints to ensure that filler metal was visible at both ends of the sleeve and at the top hole in the center of the sleeve. Randomly selected splices were removed from the structure and strength-tested for compliance with the specification. Joints that did not meet all these inspection criteria were replaced.

Randomly selected Cadweld Type "T" splices were removed from the containment structure and tensile-tested for compliance with the specifications, in accordance with the following schedule:

1. One out of first 10 splices.
2. Three of next 100 splices.
3. One out of each subsequent unit of 100 splices.

Welding inspection of reinforcing bars was by quality control inspectors. Radiographic inspection, dye-penetrant inspection, magnetic-particle inspection, or other nondestructive inspection methods for welded joints was performed on a random basis under the direction of the Senior Quality Control Engineer.

All welds were visually inspected. Any cracks, porosity, or other defects were removed by chipping or grinding until sound metal was reached, and then repaired by welding. Peening was not permitted.

Completed welded splices were selected on a random basis and removed from the structure with suitable lengths of adjacent bars. These removed splices were tensile-tested for compliance with the specifications in accordance with the same schedule followed for the Cadweld Type "T" splices.

Tack welding of special chemistry rebar was not permitted.

15.5.1.11 **Missiles and Piping Rupture**

15.5.1.11.1 Interior Missiles

Most of the high-pressure piping and equipment of the primary coolant system is located within containment cubicles protected by reinforced concrete walls and floors with a minimum thickness of 2 feet. The control rod drive mechanisms are provided with a separate missile shields (reinforced concrete for Unit 1 and steel for Unit 2). These structures will terminate the flight of any conceivable missile. Openings in the charging floor required for ventilation or access are covered by steel grating, which is designed to provide adequate missile protection. Openings in cubicle walls for overpressure blowoff protection are directed in a manner that will minimize the possibility of missiles striking the containment liner. An analysis of the missile hazard has been performed and the conclusions are as follows:

> Missiles could be either concrete or steel. Because of lower density and lower strength, a concrete missile would have to be an order of magnitude heavier than a steel missile of comparable diameter and velocity for it to cause the same damage on impact with a steel shell. Also, in the context of the design-basis accident, there are more potential steel missiles and these have been studied in detail.

The most penetrating steel missile for a given mass and velocity would be rod-shaped, impacting end-on; therefore, rods of various diameters and weights have been investigated.

Missile velocities of 100 fps might be generated by rupture of a reactor coolant loop[1], and this value has been used with penetration equations developed by D. A. Davenport (Reference 9) to estimate their penetrating capability.

Table 15.5-3 summarizes the results of the analysis. Inspection of these results indicates that, except for the containment liner, at 100 fps, the required weight and dimensions for penetration of the metal thicknesses of interest are not credible for missile sizes that can be postulated within the reactor containment. The metal thicknesses shown in the table bracket the thicknesses of interest for the containment liner and piping systems. The analysis for the containment liner does not consider the added resistance to penetration afforded by the interaction between the concrete containment structure and the containment liner. This added resistance will not permit penetration by missiles of credible weight and size. Major components, such as the steam generator, have greater shell thicknesses than the values in the table, and therefore will not be penetrated by the postulated missiles.

All potential missiles were evaluated, and those that constitute a hazard to either the liner or adjacent equipment, by virtue of their velocity and/or size, are restrained by local barriers or other mechanical means.

1. As discussed in Section 15.6.2, it is no longer necessary to consider the dynamic effects of a postulated rupture of the primary reactor coolant loop piping. However, pipe ruptures of other high-energy lines are still postulated.

15.5.1.11.2 Exterior Missiles

The Surry Power Station site is approximately 12 miles from the nearest commercial airport at Newport News, Virginia, and 15 miles from Langley Air Force Base. The site is not on the normal approach path to either of these air fields.

An analysis of hypothetical aircraft accidents indicates that the most likely missile that might penetrate the reactor containment would be a turbojet rotor. Calculations show that the 2-ft. 6-in.-thick containment dome would withstand without penetration the direct impact of a 1500-lb rotor impacting at a velocity of 400 mph. The 4-ft. 6-in.-thick containment walls would withstand a similar missile impacting at a velocity of 980 mph. These velocities are considerably in excess of low-level aircraft approach speeds.

Tornado-generated missiles are discussed in Section 15.2.3, and include two potential missiles:

1. Missile equivalent to a wooden utility pole 40 feet long, 12 inches in diameter, weighing 50 lb/ft^3, and traveling in a vertical or horizontal direction at 150 mph.
2. Missile equivalent to an automobile weighing one ton, traveling at 150 mph. Neither of these missiles would penetrate the reactor containment.

15.5.1.11.3 Pipe Rupture Incident

The containment internal structure is designed to accommodate the loading due to rupture of the reactor coolant and connecting piping[1], or main steam or feedwater piping. Incident rupture was considered in only one line at a time. The support system was designed to preclude damage to or rupture of any of the lines as a result of the incident. The snubber and key systems are designed to transmit rupture thrusts from a steam generator into the containment internal structures. In determining the steam generator support reactions, the system was reduced to a dynamic model consisting of a suitable number of masses and resistance elements under impulse loading. The structural support system resilience and mass was included in the model. The dynamic problem was solved by numerical methods, using a thrust-time history as loading. Resistance, dynamic amplification of the thrust, and rebound forces were calculated versus time. Design of the support system was based upon stress levels defined in Section 15.5.1.8. The reactor vessel and support system were similarly treated.

The steam lines are strapped to the crane wall at intervals selected to prevent a whipping pipe from contacting the liner. The straps are designed so that no interference with the normal thermal expansion modes of the steam lines results.

1. As discussed in Section 15.6.2, it is no longer necessary to consider the dynamic effects of a postulated rupture of the primary reactor coolant loop piping. However, pipe ruptures of other high-energy lines are still postulated.

15.5.1.12 Ground Water Protection and Corrosion

The ground-water level external to the membrane protection of the exterior surfaces of the containment structure will be kept below the top surface of the foundation mat by pumps, as described in Section 15.5.1.3.

If water penetrates or otherwise circumvents the membrane, it drains to a layer of porous concrete directly below the mat and above the membrane. This 4-inch-thick layer of porous concrete serves as a horizontal drain under the entire structure. The porous layer is vented by two 4-inch-diameter pipes that extend from the underside of the mat into a subsurface cubicle adjacent to the outside of the containment structure. This cubicle is inside the waterproof membrane. Access is provided by a concrete shaft from ground level. The 4-inch-diameter vent pipes are installed to discharge water to the floor of the cubicle at a level three feet below the mat liner; thus, flooding of the cubicle would have to occur before any hydrostatic head would be applied to the steel liner. A water level alarm is installed in the cubicle, and pumps are used as necessary to remove the water. Vertical drainage to the base of the mat is aided by three vertical inspection shafts, and various tunnels and cubicles located adjacent to the exposed exterior face of the concrete containment wall, in which the concrete is exposed.

Cathodic protection is not provided, since adequate corrosion protection of the embedded reinforcing is otherwise provided. Research by the National Bureau of Standards and other references indicates that cathodic currents damage the bond between the reinforcing steel and concrete. This bond softening is due to the gradual concentration of sodium and potassium ions. In time, the alkali concentration becomes strong enough to attack the steel.

The surface of the steel liner in contact with concrete is not subject to corrosion because of the alkaline nature of the concrete. The interior exposed surface of the liner is protected by one coat of inorganic zinc silicate primer with one top coat of epoxy enamel. These materials were used during construction. The repair coatings currently used are selected in accordance with administrative controls. No other protective coatings or insulation are considered necessary.

15.5.1.13 Testing and Inservice Surveillance

15.5.1.13.1 General

The completed containment structure was tested for structural integrity by subjecting the structure to an air pressure test equal to 115% of the design pressure. The structure was first carefully surveyed, measured, and inspected for cracks prior to the test, and all measurements recorded. All measurements were related to an independent datum. The pressure was then raised in 10-psi increments to the 115% test pressure (52 psig) and held at that pressure for one hour. Pressure was then reduced to complete the containment liner leak rate test described in Section 5.3.

During the 48-hour period, visual examination was made of the containment exterior surface for cracks and crack patterns as well as distortion.

Visual and instrumented observations at each pressure increment were made of the containment response during the test. Crack patterns were observed and their development noted.

Temperature, barometric pressure, and weather conditions were recorded hourly during the test period.

A further detailed dimensional survey was made of the structure on completion of the tests to record recovery of the structure.

15.5.1.13.2 Test Instrumentation

Instrumentation was designed to provide control and information on containment response during the air pressure test. Measurements were made of the radial deflection of the containment wall at selected locations from the top of the mat to the spring line of the dome. Vertical deflections were measured at the top of the mat and at the top of the dome. Additional measurements were made around the equipment access hatch and in other areas where stresses were critical.

Strain gauges were attached to the steel liner to record strains at the junction with the mat liner, at mid-height, and at the spring line of the dome. Additional strain gauges were attached to the liner around the equipment access and personnel hatches.

Exterior visual observations, above grade, were obtained using engineer's scales attached to the structure and read by transits placed nearby. Transit measurements were calibrated with independent datum points. Readings obtained by this method were considered accurate to within 0.10 inch.

Exterior deformations below grade were measured by linear variable differential transducers (LVDTs) mounted in the two pits provided for this purpose. Linear variable differential transducers recorded displacements in mils, which is an accuracy in excess of that required. Linear variable differential transducers were also used to measure displacements of the concrete rings surrounding the equipment access and personnel access hatches.

Electrical strain gauge rosettes and conventional strain gauges, reading in microinches per inch, were used to monitor strains in the liner. Since major inaccuracies with this type of gauge have resulted from inadequate installation techniques, particular attention was given to the technique used.

Redundancy of instrumentation was obtained by multiplicity of points at which measurements were made, so that loss or damage to any one station was not critical.

The range of strains and deformations expected at the 45-psig test pressure was as follows:

1. Maximum vertical elongation of the structure, not more than 1.5 inches.
2. Increase in containment diameter, not more than 1.4 inches.

3. Maximum width of new cracks or increase in existing cracks, not more than 0.03 inch per crack.
4. After containment pressure was reduced to atmospheric, the residual width of new cracks or the increased width of existing cracks, not more than 0.01 inch.
5. There was no visual distortion of the liner plate.

The containment structure remained in the elastic range during the pressure test, and there was permanent distortion in the liner or in the concrete once the pressure was reduced to atmospheric or below. However, it was fully expected that there would be small residual cracks in the concrete as a result of shrinkage in the concrete.

Under the test program outlined herein, all instruments and measuring devices were installed just prior to the test, and normal care and protection was adequate. Items damaged for any reason were readily replaced at the initiation of the test.

15.5.1.13.3 Comparison of Test Results

The selection of a test pressure, which was 115% of design pressure, was based primarily on the fact that a similar reinforced concrete containment structure for Connecticut Yankee Atomic Power Plant has been tested and accepted at 115% of its design pressure; thus, a comparative case history of structural response has been created that permits valid comparison of similar design.

The selection of 115% test pressure also conforms to the ASME Boiler and Pressure Vessel Code, Section III, Nuclear Vessels, Subsection B, Requirements for Class B Vessels, paragraph N-1312(d). This relates to metal vessels that perform the same function as a reinforced concrete containment structure.

A comparison of stresses under 115% test pressure with those in the structure under incident conditions is given in Table 15.5-4. As a sensitivity analysis, the stresses associated with 125% pressure are also included. Incident stresses shown result from incident pressure, dead load, loads due to temperature effects on the steel liner, and temperature gradients through the concrete. Stresses resulting from earthquake combined with incident loads are shown separately.

Scaled load plots comparing moments, shears, tension, and deflections resulting from the structural proof test pressure with moments, shears, tension, and deflections due to the unfactored design incident conditions are shown in Figure 15.5-13. A comparison of the test load with the hypothetical incident load conditions should include a review of the load plots in Figure 15.5-2 Sheet 2. This shows the increase in moments, radial shear, hoop tension, vertical tension, and radial deflection (deformation) imposed on the structure by the incident and test load. It can be seen that the test load conditions exceed incident conditions in all cases, except that of radial deflection.

The distribution of stress varies between the structural elements under apparently similar load conditions because of the contradictory action of the containment steel liner. Under test conditions, the steel liner was in a state of biaxial tension and gave considerable assistance to the reinforcing steel, particularly to the longitudinal reinforcing. Under incident conditions, the steel liner is subjected to a point where it is restrained in compression by the reinforcing steel. This effect is greater in the dome than in the cylindrical wall, due to the increased thickness of the dome liner and the shape factor of the dome.

This also provides an additional factor of safety against ultimate failure of the structure. In the event of excessive yield in the reinforcing steel, the liner will act as a tensile membrane that would assist the reinforcing steel. This assistance would be significant, since the liner will bring a considerable reserve of energy to bear, for which design credit has not otherwise been claimed.

The test pressure of 52 psig, based on 115% design pressure, created stresses equal to or greater than the incident stresses in the following critical areas:

1. Foundation mat, where test stresses are 30 to 40% above incident conditions.
2. Large access openings, such as equipment and personnel hatches, where test stresses are comparable with incident stresses.

It is recognized that the average stress levels attained under the test conditions in the principal longitudinal and circumferential steel are below these stresses resulting from incident conditions. This is considered acceptable when the test is associated with dimensional strain measurements, when such a test provides confirmation of structural continuity and structural ductility with the concrete cracked, and when the steel is shown to carry the load in tension according to design assumptions.

An analysis of the crack pattern of the concrete under test conditions confirms stress distribution in the structure, and also reveals areas of stress concentrations. In fact, a pattern of severe local cracking would indicate structural weakness more effectively than considerations of average stress levels.

Measured response of the structure, as indicated by increase in height, diameter, and degree of recovery, together with measurements of local deformations, is extremely important in predicting structural response to incident conditions. The structural response to the test pressure is of sufficient magnitude to allow simple direct measurements of deformations without the need for high-precision methods of measurement.

In summary, it is not possible to exactly duplicate incident stress conditions with a pressure test. An increase in the test pressure above 115% would only preserve and amplify the present stress anomalies, without furnishing more meaningful data. In addition, such a test would endanger or damage the container by seriously overstressing critical areas, or it would require a container design modification directed specifically to withstand the higher pressure test without proportionate improvement in withstanding the incident condition. Modification of the containment design to obtain closer test verification of structural integrity under the test pressure would require specific redesigning for test conditions of the critical areas in the foundation mat and at the large openings. Such redesigning would not improve the capability of the containment structure to meet the incident load conditions. A design meeting both incident and test conditions is not considered practical in this type of containment design.

The 115% pressure test provided a valid test of all criteria areas with stresses equal to or greater than incident conditions; in less critical areas, the pressure test provided sufficient information to permit a reliable evaluation of the complete structural response under incident conditions.

The average anticipated crack width at the 45-psig test pressure was 0.015 inch.

A rectangular crack pattern was anticipated, with vertical cracks spaced 12 to 15 inches on centers, and horizontal cracks spaced approximately 2 feet on centers. Horizontal crack spacing was primarily controlled by the horizontal construction joints.

The average crack width was related to the anticipated increase in containment diameter, the anticipated vertical elongation of the structure, and the crack spacing. It was assumed that the total containment extension was equal to the sum of the number of cracks multiplied by the average crack width in each direction.

Maximum summer temperature and minimum winter temperature difference is approximately 95°F. Annual average temperature variation is 40°F at the station site.

During unit operation, the annual maximum thermal cycling temperature variation is approximately 45°F.

Ambient temperature variations of this magnitude, +20°F, or even the extreme +45°F, will not reopen by any significant amount the crack pattern created in the structure by the test pressure of 45 psig.

The width of thermal cycling cracks was significantly less than the 0.010 allowed for exterior members by ACI 318.

The stresses given in Table 15.5-4 are the results obtained from computer programs referred to in the following sections:

- Section 15.5.1.5 —*Numerical Analysis of Unsymmetrical Bending of Shells of Revolution*
- Section 15.5.1.4 —*Container Vessel Seismic Analysis*
- Section 15.5.1.5 —*Flat Circular Mat Foundations for Nuclear Secondary Containment Structures*
- Section 15.5.1.7 —*Nuclear Containment Structure Access Opening* - Stone & Webster Computer Program

At large openings, the stresses due to thermal load were obtained by converting the thermal effect to a pressure equivalent, as described in Section 15.5.1.5.

Since all of the shears in the wall and dome were taken by the reinforcing, the effects of shrinkage and creep are not included.

15.5.1.13.4 Inservice Surveillance Tests

Periodic structural testing of the containment structure is not planned, since it would provide no more information on the containment structure capability than that obtained from the initial test. In fact, periodic testing would cumulatively damage the concrete in the structure to the point where the test itself would be the major cause of structural deterioration.

The inservice stress and environmental conditions are not of a nature or magnitude such that any significant deterioration of the reinforcing steel or concrete could reasonably be expected, and periodic testing for structural purposes could be duplicated if at any time further tests were required. The minimum test level required to verify continued structural integrity would be no less than the 115%, or 52-psig initial test pressure.

Periodic inspection of the steel liner is accomplished by a type A leak rate test in accordance with 10 CFR 50 Appendix J. All welded joints and all penetrations of the liner are designed for periodic halogen gas testing.

In summary, no basis exists for attempting to develop structural performance information from leak rate tests conducted at moderate pressures.

15.5.2 Reactor Pressure Vessel Head Replacement Project (Applicable to Unit 1 and Unit 2)

The Reactor Pressure Vessel (RPV) Head Replacement Project created and restored a construction opening in the reactor containment structure in accordance with administrative procedures and the design control program. The opening was used to facilitate the movement of original and replacement RPV heads in and out of the reactor containment structure. The opening was restored to meet the original design bases of the containment structure.

15.5.2.1 **Codes and Specifications**

ACI 318-63 is the design code for the restored containment structure. The restored structure meets all applicable design loads and load combinations required by ACI 318-63.

Concrete placement, curing, and repair were in accordance with ACI 301-99 with the incorporation of Hot Weather Concreting per ACI 305R-99, as appropriate, or with the incorporation of Cold Weather Concreting per ACI 306.1/ACI 306R, as appropriate. The use of ACI 301-99 is in accordance with Section 2.2 of ANSI N45.2.5-74.

Concrete mix proportioning was per ACI 211.1-91 (reapproved 1997) in accordance with Table A of ANSI N45.2.5-74.

Bechtel specifications (References 11-18) address:

- reinforcing steel procurement, testing, and placement
- Cadweld reinforcing steel splices procurement, testing, and installation
- concrete mix design, testing and placement
- structural steel and materials procurement

15.5.2.2 **Liner Restoration**

The cut section of the containment liner plate was rewelded to the liner plate with a full penetration weld. The weld was tested to ensure no leakage. In addition, the full penetration weld was covered by a seal welded leak chase channel to facilitate testing.

Replacement material was purchased for the liner plate, Nelson studs, and leak chase channels. The Nelson studs, and leak chase channels were used for the reinstallation of the plate and the leak chase channel system. Reference 18 requires the liner plate material to be ASTM A-516-Grade 60 (or better), fine-grained and normalized.

15.5.2.3 **Reinforcing Steel Restoration**

The reinforcing steel bars cut during the creation of the opening were re-installed using Cadweld splices or welding, as required, in accordance with References 14, 15, and 19. Reinforcing steel bars that were damaged during the creation of the opening were repaired in accordance with References 13 and 19 or were replaced with reinforcing steel procured in accordance with Reference 12. New N18 reinforcing steel used for containment wall restoration conforms to either ASTM A615 Grade 60 and/or ASTM A706 Grade 60, and meets or exceeds the additional elongation and chemical composition requirements described in Section 15.5.1.9.3 for the containment structure existing reinforcing steel.

In lieu of the Cadweld testing protocol, described in Section 15.5.1.10, which was used during original construction, Cadweld testing was performed in accordance with Dominion’s Operational Quality Assurance Program Topical Report which includes:

- In-process testing of Cadweld splices in accordance with Subsubparagraph CC-4333.5.2 of ASME B&PVC Section III Division 2 (1995 Edition, 1996 Addenda).
- Cadweld Splice System Qualification in accordance with Subparagraph CC-4333.2 of ASME B&PVC Section III Division 2 (1995 Edition, 1996 Addenda).
- Cadweld Operator Qualification in accordance with Subparagraph CC-4333.4 of ASME B&PVC Section III Division 2 (1995 Edition, 1996 Addenda).

- Cadweld Testing Frequency in accordance with Subsubparagraph CC-4333.5.3 of ASME B&PVC Section III Division 2 (1995 Edition, 1996 Addenda).

To minimize the size of the construction opening, the Cadweld splice locations were not staggered as described in Section 15.5.1.10. Section 805 of ACI 318-63 does not require staggered Cadweld splices if the splice can develop in tension at least 125 percent of the specified yield strength of the reinforcing steel bar. The minimum acceptance criteria for the Cadweld splice testing in Reference 15 is that the minimum tensile strength of each sample tested shall be equal to or exceed 125 percent of the yield strength of the reinforcing steel bar. Also, the splicing scheme for the RPVH Replacement Project construction opening is similar to that used during the closure of the original construction opening.

15.5.2.4 **Concrete Restoration**

As discussed in Dominion's Operational Quality Assurance Program Topical Report commits to ANSI N45.2.5-74 (with clarifications) for satisfying the quality assurance requirements for installation, inspection, and testing of structural concrete during the operational phase of Surry Power Station. Section 2.2 of ANSI N45.2.5-74 requires that the installation, inspection, and test activities be performed in accordance with the latest codes. Tables A and B of ANSI N45.2.5-74 provide the requirements for the qualification and in-process testing of the concrete ingredients and concrete mix.

The concrete was replaced and the restored structure tested in accordance with ASME B&PVC Section XI, Articles IWL 4000 and IWL 5000, respectively. In accordance with the guidance of Table A of ANSI N45.2.5-74 concrete mix design is based on ACI 211.1-91 (reapproved 1997). The activities associated with placement of concrete were performed in accordance with References 11 and 17, which meet the requirements of ACI 301 and ANSI N45.2.5-74. In-process sampling, testing, and acceptance requirements for all repair material were in accordance with Table B of ANSI N45.2.5-74. Reference 11 provides the testing frequencies, sampling and testing standards, and acceptance criteria for concrete ingredients and concrete mix. The concrete had a minimum 5-day strength of 3000 psi.

The water used for the concrete mix was evaluated in accordance with the requirements of AASHTO T-26, as specified in Table A of ANSI N45.2.5-74. The water testing and acceptance criteria included in Reference 11 required that the water used during the restoration was free of harmful levels of contaminants.

The cement used in the new concrete was Type II Low Alkali (as defined in ASTM C 150).

For RPV Head Replacement Project, the restoration of the containment wall used size 57 (25 mm to 4.75 mm) coarse aggregate due to the limited size of the opening and the use of pour ports/bird mouths for concrete placement. Both fine and coarse aggregates were tested in accordance with the requirements of ANSI N45.2.5-74 to ensure acceptable physical characteristics and that they were free of harmful levels of alkali reactivity and deleterious substances (acceptance criteria are defined in ASTM C 33).

Admixtures used to modify the concrete mix properties met the requirements of ASTM standards and were used in accordance with the manufacturer's written procedures and applicable ACI standards (primarily ACI 211.1-91 (reapproved 1997) for mixing and ACI 301-99 for placement). Reference 16 prohibited the use of admixtures with chlorides. Uniformity of admixture lots was verified with Infrared Spectrophotometry in accordance with Table B of ANSI N45.2.5-74.

In its ready mix state, the new concrete had an air content of 4.5% (± 1.5%) at the point of placement. This is consistent with Table 6.3.3 of ACI 211.1-91 (reapproved 1997) for the maximum aggregate size being used in the concrete mix (1" for Size No. 57 coarse aggregate) and air-entrained concrete.

A water-reducing admixture was utilized in the concrete resulting in a maximum slump of 8 1/2 inches at point of placement based on the footnote to Table 6.3.1 of ACI 211.1-91 (reapproved 1997), which approves higher concrete slump (than the recommended 1 inch to 4 inch slump) when chemical admixtures are used provided that there are no signs of segregation or excessive bleeding.

15.5.2.5 **Post Modification Testing**

The nondestructive examination of the containment liner was in accordance with Safety Guide 19, Nondestructive Examination of Primary Containment Liners with the following changes: after vacuum box testing of the liner seam weld and installation of the channel, the channel to liner weld was tested by a static pressure test (decay test) with an acceptance criteria of zero leakage. Soap bubble testing was used to identify leakage. Leaking areas of the joint were repaired and retested. In addition, following the containment building pressure test, the channel was re-pressurized and an "as-found" LLRT, meeting ANS 56.8-1994 requirements, was performed.

Prior to placing the containment structure in-service, a containment pressure test that bounds the calculated peak containment internal pressure was performed in accordance with IWL Article 5000 of the ASME B&PVC Section XI. The surface of the replacement concrete at the temporary construction opening was examined in accordance with IWL-5250 prior to pressurization, at test pressure, and following completion of pressurization.

Table 15.5-1
CONTAINMENT STRUCTURAL LOADING CRITERIA

Case	Loading Combination	Required Load Capacity of Structure
1	Operating plus DBA	= (1.0 ± 0.05)D + 1.5P + 1.0 (T + TL)
2	Operating plus DBA plus operating-basis earthquake	= (1.0 ± 0.05)D + 1.0P + 1.0 (T + TL) + 1.5E
3	Operating plus DBA plus design-basis earthquake	= (1.0 ± 0.05)D + (1.25P) + (T' + TL') + 1.0HE
4	Operating plus 1.25 DBA and 1.25 operating basis earthquake	= (1.0 ± 0.05)D + (1.25P) + (T' + TL') + 1.25E
5	Operating plus tornado loading	= (1.0 ± 0.05)D + 1.0T' + 1.0C

Legend

DBA - Design-basis accident.

C - Load due to negative pressure and horizontal wind velocity resulting from tornado and missiles. For description of tornado, refer to Section 15.2.3.

D - Dead load of structure and contents including effect of earth and hydrostatic pressures, buoyancy, ice and snow loads. To provide for variations in the assumed dead load, the coefficient for the dead load components is adjusted by ±5% as indicated in the above formulas to provide the maximum stress levels.

P - Pressure load from DBA. Pressure for containment design is 45 psig.

T - Load due to maximum temperature gradient through the concrete shell and mat based on temperature associated with 1.5 DBA pressure.

T' - Load due to maximum temperature gradient through the concrete shell and mat based on normal operating temperature.

TL - Load exerted by the exposed liner based upon temperature associated with 1.5 times DBA pressure.

TL'- Load exerted by the exposed liner based upon temperatures associated with 1.25 times DBA pressure.

T - Load due to maximum temperature gradient through the concrete shell and mat based upon temperature associates with 1.0 times DBA pressure.

TL - Load exerted by the exposed liner based upon temperature associated with 1.0 times DBA pressure.

E - Operating-basis earthquake loading. Based on a ground acceleration of 0.07g horizontally at zero period and a damping factor of 5%. For description of the operating-basis earthquake, refer to Section 2.5.

HE - Design-basis earthquake loading. Based on a ground acceleration of 0.15g horizontally at zero period and a damping factor of 10%. For description of the design-basis earthquake, refer to Section 2.5.

Note: Normal wind loadings replace earthquake loads where they exceed earthquake loadings. Normal wind or tornado loads are not considered coincident with earthquake loads.

15.6 OTHER CLASS I STRUCTURES

Class I structures other than the reactor containment structure are listed in Table 15.2-1. The major structures include the auxiliary building, control room area, including switchgear and relay rooms; fuel building; emergency diesel-generator rooms; containment auxiliary structures that contain main steam and feedwater isolation valves, recirculation spray and low-head safety injection pump cubicles, auxiliary steam generator feed pump cubicle, and safeguards ventilation room; and circulating water intake structures, including the high-level canal.

The fuel building, the main steam and feedwater isolation valve section of the containment auxiliary structures, and the refueling water storage tanks are supported on reinforced-concrete mats on concrete-filled steel pipe piles. All other structures are soil-supported on reinforced-concrete mats or spread footings. All Class I structures designed to meet tornado missile criteria, as listed in Table 15.2-1, are enclosed with heavily reinforced, 2-foot-thick concrete walls and roof slabs with all openings shielded against missiles.

Class I structures are designed to resist the operating-basis earthquake without exceeding allowable working stresses, where allowable stresses are one-third above the normal applicable code normal working stress. For concrete structures, a 5% critical damping function is assumed, and the accelerations selected from the acceleration response spectrum curves are considered in conjunction with the natural frequency of each structure. A check has been made to ensure that collapse-type failures will not occur under the design-basis earthquake. For this condition, a 10% damping factor is assumed for concrete structures, and stresses are limited to not more than 120% of the minimum yield point stress. In practice, the controlling feature of the design of these structures was to the satisfaction of the operating-basis earthquake requirements with the limited 5% damping factor.

The high-level intake canal is formed by excavating to Elevation +5 ft. from an average grade of approximately 35 feet. Earth fill dikes constructed on either side of the canal bring the finished height to Elevation +36 ft. throughout the length of the canal. The interior surfaces of the canal are lined with a 4.5-inch-thick reinforced-concrete slab. Under drains and pressure relief valves are provided to prevent uplift of the concrete liner by unbalanced hydrostatic pressure.

15.6.1 Other Structures

All other structures are designed to adequately support all dead, live, and wind loads. Where necessary, subsurface walls and slabs are designed to resist the horizontal component of the soil with applicable surcharge and hydrostatic pressures.

Structural steel design conforms to the 1963 issue of the *Specification for the Design, Fabrication and Erection of Structural Steel for Buildings* of the American Institute of Steel Construction, except as noted herein. Plastic design methodology, in accordance with Part 2 of the 1969 issue of the Specification for the Design, Fabrication and Erection of Structural Steel for Buildings of the American Institute of Steel Construction, has been used to modify the main bents of the Fuel Building steel superstructure. All concrete work is designed in accordance with the *Building Code Requirements for Reinforced Concrete*, serial designation 318-63 of the American Concrete Institute. Access and egress requirements, as well as fire ratings of walls and floor systems, satisfy the requirements of the Basic Building Code of the Building Officials Conference of America, 1966 issue.

Under the design-basis accident loading, the allowable stresses do not exceed 90% of the minimum yield strength of the structural steel. From mill test reports, the yield strength of structural steel is 42,000 psi, with an ultimate strength of 63,000 psi. Using a minimum yield of 36,000 psi for A36 steel, the design-allowable stress is 90% of 36,000 = 32,400 psi.

Design-allowable stress for structural steel is $\frac{32,400}{63,000}$ = 51.5% of the ultimate strength.

Tests on special reinforcing steel with a minimum yield of 50,000 psi have resulted in yield strength of 55,500 psi, with an ultimate strength of 90,000 psi; with a design-allowable stress of 90% of minimum yield, the design-allowable stress is $0.9 \times 50{,}000 = 45{,}000$ psi.

Design-allowable stress on reinforcing is $\frac{45,000}{90,000}$ = 50% of ultimate strength.

Concrete continues to increase in strength beyond the 28-day strength of 3000 psi. The Bureau of Reclamation Concrete Manual indicates that Type II cement concrete can be expected to increase in strength approximately 30% in 1 year from the 28-day strength.

Approximate 28-day strength for 3000-psi concrete from test reports = 3800 psi

Design allowable 85% of 3000 psi = 2500 psi

Ultimate strength in 1 year = $1.3 \times 3800 = 4950$ psi

Design allowable is $\frac{2500}{4950}$ = 51% of ultimate strength in 1 year.

The above figures show that, for structures designed for the design-basis accident loading, structural steel and reinforced concrete are designed at approximately 50% of their ultimate strength. In the design of concrete structural members under design-basis accident conditions, concrete strength is not the controlling factor.

Allowable soil bearing values for foundations are determined from the soil boring logs and the results of triaxial shear tests of the soil. Applicable factors of safety are applied to the test results.

15.6.2 Reactor Coolant System Supports

The reactor coolant system includes the reactor vessel, three steam generators, three reactor coolant pumps, and a pressurizer for each unit. Structures are provided to support these heavy vessels and equipment, and to ensure system integrity during normal operation and design-basis accident conditions.

The primary equipment supports of the reactor coolant system are designed to withstand the design-basis earthquake acting simultaneously with an instantaneously applied pipe break. The original configuration of the Reactor Coolant System (RCS) equipment supports included ten large-bore (12-inch diameter) hydraulic snubbers per loop to carry the loads from postulated reactor coolant system, main steam line and feedwater pipe ruptures.

Subsequently, studies to address Unresolved Safety Issue A-2 (effects of asymmetric pressure loads resulting from PWR primary loop ruptures) concluded that the probability of rupture of the primary coolant loop is extremely small, and that the presence of a pipe crack could be detected by leakage well before the crack grew to critical size which would cause rupture. These “leak-before-break” analyses, documented in References 1 and 2, were submitted to the NRC on behalf of the Westinghouse Owners Group, which included Surry Power Station.

NRC Generic Letter 84-04, *Safety Evaluation of Westinghouse Topical Reports Dealing with Elimination of Postulated Pipe Breaks in PWR Primary Loops*, provided the NRC staff safety evaluation concluding that, provided certain specific conditions are met, an acceptable technical basis exists so that asymmetric pressure loads resulting from pipe breaks in the reactor coolant system primary loop need not be considered as a design basis for the reviewed plants. The plant-specific conditions were a limitation on the maximum bending moments in the primary loop piping for normal operating and seismic loadings, and the existence of an adequate reactor coolant leakage detection system. The affected plants were encouraged to submit requests for partial exemptions from General Design Criterion 4 (GDC-4), to permit elimination of pipe rupture restraints required to protect against these previously postulated breaks.

Because a number of the large-bore snubbers served primarily as pipe rupture restraints, Surry proceeded with an exemption request to allow elimination of 6 of the 10 snubbers per loop, based on application of leak-before-break in accordance with Generic Letter 84-04. (The other 4 large-bore snubbers on the upper steam generator support were required for lateral loads due to a postulated longitudinal split of the main steam line.) The reactor coolant loop system was re-evaluated with all snubbers on the steam generator lower support and the reactor coolant pump supports eliminated, to assure that the conditions of pressure, deadweight, thermal, seismic, and remaining pipe rupture effects, would not result in unacceptable stress levels or factors of safety. Largely independent analyses were performed by Westinghouse and Stone & Webster in accordance with the original division of design responsibilities. Interface force allowable limits at NSSS boundaries were assured and support design load interfaces were reviewed for acceptance.

The exemption request to allow elimination of 18 snubbers per unit was filed with the NRC on November 5, 1985 (Reference 3). The detailed technical basis (Reference 4) provided separate attachments addressing load evaluation, leakage detection, and net safety balance. The proposed design changes were discussed with the NRC and resulting NRC concerns were addressed (References 5 & 6). The GDC-4 “limited scope” revision (Reference 7) was subsequently published (effective May 12, 1986) permitting the use of leak-before-break technology to justify elimination of the dynamic effects of primary loop breaks from the design basis of PWRs. With the publication of the notice of revision to GDC-4, a license amendment to the plant design basis was requested to implement the snubber reductions under the new rule (Reference 8). By letter dated June 16, 1986, the NRC approved the license amendment (#108) for both units (Reference 9). The snubber eliminations were implemented by Design Changes 85-04-1 and 86-12-2.

Subsequently, the NRC issued Generic Letter 87-11, *Relaxation of Arbitrary Intermediate Breaks* which provided the revised Mechanical Engineering Branch position eliminating the need to postulate Arbitrary Intermediate Breaks. As stated in the generic letter, the elimination of Arbitrary Intermediate Breaks allows elimination of the associated pipe whip restraints and jet impingement shields. Because the stresses in the main steam lines inside containment are well below the stress criteria for required mandatory intermediate breaks, the only breaks which need to be postulated are terminal end breaks which do not apply lateral loads to the steam generator. Therefore, the governing lateral loads on the steam generator become those imposed by the main feedwater break, which are low enough that only a single snubber in each pair will be required to carry the load. Analyses were performed by Westinghouse and Stone & Webster similar to those performed for the earlier large-bore snubber reduction to ensure piping stress levels and component factors of safety were acceptable. In addition, it was necessary to verify that the basis for the previous license amendment based upon leak-before-break of the primary loop remained valid. Comparison of results with the lower large-bore snubber of each pair removed as a result of eliminating the main steam line split vs. the results in the previous leak-before-break submittals, confirmed that there were no significant reduction in margins of safety. Therefore, elimination of the lower large-bore snubber of each pair does not compromise the bases for the previous leak-before-break analysis, namely:

1. The loading on the primary loop piping is still enveloped by the generic analyses submitted on behalf of the A-2 Owners Group, and accepted by the NRC staff in Generic Letter 84-04, and specifically for Surry by NRC letter dated June 16, 1986; and
2. The reactor coolant system equipment, piping, and supports continue to have acceptable margins of safety under licensed loading conditions other than the now-eliminated ruptures of the primary loop piping and Arbitrary Intermediate Break of the main steam lines.
3. The application of Leak-Before-Break (LBB) methodology to justify the elimination of postulated line breaks of reactor coolant loop piping from the structural design basis was subsequently extended to the Surry Units 1 and 2 Reactor Coolant System (RCS) branch piping including: the Pressurizer Surge, Residual Heat Removal (RHR), Accumulator, Loop Bypass, and Safety Injection (SI) piping up to each line's first pressure isolation valve. The technical evaluation justifying the extension of LBB to the RCS branch piping was performed by Westinghouse in WCAP-18491-P/NP, Rev. 0 (Reference 12), and submitted to the NRC for review and approval (Reference 13). The NRC approved the extension of LBB to the RCS branch piping noted above in their Safety Evaluation Report (SER) included in Surry Units 1 and 2 License Amendments 304 and 304 for the 80 year period of extended

operations (Reference 14). The technical basis provided in WCAP-18491-P, Rev. 0, and approved by the NRC SER, is based on the following conclusions:

a. Stress corrosion cracking (SCC) is precluded by use of fracture resistant materials in the piping system and controls on reactor coolant chemistry, temperature, pressure, and flow during normal operation. Note: Alloy 82/182 welds do not exist at the Surry Units 1 and 2 Surge, RHR, Accumulator, Loop Bypass and SI lines.

b. Water hammer should not occur in the Surge, RHR, Accumulator, Loop Bypass and SI line piping because of system design, testing, and operational considerations.

c. The effects of low and high cycle fatigue on the integrity of the Surge, RHR, Accumulator, Loop Bypass and SI line piping are negligible.

d. Ample margin exists between the leak rate of small stable flaws and the capability of the Surry Units 1 and 2 Reactor Coolant System pressure boundary leakage detection systems.

e. Ample margin exists between the small stable flaw sizes of item (d) and larger stable flaws.

f. Ample margin exists in the material properties used to demonstrate stability of the critical flaws.

For the critical locations, postulated flaws will remain stable and because of the ample margins described in d, e, and f above.

Based on loading, pipe geometry, welding process, and material properties considerations, enveloping critical (governing) locations were determined at which LBB crack stability evaluations were made. In the Extended Leak Before Break (eLBB) analysis (Reference 12), through-wall flaw sizes were postulated which would cause a leak at a rate of ten (10) times the leakage detection system capability of the plant. Large margins for such flaw sizes were demonstrated against flaw instability. Additionally, the impact of fatigue crack growth was assessed and shown not to be an issue for the Surge, RHR, Accumulator, Loop Bypass and SI line piping; therefore, the LBB conditions and margins are satisfied for this piping. Based on the WCAP (Reference 12) evaluation discussed above and the associated NRC SER (Reference 14), it was demonstrated that the dynamic effects of the pipe rupture resulting from postulated breaks in the Surge, RHR, Accumulator, Loop Bypass and SI line piping need not be considered in the structural design basis of Surry Units 1 and 2 for the 80 year period of extended operations.

15.6.2.1 **Design Basis**

All supports in the reactor coolant system are designed to withstand the design-basis earthquake acting simultaneously with an instantaneously applied pipe break. As discussed above, it is no longer necessary to consider the dynamic effects of a postulated rupture of the primary reactor coolant loop. However, single ruptures are postulated to occur in either the pressurizer surge or other reactor coolant branch lines, the main steam piping, or the main feedwater piping. In general, two types of piping failures are considered: a double-ended rupture, or a longitudinal rupture on either the horizontal or vertical axis of the pipe. The longitudinal rupture area was taken to be equal to the area of the double-ended rupture for these piping failures. Stresses in the main steam piping inside containment have been reviewed and, in accordance with NRC Generic Letter 87-11, are sufficiently low that no intermediate break need be postulated. Only terminal end breaks need be postulated; in accordance with Generic Letter 87-11, it is not necessary to postulate longitudinal rupture at terminal end breaks. Therefore, only vertical loads are considered to be applied to the steam generators due to a postulated main steam line break. For all postulated breaks, the pipe rupture loads are combined with design-basis seismic loads by the square-root-sum-of-squares (SRSS) method.

The peak value of the pipe thrust for any of the main steam piping breaks considered is approximately 620,000 lb; and the peak value for the pipe thrust for the pressurizer surge pipe break is approximately 195,000 lb. These thrust values are equal to $P \times A$, the system pressure times rupture area.

For the pressurizer surge line break and other branch line breaks, the load versus time transients of these breaks are provided by a computer program that analyzes the shock wave initiated at the break as it passes through the complete piping loop. Results from this program are used as forcing functions in a structural dynamic program that results in the dynamic loadings of the supports. For the main steam line and feedwater line breaks, the dynamic forces were applied only at the steam generator nozzles, because the primary reactor coolant loop piping remains intact. The peak values of the pipe thrust for the postulated piping breaks were computed as $C_r \times P \times A$, the thrust coefficient times the system pressure times the rupture area. These values were used as the basis for developing conservative time-history forcing functions of the postulated breaks. In addition to the thrust loading, jet impingement effects were included as appropriate. For the main steam line vertical break, credit was taken in calculating the thrust loading for the flow area reduction of the flow restrictors installed at the nozzle during the steam generator replacement project; the jet impingement loading is not reduced by the flow reducers. The time-history forcing functions are input into the structural dynamic analysis program that calculates maximum loadings on the supports. For each analyzed break, the maximum support loads are determined and then combined by SRSS summation with design-basis earthquake loads, and then added directly to the loadings due to normal operation. Combined stresses are maintained within 90% of the minimum yield point of the structural material used. For the RPV sliding foot supports, LOCA loads are developed using the AREVA methodology described in Chapter 14 Section 14.5.3.4.1.

All welding is in accordance with Section IX of the ASME Code, and all welds are examined by either radiographic, sonic, dye penetrant, or magnetic particle techniques, depending on the material and the state of stress at the weld.

The seismic restraints (snubbers) that are installed on the piping systems throughout the plant and that are required to protect the reactor coolant system or any other safety-related system are subject to operability and surveillance requirements contained within the Technical Specifications. Vepco has established a program and procedures for inspecting, testing, and maintaining snubbers in compliance with the Technical Specification requirements. A listing of all safety-related hydraulic and mechanical snubbers is maintained by Surry Power Station.

15.6.2.2 **Description**

15.6.2.2.1 Reactor Vessel Support

The reactor vessel is supported by six sliding foot assemblies mounted on the neutron shield tank. The support feet are designed to restrain lateral and rotational movement of the reactor vessel while allowing thermal expansion. The neutron shield tank is a double-walled cylindrical structure that transfers the loadings to the heavy reinforced-concrete mat of the containment structure. The tank also serves to minimize gamma and neutron heating of the primary concrete shield, and to attenuate neutron radiation outside of the primary shield to acceptable limits (Section 11.3.2.1). The neutron shield tank assembly and material listing are shown on Figure 15.6-1.

Sliding support blocks mounted on top of the shield tank support the reactor vessel. These sliding support blocks permit radial thermal expansion of the reactor vessel, while preventing translation, rotation, or uplifting[1]. The support blocks are also designed to adjust to the correct height for plumbing the reactor vessel and for distributing the load properly among the six supports.

The loading conditions used in the analysis of the neutron shield tank were the simultaneous accelerations of a design-basis earthquake, the thrust forces exerted by the reactor vessel due to a double-ended reactor coolant pipe rupture,[2] and the dead weight of the system and the tank itself, with stresses not to exceed allowable working stresses, and with no loss of integrity or function.

The neutron shield tank has been designed using the theory of a shell structure, dynamically loaded in both horizontal and axial planes, which results in meridional and circumferential stresses at all points along its length. The stresses in the tank were determined by using the methods and theories of Timoshenko for plates and shells, elasticity, and elastic stability. All membrane stress levels were held to the limits stated in Section VIII of the ASME Code; all membrane-plus-bending stresses were held to 90% of yield point. Section VIII of the ASME Boiler and Pressure Vessel Code was used as a guide in the fabrication and welding of the tank. A code stamp was not required, since this is not a code pressure vessel but a supporting structure for the reactor pressure vessel.

---

1. It is no longer necessary for the RPV sliding foot supports to restrain uplift based on new LOCA loads developed as discussed in Section 14.5.3.4.1. The combined seismic and LOCA loads when added to dead weight are not sufficient to create uplift in the supports.
2. As discussed previously in this section, it is no longer necessary to consider the dynamic effects of a postulated rupture of the primary reactor coolant loop piping. However, pipe ruptures of reactor coolant branch lines must still be considered.

All material employed in the fabrication of the tank was new and conformed to ASTM Standards. The tank shell was constructed from ASTM A516, Grade 60, and the six sliding support blocks were made of maraged steel. The material has an NDT of -20° to -40°F. Drop weight tests were performed to determine the nil ductility transition temperature of the deposited weld metal in welding the ASTM A516, Grade 60 material with an NDT of -40°F. The maraged steel was ultrasonically tested for flaws to the quality level of MIL-1-8950. Flaws detected ultrasonically were verified by X-ray. Maraged steel pieces with verified flaws larger than 1/32 in. were rejected. The maraged steel had a maximum hardness of 35 Rockwell C and a minimum grain size of 6, in accordance with ASTM E-112 and MIL-Std-430, *Macrograph Standards for Steel Bars, Billets, and Blooms.* The nonmetallic inclusion content for each billet was determined in accordance with ASTM E45. Fracture toughness tests were performed on maraged steel in accordance with ASTM Specification, *Proposed Recommended Practice for Plane-Strain Fracture Toughness Testing of High-Strength Metallic Materials Using a Fatigue-Cracked Bend Specimen,* Part 31, ASTM Standards.

All welds, where possible, were 100% radiographed in accordance with Paragraph UW-51 of the ASME Boiler and Pressure Vessel Code Section VIII, Division 1. Other welds that could not be radiographed were dye-penetrant checked at root pass, intermediate depths at half-inch increments, and the final pass, or magnetic-particle tested, in accordance with Appendices VI and VIII, Section VIII, ASME Boiler and Pressure Vessel Code. The surfaces of welds were ground to a surface condition suitable for the inspection procedure employed. Defects in welds were removed by chipping, grinding, or arc gouging until sound metal was reached. The resulting cavity was rewelded, employing an approved procedure.

After shop fabrication, the completed tank was subjected to a hydrostatic test of 15 psi, measured at the top of the tank. No water loss was observed for a 24-hour period. The tank was then leak tested with air at 5 psi gauge, applying soapsuds to all welds accessible from outside the tank. Leaks were repaired and the tank retested until no leakage was detected. All tests were recorded and certified. After installation of the neutron shield tank at the job site, the tank was hydrostatically retested.

15.6.2.2.2 Steam Generator Support

The steam generator support consists of two (upper and lower) cast rings and associated suspension rods, lateral restraints and snubbers. The lower ring, which carries the steam generator weight, is suspended by means of three pipe columns. Hydraulic snubber cylinders and rigid lateral guides connect the upper casting to the steam generator cubicle structure to allow guided thermal expansion of the steam generator outward from the reactor during normal operation, while resisting movement during seismic and pipe break conditions. Due to the design of this support system (i.e., pin-ended connections at all member joints) lamellar tearing of the supports could not occur. The steam generator support assembly and material listing is shown on Figure 15.6-2. The supports do not have any heavy section intersecting member weldments.

The major materials used in the construction of the steam generator supports are listed in Table 15.6-1. The difference between the operating temperature and the NDT of the material ensures toughness and ductility of the steam generator supports under all operating conditions. Welding associated with the supports was conducted in accordance with Section IX of the ASME code.

In addition to numerous inspections and tests carried out by the material suppliers and fabricators, all of the components for these supports were subject to inspection during fabrication and installation by Stone & Webster Engineering Corporation. All welds were subjected to examination by either the magnetic particle, liquid penetrant, or radiographic methods. The Vascomax 350 CVM and 300 CVM materials, and the A-352 grade LC3 casting materials were subjected to examination by the magnetic particle and ultrasonic methods. A visual inspection of a portion of these supports is required by the Technical Specifications.

The upper restraining ring is composed of two girth straps coupled together by studs to form a continuous ring. The studs are 1.25-inch 12UNF-2A Vascomax 18% Ni, maraging grade 350, with nickel cadmium coating. The nuts are 1.25-inch 12UNF-3B Vascomax 18% Ni, maraging grade 250, with Helicoil inserts. The studs and nuts are designed to minimize stress concentration during manufacture, and the studs are coated for environmental protection. The studs are pretensioned across a joint flange spacer block, which serves to reduce bending stresses in the studs.

A total of nine machined shoe openings are welded to each vessel girth strap. These shoe openings accommodate nine keys which themselves are fastened by dowels to the large upper restraint casting which is shown on Figure 15.6-2. These key and shoe openings function to allow vertical thermal expansion of the steam generator within the upper restraint casting, but will restrict lateral movement resulting from forces generated during a seismic event and/or a major pipe break applying lateral loads to the steam generator.

In a seismic event and/or a major pipe break applying lateral loads to the steam generator, the shoe openings in the vessel girth straps act against the keys, which results in a tangential load on the girth straps. The subject studs are designed to accommodate the maximum tangential load resulting from this accident condition. Existing space restrictions and restraint design required a limitation on stud size and quantity which necessitates the use of an ultra-high strength bolting material. The studs have a minimum yield strength of 326,000 psi. The nuts have a minimum yield strength of 150,000 psi.

The upper restraint casting is anchored to the containment structure (approximate 47-foot level) through rigid lateral guides oriented in the direction perpendicular to the outward thermal movement of the steam generator, and by two horizontal large-bore hydraulic snubbers, which permit the thermal movement of the steam generators outward from the reactor. The large-bore snubbers are 12-inch-diameter Pathon snubbers which have been refurbished and upgraded for increased reliability by Paul-Monroe/Remco Hydraulics under Design Change 85-05. The modifications included chroming the cylinder inner diameters; replacement of all non metallic seals with extended-service-life Tefzel seals or metallic seals; installation of poppet-type self-cleaning control valves for improved performance; conversion to the standard snubber hydraulic fluid (General Electric SF-1154); and incorporation of test-in-place features. In addition, the original common reservoir serving a number of snubbers has been replaced by individual pressurized reservoirs installed in more readily accessible locations in lower radiation areas outside the biological shield walls. The reservoirs are plated and the tubing and fittings are stainless steel for corrosion resistance.

The lower restraining ring is also connected to the steam generator cubicle concrete structure by couplings consisting of two end plates installed perpendicular to one another. The end plates have machined dovetails and are joined by a connector plate with mating dovetails. Although the couplings are resistant to corrosion cracking, additional protection is provided by enclosing each coupling in a rubber boot filled with silicone lubricant. The boot and lubricant are compatible with the coupling and are also radiation resistant.

15.6.2.2.3 Reactor Coolant Pump Support

The reactor coolant pumps are supported by a four-legged suspended structure. (Four small-bore snubbers originally installed in the upper frame structure of the pump support were eliminated under Design Changes 85-04-1 and 86-12-2. The dynamic characteristics of the reactor coolant pump were not significantly affected by removal of these snubbers as discussed in Reference 6.) The reactor coolant pump support assembly and material listing are shown on Figure 15.6-3. The supports do not have any heavy section intersecting member weldments.

The major materials used in the construction of the reactor coolant pump supports are listed in Table 15.6-2. Welding associated with the supports was conducted in accordance with Section IX of the ASME Code.

In addition to numerous inspections and tests carried out by the material suppliers and fabricators, all of the components for these supports were subject to inspection during fabrication and installation by Stone & Webster Engineering Corporation. All welds were subjected to examination by either the magnetic particle, liquid penetrant, or radiographic methods. The Vascomax 350 CVM and 300 CVM materials, and the A-352 grade LC3 casting materials were subjected to examination by the magnetic particle and ultrasonic methods. A visual inspection of a portion of these supports is required by the Technical Specifications; however, there is no formal inspection program for all components of the supports during the life of the facility. Major inspections potentially involving disassembly can be conducted on an as-needed basis.

During normal operation the loads and stresses for piping, component connections, and other remaining component supports are not sufficient to cause the failure of the reactor coolant system piping, should there be a complete failure of the reactor coolant pump supports. The maximum stresses that can be expected in the reactor coolant piping as a result of failure of the reactor coolant pump supports during normal operation are summarized in Table 15.6-3. These loads are within the allowable nozzle loads for both the steam generator nozzle and the reactor pressure vessel nozzles. The allowable stresses for the reactor coolant pipe material (A376 Tp 316) are also summarized below. While several of these values are above yield at 650°F, they are all less than 50% of the material's ultimate strength at that temperature. The reactor coolant pipe material has an S_n (code-allowable for normal operation) of 16 ksi at 650°F, and the faulted allowable stress would be 1.85 S_n or 28.8 ksi. All of the loads summarized below are within this faulted allowable, with the exception of the pressurizer inlet. However, thermal stresses have been conservatively included, and their deletion brings the stress levels well within the allowables.

During any postulated accident condition, i.e. seismic and/or pipe breaks, a concurrent complete failure of the reactor coolant pump support would result in unacceptable consequences throughout the reactor coolant loop piping, in terms of loads and stresses. If these supports were to fail during operation, it would be detected, as there is vibration monitoring instrumentation on both the shaft and the frame of the reactor coolant pumps. The amount of vibration is indicated in the control room, and any excessive vibration would cause an annunciator alarm to sound in the control room. To trigger the annunciator alarms, vibration greater than 3 mils on the frame and greater than 15 mils on the pump shaft must occur.

15.6.2.2.4 Pressurizer Support

The pressurizer vessel is mounted in a rigid support ring girder suspended by three hanger columns from above. Antisway brackets are welded to the shell of the pressurizer to accommodate shear blocks on the ring; the ring girder is laterally supported by a reinforcement plate attached to embedments in the concrete structure. In addition, lateral support for dynamic loads is provided near the vessel's center of gravity by four gapped restraints[1] at lugs on the pressurizer which transmit the loads into baseplates on the concrete floor. The lateral gapped restraints and hanger shear blocks and reinforcement plate are able to take all incident loads while allowing the pressurizer vessel to expand radially and vertically. The pressurizer support assembly and material listing are shown on Figure 15.6-4.

15.6.2.2.5 Evaluation

The dynamic analysis program accounts for dynamic amplification of the support forces. These forces are then combined with the design-basis seismic loadings by SRSS summation to ensure that the supports are conservatively designed to withstand the condition of a pipe break occurring as a result of an earthquake. Rigid quality assurance criteria during fabrication ensure conformance with the conservative design.

15.6.3 Containment Internal Structure

The reactor containment internal structure is a reinforced concrete structure that furnishes:

1. The four lateral gapped restraints were installed by Design Changes 85-04-1 and 85-05-2 to replace the four snubbers in the original support configuration.

1. Supports and restraints for all internal equipment and piping including the polar crane and jib crane.
2. Missile shielding for the containment steel liner and main steam lines against internally generated missiles.
3. Biological shielding for station operators inside the containment structure under all phases of reactor operation.

The structure is designed to withstand the design-basis earthquake together with the simultaneous loss-of-coolant accident (LOCA)[1], without loss of function. Clearance is maintained between all internal structures and the steel liner of the reactor containment shell to permit differential earthquake motion. The steam generator cubicles and the pressurizer cubicle are designed to withstand an internal differential pressure load of 35 psi resulting from the postulated double-ended primary coolant pipe break. The primary shield is designed to withstand an internal pressure of 100 psig resulting from a hypothetical reactor coolant pipe break within the primary shield.

The differential pressure rise within the cubicles is controlled by open and shielded vent spaces in each cubicle, which permit rapid pressure equalization within the containment structure.

This transient pressure condition has been calculated by Stone & Webster's CUPAT Program, using input from the LOCTIC Program.

Temperature differentials between cubicles are considered coincident with the pressure differentials. The short duration of the transient accident relative to the low thermal conductivity of the concrete is such that no significant temperature gradient occurs across the walls. Also, the transient accident is not considered to add to the differential cubicle wall loadings.

Structural concrete design conforms to the requirements of ACI 318, Part IV-B, Ultimate Strength design. Maximum stresses are limited to 90% of the minimum yield point in bending, or 85% of the minimum yield point in diagonal tension, bond, and anchorage.

Special large-size reinforcing steel bars No. 14 and No. 18 are controlled chemistry steel of 50,000 psi yield point, otherwise conforming to the requirements of ASTM A408. All other reinforcing steel is steel of 40,000 psi yield point conforming to ASTM A-15 and ASTM A305.

A stainless-steel-lined fuel transfer canal and reactor refueling cavity is incorporated in the concrete structure above the reactor vessel. A 0.25-inch-thick stainless-steel plate is used to prevent leakage of water from these areas into the containment structure.

1. As discussed in Section 15.6.2, "leak-before-break" analyses have demonstrated that the probability of a rupture of the primary reactor coolant loop piping is extremely low, and it is no longer necessary to consider the dynamic effects of such a break. However, the requirements for design of containment and compartments under pressures associated with a postulated primary reactor coolant loop LOCA remain unchanged.

Portions of the biological shield walls in the steam generator cubicles are composed of removable precast, reinforced-concrete sections. The wall sections are designed for nondestructive removal to assist future servicing of the steam generators.

Structural steel framing is used as bracing along the top, corners, and ends of the removable shield wall sections. The bracing components conform to ASTM A-36 specifications for structural steel. The precast concrete wall sections have an ultimate compressive strength of 3000 psi at 28 days, with steel reinforcement conforming to ASTM specifications for A615, grade 40.

15.7 MASONRY WALLS

Concrete masonry walls are used throughout the plant to provide barriers for radiation shielding, fire protection and personnel separation. Those walls utilized in the construction of Seismic Class I structures are not designed or intended to act as bearing or for transmitting building shear forces. These walls are not used as major load-bearing walls and are not included as part of the overall building shear wall system.

All of the concrete masonry walls that are in proximity to or have attachments for safety-related or equipment such that wall failure could affect a safety-related system were identified and analyzed in accordance with the requirements of IE Bulletin 80-11 (Reference 1). The reevaluation of the masonry walls was performed based upon criteria for reevaluating concrete masonry walls submitted in Reference 2, which uses as its acceptance criteria the allowable stresses specified in ACI-531-79, *Building Code Requirements for Concrete Masonry Structures.* Review of test data and the literature substantiates the use of these allowable stresses. The review also included research of acceptable damping percentages, analysis techniques, in-plane effects, arch action and local stress valves.

The reevaluation criteria considered loads from both safety- and non-safety-related attachments as well as relative interstory displacements between building elevations where applicable. All applicable loads and load combinations specified in the Surry FSAR for concrete design were included in the reevaluation. A review of the walls determined that the walls are not subjected to tornado missiles or depressurization, pipe whip or jet impingement loads. The global review of the walls included seismic inertia loads, interstory displacement loads for both in-plane and out-of-plane effects, equipment loads, and wind loads where applicable.

The local review included discontinuities such as openings and the mechanism for local load transfer into the walls. This included a review of potential local block pull out as well as possible overstress within individual blocks due to attached equipment. Multiwythe walls were also reviewed to ensure the integrity of the collar joint. Calculated shear and tension stresses across the collar joints were compared against allowable values that were conservatively chosen to account for potential small areas of voids or other discontinuities.

At the completion of the response to IE Bulletin 80-11, all identified masonry block walls were evaluated and, modified, as required, to meet the acceptance criteria. The results of this reevaluation program were transmitted to the Nuclear Regulatory Commission. The analysis results of the masonry wall reevaluation program indicated that of the walls requiring reanalysis, 79 walls were acceptable, two walls were acceptable after equipment was removed from the wall, and 31 walls were modified to meet acceptance criteria. Seven safety-related masonry walls in the fuel building were not acceptable under extreme loading conditions and were replaced with blow-off siding. An additional 217 non-safety related walls were also reviewed to ensure that they did not endanger safety-related equipment. Following the approval of responses to IE Bulletin 80-11 by the Nuclear Regulatory Commission, all subsequent modifications involving masonry block walls are evaluated under the Nuclear Design Control Program, which continues to invoke the technical requirements of IE Bulletin 80-11 (References 3 & 4).

APPENDIX 15A SEISMIC DESIGN FOR THE NUCLEAR STEAM SUPPLY SYSTEM AND MISCELLANEOUS COMPONENTS

15A.1 GENERAL SEISMIC DESIGN CRITERIA FOR THE NUCLEAR STEAM SUPPLY SYSTEM

This Appendix is based on Appendix B to the initial FSAR.

All Class I components of the nuclear steam supply system are designed in accordance with the following criteria:

1. Primary operating stresses, when combined with the operating-basis earthquake seismic stresses resulting from a dynamic analysis using a response spectrum normalized to a maximum horizontal ground acceleration of 0.07g and a simultaneous vertical ground acceleration of two-thirds the horizontal, are maintained within the allowable stress limits in Table 15A-1.
2. Primary operating stresses when combined with the design-basis earthquake seismic stresses resulting from a dynamic analysis using a response spectrum normalized to a maximum horizontal ground acceleration of 0.15g and a simultaneous vertical ground acceleration of two-thirds of the horizontal, are limited so that the function of the component or system shall not be impaired, preventing a safe and orderly shutdown of the unit. Further, the primary operating stresses are maintained within the allowed stress limits in Table 15A-1.

   “No loss of function” requires that rotating equipment will not seize, pressure vessels will not rupture, and supports will not collapse or deform to such a degree as to cause failure of the supported equipment. In addition, systems required to be leaktight will remain leaktight, and engineered safeguards will perform intended functions.

15A.2 SEISMIC DESIGN CRITERIA FOR PIPING, VESSELS, SUPPORTS AND REACTOR VESSEL INTERNALS

Following discussions with the Staff of the Atomic Energy Commission (AEC) Division of Reactor Licensing during the Construction Permit Application Review for Diablo Canyon Unit 1, the criteria presented in WCAP-5890, Revision 1 (Reference 1), for the generation of limit curves were modified. Details of the manner in which this modification was developed are given in Section 15A.5.1.

The loading conditions employed in the design of Class I piping, vessels, and supports are enumerated and defined in Section 15A.2.1. The allowable stress limits associated with the various loading conditions are shown in Table 15A-1. Since the reactor vessel internals must also satisfy deformation limits to be able to perform their function, i.e., allow core shutdown and cooling, the vessel internals are discussed separately in Section 15A.2.3.

15A.2.1 Loading Condition Definitions

The loading condition definitions given below are taken from Section III of the ASME Boiler and Pressure Vessel Code, Summer 1968 Addenda.

15A.2.1.1 **Normal Conditions**

Any condition in the course of system start-up, operation in the design power range, and system shutdown, in the absence of upset, emergency or faulted conditions.

15A.2.1.2 **Upset Conditions**

Upset conditions are any deviations from normal conditions anticipated to occur often enough that design should include a capability to withstand the conditions without operational impairment. The upset conditions include those transients which result from any single operator error or control malfunction, transients caused by a fault in a system component requiring its isolation from the system, transients due to loss of load or power, and any system upset not resulting in a forced outage. The estimated duration of an upset condition shall be included in the design specifications. The upset conditions include the effect of the operating-basis earthquake for which the system must remain operational or must regain its operational status.

15A.2.1.3 **Emergency Conditions**

Any deviations from normal conditions which require shutdown for correction of the conditions or repair of damage in the system. The conditions have a low probability of occurrence but are included to provide assurance that no gross loss of structural integrity will result as a concomitant effect of any damage developed in the system.

15A.2.1.4 **Faulted Conditions**

Those combinations of conditions associated with extremely low probability postulated events whose consequences are such that the integrity and operability of the nuclear energy system may be impaired to the extent where considerations of public health and safety are involved. Such considerations require compliance with safety criteria as may be specified by jurisdictional authorities. Among the faulted conditions may be a specified design-basis earthquake for which safe shutdown is required.

15A.2.2 Piping, Vessels, and Supports

The reasons for selection of the above-mentioned loading conditions and allowable stress limits are as follows:

1. When subjected to the operating-basis earthquake, the nuclear steam supply system is designed to be capable of continued safe operation. Equipment and supports needed for this purpose are required to operate within normal design limits, as shown in Table 15A-1. The load combination corresponding to the upset loading condition is the normal load, plus the operating-basis earthquake load.
2. In the case of the design-basis earthquake, it is necessary to ensure that components required to shut the unit down and maintain it in a safe shutdown condition do not lose their capability to perform their safety function. This capability is ensured by maintaining the emergency stress limits as shown in Table 15A-1.
3. For the highly unlikely but postulated case of pipe rupture, a reactor coolant branch or other potentially governing break, the effects of the pipe rupture will not cause failure propagation to the reactor coolant piping. The load combination corresponding to the faulted loading condition is the design-basis earthquake and/or design-basis accident load.
4. For the extremely remote event of simultaneous occurrence of a design-basis earthquake and postulated pipe rupture of a reactor coolant system branch line or other potentially controlling break, the Class I piping and component are checked for no loss of function, i.e., the capability to contain fluid, allow fluid flow, and perform vital engineered safeguards functions. This is ensured by limiting the various stress combinations within the faulted condition design limits shown in Table 15A-1.

The minimum margin of safety between the design limit stress and the expected collapse condition is for the case of pure tension, and is defined as:

$$\frac{S_{ultimate} - S_{design}}{S_{design}}$$

Under more realistic operating conditions, piping and vessels will always experience some combination of tension and bending. For these combined load cases, the margin of safety is greater than that for pure tension, as shown by the limit curves contained in WCAP-5890, Rev. 1, and shown in Figures 15A-4 and 15A-5. Therefore, it is conservative to base the margin of safety on pure tension. Table 15A-2 illustrates the margin of safety between the stress limits for various load conditions and the expected failure or collapse condition for typical materials.

Plastic or limit analyses conducted within the limits of the faulted condition were performed considering plastic material behavior, including, as required, modifications of material stiffness characteristics, formation of plastic hinges and other non-linear effects, as determined in detailed structural analysis, and provided in standard stress reports.

15A.2.3 Reactor Vessel Internals

15A.2.3.1 Design Criteria for Normal Operation

The internals and core are designed for normal operating conditions and subjected to loads of mechanical, hydraulic, and thermal origin. The response of the structure under the operating-basis earthquake is included in this category as well as operational transients (upset conditions).

The stress criteria established in Section III of the ASME Boiler and Pressure Vessel Code, Article 4, have been adopted as a guide for the design of the internals and core, with the exception of those fabrication techniques and materials not covered by the Code, such as the fuel rod cladding. Seismic stresses are combined in the most conservative way and are considered primary stresses.

The members are designed under the basic principles of: (1) maintaining deflections within acceptable limits, (2) keeping the stress levels within acceptable limits, and (3) preventing fatigue failures.

15A.2.3.2 Design Criteria for Abnormal Operation

The abnormal design condition assumes blowdown effects due to a pipe break[1] combined (by SRSS combination) in the most unfavorable manner with the effects associated with the design-basis earthquake.

For this condition, the criteria for acceptability are that the reactor is capable of safe shutdown and that the engineered safety features are able to operate as designed. Consequently, the limitations established on the internals for these types of loads are concerned principally with the maximum allowable deflections. Additional stress criteria for critical structures under normal operation, plus the design-basis earthquake and blowdown excitation, ensure that the structural integrity of the components is maintained.

15A.3 GENERAL ANALYTICAL PROCEDURE FOR SEISMIC DESIGN

The design and analysis of Class I components of the nuclear steam supply system utilizes the “response spectrum” approach.

---

1. As discussed in Section 15.6.2, it is no longer necessary to consider the dynamic effects of a postulated rupture of the primary reactor coolant loop piping. However, pipe ruptures of reactor coolant branchlines are still postulated.

The dynamic analysis is performed using the normal mode methods. The inertial properties of the models are characterized by the mass and mass moment of inertia of each mass point. The stiffness properties are characterized by the moment of inertia, area, shear shape factor, torsion constant, Young's modulus, and shear modulus.

Table 15.2-2 gives the damping ratios to be used in the dynamic analysis of components.

15A.3.1 Mechanical Equipment

The Westinghouse-supplied Class I mechanical components for Surry that require a seismic analysis were determined and checked for seismic adequacy by employing the following procedure:

1. The manufacturer's drawings were reviewed to classify the component.
    a. If the component fell within a category that was previously analyzed using a multi-degree-of-freedom model and shown to be relatively rigid, then a static seismic analysis was performed to check equipment seismic adequacy.
    b. If the component could not be categorized as similar to previously analyzed components, then a seismic modal analysis was performed, using multi-degree-of-freedom dynamic models.
2. Stresses and deflections were checked to ensure that they were within allowable limits and did not result in loss of function.

Typical Class I mechanical equipment of the engineered safety feature (ESF) systems supplied by Westinghouse was originally analyzed on a worstplant basis using a multi-degree-of-freedom modal analysis. The term "worstplant basis" is defined, for the particular component in question, as the most severe seismic response spectra applicable to any Westinghouse plant employing that particular piece of equipment. All contributing modes were considered. A sufficient number of masses was included in the mathematical models to ensure that coupling effects of members within the component were properly considered. The results of these analysis indicated that the models contained more masses than necessary, and that future analyses of comparable equipment could be considerably simplified by considering fewer masses, or merely performing a simple static analysis.

The method of dynamic analysis used a proprietary computer code called WESTDYN. This code uses inertia values, member sectional properties, elastic characteristics, support and restrain data characteristics, and the appropriate seismic response spectrum as input. Both horizontal and vertical components of the seismic response spectrum are applied simultaneously. The modal participation factors are combined with the mode shapes and the appropriate seismic response spectra to give the structural response for each mode. The internal forces and moments are computed for each mode from which the modal stresses are determined. The stresses are then summed using the square-root-sum-of-squares method, except for the major components in the reactor coolant loop. As discussed in Section 15A.3.3, for the reactor coolant loop analysis, the combination of modal responses for closely spaced modes is performed using the grouping methodology in Regulatory Guide 1.92.

In analyzing equipment to resist seismic loads, the vertical seismic spectrum, equal to two-thirds of the horizontal response spectrum, is used to determine the acceleration appropriate to the vertical frequency. An idealized umbrella spectrum was used in the analyses. The floor response spectra at the Surry site are encompassed by the umbrella spectrum used in the dynamic analysis of Westinghouse-supplied equipment.

Typical Class I engineered safeguards tanks supplied by Westinghouse, e.g., for boric acid, accumulator, and boron injection, were analyzed using the method above, with the combined horizontal and vertical seismic excitation occurring simultaneously in conjunction with normal loads. Hydrodynamic analyses of these tanks have been performed using the methods described in TID 7024 (Reference 2).

Selected critical Class I ESF valves supplied by Westinghouse have been analyzed using the above method, and the results indicate that their fundamental natural frequency is sufficiently separated from the building frequency. The results indicate that the total stress, considering all modes, is far below the allowable stress limit. Motors attached to motor-operated valves have been included in the mathematical models.

The deflections and stresses obtained from the seismic analysis are added to the deflections and stresses associated with the operational mode of the mechanical equipment to verify that clearances are not exceeded and the stresses are within allowable limits. This criterion ensures that this equipment will perform the intended function under seismic conditions.

All mechanical equipment analyzed had fundamental modes in the rigid range, with the exception of loop stop valves and some vertical tanks.

The fundamental frequency of vertical tanks and the loop stop valves was greater than 9 Hz, which is outside the resonance range of the structures in which they are housed. The component supports were modified to remove the fundamental frequency of the item from the resonance range of the structure, by providing stiffer supports to increase the fundamental frequency of the component. The selection of the type of restraint used was dependent upon the component analyzed and the structure surrounding the component.

Restraints, snubbers, or other devices are not used to preclude resonance of the electrical and control systems equipment for seismic loading. Protection system equipment that is typical of the design has been subject to tests under simulated seismic accelerations to demonstrate the ability to perform and complete its function. These data are contained in WCAP-7397-L (Reference 3).

The seismic loads for the design and analysis of Class I mechanical components, including pumps, valves, heat exchangers, and tanks within Stone & Webster's scope of responsibility, were based on the ground response spectra (GRS) shown in Figures 2.5-5 and 2.5-6 or amplified floor response spectra (ARS), depending on their location. Seismic loads were developed for the operating-basis earthquake (OBE) and the design-basis earthquake (DBE). The spectra used in the evaluation of Class I mechanical components were based on damping values consistent with those indicated in Table 15.2-2. Where applicable, seismic loads were combined with the results from other load cases such as thermal and dead load. Constraints such as snubbers or other appropriate devices are utilized wherever necessary to meet design requirements.

All Class I mechanical components are designed to withstand the operating-basis earthquake and to function through the design-basis earthquake to safe shutdown. Vendors supplying the components are required by specification to design the components to function, as outlined above, under the seismic loadings. The vendor is required to validate component integrity under the specified seismic conditions.

15A.3.2 Earthquake Experience-Based Method Developed for Unresolved Safety Issue (USI) A-46 for Seismic Verification of Equipment

In response to U.S. Nuclear Regulatory Commission Generic Letter 87-02 on USI A-46, *Verification of Seismic Adequacy of Mechanical and Electrical Equipment in Operating Reactors,* a Generic Implementation Procedure (GIP) was developed by the Seismic Qualification Utilities Group (SQUG). The criteria and methodology in Revision 3 of the GIP (Reference 40), as modified and supplemented by the NRC Supplemental Safety Evaluation Reports (SSERs) 2 and 3 (References 44 & 45) may be used, with certain additional considerations, as an alternative to other licensing basis methods for seismic design and verification of existing, modified, new and replacement equipment classified as safety-related, NSQ or seismic category 1. Considerations that are additional to the GIP pertain to the following issues:

- Use of GIP Method A for estimating seismic demand.
- Additional criteria applicable for the design and analysis of new flat bottom vertical tanks.
- Applicability of Part II, Section 5 of the GIP for conduit and cable tray raceways.
- Use of criteria associated with damping values, static coefficient and expansion anchor safety factors for equipment anchorage evaluations conforming to the current, conservative, licensing basis commitments.
- Documentation of the results of the Screening Verification and Walkdown in Section 4.6 of the GIP may be limited to the use of walkdown checklists. It is not necessary to complete the Screening Verification Data Sheets (SVDS).

- It is not necessary to identify “essential relays” and perform functionality screening as defined in Section 6 of the GIP. Relays designated as Class 1E are evaluated by comparing seismic capacity to seismic demand.

- The GIP method is generally applicable only for equipment located in mild environment. However, with case-by-case justification, it may be used for equipment in harsh environment.

Guidance for the use of the GIP for the seismic design and verification of mechanical and electrical equipment, including a discussion of the above exceptions, is provided in an engineering procedure (Reference 62).

15A.3.3 Reactor Coolant Loops and Supports

The original configuration of the reactor coolant system equipment supports included ten large-bore hydraulic snubbers per loop to carry the loads from postulated pipe ruptures of the reactor coolant system, main steam line, and feedwater line. Subsequent fracture mechanics analyses, submitted to the NRC on behalf of the Westinghouse Owners Group, demonstrated that the probability of rupture of the primary coolant loop is extremely small, and that the presence of a pipe crack could be detected by leakage well before the crack grew to a critical size which would cause rupture. NRC Generic Letter 84-04 (Reference 4) provided the NRC staff safety evaluation of these “leak-before-break” analyses, concluding that, provided certain specific conditions are met, the dynamic effects of a postulated pipe break in the reactor coolant system primary loop need not be considered as a design basis for the reviewed plants, including Surry Units 1 and 2. Subsequently, Generic Letter 87-11 (Reference 5) eliminated the need to postulate Arbitrary Intermediate Breaks and allowed removal of the associated pipe whip restraints and jet impingement shields. Because the stresses in the main steam lines inside containment are well below the stress criteria for required mandatory intermediate breaks, the only breaks which need be postulated are terminal end breaks which do not apply lateral loads to the steam generator. Based on the relief provided by these two relaxations of criteria, the reactor coolant system supports have been modified to eliminate eight of the ten large-bore snubbers per loop of the reactor coolant system. These efforts are discussed in Section 15.6.2; additional information is contained in References 6-15.

The reactor coolant loop system was re-evaluated with the snubbers eliminated to assure that the conditions of pressure, deadweight, thermal, seismic, and remaining pipe rupture effects, would not result in unacceptable stress levels or factors of safety. Two essentially independent analyses of a representative single primary loop were performed by Westinghouse Electric Corporation and Stone & Webster Engineering Corporation, in accordance with the original division of design responsibilities. Westinghouse performed deadweight, pressure, thermal and seismic analyses using a simplified model as the run of record to obtain piping stresses. Stone & Webster performed analyses using a model incorporating a detailed representation of the support members, principally to obtain component support loads under normal and accident loadings. Both analytical and models were revisions to existing models and incorporated changes due to the steam generator replacements as well as the snubber elimination efforts.

These analyses incorporated the loads from deadweight, internal pressure, thermal expansion, seismic events (OBE and DBE), and the dynamic effects of pipe ruptures of other systems (controlling breaks, for example), in the main steam line, pressurizer surge line, main feedwater line, etc.) No other hydraulic transient loading was considered as significant.

For seismic analysis, the soil structure interaction amplified response spectra for 0.5 percent critical equipment damping (OBE) and 1 percent equipment damping (DBE) were used with appropriate “bump” factors as discussed in Section 15A.3.5.3. These damping values are lower than those in Regulatory Guide 1.61, *Damping Values for Seismic Design of Nuclear Power Plants* and in ASME Code Case N-411, *Alternative Damping Values for Seismic Analysis of Classes 1, 2, and 3 Piping.* The vertical and horizontal earthquake responses were combined for piping analysis as described in Section 15A.3.3. For component support analysis, the responses to the three directions of earthquake loading were combined by SRSS. The combination of modal responses for closely spaced modes was performed using the grouping methodology in Regulatory Guide 1.92.

The Westinghouse analysis used the WESTDYN code and a simplified representation of the component supports as stiffness matrices. The component support stiffness matrices were supplied by Stone & Webster. The WESTDYN computer code has been utilized on numerous Westinghouse plants, and was reviewed and found acceptable by the NRC for the Surry units in 1974. A detailed description of the WESTDYN method of analysis is given below.

The code uses as input system geometry, inertia values, member sectional properties, elastic characteristics, support and restraint data characteristics, and the appropriate Surry seismic response spectrum of 0.5% critical damping. Both horizontal and vertical components of the seismic response spectrum are applied simultaneously.

With these input data, the overall stiffness matrix [K] of the three-dimensional piping system is generated (including translational and rotational stiffness). Restraints are deleted, and the stiffness matrix is inverted to give the flexibility matrix [F] of the system.

$$[F] = [K]^{-1}$$

A product matrix is formed by the multiplication of the flexibility and mass matrices. This product matrix forms the dynamic matrix [D] from which the modal matrix is computed.

$$[D] = [F]\,[M]$$

The modal spectral matrices are generated using a modified Jacobi method.

$$(\omega^2\,[M] - [K])\,X = O$$

From this information, the modal participation factor is combined with the mode shapes and the appropriate seismic response spectra to give the structural response for each mode.

The Stone & Webster analysis used the STARDYNE computer code and a model incorporating a detailed representation of the support members. STARDYNE is a public domain computer program and is recognized as a Category 1 computer program suitable for nuclear safety-related work. The program used is maintained under Stone & Webster's Quality Control procedures. The following modules of STARDYNE, Version 3, Level H, were used:

- STAR (Static and Modal Extraction Analysis)
- DYNRE4 (Seismic Response Spectrum Analysis)
- DYNRE6 (Time History Transient Analysis)—used only for evaluating pipe rupture loadings

Dynamic analyses were performed of the controlling pipe ruptures in the pressurizer surge line, main steam line, and main feedwater lines. The originally-postulated terminal and intermediate breaks were reviewed by Stone & Webster to determine those breaks which would cause the most severe loadings on the revised support configuration with snubbers removed. Time-history forcing functions were applied to the detailed model representing these potentially limiting breaks, to obtain maximum member loads with the revised support configuration. These loads were combined by SRSS with the seismic DBE loads and then summed with deadweight and pressure loads.

The results of the two independent analyses with revised support configuration established that the frequencies of most vibrational modes are virtually unchanged by the snubber eliminations. Comparison of the interface loads calculated by the two models was performed to ensure that the results of the two models were consistent; the significant interface loads were found to be within 15%, which is considered to be good agreement. The analyses demonstrated that the piping components and supports are stressed within acceptable limits, and adequate safety margins exist in a seismic event. The maximum level of stress (percentage) compared to the Code allowable at the highest stress point in each leg of the reactor coolant loop for thermal, deadweight, and seismic conditions are given in Table 15A-5.

In addition, the maximum resultant bending moment in the primary coolant loop piping under combined deadweight, pressure, thermal, and design basis seismic loadings is 28,860 inch-kips. This value is less than the enveloped value in the Westinghouse topical report, WCAP-9558, Revision 2 (Reference 6), and also less than 42,000 inch-kips which was identified in NRC Generic Letter 84-04 as the maximum allowable moment for the Westinghouse Owner's Group plants for justifying that pipe rupture need not be postulated in the primary reactor coolant loop piping.

For combined normal operating and seismic loads, the location of the maximum stress is the steam generator outlet elbow; for the main steam line rupture loading, the location of maximum stress is in the steam generator inlet elbow; for the pressurizer surge line break, the maximum stress occurs in the hot leg where the surge line intersects.

Stone & Webster evaluated the calculated maximum loadings on the supports of the modified support configuration with eight of the large-bore snubbers eliminated. The factors of safety (allowable load/combined load) for the combined deadweight, pressure, thermal, and design basis seismic loads are given in Table 15A-6. Similar factors of safety under the combined deadweight, pressure, thermal, and SRSS combination of design basis seismic loads plus maximum pipe rupture loads, are given in Table 15A-7. These tables demonstrate that adequate factors of safety exist under all loading conditions.

The results of these analyses confirm that the large-bore snubber eliminations do not compromise the bases for the previous leak-before-break analysis, namely:

1. The loading on the primary loop piping is still enveloped by the generic analyses submitted on behalf of the A-2 Owners Group and accepted by the NRC staff in Generic Letter 84-04, and specifically for Surry by NRC letter dated June 16, 1986; and

2. The reactor coolant system equipment, piping, and supports continue to have acceptable margins of safety under licenced loading conditions other than the now-eliminated ruptures of the primary loop piping and Arbitrary Intermediate Break of the main steam lines.

The inertial forces and moments are computed for each mode from which the modal stresses are determined. The stresses are then summed using the square-root-sum-of-squares method.

The maximum stresses in the reactor coolant loop piping imposed by the normal loads plus loads associated with the design-basis earthquake are below the allowable stress limit. The stress levels in the reactor coolant loop piping are provided in Table 15A-7 (References 9 and 11).

As noted in Section 15.6.2 and its associated references, the application of Leak-Before-Break was subsequently extended to the Surry Units 1 and 2 Reactor Coolant System branch piping including: the Pressurizer Surge, Residual Heat Removal, Accumulator, Loop Bypass, and Safety Injection piping up to each line’s first pressure isolation valve. The evaluation demonstrated the dynamic effects of the pipe rupture resulting from postulated breaks in the Surge, RHR, Accumulator, Loop Bypass and SI line piping need not be considered in the structural design basis of Surry Units 1 and 2 for the 80 year period of extended plant operations.

15A.3.4 Anchor Bolts

The majority of anchor bolts originally installed at the Surry Power Station were shell-type Phillips self-drilling anchors. A minimum safety factor of four was used. Cyclic loads and the effect of baseplate flexibility were not specifically considered; however, supports, baseplates, and anchor bolts were designed to withstand the maximum force exerted by seismic and thermal conditions.

In response to IE Bulletin 79-02 (Reference 16), all pipe support baseplates were analyzed considering baseplate flexibility, and modifications were made when baseplates and/or anchor bolts were found inadequate. Wedge-type Hilti bolts were installed in accordance with manufacturer's requirements based on onsite testing conducted by Hilti, Inc.

A finite element analysis was performed using the ANSYS computer program as provided by an owner's group organized by Teledyne Engineering Services. A description of this program was submitted to the NRC as Technical Report TR-3501-1, Revision 1 (Reference 17). In some cases where the support plate could not be modeled in the computer program, hand calculations were performed, allowing sufficient margin for baseplate flexibility and prying action.

The factors of safety of four for wedge-type anchors and five for shelltype anchors were used to determine the anchor bolt allowable loads for the reanalysis. All baseplates were reanalyzed to ensure that these factors of safety were met. Where the factors of safety were not met by analysis, modifications were provided to ensure the appropriate factor of safety. The original design for anchor bolts at Surry was based on a factor of safety of four for all anchor bolts, based on a design concrete strength of 3000 psi. In conjunction with IE Bulletin 79-02, a concrete inspection program was performed to demonstrate a concrete strength of 4000 psi, which would provide the factor of safety of five required by the Bulletin. Thirty-two Windsor probe tests were performed at various locations throughout the plant (Surry Units 1 and 2) to provide data for the evaluation. The results of this program show a 95% confidence level of at least 4000 psi concrete. Therefore, the analysis was based on 4000 psi concrete with the factors of safety of four and five required by Bulletin 79-02.

No special design requirements for the anchor bolts to withstand cyclic loads were applied. Testing performed for the owner's group, the results of which are presented in Technical Report TR-3501-1 indicates that cyclic loading on the anchors does not result in a general reduction of the ultimate capacity of the anchor. Bolts for shell-type anchors (Phillips Red-Head self-drilling anchors) were tightened snugly, but were not preloaded. Wedge anchors (Hilti bolts) were preloaded to the design allowable load.

To ensure that the design requirements have been met for the installed anchor bolts, an inspection and testing program was conducted. Under this program, one anchor bolt per accessible base plate was inspected and tension tested to at least the anchor bolt design load. Anchor bolt installations which were suspect based on the visual inspection were tension tested to at least the anchor bolt design allowable load (20% of the manufacturer's ultimate) and evaluated for a factor of safety of five by tension testing to five times the design load, or determining the anchor capacity based on the results of the visual inspection. When the anchor was found to be inadequate as a result of the evaluation, or of slippage greater than 1/16 inch under the tension test, the baseplate was reanalyzed with that bolt missing. The remaining bolts on the baseplate were inspected and tested for adequacy under the higher redistributed load when the reanalysis was acceptable, or for the original design load when the loads could not be redistributed. Inspection and test results showed that 97% of the baseplates were acceptable. All anchor bolts that were inadequate or damaged were replaced to ensure adequacy of the anchorage system.

In order to evaluate operability of each Seismic Category I piping system, the anchor bolt inspection and test results were recorded on a system basis. The system designations shown in Table 15.2-1 were used in conjunction with a QA Category I piping line table to determine systems for Bulletin 79-02 purposes. Of the 14 systems for which anchor bolt inspections were performed, 12 of the systems had acceptance percentages greater than 95%. The acceptance percentages for the other two systems, the reactor coolant system and the residual heat removal system, were 94.7% and 92.1%, respectively. All systems with baseplates inaccessible for bolt inspection and testing had remote visual inspections performed to ensure that all anchor bolts were present and no gross deficiencies existed. For the two systems with less than 95% acceptance, the inaccessible baseplates were further evaluated to ensure high design factors of safety greater than those required by the Bulletin. Review of the baseplates where anchor bolts were found to be inadequate did not indicate any common characteristic (i.e., floor plates, wall plates, or ceiling plates) which would necessitate further inspection and testing of the inaccessible baseplates with a particular characteristic.

Piping systems 2 in. in diameter or less were originally designed by a chart analysis method. To ensure adequacy of the baseplates and anchor bolts in justifying operability of the small-bore piping, a sampling program was initiated. Five 2-inch lines were selected as representative of the small bore piping. Three safety injection lines and two chemical volume and control lines, which have a total of 22 supports with 43 baseplates, were analyzed in this effort. Baseplate analysis efforts show anchor bolt factors of safety ranging from 5.2 to 638, with the majority of anchor bolts having design factors of safety above 60.

Seventy-three anchor bolts on 12 of the small-bore baseplates were inspected and tension tested. Sixty-eight of these anchor bolts (93%) were accepted. The baseplates for the five rejected anchors were reanalyzed with the discrepant bolts missing and all were found acceptable and within the allowable limits. All anchor bolts which were inadequate or damaged were replaced to ensure adequacy of the anchorage system.

The small-bore piping baseplates and anchor bolts were designed and installed by the same architect-engineer and contractor that performed the work on the large-bore piping. Therefore, based on the above results, which are consistent with the large-bore anchor bolt program, a sufficient degree of conservatism exists in the baseplates and anchor bolts of the small-bore piping to justify acceptance of this piping.

All Seismic Category I pipe supports on masonry walls were resupported without attachment to the masonry walls.

IE Bulletin 79-02 inspection details were provided to the NRC by References 18, 19, and 20.

15A.3.5 Piping Systems

The Stone & Webster PSTRESS/SHOCK 2 computer code was used in the seismic analyses of certain systems at Surry Units 1 and 2. This code summed earthquake loadings algebraically, which is unacceptable for reasons set forth by the NRC in IE Bulletin 79-14 (Reference 21) and in a March 13, 1979 Order to Show Cause (Reference 22). As a result, Vepco reanalyzed safety-related systems originally analyzed by SHOCK 2, modified those systems as necessary, depending on the results of the reanalyses, and provided support for the acceptability of the analysis methods used on the remaining Seismic Class I systems.

Portions of the following systems were identified as having been analyzed with SHOCK 2:

- Pressurizer spray and relief.
- Low-head safety injection.
- High-head safety injection.
- Containment and recirculation spray.
- Residual heat removal.
- Component cooling water.
- Service water.
- Main steam.
- High-pressure steam.
- Feedwater.
- Auxiliary feedwater.
- Containment vacuum.
- Fire protection (Unit 1 only).
- Diesel muffler exhaust (Unit 1 only).

Vepco has reanalyzed all pipe stress problems originally analyzed by SHOCK 2. All supports were reanalyzed and modifications completed as necessary.

Reanalysis and safety evaluation details are given in References 23 through 26.

15A.3.5.1 **Reanalysis Methods and Results**

As the original analysis used an algebraic intramodal summation technique, the safety-related piping system supports and attached equipment were reanalyzed with acceptable methods. The reevaluation included a dynamic computer analysis using NUPIPE programs, which incorporated a lumped mass response spectra modal analysis technique.

The floor response spectra used in the reanalysis included the original amplified response spectra specified in this appendix. In some cases, piping was reanalyzed utilizing ARS that were developed using SSI techniques. The peaks in the amplified floor response spectra were broadened by ±15% in accordance with Regulatory Guide 1.122 to account for variation in material properties and approximations in modeling.

The piping systems were modeled as three-dimensional lumped mass systems which included considerations of eccentric masses at valves and appropriate flexibility and stress intensification factors. The dynamic analysis procedures meet the criteria specified in this appendix, and are acceptable. The resultant stresses and loads from the reanalysis were used to evaluate piping, supports, nozzles, and penetrations.

Based on NRC review of the computer codes used for reanalysis, independent check analyses, and a review of modeling methods used by the Licensee, the NRC found the procedures and methods used in reanalyzing these problems acceptable.

The reanalysis included problems involving the reactor coolant system boundary and the supports associated with those problems. Since the reactor coolant system boundary is inside containment and all of the supports have been modified as necessary, there is no potential for a loss-of-coolant accident in the event of a design-basis earthquake.

At the request of the NRC, its consultant, EG&G, performed audit pipe stress calculations of five Surry 1 problems using the NUPIPE computer code. The results of the EG&G audit compared favorably with Vepco’s results.

The piping support designs for affected system piping were inspected by Vepco to verify the location, orientation, support clearances, and support type. Any deviations were incorporated into piping reanalyses. These piping systems were also verified by the NRC Office of Inspection and Enforcement.

The pipe supports were reevaluated in cases where the original support design loading was exceeded as a result of piping reanalysis. In cases where the original support capacity was exceeded, the support reevaluation included the consideration of baseplate flexibility and a verification of actual field construction of the support. Where concrete expansion anchor bolts were used, their capacities, without compromising the originally committed safety margin, were also included in the reevaluation.

The pipe break criteria of this appendix were reviewed in connection with the possible effect of changes of the high-stress point resulting from the reanalyses. Results of the evaluation of the effect the reanalysis has on the pipe break criteria show that no new whip restraints are required. Therefore, the reanalysis has not changed the pipe break protection.

The design and analysis of the supports and attached equipment are in accordance with the criteria specified in this appendix. The piping systems and supports were designed to the allowable limits of ANSI B31.1 for the gross properties, and to the limits of ANSI B31.7 Appendix F, for local stress considerations as per the criteria of this appendix. A reanalysis of the pressurizer surge line to account for the effect of thermal stratification and striping was performed in accordance with the requirements of ASME Boiler and Pressure Vessel Code, Section III 1986 with addenda through 1987 incorporating high cycle fatigue as required by NRC Bulletin 88-11, dated December 20, 1988.

15A.3.5.2 **Verification of Analysis Methods**

The following computer codes and analysis methods have been identified as the current basis for the facility piping design:

1. NUPIPE/S&W
2. NUPIPE
3. Static analysis methods
4. PIPESTRESS

15A.3.5.2.1 NUPIPE/S&W

Stone & Webster has submitted documentation on the NUPIPE/S&W code to the NRC. This code calculates intramodal and intermodal responses according to the provision in Regulatory Guide 1.92 (Reference 27). A review of the code listing by the NRC staff has confirmed this statement. The option used by Vepco specifies an intramodal combination consisting of the addition of the absolute value of the responses due to the vertical earthquake component and the root-mean-square combination of the responses due to the two horizontal earthquake components. Additional documentation has also been submitted by the originators of this code (Quadrex), providing detailed information on the methods of modal combination.

Vepco solved three NRC benchmark piping problems and the solutions showed acceptable agreement with the benchmark solutions. In addition, a confirmatory problem (No. 323A) was provided to Brookhaven National Laboratory for confirmatory solution. A comparison of the solutions demonstrated good agreement (within about 10%).

15A.3.5.2.2 NUPIPE

Ebasco Services, Inc., has submitted documentation to the NRC on the NUPIPE computer code, which was used in the piping reanalysis of Unit 2. This code is considered acceptable for analyses for both units.

This code has previously been reviewed and has been found to satisfy the requirements of Regulatory Guide 1.92. Ebasco solved three of the NRC benchmark piping problems, and its solutions were found to agree closely with the benchmark solutions. They also provided a confirmatory problem (2508A), which was solved by the Brookhaven National Laboratory. Comparison of the solutions showed good agreement.

15A.3.5.2.3 Static Analysis Methods

Static analysis methods, which were used in cases not subjected to computerized seismic analysis, are based on simple beam formulations, wherein seismic stress levels are controlled through use of pre-established seismic spans. These simple beam formulations were utilized to calculate maximum allowable spans based upon an assumed acceleration factor of 1.5 times the peak acceleration obtained from the response spectra. In calculating the maximum span lengths, it was conservatively assumed that a longitudinal pressure stress of 4000 psi and a maximum deadweight stress of 1500 psi were present in the pipe. This combined value of 5500 psi was subtracted from the allowable stress (1.8 S_h for pressure and deadweight and seismic) to obtain a seismic allowable stress.

Calculating maximum spans by this procedure results in maximum allowable spans greater than the deadweight spans recommended in ANSI B31.1. Thus, dead weight governs and provides a greater number of supports resulting in closely spaced restraints. To minimize effects of concentrated weights, restraints were placed as required at valves and other concentrated masses.

For Surry, piping 6 inches in diameter and smaller was generally analyzed using the simplified static method, with the option of utilizing more rigorous methods available to the analyst. Piping 2 inches and below was shown on the piping drawings diagrammatically (i.e., without detailed dimensions). The stress engineers located supports during the installation process working at the site with erection isometric sketches.

The stress analysis was performed by assuming many simple supported straight beams, the spans of which are governed by deadload spacing requirements of ANSI B31.1. The piping fundamental frequencies associated with these maximum allowable spans (9.7 to 13.6 cycles per sec) are not in resonance with the building in which they are located (2 to 8 cycles per sec). The method of equivalent static analysis outlined in this procedure was compared with the NRC's Standard Review Plan 3.7.2 (Reference 28) and found to be acceptable.

15A.3.5.2.4 PIPESTRESS

The Unit 2 RVLIS piping and Head Vent piping were reconfigured to accommodate the head assembly upgrade package. Reanalysis of the piping was performed using PIPESTRESS (Reference 68).

The PIPESTRESS program is a finite element computer program which performs linear elastic analysis of piping systems using the stiffness method of finite element analysis; the displacements of the joints of a given structure are considered basic unknowns. The dynamic analysis by the modal synthesis method utilizes known maximum accelerations produced in a single degree of freedom model of a certain frequency. The principal program assumptions are as follows:

- It is a linearly elastic structure.
- Simultaneous displacement of all supports is described by a single time-dependent function.
- Lumped mass model satisfactorily replaces the continuous structure.
- Modal synthesis is applicable.
- Rotational inertia of the masses has negligible effect.

The results obtained from the pipe stress program PIPESTRESS have been compared with the following:

- ASME Benchmark problem results, Pressure Vessel and Piping 1972 computer programs verification, American Society of Mechanical Engineers.
- Longhand calculations - PIPESTRESS is compatible with NRC Regulatory Guide 1.92. A synthesis of closely spaced modes is provided based on equation 4 of Regulatory Guide 1.92.
- Benchmark confirmatory piping analysis problems were reviewed by the NRC and Brookhaven National Laboratory.

The PIPESTRESS program is used to determine stresses and loads in the piping systems due to restrained thermal expansion, deadweight, seismic inertia and anchor movements, externally applied loads such as jet-loads, and transient forcing functions such as created by fast relief valve opening and closing, fast check valve closure after pipe breaks in main feedwater line, fast valve closure in main steam line, etc. PIPESTRESS analyzes piping systems in accordance with ANSI and ASME codes.

15A.3.5.3 **Soil Structure Interaction**

Soil structure interaction amplified response spectra (SSI-ARS) were used in reanalyzing the piping systems for those cases where the original amplified response spectra did not give satisfactory results. Based upon review of Vepco's information submitted by References 29 and 30, the NRC informed Vepco by Reference 31 and 32 that SSI-ARS was acceptable.

The amplified floor response spectra (ARS) for three levels in the containment, base mat, operating floor and spring line were computed using the multi-layered elastic half-space method and the finite element methods. The results of these analyses were compared for frequency and acceleration of the floor response spectra. The elastic half-space method gave acceleration values that were larger than the finite element method for the operating floor and the spring line. The finite element method gave accelerations slightly higher than the elastic half-space method for the containment base mat. Since no piping systems are located at, and would not use, the base mat spectra for analysis, it was concluded the elastic half-space method would be used for the reevaluation because that would be conservative. The time history used for this comparison was the original design time history used in the original design of the plant, along with the original damping values.

The same floor response spectra were generated for the Regulatory Guide 1.60 (Reference 33) requirements anchored at 0.15g, along with the Regulatory Guide 1.61 (Reference 34) damping values for comparison with the original earthquake input requirements. The time history and the damping values are considered as a consistent set of design parameters. The comparison of the original FSAR design requirements and the Regulatory Guide 1.60 and 1.61 set of values shows that the responses are very consistent, and that the original design requirements are adequate.

The ground-response spectra at the base of the reactor containment structure were calculated and plotted using SHAKE. The response spectra were calculated for three soil profiles, represented by the average low-strain shear modulus, G_{max}, calculated from seismic cross-hole surveys, G_{max} plus 50%, and G_{max} minus 50%. The spectra for each soil profile are plotted on Figures 15A-1, 15A-2, and 15A-3, respectively. Also plotted on these figures is the envelope for 0.5% damping, as presented on Figure 2.5-6.

A study of the effects of the variation of the soil properties was undertaken. The response spectra for the three locations in the containment building were computed for five variations of the soil properties. Variation one considered the computed strain dependent properties using the best estimate of the in-situ properties as input to computer code SHAKE; variation two used the in-situ properties plus 50% as input to the computer code SHAKE; variation three used the in-situ properties minus 50% as input to the computer code SHAKE; variation four considered the first iteration value of the computer code SHAKE using the in-situ properties as input; and variation five used the measured values (low strain) of the soil properties. This study indicated that the response of the structure to the variations in the soil properties is essentially limited to the amplitude of the floor response spectra. It was determined that an increase of the values of the response spectra already used in piping stress calculations by a factor of 1.50 would be acceptable. This increase in the acceleration value for the floor response spectra results in a conservative reanalysis.

To further verify that this increase (1.5) is conservative, the NRC staff conducted an independent study of the variation of soil properties used in the dynamic analyses. First the staff confirmed the adequacy of the average soil properties selected by Vepco and then considered parametric studies of these properties. The results of this effort indicated that a variation of ±25% for the input shear modulus (G_{max}) would accommodate uncertainties in the in-situ soil properties. The results of this variation appear to bound the possible range in soil properties based on staff experience with other site studies. Therefore, Vepco’s studies for ±50% and the increase (1.5 factor) in the response spectra are conservative.

Because the soil shear moduli used in the generation of amplified floor response spectra depend upon the level of strain induced by earthquake motion, the amplified floor response spectra are not in direct proportion to the maximum ground acceleration. Therefore, an investigation of the effects of earthquakes smaller than the design-basis earthquake was also undertaken. For the purpose of this study, amplified floor response spectra were computed for various average strain compatible shear moduli, each due to a peak horizontal ground acceleration ranging from 0.15 to 0.05g. Vepco has provided the resulting family of amplified floor response spectra at the operating floor, which show the design-basis earthquake spectrum to envelope the other spectra due to smaller earthquakes. This demonstrated that the effects of design-basis earthquake are not exceeded by those of smaller earthquakes.

The computer codes used in the reanalysis for the soil structure interaction were:

1. SHAKE
2. PLAXLY
3. REFUND
4. KINACT
5. FRIDAY

The computer code SHAKE is a public domain program and was used to compute only the strain-dependent properties of the supporting soil under the structures. Because this code was only used to compute soil properties, no further verification was necessary.

The computer code PLAXLY is a proprietary code and was qualified by comparison to the existing public domain computer code FLUSH. Amplified response spectra for the containment operating floor computed by both codes were compared.

The computer code REFUND computes the frequency dependent compliance functions for a multi-layered elastic half-space. This code is a proprietary code and was qualified by comparing the results of a sample problem with the results published in the literature.

The computer code KINACT is a proprietary code and is used to compute the translation and rotation time history at the base of the structure from the design time history applied at the free ground surface. This code was qualified by comparing the results of a sample problem to the results of the computer code PLAXLY.

The computer code FRIDAY uses the results of REFUND and KINACT to compute the floor response spectra for each mass point in the mathematical model of the structure. The code is a proprietary program and was qualified by comparing the results of a sample problem with the results of the public domain program STARDYNE.

Additional soil-structure interaction analysis was performed for the Service Building, Safeguards Building, emergency diesel generator rooms, and Containment Spray Pump House to develop in-structure response spectra (ISRS) at certain spectral damping values that were not originally developed for these buildings. A discussion of the methods and criteria used in developing these ISRS was provided to the NRC in Reference 42, as part of the resolution to Generic Letter 87-02 (Reference 39) and Unresolved Safety Issue A-46. These methods and criteria were found adequate and acceptable in the NRC's Safety Evaluation, as indicated in Reference 43. This analysis utilized synthetic time histories as free-field motions. Three synthetic time-histories were developed such that their spectra at 5% damping closely matched the corresponding UFSAR horizontal and vertical ground spectra for Surry, consistent with Figures 2.5-5 and 2.5-6 for OBE and DBE respectively. A very close fit was reached to ensure that no lack of energy occurs at any frequency of interest. The three time histories were statistically independent. Soil and structures were modeled in detail, as discussed below.

The low strain soil properties were obtained from Section 2.4. Industry Standard Code SHAKE was used to perform dynamic analyses of the soil profile to generate the strain compatible soil properties. To account for uncertainties in the soil properties, three low strain soil properties were considered for each seismic input, in accordance with the recommendations in the Standard Review Plan (SRP - NUREG 0800). They are: best estimate, lower bound (shear modulus equal to half the best estimate shear modulus), and upper bound (shear modulus equal to twice the best estimate shear modulus). Thus, three strain compatible soil profiles were developed consistent with soil strains induced by the Housner input.

The structures were modeled as three-dimensional "stick" models with lumped mass and with six degrees of freedom at each node. Eccentricities were explicitly considered at each modeled elevation to account for the effects of torsion and rocking. The damping values were in accordance with Table 15.2-2. For the cases where different portions of the structures were assigned different damping, composite modal damping values were generated based on the strain energy weighted approach.

For each structure, the proper foundation embedment was considered and frequency dependent impedance and scattering functions were calculated for each strain compatible soil case. In addition, the deconvolved time-histories at the foundation levels were verified according to the recommendation of the SRP such that their response spectra (envelop of three soil cases) are not less than sixty percent of the surface spectra. The building models were used together with the proper impedance and scattering functions and for each strain compatible soil case, the three orthogonal time-histories were applied individually. The In Structure Response Spectra (ISRS) in this effort were developed at each elevation for each structure, and peak broadened +15% and -15% to account for uncertainties and variabilities in the structural frequencies, in accordance with Regulatory Guide 1.122.

Additional information on soil-structure interaction can be found in Chapter 2.

15A.4 MOVEMENT OF REACTOR COOLANT SYSTEM COMPONENTS

The criterion for movement of the reactor pressure vessel, under the worst combination of loads, i.e., normal plus the design-basis earthquake plus reactor coolant pipe rupture loads[1], is that the movement of the reactor vessel will not exceed the clearance between a reactor coolant pipe and the surrounding concrete.

The relative motions between reactor coolant system components will be controlled by the structures that are used to support the reactor pressure vessel, steam generators, pressurizer and reactor coolant pumps.

Piping runs that are external to the plant or between buildings and that would affect the health and safety of the public are dynamically stress analyzed. Necessary earthquake stops, constraints, or anchors are judiciously located to withstand motion, but allow for thermal movement.

The dynamic seismic stresses are calculated using the appropriate operational-basis earthquake and design-basis earthquake response spectrum. The design criteria for the analysis of Class I piping systems are in accordance with the code requirements of ANSI B31.1. Pressure, deadload, thermal, and seismic pipe stresses are combined in accordance with the code.

The structures to which the piping is attached are also designed to withstand these loads. Included in the pipe stress analysis are horizontal and vertical differential motion caused by rotation, translation, and flexure of the respective structures assumed to be out of phase with each other, plus the relative motion from earthquake orbital displacement of the founding soil.

1. As discussed in Section 15.6.2, it is no longer necessary to consider the dynamic effects of a postulated rupture of the primary reactor coolant loop piping. However, pipe ruptures of reactor coolant branch lines, the main steam lines are still postulated.

In most cases, piping runs are stress-analyzed by system, thus determining the effect of branch lines joining the main run or other piping.

In the analysis of piping running between structures, and to different elevations within the same structure, consideration has been given to differential motion of the piping supports and anchors.

The building displacements caused by an earthquake, which include rocking and translation of the structures, as well as the relative motion from orbital displacement of the foundation soil, are evaluated at the elevation or elevations at which the piping is supported. These displacements are then applied to the supports and anchors as external movements to the piping system, and stresses are calculated.

For the analysis of piping supported by different structures, an out-of-phase condition is always assumed, and the direction of the displacements applied to the piping supports and anchors are chosen to reflect the out-of-phase condition to yield the most conservative results.

15A.5 TESTS TO DEMONSTRATE THE CONSERVATISM OF THE LIMIT CURVES

Tests performed at Westinghouse Material Testing Laboratory in Pittsburgh demonstrate the conservatism of the limit curves presented in WCAP-5890, Revision 1 (Reference 35). Carbon steel and stainless steel pipes have been tested under various combinations of axial and transverse loads to determine failure loads. Specimens about 1.5 foot long have been cut from 1.5-inch nominal diameter Schedule 160 pipes. The materials employed were SA 106B carbon steel and Type 304 stainless steel. These specimens were kept internally pressurized to 3000 psia for the entire duration of the tests. Tables 15A-3 and 15A-4 summarize the tests that have undergone evaluation and the results of this evaluation.

Standard ASTM tensile specimens have been modeled from pieces of the test pipes and stress-strain curves determined. These curves have been conservatively approximated with trapezoidal stress-strain curves as indicated in WCAP-5890, Revision 1. The limit curves for both SA 106B carbon steel and Type 304 stainless steel for the test conditions have been calculated and are reported in Figures 15A-4 and 15A-5, respectively. The experimental points, i.e., stress intensities versus axial stress as listed in Tables 15A-3 and 15A-4 are shown in Figures 15A-4 and 15A-5. Also shown in these figures are the limit curves as calculated by the use of the trapezoidal stress-strain curves up to the ultimate stress. Comparisons between the experimental points and the design limit curves show the conservatism of the latter.

15A.5.1 Westinghouse Topical Reports

WCAP-5890, Rev. 1, has been replaced by WCAP-7287 (Reference 36). The revisions affected limits for the combination of normal loads plus design-basis earthquake loads plus pipe rupture loads associated with a loss-of-coolant accident. The changes reflected agreement with the staff of the Atomic Energy Commission (AEC) Division of Reactor Licensing on the stress limits for the above-mentioned load combinations. Details of the manner in which the revisions were developed are as follows:

1. Material data used to develop stress-strain curves.

   Typical stress-strain curves of type 304 stainless steel (Figure 15A-6), Inconel 600 (Figure 15A-7) and SA 302B low alloy steel (Figure 15A-8) at 600°F were generated from tests using graphs of applied load versus cross-head displacement as automatically plotted by the recorder of the tensile test apparatus. The scale and sensitivity of the test apparatus recorder ensured accurate measurement of the uniform strain.

   For materials other than these three, stress-strain curves were developed by conservative use of pertinent available material data (i.e., lowest values of uniform strain and initial strain hardening). Where the available data were not sufficient to develop a reliable stress-strain curve, three standard ASTM tensile tests of the material in question were performed at design temperature. These data were conservatively applied in developing a stress-strain curve as described above.

2. The ordinate (stress) of the stress-strain curves was normalized to the measured yield strength.

3. Twenty percent of uniform strain as defined on the curve developed under Item 1 was used as the allowed membrane strain.

4. The normalized stress ratio was established at 20% of uniform strain on the normalized stress-strain curves developed under item 2.

5. The value of the membrane stress limit was established.

6. The normalized stress ratio in item 4 was multiplied by the applicable code yield strength at the design temperature to get the membrane stress limit. The actual physical properties as determined from standard ASTM tensile tests on specimens from the same heats was allowed as an alternate method of determining the membrane stress limit. Sufficient documentation was provided to support the actual material properties used.

7. Limit curves for the combination of local membrane and bending stresses were developed.

   The limit curves were developed by using the analytical approach presented in WCAP-5890, Revision 1, and the stress-strain curve up to the membrane stress limit as developed under item 5. These limit curves were within the limit curves discussed with the staff of the AEC Division of Reactor Licensing during meetings on November 30 and December 1, 1967, for the same materials.

15A.5.2 Framatome Computer Programs (Unit 1 only)

This section describes computer programs that were used by Framatome ANP for the dynamic and static analysis of Class 1 equipment and components during the process of qualifying the Unit 1 replacement reactor vessel closure head to ASME Section III requirements. These computer programs meet the requirements of the Dominion and Framatome ANP software validation programs. The validation program meets the requirements of 10 CFR 50 Appendix B, ASME NQA 1, and ANSI N45.2. The software validation compliance was verified during an onsite quality audit of the replacement closure head vendor. Audit results and objective evidence of the software validation are available in the Framatome ANP audit file. These programs provide results that are essentially the same or more conservative than the analyses of record.

15A.5.2.1 **BWSPAN**

BWSPAN (Reference 63) is designed to perform analysis in accordance with the ASME Boiler and Pressure Vessel Code, Section III Nuclear Power Plant Components and the ANSI B31.1 Power Piping Code. This code has been specifically used for evaluating the configuration of the RVLIS piping routed from the closure head up to and including “RX Vessel Vent Line to RVLIS Isolation Valve,” 1-RC-603, “Rx Vessel Vent Line to RVLIS Isolation Vent Valve,” 1-RC-36 (including associated drain valve 1-RC-186) and to a location in the run of the pipe just upstream of valve 1-RC-185.

15A.5.2.2 **BIJLAARD**

BIJLAARD (Reference 64) is designed to calculate local stresses in a cylindrical or spherical shell induced by a nozzle or support.

15A.5.2.3 **FERMETURE**

FERMETURE (Reference 65) is designed to calculate the loadings used for the closure analysis. FERMETURE calculates the stud load components for a given set of temperature and pressure values. Additionally, FERMETURE verifies the leak tightness of the vessel closure.

15A.5.2.4 **SYSTUS**

SYSTUS (Reference 66) is designed to analyze the thermal-mechanical behavior of beams and solid structures in two or three dimensions.

15A.5.2.5 **RCCM-ASME**

RCCM-ASME Program (Reference 67) is a special postprocessor of SYSTUS that allows manipulation of SYSTUS results for stress analyses in accordance with the rules defined by the ASME Code Section III including stresses linearization, usage factor calculation and thermal ratchet analysis.

15A.6 REACTOR COOLANT LOOP (RCL) PIPING REANALYSIS SUBSEQUENT TO LEAK BEFORE BREAK AND SNUBBER ELIMINATION

Table 15A-5 identifies the maximum level of stress as a percentage of the Code allowable stress for the analysis that was performed for implementation of Leak Before Break (LBB), which allowed for the removal of large snubbers connected to the primary loop piping. Reanalysis of the Reactor Coolant Loop piping and supports was performed subsequent to the implementation of LBB to support implementation of several plant changes and refinement of analytical modeling, which include:

- Measurement Uncertainty Recapture (MUR) power uprate
- Implementation of the 15 x 15 Upgrade Fuel Design
- Nuclear Safety Advisory Letter NSAL-11-2 (Reference 71) concerning the assumed stiffness of the Reactor Vessel Lower Radial Keys.

The resultant updated stresses as a percentage of the Code allowable stress and factors of safety for supports are shown in Table 15A-8 and Table 15A-9 respectively.

In the stress reanalyses performed by Westinghouse, and documented in References 69 and 70, two additional RCL branch line pipe break cases, consisting of RHR Suction and Accumulator Injection line breaks, were added, which were not analyzed previously. Addition of these postulated breaks increased the faulted stresses. However, the recalculated stresses still remain below the code allowable stress of 2.4 S_h. The recalculated stresses for analyzed loading conditions are shown in Table 15A-8. The change only affects the faulted condition evaluation. All the other stresses (Pressure, Deadweight, Thermal, Seismic OBE and DBE) are unchanged. The recalculated margins for pipe supports based upon Shaw calculation 13019801-P-0001 (Reference 71) are shown in Table 15A-9. The stated change affects only the faulted loads due to the two additional pipe break cases analyzed. There is no change in other loads, including seismic OBE and DBE loads.

As noted in Section 15.6.2 and its associated references, the application of Leak-Before-Break was subsequently extended to the Surry Units 1 and 2 Reactor Coolant System branch piping including: the Pressurizer Surge, Residual Heat Removal, Accumulator, Loop Bypass, and Safety Injection piping up to each line’s first pressure isolation valve. The evaluation demonstrated the dynamic effects of the pipe rupture resulting from postulated breaks in the Surge, RHR, Accumulator, Loop Bypass and SI line piping need not be considered in the structural design basis of Surry Units 1 and 2 for the 80 year period of extended plant operations.

Table 15A-1
LOADING CONDITIONS AND STRESS LIMITS

Pressure Vessels

Loading Conditions	Stress Limits	
1. Normal conditions	a. $P_m \leq S_m$	
	b. P_m(or P_L)+$P_B \leq 1.5S_m$	(Note 1)
	c. P_m(or P_L)+P_B+$Q \leq 3.0S_m$	(Note 2)
2. Upset conditions	a. $P_m \leq S_m$	
	b. P_m (or P_L)+$P_B \leq 1.5S_m$	(Note 1)
	c. P_m(or P_L)+P_B+$Q \leq 3.0S_m$	(Note 2)
3. Emergency conditions	a. $P_m \leq 1.2S_m$, or $P_m \leq S_y$, whichever is larger	
	b. P_m (or P_L)+$P_B \leq 1.5(1.2S_m)$, or P_m (or P_L)+$P_B \leq 1.5$ (S_y) whichever is larger	(Note 3) (Note 3)
4. Faulted conditions	Design limit curves of WCAP-5890, Rev. 1, as modified by Section 15A.5.1	(Note 4)

where:

P_m = primary general membrane stress intensity
P_L = primary local membrane stress intensity
P_B = primary bending stress intensity
Q = secondary stress intensity
S_m = stress intensity value from ASME B&PV Code, Section III, Nuclear Vessels
S_y = minimum specified material yield

Pressure Piping (Note 6)

Loading Conditions	Stress Limits	
1. Normal conditions	$P_m \leq S$	
2. Upset conditions	$P_m \leq 1.2S$	
3. Emergency conditions	$P_m \leq 1.8S$	
4. Faulted conditions	Design limit curves of WCAP-5890, Revision 1, as modified by Section 15A.5.1	(Note 4)

where

P_m = principal stress
S = Allowable stress from USAS B31.1, Code for Power Piping

7	Equipment Supports
1. Normal conditions	Within working limits
2. Upset conditions	Within working limits

Table 15A-1 (CONTINUED)
LOADING CONDITIONS AND STRESS LIMITS

	Equipment Supports (continued)	
3. Emergency conditions	Within material yield strength after load redistribution	(Note 5)
4. Faulted conditions	Within material yield strength after load redistribution	(Note 5)

Note 1: The limits on local membrane stress intensity ($P_L \leq 1.5Sm$) and primary membrane plus primary bending stress intensity (P_M (or P_L) + $P_B \leq 1.5S_m$) need not be satisfied at a specific location if it can be shown by means of limit analysis or by tests that the specified loadings do not exceed 2/3 of the lower bound collapse load as per paragraph N-417.6(b) of the ASME B&PV Code, Section III, Nuclear Vessels.

Note 2: In lieu of satisfying the specific requirements for the local membrane ($P_L \leq 1.5Sm$) or the primary plus secondary stress intensity ($P_L + P_B + Q \leq 3S_m$) at a specific location, the structural action may be calculated on a plastic basis and the design will be considered to be acceptable if shakedown occurs, as opposed to continuing deformation, and if the deformation which occur prior to shakedown do not exceed specified limits, as per paragraph N-417.6(a)(2) of the ASME B&PV Code, Section III, Nuclear Vessels.

Note 3: The limits on local membrane stress intensity ($P_L \leq 1.5S_m$) and primary membrane plus primary bending stress intensity (P_m (or P_L) + $P_B \leq 1.5S_m$) need not be satisfied at a specific location if it can be shown by means of limit analysis or by test that the specified loadings do not exceed 120% of 2/3 of the lower bound collapse load as per paragraph N-417.10(c) of the ASME B&PV Code, Section III, Nuclear Vessels.

Note 4: As an alternate to the design limit curves that represent a pseudo plastic instability analysis, a plastic instability analysis may be performed in some specific cases considering the actual strainhardening characteristics of the material, but with the yield strength adjusted to correspond to the tabulated value at the appropriate temperature in Table N-424 or N-425, as per paragraph N-417.11c of the ASME B&PV Code, Section III, Nuclear Vessels. These specific cases will be justified on an individual basis.

Note 5: Higher stress values can be adopted if a valid limit or plastic instability analysis of the support and supported component/system is performed.

Note 6: As required by NRC Bulletin 88-11, pressurizer surge line is re-evaluated in accordance with the requirements of ASME Boiler and Pressure Vessel Code, Section III, Subsection NB, 1986 with addenda through 1987 incorporating high cycle fatigue.

Table 15A-2
MINIMUM MARGINS OF SAFETY

	Loading Conditions		
Material	Upset Conditions	Emergency Conditions	Faulted Conditions (Note 1)
SA302 Grade B	200%	150%	27%
Inconel 600	228%	172%	43%
316 SST	222%	169%	60%
A212 Grade B	346%	272%	55%

Note: Based upon the limit curves computed using Section 15A.5.1.

Table 15A-3

TESTS AND TEST RESULTS ON SA 106B CARBON STEEL PIPE SPECIMENS

(INTERNAL PRESSURIZATION = 3000 PSIA)

	Pseudo-elastic Axial Stress Normalized to the Yield Stress	Pseudo-elastic Bending Stress Normalized to the Yield Stress	Pseudo-elastic Stress Intensity Normalized to the Yield Stress	Strain Percent (gauge length)
Pure tension (no weld)	1.736	0.0	1.770	22.61% (12 in.)
	1.840	0.0	1.847	22.32% (12 in.)
Pure bending [a]	0.10	>2.348	2.382	>35.4X (1 in.)
Tension + bending (no weld)	>1.375	>1.030	2.440	>7.75% (6 in.)
	>1.585	>0.565	2.180	--
	>1.845	>0.266	2.145	--
Compression + bending (no weld)	>1.130	1.08	2.410	--
Pure tension (circumf. weld)	1.852	0.0	1.886	20.05% (12 in.)
Pure bending (circumf. weld)	0.10	>2.580	2.614	>30.19X (1.5 in.)
Pure bending [b] (rejected circumf. weld)	0.10	2.460	2.494	14.51% (2 in.)

a. The limit capability of the test apparatus has been reached before failure of these specimens was approached.

b. This test was performed on a welded pipe specimen that has been rejected by the inspector prior to the test for gross lack of penetration in weld. This was the only test in which the weld failed. The specimen exhibited substantial ductility prior to failure.

Table 15A-4
TESTS AND TEST RESULTS ON 304 STAINLESS STEEL SPECIMENS
(INTERNAL PRESSURIZATION = 3000 PSIA)

	Pseudo-elastic Axial Stress Normalized to the Yield Stress	Pseudo-elastic Bending Stress Normalized to the Yield Stress	Pseudo-elastic Stress Intensity Normalized to the Yield Stress	Strain Percent (gauge length)
Pure tension (no weld)	2.495	0.0	2.53	52. 12 (12 in.)
Pure bending [a]	+0.10	>2.91	>2.945	>30.0% (1 in.)
Tension + bending (no weld)	>+2.09	>0.42	>2.55	--
Pure bending (circumf. weld)	+0.10	>3 27	>3.30	>25.0% (1.5 in.)
Pure tension (circumf. weld)	+2.46	0.0	2.49	44.6% (12 in.)

a. The limit capability of the test apparatus has been reached before failure of these specimens was approached.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 15A-5

LEVEL OF STRESS AS A PERCENTAGE OF CODE ALLOWABLE STRESS

Loading	Hot Leg	Crossover Leg	Cold Leg	Code Allowable Stress
Thermal	38.6%	15.6%	7.4%	S_A
Pressure + Deadweight	68.0%	48.7%	53.3%	$1.0S_h$[a]
Pressure + Deadweight + OBE	65.5%	65.0%	60.0%	$1.2S_h$[a]
Pressure + Deadweight + DBE	49.6%	51.1%	48.9%	$1.8S_h$[a]

In addition, the pipe Stresses in the primary reactor coolant loop piping under combined accident loadings from pressure, deadweight, plus SRSS of design-basis earthquake and controlling pipe ruptures are less than $1.8S_h$, which is conservative both respect to the allowables per Section 15A.5 and to $2.4S_h$ which is permitted by the current ASME Code.

a. S_h =15 Ksi

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 15A-6

FACTORS OF SAFETY FOR COMPONENT SUPPORTS UNDER DESIGN-BASIS SEISMIC AND NORMAL OPERATING LOADS SURRY UNITS 1 AND 2

Component	Factor of Safety[a]		
	Original Design[b]	Modified Design[c]	Final Design[d]
Steam Generator Shell	>20.0	>20.0	>20.0
Steam Generator Upper Support			
Component	19.2	15.9	13.7
Upper Guide	7.3	4.6	3.3
Snubber	14.2	14.2	6.3
Steam Generator Lower Support			
Hanger Rod	1.8	1.8	1.8
Swivel End Coupling	16.3	13.4	12.2
Steam Generator Foot			
Vertical Force	2.7	2.8	2.8
Tangential Force	16.0	12.4	12.4
Reactor Coolant Pump Foot			
Vertical Force	5.5	5.2	5.3
Tangential Force	15.4	15.8	15.9
Radial Force	15.4	15.0	12.8
Reactor Coolant Pump Support			
Upper Vertical	5.5	5.0	5.0
Upper Horizontal	5.0	5.0	5.0
Lower Vertical	3.6	3.6	3.6
Lower Diagonal	4.6	4.6	4.6

a. Factor of Safety - (Allowable Load)/(TotaL Load of Deadweight, Pressure, Thermal and DBE)

b. Original design incorporated ten large-bore snubber per loop for primary reactor coolant system pipe rupture loads.

c. Modified design implemented elimination of six large-bore snubbers based on “leak-before-break”; n the four remaining large-bore snubbers were required to carry loads of main steam line rupture.

d. Final design incorporates only two large-bore snubbers on Steam Generator, following elimination of lateral loads due to postulated AIB of Main Steam Line.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Table 15A-7

FACTORS OF SAFETY FOR COMPONENT SUPPORTS UNDER COMBINED ACCIDENT LOADS SURRY UNITS 1 AND 2

Component	Factor of Safety[a]		
	Original Design[c]	Modified Design[d]	Final Design[e]
Steam Generator Shell	2.5	2.4	8.3
Steam Generator Upper Support			
Component	2.8	2.8	7.5
Upper Guide	1.1	1.1	2.6
Snubber	1.3	1.4	1.9
Steam Generator Lower Support			
Hanger Rod	1.7	1.7	1.7
Swivel End Coupling	2.3	2.3	2.3
Steam Generator Foot[b]			
Vertical Force	4.0	4.2	4.3
Tangential Force	7.4	7.2	7.3
Reactor Coolant Pump Foot[b]			
Vertical Force	11.9	11.3	10.9
Tangential Force	>20.0	>20.0	>20.0
Radial Force	>20.0	>20.0	>20.0
Reactor Coolant Pump Support			
Upper Vertical	4.5	4.3	4.2
Upper Horizontal	5.3	4.8	4.6
Lower Vertical	3.8	3.5	3.5
Lower Diagonal	3.0	3.0	3.0

a. Factor of Safety - (Allowable Load)/[TotaL Load of Deadweight, Pressure, Thermal and SRSS (DBE+Pipe Rupture)].

b. Allowable loads from Westinghouse specification are higher for pipe rupture case; this results in higher normal factors of safety for some components for this case compared with factors of safety for design basis seismic loads only (Table 15A-4).

c. Original design incorporated ten large-bore snubber per loop for primary reactor coolant system pipe rupture loads.

d. Modified design implemented elimination of six large-bore snubbers based on “leak-before-break”; n the four remaining large-bore snubbers were required to carry loads of main steam line rupture.

e. Final design incorporates only two large-bore snubbers on Steam Generator, following elimination of lateral loads due to postulated AIB of Main Steam Line.

Table 15A-8
CALCULATED STRESS AS PERCENTAGE OF CODE ALLOWABLE STRESS
(REFERENCE 69)

Loading	Hot Leg	Crossover Leg	Cold Leg	Code Allowable Stress
Thermal	38.6% (unchanged)	15.6% (unchanged)	7.4% (unchanged)	S_A
Pressure + Deadweight	68.0% (unchanged)	48.7% (unchanged)	53.3% (unchanged)	1.1 S_h[a]
Pressure + Deadweight + OBE	65.5% (unchanged)	65.0% (unchanged)	60.0% (unchanged)	1.2 S_h[a]
Pressure + Deadweight + DBE	49.6% (unchanged)	51.1% (unchanged)	48.9% (unchanged)	1.8 S_h[a]
Pressure + Deadweight + $\{(DBE)^2 + (LOCA/Pipe Rupture)^2\}^{1/2}$	50.8%	53.9%	98.1%	2.4 S_h[b, c]

a. S_h = 15 ksi

b. The faulted case maximum calculated stress which includes maximum stress for worst case LOCA/pipe break is compared against ASME code allowable stress of 2.4 S_h. This is acceptable under current industry practice and widely used by Westinghouse in the reanalysis of RCL piping for their plants. Based upon the material test data performed by Westinghouse, documented in WCAP-5890, Rev. 1 which was later replaced by WCAP-7287 and shown summarily in Tables 15A-3 plus 15A-4 and Figures 15A-4 plus 15A-5, the design limit curves are conservative compared to test results shown.

c. RCL LOCA analysis has been revised and upgraded to incorporate ELBB (Extended Leak Before Break) technology resulting in significant reduction in pipe support loads and pipe stresses. As a result, LOCA loads and stress values shown in the above table will be significantly reduced once these tables are revised.

Table 15A-9
FACTORS OF SAFETY FOR STEAM GENERATOR AND REACTOR COOLANT PUMP SUPPORTS (REFERENCE 70)

Component	**Factor of Safety**
Steam Generator Upper Support:	
Component	7.5
Upper Guide	2.5
Snubber	1.5
Steam Generator Lower Support:	
Hanger Rod	1.2
Swivel End Coupling	1.7
Reactor Coolant Pump Support:	
Upper Vertical	3.1
Upper Horizontal	3.4
Lower Vertical	2.6
Lower Diagonal	2.2

a. RCL LOCA analysis has been revised and upgraded to incorporate ELBB (Extended Leak Before Break) technology resulting in significant reduction in pipe support loads and pipe stresses. As a result, LOCA loads shown in the above table will be significantly reduced once this table is revised.

CHAPTER 16 TECHNICAL SPECIFICATIONS AND TECHNICAL REQUIREMENTS

16.1 TECHNICAL SPECIFICATIONS

Technical Specifications were proposed in accordance with 10 CFR 50.36 during the initial licensing of the plant. The Technical Specifications now reside in Appendix A of the Operating License for each unit.

Technical Specifications define plant variables, operating conditions, surveillance requirements, and administrative controls that are considered necessary to ensure the health and safety of the public.

Intentionally Blank

16.2 TECHNICAL REQUIREMENTS

The Technical Requirements Manual (TRM) contains requirements for plant operation and surveillance of systems formerly contained in the Technical Specifications, along with other selected items. Some requirements were removed from the Technical Specifications as part of NRC and industry efforts to simplify Technical Specifications.

The TRM is controlled by station procedure, and a 10 CFR 50.59 review is required to change the TRM. Changes to the TRM may be made without prior NRC approval, provided that the changes do not involve a license amendment as defined in 10 CFR 50.59. Changes to the TRM that are implemented without prior NRC approval are reported to the NRC in accordance with 10 CFR 50.59. Proposed changes that involve a license amendment are reviewed and approved by the NRC prior to implementation.

CHAPTER 17 QUALITY ASSURANCE

The Quality Assurance Program is described in Topical Report DOM-QA-1, Dominion Nuclear Facility Quality Assurance Program Description (QAPD). This topical report provides the QAPD for Dominion's nuclear power stations and independent spent fuel storage installations. The Dominion QAPD conforms to applicable regulatory requirements, such as 10 CFR 50, Appendix B, and approved industry standards, including equivalent alternatives, where identified. This program applies to activities during design, construction, operation, and decommissioning as well as siting. The Dominion QAPD is incorporated by reference and describes how 10 CFR 50, Appendix B requirements are met.

CHAPTER 18 PROGRAMS AND ACTIVITIES THAT MANAGE THE EFFECTS OF AGING

The following sections provide summary descriptions of the aging management programs (AMPs), which Surry is crediting for the purposes of complying with the license renewal rule, necessary to manage TLAAs and aging of various station systems, structures, and components through the subsequent period of extended operation. The AMPs are either consistent with generally accepted industry methods as discussed in NUREG-2191, “Generic Aging Lessons Learned for Subsequent License Renewal (GALL-SLR) Report,” or require enhancements. Commitments for program additions and enhancements are identified in Section 18.5.

Evaluation summaries of TLAAs applicable to the subsequent period of extended operation are provided in Section 18.3.

This Chapter also includes a discussion on quality assurance and operating experience related to aging management programs.

18.1 SUMMARY DESCRIPTIONS OF AGING MANAGEMENT PROGRAMS

The results of the integrated plant assessment and evaluation of time-limited aging analyses (TLAA) identified new and existing aging management programs necessary to provide reasonable assurance that components within the scope of license renewal will continue to perform their intended functions consistent with the current licensing basis (CLB) through the subsequent period of extended operation. Section 18.1 and Section 18.2 describe these programs.

Evaluation summaries of TLAAs for the subsequent period of extended operation are provided in Section 18.3.

The U.S. Nuclear Regulatory Commission (NRC) Safety Evaluation Report (SER) (Reference 1) for the Surry subsequent renewed operating licenses identified commitments associated with the future development and enhancement of various aging management programs and activities used to manage aging effects for structures and components for the subsequent period of extended operation. These commitments are compiled and listed in Appendix A of the SER and are listed in Section 18.5, Table 18-1, Subsequent License Renewal Commitments. The associated implementation schedules and a reference to the source(s) are provided for each commitment.

Quality Assurance for Aging Management Process

The Quality Assurance (QA) Program is described in Topical Report DOM-QA-1, “Dominion Energy Nuclear Facility Quality Assurance Program Description,” which implements the requirements of 10 CFR 50, Appendix B, “Quality Assurance Criteria for Nuclear Power Plants and Fuel Reprocessing Plants.” The QA Program is consistent with the summary in Appendix A.2, “Quality Assurance for Aging Management Programs (Branch Technical Position

IQMB-1)," of NUREG-2192. The QA Program provides the basis for the corrective actions, confirmation process, and administrative controls elements of aging management programs (AMPs). The scope of the existing QA Program is expanded to also include safety-related and non safety-related structures and components (SCs) subject to AMPs.

Consideration of Operating Experience in Aging Management Programs (AMPs)

Operating experience (OE) from plant-specific and industry sources is captured and systematically reviewed on an ongoing basis in accordance with the QA Program, which meets the requirements of 10 CFR 50, Appendix B, and the OE program, which meets the requirements of NUREG-0737, "Clarification of TMI Action Plan Requirements," Item I.C.5, "Procedures for Feedback of Operating Experience to Plant Staff."

The Dominion OE program interfaces with and relies on active participation in the INPO OE program, as endorsed by the NRC. In accordance with these programs, all incoming OE items are screened to determine whether they may involve age-related degradation or aging management impacts. Research and development is also reviewed. Items so identified are further evaluated and the AMPs are either enhanced or new AMPs are developed, as appropriate, when it is determined through these evaluations that the effects of aging may not be adequately managed. Training on age-related degradation and aging management is provided to those personnel responsible for implementing the AMPs and to those who may submit, screen, assign, evaluate, or otherwise process plant-specific and industry OE. Plant-specific OE associated with aging management and age-related degradation is reported to the industry in accordance with guidelines established in the Dominion OE program.

18.1.1 ASME Section XI Inservice Inspections, Subsections IWB, IWC, and IWD

The ASME Section XI Inservice Inspection, Subsections IWB, IWC, and IWD program is an existing condition monitoring program that manages cracking, loss of fracture toughness, and loss of material. The program consists of periodic volumetric, surface, and/or visual examinations and leakage tests of ASME Class 1, 2, and 3 pressure-retaining components, including welds, pump casings, valve bodies, integral attachments, and pressure-retaining bolting for assessment, identification of signs of degradation, and establishment of corrective actions. The ASME Section XI Inservice Inspection, Subsections IWB, IWC, and IWD program is implemented in accordance with 10 CFR 50.55a and ASME Code, Section XI. The ASME Code, Section XI, edition and addenda used will be consistent with the provisions of 10 CFR 50.55a during the subsequent period of extended operation. Additional examinations associated with the ASME Code, Section XI, Inservice Inspection program are identified in the Augmented Inspection program, and are included in the ISI Schedule, for the following components:

- Sensitized stainless steel [Class 1, Class 2, and Containment and Recirculation Spray]
- High energy lines outside of Containment [Main Steam and Feedwater lines]

- Component supports [the first seismic restraint beyond the defined ASME functional isolation boundary]
- Steam generator feedwater nozzles [feedwater piping welds from the steam generators to the first elbow]
- Pressurizer instrument connections
- Pressurizer surge line
- MRP-146 thermal stratification inspections

Inspections for three other aspects of the Augmented Inspection program are included in non-ISI programs. Inspections of Reactor Vessel Incore Detector Thimble Tubes are described in the Flux Thimble Tube Inspection program (18.1.24). Inspections of the Reactor Vessel Head are described in the Cracking of Nickel-Alloy Components and Loss of Material Due to Boric Acid-Induced Corrosion in Reactor Coolant Pressure Boundary Components program (18.1.5). Inspections of the PWR vessel internals are described in the PWR Vessel Internals program (18.1.7).

18.1.2 Water Chemistry

The Water Chemistry program is an existing preventive program that manages loss of material, cracking, reduction of heat transfer, and wall thinning of components exposed to a reactor coolant, steam, treated borated water, and treated water environment.

The scope of the Primary Water Chemistry program includes monitoring and control of the chemical environment in the reactor coolant system and related pressurized water reactor interfacing systems. The Primary Water Chemistry program is consistent with Electric Power Research Institute (EPRI) Report 3002000505, “Pressurized Water Reactor Primary Water Chemistry Guidelines,” Revision 7.

The scope of the Secondary Water Chemistry program includes monitoring and control of the chemical environment in the steam generator secondary side and the secondary cycle systems. The Secondary Water Chemistry program is consistent with EPRI Report 3002010645, “Pressurized Water Reactor Secondary Water Chemistry Guidelines,” Revision 8.

The primary and secondary water chemistry control strategies are set forth in strategic plans and implemented by procedures. The programmatic control of the chemical environment ensures that the aging effects due to contaminants (e.g., chloride, fluoride, and sulfate) are limited. The methods used to manage both the primary and secondary chemical environments rely on the principles of: (1) limiting the concentration of chemical species known to cause corrosion and (2) addition of chemical species known to inhibit material degradation by their influence on pH and dissolved oxygen levels.

The One-Time Inspection program (18.1.20) verifies the effectiveness of the Water Chemistry program.

18.1.3 Reactor Head Closure Stud Bolting

The Reactor Head Closure Stud Bolting program is an existing condition monitoring program that manages cracking and loss of material for the reactor head closure stud assembly (which includes the closure studs, nuts and washers) and for the threads in the reactor vessel flange.

The Reactor Head Closure Stud Bolting program is implemented through procedures based on the examination requirements specified in the ASME Code, Section XI, Subsection IWB, Table IWB-2500-1 and preventive measures to mitigate cracking. The program relies on preventive measures to address reactor head closure stud bolting degradation consistent with those identified in NRC Regulatory Guide 1.65, Revision 1, “Material and Inspection for Reactor Vessel Closure Studs.”

18.1.4 Boric Acid Corrosion

The Boric Acid Corrosion program is an existing condition monitoring program that manages loss of material due to leaking borated water on structures and components (including electrical equipment / junction boxes) within the scope of subsequent license renewal that are susceptible to boric acid corrosion. The program provides for identification of leakage through inspection and examination. When leakage is identified, a visual inspection is performed that identifies the leakage pathway and any boric acid residue on adjacent structures, components, and supports so that leakage clean-up can be initiated, and corrective actions can be implemented as necessary. This program includes provisions to initiate evaluations and assessments when leakage is discovered by activities not associated with the program, such as routine plant walkdowns and surveys. When it is determined that an evaluation is necessary, it is performed in a timely manner.

The Boric Acid Corrosion program relies in part on NRC Generic Letter 88-05, “Boric Acid Corrosion of Carbon Steel Reactor Pressure Boundary Components in PWR Plants,” to identify, evaluate, and correct borated water leaks that could cause corrosion damage to reactor coolant pressure boundary components. The program is consistent with Section 7 of WCAP-15988-NP, Revision 2, “Generic Guidance for an Effective Boric Acid Inspection Program for Pressurized Water Reactors.” Additionally, the program includes examinations conducted during inservice inspection pressure tests performed in accordance with ASME Code, Section XI, requirements.

18.1.5 Cracking of Nickel-Alloy Components and Loss of Material Due to Boric Acid-Induced Corrosion in Reactor Coolant Pressure Boundary Components

The Cracking of Nickel-alloy Components and Loss of Material Due to Boric Acid-induced Corrosion in Reactor Coolant Pressure Boundary Components program is an existing condition monitoring program that manages loss of material and cracking due to primary water stress corrosion cracking (PWSCC) for components or welds constructed from Alloy 600/82/182 and exposed to pressurized water reactor primary coolant at elevated temperatures. Initiation and growth of PWSCC cracks can occur as a function of variables which include, but are not limited to temperature, stress, microstructure, time, and water chemistry. This program is used in conjunction with the Water Chemistry program (18.1.2).

The Cracking of Nickel-alloy Components and Loss of Material Due to Boric Acid-induced Corrosion in Reactor Coolant Pressure Boundary Components program is patterned after the industry guidance document, “Materials Reliability Program: Generic Guidance for Alloy 600 Management,” (MRP-126). Bare-metal visual, surface, and volumetric examinations are used to detect the presence of PWSCC. Inspections are performed periodically.

The nickel-alloy components that are inspected due to susceptibility to PWSCC include the reactor vessel bottom-mounted instrumentation nozzles and J-groove welds (ASME Code Case N-722, as incorporated by reference in 10 CFR 50.55a). Other nickel-alloy components that are inspected, but are resistant to PWSCC, include the reactor vessel head penetration nozzles and J-groove welds (ASME Code Case N-729, as incorporated by reference in 10 CFR 50.55a). There are no susceptible nickel-alloy branch line connections that would require a baseline volumetric or inner diameter surface inspection in accordance with ASME Code Case N-770, as incorporated by reference in 10 CFR 50.55a. The Cracking of Nickel-alloy Components and Loss of Material Due to Boric Acid-induced Corrosion in Reactor Coolant Pressure Boundary Components program inspects components that are susceptible to corrosion due to boric acid leakage from nearby or adjacent nickel-alloy components previously described.

18.1.6 Thermal Aging Embrittlement of Cast Austenitic Stainless Steel (CASS)

The Thermal Aging Embrittlement of Cast Austenitic Stainless Steel (CASS) program is an existing condition monitoring program that manages loss of fracture toughness of cast austenitic stainless steel reactor coolant pressure boundary components with service conditions above 250 °C (Celsius) [482 °F (Fahrenheit)].

The program determines the susceptibility of CASS piping and piping components in reactor coolant pressure boundaries with regard to thermal aging embrittlement based on the casting method, molybdenum content, and ferrite percentage.

Aging management of potentially susceptible piping and piping components is accomplished through a component-specific flaw tolerance evaluation in accordance with the ASME Code, Section XI. Based on the completed flaw tolerance evaluation in WCAP-18258, “Flaw Tolerance Evaluation for Susceptible Reactor Coolant Loop Cast Austenitic Stainless Steel Elbow Components for Surry Units 1 and 2,” flaw crack growth remains acceptable for the subsequent period of extended operation.

For valve bodies, screening for significance of thermal aging embrittlement is not required. The existing ASME Code, Section XI visual inspection requirements are adequate for valve bodies. The existing ASME Code, Section XI visual inspection requirements are also adequate for managing the aging effects of reactor coolant pump casings because the original flaw tolerance evaluation performed as part of Code Case N-481 remains bounding and is applicable for the subsequent period of extended operation as described in Section 18.3.7.6, Reactor Coolant Pump Code Case N-481.

18.1.7 PWR Vessel Internals

The PWR Vessel Internals program is an existing condition monitoring program that manages cracking, loss of material, loss of fracture toughness, change in dimensions due to void swelling, and loss of pre-load for the reactor vessel internals (RVI). The aging effect of cracking includes stress corrosion cracking, primary water stress corrosion cracking, irradiation-assisted stress corrosion cracking, and cracking due to fatigue/cyclic loading. Degradation due to loss of material can be induced by wear, and loss of fracture toughness is the result of thermal aging and neutron irradiation embrittlement. Potential causes for the aging effect of changes in dimensions are void swelling or distortion, and loss of pre-load can result from thermal and irradiation-enhanced stress relaxation or creep.

The PWR Vessel Internals program relies on implementation of the inspection and evaluation guidelines in Electric Power Research Institute (EPRI) Technical Report 1022863, "Materials Reliability Program: Pressurized Water Reactor Internals Inspection and Evaluation Guidelines (MRP-227-A)," and EPRI Technical Report 1016609, "Materials Reliability Program: Inspection Standard for Pressurized Water Reactor Internals (MRP-228)," to manage the aging effects on the reactor vessel internal components, as supplemented by a gap analysis. The gap analysis includes integration of EPRI Technical Report 3002005349, "Materials Reliability Program: Pressurized Water Reactor Internals Inspection and Evaluation Guidelines," (MRP-227, Revision 1), which is implemented in accordance with Nuclear Energy Institute (NEI) 03-08, "Guideline for the Management of Materials Issues". MRP-227, Revision 1, includes one "mandatory" and four "needed" NEI 03-08 implementation requirements for the PWR Vessel Internals program. The guidelines listed in MRP-227, Revision 1, provide an appropriate aging management methodology for the RVI components. The gap analysis also integrates the interim guidance from MRP 2018-022, "Transmittal of MRP-191 Screening, Ranking, and Categorization Results and Interim Guidance in Support of Subsequent License Renewal at U.S. PWR Plants". The inspections of the RVI components are implemented in accordance with EPRI Report 3002005386, "Materials Reliability Program: Inspection Standard for Pressurized Water Reactor Internals – 2015 Update (MRP-228, Rev. 2)".

The Safety Evaluation Report that the NRC issued for the approved version (i.e., MRP-227-A) of MRP-227, Revision 0, dated December 16, 2011, included eight Applicant/Licensee Action Items (A/LAI) that required resolution. Six of those items are applicable for Westinghouse reactors. The six items that require resolution for SPS have been addressed such that no open items exist for the PWR Vessel Internals program in preparation for the subsequent period of extended operation.

18.1.8 Flow-Accelerated Corrosion

The Flow-Accelerated Corrosion program is an existing condition monitoring program that manages wall thinning caused by flow-accelerated corrosion, as well as wall thinning due to erosion mechanisms. Erosion monitoring is performed for the internal surfaces of metallic piping and components to manage the aging effect of wall thinning due to cavitation, flashing, liquid droplet impingement, and solid particle erosion.

The program is consistent with the Virginia Electric and Power Company response to NRC Generic Letter 89-08, “Erosion/Corrosion-Induced Pipe Wall Thinning,” and relies on implementation of EPRI guidelines listed in NSAC-202L, Revision 4, “Recommendations for an Effective Flow Accelerated Corrosion Program.” The erosion activity implements the recommendations of EPRI 3002005530, “Recommendations for an Effective Program Against Erosive Attack.”

The program includes (a) identifying all flow accelerated corrosion (FAC)-susceptible piping systems and components; (b) developing FAC predictive models to reflect component geometries, materials, and operating parameters; (c) performing analyses of FAC models and, with consideration of operating experience, selecting a sample of components for inspections; (d) inspecting components; (e) evaluating inspection data to determine the need for inspection sample expansion, repairs, or replacements, and to schedule future inspections; and (f) incorporating inspection data to refine FAC modeling.

The program tracks and predicts occurrences of wall thinning due to FAC using CHECWORKS-SFA™ software. The CHECWORKS-SFA™ model is evaluated and updated as required to reflect any significant changes in plant operating parameters such as power uprates. Wall thinning information available from the CHECWORKS-SFA™ software is one of the tools used to determine the scope and required schedule for inspections of FAC-susceptible components.

In addition to planned inspections performed for the Flow-Accelerated Corrosion program, opportunistic visual inspections of internal surfaces are conducted during routine maintenance activities to identify degradation.

18.1.9 Bolting Integrity

The Bolting Integrity program is an existing condition monitoring program that manages cracking, aging by performing periodic visual inspections for indications of cracking, loss of material due to, general, pitting, and crevice corrosion, microbiologically-influenced corrosion, wear and loss of preload as evidenced by leakage for safety-related and non safety-related closure bolting on pressure-retaining components within the scope of subsequent license renewal.

The program refers to NUREG-1339, “Resolution of Generic Safety Issue 29: Bolting Degradation or Failure in Nuclear Power Plants”. NUREG-1339 includes guidance from EPRI report NP-5067, “Good Bolting Practices Volume 1 (Large Bolt Manual),” and from EPRI report NP-5769, “Degradation and Failure of Bolting in Nuclear Power Plants”.

The listing for EPRI NP-5769 mentions an exception noted in NUREG-1339 for safety-related bolting. That exception is applicable for bolting used in pressure-retaining applications, and indicates that experimentally–verified fastener material properties and fracture mechanics evaluations should be used to ensure that safety-related fasteners are unlikely to be susceptible to stress corrosion cracking. EPRI Report 1015336, “Nuclear Maintenance Application Center: Bolted Joint Fundamentals,” is applicable for the Bolting Integrity program, and states that applicable material properties should be confirmed with the fastener manufacturer. EPRI Report 1015336 includes guidance for preventing or mitigating stress corrosion cracking by the proper selection of bolting. Table B-1 of EPRI Report 1015336 lists appropriate bolting, and is a reference for the bolting design standard at SPS.

The program includes guidance provided by EPRI reports 1015336, “Nuclear Maintenance Application Center: Bolted Joint Fundamentals,” and 1015337, “Nuclear Maintenance Application Center: Assembling Gasketed Flanged Bolted Joints,” for assembling bolted connections, and for performing visual examinations of pressure-retaining closure bolting. Preventive measures to preclude or mitigate cracking and loss of preload include proper selections of bolting material and lubricant, and proper application of preload. The absence of high-strength pressure-retaining closure bolting precludes the need for volumetric inspections.

The program addresses management of age-related degradation for applicable submerged bolting, and for piping systems that contain compressed air, hydrogen gas, nitrogen gas, and carbon dioxide.

The ASME Section XI Inservice Inspections, Subsections IWB, IWC, AND IWD program (Section 18.1.1) includes inspections of closure bolting within the scope of ASME Code, Section XI, and supplements this Bolting Integrity program. The reactor vessel closure head studs are addressed in the Reactor Head Closure Stud Bolting program (Section 18.1.3). The following aging management programs for SPS manage aging effects associated with safety-related and non safety-related structural bolting:

- ASME Section XI, Subsection IWE program (Section 18.1.29)
- ASME Section XI, Subsection IWF program (Section 18.1.31)
- Structures Monitoring program (Section 18.1.34)
- Inspection of Water-Control Structures Associated With Nuclear Power Plants program (Section 18.1.35)
- Inspection of Overhead Heavy Load and Light Load (Related to Refueling) Handling Systems program (Section 18.1.13)

The External Surfaces Monitoring of Mechanical Components program (Section 18.1.23) describes the inspections for non-ASME pressure-retaining bolting.

18.1.10 Steam Generators

The Steam Generators program is an existing condition monitoring program that manages the aging effects of cracking, loss of material (e.g., wall thinning), and reduction of heat transfer for the steam generators. The scope of the program includes primary-side components (e.g., U-tubes [tubes], plugs, sleeves, channel head divider plate, channel head, tubesheet, etc.), and secondary-side components that are contained within the steam generator. The program uses volumetric inspections for the tubes, and visual inspections for the other primary-side and secondary-side components. The visual inspections of the primary-side components listed above are performed in accordance with the Degradation Assessment (DA) that is prepared as each steam generator is scheduled for examination. Tube-to-tubesheet welds do not require aging management because the H* alternate repair criteria have been permanently approved to eliminate those hot-leg and cold-leg welds as reactor coolant pressure boundaries.

Provisions in the Steam Generators program address reporting criteria, inspection scope and frequency, assessments, plugging criteria, and water chemistry monitoring to maintain consistency with established requirements. NEI 97-06, Revision 3, “Steam Generator Program Guidelines” and associated EPRI guidelines provide a generic industry program to implement Technical Specifications.

As stated in the steam generator DA, tubing and primary-side inspections typically are performed every other refueling outage for each steam generator, thus satisfying the guidance for visual inspections to be performed at least every 72 effective full power months or every third refueling outage, whichever results in more frequent inspections.

The Steam Generators program includes preventive measures to mitigate aging related to corrosion phenomena through foreign material exclusion as a means to inhibit tube degradation due to wear. Identification of deposits on the secondary-side of the steam generator, and the subsequent removal of sludge deposits help avoid tube degradation.

The Technical Specifications include the following requirements which are included in the Steam Generators program:

- Conducting condition monitoring assessments for each refueling outage during which steam generator tubes are inspected or plugged.
- Maintaining steam generator tube integrity by meeting performance criteria for tube structural integrity, accident-induced leakage, and operational leakage.
- Installing plugs in tubes found by inservice inspection to contain flaws that exceed acceptance criteria.

- Performing periodic inspections of steam generator tubes. Inspection scope, methods, and interval, ensure that tube integrity is maintained until the next planned inspection.
- Monitoring primary-to-secondary leakage.
- Monitoring secondary water chemistry to ensure controls are in place to inhibit steam generator tube degradation.

18.1.11 Open-Cycle Cooling Water System

The Open Cycle Cooling Water System program is an existing preventive, mitigative, condition monitoring, and performance monitoring program that manages loss of material, reduction of heat transfer, flow blockage, cracking, and loss of coating or lining integrity, for the piping, piping components, and heat exchangers identified by the Dominion Energy responses to NRC Generic Letter (GL) 89-13, "Service Water System Problems Affecting Safety-Related Equipment." The program is comprised of the aging management aspects of the Virginia Electric and Power Company response to NRC GL 89-13 and includes: (a) surveillance and control to reduce the incidence of flow blockage problems as a result of biofouling, (b) tests to verify heat transfer of safety-related heat exchangers, (c) routine inspection and maintenance so that loss of material, corrosion, erosion, cracking, fouling, and biofouling cannot degrade the performance of systems serviced by the open-cycle cooling water system. This program includes enhancements to the guidance in NRC GL 89-13 that address operating experience such that aging effects are adequately managed.

System and component testing, visual inspections, nondestructive examination (e.g., ultrasonic testing, eddy current testing and acoustic impact tap examination), and chemical injection are conducted to ensure that identified aging effects are managed such that system and component intended functions and integrity are maintained. Periodic heat transfer testing, visual inspection, and cleaning of safety-related heat exchangers with a heat transfer intended function is performed in accordance with the Virginia Electric and Power Company commitments to GL 89-13 to verify heat transfer capabilities.

The Internal Coatings/Linings For In-Scope Piping, Piping Components, Heat Exchangers, and Tanks program (18.1.28) will manage the aging effects of internal surface coatings except those of metallic surfaces lined with Carbon Fiber Reinforced Polymer that is used as a pressure boundary.

18.1.12 Closed Treated Water Systems

The Closed Treated Water Systems program is an existing program that manages loss of material, cracking, and reduction of heat transfer for components exposed to a closed treated water environment.

This is a mitigation program that also includes a condition monitoring program to verify the effectiveness of the mitigation activities. The program consists of: (a) water treatment, including the use of corrosion inhibitors, to modify the chemical composition of the water such that the effects of corrosion are minimized; (b) chemical testing of the water so that the water treatment program maintains the water chemistry within acceptable guidelines; and (c) inspections to determine the presence or extent of degradation. The program uses as applicable, EPRI Report 3002000590, “Closed Cooling Water Chemistry Guideline”. Microbiological testing is performed as a diagnostic chemistry parameter for selected system water treatments.

18.1.13 Inspection of Overhead Heavy Load and Light Load (Related to Refueling) Handling Systems

The Inspection of Overhead Heavy Load and Light Load (Related to Refueling) Handling Systems program is an existing condition monitoring program that manages cracking, loss of material due to corrosion and wear, and loss of preload on bolted connections for cranes and hoists within the scope of subsequent license renewal. The program includes periodic visual inspections to detect degradation of bridge, rail, and trolley structural components and indications of loss of preload on bolted connections. This program relies on the guidance in NUREG-0612, “Control of Heavy Loads at Nuclear Power Plants,” ASME B30.2, “Overhead and Gantry Cranes (Top Running Bridge, Single or Multiple Girder, Top Running Trolley Hoist),” ASME B30.11, “Monorail Systems and Underhung Cranes,” and ASME B30.16, “Overhead Hoists (Underhung).”

For those cranes or hoists associated with Time-Limited Aging Analyses, the effects of past and future usage, including the number and magnitude of lifts, are evaluated in Section 18.3.7.1, Crane Load Cycle Limits.

18.1.14 Compressed Air Monitoring

The Compressed Air Monitoring program is an existing preventive and condition monitoring program that manages loss of material. The Compressed Air Monitoring program includes monitoring of air moisture content and contaminants such that specified limits are maintained, and performance of opportunistic inspections of components for indications of loss of material.

This program is based on the Surry response to NRC GL 88-14, “Instrument Air Supply Problems;” and utilizes guidance and standards provided in EPRI TR 108147 “Compressor and Instrument Air System Maintenance Guide: Revision to NP-7079,” and ANSI/ISA-S7.3-1975, “Quality Standard for Instrument Air.” The Compressed Air Monitoring program activities implement the moisture content and contaminant criteria of ANSI/ISA-S7.3-1975 (incorporated into ISA-S7.0.01-1996).

Program activities include air quality checks at various locations to ensure that dew point, particulates, and hydrocarbons are maintained within the specified limits. Opportunistic inspections of the internal surfaces of select compressed air system components for signs of loss of material will be performed.

18.1.15 Fire Protection

The Fire Protection program is an existing condition and performance monitoring program comprised of functional tests and visual inspections. The program manages:

- loss of material for fire-rated doors, fire damper assemblies, the halon systems, RCP oil collection system, steel seismic gap covers and the low-pressure carbon dioxide systems
- loss of material (spalling) or cracking for concrete structures, including fire barrier walls, ceilings, and floors
- hardening, shrinkage, and loss of strength for elastomer fire barrier penetration seals and seismic gap elastomers
- loss of material, change in material properties, cracking/delamination, and separation for non-elastomer fire barrier penetration seals, fire stops, fire wraps, and coatings cracking/delamination, and separation
- loss of material and cracking for aluminum seismic gap covers

This program includes fire barrier inspections. The fire barrier inspection program requires periodic visual inspection of fire barrier penetration seals, fire barrier walls, ceilings, and floors, fire damper assemblies, and periodic visual inspection and functional tests of fire-rated doors to demonstrate that their operability is maintained. The program also includes periodic inspections and functional tests of the halon systems and low-pressure carbon dioxide systems.

18.1.16 Fire Water System

The Fire Water System program is an existing condition monitoring program that manages cracking, loss of material, flow blockage due to fouling, and loss of coating integrity for in-scope water-based fire protection systems. This program manages aging effects by conducting periodic visual inspections, flow testing, and flushes consistent with provisions of the 2011 Edition of National Fire Protection Association (NFPA) 25. Testing of sprinklers that have been in place for 50 years is performed consistent with NFPA 25, 2011 Edition. With exception of two locations, portions of the water-based fire protection system that have been wetted but are normally dry have been confirmed to drain and are not subjected to augmented testing and inspections.

The water-based fire protection system is normally maintained at required operating pressure and is monitored such that loss of system pressure is detected and corrective actions initiated. Piping wall thickness measurements are conducted when visual inspections detect surface irregularities indicative of unexpected levels of degradation. When the presence of organic or inorganic material sufficient to obstruct piping or sprinklers is detected, the material is removed and the source is detected and corrected. Non-code inspections and tests follow site procedures that include inspection parameters for items such as lighting, distance offset, presence of protective coatings, and cleaning processes that ensure an adequate examination.

The training and qualification of individuals involved in coating/lining inspections of non-cementitious coatings/linings are conducted in accordance with ASTM International Standards endorsed in RG 1.54 including guidance from the staff associated with a particular standard.

18.1.17 Outdoor and Large Atmospheric Metallic Storage Tanks

The Outdoor and Large Atmospheric Metallic Storage Tanks program is an existing condition monitoring program that manages the effects of loss of material and cracking on the outside and inside surfaces of aboveground metallic tanks constructed on concrete or soil. This program is a condition monitoring program that manages aging effects associated with outdoor tanks with internal pressures approximating atmospheric pressure including the refueling water storage tanks (RWSTs), emergency condensate storage tanks (ECSTs), and the emergency condensate makeup tanks (ECMTs). This program also manages aging of the fire protection/domestic water storage tanks (FWSTs) bottom surfaces exposed to soil. The program includes preventive measures to mitigate corrosion by protecting the external surfaces of steel components per standard industry practice. The RWSTs are insulated and rest on a concrete foundation covered with an oil sand cushion. Caulking is used at t he concrete-component interface of the RWSTs. The ECSTs and ECMTs are internally coated and protected by concrete missile barriers. Weep holes, located around the circumference of the ECSTs where the concrete missile shield meets the concrete foundation, allow drainage of leakage or condensation to the outside perimeter of the ECSTs. The weep holes will be inspected for water leakage once each refueling cycle. The CATs are skirt supported and insulated with sprayed-on rigid polyurethane foam.

The program manages loss of material on tank internal bare metal surfaces by conducting visual inspections. Surface exams of external tank surfaces are conducted to detect cracking on the stainless steel tanks. Inspections of RWST caulking are supplemented with physical manipulation. Thickness measurements of the tanks bottoms are conducted to ensure that significant degradation is not occurring. The external surfaces of insulated tanks are periodically sampling-based inspected. Inspections not conducted in accordance with ASME Code Section XI requirements are conducted in accordance with plant-specific procedures that include inspection parameters such as lighting, distance, offset, and surface conditions.

The Internal Coatings/Linings For In-Scope Piping, Piping Components, Heat Exchangers, and Tanks program (18.1.28) will manage the internally coated surfaces of the ECSTs and ECMTs. Internal surfaces of the RWSTs and CATs will be managed by the One-Time Inspection program (18.1.20). Tank reinforced concrete foundations and the reinforced concrete missile barrier of the ECSTs and ECMTs will be managed by the Structures Monitoring program (18.1.34).

18.1.18 Fuel Oil Chemistry

The Fuel Oil Chemistry program is an existing mitigative and condition monitoring and preventive program that manages loss of material and reduction of heat transfer from tanks, piping, and components in a fuel oil environment. The program includes activities which provide assurance that contaminants are maintained at acceptable levels in fuel oil for systems and components within the scope of subsequent license renewal.

The fuel oil tanks within the scope of subsequent license renewal are maintained by monitoring and controlling fuel oil contaminants in accordance with the Technical Requirements Manual, and ASTM standards such as ASTM D 975, D 1796, D 6217, and D 4057. Fuel oil sampling and analysis is performed in accordance with approved procedures for new fuel oil and stored fuel oil.

Fuel oil tanks are periodically drained of water and accumulated sediment, cleaned, and internally inspected when accessible. These activities effectively manage the effects of aging by maintaining potentially harmful contaminants at low concentrations. Where internal cleaning and inspection are not physically possible, bottom thickness measurements of inaccessible tanks are performed in lieu of cleaning and internal inspection. Tanks that cannot be cleaned and internally inspected, and are physically inaccessible for bottom thickness measurements, are monitored for leakage consistent with the current licensing basis.

18.1.19 Reactor Vessel Material Surveillance

The Reactor Vessel Material Surveillance program is an existing condition monitoring program that manages reduction of fracture toughness of the ferritic reactor vessel beltline materials, in accordance with the version of ASTM E-185 available and used during fabrication of the reactor vessels. The program provides sufficient material to monitor reduction of fracture toughness due to neutron irradiation embrittlement until the end of the subsequent period of extended operation, and determine the need for operating restrictions on the irradiation temperature (i.e., cold leg operating temperature), neutron spectrum, and neutron fluence.

The Reactor Vessel Material Surveillance program was developed by Westinghouse Electric Company prior to 10CFR50 Appendix H. The Reactor Vessel Material Surveillance program consists of two elements. The first element is related to the number of capsules, location of capsules, and content of specimens. The second element is related to the test methods and schedule for testing. For the first element, related to the design of the program, WCAP-7723, “Virginia Electric and Power Co. Surry Unit No. 1 Reactor Vessel Radiation Surveillance Program” and WCAP-8085, “Virginia Electric and Power Co. Surry Unit No. 2 Reactor Vessel Radiation Surveillance Program” for Units 1 and 2, documented the program. The Reactor Vessel Material Surveillance program for Unit 1 meets either ASTM E 185-66 or ASTM E 185-70. WCAP-8085 states that the Unit 2 Reactor Vessel Material Surveillance program meets ASTM E-185-70. Initially, the requirements relating to the testing method was not mandated by the NRC through a particular version of ASTM E185. Therefore, when a capsule was removed from the reactor vessel, it was customary at the time to document which version of ASTM E185 was used for testing. Overtime, the NRC began the process of approving various editions of ASTM E185 for testing. To date, for testing and schedule considerations, the NRC has approved three editions of ASTM E185-73, -79, and -82. Currently, the Reactor Vessel Material Surveillance program complies with ASTM E-185-82 for testing and scheduling. Since the withdrawal schedule in Table 1 of ASTM E 185-82 is based on plant operation during the original 40-year initial license term, standby capsules have been incorporated to ensure appropriate monitoring during the subsequent period of extended operation. The Reactor Vessel Material Surveillance program includes removal and testing of at least one capsule, with a neutron fluence of the capsule between one and two times the projected peak vessel neutron fluence at the end of the subsequent period of extended operation. If a capsule meeting this criteria has not been tested previously, then at least one capsule will be removed and tested during the subsequent period of extended operation (or earlier) to meet this criterion.

Data from the Reactor Vessel Material Surveillance program is used to monitor neutron irradiation embrittlement of the reactor vessel, and is provided as input to the neutron embrittlement time-limited aging analyses described in Section 18.3.2, Reactor Vessel Neutron Embrittlement Analysis.

In accordance with 10 CFR Part 50, Appendix H, all surveillance capsules, including those previously removed from the reactor vessel, meet the test procedures and reporting requirements of ASTM E 185-82, to the extent practicable, for the configuration of the specimens in the capsule. Any changes to the capsule withdrawal schedule, including the conversion of standby capsules into the Appendix H program and extension of the surveillance program for the subsequent period of extended operation, are submitted for approval by the Nuclear Regulatory Commission (NRC) prior to implementation, in accordance with 10 CFR Part 50, Appendix H, Paragraph III.B.3. Standby capsules placed in storage (e.g., removed from the reactor vessel) are maintained for possible future insertion. If one or more capsules will not be maintained in such a way as to permit future insertion, then the NRC will be notified of the change.

The Reactor Vessel Material Surveillance program is also used in conjunction with the Neutron Fluence Monitoring program (18.2.2) which monitors neutron fluence for reactor vessel components and reactor vessel internal components.

18.1.20 One-Time Inspection

The One-Time Inspection program is a new condition monitoring program that will manage loss of material, cracking, and reduction of heat transfer of components containing reactor coolant, treated borated water, secondary water, fuel oil, or lubricating oil environments.

The One-Time Inspection program will conduct one-time inspections of susceptible locations to verify the effectiveness of the Water Chemistry program (18.1.2), the Fuel Oil Chemistry program (18.1.18), and Lubricating Oil Analysis program (18.1.26). The program will verify either no unacceptable age-related degradation is occurring or trigger additional actions that will assure the intended function of affected components will be maintained during the subsequent period of extended operation. For steel components exposed to environments that do not include corrosion inhibitors, the One-Time Inspection program will verify that long-term loss of material will not result in a loss of intended function.

The elements of the One-Time Inspection program will include: (a) determination of sample size for the components to be inspected based on an assessment of materials of fabrication, environment, plausible aging effects, and operating experience; (b) identification of the inspection locations in the system or component based on the potential for the aging effect to occur; (c) determination of the examination technique, including acceptance criteria that would be effective in managing the aging effect for which the component is examined, and (d) evaluation of the need for follow-up examinations to monitor the progression of aging if age-related degradation is found that could jeopardize an intended function before the end of the subsequent period of extended operation.

This program will not be used for components with known age-related degradation mechanisms, or when the environment in the subsequent period of extended operation is not expected to be equivalent to that in the prior operating period. Periodic inspections will be conducted in those cases.

ASME Code components and non-ASME Code components will be inspected using procedures consistent with the ASME Code.

Industry and plant specific operating experience will be evaluated in the development and implementation of this program.

18.1.21 Selective Leaching

The Selective Leaching program is a new condition monitoring program that will manage loss of material of the susceptible materials located in a potentially aggressive environment. The materials of construction for these components may include gray cast iron, ductile iron, and copper alloys (greater than 15% zinc or greater than 8% aluminum).

One-time inspections for components exposed to closed-cycle cooling water or treated water environments will be conducted when plant-specific operating experience has not revealed selective leaching in these environments. Opportunistic and periodic inspections will be conducted for raw water, waste water, soil, and groundwater environments, and for closed-cycle cooling water or treated water environments when plant specific operating experience has revealed selective leaching in these environments. Visual inspections coupled with mechanical examination techniques such as chipping or scraping will be conducted. Periodic destructive examinations of components for physical properties (i.e., degree of de-alloying, through-wall thickness, and chemical composition) will be conducted for components exposed to raw water, waste water, soil, and groundwater environments or for closed-cycle cooling water or treated water environments when plant specific operating experience has revealed selective leaching in these environments.

Inspections and tests will be conducted to determine whether loss of material will affect the ability of the components to perform their intended function for the subsequent period of extended operation. Inspections are performed by personnel qualified in accordance with procedures and programs to perform the specified task. Inspections within the scope of the ASME Code will follow procedures consistent with the ASME Code. Non-ASME Code inspection procedures will include requirements for items such as lighting, distance, offset, and surface conditions. When the acceptance criteria are not met such that it is determined that the affected component be replaced prior to the end of the subsequent period of extended operation, additional inspections will be performed.

Industry and plant specific operating experience will be evaluated in the development and implementation of this program.

18.1.22 ASME Code Class 1 Small-Bore Piping

The ASME Code Class 1 Small-Bore Piping program is a new condition monitoring program that will manage cracking in ASME Code Class 1 small-bore piping that is defined as greater than or equal to one inch nominal pipe size (NPS) and less than four inches NPS. This program will utilize volumetric examination techniques demonstrated to be capable of detecting cracking, or destructive examinations to augment the visual examinations (VT-1) required by the ASME Code, Section XI. One-time inspections will determine the presence of cracking for locations within the scope of the ASME Code Class 1 Small-Bore Piping program. With the exception of socket welds for the seal injection line attachments to the reactor coolant pump (RCP) thermal barrier casings at the seal injection nozzles, there is no operating experience of age-related cracking. Therefore, except for those seal injection socket welds, inspection samples will be selected consistent with NUREG-2191 Section XI.M35, Table XI.M35-1, Category A. One-time inspection samples will consist of 3% of the total population in each unit (up to ten maximum) for susceptible butt welds and susceptible socket welds. Each socket weld subject to destructive examination can be credited twice toward the total number of examinations.

For the socket welds on the seal injection lines to the RCP thermal barrier casings, Category B from NUREG-2191, Section XI.M35, Table XI.M35-1 is applicable due to the cracking that occurred in 1998. However, an exception will be taken for the volumetric inspections. As a result of exceedingly limited space in the area of the seal injection line to the thermal barrier casing, a meaningful volumetric examination is not feasible. Volumetric examination could be performed only if the RCP assembly is disassembled for maintenance which could provide for an opportunistic volumetric examination. In lieu of a volumetric examination, a liquid penetrant (LP) examination, that can be performed when sufficient accessibility exists, will provide an acceptable level of information regarding the integrity of the weld. The LP examination for the seal injection line weld at one of the three RCPs will be performed prior to the subsequent period of extended operation. Examinations for the seal injection line welds at the two remaining RCPs will be performed, one per ISI interval, during the subsequent period of extended operation.

Industry and plant specific operating experience will be evaluated in the development and implementation of this program.

18.1.23 External Surfaces Monitoring of Mechanical Components

The External Surfaces Monitoring of Mechanical Components program is an existing condition monitoring program that manages loss of material, cracking, and reduction of heat transfer of metallic components; hardening or loss of strength, loss of material, and cracking or blistering of polymeric components; loss of preload of HVAC closure bolting; and reduced thermal insulation resistance. Periodic visual inspections, not to exceed a refueling outage interval, of metallic, polymeric, and insulation jacketing (insulation when not jacketed) are conducted. For certain materials, such as flexible polymers, physical manipulation or pressurization to detect hardening or loss of strength is used to augment the visual inspections conducted under this program.

Surface examinations or ASME Code, Section XI, visual examinations (VT-1) are conducted to detect cracking of stainless steel, aluminum and copper alloy (>15% Zn or >8% Al) components.

A sample of outdoor component surfaces that are insulated and a sample of indoor insulated components exposed to condensation (due to the in-scope component being operated below the dew point), are periodically inspected every ten years during the subsequent period of extended operation. Following insulation removal, surface examinations or ASME Code, Section XI, visual examinations (VT-1) are conducted to detect loss of material and cracking of the component surfaces.

Non-ASME Code inspection procedures include inspection parameters such as lighting, distance, offset, and surface conditions.

Acceptance criteria are such that the component will meet its intended function until the next inspection or the end of the subsequent period of extended operation. Qualitative acceptance criteria are clear enough to reasonably assure a singular decision is derived based on observed conditions.

The external surfaces of components that are buried or in underground environments are inspected by the Buried And Underground Piping And Tanks program (18.1.27). The external surfaces of outdoor tanks and indoor large volume metallic storage tanks (capacity >100,000 gallons) are inspected by the Outdoor and Large Atmospheric Metallic Storage Tanks program (18.1.17). Loss of material due to boric acid corrosion is managed by the Boric Acid Corrosion program (18.1.4).

18.1.24 Flux Thimble Tube Inspection

The Flux Thimble Tube Inspection program is an existing condition monitoring program that manages loss of material due to wear by inspecting for the thinning of flux thimble tube walls. Flux thimble tubes provide a path for the in-core neutron flux monitoring system detectors and forms part of the reactor coolant system pressure boundary. Flux thimble tubes are subject to loss of material at certain locations in the reactor vessel (RV) where flow-induced fretting causes wear at discontinuities in the path from the RV instrument nozzle to the fuel assembly instrument guide tube. The thimble tube design is a double-walled, asymmetrical configuration to accommodate thermocouple leads located in the annulus between the inner and outer flux thimble tubes. The outer tube is the component that is most susceptible to wear due to its contact with the discontinuities. The inner tube through which the incore detector travels is the reactor coolant system pressure boundary. The double wall design significantly reduces the potential for wear of the inner tube pressure boundary. Periodic eddy current examinations are performed to confirm the integrity of the inner flux thimble tube, and are consistent with the recommendations of NRC Bulletin 88-09, “Thimble Tube Thinning in Westinghouse Reactors.”

18.1.25 Inspection of Internal Surfaces in Miscellaneous Piping and Ducting Components

The Inspection of Internal Surfaces in Miscellaneous Piping and Ducting Components program is an existing condition monitoring program that manages loss of material, cracking, reduction of heat transfer, and flow blockage of metallic components. The program also manages hardening or loss of strength, loss of material, cracking or blistering, and flow blockage of polymeric components. This program consists of visual inspections of all accessible internal surfaces of piping, piping components, ducting, heat exchanger components, polymeric and elastomeric components, and other components exposed to air, condensation, diesel exhaust, fuel oil, gas, lubricating oil, and any water environment. Aging effects associated with items (except for elastomers) within the scope of the Open-Cycle Cooling Water System program (18.1.11), Closed Treated Water Systems program (18.1.12), and Fire Water System program (18.1.16) are not managed by this program. For certain materials, such as flexible polymers, physical manipulation or pressurization to detect hardening or loss of strength is used to augment the visual examinations conducted under this program.

Surface examinations or ASME Code, Section XI, visual examinations (VT-1) are conducted to detect cracking of stainless steel, aluminum, copper alloy (>15% Zn), and Grade 2 titanium components.

The internal inspections are performed during the periodic system and component surveillances or during the performance of maintenance activities when the surfaces are made accessible for visual inspection. At a minimum, in each 10-year period during the subsequent period of extended operation, a representative sample of 20% of the population (defined as components having the same combination of material, environment, and aging effect) or a maximum of nineteen components per population at each unit is inspected. Where practical, the inspections focus on the bounding or lead components most susceptible to aging because of time in service and severity of operating conditions. Opportunistic inspections continue in each period, even if the minimum number of inspections has been conducted.

Inspections are performed by personnel qualified in accordance with procedures and programs to perform the specified task. Inspections within the scope of the ASME Code will follow procedures consistent with the ASME Code. Non-ASME Code inspection procedures include requirements for items such as lighting, distance, offset, and surface conditions.

Acceptance criteria are such that the component will meet its intended function until the next inspection or the end of the subsequent period of extended operation. Qualitative acceptance criteria are clear enough to reasonably ensure a singular decision is derived based on observed conditions.

18.1.26 Lubricating Oil Analysis

The Lubricating Oil Analysis program is an existing preventive program that ensures that loss of material and reduction of heat transfer is not occurring by maintaining the quality of the lubricating oil or hydraulic oil. The program ensures that contaminants (primarily water and particulates) are within acceptable limits. Testing activities include sampling and analysis of lubricating oil for contaminants. Oil testing that indicates the presence of water results in the initiation of corrective action that may include evaluating for in-leakage.

18.1.27 Buried and Underground Piping and Tanks

The Buried and Underground Piping and Tanks program is an existing condition monitoring program that manages loss of material, blistering, and cracking on external surfaces of components in soil or underground environments within the scope of subsequent license renewal through preventive and mitigative actions. The program addresses piping and tanks composed of steel, stainless steel, copper alloys, fiberglass reinforced plastic, and concrete. Depending on the material, preventive and mitigative techniques include external coatings, cathodic protection (CP), and the quality of backfill. Direct visual inspection quantities for buried components are planned using procedural categorization criteria. Transitioning to a higher number of inspections than originally planned is based on the effectiveness of the preventive and mitigative actions. Also, depending on the material, inspection activities include electrochemical verification of the effectiveness of CP, nondestructive evaluation of pipe or tank wall thicknesses, performance monitoring of fire mains, and visual inspections of the pipe from the exterior.

The buried carbon steel piping of the fuel oil system for emergency electrical power system is protected by an active CP system. Monthly periodic inspections confirm CP system availability and annual CP surveys are conducted to assess the effectiveness of the CP system. For steel components, where the acceptance criteria for the effectiveness of the cathodic protection is other than -850 mV instant off, loss of material rates are measured.

Five years prior to entering the subsequent period of extended operation, each unit’s buried carbon steel piping within the scope of subsequent license renewal will be cathodically protected.

This will include the buried carbon steel condensate system and auxiliary feedwater system piping from the emergency condensate storage tank and the emergency condensate makeup tank to the service building and the 24-inch service water piping at the Low Level Intake Structure on each unit.

Soil sampling and testing is performed during each excavation and a station-wide soil survey is also performed once in each 10-year period to confirm that the soil environment of components within the scope of subsequent license renewal is not corrosive for the installed material types.

Inspections are conducted by qualified individuals. Where the coatings, backfill or the condition of exposed piping does not meet acceptance criteria such that the depth or extent of degradation of the base metal could have resulted in a loss of pressure boundary function when the loss of material rate is extrapolated to the end of the subsequent period of extended operation, the sample size is increased.

As an alternative to performing visual inspections of the buried fire protection system components, monitoring the activity of the jockey pump is performed by the Fire Water System program (18.1.16).

18.1.28 Internal Coatings/Linings For In-Scope Piping, Piping Components, Heat Exchangers, and Tanks

The Internal Coatings/Linings for In-Scope Piping, Piping Components, Heat Exchangers, and Tanks program is an existing condition monitoring program that manages loss of coating integrity of the internal coatings/linings of the in-scope components, exposed to closed-cycle cooling water, raw water, treated water, treated borated water, waste water, and air-dry environments, that can lead to loss of base material or downstream effects such as reduction in flow, reduction in pressure or reduction of heat transfer when coatings/linings become debris.

Periodic visual inspections are conducted of each coating/lining material and environment combinations applied to the internal surfaces of in-scope piping and components where loss of coating or lining integrity could impact the components or downstream component's intended function(s).

For tanks, heat exchangers, and piping, all accessible surfaces are inspected. The training and qualification of individuals involved in coating/lining inspections of non-cementitious coatings/linings are conducted in accordance with ASTM International Standards endorsed in RG 1.54, “Service Level I, II and II Protective Coatings Applied to Nuclear Power Plants,” including guidance from the staff associated with a particular standard. For cementitious coatings, training and qualifications are based on an appropriate combination of education and experience related to inspecting concrete surfaces. Peeling and delamination is not acceptable. Blisters are evaluated by a coatings specialist. Blisters are limited to a few intact small blisters that are completely surrounded by sound material and with the size and frequency not increasing between inspections.

Minor cracks in cementitious coatings are acceptable provided there is no evidence of debonding. All other degraded conditions are evaluated by a coatings specialist. For coated/lined surfaces determined to not meet the acceptance criteria, the coating can be removed or physical testing is performed where physically possible (i.e., sufficient room to conduct testing) in conjunction with repair or replacement of the coating/lining.

18.1.29 ASME Section XI, Subsection IWE

The ASME Section XI, Subsection IWE program is an existing condition monitoring program that manages cracking, loss of material, loss of sealing, loss of preload, and loss of leak tightness. This program is in accordance with ASME Section XI, Subsection IWE, consistent with 10 CFR 50.55a “Codes and standards,” with supplemental recommendations. The ASME Section XI, Subsection IWE program includes periodic visual, surface, and volumetric examinations, where applicable, of the metallic pressure-retaining components of the concrete containment for signs of degradation, damage, irregularities including discernible liner plate bulges, and for coated areas distress that might be indicative of degradation of the underlying metal shell or liner, and corrective actions. Acceptability of inaccessible areas of the concrete containment steel liner is evaluated when conditions found in accessible areas, indicate the presence of, or could result in, flaws or degradation in inaccessible areas.

This program also includes surface examination for the detection of cracking of structural bolting. In addition, the program includes supplemental surface or enhanced examinations to detect cracking for specific pressure-retaining components. Containment penetrations were not analyzed for cyclic fatigue and will require surface examinations in addition to visual examinations to detect cracking in stainless steel and dissimilar metal welds of penetration sleeves and components that are subject to cyclic loading. A one-time volumetric examination of metal liner surfaces that are inaccessible from one side will be performed if triggered by plant-specific operating experience. Sampling locations will be those susceptible to loss of thickness due to corrosion of the Containment liner that is inaccessible from one side. Inspection results will be compared with prior recorded results in acceptance of components for continued service.

In conformance with 10 CFR 50.55a(g)(4)(ii), the Containment inservice inspection program will be updated during each successive 120 month inspection interval to comply with the requirements of the latest edition and addenda of the Code specified 12 months before the start of the inspection interval.

18.1.30 ASME Section XI, Subsection IWL

The ASME Section XI, Subsection IWL program is an existing condition monitoring program that manages the following aging effects for containment concrete:

- Cracking
- Cracking; Loss of material

- Cracking and distortion
- Cracking; loss of bond; and loss of material (spalling, scaling)
- Increase in porosity and permeability; cracking; loss of material (spalling, scaling)
- Loss of material (spalling, scaling) and cracking

Qualified inspectors identify changes that could be indicative of Alkali-Silica Reaction (ASR). If indications of ASR development are identified, evaluations are performed which consider the potential for ASR development in concrete that is within the scope of the ASME Section XI, Subsection IWL program (18.1.30), the Structures Monitoring program (18.1.34), or the Inspection of Water-Control Structures Associated With Nuclear Power Plants program (18.1.35).

The design of the reinforced concrete containment does not utilize prestressing tendons. This program consists of periodic visual inspection of concrete surfaces for reinforced concrete containments for signs of degradation, assessment of damage, and corrective actions. The Subsection IWL requirements are supplemented to include quantitative acceptance criteria for concrete surfaces based on the “Evaluation Criteria” provided in Chapter 5 of ACI 349.3R-02.

In conformance with 10 CFR 50.55a(g)(4)(ii), the Containment inservice inspection program will be updated during each successive 120 month inspection interval to comply with the requirements of the latest edition and addenda of the Code specified 12 months before the start of the inspection interval.

18.1.31 ASME Section XI, Subsection IWF

The ASME Section XI, Subsection IWF program is an existing condition monitoring program that manages loss of material, cracking, loss of preload, and loss of mechanical function for supports of Class 1, 2, and 3 components. There are no Class MC supports at SPS. This program consists of periodic visual examination of piping and component supports for signs of degradation, evaluation, and corrective actions. This program recommends additional inspections beyond the inspections required by the 10 CFR Part 50.55a ASME Section XI, Subsection IWF program. This includes a one-time inspection within five years prior to entering the subsequent period of extended operation of an additional 5% of the sample populations for Class 1, 2, and 3 piping supports. The additional supports will be selected from the remaining population of IWF piping supports and will include components that are most susceptible to age-related degradation. For high-strength bolting with an actual yield strength equal to or greater than 150 ksi in sizes greater than one inch nominal diameter, volumetric examination comparable to that of ASME Code, Section XI, Table IWB-2500-1, Examination Category B-G-1 are performed to detect cracking in addition to the VT-3 examination. If a component support does not exceed the acceptance standards of IWF-3400, but is electively repaired to as-new condition, the sample is increased or modified to include another support that is representative of the remaining population of supports that were not repaired.

18.1.32 10 CFR Part 50, Appendix J

The 10 CFR Part 50, Appendix J program is an existing performance monitoring program that manages cracking, loss of leak tightness, loss of material, loss of preload and loss of sealing. Leakage rates through the Containment pressure boundary are monitored, including the Containment liner, associated welds, penetrations, isolation valves, fittings, and other access openings to detect degradation of the Containment pressure boundary. Corrective actions are taken if leakage rates exceed acceptance criteria. Leakage rate testing is performed in accordance with the regulations and guidance provided in 10 CFR Part 50 Appendix J, Option B; Regulatory Guide 1.163, "Performance-Based Containment Leak-Test Program;" NEI 94-01, "Industry Guideline for Implementing Performance-Based Option of 10 CFR 50, Appendix J;" and subject to the requirements of 10 CFR Part 54.

18.1.33 Masonry Walls

The Masonry Walls program is an existing condition monitoring program that is implemented as part of the Structures Monitoring program (18.1.34) and manages loss of material, cracking, and loss of material (spalling and scaling) that could impact the intended function of the masonry walls.

The Masonry Walls program consists of inspections, consistent with Inspection and Enforcement Bulletin (IEB) 80-11 and plant-specific monitoring proposed by Information Notice (IN) 87-67, for managing shrinkage, separation, gaps, loss of material and cracking of masonry walls such that the evaluation basis is not invalidated and intended functions are maintained. The inspections of the masonry walls within the scope of subsequent license renewal are conducted by qualified personnel at a frequency not to exceed five years.

18.1.34 Structures Monitoring

The Structures Monitoring program is an existing condition monitoring program that monitors the condition of structures and structural supports that are within the scope of subsequent license renewal to manage the following aging effects:

- Cracking
- Cracking and distortion
- Cracking, loss of material
- Cracking, loss of bond, and loss of material (spalling, scaling)
- Increase in porosity and permeability, cracking, loss of material (spalling, scaling)
- Loss of material
- Loss of material, loss of form

- Loss of material, change in material properties
- Loss of material (spalling, scaling) and cracking
- Loss of mechanical function
- Loss of preload
- Loss of sealing
- Reduction in concrete anchor capacity
- Reduction of foundation strength and cracking
- Reduction or loss of isolation function

This program consists of periodic visual inspection and monitoring the condition of concrete and steel structures, structural components, component supports, and structural commodities to ensure that aging degradation (such as those described in ACI 349.3R, ACI 201.1R, and other documents) will be detected, the extent of degradation determined and evaluated, and corrective actions taken prior to loss of intended functions. Inspections also include seismic joint fillers, elastomeric materials; and steel edge supports and steel bracings associated with masonry walls, and periodic evaluation of groundwater chemistry and opportunistic inspections for the condition of below grade concrete. Quantitative results (measurements) and qualitative information from periodic inspections are trended with photographs and surveys for the type, severity, extent, and progression of degradation. The acceptance criteria are derived from applicable consensus codes and standards. For concrete structures, the program includes personnel qualifications and quantitative acceptance criteria of ACI 349.3R-02, "Evaluation of Existing Nuclear Safety-Related Concrete Structures." The inspection of structural components, including masonry walls and water-control structures, are performed at intervals not to exceed five years, except for wooden poles, which are inspected on a frequency not to exceed every eight years.

Qualified inspectors identify changes that could be indicative of Alkali-Silica Reaction (ASR). If indications of ASR development are identified, the evaluation considers the potential for ASR development in concrete that is within the scope of the Structures Monitoring program (18.1.34), the ASME Section XI, Subsection IWL program (18.1.30), or the Inspection of Water-Control Structures Associated With Nuclear Power Plants program (18.1.35).

ASME Code, Section XI, visual examinations (VT-1) are conducted to detect cracking of stainless steel and aluminum components.

18.1.35 Inspection of Water-Control Structures Associated With Nuclear Power Plants

The Inspection of Water-Control Structures Associated with Nuclear Power Plants program is an existing condition monitoring program, which is implemented as part of the Structures Monitoring program (18.1.34), and manages the following aging effects:

- Cracking
- Cracking; blistering
- Cracking; blistering; loss of material
- Cracking; loss of bond; loss of material (spalling, scaling)
- Increase in porosity and permeability; loss of strength
- Loss of material
- Loss of material (spalling, scaling) and cracking
- Loss of material; loss of form

This program consists of inspection and surveillance of raw-water control structures associated with emergency cooling systems or flood protection, which are the Discharge Canal, Intake Canal, Discharge Tunnel and Seal Pit, High Level Intake Structure, and the Low Level Intake Structure. The program also includes structural steel and structural bolting associated with water-control structures. In general, parameters monitored are consistent with Section C.2 of Regulatory Guide 1.127, Revision 1 (March 1978), "Inspection of Water-Control Structures Associated with Nuclear Power Plants," and quantitative measurements are recorded for findings that exceed the acceptance criteria for applicable parameters monitored or inspected. The inspections of the water control structures within the scope of subsequent licensing renewal are conducted by qualified personnel at a frequency not to exceed five years. In order to evaluate the potential of water to cause degradation of concrete, samples of groundwater are taken at intervals not to exceed five years. The water chemistry is evaluated, and should the results of water testing indicate potentially harmful levels of substances such as chlorides > 500 ppm, sulfates > 1,500 ppm, or a pH < 5.5, inaccessible areas are assessed for aging and opportunistically inspected when excavated. Plant operating experience has not identified any structural degradation due to aggressive water chemistry.

18.1.36 Protective Coating Monitoring and Maintenance

The Protective Coating Monitoring and Maintenance program is an existing mitigative and condition monitoring program that manages loss of coating integrity of Service Level I coatings inside Containment. The program maintains and monitors the aging of Service Level 1 coatings consistent with RG 1.54, "Service Level I, II, and III Protective Coatings Applied to Nuclear

Power Plants". The program consists of guidance for selection, application, inspection, and maintenance of protective coatings.

Maintenance of Service Level I coatings applied to carbon steel and concrete surfaces inside Containment (e.g., steel liner, structural steel, supports, penetrations, and concrete walls and floors) will serve to prevent or minimize the loss of material of carbon steel components due to corrosion and aids in decontamination, but these coatings are not credited for managing the effects of corrosion for the carbon steel containment liner and components. This program ensures that the Service Level I coatings maintain adhesion so as to not affect the intended function of the emergency core cooling systems (ECCS) suction strainers.

The program also provides controls over the amount of unqualified coatings. Unqualified coating may fail in a way to affect the intended function of the ECCS suction strainers. Therefore, the quantity of degraded and unqualified coating is controlled and assessed periodically to ensure that the amount of unqualified coating in the primary containment is kept within acceptable design limits to support the post-accident operability of the ECCS.

18.1.37 Electrical Insulation For Electrical Cables and Connections Not Subject to 10 CFR 50.49 Environmental Qualification Requirements

The Electrical Insulation for Electrical Cables and Connections Not Subject to 10 CFR 50.49 Environmental Qualification Requirements program is an existing condition monitoring program that manages the aging effect of reduced electrical insulation resistance of the accessible electrical cable and connection insulation material subject to an adverse localized environment.

The program performs a plant walkdown of in-scope structures to visually inspect for accessible cables and connections located in an adverse localized environment. If an adverse localized environment is observed, accessible electrical cables and connections installed within that environment will be visually inspected for the aging mechanisms associated with jacket surface and connection covering anomalies, such as embrittlement, discoloration, cracking, melting, swelling or surface contamination. These anomalies may indicate signs of reduced electrical insulation resistance.

A review of previously identified and mitigated adverse localized environments cumulative aging effects applicable to in-scope cable and connection electrical insulation will be performed.

Additionally, visual inspection findings may necessitate testing. Should testing be deemed necessary based on the unacceptable visual indications of surface anomalies, a sample of each cable and connection insulation material type found within the adverse localized environment will be tested. Testing may include thermography and other proven condition monitoring test methods applicable to the cable and connection insulation. Testing as part of an existing maintenance, calibration or surveillance program may be credited. The electrical cable and connection insulation material test results are to be within the acceptance criteria, as identified in the procedures.

The visual inspection frequency is based on engineering evaluation and will be performed at least once every ten years.

18.1.38 Electrical Insulation For Electrical Cables and Connections Not Subject to 10 CFR 50.49 Environmental Qualification Requirements Used In Instrumentation Circuits

The Electrical Insulation for Electrical Cables and Connections Not Subject to 10 CFR 50.49 Environmental Qualification Requirements Used in Instrumentation Circuits program is an existing performance monitoring program that manages the aging effects of reduced electrical insulation resistance of the electrical cables and connections (cable system) insulation material subject to sensitive, high-voltage, low-level current signals that are subjected to adverse localized environments caused by temperature, radiation, or moisture.

The program applies to the containment high range radiation monitor system, the post-accident neutron monitoring system, and the excore neutron monitoring system.

The containment high range radiation monitor system cables are connected during calibration. Therefore, the calibration results or findings of surveillance testing programs are evaluated to identify the existence of electrical cable and connection insulation material aging degradation. The reviews are completed prior to the subsequent period of extended operation and at least every ten years thereafter.

The excore neutron monitoring system cables are disconnected during calibration. The program performs a proven cable test for detecting deterioration of the cable system insulation material. The test frequency is based on engineering evaluation and is performed at least once every ten years.

The post-accident neutron monitoring system cables are disconnected during calibration. The program will perform a proven cable test for detecting deterioration of the cable system insulation material. The tests will be completed prior to the subsequent period of extended operation and at least every ten years thereafter.

18.1.39 Electrical Insulation For Inaccessible Medium-Voltage Power Cables Not Subject to 10 CFR 50.49 Environmental Qualification Requirements

The Electrical Insulation for Inaccessible Medium-Voltage Power Cables Not Subject to 10 CFR 50.49 Environmental Qualification Requirements program is an existing condition monitoring program that manages the aging effect of reduced electrical insulation resistance of inaccessible medium-voltage cables (operating voltages of 2kV to 35kV) exposed to significant moisture.

The program applies to inaccessible or underground (e.g., installed in buried conduits, cable trenches, cable troughs, duct banks, underground vaults, or direct buried installations) non-EQ medium-voltage power cables within the scope of subsequent license renewal exposed to significant moisture. Significant moisture is defined as exposure to moisture that lasts more than three days (i.e., long term wetting or submergence over a continuous period), that if left unmanaged, could potentially lead to a loss of intended function.

Periodic actions are taken to prevent non-EQ inaccessible medium-voltage power cables from being exposed to significant moisture. Accessible cable conduit ends and manholes/vaults associated with the cables included in this program are inspected for water collection and the water is drained, as necessary. This inspection and water removal is performed based on actual plant experience over time with an inspection frequency being at least annually and after event driven occurrences (such as heavy rain, rapid thawing of ice and snow, or flooding).

In-scope non-EQ inaccessible medium-voltage power cables routed through manholes and duct banks are tested to detect reduced electrical insulation resistance of the cable's insulation system. Testing that is appropriate to the application at the time of the testing is performed. Cable testing includes one or more proven testing methods (such as dielectric loss [dissipation factor (Tan-Delta)/power factor], AC voltage withstand, partial discharge, step voltage, time domain reflectometry, insulation resistance and polarization index, or line resonance analysis). Cable testing acceptance criteria are defined prior to each test. Cables are tested at least once every six years. More frequent testing may occur based on test results and operating experience.

There are no submarine cables or other cables designed for continuous wetting or submergence currently in the scope of this program. Future installed cables of this design would be considered for inclusion in this program.

18.1.40 Electrical Insulation For Inaccessible Instrument and Control Cables Not Subject to 10 CFR 50.49 Environmental Qualification Requirements

The Electrical Insulation for Inaccessible Instrument and Control Cables Not Subject to 10 CFR 50.49 Environmental Qualification Requirements program is a new condition monitoring program that will manage the aging effect of reduced electrical insulation resistance leading to electrical failure of in-scope non-EQ inaccessible instrument and control cables.

This program will apply to inaccessible or underground (e.g., installed in buried conduit, cable trenches, cable troughs, duct banks, underground vaults, or direct buried installations) non-EQ instrument and control cable, within the scope of subsequent license renewal that are exposed to significant moisture, including cables designed for continuous wetting or submergence. Significant moisture is defined as exposure to moisture that lasts more than three days (i.e., long term wetting or submergence over a continuous period), that if left unmanaged, could potentially lead to a loss of intended function.

Periodic actions will be taken to prevent inaccessible instrument and control cables from being exposed to significant moisture. Accessible cable conduit ends and manholes/vaults associated with the cables included in this program are inspected for water collection and the water is drained, as necessary. This inspection and water removal will be performed based on actual plant experience over time with an inspection frequency being at least annually and after event driven occurrences (such as heavy rain, rapid thawing of ice and snow, or flooding).

Inaccessible instrument and control cables that are exposed to significant moisture, or are found to be degraded during a periodic inspection, are evaluated to determine if testing is required. If testing is required, the cables will be tested using one or more proven tests for detecting reduced insulation resistance.

Industry and plant specific operating experience will be evaluated in the development and implementation of this program.

18.1.41 Electrical Insulation For Inaccessible Low-Voltage Power Cables Not Subject to 10 CFR 50.49 Environmental Qualification Requirements

The Electrical Insulation for Inaccessible Low-Voltage Power Cables Not Subject to 10 CFR 50.49 Environmental Qualification Requirements program is a new condition monitoring program that will manage the aging effect of reduced electrical insulation resistance of inaccessible low-voltage power (operating voltage less than 2kV) cables exposed to significant moisture.

The program will apply to inaccessible or underground (e.g., installed in buried conduit, cable trenches, cable troughs, duct banks, underground vaults, or direct buried installations) non-EQ low-voltage power cables, within the scope of subsequent license renewal that are exposed to significant moisture, including cables designed for continuous wetting or submergence. Significant moisture is defined as exposure to moisture that lasts more than three days (i.e., long term wetting or submergence over a continuous period), that if left unmanaged, could potentially lead to a loss of intended function.

Periodic actions will be taken to prevent inaccessible low-voltage power cables from being exposed to significant moisture. Accessible cable conduit ends and manholes/vaults associated with the cables included in this program are inspected for water collection and the water is drained, as necessary. This inspection and water removal will be performed based on actual plant experience over time with an inspection frequency being at least annually and after event driven occurrences (such as heavy rain, rapid thawing of ice and snow, or flooding).

Inaccessible low-voltage power cables that are exposed to significant moisture, or are found to be degraded during a periodic inspection, are evaluated to determine if testing is required. If testing is required, the cables will be tested using one or more proven tests for detecting reduced insulation resistance.

Industry and plant specific operating experience will be evaluated in the development and implementation of this program.

18.1.42 Metal Enclosed Bus

The Metal Enclosed Bus program is an existing condition monitoring program that manages the aging effect of degradation of electrical insulating material, reduced electrical insulation resistance, cracking, and loss of continuity or increased contact resistance of the bolted connections for metal enclosed bus (MEB) and internal components. Bus enclosure assemblies (internal and external), bus bar insulation, bus bar insulating supports, and bus bar bolted connections are included.

Visual inspection of accessible metal enclosed bus internal surfaces is performed to detect age-related degradation, including cracks, corrosion, foreign debris, excessive dust buildup, and evidence of moisture intrusion. Accessible metal enclosed bus insulating material is visually inspected for signs of embrittlement, cracking, chipping, melting, swelling, discoloration, or surface contamination, which may indicate overheating or aging degradations. The accessible internal bus insulating supports are visually inspected for structural integrity and signs of cracks. Accessible metal enclosed bus external surfaces are visually inspected for loss of material due to general, pitting, and crevice corrosion.

Accessible elastomers (e.g., gaskets, boots, and sealants) are inspected for degradation, including surface cracking, crazing, scuffing, and changes in dimensions (e.g., “ballooning” and “necking”), shrinkage, discoloration, hardening and loss of strength. A sample of accessible bolted connections is inspected for increased resistance of connection by measuring connection resistance using a micro-ohmmeter.

The first inspection, including measuring connection resistance, is completed prior to the subsequent period of extended operation and at least every twelve years thereafter for emergency buses and every ten years thereafter for non-emergency buses, with the exception of MEB associated with transfer bus F. If internal inspections of metal enclosed bus associated with either transfer bus D or E identify degradation that would result in a loss of intended function, MEB associated with transfer bus F will be scheduled for inspection and testing. An opportunistic inspection of MEB associated with transfer bus F will also be performed if a dual unit outage of at least ten days duration occurs and transfer bus F can be deenergized without a significant safety impact to the units.

18.1.43 Electrical Cable Connections Not Subject to 10 CFR 50.49 Environmental Qualification Requirements

The Electrical Cable Connections Not Subject to 10 CFR 50.49 Environmental Qualification Requirements program is a new condition monitoring program that will manage the aging effect of increased electrical resistance of electrical cable connections (metallic parts).

This program will perform a one-time inspection, on a representative sampling basis, to confirm the absence of loosening of connections due to thermal cycling, ohmic heating, electrical transients, vibration, chemical contamination, corrosion and oxidation. The following factors will be considered for sampling: application (medium and low voltage), circuit loading (high load), connection type, and location (high temperature, high humidity, vibration, etc.).

Non-EQ electrical cable connections (metallic parts) associated with cables within the scope of subsequent license renewal will be tested prior to the subsequent period of extended operation to provide an indication of the integrity of the cables connections. The specific type of test to be performed will be determined based on the type of connection and will be a proven method for detecting loose connections, such as thermography, contact resistance testing, or other appropriate testing methods without removing the connection insulation such as heat shrink tape, sleeving, or insulating boots, etc.

Twenty percent of a connector type population with a maximum sample of 25 constitutes a representative connector sample size. Otherwise a technical justification of the methodology and sample size used for selecting components under test will be included as part of the program's documentation.

A sample of cable connections within the scope of subsequent license renewal will be tested on a one-time test basis or at least once every five years if only visual inspection is used to provide an indication of the integrity of the cable connections. Depending on the findings of the one-time test, subsequent testing may have to be performed within ten years of initial testing. The first visual inspections or tests for license renewal are to be completed prior to the subsequent period of extended operation.

As an alternative to testing for accessible cable connections that are covered with heat shrink tape, sleeving, insulating boots, etc., a visual inspection of insulation materials to detect surface anomalies, such as embrittlement, cracking, chipping, melting, discoloration, swelling or surface contamination may be implemented. When this alternative visual inspection is used to check cable connections, the inspection will be completed prior to the subsequent period of extended operation, and repeated at least every five years, thereafter. The basis for performing only the alternative visual inspection to monitor age-related degradation of cable connections will be documented.

Industry and plant specific operating experience will be evaluated in the development and implementation of this program.

18.1.44 High-Voltage Insulators

The High-Voltage Insulators program is a new condition monitoring program that will manage loss of material and reduced electrical insulation resistance for high-voltage insulators that are credited for recovery of offsite power.

High Voltage insulator surfaces will be visually inspected to detect reduced electrical insulation resistance aging effects including cracks, foreign debris, excessive salt, dust, fog, and industrial effluent contamination. Metallic parts of the insulator will be visually inspected to detect loss of material due to mechanical wear or corrosion.

The high-voltage insulators within the scope of the High-Voltage Insulators program will be visually inspected at least once every two years initially with the frequency adjusted based on plant specific operating experience. For high-voltage insulators that are coated, the visual inspection will be performed at least once every five years.

The first inspections will be completed prior to the subsequent period of extended operation.

Industry and plant specific operating experience will be evaluated in the development and implementation of this program.

18.2 SUMMARY DESCRIPTIONS OF TIME-LIMITED AGING ANALYSIS AGING MANAGEMENT PROGRAMS

18.2.1 Fatigue Monitoring

The Fatigue Monitoring program is an existing preventive program that manages cycle-based fatigue of the mechanical or structural components with a fatigue time-limited aging analysis (TLAA) or other analysis that depends on the number of occurrences and severity of transient cycles.

This program is used to accept fatigue or other types of cyclical loading TLAAs in accordance with the acceptance criterion in 10 CFR 54.21(c)(1)(iii). The aging management program monitors and tracks the number of occurrences and severity of design basis transients assessed in the applicable fatigue or cyclical loading analyses, including those in applicable cumulative usage factor (CUF) analyses, environmental-assisted fatigue analyses (CUFen analyses), maximum allowable stress range reduction/expansion stress analyses for ANSI B31.1 and ASME Code Class 2 and 3 components, ASME III fatigue waiver analyses, and cycle-based flaw growth, flaw tolerance, or fracture mechanics analyses.

The program manages cumulative fatigue damage or cracking induced by fatigue or cyclic loading in the applicable structures and components through performance of activities that monitor one or more relevant analysis parameters, such as CUF values, CUFen values, design transient cycle limit values, or predicted flaw size values. The program also sets applicable acceptance criteria (limits) on these parameters. Therefore, the program has two aspects, one to verify the continued acceptability of existing analyses through cycle counting or parameter monitoring and the other to provide periodically updated evaluations of the analyses to demonstrate that they continue to meet the appropriate limits.

The program also implements appropriate corrective actions (e.g., reanalysis, component or structure inspections, or component or structure repair or replacement activities) when acceptance limits are approached.

18.2.2 Neutron Fluence Monitoring

The Neutron Fluence Monitoring program is an existing condition monitoring program that manages loss of fracture toughness due to neutron fluence of the reactor pressure vessel (RPV) regions for which neutron fluence is projected to exceed 1 x 10^{17} n/cm^2 (E>1MeV) during the subsequent period of extended operation to ensure that applicable reactor pressure vessel neutron irradiation embrittlement analysis will remain within their applicable limits.

This program has two aspects, one to verify the continued acceptability of existing analyses through neutron fluence monitoring and the other to provide periodically updated evaluations of the analyses involving neutron fluence inputs to demonstrate that they continue to meet the appropriate limits defined in the current licensing basis (CLB).

Monitoring is performed in accordance with neutron flux determination methods and neutron fluence projection methods that are defined for the CLB in NRC-approved reports. For fluence monitoring activities that apply to components located in the beltline region of the RPVs, the monitoring methods are performed in a manner that is consistent with the monitoring methodology guidelines in Regulatory Guide (RG) 1.190, “Calculational and Dosimetry Methods for Determining Pressure Vessel Neutron Fluence.” Neutron fluence monitoring methods that are applied to RPV locations outside of the beltline region of the RPVs were justified and are consistent with NRC-approved methodology.

This program's results are compared to the neutron fluence parameter inputs used in the neutron embrittlement analyses for RPV components. This includes but is not limited to the neutron fluence inputs for the RPV upper-shelf energy analyses and equivalent margin analyses, pressure-temperature analyses, and low temperature overpressure protection (LTOP) that are required to be performed in accordance in 10 CFR Part 50, Appendix G requirements, and safety analyses that are performed to demonstrate adequate protection of the RPVs against the consequences of pressurized thermal shock (PTS) events, as required by 10 CFR 50.61 and applicable to the CLB. Comparisons to the neutron fluence inputs for other analyses (as applicable to the CLB) includes those for RT_{NDT}.

Reactor vessel surveillance capsule dosimetry data obtained in accordance with 10 CFR Part 50, Appendix H requirements and through implementation of the Reactor Vessel Material Surveillance program (18.1.19) provides inputs to and have impacts on the neutron fluence monitoring results that are tracked by this program. In addition, regulatory requirements in the plant technical specifications or in specific regulations of 10 CFR Part 50 apply, including those in 10 CFR Part 50, Appendix G; 10 CFR 50.55a; and the PTS requirements in 10 CFR 50.61, as applicable for the CLB.

18.2.3 Environmental Qualification of Electric Equipment

The Environmental Qualification of Electrical Equipment program manages equipment thermal, radiation, and cyclical aging through the use of aging evaluations based on qualification methods given in 10 CFR 50.49. This program implements the EQ requirements in 10 CFR 50.49. 10 CFR 50.49 specifically requires that an EQ program be established to demonstrate that certain electrical equipment located in harsh plant environments will perform applicable safety functions in those harsh environments after the effects of inservice aging. 10 CFR 50.49 requires that the effects of significant aging mechanisms be addressed as part of environmental qualification.

As required by 10 CFR 50.49, environmentally qualified equipment not qualified for the current license term is refurbished or replaced, or has its qualified life extended through reanalysis or ongoing qualification prior to reaching the designated life aging limits established in the evaluation. Aging evaluations for environmentally qualified equipment that specify a qualified life of at least 40 to 60 years are time-limited aging analyses (TLAAs) for subsequent license renewal.

The Environmental Qualification of Electrical Equipment program is consistent with the guidance of 10 CFR 50.49; Inspection and Enforcement Bulletin (IEB) 79-01B, “Environmental Qualification of Class 1E Equipment”; “Guidelines for Evaluation of Environmental Qualification of Class 1E Electrical Equipment in Operating Reactors” (DOR Guidelines); and IEEE Standard 323-1974, “IEEE Standard for Qualifying Class 1E Equipment for Nuclear Power Generating Stations.”

Reanalysis of an aging evaluation to extend the qualification of equipment qualified under the program requirements of 10 CFR 50.49(e) is performed as part of the EQ program. Important attributes for the reanalysis of an aging evaluation include analytical methods, data collection and reduction methods, underlying assumptions, acceptance criteria, and corrective actions (if acceptance criteria are not met). The analytical models used in the reanalysis of an aging evaluation are the same as those previously applied during the prior evaluation. The identification of excess conservatism in electrical equipment service conditions (for example, temperature, radiation, and cycles) used in the prior aging evaluation is the primary method used for a reanalysis. A reanalysis demonstrates that adequate margin is maintained consistent with the original analysis in accordance with 10 CFR 50.49 requiring certain margins and accounting for the unquantified uncertainties established in the EQ aging evaluation of the equipment. Reanalysis of an aging evaluation can be used to extend the environmental qualification of the equipment. If the qualification cannot be extended by reanalysis, the equipment is refurbished, replaced, or requalified prior to exceeding the current qualified life.

When the reanalysis assessed margins, conservatisms, or assumptions do not support reanalysis (e.g., extending qualified life) of environmentally qualified equipment, the use of on-going qualification techniques including condition monitoring or condition based methodologies may be implemented. Ongoing qualification is an alternative means to provide reasonable assurance that equipment environmental qualification is maintained for the subsequent period of extended operation. Ongoing qualification of electric equipment within the scope of the EQ program involves the inspection, observation, measurement, or trending of one or more indicators, which can be correlated to the condition or functional performance of the environmentally qualified equipment.

18.3 EVALUATION SUMMARIES OF TIME-LIMITED AGING ANALYSES

As part of the application for a renewed license, 10 CFR 54.21(c) requires that an evaluation of Time-Limited Aging Analyses (TLAAs) for the subsequent period of extended operation be provided. The following TLAAs, as defined in 10 CFR 54.3, have been identified and evaluated to meet this requirement.

18.3.1 Identification of Time-Limited Aging Analyses

10 CFR 54.21(c)(2) requires that the application for a renewed license include a list of plant-specific exemptions granted pursuant to 10 CFR 50.12 and in effect that are based upon TLAAs as defined in 10 CFR 54.3. It also requires an evaluation that justifies the continuation of these exemptions for the subsequent period of extended operation. There were no exemptions to 10 CFR 50.12 identified that are currently in effect that are based upon or are associated with a TLAA.

The following TLAAs have been identified and evaluated to meet 10 CFR 54.21(c) requirements. Summaries of the TLAAs applicable to the subsequent period of extended operation are included in the following sections:

- Reactor Vessel Neutron Embrittlement Analysis (Section 18.3.2)
- Metal Fatigue (Section 18.3.3)
- Environmental Qualification of Electric Equipment (Section 18.3.4)
- Concrete Containment Tendon Prestress (Section 18.3.5)
- Containment Liner Plate, Metal Containments, and Penetrations Fatigue Analysis (Section 18.3.6)
- Other Plant-Specific Time-Limited Aging Analyses (Section 18.3.7)

18.3.2 Reactor Vessel Neutron Embrittlement Analyses

10 CFR 50.60 requires that all light water reactors meet the fracture toughness, P-T limits, and materials surveillance program requirements for the reactor coolant pressure boundary as set forth in 10 CFR 50, Appendices G and H. The Reactor Head Closure Stud Bolting program is described in Section 18.1.19. The ferritic materials of the reactor pressure vessel (RPV) are subject to embrittlement due to high energy ($E > 1.0$ MeV) neutron exposure. Embrittlement means the material has lower toughness (i.e., will absorb less strain energy during a crack or rupture), thus allowing a crack to propagate more easily under thermal and pressure loading. Neutron embrittlement analyses are used to account for the reduction in fracture toughness

associated with the cumulative neutron fluence (total number of neutrons that intersect a square centimeter of component area during the life of the plant). Since these neutron embrittlement analyses are calculated based on plant life, they are identified as TLAAs. The following RPV neutron embrittlement TLAAs have been identified and evaluated to meet 10 CFR 54.21(c) requirements:

- Neutron Fluence Projections
- Upper-Shelf Energy
- Pressurized Thermal Shock
- Adjusted Reference Temperature
- Pressure Temperature Limits
- Low Temperature Overpressure Protection

18.3.2.1 Neutron Fluence Projections

Updated neutron fluence evaluations were performed and documented in WCAP-18028-NP, “Extended Beltline Pressure Vessel Fluence Evaluations Applicable to Surry Power Station Units 1 & 2.” RPV beltline and extended beltline fast neutron fluences (E > 1.0 MeV) at the end of 80 years of operation were calculated for Units 1 and 2. The analyses methodologies used to calculate the Units 1 and 2 RPV fluences satisfy the guidance set forth in Regulatory Guide 1.190, “Calculational and Dosimetry Methods for Determining Pressure Vessel Neutron Fluence.” These methodologies have been approved by the NRC and are described in detail in WCAP-14040, “Methodology Used to Develop Cold Overpressure Mitigating System Setpoints and RCS Heatup and Cooldown Limit Curves,” and are documented in UFSAR Section 4.1.7.3, “Calculation of Integrated Fast Neutron (E Greater than 1.0 MeV) Flux at the Irradiation Samples.” The fluence analyses have been projected to the end of the subsequent period of extended operation and are dispositioned in accordance with 10 CFR 54.21(c)(1)(ii).

18.3.2.2 Upper-Shelf Energy

Appendix G of 10 CFR 50, Paragraph IV.A.1.a, indicates that reactor pressure vessel (RPV) beltline materials must have Charpy upper-shelf energy of no less than 75 ft-lb initially, and must maintain Charpy upper-shelf energy throughout the life of the vessel of no less than 50 ft-lb, unless it is demonstrated in a manner approved by the Director, Office of Nuclear Reactor Regulation, that lower values of Charpy upper-shelf energy will provide margins of safety against fracture equivalent to those required by Appendix G of Section XI of the ASME Code, “Fracture Toughness Criteria for Protection Against Failure”. For materials outside the beltline, a minimum value of 30 ft-lbs at 10 °F was specified by ASTM E208 at the time of the initial design of Units 1 and 2. The upper shelf energy (USE) analyses for the ferritic steel components (i.e., RPV shell plates or forgings, nozzle plates or forgings, and associated pressure retaining welds) in the beltline region of the RPV have been updated based on component neutron fluence values that have been projected to the end of the subsequent period of extended operation and the current RPV surveillance test data for the facility. Based on WCAP-18242-NP, Surry Power Station Units 1 and 2 Time Limited Aging Analysis on Reactor Vessel Integrity for Subsequent License Renewal, the materials that exceeded the 1.0×10^{17} n/cm^2 (E > 1.0 MeV) threshold at 68 EFPY are considered to be the Units 1 and 2 extended beltline materials and were evaluated to determine their impact on the subsequent period of extended operation. The forgings and welds corresponding to the Units 1 and 2 Inlet Nozzles 1, Inlet Nozzles 3, and Outlet Nozzles 3 are predicted to experience neutron fluence greater than 1.0×10^{17} n/cm^2 at the end of the period of extended operation. However, for conservatism all of the Units 1 and 2 inlet and outlet nozzle materials are considered part of the extended beltline.

For Unit 1, the limiting USE value at 68 EFPY is 32 ft-lb; this value corresponds to the Intermediate to Lower Shell Circumferential Weld (Heat # 72445). For Unit 2, the limiting USE value at 68 EFPY is 41 ft-lb; this value corresponds to the Upper to Intermediate Shell Circumferential Weld (Heat # 4275).

The NRC has previously approved the use of the equivalent margins analysis (EMA) BAW-2494, Low Upper-Shelf Toughness Fracture Mechanics Analysis of Reactor Vessel of Surry Power Station Units 1 and 2 for Extended Life through 48 Effective Full Power Years to qualify all of the materials currently projected to drop below 50 ft-lb USE at 68 EFPY. The EMAs for these materials are updated for the subsequent period of extended operation under ANP-3679NP, “Low Upper-Shelf Toughness Fracture Mechanics Analysis for Surry Units 1 and 2 Reactor Vessels for Levels A & B Service Loads at 80 Years” and ANP-3680NP, “Low Upper-Shelf Toughness Fracture Mechanics Analysis for Surry Units 1 and 2 Reactor Vessels for Levels C & D Service Loads at 80 Years” The updated EMA is based upon the provisions outlined in NRC Regulatory Guide 1.161 and Section XI of the ASME Code, Appendix K. The EMAs were submitted with the subsequent license renewal application.

The following Units 1 and 2 materials are addressed by EMAs in ANP-3679NP and ANP-3680NP for the subsequent period of extended operation:

Unit 1:

- Upper to Intermediate Shell Circumferential Weld, Heat # 25017 (J726)
- Intermediate Shell Longitudinal Welds L3 and L4, Heat # 8T1554
- Intermediate to Lower Shell Circumferential Weld, Heat # 72445
- Lower Shell Longitudinal Weld L1, Heat # 8T1554
- Lower Shell Longitudinal Weld L2, Heat # 299L44
- Inlet Nozzle to Shell Welds, Heat # 299L44 and # 8T1762; (Projected USE > 50 ft-lbs at 68 EFPY)

- Outlet Nozzle to Shell Welds, Heat # 8T1762 and # 8T1554B; (Projected USE > 50 ft-lbs at 68 EFPY)

Unit 2:

- Upper to Intermediate Shell Circumferential Weld, Heat # 4275 (J737)
- Intermediate Shell Longitudinal Welds L3 and L4, Heat # 72445
- Intermediate Shell Longitudinal Weld L4, Heat # 8T1762
- Intermediate to Lower Shell Circumferential Weld, Heat # 0227
- Lower Shell Longitudinal Weld L1 and L2, Heat # 8T1762
- Inlet Nozzle to Shell Welds, Heat # 8T1762; (Projected USE not projected > 50 ft-lbs at 68 EFPY)
- Outlet Nozzle to Shell Welds, Rotterdam Weld; (Projected USE > 50 ft-lbs at 68 EFPY)

Note that as a conservative measure, an EMA has been completed for Units 1 and 2 Inlet and Outlet Nozzle to Shell Welds even though these materials are not projected to drop below 50 ft-lbs through 68 EFPY. The inlet and outlet nozzle welds are the only materials included in ANP-3679NP and ANP-3680NP that were not previously addressed by EMA. The EMA is applicable to Units 1 and 2 nozzle to shell welds which exceed the fluence criterion of 1.0×10^{17} n/cm^2 before 68 EFPY. These materials include those listed below.

- Unit 1 Outlet Nozzle 1 to Upper Shell Weld
- Unit 1 Inlet Nozzle 1 to Upper Shell Weld
- Unit 1 Inlet Nozzle 3 to Upper Shell Weld
- Unit 2 Outlet Nozzle 1 to Upper Shell Weld
- Unit 2 Inlet Nozzle 1 to Upper Shell Weld
- Unit 2 Inlet Nozzle 3 to Upper Shell Weld

For Unit 1, the limiting USE value for materials not requiring an EMA at 68 EFPY is 54 ft-lb; this value corresponds to the Inlet Nozzle to Upper Shell Welds (Heat # 299L44). For Unit 2, the limiting USE value for materials not requiring an EMA at 68 EFPY is also 54 ft-lb; this value corresponds to the Outlet Nozzle to Upper Shell Welds (Rotterdam). Except for the materials listed above, all of the beltline and extended beltline materials in Units 1 and 2 RPVs are projected to remain above the USE screening criterion value of 50 ft-lb (per 10 CFR 50, Appendix G) through the subsequent period of extended operation (68 EFPY).

The USE TLAA has been projected to the end of the subsequent period of extended operation and is dispositioned in accordance with 10 CFR 54.21(c)(1)(ii).

18.3.2.3 **Pressurized Thermal Shock**

10 CFR 50.61(b)(1) provides rules for protection against pressurized thermal shock (PTS) events for pressurized water reactors and requires the reference temperature RTPTS for reactor pressure vessel (RPV) beltline materials to be less than the PTS screening criteria at the expiration date of the operating license unless otherwise approved by the NRC. All of the beltline and extended beltline materials in the Units 1 and 2 RPV are below the RTPTS screening criteria values of 270 °F for base metal and/or longitudinal welds, and 300 °F for circumferentially oriented welds through 68 EFPY. The PTS analyses have been projected to the end of the subsequent period of extended operation and are dispositioned in accordance with 10 CFR 54.21(c)(1)(ii).

18.3.2.4 **Adjusted Reference Temperature**

The adjusted reference temperature (ART) of the limiting beltline material is used to adjust the beltline P-T limit curves to account for irradiation effects. 10 CFR 50, Appendix G, defines the fracture toughness requirements for the life of the vessel. Regulatory Guide 1.99 provides the methodology for determining the ART of the limiting material. RTNDT was evaluated in accordance with PWROG-16045-NP. The limiting ART values at 48 EFPY and 68 EFPY are less than the limiting ART values used to develop the existing P-T limit curves. The ART analyses have been projected to the end of the period of extended operation and are dispositioned in accordance with 10 CFR 54.21(c)(1)(ii).

18.3.2.5 **Pressure-Temperature Limits**

10 CFR 50 Appendix G requires that the RPV be maintained within established pressure-temperature (P-T) limits, including heatup and cooldown operations. These limits specify the maximum allowable pressure as a function of reactor coolant temperature. As the RPV is exposed to increased neutron irradiation, its fracture toughness is reduced. The P-T limits must account for the anticipated RPV fluence.

According to NUREG-2192, Section 4.2.2.1.4, the P-T limits for the subsequent period of extended operation need not be submitted as part of the subsequent license renewal application since the P-T limits are required to be updated through the 10 CFR 50.90, “Application for Amendment of License, Construction Permit, or Early Site Permit,” licensing process when necessary for P-T limits that are located in the Technical Specifications. The P-T limit curves for normal heatup and cooldown of the primary reactor coolant system for Units 1 and 2 were previously developed in WCAP-14177.

The Reactor Vessel Material Surveillance program (18.1.19) will ensure that updated P-T limits based upon updated ART values will be submitted to the NRC for approval prior to exceeding the current terms of applicability for Units 1 and 2. Since the P-T limits will be updated through 10 CFR 50.90 at a later, appropriate date, the effects of aging on the intended function(s) of the RPVs will be adequately managed for the period of extended operation and are dispositioned in accordance with 10 CFR 54.21(c)(1)(iii).

18.3.2.6 **Low Temperature Overpressure Protection**

The Units 1 and 2 low temperature overpressure protection (LTOP) system is required by Technical Specification Limited Condition for Operation 3.1.G. Two pressurizer power operated relief valves (PORV) are used to provide the automatic relief capability during the design basis mass input and the design basis heat input transients to automatically prevent the reactor coolant system pressure from exceeding the pressure temperature limit curves based on 10 CFR 50, Appendix G.

The LTOP enabling temperature has been determined for 68 EFPY. Using Code Case N-514, the LTOP enabling temperature is 283°F. Using Code Case N-641, the LTOP enabling temperature can be either 273°F or 262°F. The Surry Technical Specification 3.1.G.1.c (4) specifies an arming temperature of 350°F which is conservative and remains valid for the subsequent period of extended opeation.

In WCAP-18242-NP, "Surry Units 1 and 2 Time-Limited Aging Analysis on Reactor Vessel Integrity for Subsequent License Renewal," the maximum allowable Low Temperature Overpressure Protection System (LTOPS) pressurizer PORV setpoint was calculated to be 399.6 psig for the subsequent period of extended operation. The calculation was performed in accordance with the WCAP-14040-A, "Methodology Used to Develop Cold Overpressure Mitigating System Setpoints and RCS Heatup and Cooldown Limit," methodology using critical LTOPS input parameters and the limiting axial flaw steady state Appendix G limits calculated for 68 EFPY. The evaluation showed that the current Technical Specification value of ≤ 390.0 psig is bounding and will remain valid for the subsequent period of extended operation.

The LTOP system licensing and design basis analyses have been projected to the end of the subsequent period of extended operation and are dispositioned in accordance with 10 CFR 54.21(c)(1)(ii).

18.3.3 Metal Fatigue

Fatigue analyses are required on components designed to ASME Code, Section III, Class 1. Also, certain other codes such as ASME Code, Section III, Class 2 and 3, USAS (ANSI) B31.1, and ASME Code, Section VIII, Division 2, may require a fatigue analysis or assume a stated number of full-range thermal and displacement transient cycles. NUREG-2192 also provides examples of components that are likely to have fatigue TLAAs within the current licensing basis (CLB) that would require evaluation for the subsequent period of extended operation. Searches were performed to identify these and any other potential fatigue TLAAs within the current licensing bases for Units 1 and 2. Each of the potential TLAAs were evaluated against the six

TLAA screening criteria specified in 10 CFR 54.3. Those that were identified as fatigue TLAAs are evaluated in the following Subsections:

- Transient Cycle Projections for 80 years (Section 18.3.3.1)
- ASME Code, Section III, Class 1 Fatigue Analyses (Section 18.3.3.2)
- ANSI B31.1 Allowable Stress Analyses (Section 18.3.3.3)
- Environmental- Assisted Fatigue (Section 18.3.3.4)
- Reactor Vessel Internals Fatigue Analyses (Section 18.3.3.5)

18.3.3.1 **Transient Cycle Projections for 80 years**

Fatigue analyses are based upon explicit numbers and amplitudes of thermal and pressure transients. UFSAR Table 4.1-8 and Section 18.4.1 provides a listing of design transients and associated design cycles. The intent of the design basis transient definitions is to bound a wide range of possible events with varying ranges of severity in temperature and pressure. The existing fatigue analyses are based upon the original number of design cycles (40 years) and are postulated to bound 60 years of service. Since the fatigue analyses are based upon a number of cycles postulated to bound sixty years of service for the current license basis, these analyses constitute a TLAA.

Baseline cycle counts were projected to an 80-year operating life based on the actual accumulation history over the 10-year period from June 30, 2006 to June 30, 2016. Since most nuclear power plants, including SPS Units 1 and 2, have experienced a significant declining trend in accumulation of transients over time, transient projections based on recent operating experience provide an appropriate basis for future projections. Therefore, each monitored design transient was evaluated to determine if the recent 10-year trend had a consistent cycle accumulation rate. The 10-year rate was used to extrapolate the projected number of future occurrences beginning June 30, 2016 and ending at 80 years of plant operation. The end of 80-year life is June 2052 for Unit 1 and March 2053 for Unit 2. The projected cycles for 80 years of plant operation were less than the 40-year design cycles (CLB cycles) used in the fatigue analyses. Therefore, the fatigue analyses for ASME Code, Section III components remain valid for the subsequent period of extended operation. In order to ensure the design cycles remain bounding in the ASME Code, Section III fatigue analyses, the Fatigue Monitoring program (Section 18.2.1) will track cycles for significant fatigue transients and ensure corrective action is taken prior to potentially exceeding fatigue design limits. A Condition Report will be initiated based upon an administrative limit of 90% of the fatigue cycles.

18.3.3.2 **ASME Code, Section III, Class I Fatigue Analyses**

Fatigue analyses are performed per ASME Code, Section III. Each analysis is required to demonstrate that the Cumulative Usage Factor (CUF) for the component will not exceed the Code design limit 1.0 when the component is exposed to all postulated transients.

The following ASME Code, Section III components were assessed for impact on fatigue:

- Control Rod Drive Mechanism (CRDM)
- Pressurizer
- Reactor Coolant Pump
- Reactor Vessel
- Steam Generator
- Pressurizer Surge Line
- Charging and Accumulator Piping

In addition, a detailed fatigue evaluation is not required if components conform to the waiver of fatigue requirements per ASME Code, Section III. These fatigue waivers depend on the numbers of anticipated transients over the life of the plant and therefore constitute TLAAs.

The 40-year design cycles (CLB cycles) were postulated to bound 80 years of plant operations. Therefore, the fatigue analyses and fatigue waivers remain valid for the subsequent period of extended operation. In order to ensure the design cycles remain bounding in the fatigue analyses and fatigue waivers, the Fatigue Monitoring program (Section 18.2.1) will track cycles for significant fatigue transients listed in the UFSAR, Table 4.1-8 and Section 18.4.1, and ensure corrective action is taken prior to potentially exceeding fatigue design limits.

The effects of fatigue on the intended function(s) of ASME Code, Section III components will be adequately managed by the Fatigue Monitoring program (Section 18.2.1) for the subsequent period of extended operation in accordance with 10 CFR 54.21(c)(1)(iii).

18.3.3.3 **ANSI B31.1 Allowable Stress Analyses**

The reactor coolant system's primary loop piping and the balance-of-plant piping in scope for subsequent license renewal are analyzed to the requirements of ANSI B31.1, "Power Piping." There are two aspects of note that pertain to fatigue for the ANSI B31.1 piping. The first aspect is discussed below and is related to the design of the piping which does not utilize fatigue usage factors. The second aspect deals with the concern of environmental effect which is discussed in Section 18.3.3.4.

For piping systems designed in accordance with ANSI B31.1, explicit analyses of cumulative fatigue usage are not required. Instead, cyclic loading is considered in a simplified manner in the design process. Allowable thermal stresses are reduced using a stress range reduction factor based on the number of anticipated thermal cycles expected during the component operating lifetime. Stress range reduction factors are specified in ANSI B31.1, Table 102.3.2(c). No reduction of allowable stresses is required for piping that is subjected to less than 7,000 equivalent full temperature cycles during plant service. The stress range reduction factor for higher numbers of fatigue cycles is less than 1.0 and is gradually reduced until a range of 100,000 cycles is reached. For piping anticipated to experience 100,000 or more equivalent full temperature cycles, the allowable stress range would be reduced to half of the maximum nominal allowable stress. The evaluations for required stress reduction factors are implicit fatigue analyses because they are based on the number of fatigue cycles anticipated for the life of the component, therefore they are TLAAs requiring evaluation for the subsequent period of extended operation.

ANSI B31.1 systems are generally subject to continuous steady state operation and operating temperatures vary only during plant heatup and cooldown, during plant transients, or during periodic testing. Portions of piping systems designed in accordance with ANSI B31.1 requirements that are attached to the reactor coolant system or other power cycle related systems are subject to a similar number or fewer cycles as the reactor coolant system. These include generator nitrogen, main steam, blowdown, feedwater, condensate, chemical and volume control, extraction steam, residual heat removal, and safety injection. Portions of some of these systems are normally isolated from the normal power cycle and would experience fewer cycles than those portions at the system boundary. For example, residual heat removal system cycles twice per shutdown/start up and therefore has fewer cycles than the residual heat removal system piping at the boundary with the reactor coolant system. The expected transients for these systems are much less than 7,000 cycles for 80 years of plant operation.

Portions of the following systems, designed in accordance with ANSI B31.1 requirements, are affected by thermal and pressure transients that are different than the reactor coolant and power cycles discussed above: auxiliary steam, boron recovery, containment vacuum and leakage monitoring, emergency diesel generator (engine exhaust), alternate AC diesel generator (engine exhaust), security diesel (engine exhaust), fire protection (fire pump diesel exhaust), heating steam, recirculation spray, sampling system, and steam drains. The basis for cycle projections have been reviewed for these systems to validate that the projected cycles for 80 years of operation remains less than 7,000 cycles. The number of cycles for each of these piping systems is projected to be less than 7,000 for 80 years of plant operation.

The ANSI B31.1 allowable stress analyses remain valid for the subsequent period of extended operation in accordance with 10 CFR 54.21 (c)(1)(i).

18.3.3.4 **Environmental- Assisted Fatigue**

As outlined in Section X.M1 of NUREG-2191 and Section 4.3 of NUREG-2192, the effects of the reactor water environment on cumulative usage factor (CUF) must be examined for a set of sample critical components for the plant. This sample set includes the locations identified in NUREG/CR-6260 and additional plant-specific component locations in the reactor coolant pressure boundary if they may be more limiting than those considered in NUREG/CR-6260.

Additional limiting locations were identified through an environmental fatigue screening evaluation. The environmentally-assisted fatigue (EAF) screening evaluation reviewed the CLB fatigue evaluations for all ASME Code, Section III reactor coolant pressure boundary components and ANSI B31.1 piping, including the NUREG/CR-6260 locations, to determine the lead indicator (also referred to as sentinel) locations for EAF.

The sentinel locations are listed below:

- CRDM head adapters (J-groove weld) - replacement RV closure heads
- RV outlet nozzles and support pads (NUREG/CR-6260 location)
- RV inlet nozzles (NUREG/CR-6260 location)
- RV bottom head-to-shell juncture (NUREG/CR-6260 location)
- CRDM upper latch housing and rod travel housing – upper latch housing
- CRDM upper joint – Canopy
- Pressurizer spray nozzle
- Pressurizer spray nozzle – Piping
- Pressurizer
- Upper shell
- Pressurizer Safety and Relief nozzles
- Pressurizer lower head at heater penetration
- Hot leg surge nozzle - bounding location (NUREG/CR-6260 location)
- Pressurizer surge piping
- Pressurizer surge nozzle to safe end weld
- Charging nozzle (NUREG/CR-6260 location)
- Safety injection nozzle (NUREG/CR-6260 location)
- Residual heat removal piping (NUREG/CR-6260 location)
- Steam generator tubes
- Accumulator piping NUREG/CR-6260 location)

For sentinel ASME Code, Section III components with environmentally-assisted fatigue usage (CUF_{en}) greater than 1.0, ASME Code, Section III, NB-3200 calculations were prepared to remove conservatisms used in the analysis of record, thereby reducing the CUF_{en} to less than 1.0. The effects of fatigue on the intended functions of these ASME Code, Section III components will be managed by the Fatigue Monitoring program (Section 18.2.1) through the use of cycle counting.

For sentinel piping locations, Dominion has elected to manage the effects of fatigue by application of the ASME Section XI Inservice Inspections, Subsections IWB, IWC, AND IWD program (Section 18.1.1) during the subsequent period of extended operation based on results of flaw tolerance evaluation conducted per the guidance of ASME Code, Section XI, Non-mandatory Appendix L. NUREG-2192 permits inspections as a management method for fatigue as long as a flaw tolerance evaluation is performed to determine the acceptable time between inspections. The ASME Code, Section XI, Appendix L crack growth evaluation is used in conjunction with calculated allowable flaw sizes to determine the required inspection interval for a postulated flaw in the piping at the bounding location. For a postulated initial flaw, crack growth is simulated until the flaw has reached the allowable flaw depth or the end of the subsequent period of extended operation, whichever comes first.

In-service inspections of the Appendix L piping will be performed at a 10-year inspection frequency. Each weld in the inspection population will be ultrasonically inspected once prior to turning on the clock for the re-inspection schedule associated with the Appendix L evaluations. Going forward after the first ultrasonic inspection, one weld in each of the six groups will be ultrasonically inspected every ten years.

Fatigue of the steam generator tubes will be managed by the Steam Generators program (Section 18.1.10).

The effects of fatigue on the intended functions of ASME Code, Section III components and piping that contact reactor coolant will be managed by the Fatigue Monitoring program (Section 18.2.1), the ASME Section XI Inservice Inspections, Subsections IWB, IWC, AND IWD program (Section 18.1.1) and the Steam Generators program (Section 18.1.10) through the subsequent period of extended operation in accordance with 10 CFR 54.21(c)(1)(iii).

18.3.3.5 **Reactor Vessel Internals Fatigue Analyses**

The RV internals were designed before ASME Code, Section III, Division 1, Subsection NG was established. Therefore, no CUF values were calculated as part of the original RV internals design. However, as part of engineering evaluations to support Units 1 and 2 operations at MUR power uprate conditions, updated structural evaluations were performed for the upper and lower core plates to demonstrate that they would maintain their structural integrity at proposed power uprate conditions. The lower and upper core plates are not part of the reactor coolant system pressure boundary. As part of the structural evaluations, fatigue analyses of the upper and lower core plates were performed to the 1989 edition of ASME Code, Section III, Division 1, Subsection NG. Fatigue analyses that consider transient cycles that occur over the life of the plant constitute TLAAs. The analysis of record fatigue CUF results are less than 1.0.

The 40-year design cycles (CLB cycles) were postulated to bound 80 years of plant operations. Therefore, the reactor vessel internals fatigue analyses remain valid for the subsequent period of extended operation in accordance with 10 CFR 54.21(c)(1)(i).

18.3.4 Environmental Qualification of Electric Equipment

Thermal, radiation, and cyclical aging analyses of plant electrical and I&C components, developed to meet 10 CFR 50.49 requirements, have been identified as time-limited aging analyses (TLAAs). The NRC nuclear station environmental qualification (EQ) requirements in 10 CFR 50.49 require that an EQ program be established to demonstrate that certain electrical equipment located in harsh plant environments is qualified to perform applicable safety functions in those harsh environments after the effects of in-service aging. Harsh environments are defined as those areas of the plant that could be subject to the harsh environmental effects of a loss-of-coolant accident (LOCA), high energy line break (HELB) or post-LOCA radiation. 10 CFR 50.49 requires that the effects of significant aging mechanisms be addressed as part of environmental qualification.

The Environmental Qualification of Electric Equipment program (18.2.3) will manage the effects of aging for EQ equipment through the subsequent period of extended operation in accordance with 10 CFR 50.49(c)(1)(iii). The program meets the requirements of 10 CFR 50.49 for the applicable electrical equipment important to safety. Reanalysis of an aging evaluation to extend the qualifications of equipment is performed on a routine basis as part of the EQ program. Important attributes for the reanalysis of an aging evaluation include analytical methods, data collection and reduction methods, underlying assumptions, acceptance criteria, ongoing qualification, and corrective actions if acceptance criteria are not met.

If the qualification cannot be extended by reanalysis, the equipment must be refurbished, replaced, or requalified prior to exceeding the period for which the current qualification remains valid. A reanalysis is to be performed in a timely manner such that sufficient time is available to refurbish, replace, or requalify the equipment if the reanalysis is unsuccessful.

The EQ program was evaluated against the DOR Guidelines and the basis for equipment qualification is Inspection and Enforcement Bulletin (IEB) 79-01B (IEB 79-01B), "Environmental Qualification of Class 1E Equipment," and IEEE Standard 323-1974, "IEEE Standard for Qualifying Class 1E Equipment for Nuclear Power Generating Stations," as codified by 10 CFR 50.49.

The Environmental Qualification of Electrical Equipment program ensures that the aging effects will be managed and that EQ equipment will continue to perform its intended function for the subsequent period of extended operation. Aging effects addressed by the EQ program will therefore be managed for the subsequent period of extended operation and are dispositioned in accordance with 10 CFR 54.21(c)(1)(iii).

Accessible passive EQ electrical equipment within the scope of subsequent license renewal will be inspected at least once every ten years to identify EQ electrical equipment subjected to an adverse localized environment with the first inspection performed prior to the subsequent period of extended operation.

18.3.5 Concrete Containment Tendon Prestress

Not applicable

18.3.6 Containment Liner Plate, Metal Containments, and Penetrations Fatigue Analysis

18.3.6.1 Containment Liner Plate

The accumulated fatigue effects of all applicable liner loading conditions are evaluated based on cycles of operating pressure variations, cycles of operating temperature variations, and design earthquake cycles. The anticipated operating pressure variations were extrapolated for 80 years of operation and determined to be acceptable. The number of design cycles was conservatively increased to account for the subsequent period of extended operation. Therefore, the Containment liner is adequate for an 80-year operating period as currently designed. The analyses associated with the Containment liner plate have been revised and projected to remain valid for the period of extended operation, in accordance with 10 CFR 54.21(c)(1)(ii).

18.3.6.2 Metal Containments

Not applicable

18.3.6.3 Containment Penetrations Fatigue Analysis

There are no TLAAs for Containment penetrations. The penetrations are designed for a one-time load, which is equal to the collapse loads of the pipe. The stresses due to the normal operating conditions are within the endurance limit. Therefore, the penetrations will not fail for a large number of operating cycles. No time-limited aging analysis has been performed for the penetrations.

18.3.7 Other Plant-Specific Time-Limited Aging Analyses

18.3.7.1 Crane Load Cycle Limits

The design standard number of full-capacity lifts far exceeds the number expected of each machine for a 80-year life, even with a significant number of unforeseen lifts. The lifting machine designs therefore remain valid for the period of extended operation. These TLAAs are dispositioned in accordance with 10 CFR 54.21(c)(1)(i).

18.3.7.2 Reactor Coolant Pump Flywheel Fatigue Crack Growth Analysis

Fatigue crack initiation and growth in reactor coolant pump (RCP) flywheels was evaluated for the subsequent period of extended operation and documented in PWROG-17011-NP, “Update for Subsequent License Renewal: WCAP-14535A, “Topical Report on Reactor Coolant Pump

Flywheel Inspection Elimination," and WCAP-15666-A, "Extension of Reactor Coolant Pump Motor Flywheel Examination," Revision 0," which confirms that the analysis of WCAP-14535A and WCAP-15666-A remains appropriate. The fatigue crack growth calculations assumed 6000 cycles of RCP start/stop for 80 years of plant life which bounds the projected cycle count of 1158. The RCP fatigue analysis remains valid for the subsequent period of extended operation and the TLAA is dispositioned in accordance with 10 CFR 54.21(c)(1)(i).

18.3.7.3 **Leak-Before-Break**

10 CFR 50 General Design Criterion 4 allows use of leak-before-break technology for excluding from the design basis the dynamic effects of postulated ruptures in primary coolant loop piping in PWRs. WCAP-15550-NP, Revision 2, "Technical Justification for Eliminating Large Primary Loop Pipe Rupture as the Structural Design Basis for Surry Units 1 and 2 Nuclear Power Plants for the Subsequent License Renewal Program (80 Years) Leak-Before-Break Evaluation," demonstrated compliance with leak-before-break (LBB) technology for the reactor coolant system piping for an 80-year plant life based on a plant specific analysis that showed all LBB conditions and margins are satisfied. It is therefore concluded that dynamic effects of reactor coolant system primary loop pipe breaks need not be considered in the structural design basis. The LBB analysis has been projected to the end of the subsequent period of extended operation and the TLAA is dispositioned in accordance with 10 CFR 54.21(c)(1)(ii).

The Leak-Before-Break (eLBB) methodology currently applied to the Reactor Coolant System main piping was extended to the Reactor Coolant System branch piping listed below for the 80 year extended period of plant operations. Details related to the RCS branch line Leak-Before-Break analysis and associated references are included in UFSAR Section 15.6.2.

1. Pressurizer Surge Line
2. Residual Heat Removal Line
3. Accumulator Line
4. Loop Bypass Line
5. Safety Injection Line

18.3.7.4 **Spent Fuel Pool Liner Fatigue Analysis**

A design calculation has been identified which documents that the spent fuel pool liner design meets general industry criteria. A revised calculation includes a fatigue analysis based on the number of thermal cycles corresponding to an 80-year plant operating term. The thermal stresses in the spent fuel pool liner due to conservatively assumed temperature gradients and thermal cycles during an 80-year plant operating term satisfy ASME Code fatigue criteria. Therefore, the revised calculations are projected through the subsequent period of extended operation, in accordance with 10 CFR 54.21(c)(1)(ii).

18.3.7.5 **Piping Subsurface Flaw Evaluations**

Piping subsurface flaws were detected during original plant construction. Flaw tolerance conclusions of the piping subsurface flaws evaluations have been projected to the end of the subsequent period of extended operation. The piping flaw TLAA is dispositioned in accordance with 10 CFR 54.21(c)(1)(ii).

18.3.7.6 **Reactor Coolant Pump Code Case N-481**

ASME Code Case N-481 allows the replacement of volumetric examinations of primary loop pump casings with fracture mechanics-based integrity evaluations supplemented by specific visual examinations. The fracture mechanics integrity assessment in PWROG-17033 -NP, "Update for Subsequent License Renewal: WCAP-13045, "Compliance to ASME Code Case N-481 of the Primary Loop Pump Casings of Westinghouse Type Nuclear Steam Supply Systems," Revision 0," which updated the analysis in WCAP-13045, demonstrated that the visual inspections, in lieu of volumetric inspections, for pump casings remain valid for an 80-year life and the TLAA is dispositioned in accordance with 10 CFR 54.21(c)(1)(i).

18.3.7.7 **Cracking Associated With Weld Deposited Cladding**

Reactor vessel underclad cracking involves cracks in base metal forgings immediately beneath austenitic stainless steel cladding which are created as a result of the weld-deposited cladding process. PWROG-17031-NP, "Update for Subsequent License Renewal: WCAP-15338-A, "A Review of Cracking Associated with Weld Deposited Cracking in Operating PWR Plants," Revision 0," updated the 60-year fatigue crack growth analysis in WCAP-15338-A and confirmed the analysis remains appropriate for 80 years of operation. The crack growth analysis has been projected to the end of the subsequent period of extended operation and the TLAA is dispositioned in accordance with 10 CFR 54.21(c)(1)(ii).

18.3.7.8 **Steam Generator Tube High Cycle Fatigue Evaluation**

WCAP-18379-P, "Surry Units 1 and 2 Steam Generator U-Bend Tube Vibration and Fatigue Assessment" evaluated the SG tubes that are unsupported by an AVB which is contrary to the design requirements, or tubes that are subject to significant flow peaking due to non-uniform insertion of the AVBs, to determine if they are subject to possible fatigue related failure during the planed 80 years of plant life.

The new fatigue analysis demonstrates that all unsupported tubes are acceptable without remediation through 80 years. This evaluation is projected through the subsequent period of extended operation and this TLAA is dispositioned in accordance with 10 CFR 54.21(c)(1)(ii).

18.3.7.9 **Steam Generator Tube Wear Evaluation**

WCAP-18341-P, "Resolution of Surry Power Station Units 1 & 2 Time-Limited Aging Analyses for Subsequent License Renewal," shows that for the increase the operating term from 60 years to 80 years, the calculated tube wear remains acceptable. The steam generator tube wear will be managed by the Steam Generators program (18.1.10) using the existing steam generator eddy current inspection consistent with NEI 97-06, “Steam Generator Program Guidelines”

The wear evaluation for operation under MUR power uprate conditions demonstrates wear of the steam generator tubes will be acceptable through 80 years of plant operation. The steam generator tube wear will be managed by the Steam Generators program (18.1.10) in accordance with 10 CFR 54.21(c)(iii).

18.4 TLAA SUPPORTING ACTIVITIES

18.4.1 Transient Cycle Counting

During normal, upset, and test conditions; reactor coolant system pressure boundary components are subjected to transient temperatures, pressures, and flows, resulting in cyclic changes in internal stresses in the equipment. The cyclic changes in internal stresses cause metal fatigue. Class 1 reactor coolant system components have been designed to withstand a number of design transients without experiencing fatigue failures during their operating life. The purpose of the Transient Cycle Counting is to record the number of normal, upset, and test events, and their sequence that the station experiences during operation. Design transients are counted to provide reasonable assurance that plant operation does not occur outside the design assumptions.

The Transient Cycle Counting activities are applicable to the reactor coolant system pressure boundary components for which the design analysis assumes a specific number of design transients. A summary of reactor coolant system design transients for which transient cycle counting is performed is listed below:

- Heatups/Cooldowns < 100°F/Hr.
- Step load increase/decrease of 10%
- Large load reduction of 50%
- Loss of load > 15%
- Loss of AC power
- Loss of flow in one loop
- Full power reactor trip
- Inadvertent auxiliary pressurizer spray

The aging effect that is managed by counting transient cycles is cracking due to metal fatigue. The Transient Cycle Counting activities monitor transient cycles that have been experienced by each unit and compare the actual number of cycles to a design assumption. Any concerns related to fatigue are mitigated, as long as the number and magnitude of transient cycles are less than the design assumptions. Approaching a design limit may indicate a situation that is adverse to quality, and would initiate the Corrective Action System. Subsequently, an engineering analysis will determine the design margin remaining, taking credit for the actual magnitude of transients and their sequence to confirm that the allowable factor has not been exceeded. If warranted, component repair or replacement would be initiated.

18.5 SUBSEQUENT LICENSE RENEWAL COMMITMENTS

Table 18-1

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
1	ASME Section XI Inservice Inspection, Subsections IWB, IWC, and IWD program	The ASME Section XI Inservice Inspection, Subsections IWB, IWC, and IWD program is an existing condition monitoring program that will be enhanced as follows: 1. Procedures will be revised to require inspections be performed for welds associated with sentinel locations assessed under ASME Code, Section XI, Appendix L for the following auxiliary lines: • Safety injection • Residual heat removal • Spray • Charging • Accumulator • Surge	Program enhancements for SLR will be implemented 6 months prior to the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1	2
2	Water Chemistry program	The Water Chemistry program is an existing preventive program that is credited.	Ongoing	SLRA, Appendix A, Table A4.0-1	2
3	Reactor Head Closure Stud Bolting program	The Reactor Head Closure Stud Bolting program is an existing condition monitoring program that will be enhanced as follows: 1. Procurement documents for reactor head closure studs will be revised to incorporate guidance from RG 1.65, Revision 1 and NUREG-2191, Section XI.M3, to add a limit for the maximum measured yield strength of 150 ksi and a limit for maximum tensile strength of 170 ksi. 2. Procedures will be revised to require the performance of a one-time visual inspection of the bottom plates in Unit 2 vessel flange closure stud holes #36 and #37 to confirm that no corrosion, cracking, or degradation is occurring.	Program enhancements for SLR will be implemented 6 months prior to the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1	
4	Boric Acid Corrosion program	The Boric Acid Corrosion program is an existing condition monitoring program that is credited.	Ongoing	SLRA, Appendix A, Table A4.0-1	2

7	PWR Vessel Internals program	The PWR Vessel Internals program is an existing condition monitoring program that will be enhanced as follows: 1. Procedures will be revised for each reload to summarize the average power density, the heat generation figure-of-merit, and the dimensional parameter for the distance between the active fuel and the upper core plate. 2. Procedures will be revised to require the visual inspection (EVT-1) of the control rod guide tube (CRGT) lower flange weld to require that the inspection include 100% of the outer CRGT lower flange weld surfaces and 0.25-inch of the adjacent base metal. 3. Procedures will be revised to require the visual inspection (VT-3) of the accessible surfaces for the control rod guide tube support pins and support pin nuts for Unit 1 only (plant-specific component). 4. Procedures will be revised to require the addition of a note indicating that a bolting inspection can be credited only if at least 75% of the total bolt population is examined. 5. Procedures will be revised to require visual inspection (VT-3) for 100% of the baffle-edge bolts that are accessible from the core side. 6. Procedures will be revised to require volumetric (UT) examinations for 100% of accessible baffle-former bolts (including corner bolts) at least every 10 years. MRP-2017-009 states that baseline volumetric (UT) examinations shall be performed no later than 30 EFPY for NSAL 16-1 Tier 2 plants, including the Surry units. The guidance further states that initial baseline UT exams performed prior to 1/1/2018 are acceptable. Examinations were performed in 2010 for Unit 1 and in 2011 for Unit 2. For the Surry units with the down-flow configuration that have <3% indications and no clustering, subsequent UT examinations are performed on a 10-year interval.	Program, accounting for the impacts of a gap analysis, will be implemented 6 months prior to the subsequent period of extended operation, or alternatively, a plant-specific program may be implemented 6 months prior to the subsequent period of extended operation. 7 cont'd		7. Procedures will be revised to address expansion criteria when degradation occurs for clusters of baffle-former bolts. MRP 2018-002 identifies expansion criteria as a Needed requirement (per NEI 03-08) to include one-time visual (VT-3) examination of barrel-former bolts if large clusters of baffle-former bolts are found during the initial volumetric (UT) examination. Confirmation that one or more large clusters of baffle-former bolts with unacceptable indications are detected by the UT inspection of the baffle-former bolts shall require a visual (VT-3) inspection of the accessible barrel-former bolts adjacent to the large cluster of baffle-former bolt indications within three refueling cycles. A large cluster is defined (MRP 2018-002, Item 3.b) as any group of adjacent baffle-former bolts at least 3 rows high by at least 10 columns wide, or at least 4 rows high by at least 6 columns wide where 80% or greater of the baffle-former bolts have unacceptable UT indications or are visibly degraded.			

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
7 (cont'd)		The barrel-former bolts adjacent to the cluster include: • Barrel-former bolts in the same area as the cluster of baffle-former bolts with indications if that area is projected radially onto the core barrel. • Barrel-former bolts on the two rows above and the two rows below the projected area. • Barrel-former bolts on each of the two columns of bolts that are circumferentially adjacent to the projected area. Confirmation that more than 5% of the lower support column bolts actually examined contain unacceptable UT indications shall require UT inspection of the accessible barrel-former bolts within three refueling cycles of identifying lower support column bolts with unacceptable UT indications. 8. Procedures will be revised to require visual examinations (EVT-1) for 100% of one side (ID or OD) of the circumference for the core barrel upper flange weld, and 3/4" of adjacent base metal (minimum 50% examination coverage) (Primary component) 9. Procedures will be revised to require visual examinations (EVT-1) for 100% of the OD surface of the core barrel lower flange weld and 3/4" adjacent base metal (minimum 75% examination coverage unless access limitations prevent examination of more than 50% of the weld). (Expansion component)

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
7 (cont'd)		10. Procedures will be revised to perform inspections of control rod guide tube (CRGT) thermal sleeves as indicated in MRP 2018-027. MRP 2018-027 refers to the Westinghouse NSAL 18-1 recommendation that, based on operating experience (OE) from international PWR plants related to wear of reactor vessel closure head control rod drive mechanism (CRDM) thermal sleeve flanges resulting in control rod stoppage during plant restart operations, a visual inspection should be performed during the next refueling outage after issuance of the NSAL, and during each subsequent refueling outage, for the tops of the CRGTs to determine whether any thermal sleeves have lowered significantly or are in a failed state. For the Surry plants, the guidance is to look for shiny marks on the top edge of the upper guide tube enclosure. Also, during the next under-head inspection, the guidance is to perform a visual inspection of the bottom of the thermal sleeve guide funnels to look for any shiny surfaces on the bottom surface of the guide funnel that would indicate that the thermal sleeve guide funnels have dropped to a point where they are in contact with the top of the guide tube. A visual inspection of thermal sleeve guide funnel elevations is recommended to identify whether any sleeves are noticeably lower than others (Primary component). 11. Procedures will be revised to require visual examinations (VT-3) for the following: a. Top and bottom edges of baffle plates to identify misalignment (Primary component). b. General condition of the baffle plates to identify warping or void swelling (Primary component). c. Surfaces of the upper internals fuel alignment pins to identify wear of the malcomized surface (Existing Programs component). d. Surfaces of the lower internals fuel alignment pins to identify wear of the malcomized surface (Existing Programs component). e. Clevis insert bolts and clevis insert dowels (Primary component).			

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
7 (cont'd)		12. Procedures will be revised for contingency tasks to require inspection of the following expansion components if necessitated by relevant indications being found for associated primary components: a. Remaining control rod guide tube lower flange welds not inspected as Primary component (EVT-1) b. Control rod guide tube (CRGT) continuous section sheaths and C-tubes in accordance with the requirements of WCAP-17451-P, Revision 2. c. Bottom-mounted instrumentation column bodies (100% of BMI column bodies for which difficulty is detected during flux thimble insertion / withdrawal; VT-3) d. Lower support column bodies (25% of column bodies as visible from above the core plate; VT-3) e. Barrel-former bolts (100% of accessible bolts, minimum of 75% of the total population; UT) f. Lower support column bolts (100% of accessible bolts, minimum of 75% of the total population; UT) 13. Procedures will be revised to require that the inspections for the radial support keys and clevis inserts are to include the Stellite wear surfaces (Primary component, MRP 2018-022). 14. Procedures will be revised to require visual inspections (VT-3) of the guide cards in at least 37 of the 48 control rod guide tubes, and will include associated acceptance criteria. Guidance from WCAP-17451-P, "Reactor Internals Guide Tube Wear – Westinghouse Domestic Fleet Operational Projections," and MRP 2018-07, "Transmittal of NEI 03-08 Needed Guidance to Address Accelerated Guide Card Wear Operating Experience (OE) Discussed in NSAL-17-1," will be included for the inspection of control rod guide cards.			

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
7 (cont'd)		15. Procedures will be revised to require visual examinations (EVT-1), and will include associated acceptance criteria, for 100% of the accessible weld length of the OD of the LGW and 3/4" of adjacent base metal (minimum 50% examination coverage). (Primary component) 16. Procedures will be revised for contingency tasks to inspect the following expansion components if necessitated by relevant indications being found for associated primary components, and will include associated acceptance criteria: a. Core barrel upper, middle, and lower axial welds (100% of weld length and 3/4" of adjacent base metal - minimum 75% examination coverage unless access limitations prevent examination of more than 50% of the weld; EVT-1) • A one-time enhanced visual (EVT-1) examination of the core barrel middle axial weld (MAW) and lower axial weld (LAW) will be performed during the sixth inservice inspection interval (i.e., a "50-year inspection") no later than six months prior to the subsequent period of extended operation. The examination will include coverage for 100% of the accessible weld lengths from the core barrel OD and 3/4" of base metal on each side the weld AND a vertical zone on each side of the inaccessible portion of the barrel containing the known location of the axial weld. Each vertical zone shall be a minimum of 3/4" wide and cover the full distance parallel to the inaccessible height of the weld. b. Core barrel upper girth weld (100% of weld length and 3/4" of adjacent base metal –minimum 75% examination coverage unless access limitations prevent examination of more than 50% of the weld; EVT-1) c. Lower support forging (25% of bottom (non-core side) surface; VT-3) d. Upper core plate (25% of core-side surfaces; VT-3) 17. A procedure for visual examinations will be revised to identify the examiner qualifications which are applicable for EVT-1 examinations.

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
8	Flow-Accelerated Corrosion program	The Flow-Accelerated Corrosion program is an existing condition monitoring program that will be enhanced as follows: 1. An engineering evaluation will be performed for systems that have been excluded from the FAC program due to no flow or infrequently used lines with a total operating and testing time that is less than 2% of the plant operating time. The purpose of the engineering evaluation is to confirm the scope of components that will qualify for the exclusion being extended into the subsequent period of extended operation. The engineering evaluation and modeling changes for the FAC program will be completed prior to entering the subsequent period of extended operation. 2. A re-evaluation of the erosion susceptibility determination that identified plant systems in the scope of subsequent license renewal that were previously excluded from monitoring will be performed to re-affirm that the appropriate basis for exclusion either is in-service operational and testing time less than 100 hours per year, or is a technical evaluation specifically developed to exclude a system. 3. A re-evaluation will be performed to determine whether plant conditions (e.g., valve throttling) have changed such that susceptibility to erosion has increased for plant systems within the scope of subsequent license renewal. 4. Procedure will be revised to confirm that inspection scope expansions include the items noted below and to confirm that independent reviews of inspection scope expansions are independently reviewed by a qualified FAC engineer. • Any component within two pipe diameters downstream of the component displaying significant wear, or within two pipe diameters upstream if that component is an expander or expanding elbow. • The two most susceptible components from the CHECWORKS relative wear rate ranking in the same train containing the piping component displaying significant wear	Program enhancements for SLR will be implemented 6 months prior to the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1 Supplement to SLRA: Change Notice 2 Response to RAIs - Set 2 Response to RAIs - Set 3 & 4 Correction to Response to RAIs - Set 3 & 4	2,4, 7,8,9

Table 18-1 (CONTINUED)

8 (cont'd)		• Corresponding components from other trains. • Inspections of additional components until no additional components with significant wear are detected.			
9	Bolting Integrity program	The Bolting Integrity program is an existing condition monitoring program that will be enhanced as follows: 1. Procedures will be revised to provide inspection guidance related to lighting, distance, offset, surface coverage, presence of protective coatings, and cleaning processes. The procedure will specify adequate lighting be verified at the inspection location to detect degradation. Lighting may be permanently installed, temporary, or portable (e.g., flashlight), as appropriate. For accessible surface inspections, inspecting from a distance of two feet to four feet (or less) will be appropriate. For viewing angles which may prevent adequate inspection, a viewing aid such as an inspection mirror or boroscope should be used. 2. Procedures will be revised for inspections of pressure-retaining closure bolting in locations that preclude detection of joint leakage, such as in submerged environments or where the piping system contains air for which leakage is difficult to detect. The inspections will be performed to detect loss of material. A requirement will be included to inspect bolt heads when made accessible, and bolt threads if joints are disassembled. At a minimum, in each 10-year interval during the subsequent period of extended operation, inspections shall be completed for a representative sample of at least 20% of the population, up to a maximum of nineteen, for each material/environment combination.	Program enhancements for SLR will be implemented 6 months prior to the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1	2

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
9 (cont'd)		3. A new procedure will be developed to provide guidance for a situation in which an acceptance criterion for allowable degradation is exceeded, and the aging effect causing the degradation for the material/environment combination is not corrected by repair or replacement, thus requiring that additional inspections be performed. The number of additional inspections will be determined in accordance with the Corrective Action Program; however no fewer than five additional (or 20%, whichever is less) inspections of different components having the same material/environment/aging effect combination are required for each inspection that did not meet the acceptance criterion. For a two-unit site, the additional inspections include inspections at the same unit, and at the opposite unit, for components having the same material, environment, and aging effect combination. The additional inspections are to be completed within the same interval (e.g., refueling outage or 10-year inspection interval). If any projected inspection results will not meet acceptance criteria prior to the next scheduled inspection, sampling frequencies are adjusted as determined by the Corrective Action Program.			
10	Steam Generators program	The Steam Generators program is an existing condition monitoring program that is credited.	Ongoing	SLRA, Appendix A, Table A4.0-1	2

SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
11	Open-Cycle Cooling Water program	The Open-Cycle Cooling Water program is an existing preventive, mitigative, condition monitoring, and performance monitoring program that will be enhanced as follows: 1. Selected fiberglass reinforced plastic (FRP) piping in the service water system will be replaced with a more degradation resistant material such as copper-nickel (Cu-Ni) prior to entering the subsequent period of extended operation. FRP piping associated with the Units 1 and 2 charging pump cooling water subsystems, service water rotating strainers, and the control room chillers may be replaced as part of a time-phased program. 2. Modifications necessary to provide new chemical injection site upstream of the service water rotating strainers will be completed prior to entering the subsequent period of extended operation. 3. The internal lining of 30 inch and larger service water inlet piping with carbon fiber reinforced polymer, with the exception of the recirculation spray heat exchanger piping downstream of the inlet motor-operated valves, will be completed prior to entering the subsequent period of extended operation. 4. Procedures will be revised to provide additional guidance for identifying and evaluating applicable concrete aging effects such as loss of material due to delamination, exfoliation, spalling, popout, scaling, or cavitation; and cracking due to chemical reaction, or corrosion of reinforcement. 5. Procedures will be revised to provide guidance for internal inspection of carbon fiber reinforced polymer piping for aging effects such as voids, blistering, bubbles, cracking, crazing and delamination. 6. Procedures will be revised to require personnel who perform inspections and evaluation of concrete components to be qualified consistent with the qualifications identified in the Structures Monitoring program (B2.1.34) that are consistent with the requirements of ACI 349.3R.	Program enhancements for SLR will be implemented 6 months prior to the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1 Supplement to SLRA: Change Notice 1 Response to RAIs - Set 1 Response to RAIs - Set 2 Response to RAIs - Set 3 & 4 Correction to Response to RAIs - Set 3 & 4 First Annual Amendment and Supplement to SLRA: Change Notice 4 Supplement to SLRA: Change Notice 5	2,3,6, 7,8,9 10, 11

Table 18-1 (CONTINUED)

11 (cont'd)		7. Procedures will be revised to require personnel who perform visual inspections and evaluation of carbon fiber reinforced polymer piping to be VT-1 qualified consistent with IWA-2300 of ASME Section XI and Mandatory Appendix II of ASME Code Case N-871. Examination procedures and personnel who perform acoustic examinations of CFRP lined piping will be qualified consistent with mandatory Appendix VI and section 5400 of ASME Code Case N-871. 8. Procedures will be revised to require installed CFRP linings be 100% visually examined in accordance with ASME Code Case N-871 section 5213 during an inspection period between three and six years following return of the repaired area to service; and a minimum of once per 10 year inservice inspection interval thereafter in the same inspection period of each succeeding inspection interval. 9. Procedures will be revised to require accessible surfaces of the CFRP linings at each terminal end to be acoustically impact tap examined in accordance with Mandatory Appendix V, "Inservice Examination", Section V-2500, ASME Code Case N-871 section 5250(a), section 5250(c), and Section 5350. The acoustic examination of terminal ends will be capable of detecting and sizing delaminations and voids in any composite or bonding layer with dimensions equal to or less than those permitted by Section 4390(b)(3). The acoustic impact tap examination procedure sections will also be enhanced to add Section 5111(d), that provides consideration of the impact of in-situ ambient noise levels on application of the procedure and qualification of procedures and personnel. The qualification testing will be conducted in an area where the ambient noise level is equal to or higher than the noise level where the in-situ testing will be performed. The expansion rings need not be removed for this examination provided examinations of adjacent surfaces do not indicate the presence of new unacceptable indications that could extend beneath the rings.			

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
11 (cont'd)		10. Procedures will be revised to periodically inspect for evidence of concrete aging in accessible internal surfaces of the concrete circulating water lines. One hundred percent of the accessible circulating water line internal surfaces will be inspected in a ten year period. 11. Procedures will be revised to require trending of charging pump lube oil cooler and emergency service water pump engine heat exchanger inspection results by Engineering. 12. Procedures will be revised to require trending of wall thickness measurements. The frequency and number of wall thickness measurements will be based on trending results. 13. Procedures will be revised to require all areas previously documented in accordance with ASME Code Case N-871 Section V-1100(b) shall be re-examined, measured, and compared with the previous inspection records. Any indications of flaw growth will be required to be repaired consistent with ASME Code Case N-871. Documentation of the repair, location and dimensions will be required. Any new flawed areas shall be evaluated consistent with ASME Code Case N-871. 14. Procedures will be revised to include verification that predicted wall thicknesses at the next scheduled inspection will be greater than the minimum wall thicknesses. 15. Procedures will be revised to include criteria for the extent and rate of on-going degradation that will prompt additional corrective actions. 16. Procedures will be revised to identify acceptance criteria for visual inspection of concrete piping and components such as the absence of cracking and loss of material, provided that minor cracking and loss of material in concrete may be acceptable where there is no evidence of leakage, exposed rebar or reinforcing "hoop" bands or rust staining from such reinforcing elements.			

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
11 (cont.'d)		17. Procedures will be revised to include the following CFRP defect inspection acceptance criteria for air voids, bubbles, blisters, delaminations and other defects (such as cracking and crazing): <u>Air Voids</u> For embedded air voids of area less than or equal to 25 square inches that have been visually detected in layers beneath the topcoat, they shall be repaired in accordance with ASME Code Case N-871 section 4390 (b)(1) and (b)(2) unless otherwise specified in the design documents. All other defects and all voids larger greater than 25 square inches shall be rejected, and a repair designed to maintain water tightness of the system. <u>Bubbles, blisters or other defects</u> If bubbles or blisters with major dimension exceeding one inch are detected anywhere within the protective epoxy topcoat, they shall be removed and repaired in accordance with ASME Code Case N-871 Section 4380(d). <u>Delaminations or Voids</u> Unless permitted by design documents, acceptance criteria for acoustic tap examination of terminal ends shall be consistent with ASME Code Case N-871 section 5350 (a) and (b)			

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
11 (cont'd.)		18. Procedures will be revised to include the following defect repair criteria as part of the corrective actions.: For air void defects Repairs shall be consistent with ASME Code Case N-871 section 4390 (b)(3) and (b)(4) For bubbles, blisters or other surface defects Repairs shall be consistent with ASME Code Case N-871 section 4390 (d) For all other defects and all voids larger than 25 square inches A repair shall be designed to maintain water-tightness of the system consistent with ASME Code Case N-871 section 4390 (d) A final visual inspection shall be performed to verify the CFRP system has achieved the percentage of cure corresponding to achievement of required mechanical properties before placing the repaired piping back in service. In no case shall the system be placed in service before achieving 85% cure. 19. Procedures will be revised to ensure that for ongoing degradation mechanisms (e.g., MIC), the frequency and extent of wall thickness inspections at susceptible locations are increased commensurate with the significance of the degradation. 20. Procedures will be revised to ensure that when measured parameters do not meet the acceptance criteria, additional inspections are performed, when the cause of the aging effect is not corrected by repair or replacement for components with the same material and environment combination. The number of inspections will be determined by the Corrective Action Program, but no fewer than five additional inspections will be performed for each inspection that did not meet the acceptance criteria, or 20% of the applicable material, environment, and aging effect combination inspected, whichever is less. The additional inspections will include inspections at both Unit 1 and Unit 2 with the same material, environment, and aging effect combination.	Program enhancements for SLR will be implemented 6 months prior to the subsequent period of extended operation.		

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
12	Closed Treated Water Systems program	The Closed Treated Water Systems program is an existing condition monitoring and mitigation program that will be enhanced as follows: 1. Procedures will be revised to provide non-ASME Code inspection guidance related to lighting, distance, offset, surface coverage, presence of protective coatings, and cleaning processes. The procedure will specify adequate lighting be verified at the inspection location to detect degradation. Lighting may be permanently installed, temporary, or portable (e.g., flashlight), as appropriate. For accessible surface inspections, inspecting from a distance of two feet or less will be appropriate. For viewing angles which may prevent adequate inspection, a viewing aid such as an inspection mirror or boroscope should be used. For component internal inspections, accessible surfaces will be inspected, subject to a minimum 20% surface area examination coverage. If inspecting piping internal surfaces, a minimum of one linear foot will be inspected, if accessible. Cleaning will be performed as necessary to allow for a meaningful examination. The surface to be examined should be clean and free of corrosion products, slag, dirt, grease, and scale, loose or cracked paint or any foreign material that interferes with examination results. If protective coatings are present, the condition of the coating will be documented. 2. A new procedure will be developed to specify that in each 10-year period during the subsequent period of extended operation, the minimum number of inspections is completed for the various sample populations (each material, water treatment program, and aging effect combination). If opportunistic inspections will not fulfill the minimum number of inspections by the end of each 10-year period, the program owner will initiate work orders as necessary to request additional inspections. A representative sample of 20% of the population (defined as components having the same material, water treatment program, and aging effect combination) or a maximum of nineteen components per population at each unit will be inspected. The new procedure will specify that the inspections focus on the bounding or lead components most susceptible to aging due to time in service, and severity of operating conditions.	Program enhancements for SLR will be implemented 6 months prior to the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1	2

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
12 (cont'd.)		3. A new procedure will be developed to specify that, where practical, the rate of any degradation is evaluated and projected until the end of the subsequent period of extended operation or the next scheduled inspection, whichever is shorter. The sampling bases (e.g., selection, size, frequency) will be adjusted as necessary based on the projection. 4. A new procedure will be developed to specify that additional inspections will be performed if any inspections do not meet the acceptance criteria, unless the cause of the aging effect for each applicable material and environment is corrected by repair or replacement. There will be no fewer than five additional inspections for each inspection that did not meet acceptance criteria, or 20% of each applicable material, environment, and aging effect combination inspected, whichever is less. If any subsequent inspections do not meet acceptance criteria, an extent of condition and extent of cause analysis will be conducted to determine the further extent of inspections required. Additional samples will be inspected for any recurring degradation to ensure corrective actions appropriately address the associated causes. The additional inspections will include inspections of components with the same material, environment, and aging effect combination at both Unit 1 and Unit 2. The additional inspections will be completed within the interval (e.g., refueling outage interval, 10-year inspection interval) in which the original inspection was conducted.			
13	Inspection of Overhead Heavy Load and Light Load (Related to Refueling) Handling Systems program	The Inspection of Overhead Heavy Load and Light Load (Related to Refueling) Handling Systems program is an existing condition monitoring program that will be enhanced as follows: 1. Procedures will be revised to specify visual inspections for the effects of general corrosion, deformation, cracking, and wear on the rails in the rail system. 2. Procedures will be revised to specify visual inspections for general corrosion, deformation, cracking, wear and loose or missing fasteners and other conditions indicative of loss of bolting preload for the new fuel transfer elevator.	Program enhancements for SLR will be implemented 6 months prior to the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1	2

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
14	Compressed Air Monitoring program	The Compressed Air Monitoring program is an existing condition monitoring program that will be enhanced as follows: 1. Procedures will be revised to perform opportunistic visual inspections of internal surfaces of compressed air system components downstream of the dryers to verify the effectiveness of the compressed air system control of moisture (dewpoint) and particulate. Visual inspection results will be compared to previous results to ascertain if adverse long-term trends exist. Deficiencies will be documented in the Corrective Action Program and evaluations performed for test or inspection results that do not satisfy established criteria as defined in the applicable procedures.	Program enhancements for SLR will be implemented 6 months prior to the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1	2

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
15	Fire Protection program	The Fire Protection program is an existing condition and performance monitoring program that will be enhanced as follows: 1. Procedures will be enhanced to require fire damper assemblies (rather than fire damper housings) to be visually inspected for loss of material and determined to be acceptable if there are no signs of degradation that could result in loss of fire protection capability due to loss of material. 2. Carbon dioxide and halon systems air flow testing procedures will be enhanced to trend air flow test data. In addition, procedures will be enhanced to specify that inspection results for the halon and CO2 systems meet the acceptance criteria if there are no indications of excessive loss of material. 3. Procedures will be revised to require an assessment for additional inspections to be conducted if one of the inspections does not meet acceptance criteria due to current or projected degradation. For sampling-based inspections, results are evaluated against acceptance criteria to confirm that the sampling bases (e.g., selection, size, frequency) will maintain the components' intended functions throughout the subsequent period of extended operation based on the projected rate and extent of degradation. If degradation is detected within the inspection sample of penetration seals, the scope of the inspection is expanded to include additional seals in accordance with the plant's corrective action program. Additional inspections would be 20% of each applicable inspection sample; however, additional inspections would not exceed five. If any projected inspection results will not meet acceptance criteria prior to the next scheduled inspection, inspection frequencies are adjusted as determined by the site's corrective action program.	Program enhancements for SLR will be implemented 6 months prior to the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1 Response to RAIs - Set 2	2,7

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
16	Fire Water System program	The Fire Water System program is an existing condition monitoring program that will be enhanced as follows: 1. Prior to 50 years in service, sprinkler heads will be submitted for field-service testing by a recognized testing laboratory consistent with NFPA 25, 2011 Edition, Section 5.3.1. Additional representative samples will be field-service tested every 10 years thereafter to ensure signs of aging are detected in a timely manner. For wet pipe sprinkler systems, a one-time test of sprinklers that have been exposed to water including the sample size, sample selection criteria, and minimum time in service of tested sprinklers will be performed. At each unit, a sample of 3% or a maximum of ten sprinklers with no more than four sprinklers per structure shall be tested. Testing is based on a minimum time in service of fifty years and severity of operating conditions for each population. 2. Procedures will be revised to specify: a. Standpipe and system flow tests for hose stations at the hydraulically most limiting locations for each zone of the system on a five year interval to demonstrate the capability to provide the design pressure at required flow. b. Acceptance criteria for wet pipe main drain tests. Flowing pressures from test to test will be monitored to determine if there is a 10% reduction in full flow pressure when compared to previously performed tests. The Corrective Action Program will determine the cause and necessary corrective action. c. If a flow test or a main drain test does not meet acceptance criteria due to current or projected degradation additional tests are conducted. The number of increased tests is determined in accordance with the corrective action process; however, there are no fewer environment, and aging effect combination. d. Main drains for the standpipes associated with hose stations within the scope of subsequent license renewal will also be added to main drain testing procedures.	Program will be implemented and inspections or tests begin 5 years before the subsequent period of extended operation. Inspections or tests that are to be completed prior to the subsequent period of extended operation are completed 6 months prior to the subsequent period of extended operation or no later than the last refueling outage prior to the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1 Supplement to SLRA: Change Notice 1 Supplement to SLRA: Change Notice 2 Supplement to SLRA: Change Notice 3 Response to RAIs - Set 3 & 4 Correction to Response to RAIs - Set 3 & 4	2,3,4, 5,8,9

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
16 (cont'd)		3. Procedures will be revised to perform internal visual inspections of sprinkler and deluge system piping to identify internal corrosion, foreign material, and obstructions to flow. Follow-up volumetric examinations will be performed if internal visual inspections detect age-related degradation in excess of what would be expected accounting for design, previous inspection experience, and inspection interval. If organic or foreign material, or internal flow blockage that could result in failure of system function is identified, then an obstruction investigation will be performed within the Corrective Action Program that includes removal of the material, an extent of condition determination, review for increased inspections, extent of follow-up examinations, and a flush in accordance with NFPA 25, 2011 Edition, Annex D.5, Flushing Procedures. The internal visual inspections will consist of the following: a. Wet pipe sprinkler systems - 50% of the wet pipe sprinkler systems in scope for subsequent license renewal will have visual internal inspections of piping by removing a hydraulically remote sprinkler, performed every five years, consistent with NFPA 25, 2011 Edition, Section 14.2. During the next five-year inspection period, the alternate systems previously not inspected shall be inspected. b. Pre-action sprinkler systems - pre-action sprinkler systems in scope for subsequent license renewal will have visual internal inspections of piping by removing a hydraulically remote nozzle, performed every five years, consistent with NFPA 25, 2011 Edition, Section 14.2. c. Deluge systems - deluge systems in scope for subsequent license renewal will have visual internal inspections of piping by removing a hydraulically remote nozzle, performed every five years, consistent with NFPA 25, 2011 Edition, Section 14.2. 4. Procedures will be revised to perform system flow testing at flows representative of those expected during a fire. A flow resistance factor (C-factor) will be calculated to compare and trend the friction loss characteristics to the results from previous flow tests.			

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
16 (cont'd)		5. Prior to the subsequent period of extended operation, the insulation on the exterior surfaces of the fire water storage tanks (FWSTs) will be permanently removed. Wall thickness measurements will be performed on external tank areas exhibiting unexpected degradation. Refurbishment/recoating will be performed consistent with the severity of the degradation identified and commensurate with the potential for loss of intended function. Inspections of external tank surfaces will be on a refueling cycle frequency. 6. A procedure will be created to provide a Turbine Building oil deluge systems spray nozzle air flow test to ensure that patterns are not impeded by plugged nozzles, to ensure that nozzles are correctly positioned, and to ensure that obstructions do not prevent discharge patterns from wetting surfaces to be protected. 7. Procedure will be revised to provide inspection guidance related to lighting, distance and offset for non-ASME Code inspections. The procedure will specify adequate lighting be verified at the inspection location to detect degradation. Lighting may be permanently installed, temporary, or portable (e.g., flashlight), as appropriate. For accessible surface inspections, inspecting from a distance of two to four feet (or less) will be appropriate. For distant surface inspections, viewing aids such as binoculars may be used. For viewing angles which may prevent adequate inspection, a viewing aid such as an inspection mirror or boroscope should be used. 8. The Unit 1 hydrogen seal oil system deluge sprinkler pipe and Unit 1 station main transformer '1A' deluge sprinkler piping will be reconfigured to allow drainage. As part of the drainage reconfiguration, visual inspections and wall thickness measurements will be performed on the Unit 1 hydrogen seal oil system deluge sprinkler pipe that does not drain. In addition, wall thickness examination of the Unit 1 main transformer deluge sprinkler piping that does not allow drainage will also be performed as part of the drainage reconfiguration. Piping with unexpected degradation will be replaced.			

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
16 (cont'd)		9. The program will be revised to require inspections and tests be performed by personnel qualified in accordance with site procedures and programs for the specified task. 10. Procedures will be revised to require when degraded coatings are detected by internal coating inspections, acceptance criteria and corrective action recommendations consistent with the Internal Coatings/Linings for In-Scope Piping, Piping Components, Heat Exchangers and Tanks program are followed in lieu of NFPA 25 section 9.2.7 (1), (2), and (4). When interior pitting or general corrosion (beyond minor surface rust) is detected, tank wall thickness measurements are conducted as stated in NFPA 25 Section 9.2.7(3) in vicinity of the loss of material. Vacuum box testing as stated in NFPA 25 Section 9.2.7(5) is conducted when pitting, cracks, or loss of material is detected in the immediate vicinity of welds. 11. The activity of the jockey pump will be monitored consistent with the "detection of aging effects" program element of NUREG-2191, Section XI.M41. 12. Procedures will be revised to address recurring internal corrosion with the use of Low Frequency Electromagnetic Technique (LFET) or a similar technique on 100 feet of piping during each refueling cycle to detect changes in the pipe wall thickness. LFET screening or a similar technique will also be performed on accessible interior fire water storage tank bottoms during periodic inspections. The procedure will specify thinned areas found during the LFET screening be followed up with pipe wall thickness examinations to ensure aging effects are managed and wall thickness is within acceptable limits. In addition to the pipe wall thickness examination, the performance of opportunistic visual inspections of the fire protection system will be required whenever the fire water system is opened for maintenance.			

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
17	Outdoor and Large Atmospheric Metallic Storage Tanks program	The Outdoor and Large Atmospheric Metallic Storage Tanks program is an existing condition monitoring program that will be enhanced as follows: 1. Procedures will be revised to require periodic visual inspections of the refueling water storage tanks (RWSTs) be performed at each outage to confirm that the insulation caulking/sealant at the RWST concrete foundation is intact. The visual inspections of caulking/sealant will be supplemented with physical manipulation to detect any degradation. If there are any identified flaws, the caulking/sealant will be repaired or replaced and follow-up examination of the tank's surfaces conducted if deemed appropriate. An inspection of the caulk at the tank and concrete foundation interface will be included in the sample when the RWST external insulation is removed and sampled for external surface visual examinations. 2. Procedures will be revised to require visual and surface examination of the exterior surfaces of the RWSTs and CATs be performed to identify any loss of material or cracking. A minimum of either 25, one square foot sections or 20% of the surface area of insulation will be required to be removed to permit inspection of the exterior surface of each tank. The procedure will specify that sample inspection points be distributed in such a way that inspections occur near the bottoms, at points where structural supports, pipe, or instrument nozzles penetrate the insulation, and where water could collect such as on top of stiffening rings. If no unacceptable loss of material or cracking is observed, subsequent external surface examinations of insulated tanks will inspect for indications of damage to the jacketing, evidence of water intrusion through the insulation, or evidence of damage to the moisture barrier of tightly adhering insulation.	Program will be implemented and inspections or tests begin 10 years before the subsequent period of extended operation. Inspections or tests that are to be completed prior to the subsequent period of extended operation are completed 6 months prior to the subsequent period of extended operation or no later than the last refueling outage prior to the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1 Response to RAIs -Set 2	2,7

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
17 (cont'd)		3. Procedures will be revised to require emergency condensate storage tank (ECST) weep holes be inspected for water leakage/condensation once each refueling cycle and corrective action taken if excessive leakage is observed. Accessible external metallic tank surfaces visible from inside the ECST piping penetration house will also require inspection once each refueling cycle as an indication of external ECST surface condition. Volumetric examination thickness measurements of the bottom of both emergency condensate makeup tanks (ECMTs) (100% of the surface exposed to soil) and both emergency condensate storage tanks will be performed and will occur during each 10-year period starting ten years before the subsequent period of extended operation. Results will be forwarded to engineering for evaluation and the need for additional inspections will be determined based on projected corrosion rates. One-time thickness measurements of a sample of the ECSTs vertical wall will be performed prior to the subsequent period of extended operation (SPEO) to assess potential degradation due to removable access plug leakage. The sample will examine the ECST vertical steel shell region between the three weep holes at the tank bottom associated with removable access plug leakage and vertically from that tank bottom junction to a distance of six feet along the vertical shell at the tank as a region potentially most susceptible to degradation. The inspection results will be projected to end of the SPEO to confirm the ECSTs intended functions will be maintained throughout the SPEO based on the projected rate of degradation. Any degradation not meeting acceptance criteria will require periodic 10-year thickness measurements and a sample expansion along the leakage path consistent with the observed degradation.			

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
17 (cont'd)		4. Procedures will be revised to require volumetric examination thickness measurements of the bottom of both FWSTs and both RWSTs be performed each 10-year period during the subsequent period of extended operation starting ten years before the subsequent period of extended operation. Results will be forwarded to Engineering for evaluation and the need for additional inspections will be determined based on projected corrosion rates 5. For the carbon steel tanks (FWST, ECST, ECMT), procedures will be revised to provide non-ASME Code inspection guidance related to lighting, distance, offset, and surface conditions. The revised procedure will require the inspector confirm adequate lighting is available at the inspection location to detect degradation. Lighting may be permanently installed, temporary, or portable (e.g., flashlight), as appropriate. For accessible surface inspections, inspecting from a distance of two feet or less is recommended. For distant surface inspections, viewing aids such as binoculars may be used. For internal inspections, accessible surfaces will be inspected. Cleaning will be performed as necessary to allow for a meaningful examination. If protective coatings are present, the condition of the coating will be noted. 6. A new procedure will be developed to specify that additional inspections be performed consistent with NUREG-2191. If any inspections do not meet the acceptance criteria, additional inspections are conducted if one of the inspections does not meet acceptance criteria due to current or projected degradation (i.e., trending). a. For inspections where only one tank of a material, environment, and aging effect was inspected, all tanks in that grouping are inspected.			

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
17 (cont'd)		b. For other sampling based inspections there will be no fewer than five additional inspections for each inspection that did not meet acceptance criteria, or 20% of each applicable material, environment, and aging effect combination inspected, whichever is less. If any subsequent inspections do not meet acceptance criteria, an extent of condition and extent of cause analysis will be conducted to determine the further extent of inspections required. Additional samples will be inspected for any recurring degradation to ensure corrective actions appropriately address the associated causes. The additional inspections will include inspections of components with the same material, environment, and aging effect combination at the other unit. The additional inspections will be completed within the interval (i.e., 10-year inspection interval) in which the original inspection was conducted or, if identified in the latter half of the current inspection interval, within the next refueling outage interval. These additional inspections conducted in the next inspection interval cannot also be credited towards the number of inspections in the latter interval. If any projected inspection results will not meet acceptance criteria prior to the next scheduled inspection, inspection frequencies are adjusted as determined by the Corrective Action Program. However, for one-time inspections that do not meet acceptance criteria, inspections are subsequently conducted at least at 10-year inspection intervals.

SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
18	Fuel Oil Chemistry program	The Fuel Oil Chemistry program is an existing mitigative and condition monitoring and preventive program that will be enhanced as follows: 1. Procedures will be revised to include the emergency diesel generator (EDG) fuel oil base tanks within the scope of the Fuel Oil Chemistry program. 2. Existing procedures will be revised to include a requirement for quarterly sampling of the EDG auxiliary fuel oil tanks and EDG fuel oil base tanks for particulates and water. 3. Procedures will be revised to require the following fuel oil storage tanks within the scope of subsequent license renewal be drained, cleaned, and the internal surfaces visually inspected for degradation within ten years of entering the subsequent period of extended operation, and every ten years during the subsequent period of extended operation: • Underground fuel oil storage tanks • AAC diesel generator fuel oil tank If degradation is found during the internal visual inspection, bottom thickness measurements will be performed. Visual and volumetric examinations will be performed by personnel qualified in accordance with the standards of the American Petroleum Institute. 4. Procedures will be developed to perform periodic bottom thickness measurements of the following tanks within ten years of entering the subsequent period of extended operation, and every ten years during the subsequent period of extended operation: • EDG auxiliary fuel oil tanks • Diesel fire pump fuel oil tank • Emergency service water pump fuel oil tank Volumetric examinations will be performed by personnel qualified in accordance with the standards of the American Petroleum Institute.	Program will be implemented and inspections begin 10 years before the subsequent period of extended operation. Inspections that are to be completed prior to the subsequent period of extended operation are completed 6 months prior to the subsequent period of extended operation or no later than the last refueling outage prior to the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1 Supplement to SLRA: Change Notice 2	2,4

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
18 (cont'd)		5. Procedures will be developed to require an engineering evaluation be performed to document, evaluate, and trend visual and volumetric (as applicable) inspection results for the following fuel oil storage tanks: • Underground fuel oil storage tanks • AAC diesel generator fuel oil tank • EDG auxiliary fuel oil tanks • Diesel fire pump fuel oil tank • Emergency service water pump fuel oil tank The procedures will require unacceptable inspection results, as determined in the engineering evaluation, be documented in the Corrective Action Program. Bottom thickness measurements will be required to be evaluated against the design thickness and corrosion allowance. The frequency of future inspections will not be allowed to be reduced if bottom thickness measurements indicate the corrosion allowance will be exceeded prior to the next scheduled inspection. If a tank does not have a stated corrosion allowance, the tank will be evaluated for acceptability in the engineering evaluation. The engineering evaluation will evaluate the need to reduce the time period between future inspections based on inspection results. 6. Prior to the subsequent period of extended operation, a one-time inspection will be performed on the accessible internal surfaces on one EDG fuel oil base tank at Surry. Inspection will be limited due to the restricted accessibility through the tank sampling port. A visual inspection will be performed using a boroscope or equivalent instrument which will provide an acceptable level of information regarding tank degradation on the accessible internal surfaces. 7. Procedures will be revised to require a biocide be added when biological activity is detected or if there is evidence of tank internal corrosion.

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
19	Reactor Vessel Material Surveillance program	The Reactor Vessel Material Surveillance program is an existing condition monitoring program that will be enhanced as follows: 1. The RV Material Surveillance program for Unit 1 will be amended for Capsule Y to be pulled during the subsequent period of extended operation. Capsule Y will be pulled during the first refueling outage after the capsule reaches fluence greater than 100-year vessel irradiation which is between one and two times the projected peak vessel neutron fluence at the end of the subsequent period of extended operation. 2. The RV Material Surveillance program for Unit 2 will be amended for Capsule T to be pulled during the subsequent period of extended operation. Capsule T will be pulled during the first refueling outage after the capsule reaches fluence greater than 100-year vessel irradiation which is between one and two times the projected peak vessel neutron fluence at the end of the subsequent period of extended operation.	Program and SLR enhancements will be implemented 6 months prior to the subsequent period of extended operation. This program includes removal and testing of at least one capsule during the subsequent period of extended operation, with a neutron fluence of the capsule between one and two times the projected peak vessel neutron fluence at the end of the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1	2

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
20	One-Time Inspection program	The One-Time Inspection program is a new condition monitoring program consisting of a one-time inspection of selected components to verify: (a) the system-wide effectiveness of an aging management program that is designed to prevent or minimize aging to the extent that it will not cause the loss of intended function during the subsequent period of extended operation; (b) the insignificance of an aging effect; and (c) that long-term loss of material will not cause a loss of intended function for steel components exposed to environments that do not include corrosion inhibitors as a preventive action. The One-Time Inspection program will perform a magnetic particle test inspection of the continuous circumferential transition cone closure weld on each steam generator (essentially 100% examination coverage of each weld) prior to the subsequent period of extended operation. Industry and plant-specific operating experience will be evaluated in the development of this program.	Program will be implemented and inspections begin 10 years before the subsequent period of extended operation. Inspections that are to be completed prior to the subsequent period of extended operation are completed 6 months prior to the subsequent period of extended operation or no later than the last refueling outage prior to the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1 Response to RAIs -Set 1	2,6

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
21	Selective Leaching program	The Selective Leaching program is a new condition monitoring program that will monitor components constructed of materials which are susceptible to selective leaching. The selective leaching program includes a one-time inspection for susceptible components exposed to closed cycle cooling water and treated water environment since plant-specific operating experience has not revealed selective leaching in these environments, as well as opportunistic and periodic inspections for susceptible components exposed to raw water, waste water, and soil (which may include groundwater) environments. Industry and plant-specific operating experience will be evaluated in the development of this program.	Program will be implemented and inspections begin 10 years before the subsequent period of extended operation. Inspections that are to be completed prior to the subsequent period of extended operation are completed 6 months prior to the subsequent period of extended operation or no later than the last refueling outage prior to the subsequent period of extended operation. Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
22	ASME Code Class 1 Small-Bore Piping program	The ASME Code Class 1 Small-Bore Piping program is a new condition monitoring program that augments the existing ASME Code, Section XI requirements and is applicable to ASME Code Class 1 small-bore piping and systems with a NPS diameter less than 4 inches and greater than or equal to 1 inch. This program provides for volumetric examination of a sample of full penetration (butt) welds and partial penetration (socket) welds in Class 1 piping to manage cracking due to stress corrosion cracking or thermal or vibratory fatigue loading. Volumetric examinations will employ techniques that have been demonstrated to be capable of detecting flaws and discontinuities in the examination volume of interest. The extent and schedule for volumetric examination is based on plant-specific operating experience and whether actions have been implemented that effectively mitigate the cause(s) of any past cracking. The program provides for a one-time inspection of a sample of the population of welds (butt welds or socket welds) for plants that have not experienced cracking or have experienced cracking but have implemented corrective actions, such as a design change, to effectively mitigate the cause(s) of the cracking. The program provides for periodic inspection of a sample of the population of welds (butt welds or socket welds) that have experienced cracking and have not implemented corrective actions to effectively mitigate the cause(s) of the cracking. Industry and plant-specific operating experience will be evaluated in the development of this program.	Program will be implemented and inspections are completed within 6 years before the subsequent period of extended operation. Inspections that are to be completed prior to the subsequent period of extended operation are completed 6 months prior to the subsequent period of extended operation or no later than the last refueling outage prior of extended operation. 23	External Surfaces Monitoring of Mechanical Components program	The External Surfaces Monitoring of Mechanical Components program is an existing condition monitoring program that will be enhanced as follows: 1. The Engineering walkdown procedure will be revised to include an item in the walkdown checklist to inspect insulation metallic jacketing for any damage that would permit in-leakage of moisture. 2. The Engineering walkdown procedure will be revised to add the following requirements: a. Metallic Components • No surface imperfections, loss of wall thickness, flaking, or oxide coated surfaces • No blistering of protective coating • No evidence of leakage (for detection of cracks) on the surfaces of stainless steel, aluminum, and copper alloy (>15% Zn or >8% Al) components • No accumulation of debris on air-side heat exchanger surfaces b. Elastomers and Flexible Polymers • No exposure of reinforcing fibers, mesh or underlying metal (for elastomers or flexible polymers with internal reinforcement) • No blistering, loss of thickness, dimensional change, or scuffing • No hardening of elastomeric elements as evidenced by a loss of suppleness during tactile inspection c. Insulation Metallic Jacketing • Inspect insulation metallic jacketing for any damage that would permit in-leakage ofmoisture. d. HVAC Closure Bolting • Check that a sample of closure bolting that is in reach is not loose	Program enhancements for SLR will be implemented 6 months prior to the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1 Supplement to SLRA: Change Notice 1	2,3

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
23 (cont'd)		3. The Engineering walkdown procedure will be revised to specify that walkdowns will be performed at a frequency not to exceed one refueling cycle. Since some surfaces are not readily visible during both plant operations and refueling outages, the enhancement will also specify that such surfaces will be inspected when they are made accessible and at such intervals that would ensure the components' intended functions are maintained. 4. The Engineering walkdown procedure will be revised to provide non-ASME Code inspection guidance related to lighting, distance and offset for walkdown inspections. The procedure will specify adequate lighting be verified at the inspection location to detect degradation. Lighting may be permanently installed, temporary, or portable (e.g., flashlight), as appropriate. For accessible surface inspections, inspecting from a distance of two to four feet (or less) will be appropriate. For distant surface inspections, viewing aids such as binoculars may be used. For viewing angles which may prevent adequate inspection, a viewing aid such as an inspection mirror or boroscope should be used. 5. A new procedure will be developed to specify that in each 10-year period during the subsequent period of extended operation, the minimum number of inspections is completed. A minimum of 25 inspections for cracking will be performed from each of the stainless steel, aluminum, and copper alloy (>15% Zn or >8% Al) component populations assigned to the program every ten years. For insulated components exposed to condensation, a minimum of 25 one foot axial length sections and components for each material and environment combination will be inspected for loss of material and cracking after the insulation is removed. The new procedure will specify that the inspections focus on the components most susceptible to aging because of time in service, severity of operating conditions, and lowest design margin.			

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
23 (cont'd)		6. The Engineering walkdown procedure will be revised to specify that visual inspection of elastomers and flexible polymers will be supplemented by tactile inspection to detect hardening. Visual inspections will cover 100% of accessible component surfaces. The minimum surface area for tactile inspections will be at least 10% of the accessible surface area. 7. A new procedure will be developed to evaluate and project the rate of any degradation until the end of the subsequent period of extended operation or the next scheduled inspection, whichever is shorter. The inspection sampling bases (e.g., selection, size, frequency) will be adjusted as necessary based on the projection. 8. A new procedure will be developed to specify that, where practical, acceptance criteria are quantitative (e.g., minimum wall thickness). For quantitative analyses, the required minimum wall thickness to meet applicable design standards will be used. For qualitative evaluations, applicable parameters such as ductility, color, and other indicators will be addressed to ensure a decision is based on observed conditions. 9. A new procedure will be developed to specify that additional inspections will be performed if any sampling-based inspections to detect cracking in aluminum, stainless steel, and copper alloy (>15% Zn or >8% Al) components do not meet the acceptance criteria, unless the cause of the aging effect for each applicable material and environment is corrected by repair or replacement. There will be no fewer than five additional inspections for each inspection that did not meet acceptance criteria, or 20% of each applicable material, environment, and aging effect combination inspected, whichever is less. If any subsequent inspections do not meet acceptance criteria, an extent of condition and extent of cause analysis will be conducted to determine the further extent of inspections required. Additional samples will be inspected for any recurring degradation to ensure corrective actions appropriately address the associated causes.			

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
23 (cont'd)		The additional inspections will include inspections of components with the same material, environment, and aging effect combination at both Unit 1 and Unit 2. The additional inspections will be completed within the interval (e.g., 10-year inspection interval) in which the original inspection was conducted.			
24	Flux Thimble Tube Inspection program	The Flux Thimble Tube Inspection program is an existing condition monitoring program that will be enhanced as follows: 1. An inspection procedure will be developed specifically for flux thimble tube eddy-current inspections, rather than continuing to use a generic procedure for tubing inspection. The procedure will include the acceptance criterion, with the basis, for loss of material for the inner flux thimble tube, and identify remediating actions to be implemented if the acceptance criterion is exceeded.	Program enhancements for SLR will be implemented 6 months prior to the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1	2
25	Inspection of Internal Surfaces in Miscellaneous Piping and Ducting Components program	The Inspection of Internal Surfaces in Miscellaneous Piping and Ducting Components program is an existing condition monitoring program that will be enhanced as follows: 1. Procedures will be revised to require inspection of metallic components for flaking or oxide-coated surfaces. 2. Procedures will be revised to require inspection of elastomeric and flexible polymeric components for the following: a. Surface crazing, scuffing, loss of sealing, blistering, and dimensional change (e.g., "ballooning" and "necking") b. Loss of wall thickness c. Exposure of internal reinforcement (e.g., reinforcing fibers, mesh, or underlying metal) for reinforced elastomers		SLRA, Appendix A, Table A4.0-1 Supplement to SLRA: Change Notice 2	2,4

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
25 (cont'd)		3. Procedures will be revised to specify that visual inspection of elastomeric and flexible polymeric components is supplemented by tactile inspection to detect hardening or loss of suppleness. The minimum surface area for tactile inspections will be at least 10% of the accessible surface area. 4. Procedures will be revised to provide non-ASME Code inspection guidance related to lighting, distance, offset, surface coverage, presence of protective coatings, and cleaning processes. The procedure will specify adequate lighting be verified at the inspection location to detect degradation. Lighting may be permanently installed, temporary, or portable (e.g., flashlight), as appropriate. For accessible surface inspections, inspecting from a distance of two feet or less will be appropriate. For viewing angles which may prevent adequate inspection, a viewing aid such as an inspection mirror or boroscope should be used. For internal inspections, accessible surfaces will be inspected. If inspecting piping internal surfaces, a minimum of one linear foot will be inspected, if accessible. Cleaning will be performed, as necessary, to allow for a meaningful examination. If protective coatings are present, the procedure will require the condition of the coating to be documented. 5. Procedures will be revised to specify that follow-up volumetric examinations are performed where irregularities that could be indicative of an unexpected level of degradation are detected for steel components exposed to raw water, raw water (potable), or waste water. 6. A new procedure will be developed to specify that in each 10-year period during the subsequent period of extended operation, the minimum number of inspections is completed for the various sample populations (each material, environment, and aging effect combination). If opportunistic inspections will not fulfill the minimum number of inspections by the end of each 10-year period, the program owner will initiate work orders as necessary to request additional inspections. A representative sample of 20% of the population (defined as components having the same material, environment, and aging effect combination) or a maximum of nineteen components per population at each unit will be inspected.

27	Buried and Underground Piping and Tanks program	The Buried and Underground Piping and Tanks program is an existing condition monitoring program that will be enhanced as follows: 1. Procedures will be revised to establish an upper limit of -1200mV for pipe-to-soil potential measurements of coated pipes so as to preclude potential damage to coatings. 2. Procedures will be revised to obtain pipe-to-soil potential measurements for piping in the scope of SLR during the next soil survey within 10 years prior to entering the subsequent period of operation. 3. Procedures will be revised to require uncoated buried stainless steel tubing segments in the fuel oil system be inspected prior to the subsequent period of extended operation. After inspection, each uncoated stainless steel segment will be coated consistent with Table 1 of NACE SP0169-2007, "Control of External Corrosion on Underground or Submerged Metallic Piping Systems." 4. A cathodic protection system will be installed for protection of the 24-inch service water piping at the Low Level Intake Structure five years before entering the subsequent period of operation. 5. A cathodic protection system will be installed for protection of each unit's buried carbon steel condensate system and auxiliary feedwater system piping from the emergency condensate storage tank and the emergency condensate makeup tank to the service building five years before entering the subsequent period of operation. 6. Procedures will be enhanced to perform two soil corrosivity samples: one adjacent to the Unit 1 circulating water inlet piping and another adjacent to the Unit 2 circulating water inlet piping. Sampling will be performed on a ten year interval. Data collected at each location will include: soil resistivity, soil consortia (bacteria), pH, moisture, chlorides, sulfates, and redox potential. In addition to evaluating each individual parameter, corrosivity of carbon steel reinforcement and concrete degradation in high sulfate, high chlorides, and acidic environments will be evaluated.	Program will be implemented and inspections begin 10 years before the subsequent period of extended operation. Inspections that are to be completed prior to the subsequent period of extended operation are completed 6 months prior to the subsequent period of extended operation or no later than the last refueling outage prior to the subsequent period of extended operation. 27 (cont'd)		7. Procedure(s) will be developed to perform a one-time inspection (one excavation) for evidence of concrete aging (below grade) associated with the south side of the Turbine Building, with the following requirements: a. Prior to excavation, it shall be confirmed that the south side of the Turbine Building is bare concrete below grade. b. If bare concrete is confirmed, then: • A minimum of 50 ft^2 concrete surface area below groundwater level will be inspected by the one-time inspection. • The evaluation of the one-time inspection results shall include evaluation of the acceptability of the eight inaccessible 96-inch CW pipes located between the High Level Intake Structures and the Turbine Building using the guidance in ACI 349.3R. • If observed age-related degradation exceeds ACI 349.3R Tier-1 criteria, then the area containing the degradation will be evaluated for acceptability by a responsible Civil Engineer using the Corrective Action Program. The evaluation shall include the acceptability of the eight inaccessible 96-inch CW pipes located between the High Level Intake Structures and the Turbine Building using the guidance in ACI 349.3R. • If observed age-related degradation exceeds ACI 349.3R Tier-1 criteria, a subsequent inspection will be performed within ten years to determine if the previously observed degradation remains within the parameters evaluated during the previous inspection. If the degradation during the subsequent inspection more than marginally exceeds the evaluated parameters from the previous inspection, then within five years an excavation of one 96-inch CW pipe will be performed to inspect a surface area of 50 ft^2 located below groundwater level. c. If bare concrete is not confirmed, then: • Excavation of one 96-inch CW pipe will be performed to inspect a surface area of 50 ft2 located below groundwater level.

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
27 (cont'd)		8. Procedures will be revised to specify that cathodic protection surveys use the -850mV polarized potential, instant off criterion specified in NACE SP0169-2007 for steel piping acceptance criteria unless a suitable alternative polarization criteria can be demonstrated. Alternatives include the -100mV polarization criteria, -750mV criterion (soil resistivity is less than 100,000 ohm-cm), -650mV criterion (soil resistivity is greater than 100,000 ohm-cm), or verification of less than 1 mpy loss of material rate. The external loss of material rate is verified: • Every year when verifying the effectiveness of the cathodic protection system by measuring the loss of material rate. • Every 2 years when using the 100 mV minimum polarization. • Every 5 years when using the -750 or -650 criteria associated with higher resistivity soils. The soil resistivity is verified every 5 years. As an alternative to verifying the effectiveness of the cathodic protection system every five years, soil resistivity testing is conducted annually during a period of time when the soil resistivity would be expected to be at its lowest value (e.g., maximum rainfall periods). Upon completion of ten annual consecutive soil samples, soil resistivity testing can be extended to every five years if the results of the soil sample tests consistently have verified that the resistivity did not fall outside of the range being credited (e.g., for the -750 mV relative to a CSE, instant off criterion, measured soil resistivity values were greater than 10,000 ohm-cm). When using the electrical resistance corrosion rate probes: a. The individual determining the installation of the probes and method of use will be qualified to NACE CP4, "Cathodic Protection Specialist" or similar b. The impact of significant site features and local soil conditions will be factored into placement of the probes and use of the data

28	Internal Coatings/Linings for In-Scope Piping, Piping Components, Heat Exchangers, and Tanks program	The Internal Coatings/Linings for In-Scope Piping, Piping Components, Heat Exchangers, and Tanks program is an existing condition monitoring program that will be enhanced as follows: 1. Procedures will be revised to require baseline inspections (100% of accessible coatings/linings) of the following tanks, piping, and miscellaneous components within the scope of subsequent license renewal and inspection intervals will not exceed those specified in NUREG-2191, Table XI.M42-1, “Inspection Intervals for Internal Coatings/Linings for Tanks, Piping, Piping Components, and Heat Exchangers.” • Circulating water system waterbox air separating tanks • Condensate polishing outlet piping (short segment; entire length is inspected) • Vacuum priming tanks • Vacuum priming seal water separator tanks • Auxiliary steam drain receiver tank • Water treatment piping (short segment; entire length is inspected) • Flash evaporator demineralizer isolation valve • Brominator mixing tank • Pressurizer relief tanks 2. Programs will be revised to consistently reference coating aging mechanisms and add definitions for rusting, wear/erosion, and physical damage. 3. Procedures will be revised to require alignment of the internal coating/lining inspection criteria with the inspection criteria and aging mechanisms specified in the Coatings Condition Assessment Program.	Program will be implemented and inspections begin 10 years before the subsequent period of extended operation. Inspections that are to be completed prior to the subsequent period of extended operation are completed 6 months prior to the subsequent period of extended operation or no later than the last refueling outage prior to the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1 Supplement to SLRA: Change Notice 2 Response to RAIs -Set 1 Response to RAIs -Set 3 & 4 Correction to Response to RAIs -Set 3 & 4	2,4,6, 8,9

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
28 (cont'd)		4. Procedures will be revised to require inspections of cementitious coatings/linings and include aging mechanisms associated with cementitious coatings/linings described as cracking due to chemical reaction, weathering, settlement, or corrosion of reinforcement; loss of material due to delamination, exfoliation, spalling, popout, scaling, or cavitation. 5. Procedures will be revised to require cementitious coatings/linings inspectors to have a minimum of five years of experience inspecting or testing concrete structures or cementitious coatings/linings or a degree in the civil/structural discipline and a minimum of one year of experience. 6. Procedures will be revised to require opportunistic inspections of piping internally lined with concrete and include aging associated with cementitious coatings/linings described as cracking due to chemical reaction, weathering, settlement, or corrosion of reinforcement; loss of material due to delamination, exfoliation, spalling, popout, scaling, or cavitation. 7. Component cooling heat exchanger channel head coatings are inspected on a one-year inspection interval. Procedures will be revised to require that if two subsequent inspections demonstrate no change in coating condition (i.e. at least three consecutive inspections with no change in condition), inspection frequencies at those locations may be conducted consistent with inspection Category B of NUREG-2191 Table XI.M42-1. 8. Procedures will be revised to require a coatings specialist to prepare the coatings post-inspection condition assessment report. A pre-inspection review will be performed of the coating inspections and any subsequent repair activities from the previous two coatings post-inspection condition assessment reports, when available. 9. Procedures will be revised to require inspection results are evaluated against acceptance criteria to confirm that the components' intended functions will be maintained throughout the subsequent period of extended operation based on the projected rate and extent of degradation. Where practical, (e.g., wall thickness measurements, blister size and frequency), degradation is projected until the next scheduled inspection.			

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
28 (cont'd)		10. Procedures will be revised to: a. Specify there are no indications of peeling or delamination. b. Require inspection of cementitious coatings/linings. Minor cracking and spalling is acceptable provided there is no evidence that the coating/lining is debonding from the base material. c. Require, as applicable wall thickness measurements, projected to the next inspection, meet design minimum wall requirements. 11. Procedures will be revised to permit the "removal" of coatings/linings that do not meet acceptance criteria, with the required evaluation and documentation. 12. Procedures will be revised to include as an alternative to repair, rework, or removal, internal coatings/linings exhibiting indications of peeling and delamination. The component may be returned to service if: a. Physical testing is conducted to ensure that the remaining coating is tightly bonded to the base metal b. the potential for further degradation of the coating is minimized, (i.e., any loose coating is removed, the edge of the remaining coating is feathered) c. adhesion testing using ASTM International Standards endorsed in RG 1.54 (e.g., pull-off testing, knife adhesion testing) is conducted at a minimum of 3 sample points adjacent to the defective area, d. an evaluation is conducted of the potential impact on the system, including degraded performance of downstream components due to flow blockage and loss of material or cracking of the coated component and e. follow-up visual inspections of the degraded coating are conducted within two years from detection of the degraded condition, with a re-inspection within an additional two years, or until the degraded coating is repaired or replaced.			

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
28 (cont'd)		13. Procedures will be revised to require when a blister does not meet acceptance criteria, and it is not repaired, physical testing is conducted to ensure that the blister is completely surrounded by sound coating/lining bonded to the surface. Physical testing consists of adhesion testing using ASTM International standards endorsed in RG 1.54. Where adhesion testing is not possible due to physical constraints, another means of determining that the remaining coating/lining is tightly bonded to the base metal is conducted such as lightly tapping the coating/lining. Acceptance of a blister to remain inservice should be based both on the potential effects of flow blockage and degradation of the base material beneath the blister. 14. Procedures will be revised to require additional inspections be conducted if one of the inspections does not meet acceptance criteria due to current or projected degradation (i.e., trending) unless the cause of the aging effect for each applicable material and environment is corrected by repair or replacement for all components constructed of the same material and exposed to the same environment. The number of increased inspections will be determined in accordance with the Corrective Action Program. However, there are no fewer than five additional inspections for each inspection that did not meet acceptance criteria, or 20% of each applicable material, environment, and aging effect combination inspected, whichever is less. When inspections are based on the percentage of piping length, an additional 5% of the total length will be inspected. The timing of the additional inspections will be based on the severity of the degradation identified and will be commensurate with the potential for loss of intended function. However, in all cases, the additional inspections will be completed within the interval in which the original inspection was conducted, or if identified in the latter half of the current inspection interval, within the next refueling outage interval.			

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
28 (cont'd)		These additional inspections conducted in the next inspection interval cannot also be credited towards the number of inspections in the latter interval. If subsequent inspections do not meet acceptance criteria, an extent of condition and extent of cause analysis will be conducted to determine the further extent of inspections. Additional samples will be inspected for any recurring degradation to provide reasonable assurance that corrective actions appropriately address the associated causes. The additional inspections will include inspections with the same material, environment, and aging effect combination at both Unit 1 and Unit 2. 15. Physical testing is performed where physically possible (i.e., sufficient room to conduct testing) or examination is conducted to ensure that the extent of repaired or replaced coatings/linings encompasses sound coating/lining material.			

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
29	ASME Section XI, Subsection IWE program	The ASME Section XI, Subsection IWE program is an existing condition monitoring program that will be enhanced as follows: 1. Procedures will be revised to specify that whenever replacement of bolting is required, bolting material, installation torque or tension, and use of lubricants and sealants are in accordance with the guidelines of EPRI NP-5769, "Degradation and Failure of Bolting in Nuclear Power Plants," EPRI TR-104213, "Bolted Joint Maintenance & Application Guide," and the additional recommendations of NUREG-1339, "Resolution of Generic Safety Issue 29: Bolting Degradation of Failure in Nuclear Power Plants." 2. Procedures will be revised to specify that for structural bolting consisting of ASTM A325, ASTM F1852, and/or ASTM A490 bolts, the preventive actions for storage, lubricants, and stress corrosion cracking potential discussed in Section 2 of RCSC (Research Council for Structural Connections) publication "Specification for Structural Joints Using ASTM A325 or A490 Bolts," will be used. 3. Procedures will be revised to augment visual examinations with surface examinations to manage cracking in the containment pressure retaining portions of the fuel transfer tube, fuel transfer tube enclosure, fuel transfer tube blind flange, dissimilar metal weld penetrations, and high-temperature steel piping penetrations. Surface examinations will be performed once during each ten year interval. 4. Procedures will be revised to specify a one-time volumetric examination of metal liner surfaces that are inaccessible from one side if triggered by plant-specific operating experience. The trigger for this supplemental examination is plant-specific occurrence or recurrence of measurable metal liner corrosion (base metal material loss exceeding 10% of nominal plate thickness) initiated on the inaccessible side or areas, identified since the date of issuance of the initial renewed license.	Program and SLR enhancements, will be implemented 6 months prior to the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1 Supplement to SLRA: Change Notice 2	2,4

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
29 (cont'd)		This supplemental volumetric examination consists of a sample of one-foot square locations that include both randomly-selected and focused areas most likely to experience degradation based on operating experience and/or other relevant considerations such as environment. Any identified degradation is addressed in accordance with the applicable provisions of the ASME Section XI, Subsection IWE program. The sample size, locations, and any needed scope expansion (based on findings) for this one-time set of volumetric examinations should be determined on a plant-specific basis to demonstrate statistically, with 95% confidence, that 95% of the accessible portion of the containment liner is not experiencing corrosion degradation with greater than 10% loss of nominal thickness.			
30	ASME Section XI, Subsection IWL program	The ASME Section XI, Subsection IWL program is an existing condition monitoring program that will be enhanced as follows: 1. Procedures will be revised to specify that inspection results be compared to previous results to identify changes from prior inspections, and that quantitative measurements are recorded and trended for applicable parameters monitored or inspected. 2. Procedures will be revised to specify that inspection results be compared to previous results to determine if degradation is passive for application of second-tier acceptance criteria as specified in ACI 349.3R-02, "Evaluation of Existing Nuclear Safety-Related Concrete Structures."	Program enhancements for SLR will be implemented 6 months prior to the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1	2

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
31	ASME Section XI, Subsection IWF program	The ASME Section XI, Subsection IWF program is an existing condition monitoring program that will be enhanced as follows: 1. Procedures will be enhanced to evaluate the acceptability of inaccessible areas (e.g., portions of supports encased in concrete, buried underground, or encapsulated by guard pipe) when conditions in accessible areas that could indicate the presence of, or result in, degradation to such inaccessible areas. 2. Procedures will be revised to specify that whenever replacement of bolting is required, bolting material, installation torque or tension, and use of lubricants and sealants will be in accordance with the guidelines of EPRI NP-5769, EPRI TR-104213, and the additional recommendations of NUREG-1339. 3. Procedures will be revised to specify that for structural bolting consisting of ASTM A325, ASTM F1852, and/or ASTM A490, the preventive actions for storage, lubricants, and stress corrosion cracking potential discussed in Section 2 of RCSC (Research Council for Structural Connections) publication, "Specification for Structural Joints Using ASTM A325 or A490 Bolts," will be used. 4. Procedures will be revised to specify that for NSSS component supports, Class 1 high strength bolting greater than one inch nominal diameter, including ASTM A325 and/or ASTM A490 bolts (including respective equivalent twist-off type ASTM F1852 and/or ASTM F2280 bolts), will be monitored for SCC. 5. Procedures will be revised to specify a one-time inspection within five years prior to entering the subsequent period of extended operation of an additional 5% of the sample populations for Class 1, 2, and 3 piping supports. The additional supports will be selected from the remaining population of IWF piping supports and will include components that are most susceptible to age-related degradation.	Program will be implemented and a one-time inspection of an additional 5% of the sample size specified in Table IWF-2500-1 for Class 1, 2, and 3 piping supports is conducted within 5 years prior to the subsequent period of extended operation, and are to be completed prior to the subsequent period of extended operation, are completed 6 months prior to the subsequent period of extended operation or no later than the last refueling outage prior to the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1 Supplement to SLRA: Change Notice 2	2,4

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
31 (cont'd)		6. Procedures will be revised to specify that, for NSSS component supports, high-strength bolting greater than one inch nominal diameter, volumetric examination comparable to that of ASME Code, Section XI, Table IWB-2500-1, Examination Category B-G-1 will be performed to detect cracking in addition to the VT-3 examination. In each 10-year period during the subsequent period of extended operation, a representative sample of bolts will be inspected. The sample will be 20% of the population (for a material / environment combination) up to a maximum of 25 bolts. 7. Procedures will be revised to specify that, if a component support does not exceed the acceptance standards of IWF-3400, but is electively repaired to as-new condition, then the sample is increased or modified to include another support that is representative of the remaining population of supports that were not repaired.			
32	10 CFR 50, Appendix J program	The 10 CFR 50, Appendix J program is an existing performance monitoring program that is credited.	Ongoing	SLRA, Appendix A, Table A4.0-1	2
33	Masonry Walls program	The Masonry Walls program is an existing condition monitoring program that will be enhanced as follows: 1. Procedures will be revised to clarify qualifications for personnel performing inspections of masonry walls and concrete to be consistent with ACI 349.3R-02. 2. Procedures will be revised to explicitly address the trending of inspection results and projection to the next inspection interval. The procedure will be revised to include acceptance criteria for masonry wall inspections that will be used to ensure observed aging effects (cracking, loss of material, or gaps between the structural steel supports and masonry walls) do not invalidate the evaluation basis of the wall or impact its intended function.	Program enhancements for SLR will be implemented 6 months prior to the subsequent period of extended operation	SLRA, Appendix A, Table A4.0-1	2

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
34	Structures Monitoring program	The Structures Monitoring program is an existing condition monitoring program that will be enhanced as follows: 1. Procedures will be revised to include inspection of the following structures that are within the scope of subsequent license renewal: decontamination building, radwaste facility, health physics yard office building, laundry facility, and machine shop. Inspections for the added structures will be performed under the enhanced program in order to establish quantitative baseline inspection data prior to the subsequent period of extended operation. 2. Procedures will be revised to add the oiled-sand cushion to the inspection of the fire protection/domestic water tank foundation. 3. Procedures will be revised to include preventive actions to ensure bolting integrity for replacement and maintenance activities by specifying proper selection of bolting material and lubricants, and appropriate installation torque or tension to prevent or minimize loss of bolting preload and cracking of high-strength bolting. For structural bolting consisting of ASTM A325, ASTM A490, ASTM F1852 and/or ASTM F2280 bolts, the preventive actions for storage, lubricant selection, and bolting and coating material selection discussed in Section 2 of the Research Council for Structural Connections publication, “Specification for Structural Joints Using High-Strength Bolts,” will be used. 4. The checklist for structural and support steel will be revised to indicate: “Are any connection members loose, missing or damaged (bolts, rivets, nuts, etc.)?”. 5. Procedures will be revised to require at least five years of experience (or ACI inspector certification) for concrete inspectors to be consistent with ACI 349.3R-002. Procedures will be revised to eliminate options for inspector qualifications that are not consistent with ACI 349.3R-002.	Program enhancements for SLR will be implemented 6 months prior to the subsequent period of extended operation. A baseline inspection for wooden poles will be performed prior to January 1, 2031	SLRA, Appendix A, Table A4.0-1 Supplement to SLRA: Change Notice 2 Supplement to SLRA: Change Notice 3 Response to RAIs -Set 2 Response to RAIs -Set 3 & 4 Correction to Response to RAIs -Set 3 & 4	2,4,5, 7,8,9

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
34 (cont'd)		6. Procedures will be revised to specify that wooden pole inspections will be performed at a frequency not to exceed every eight years. Visual examinations will detect loss of material and change in material properties. Visual examinations will be augmented, as required to detect change in material properties, with soundings or other techniques appropriate for the type, condition, and treatment of the wooden poles, including borings and excavations. 7. Procedures will be revised to specify that evaluation of inspection results includes consideration of the acceptability of inaccessible areas when conditions exist in accessible areas that could indicate the presence of, or result in, degradation to such inaccessible areas. 8. Procedures will be enhanced to specify VT-1 inspections to identify cracking on stainless steel and aluminum components. A minimum of 25 inspections will be performed every ten years during the subsequent period of extended operation from each of the stainless steel and aluminum component populations assigned to the Structures Monitoring program. If the component is measured in linear feet, at least one foot will be inspected to qualify as an inspection. For other components, at least 20% of the surface area will be inspected to qualify as an inspection. The selection of components for inspection will consider the severity of the environment. For example, components potentially exposed to halides and moisture would be inspected, since those environmental factors can facilitate stress corrosion cracking. 9. Procedures will be enhanced to specify that for the neutron shield tank (NST), loss of material due to corrosion, other than superficial corrosion, will be evaluated to ensure that the NST will continue to perform its intended functions, including structural support of the RPV.			

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
34 (cont'd)		10. Procedures will be enhanced to specify for the sampling-based inspections to detect cracking in stainless steel and aluminum components, additional inspections will be conducted if one of the inspections does not meet acceptance criteria due to current or projected degradation, unless the cause of the aging effect for each applicable material and environment is corrected by repair or replacement for all components constructed of the same material and exposed to the same environment. No fewer than five additional inspections for each inspection that did not meet acceptance criteria or 20% of each applicable material, environment, and aging effect combination will be inspected, whichever is less. Additional inspections will be completed within the 10-year inspection interval in which the original inspection was conducted. The responsible engineer will initiate condition reports to generate work orders to perform the additional inspections. The responsible engineer will evaluate the inspection results, and if the subsequent inspections do not meet acceptance criteria, an extent of condition and extent of cause analysis will be conducted. The responsible engineer will then determine the further extent of inspections. Additional samples will be inspected for any recurring degradation to ensure corrective actions appropriately address the associated causes. The additional inspections will include inspections of components with the same material, environment, and aging effect combination at both Unit 1 and Unit 2. If any projected inspection results will not meet acceptance criteria prior to the next scheduled inspection, inspection frequencies will be adjusted as determined by the Corrective Action Program. 11. Procedures will be enhanced to specify that evaluation of neutron shield tank findings consider its structural support function for the reactor pressure vessel. 12. Procedures will be enhanced to also include LOCAs as events that require evaluation for potentially degraded structures by Civil/Mechanical Design Engineering.

SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
35	Inspection of Water Control Structures Associated with Nuclear Power Plants program	The Inspection of Water Control Structures Associated with Nuclear Power Plants program is an existing condition monitoring program that will be enhanced as follows: 1. Procedures will be revised to provide guidance for specification of bolting material, lubricants and sealants, and installation torque or tension to prevent degradation and assure structural bolting integrity. 2. Procedures will be revised to specify the preventive actions for storage discussed in Section 2 of Research Council for Structural Connections publication “Specification for Structural Joints Using ASTM A325 or A490 Bolts” for ASTM A325, ASTM F1852, ASTM F2280, and/or ASTM A490 structural bolts. 3. Procedures will be revised for concrete inspection to require at least five years of experience (or ACI inspector certification) to be consistent with ACI 349.3R-2002.	Program enhancements for SLR will be implemented 6 months prior to the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1	2
36	Protective Coating Monitoring and Maintenance program	The Protective Coating Monitoring and Maintenance program is an existing mitigative and condition monitoring program that will be enhanced as follows: 1. Procedures will be revised to require that a pre-inspection review of the previous “two” condition assessment reports be performed prior to each refueling outage.	Program enhancements for SLR will be implemented 6 months prior to the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1	2

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
37	Electrical Insulation for Electrical Cables and Connections Not Subject to 10 CFR 50.49 Environmental Qualification Requirements program	The Electrical Insulation for Electrical Cables and Connections Not Subject to 10 CFR 50.49 Environmental Qualification Requirements program is an existing condition monitoring program that will be enhanced as follows: 1. A new procedure will be developed that will include guidance for the identification of adverse localized environments of temperature, moisture, radiation, contamination, and oxygen. 2. A new procedure will be developed that includes a description of testing methodology. Should testing be deemed necessary based on unacceptable visual indications of surface anomalies, a sample size of 20% of each cable and connection insulation material type found within the adverse localized environment with a maximum sample size of 25 will be tested. The following factors will be considered in the development of the cable and connection insulation test sample: environment including identified adverse localized environments (high temperature, high humidity, vibration, etc.), voltage level, circuit loading, connection type, location (high temperature, high humidity, vibration, etc.), and insulation material. Testing may include thermography and other proven condition monitoring test methods applicable to the cable and connection insulation. Testing as part of an existing maintenance, calibration or surveillance program may be credited. The technical basis for the sample selected is provided. 3. A new procedure will be developed that includes an inspection frequency of at least once every ten years. 4. A new procedure will be developed that includes the addition of jacket surface and connection covering material anomalies including embrittlement, melting, swelling, and surface contamination. 5. A new procedure will be developed that includes the performance of a review of previously identified and mitigated adverse localized environments cumulative aging effects applicable to in-scope cable and connection electrical insulation.	Program enhancements for SLR will be implemented 6 months prior to the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1	2

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
37 (cont'd)		6. A new procedure will be developed that describes acceptance criteria for both tests and visual inspections of the electrical cable and connection insulation material. 7. A new procedure will be developed that includes performance of an engineering evaluation of unacceptable test results and visual indications of cable and connection electrical insulation abnormalities. The evaluation will consider the age and operating environment of the component, as well as the severity of the abnormality and whether such an abnormality has previously been correlated to degradation of cable or connection insulation. Corrective actions include, but are not limited to, testing, shielding, or otherwise mitigating the environment or relocation or replacement of the affected cables or connections. When an unacceptable condition or situation is identified, a determination is made as to whether the same condition or situation is applicable to additional in-scope accessible and inaccessible cables or connections (extent of condition).			
38	Electrical Insulation for Electrical Cables and Connections Not Subject to 10 CFR 50.49 Environmental Qualification Requirements Used in Instrumentation Circuits program	The Electrical Insulation for Electrical Cables and Connections Not Subject to 10 CFR 50.49 Environmental Qualification Requirements Used in Instrumentation Circuits program is an existing performance monitoring program that will be enhanced as follows: 1. A new procedure will be developed for testing the post-accident neutron monitoring system cables and connections external to containment to evaluate reduced electrical insulation resistance by measuring cable resistance and capacitance. 2. A new procedure will be developed for testing the post-accident neutron monitoring system cables and connections external to containment that includes recommendations for types of electrical insulation tests including insulation resistance tests, time domain reflectometry tests, or other tests judged to be effective in determining cable system insulation physical, mechanical, and chemical properties.	Program enhancements for SLR will be implemented 6 months prior to the subsequent period of extended operation	SLRA, Appendix A, Table A4.0-1	2

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
38 (cont'd)		3. A new procedure will be developed for testing the post-accident neutron monitoring system cables and connections external to containment that includes a test frequency of at least once every ten years with the first test completed prior to the subsequent period of extended operation. 4. A new procedure will be developed for testing the post-accident neutron monitoring system cables and connections external to containment that includes acceptance criteria for the recommended test methods. 5. A new procedure will be developed for testing the post-accident neutron monitoring system cables and connections external to containment. The new procedure will include corrective actions and a requirement for an engineering evaluation to be performed when acceptance criteria are not met. The engineering evaluation will include a determination of whether the test frequency needs to be increased.			
39	Electrical Insulation for Inaccessible Medium-Voltage Power Cables Not Subject to 10 CFR 50.49 Environmental Qualification Requirements program	The Electrical Insulation for Inaccessible Medium-Voltage Power Cables Not Subject to 10 CFR 50.49 Environmental Qualification Requirements program is an existing condition monitoring program that will be enhanced as follows: 1. Procedures will be revised to require inspection of in-scope manholes after event driven occurrences, such as heavy rain, rapid thawing of ice and snow, or flooding. 2. Procedures will be revised to add a step stating that automatic or passive drainage features of manholes are operating properly. 3. A procedure will be created for testing medium-voltage cable that includes a requirement for testing medium-voltage cables that are exposed to significant moisture to determine the condition of the electrical insulation. 4. Procedures will be revised to add a step to evaluate adjusting the inspection frequency of manholes based on plant-specific operating experience over time with water collection. 5. A new recurring event and maintenance schedule will be created for testing the "A" RSST cables at least once every six years.	Program enhancements for SLR will be implemented 6 months prior to the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1 Supplement to SLRA: Change Notice 2	2,4

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
39 (cont'd)		6. A new recurring event and maintenance schedule will be created for testing the "B" RSST cables at least once every six years. 7. A new recurring event and maintenance schedule will be created for testing the "C" RSST cables at least once every six years. 8. A new procedure will be created for testing medium-voltage cable that includes a requirement that the specific type of test performed will be a proven test, utilizing one or more tests such as dielectric loss (dissipation factor (Tan-Delta)/power factor), AC voltage withstand, partial discharge, step voltage, time domain reflectometry, insulation resistance and polarization index, or line resonance analysis, for detecting deterioration of the insulation system due to submergence (e.g., selected test is applicable to the specific cable construction: shielded and non-shielded, and the insulation material under test). 9. A plant-specific inaccessible medium-voltage cable test matrix that documents inspection methods, test methods, and acceptance criteria for the in-scope inaccessible medium-voltage power cables will be developed based on OE. 10. A new procedure will be created for testing medium-voltage cable that includes a requirement to review visual inspection and physical test results that are trendable and repeatable to provide additional information on the rate of cable or connection insulation degradation. 11. A new procedure will be created for testing medium-voltage cable that includes acceptance criteria for tests and inspections.

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
40	Electrical Insulation for Inaccessible Instrument and Control Cables Not Subject to 10 CFR 50.49 Environmental Qualification Requirements program	The Electrical Insulation for Inaccessible Instrument and Control Cables Not Subject to 10 CFR 50.49 Environmental Qualification Requirements program is a new condition monitoring program that will manage the effects of reduced insulation resistance of non-EQ, in scope, inaccessible (e.g., installed in buried conduits, cable trenches, cable troughs, duct banks, underground vaults, or direct buried installations), instrument and control cables, exposed to significant moisture. Industry and plant-specific operating experience will be evaluated in the development of this program.	Program will be implemented 6 months prior to the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1	2
41	Electrical Insulation for Inaccessible Low-Voltage Power Cables Not Subject to 10 CFR 50.49 Environmental Qualification Requirements program	The Electrical Insulation for Inaccessible Low-Voltage Power Cables Not Subject to 10 CFR 50.49 Environmental Qualification Requirements program is a new condition monitoring program that will manage the effects of reduced insulation resistance of non-EQ, in scope, inaccessible (e.g., installed in buried conduits, cable trenches, cable troughs, duct banks, underground vaults, or direct buried installations), low-voltage power cables (operating voltage less than 2 kV), exposed to significant moisture. Industry and plant-specific operating experience will be evaluated in the development of this program.	Program will be implemented 6 months prior to the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1	2

Table 18-1 (CONTINUED)
SUBSEQUENT LICENSE RENEWAL COMMITMENTS

#	Program	Commitment	Implementation Schedule[a]	Source	Ref.
42	Metal-Enclosed Bus program	The Metal-Enclosed Bus program is an existing condition monitoring program that will be enhanced as follows: 1. Inspection procedures similar in scope and content to the procedures used to inspect other metal enclosed bus within scope of subsequent license renewal will be developed for the in-scope metal enclosed bus (MEB) associated with the 1A2 480V bus. 2. For inaccessible MEB internal or external segments, procedures will be revised to require initiation of a condition report that will result in an engineering evaluation of the inaccessible MEB segments that, together with the accessible MEB inspection and test program, will continue to maintain the MEB consistent with the current licensing basis during the subsequent period of extended operation. 3. Procedures will be revised to require inspection of accessible internal portions (bus enclosure assemblies) of MEBs for cracks, corrosion, and foreign debris. Accessible bus electrical insulation material will be inspected for signs of reduced insulation resistance due to thermal/thermoxidative degradation of organics/thermoplastics, radiation-induced oxidation, moisture/debris intrusion, or ohmic heating, as indicated by embrittlement, cracking, chipping, melting, discoloration, or swelling, indicating overheating or aging degradation. Accessible internal bus insulating supports will be inspected for structural integrity and signs of cracks. Accessible gaskets, boots, and sealants will be inspected for elastomer degradation including surface cracking, crazing, scuffing, dimensional change (e.g., “ballooning” and “necking”), shrinkage, discoloration, hardening, and loss of strength that could permit water or foreign debris to enter the bus 4. Procedure revisions will include a requirement for a sample of accessible bolted connections not covered with heat shrink tape or boots to be inspected for loose or corroded bolted connections and damaged hardware including cracked or split washers.	Program enhancements for SLR will be implemented 6 months prior to the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1	2

42 (cont'd)		5. Inspection procedures will be revised to add a note stating that 20% of the accessible bolted connection population, with a maximum of 25, is a representative sample. 6. A new recurring event and maintenance schedule will be created to inspect MEB associated with the 0-AAC-SW-0L bus on a maximum ten-year frequency. The first occurrence will be scheduled prior to the subsequent period of operation. 7. A new recurring event and maintenance schedule will be created to inspect MEB associated with the 1-EP-LCC-1A2 bus on a maximum ten-year frequency. The first occurrence will be scheduled prior to the subsequent period of operation. 8. Procedures will be revised to trend bus connection resistance values to provide information on the rate of connection degradation. 9. Accessible electrical insulation materials will be verified free from regional indications of surface anomalies such as embrittlement, cracking, chipping, melting, discoloration, and swelling. Accessible MEB internal surfaces will be verified to show no indications of corrosion, cracks, and foreign debris. Accessible elastomers (e.g., gaskets, boots, and sealants) will be verified to show no indications of surface cracking, crazing, scuffing, dimensional change (e.g., "ballooning" and "necking"), shrinkage, discoloration, hardening, and loss of strength. 10. Procedures will be revised to specify that when any acceptance criterion is not met, the unacceptable results are entered into the Corrective Action Program.

43	Electrical Cable Connections Not Subject to 10 CFR 50.49 Environmental Qualification Requirements program	The Electrical Cable Connections Not Subject to 10 CFR 50.49 Environmental Qualification Requirements program is a new condition monitoring program that consists of a representative sample of electrical connections tested prior to the subsequent period of extended operation. The results will be evaluated to determine if there is a need for subsequent periodic testing on a 10-year frequency. Industry and plant-specific operating experience will be evaluated in the development of this program.	Program will be implemented 6 months prior to the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1	2
44	High-Voltage Insulators program	The High-Voltage Insulators program is a new condition monitoring program that visually inspects high voltage insulator surfaces and metallic parts at least once every two years initially with the frequency adjusted based on plant specific operating experience. For high-voltage insulators that are coated, the visual inspection will be performed at least once every five years. Industry and plant-specific operating experience will be evaluated in the development of this program.	Program will be implemented 6 months prior to the subsequent period of extended operation. Inspections that are to be completed prior to the subsequent period of extended operation are completed 6 months prior to the subsequent period of extended operation or no later than the last refueling outage prior to the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1	2

45	Fatigue Monitoring program	The Fatigue Monitoring program is an existing preventive program that will be enhanced as follows: 1. The program cycle counting procedures will be revised to add the “Normal Charging and Letdown Shutdown and Return to Service” transient cycle associated with the ASME Code, Section XI, Appendix L analysis. 2. Procedures will be revised to require monitoring and tracking of transient cycles associated with the ASME Code, Section XI, Appendix L analysis be performed between the inspections for each ASME Code, Section XI, Appendix L location. Consistent with existing program cycle counting, a surveillance limit will be established to initiate corrective action prior to exceeding transient cycle assumptions in the ASME Code, Section XI, Appendix L analysis. 3. Procedures will be revised to expand existing corrective action guidance associated with exceeding a cycle counting surveillance limit to recommend consideration of component repair, component replacement, performance of a more rigorous analysis, performance of an ASME Code, Section XI, Appendix L flaw tolerance analysis, or scope expansion to consider other locations with the highest expected U_{en} values.	Program enhancements for SLR will be implemented 6 months prior to the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1	2
46	Neutron Fluence Monitoring program	The Neutron Fluence Monitoring program is an existing condition monitoring program that is credited.	Ongoing	SLRA, Appendix A, Table A4.0-1	2

47	Environmental Qualification of Electric Equipment program	The Environmental Qualification of Electric Equipment program is an existing program that will be enhanced as follows: 1. Existing procedures will be enhanced to include a requirement for plants that are entering or have entered their subsequent period of extended operation to perform a walkdown once prior to the subsequent period of extended operation and every ten years thereafter. Accessible electrical EQ equipment will be visually inspected and the EQ environment evaluated to identify in-scope electrical equipment subjected to an adverse localized environment (ALE). If an ALE is found, evaluation of the impact of the ALE on EQ electrical equipment, including qualified life, will be performed. 2. Existing procedures will be enhanced to evaluate and take appropriate corrective actions, which may include changes to qualified life, when an unexpected adverse localized environment or condition is identified during operational or maintenance activities that affect the qualification of electrical equipment.	Program enhancements for SLR will be implemented 6 months prior to the subsequent period of extended operation.	SLRA, Appendix A, Table A4.0-1	2

a. The subsequent period of extended operation (SPEO) for Surry begins on May 25, 2032, for Unit 1 and January 29, 2033, for Unit 2.
